Melatonin binding sites have been localized in avian brains using image analysis of 2-[121]-iodomelatonin (IMEL) autoradiography (Rivkees et al. Endocrinology 125:363-368, 1989, Cassone et al., in press.). We characterized the daily and circadian patterns of IMEL binding in avian brain. Newly hatched chicks and adult house sparrows were obtained locally. The daily and circadian pattern of binding was investigated over 48 hours in a 12:36 LD cycle. Five birds were sacrificed every 4 hours beginning on Day 1, Zeitgeber time (ZT), and continuing Day 2, circadian time (CT). Anesthetized birds were perfused and brains were removed and immediately frozen. The brains were sectioned coronally at 20 µm on a cryostat. Brain sections were incubated with IMEL at varying concentrations from 5 to 500 pM for the binding characteristic study and at 75 pM for the daily binding study. Non-specific binding was determined in the presence of 1 μ M melatonin. The slides were exposed to X-ray film for 7 days and the binding densities quantified to "3-I-microscale standards. As previously shown, specific binding sites are located in several structures of the telencephalon, thalamus, hypothalamus, and midbrain of the chick including structures associated with the visual and auditory systems. Scatchard analysis of the binding indicates a low affinity and high affinity binding site, with a change in B-Max occurring in both sites from (subjective) day to (subjective) night. Analysis of data collected every four hours reveal a daily rhythm in binding sites with a peak occurring at ZT 10. This rhythm persisted in DD with a peak occurring at CT 10. The source(s) of this endogenous rhythm and its consequences to avian circadian organization are currently under investigation.(Supported by NSF Grants BNS 85-19660 and BNS 88-96225)

INGESTIVE BEHAVIOR: PEPTIDES I

318.1

PATTERNS OF EATING BEHAVIOR ELICITED BY NEUROPEPTIDE Y INJECTED INTO THE MEDIAL PERIFORNICAL HYPOTHALAMUS. B. G Stanley and W. J. Thomas*. Dept. of Psychology, Univ. of California, Riverside, CA 92521.

Neuropeptide Y (NPY) is a powerful stimulant of eating behavior that appears to be most effective when injected directly into the medial perifornical region of the hypothalamus (mPFH). Little, however, is known about the patterns of food intake elicited by this peptide. To elucidate these patterns, we injected NPY (78 pM/10 nl) or vehicle into the mPFH of 10 satiated rats and measured intake of the mash diet every 60 sec for 24 hrs. These NPY-elicited intake patterns were compared to naturallyoccurring nocturnal feeding patterns. The results indicate that NPY produced a marked increase in food intake, predominantly within 2 hrs of injection (9.8 g for NPY versus 1.9 g for vehicle). The feeding behavior was not fragmented, but rather occurred within discrete clearly defined meals, during which eating was relatively continuous. Compared to the mean nocturnal-phase meal size of 2.2±0.3 g, meal duration of 12.8±1.2 min, and intermeal interval of 98.4±9.4, the NPY-elicited meals were both larger and more frequent. Specifically, the animals began to eat 14.1±1.5 min postinjection, ate a 5.9±1.3 g meal lasting 21.7 min, paused for 30±8.6 min, and then ate another meal of 3.2±0.8 g. These results indicate that NPY may produce eating through mechanisms that influence both meal size and intermeal interval.

318.2

COLOCALIZATION OF NEUROPEPTIDE Y (NPY) AND TYROSINE HYDROXYLASE (TH) IMMUNOREACTIVITY IN CAUDAL MEDULLARY NEURONS PROJECTING TO THE REGION OF THE ANTEROVENTRAL THIRD VENTRICLE (AV3V). G.L. Edwards and A.K. Johnson. Dept. of Physiol. and Pharmacol., Univ. of Georgia, Athens, GA 30602 and Depts. of Psychol. and Pharmacol. and the CV Center, Univ. of Iowa, Iowa City, IA 52242.

We have previously demonstrated that neurons containing NPY-immunoreactivity (NPY-IR) project from the caudal ventral lateral medulla (CVLM) and caudal nucleus of the solitary tract (NTS) to the AV3V region (Neurosci. Lett. 105: 19, 1989). Since catecholamines in the AV3V are reportedly important in the control of drinking behavior, we have investigated the possibility that NPY-IR and TH-IR are colocalized in neurons of the caudal medulla. We have utilized rhodamine labelled beads injected into the AV3V region to retrogradely label neurons in the caudal medulla. Sections from the medulla were then immunostained for NPY-IR and TH-IR using rabbit anti-NPY and mouse anti-TH antibodies to localize NPY-IR and TH-IR in the same cell. We observed that many cells that were retrogradely filled from injections in the AV3V region were immunoreactive for both NPY and TH, particularly in the CVLM and NTS. These data suggest that many of the catecholamine projections from the caudal medulla may also contain NPY. Thus, NPY may interact with catecholamines at the level of the AV3V to modulate drinking behavior. interact with catecholamines at the level of the AV3V to modulate drinking behavior.

DISCRIMINATIVE CHARACTERISTICS OF NEUROPEPTIDE Y (NPY) IN RATS. D. C. Jewett, A. S. Levine, J. Cleary* and T. Thompson*. University of Minnesota, Minneapolis, MN 55455 and VA Medical Center, Minneapolis, MN 55417

The ability of rats to discriminate certain agents following intracere-broventricular (ICV) injection has been demonstrated in previous studies. We asked if the subjective stimuli associated with NPY can be discriminated from those stimuli associated with an injection of vehicle. Rats were maintained at 80% of their free feeding weight and trained to press one of two levers depending upon whether they had received NPY or vehicle. Rats were injected ICV with either 5.0 µg of NPY or saline 30 minutes before the session. Responses on one lever following injection with NPY were reinforced, while responses on the other lever following injection of saline were reinforced. Responses prior to the first reinforcer or timeout were a measure of the discriminative stimulus properties of the agent. Our findings suggest that NPY can be rapidly discriminated from saline. The NPY-saline discrimination was discriminated from saline. The NPY-saline discrimination was established within 11 sessions for all subjects (n=4). In addition, rats were injected with 1, 3, 5 and 10 μ g of NPY (1μ g/ 1μ l). A 1μ g dose of NPY generalized to saline (i.e. rats responded as if they were injected with saline). A $10\,\mu$ g dose of NPY completely generalized to the training dose (5μ g), suggesting that the higher dose of NPY feels similar to an injection of $5\,\mu$ g of NPY. An intermediate dose of NPY (3μ g) partially generalized to the training dose. Approximately 60% of the responses following the $3\,\mu$ l injection were made on the NPY appropriate lever. Thus, $5\,\mu$ g NPY can be discriminated from saline and other doses of NPY may generalize to the training dose.

318.5

INVESTIGATION OF PITUITARY-ADRENAL AXIS IN NEUROPEPTIDE Y-INDUCED FEEDING. S. Sheriff*, A. Balasubramaniam*, F. Zhang*, M. Kalmonpunpour*, T. Foley-Nelson, J.E. Fischer* and W.T. Chance. Dept. of Surgery, Univ. Cincinnati Med. Ctr. and V.A. Med. Ctr., Cincinnati, OH 45267. Although neuropeptide Y (NPY) is a potent orexigenic agent, mediation of this effect is not well understood. Recent results (Inoue et al., Life Sci. 44:1043, 1989) suggests that intraventricular NPY stimulates the pituitary-adrenal axis. To assess pituitary-adrenal involvement in NPY-induced feeding, 24 ga cannulae were implanted into the paraventricular hypothalamic area of 28 adult, male S.D. rats. Two weeks later half of these rats were treated with saline (SAL) or dexamethasone (DEX: 50 & 200 μ g/kg, sc) for 5 days. Feeding was assessed for 4 hrs following the iht injection of 2 μ g NPY or artificial CSF 3 days after 50 μ g/kg DEX and 1 day after 200 μ g/kg DEX. Although the intake of rat chow was increased (p<0.01) by NPY in both groups, intake by the DEX-NPY group was reduced (p<0.05) by 38% as intake by the DEX-NPY group was reduced (p<0.05) by 38% as compared to NPY controls. Ad lib. intake was also reduced (p<0.01) by 30% in DEX-treated rats. Assessment of immunoreactive CRF in the hypothalamus 30 and 60 min after injection of NPY or CSF revealed decreased (p<0.05) CRF in DEX-CSF rats, while CRF was increased (p<0.05) in the SAL-NPY group. In the DEX-NPY rats, however, no elevation of CRF was observed. These results indicate an interaction of NPY with the pituitary-adrenal axis in the control of NPY feed-ing and ad lib. feeding, possibly involving release of CRF. ESupported by NIH grant CA48057 and a V.A. grant to W.T.C.J

318.7

FOOD DEPRIVATION EPISODES CHANGE THE RESPONSE TO OPIATE AGONISTS AND EATING BEHAVIOR IN AN ANIMAL MODEL OF BULIMIA AND ANOREXIA NERVOSA. M.M. Hagan* and D.E. Moss, Univ. of Texas at El Paso, Texas $\overline{79968}$.

Fasting patterns in eating disorders may trigger changes in opiate systems that control eating (Marrazzi, M.A. and Luby, E.D., Int. J. Eat. Disord. 5: 191-208, 1986). Littl is known, however, about the interaction between a history of fasting episodes (i.e., an animal model of eating disorders) and the effect of opiate agonists. Therefore, one group of female rats was deprived (DEP) to 75% of body weight three times (at 25, 90, and 140 days of age). Littermates were maintained as controls and to establish the "normal" body weight. Food intake was measured with and without butorphanol tartrate (BUTR, a kappa-sigma agonist, 8 mg/kg SC) following recovery to normal weight from the second and third episodes. DEP history produced an increase in post-recovery eating (at normal body weight and satiated at testing) [p<0.01]. BUTR affected eating [p<0.05] and its effect changed with DEP [p<0.05]. BUTR respectively, whereas controls consumed only 5.7 g under both conditions. Fasting episodes, therefore, may be a cause of bulimia or anorexia nervosa by changing opiate sensitivity

[BUTR was from Bristol Myers. Supported by NIMH (MBRS)]

NEUROPEPTIDE Y (NPY) INDUCED FEEDING: CALORIES OR VOLUME? M. Grace*, C.J. Billington* and A.S. Levine, Neuroendocrine Research Laboratory, VA Medical Center, Minneapolis, MN. and the University of Minnesota, Minneapolis and St. Paul, MN. 55108

Central administration of NPY is a potent stimulator of feeding in a variety of species. We asked whether rats given NPY intracerebroventricularly would differentiate the energy content from volume of food. The third with the terminal three the type of the third with the terminal three thr These two groups were then given a high fat (68% of calories) or a low fat diet (12% of calories). During a four hour period the NPY-injected rats in the high fat group ate the same amount of volume (4.0 \pm 1.0 g) as those in the low fat group (3.9 \pm 0.9 g), although the high fat group contained about 1.5 times the calories. Finally, the rats were divided into four groups and were given either water or a 10%, 20% or 40% sucrose solution. During the first two hours of the study the NPY-injected rats drank the same volume of all of the sucrose containing solutions (water: 2.7 ± 0.8; 10% sucrose: 11.4 ± 4.9; 20% sucrose: 9.8 ± 3.4; 40% sucrose: 9.6 ± 2.0 g/2 hr). Our results suggest that NPY-injected rats eat for volume without relation to

318.6

REDUCTION OF PLASMA AND HYPOTHALAMIC NEUROPEPTIDE Y IN ANORECTIC TUMOR-BEARING RATS. W.T. Chance, S. Sheriff*, F. Zhang*, M. Kalmonpunpour*, J.E. Fischer* and A. Balasubramaniam*. Dept. of Surgery, Univ. Cincinnati Med. Ctr. and V.A. Med. Ctr., Cincinnati, 0H 45267.

The potent orexigenic action of neuropeptide Y (NPY) suggests that it might be involved in the normal control of

The potent orexigent action of neuropeptite (NFT) suggests that it might be involved in the normal control of food intake. We reported (Ann. N.Y. Acad. Sci., in press, 1990) that tumor-bearing (TB) rats exhibit decreased feeding to NPY. To determine if endogenous concentrations of NPY were altered as TB rats became anorectic, we measured immunoreactive NPY in plasma and hypothalamus of control rats and 32 days after transplantation of methylcholanthrene sarcomas. Food intake by TB rats was significantly reduced (1.3±0.7 vs 8.5±0.3 g/100 g BW on day of sacrifice) and nontumor body weight was reduced by 40%. To approximate this cachectic response, a 16-day period of food restriction resulted in the reduction of body weight of one control group by 33%. Immunoreactive NPY level was decreased significantly in both the plasma (4.9±0.3 vs 9.2±0.3 ng/ml) and hypothalamus (0.33±0.03 vs 1.64±0.08 ng/mg wet wt.) of TB rats as compared to ad lib.-fed rats. Food-restricted rats exhibited significant increases in NPY in both plasma (16.3±0.4 ng/ml) and hypothalamus (2.08±0.11 ng/mg). These results indicate that NPY is altered in anorectic TB rats and that this change is not secondary to the anorexia. gests that it might be involved in the normal control of and that this change is not secondary to the anorexia. Therefore, aberration in NPY function may be of importance in the mediation of experimental cancer anorexia. [Supported by NIH grant CA48057 and a V.A. grant to W.T.C.]

318.8

EFFECT OF VENTRAL TEGMENTAL AREA (VTA) MORPHINE ON FEEDING. M.B. Noel and R.A. Wise. Ctr. Stud. Behav. Neurobiol., Dept. Psychol., Concordia U., Montreal, Canada.

VTA morphine injections facilitate brain stimulation reward and are rewarding in their own right; they also facilitate feeding induced by lateral hypothalamic stimulation. We determined the effects of VTA morphine on deprivation-induced feeding. Rats were implanted with stainless steel cannulae aimed at or dorsal to the VTA. Feeding behavior was determined daily after 18 hours of food deprivation; food was presented in 18 meal segments consisting of five 45mg food pellets per segment. VTA morphine (0.1, 1.0 and 10 nmol) had no effect on the latency to initiate feeding, but caused a dose-dependent acceleration of feeding. VTA saline and morphine injected dorsal to the VTA were ineffective. VTA morphine had motivational rather than motoric effects, since its effect on speed of feeding was to reduce the response-slowing effects of satiation rather than to accelerate uniformly across trials.

PARABRACHIAL OPIOID ANTAGONISM BLOCKS STIMULATION-INDUCED FEEDING. K.D. Carr and D. Aleman*. NYU Med. Ctr., New York, NY 10016. Dept. of Psychiatry.

The pontine parabrachial area contains cell bodies of third order gustatory relay neurons (Norgren and Leonard, 1973) and a high density of mu and a moderate density of kappa opioid binding sites (Mansour et al., 1987). In the present study, bilateral parabrachial microinjection of the universal opioid antagonist, naloxone (10 ug), produced a 49.1% (\pm 12.4) elevation in lateral hypothalamic electrical stimulation threshold for eliciting feeding behavior in rats. This differed significantly from the 12.7% (\pm 3.7) elevation produced by microinjection of the distilled water vehicle (n=8; p<.01). Injection of the selective kappa antagonist, nor-binaltorphimine (10 ug), produced an 18.6% (\pm 8.3) elevation which did not differ from the vehicle effect. Microinjection of naloxone and nor-binaltorphimine into extra-parabrachial pontine sites produced nonsignifi-The pontine parabrachial area contains cell bodies of fect. Microinjection of naloxone and nor-binaltorphimine into extra-parabrachial pontine sites produced nonsignificant elevations of 15.8% (±9.6) and 20.9% (±5.7), respectively (n=8). Thus, injection of naloxone within the parabrachial complex elevates feeding threshold while nor-binaltorphimine does not. This effect is not likely due to naloxone's diffusion to the fourth ventricle because direct i.c.v. injection of the same dose of naloxone elevated threshold by only 9.6% (±3.9) (n=6). These findings sugest that mu opioid activity within the parabrachial area is involved in the mediation of stimulation-induced feeding. Supported by 2003666 from MIDA ing. METHADONE AND FEEDING: SPACED VERSUS DAILY METHADONE AND FEEDING: SPACED VERSUS DAILY
INJECTIONS. J.M. Rudski, T. Thompson*, J. Cleary*, and A.S.
Leving University of Minnesota, Minneapolis, MN 55455 and VA
Medical Center, Minneapolis, MN 55417.

Peripheral administration of opiates stimulates feeding. In Experiment
1, food intake was measured 1,2,4, and 6 hours following 0, 1.5, 3.0,

Methadone increased feeding in a dose-dependent manner, and feeding occurred earlier in the session following each subsequent injection.

Both the overall increase and earlier onset of food intake might be due to both the development of folerance to the sedative properties of methadone. Tolerance may be inhibited by the spacing of opiate injections. Experiment 2 compared food intake following 0 or 5.0 mg/kg SC methadone presented daily or once every fifth day. Both schedules of methadone presentation increased food intake 4 and 6 hours postmethadone presentation increased food intake 4 and 6 hours postinjection, with increased intake occurring following subsequent injections. Two hours post-injection feeding was significantly increased following repeated daily but not spaced methadone presentation.

TABLE (Mean 2 Hour Food Intake in grams per injection)

| 1st | 2nd | 3rd | 4th | 5th | 6th | 7th | 8th |
| daily | 0.2* | 0.4 | 1.8 | 2.2* | 3.1* | 3.5* | 3.8 | 3.3* |
| spaced | 0.1 | 0.7 | 1.6 | 0.5 | 1.5 | 1.6 | 2.6 | 1.0*

Tag(0.05 compared to great)

4th 2.2* 0.5 p<0.05 compared to spaced

Thus, spaced injections of methadone are not as effective as daily injections in stimulating feeding, possibly due to an inhibition of tolerance to methadone's sedative effect.

DECREASES IN SPONTANEOUS AND GLUCOPRIVIC FEEDING

DECREASES IN SPONTANEOUS AND GLUCOPRIVIC FEEDING FOLLOWING SELECTIVE MU AND KAPPA OPIOID ANTAGON-ISTS IN RATS. D. Arjune and R.J. Bodnar. Dept. of Psychology, Queens Col., CUNY, Flushing, NY11367. While central administration of selective mu, kappa and delta opioid agonists stimulate food intake in rats, general antagonists, like naloxone decrease intake. The present study examined the central hypophagic properties of beta-funalone decrease intake. The present study examined the central hypophagic properties of beta-funal-trexamine (BFNA: 1-20 ug, ICV), a reversible kappa agonist and irreversible mu antagonist, and nor-binaltorphamine (Nor-BNI: 1-20 ug, ICV), a reversible kappa antagonist, under different spontaneous and regulatory challenge conditions. BFNA stimulated free feeding for up to 6 h which was blocked by Nor-BNI, but not BFNA pretreatment, indicating a kappa action. BFNA decreased free feeding at 24, 48 and 72 h, and BFNA pretreatment (24 h) decreased intake following either food deprination (24 h) relucions of the production of the producti vation (24 h) or glucoprivation with 2-deoxy-D-glucose (2DG), indicating mu-mediated actions. Nor-BNI decreased 2DG hyperphagia, nocturnal free feeding and hyperphagia stimulated by a high fat diet, indicating kappa-mediated actions in these responses. These data indicate the importance of both mu and kappa receptors in the opioid control of ingestive behavior. Supported by DA 04192.

THE EFFECT OF MORPHINE ON DIET SELECTION IN RATS IS DEPENDENT UPON BASELINE DIET PREFERENCES. B.A. Gosnell, D.D. Krahn and M.J. Majchrzak. Dept. of Psychiatry, University of Michigan, Ann Arbor, MI 48109. It has been reported that morphine increases fat intake in dietary self-

selection regimes (Marks-Kaufman, *Pharmacol. Biochem. Behav.* 16:949-955, 1982). Because we have noted considerable variability among rats in their preferences for carbohydrate and fat, we reasoned that the effect of morphine on diet selection may differ in fat-preferring vs. carbohydrate-preferring rats.

Male Sprague-Dawley rats (n=25) were given ad lib access to 2 diets: a carbohydrate diet (corn starch, dextrin and sucrose) and a fat diet (vegetable shortening and safflower oil). Both diets contained equal amounts of protein (20% of total energy), vitamins, minerals, choline chloride and fiber. After adaptation to the diets, daily intake was measured for 2 days. Percent of total calories consumed from the carbohydrate diet ranged from 5 to 98%. On the basis of these percentages, rats were divided into 3 groups: a carbohydrate preferring group (n=8), a fat-preferring group (n=8), and an intermediate group (n=9). The effect of morphine sulfate (0, 2 and 10 mg/kg, s.c.) on intake was then tested in all rats. Each rat was tested with all doses, and all trials were 2 days apart. Both doses of morphine significantly increased 4 hr total intake in all 3 groups. There was, however, a significant group x diet x morphine interaction: morphine significantly increased intake of the fat diet only in the fat-preferring group; the 2 mg/kg dose increased carbohydrate intake in all groups, but the increase was smaller in the fat-preferring group than in the other groups. The 10 mg/kg dose increased carbohydrate intake only in the carbohydrate-preferring group. These results indicate that the effect of morphine is to increase intake of the preferred diet rather than to increase intake of a specific macronutrient. (Supported by NIDA Grant DA05471)

INTERACTIONS BETWEEN OPIOID AND SEROTONIN RECEP-TOR ANTAGONISTS UPON FOOD INTAKE IN RATS. I.W. Beczkowska and R.J. Bodnar. Dept. of Psychology, Queens Col., CUNY, Flushing, NY 11367. Ingestive interactions between endogenous opi-

oid and serotonergic (5HT) systems were examined by pairing systemic naloxone with antagonists of different 5HT receptor subtypes in rats deprived of food for 24 h. Naloxone (NAL: 1-5 mg/kg) decof food for 24 h. Naloxone (NAL: 1-5 mg/kg) decreased intake by 29-45%. The nonspecific 5HT antagonist, methysergide (1-5 mg/kg) reduced intake by 25% and augmented NAL hypophagia (20-34%). A highly selective 5HT2 antagonist, ritanserin, increased intake by 20% and reversed NAL hypophagia by 33%. A less selective 5HT2 antagonist, ketanserin decreased intake by 25% and augmented NAL hypophagia by 25%. The selective 5HT3 antagonist, ICS205930 decreased intake by 16% and dose-dependently augmented NAL hypophagia (30-70%) with higher NAL and ICS205930 doses also producing parasymmathetic activation and hypoactivity. The parasympathetic activation and hypoactivity. data indicate heterogeneity among 5HT receptor subtypes in their ingestive effects upon both deprivation-induced feeding itself and NAL hypophagia. Supported by DA0419.

BOMBESIN-LIKE PEPTIDE EFFECTS ON INGESTIVE BEHAVIOR AND PLASMA GLUCOSE IN DECEREBRATE RATS. F.W. Flynn, Dept. of Psychology, Univ. of Wyoming, Laramie, WY 82071

Bombesin (BN)-like peptides are implicated in the suppression of food intake. These peptides are present in mammalian brain stem nuclei that often have reciprocal connections with forebrain sites. To determine if forebrain input to brain stem nuclei is involved, sucrose intake and plasma glucose were measured in decerebrate rats following a range of doses of BN and gastrin releasing peptide (GRP). Ten min following an ip injection (saline; BN and GRP in doses of 1 µg/kg, 2.5 µg/kg, 5 µg/kg, and 10 µg/kg) intraoral sucrose (0.1 M) intake was measured in intact (N=25) and supracollicular decerebrate rats (N=18). All doses of BN suppressed intake in both groups p's < .05. Injections of 5 µg/kg BN produced a significantly greater percent suppression of intake in decerebrate rats than in intact rats, p < .05. All doses of GRP suppressed sucrose intake by intact rats, p's<.05. In decerebrates, l µg/kg GRP was ineffective but higher doses produced a suppression in intake similar to that observed in intact rats. Thus, while the caudal brain stem contains the requisite neural systems to mediate the effects of BN-like peptides, forebrain systems appear to contribute to the expression of the responses elicited by these peptides. CENTRAL EFFECTS OF VASOACTIVE INTESTINAL POLYPEPTIDE (VIP)
ON FOOD INTAKE IN FASTED RATS. R. R. Schick, V.
Schusdziarra*, C. Nussbaumer*, M. Classen*, 2nd Dept. of
Internal Medicine, Techn. Univ. of Munich, D-8000, Germany
VIP is present in brain areas concerned with the
regulation of feeding. Therefore, the aim of this study

VIP is present in brain areas concerned with the regulation of feeding. Therefore, the aim of this study was to determine the central effects of VIP on food intake. 24-hr fasted rats (N=16) were injected (10 μ l) with saline or VIP at 1, 5, 10 and 25 μ g into the lateral cerebral ventricles. In some animals (N=7), the putative VIP receptor antagonist Ac-Tyr^1-D-Phe^2-GRF-(1-29)-amide (ANTAG; 25 μ g) was given with or without 25 μ g VIP. After injection, the rats received food pellets and latency to feed (L) and food intake after initiation of feeding (F) were recorded. L was dose-dependently augmented by VIP (4; 9; 15; 29 min) vs. saline (4 min; p < 0.05) and F 0-20 min was significantly reduced to 1.5 g (5 μ g) or 1.4 g (25 μ g) vs. 2.1 g (saline). The VIP-induced overall reduction of food consumption after 2 hours was mainly due to the robust increase in L. Peripherally injected VIP did not affect feeding behavior. Following injection of VIP + ANTAG, L was reduced to 17 min vs. 29 min (VIP alone; p < 0.05) and F 0-20 min was 2.2 g vs. 1.4 g (VIP alone; p < 0.05), thus restoring the saline value (2.1 g). These data suggest that VIP may act as a central inhibitor of food intake. However, further studies are required to determine the brain site(s) acted upon by ventricularly injected VIP. CCK CONDENTRATION IN SPECIFIC BRAIN AREAS OF SHAM (SF)
AND REAL FED (RF) RATS. M.A. <u>Della-Fera</u>, <u>B. Colemant</u>,
<u>R.L. Gingerich* and C.A. Baile</u> Washington U. Sch. Med.
St. Louis, MD 63104.

Feeding has been found to alter CCX concentrations ([CCX]) in specific brain areas of rats, but the site(s) of origin of the signals which trigger these changes are not known. To determine whether food stimulation of the oropharyngeal region might cause activation of CCK-containing brain areas, the effect of SF on [CCX] in specific brain areas was studied. Three groups of rats (N=12) with gastric cannulas were used. All were fasted 6 hr. One group consumed liquid diet with cannulas open (SF), one group with cannulas closed (NF), and one group consumed no food (NF). After 30 min of eating, rats were euthanized and brain tissues collected. [CCX] was measured in tissue extracts by RIA. [CCX] was increased (pX.05) by both SF and RF, compared to NF, in three areas: paraventricular nucleus, area postrema-nucleus of the solitary tract and dorsal parabrachial nucleus. In on area studied did either SF or RF alone cause changes in [CCX]. These findings indicate that food stimulation of the oropharyngeal region is sufficient to result in activation of CCK-containing neurons in these areas. They also suggest that CCK-containing pathways transmit gustatory information to an area of the hypothalamus which has been implicated in its centrally-mediated satiety effect. Supported by NIH grant NS-20000.

ENDOGENOUS CCK DELAYS GASTRIC EMPTYING IN FASTED RATS. A.J. Strohmayer, D. Greenberg, G.P. Smith and J. Gibbs. Dept. of Psychiatry, Cornell Univ. Med. Coll.: North Shore Univ. Hosp. Manhasset, NY 11030 and The New York Hosp., White Plains, NY 10605.

One proposed role for endogenous CCK is to slow gastric emptying. Green et al. (Am. J. Physiol., 1988) demonstrated that the protease inhibitor FOY-305 would slow gastric emptying of saline through the release of endogenous CCK. Previously, we (Smith et al. Am. J. Physiol., 1989) were unable to show this effect with soybean trypsin inhibitor (STI) using a phenol red dilution marker technique. We now report that STI can be shown to slow gastric emptying when a more direct technique was used.

Adult male Sprague-Dawley rats (n=10; body weight approximately 300 g) were maintained on a liquid diet (BioServ) for 2 weeks prior to testing to insure that stomachs would be free of solids. Rats were 17h food deprived then gavaged with 5 ml 0.15M NaCl alone or STI (200 mg/rat) dissolved in 5 ml 0.15M NaCl. Ten minutes later rats were sacrificed, their stomachs were removed and weighed. Gastric contents were then expressed and measured, and the stomachs were weighed empty. The volume of gastric contents after STI (1.98 ± .33 ml) was significantly more than the volume after 0.15M NaCl (0.61 ± .24 ml; t=3.3(9), n < 0?)

Since this dose of STI releases CCK from the small intestine in the rat, these results are additional evidence that endogenous, small intestinal CCK decreases the rate of eastric emptying in the rat.

rate of gastric emptying in the rat.

CENTRAL VASOPRESSIN CAN MODULATE THE FEEDING BEHAVIOR OF THE RAT. A. BURLET, J. PERANI*, J.P. MAX*, J.P. NICOLAS* and C. BURLET *. INSERM U.308, Nancy, France.

Vasopressin (VP) has been shown to decrease food intake after peripheral injection in the goat. The selection between two contrasted diets, containing carbohydrate (80 % CHO) or protein (80 % P), was studied in the rat genetically unable to synthesize central VP (Brattleboro strain, DI). The effects of the VP infusion in this rat strain were compared to the disturbances induced by specific immunotoxins injected into the brain of Long Evans (LE) rats.

When they were fed during the dark period, DI rats consumed more CHO than LE rats whereas P intake was equal. The chronic subcutaneous infusion of dDAVP restored a normal drinking behavior but failed to modify the diet selection of DI rats. Conversely, the central infusion of AVP did not decline the water intake but significantly decreased P intake (17.07 \pm 1.22 before AVP versus 17.88 \pm 1.27 g/24h, p<0.01); $\overline{\rm CHO}$ intake was unchanged. One microinjection of a monoclonal antibody to VP (IgG2a), with ricin A and monensine into the paraventricular nuclei of LE rats disturbed the local synthesis of VP (Burlet et al., Ann. Endocr. 50 : 20N, 1989). In the same time, it increased the total food intake (10 %) of LE rats, especially during the light period (35 %). These data confirmed that the central release of AVP could play a role in the regulation of food intake.

FPL 14294: A NOVEL CCK-8 AGONIST WITH POTENT INTRANASAL ANORECTIC ACTIVITY IN THE RAT. RD Simmons. SA McCreedy. JA Zongrone. JD Rosamond. Blosser. Depts. Biology & Chemistry, Fisons Pharmaceuticals, Rochester, NY 14603 FPL 14294 (4-(sulfooxy)phenylacetyl-[MePhe CCK-6) is

FPL 14294 (4-(sulfooxy)phenylacetyl-[MePhe⁶]CCK-6) is a CCK analog with enhanced metabolic stability as assessed using <u>in vitro</u> kidney protease preparations. <u>In vitro</u>, FPL 14294 was comparable to CCK-8 in affinity at the pancreatic CCK-A receptor (K₁-0.3 vs 0.3 mM) and at the cortical CCK-B receptor (K₁-0.3 vs 0.3 mM). Potency to contract isolated gallbladder was also equivalent to CCK-8 (EDso-1.09 vs 1.05 mM), although the time to peak contraction was longer for FPL 14294 (10 vs 1.0 min). However, FPL 14294 was >50 times more potent than CCK-8 in inhibiting 30 min feeding in 21 hr fasted rats (RDso-0.04 vs 2.6 μg/kg i.p.). With 3 hr feeding periods, FPL 14294 was >200 times more potent (RDso-0.56 vs 101 μg/kg i.p.), suggesting a greater duration of action. FPL 14294 also possessed intranasal anorectic activity at doses up to 500 μg/kg. Anorectic activity was inhibited by pretreatment with a CCK-B antagonist (MK-329, 100 μg/kg i.p.), un not by a CCK-B antagonist (1365,260, 300 μg/kg i.p.).

In summary, these results indicate that FPL 14294 is

In summary, these results indicate that FPL 14294 is a highly potent, intranasally active anorectic agent whose enhanced potency over that of CCK-8 may reflect differences in stability, bioavailability or receptor kinetics, but not affinity for CCK receptors.

318.20

EFFECT OF AREA POSTREMA ABLATION ON GASTRIC EMPTYING. M. Kathleen Gruver, M. M. Heitkemper and Nancy J. Kenney, Dept. of Psychology and Physiological Nursing, University of Washington, Seattle, Ma. 98195.

of Washington, Seattle, WA 98195.

Vagal afferents, including those from the stomach, terminate within the area postrema and subjacent caudalmedial aspect of the nucleus of the solitary tract (AP/cmNTS). Vagal efferents arise mainly from the dorsal motor nucleus of the vagus which is interconnected with the AP/cmNTS region. This study examines the effect of AP/cmNTS ablation on gastric-emptying rate of rats.

Charcoal suspension (200 ul of a 20% solution) was injected into the fundus of the stomach of Urethaneanesthetized (1.25 g/kg) AP/cmNTS-lesioned and shamlesioned rats 4 days after neural surgery. Two hours after charcoal injection, the suspension had traversed only 5% of the total intestinal length of the lesioned rats as compared with 26% of controls.

These data suggest that the AP/cmNTS region is

These data suggest that the AP/cmNTS region is involved in the control of gastric emptying. Further research is needed to determine whether decreased gastric emptying may underlie the decrease of food intake and/or the development of food aversions which also result from

FEEDING RESPONSES TO BACTERIAL LIPOPOLY-SACCHARIDE AND MURAMYL DIPEPTIDE. W. Langhans and G. Balkowski* Institute of Animal Science, Swiss Federal Institute of Technology, 8092-Zurich, Switzerland.

Lipopolysaccharide (LPS) derived from gram negative bacteria and muramyl dipeptide (MDP), the minimal immunologically active structure of gram positive bacterial cell immunologically active structure of gram positive bacterial cell walls, may be involved in the anorexia during severe bacterial infection in man and animals. We have recently shown that the anorectic effects of LPS (from *E. coli*) or MDP in rats both are due to increases in meal frequency and are similarly attenuated by the antiphlogistic and antipyretic drug indomethacin. To further test whether LPS and MDP inhibit feeding through the same mechanism, rats were given MDP (1.6 mg/kg b.wt., IP) after repeated injections of LPS (3 x 100µg/kg b.wt. IP, within 5 days) or LPS after repeated injections of MDP and food intake was measured. MDP reduced food intake after repeated injections of LPS, despite the tachyphylaxis that developed to the anorectic effect of LPS. With repeated injections of MDP, a tachyphylaxis to its anorectic effect did not develop and LPS also still reduced food intake. In further experiments, a potentiation of the food intake suppression was observed after aso still reduced food intake. In further experiments, a potentiation of the food intake suppression was observed after combined injection of lower doses of LPS and MDP (50µg and 0.8mg/kg b.wt., respectively), which had only a weak effect on food intake when given alone. The results indicate that LPS and MDP inhibit fooding through extractions. MDP inhibit feeding through activation of separate mechanisms. These mechanisms, however, seem to interact.

TRAUMA: BRAIN INJURY

BEHAVIORAL CONSEQUENCES OF MODERATE AND SEVERE CORTICAL CONTUSION IN THE RAT. L. Lescaudron and D.G. Stein. Brain Research
Laboratory, Rutgers University, Newark, NJ 07102.
To evaluate a pneumatically-controlled device

that allows independent control of cortical compression and impact velocity, adult, male rats were assessed for neurologic outcome following moderate (MTBI) or severe (STBI) traumatic brain moderate (MTBI) or severe (STBI) traumatic brain injury. Rats with STBI to the right sensorimotor cortex had significant (8 d) impairments of beam-walking ability compared to MTBI rats who showed a mild, transient (2-4 d) deficit relative to sham operates. All TBI rats showed deficits in retraction of the left hindlimb after lateral displacement (at 6 h, 24 h and 8 d postinjury). STBI, but not MTBI, rats had greater L-R forepaw griptimes from a suspended 1mm wire (vs shams) at of and 24 h, suggesting pathologic grasp in the left forepaw after severe injury. Extent and recovery from initial deficits in tactile and chin placing with the left forelimb was found to be time and injury dependent. TBI rats placed the left forelimb after the right in tests of visual placing, in contrast to simultaneous limb placements exhibited by sham operates. These results indicate this novel device reliably induces deficits correlated with TBI severity. Supported by FIDIA and 9 RO1 NS25685-05.

IMMEDIATE HYPERTENSIVE RESPONSE TO GRADED FLUID PERCUSSION BRAIN INJURY IS CLOSELY CORRELATED WITH PERCUSSION MAGNITUDE AND MAY BE RELATED TO INTRACKERBARA HEMDRRHAGE AND HYPOTHALAMIC DAMAGE. X—Q, Yuan, C. E. Made, C. B. Clifford* G. Hanson*, M. Bozzo* and W. G. Rodkey*. Letterman Army Institute of Research, San Francisco, CA 94129 Fluid percussion brain injury is associated with an immediate rise in systemic mean arterial pressure (MAP). However, the cerebral morphological basis for this response is still not clear. Thirty-four anesthetized rats were injured through a lateral cranitomy preparation to examine the postinjury hypertensive response. The impact levels ranged from 1.3 to 3.5 atmospheres (atm), and the impact duration was kept at 25 msec. MAP was monitored for two hours following injury. Fluid percussion injury produced a remarkable increase in MAP from 33-22 to 140-4 mmHg (pc.0.001) with an increment range of ~2 to 108 mmHg (47-25 mmHg) or 0 to 144% increase. The MAP peak appeared at 152-2 seconds and then rapidly returned to the preinjury level. There was a linear relationship between impact magnitude (X, atm) and increment in MAP (Y, mmHg) (Y~28.1*X-14.0, ~0.6.52.p<0.001). Nineteen brains underwent histopathological examination. Mistologic findings, principally in ranking the lesions, hypothalamic damage was given relatively greater weight than cerebral cortical or ventricular hemorrhage, MAP rise was also related to the injury ranking (~0.66, p<0.05), and there was a trend of correlation between impact magnitude and brain lesion score (~0.43, p<0.058). Our study indicates that the immediate post injury hypertensive response is closely correlated with the magnitude of fluid percussion implemented and may be related to intracerebral hemorrhage and hypothalamic damage.

BLOCKADE OF ACUTE HYPERTENSIVE RESPONSE DOES NOT PREVENT CHANGES IN BEHAVIOR OR IN CSF ACETYL-CHOLINE (ACH) CONTENT FOLLOWING TRAUMATIC BRAIN CHOLINE (ACH) CONTENT FOLLOWING TRAUMATIC BRAIN INJURY (TBI). E.K. Enters. J.R. Pascua*. K.P. McDowell*. C.A. Stamford*. J.T. Povlishock, and S.E. Robinson. Dept. of Pharmacology & Toxicology and Dept. of Anatomy, Medical College of Virginia, Virginia Commonwealth University, Richmond, VA 23298. Depletion of circulating ACh by A-5 reduces behavioral deficits and increased CSF ACh content following TBI (Brain Res. 509: 41, 1990). As hypertension has been associated with opening of the blood-brain learner (bbb), was tudied the effect of heaverschoping (TI) ochopairant.

has hypertension has been associated with opening of the blood-rain barrier (bbb), we studied the effect of hexamethonium (H) on behavioral and CSF neurochemical changes following TBI. Male Sprague-Dawley rats (294-322 g) were surgically prepared under Equithesia anesthesia 24 h prior to injury. Fifteen min after H (30 mg/kg, i.p.) or saline, rats received fluid percussion injury (2.1-2.2 atm) while under methoxy-flurane anesthesia. This dose of H had been demonstrated to block the hypertensive response to TBI. The duration of suppression of several reflexes and responses was measured up to 60 min after TBI and performance in measures of motor and vestibular function was recorded daily up to 10 days after TBI. Pretreatment with H prevented neither the did not prevent TBI-associated increases in CSF ACh content in separate groups of rats sampled 12 min following TBI. Histological inspection of rats treated with horseradish peroxidase indicated that H did not prevent TBI-induced disruption of the bbb. Thus, blockade of the hypertensive response to TBI does not afford behavioral protection nor does it prevent changes in the bbb or CSF ACh content following TBI. (Supported by NS#24413 and NS#7288).

THE EFFECTS OF EXPERIMENTAL BRAIN INJURY ON REGIONAL CATION CONCENTRATIONS. M.J. Thomas, D. Breault, B. Nolan, D. Smith and T.K. McIntosh. Department of Surgery, Univ. of Connecticut Health Ctr., Farmington, CT 06032.

Recently it has been demonstrated that tissue cation concentrations change markedly following traumatic spinal cord and brain injury. The specific time course of cation changes following brain injury have not been elucidated. In the present study, anesthetized rats (300-350gm) were subelucidated. In the present study, anestnetized rats (300-350gm) were subjected to lateral fluid percussion (FP) brain injury (over the left parietal cortex) of moderate severity (2.3 - 2.5 atms). Sham-operated control and injured animals were sacrificed at 10 min., 1, 6 and 24 hrs post-injury, brains removed and dissected into injured left parietal cortex, cortex adjacent to the injury site, contralateral right parietal cortex, bilateral hippocampi and brainstem. Dissected samples were weighed, extracted and analyzed for Mg++ and Ca++ concentrations using flame atomic absorption spectrophotometry (Perkin-Elmer 403 Spectrophotometer). At 10 min. postinjury, Mg++ increased in the injured cortex (p=0.03), while Ca+ remained at control levels. At 1 hr postinjury, Mg++ decreased in the cortex adjacent to the injury site (p=0.001) and the brainstem (p=0.002), while Ca++ increased in the injured cortex (p<0.0001). Mg++ remained decreased in the injured cortex at 6 and 24 hours (p=0.005 and p=0.009,respectively). Ca++ concentrations increased in the ipsilateral hippocampus at 6 hrs (p=0.005) and in the contralateral hippocampus (p=0.05), contralateral cortex (p=0.03) and brainstem (p=0.03) by 24 hrs. These changes in ion homeostasis after injury may play a role in the pathophysiology of irreversible posttraumatic tissue damage. Supported, in part, by NIH NS26818, a VA Merit Review grant 74R and a grant from the Sunny Von Bulow Coma and Head Trauma Foundation.

EFFECTS OF CALCIUM ENTRY BLOCKER (S)-EMOPAMIL ON EXPERIMENTAL BRAIN INJURY.

K Okiyama* DH Smith, MJ Thomas and TK McIntosh. Surg. Res. Ctr., Dept. of Surg., Univ. of Connecticut Health Center, Farmington CT 06032 Calcium may play a pivotal role in the pathogenesis of traumatic central nervous system injury. In this study, we investigated the effect of (S)-emopamil, a calcium channel blocker and serotonin-2 antagonist, on post-traumatic brain edema. Sprague-Dawley rats (330-400g, n=36) were anesthetized (sodium pentobarbital 60 mg/kg ip) and subjected to lateral fluid percussion (FP) injury of moderate severity (2.4-2.5 atm). Fifteen minutes post-injury, the animals randomly received 1 ml of either (S)emopamil (10 mg/kg ip, n=12), (S)-emopamil (20 mg/kg ip, n=12), or saline (ip, n=12). Mean arterial blood pressure (MAP), arterial blood gasses, core body and brain (temporalis muscle) temperature were measured during a 1 hour post-injury period. At 48 hours post-injury, all animals were sacrificed, brains removed and sectioned into : injured left parietal cortex, cortex adjacent to the injury site, contralateral right parietal cortex, bilateral hippocampi and thalami. Brain water content was evaluated by the wet weight/dry weight technique. Although a transient decline in MAP was seen after injection of (S)-emopamil, there were no significant differences in arterial blood gasses or in temperature compared to the control group. FP brain injury caused significant cerebral edema in saline-treated animals 48 hours post-injury. Administration of (S)-emopamil significantly attenuated edema in both right (p=.004) and left (p=.001) thalami compared to saline-treated controls. These results suggest that (5)-emopamil might have a beneficial effect on post-traumatic brain edema. Supported, in part, by a grant from Knoll AG Pharmaceuticals.

TREATMENTS WITH ACTH₄₋₁₀ ANALOGUE (BIM-22015) REDUCES COGNITIVE AND ANATOMICAL ALTERATIONS FOLLOWING MEDIAL FRONTAL CORTEX ABLATION. <u>S. W. Hoffman, R. L. Sutton, and D. G. Stein.</u> Brain Research Lab., Rutgers University, Newark, NJ 07102.

Adult rats with bilateral medial frontal cortex lesions were given s.c. injections of either sterile water or 1, 10, 100, or 100Cµg/kg of ACTH₄₋₁₀ analogue (BIM-22015) every other day for 28 days after surgery. Seven days after surgery the rats were tested on a water maze task for ten days (2 trials/day). Repeated measures ANOVA revealed a significant difference between the groups on time (p < 0.01) and distance (p < 0.05) to locate the escape platform over the 10 days of acquisition. Post-hoc analyses indicated that only the 1µg/kg dosage improved water maze acquisition as compared to lesion controls (p < 0.05). No significant effects of lesion or treatment were found for retention tests conducted 10 days following acquisition. Fifty-six days after surgery the rats were given one week of pretraining, followed by acquisition testing, in a T-maze test of delayed spatial alternation learning. No group differences for number of days to criterion, errors, or perseverations were found on this task. Histological analyses showed the lesions were restricted to the anterior portions of the medial frontal cortex. These overall findings are in agreement with those Silva et al. (Exp. Brain Res.,1986), who reported that rats with small medial frontal lesions lack spatial alternation deficits. An ANOVA revealed that there were significant differences between the treatment groups with respect to the number of AChE-positive neurons in the nucleus basalis magnocellularis (NBM) (p < 0.001). Post hoc analyses showed that rats with the 1µg/kg treatments had significantly more AChE-positive neurons in the NBM than lesion controls.

Supported by Biomeasure Inc., Hopkinton, MA., who also provided the analogue.

ADMINISTRATION OF EXCITATORY AMINO ACID ANTAGONISTS VIA MICRODIALYSIS PREVENTS THE INCREASE IN GLUCOSE UTILIZATION SEEN IMMEDIATELY FOLLOWING CONCUSSIVE BRAIN INJURY. T.Kawamata, D.A.Hovda, A.Yoshino, Y.Katayama and D.P.Becker. Dept. Surg./Neurosurg., UCLA Sch. Med., Los Angeles, CA, 90024 USA.

In previous work we demonstrated that glucose utilization is increased immediately following a fluid percussion (FP) injury in rat using [14C]-2-deoxy-D-glucose (2DG) autoradiography. In order to determine the possible reasons for this high metabolic demand, excitatory amino acid (EAA) antagonists (kynurenic acid (KYN): 10 mM, CNQX: 0.3, 1.0, 10 mM, AP5: 0.1, 1.0, 10 mM) and the calcium channel blocker cobalt (Co²+: 10 mM) which prevents neurotransmitter release were perfused (5 µl/min) through a microdialysis probe positioned in the parietal cortex of rats. Following 30 min of dialysis the probe was removed, 2DG administered (i.v) and the FP injury applied. Animals who did not receive dialysis showed an increase (up to 94%) in cortical glucose utilization following injury. In contrast, this high demand for glucose was prevented in areas infiltrated with KYN, CNQX (high dose), AP5 and Co²+. These results suggest that the EAAs are involved in the increase glucose utilization seen immediately after the concussive injury reflecting the energy demand of cells required to reestablish normal ionic balance disrupted by ionic shifts through EAA activated ion channels.

TRAUMA: BRAIN INJURY

CALCIUM ACCUMULATES FOR AT LEAST 48 HOURS FOLLOWING FLUID PERCUSSION BRAIN INJURY IN THE RAT. I. Fineman, D.A. Hovda, T. Kawamata, A. Yoshino, and D.P. Becker, Dept. of Surg./Neurosurg., UCLA Sch. Med., Los Angeles, CA 90024, USA.

Calcium is known to accumulate following cerebral ischemia and spinal cord contusion. To determine if a similar accumulation exists following a concussive brain injury, we gave male rats (250-300 g) a 2-4 atm. fluid percussion epidurally over the left frontoparietal region. Five animals served as sham controls. Injured rats were administered a bolus injection of 45Ca++ (1 uCi/g, i.v.) at 0 (n=5), 5 (n=3), 24 (n=3), and 48 h (n=3) following injury. Five hours after the injection animals were sacrificed, and 20 um frozen coronal sections were processed for autoradiography and thionin staining. Histological evaluation revealed no remarkable cellular disruption at the injury site. Digitized autoradiographs showed markedly higher concentrations of 45Ca++ in the cortex and hippocampus of the injured hemisphere (200-400% of sham and injured contralateral) at all injection time points. These results suggest an elevated flux of calcium into affected regions for at least 2 days following concussion.

319.8

DSP-4 SIGNIFICANTLY RETARDS RECOVERY FROM SENSORIMOTOR CORTEX INJURY. M.G.Boyeson and T.R.Callister*. Dept. of Rehab.Medicine,Univ.of Wisconsin, Madison,WI 53706.

Rats were trained to walk on a narrow, elevated beam. When animals reached criterion on the task, they were injected with 50 mg/kg ip of DSP-4 (a NE neurotoxin) or saline and tested on the beam every other day for 15 days, at which time both groups received a unilateral right sensorimotor cortex (SMCX) injury. Beam walking ability was assessed every other day for an additional 17 days. At 24 days postinjury, when all groups had reached recovery on the beam, they were administered ip 10 mg/kg phenoxybenzamine (PBZ; an Cl receptor blocker). The results indicated that DSP-4 caused a transient deficit in beam walking ability and significantly retarded functional recovery after the SMCX injury compared to saline injected SMCX injured controls. Additionally, PBZ profoundly reinstated a unilateral beam walking deficit (hemiplegia) in DSP-4 treated animals compared to saline injected SMCX injured controls, indicating an upregulation of alpha receptors. The results are discussed in terms of the important role the NE system plays in behavioral recovery from cortical injury.

319.10

DYNAMIC CHANGES IN LOCAL CEREBRAL GLUCOSE UTILIXATION FOLLOWING FLUID PERCUSSION INJURY: EVIDENCE OF A HYPER- AND SUBSEQUENT HYPOMETABOLIC STATE. A.Yoshino. D.A.Hovda. T.Kawamata. Y.Katayama and D.P.Becker. Dept. Surg./ Neurosurg., UCLA Sch. Med., Los Angeles, CA, 90024.

We have previously determined that following a fluid percussion (F-P) brain injury in rat, cells are subjected to ionic shifts across their membrane. In order to determine the extent of metabolic demand required to reestablished normal ionic balance, the present study measured local cerebral metabolic rates for glucose (ICMRGlc; µmol/100g/min) utilizing [14C]-2-deoxy-D-glucose autoradiography in rats (N=72, 200-250 g) immediately, 30 min, 6 h, 1, 2, 3, 5 and 10 days following unilateral frontoparietal F-P injury (3.7-4.3 atm). Compared to sham controls injured animals showed a marked increase in ICMRGlc primarily in the ipsilateral cortex (134-153 %) and hippocampus (142-187 %) during the first few minutes following injury. Whereas by 6 h ICMRGlc in these same regions went into a state of metabolic depression (77 %) lasting for several days. We conclude that following concussion, cells must increase their energy demands in order to return to ionic equilibrium. After this short period of hypermetabolism they go into a state of metabolic depression which may reflect a period of vulnerability.

EFFECTS OF TRAUMATIC BRAIN INJURY IN RATS ON BINDING TO OPIATE RECEPTOR SUBTYPES. D.C. Perry', B.G. Lyeth³, L.P. Miller², R.L. Getz¹, L.W. Jenkins^{3,4} & R.L. Sprague-Dawley rats were subjected to a moderate level (2.2 Atm) of traumatic brain injury (TBI) using fluid percussion. Injured animals were allowed to survive post-trauma for periods of 5 minutes, 3 hours and 24 hours. The effect of TBI on binding to forebrain opiate receptors was assessed using quantitative receptor autoradiography, and compared to a sham control group. Binding of [3H]DAGO to mu receptors in neocortex was significantly lower in the 24 hour group (p < 0.05). [3H]Bremazocine binding to kappa receptors was unchanged at 5 min and 24 hour, but showed large decreases 3 hour after TBI in the CA1 pyramidal layer (65%, p<0.05) and dentate gyrus (43%, p<0.05). Delta binding (using [3H]DSLET) was very low throughout the brain; no changes were detected. Lambda binding, measured by [3H]naloxone, was high in hippocampus, cortex, and amygdala; no changes were detected at any time points. These data support previous suggestions of a role for endogenous opioids in TBI, and furthermore indicate that mu and kappa opioid receptor subtypes may have different functions in TBI.

STEPPET OF DELAYED AMPHETAMINE TREATMENT ON PRIMARY AND SECONDARY NEUROPATHOLOGY AFTER CORTICAL CONTUSTON D.M. Feeney, R.L. Sutton, M.P. Weisend, and K.P.Bagan* Dept. of Psychology, Univ. Of New Mexico, Albuquerque, NM 87131 & I.A.B. Rutgers Univ., Newark, NJ 07102.

Delayed, amphetamine (AMPH) treatment reduces the extent of cortical necrosis, morbidity and mortality produced by embolic stroke in rat (Neurosci. Abst. 13:1268, 1987) and promotes locomotor recovery in other models of brain injury. This study compared the effect of a single ip. treatment of AMPH (2 mg/kg) or saline (SAL), given 24h postinjury, on cortical necrosis and subcortical neuronal pathology and gliosis 90 days after unilateral cortical contusion in the rat (Brain Res., 211, 1981). Focal impact (400 mg/cm) injury was centered over bregma in one group (ANT) and 2.25 mm posterior to bregma in another (POST). Reconstructions from serial, thionin sections were used to calculate the volume of cortical necrosis. Subcortical pathology and gliosis (Neurosci. Abst., 15:69, 1989) in the hippocampal CA3, ventral basal complex, dorsolateral striatum, substantia nigra, medial geniculate, arcuate and red nuclei was evaluated by raters uninformed of the treatment. Compared to SAL, AMPH significantly reduced cortical necrosis following ANT but not POST cortical necrosis by AMPH after ANT contusion injury may be due to the dense noradrenergic innervation to cortical necrosis by AMPH after ANT contusion injury must consider the differing neurochemistry and connectivity of the lesion sites. Supported by DHIS Grant ROI NS 20220 and #3 SO6 RRO8134.

MEMORY IMPAIRMENT FOLLOWING EXPERIMENTAL TRAUMATIC BRAIN INJURY IN THE RODENT. M. Ray, D. White, R.J. Hamm, R.L. Hayes. Depts. of Psychology and Neurosurgery, Virginia Commonwealth U., Med. Sch. of Va., Richmond, VA 23298.

Memory deficits are generally regarded as one of the most important sequelae of human traumatic brain injury (TBI). While cognitive function following TBI is of great importance, tests of motor performance have exclusively been used to evaluate outcome following experimental TBI. The development and validation of an animal model of cognitive function following TBI will allow the examination of putative therapeutic interventions in promoting cognitive recovery.

We used the Morris water maze, a task known to be dependent on hippocampal function, to assess memory performance following TBI. Rats were injured at moderate (n=5) or mild (n=5) levels of fluid percussion TBI. Additional rats served as uninjured control animals (n=6). Following injury or control treatment rats were assessed on weight, beam balance, and beam walking for 6 days until motor deficits were absent. Morris water maze performance was assessed on days 6-10 after injury. Results revealed that the moderately injured animals exhibited significant memory deficits over all test days [F(2,13) = 4.49, p < .05].

Previous research in our laboratory has shown that the hippocampus, a critical brain area for cognitive function in humans and rats, is selectively vulnerable after TBI. Since the Morris water maze is sensitive to hippocampal damage, our current observations support the hypothesis that memory deficits following TBI are the result of hippocampal dysfunction. Future therapeutic interventions directed at preventing hippocampal dysfunction may attenuate the occurrence of memory deficits after TBI. Supported by NIH grant NS12587

GFAP IMMUNOREACTIVITY FOLLOWING CORTICAL DEVASCULARIZA-TION. D.G. Herrera, and A.C. Cuello. Dept. of Pharmacology and Therapeutics. McGill University, Montreal, P.Q., H3G 1Y6, Canada.

Disruption of a restricted area of pia-arachnoid compromises vascular irrigation of the underlying cortex. This form of brain injury is accompanied by both tex. This form of brain injury is accompanied by both short- and long-term effects including c-fos activation in neurons and putative neuroglia cells, and a decrease of cholinergic markers in the ipsilateral nucleus basalis magnocellularis. The latter effect can be attenuated by GM1 and NGF treatment. The present study was undertaken to examine the effects of such a brain injury on glial cells. Adult male Wistar rats with unilateral cortical devascularizing lesioning were intracardially perfused with 4% paraformaldehyde at 1, 7, 15 and 30 days post-operatively and processed for glial fibrillary acidic protein (GFAP) immunoreactivity one day nost-lesioning reactive glia containtivity. One day post-lesioning, reactive glia containing intense GFAP immunostaining were localized to the affected cortex and subjacent corpus callosum. At longer survival times (7 to 30 days) reactive glia were also present in ipsilateral striatum and thalamus. Administration of NGF and/or the glycosphingolipid GMl did not appear to affect the glial reaction. Supported by M.R.C. (Canada) and Canadian Centers of Excellence Network for Neural Repair and Functional Recovery.

FETAL CORTICAL TRANSPLANTS PROMOTE NEURONAL SURVIVAL IN HIPPOCAMPUS OF ADULT RATS SUBJECTED TO EXPERIMENTAL FLUID PERCUSSION BRAIN INJURY. T.K. McIntosh and H. Soares. Surgical Res. Ctr., Univ of Connecticut Health Ctr, Farmington, CT 06032. Fluid percussion (FP) traumatic brain injury induces contralateral motor

deficits associated with neuronal death and cavity development in the left parietal motor cortex. Pronounced damage is also evident in the hippocampus ipsilateral to the injured cortex. In the present study, anesthetized rats (sodium pentobarbital, 60 mg/kg ip) were subjected to FP brain injury of moderate severity (2.2-2.4 atmospheres). Fetal cortical transplants (E16) were then injected into the injured motor cortex at 2 days (n=6), 1 week (n=6), 2 weeks (n=6) or 4 weeks (n=6) postinjury. Histological assessment of transplant survival and integration was based upon Nissl staining, glial fibrillary acidic protein (GFAP) immunocytochemistry and staining for acetylcholin esterase. Fetal cortical tissue injected at 2 days, 1 week or 2 weeks postinjury survived, incorporated with host brain, exhibited little GFAP immunoreactivity and successfully attenuated glial scaring. Neuronal sparing of CA2/CA3 hippocampal regions was dramatically evident in host brains receiving transplants at 2 days postinjury. Fetal cortical tissue injected into injured cortex 4 weeks postinjury failed to incorporate with host brain, exhibited extensive GFAP immunoreactivity and did not affect glial scar formation. These results suggest that there exists a temporal window in which fetal cortical transplants can attenuate glial scarring and spare neuronal populations within injured host brain. Attenuation of hippocampal neuronal death after fetal cortical transplants suggests a possible trophic role for CNS transplants in brain injury. Supported, in part, by NIH NS26818, the Sunny von Bulow Coma and Head Injury Foundation and a NIDCD training grant T32 DC00025.

AN NMDA RECEPTOR-ASSOCIATED GLYCINE SITE ANTAGONIST ATTEN-UATES MEMORY LOSS AFTER EXPERIMENTAL BRAIN INJURY.

DH Smith, K Okiyama*, MJ Thomas and TK McIntosh.

Surgical Research Center, Dept. of Surg., Univ. of Connecticut Health Center,

Farmington CT 06032.

The N-methyl-D-aspartate (NMDA) receptor has been shown to mediate hippocampal damage in central nervous system injury. Memory function has also been shown to be mediated by the NMDA receptor with the glycine site playing an integral role. In the present study, we examined the ability of the glycine site antagonist indole-2-carboxylic acid (I2CA) to attenuate posttraumatic memory deficits. Male Sprague-Dawley rats (350-400g) were trained in the Morris water maze (MWM) to find a submerged platform (20 trials over 2 days) using external visual cues. Four hours after the final trial, animals were anesthetized (sodium pentobarbital 60mg/kg ip) and subjected to lateral fluid percussion (FP) brain injury of moderate severity (2.2-2.3atm). Fifteen minutes post-injury, the animals randomly received 1ml of either I2CA (20mg/kg IV n=12), I2CA (50mg/kg IV n=12) or buffer (IV n=13). 42 hours post-injury, animals were tested for memory retention in the MWM using a video/computer recording unit. FP brain injury induces bilateral hippocampal cell loss as well as significant memory loss. Animals treated with either 20mg or 50mg I2CA showed highly significant memory preservation (p=.02 and p=.009 respectively) compared to buffer treated control animals. These results suggest that the NMDA receptor may play a role in post-traumatic memory dysfunction and that glycine antagonists may be potentially beneficial in the treatment of this memory dysfunction. Supported, in part, by NS2681-8, a VA Merit Review grant 74R and a grant from the Sunny von Bulow Coma and Head Trauma Foundation.

MEMORY DEFICITS FOLLOWING TRAUMATIC BRAIN INJURY PRODUCED BY CONTROLLED CORTICAL CONTUSION. D. White, A. Singha*, R.J. Hamm, C.E. Dixon, L.W. Jenkins, B.G. Lyeth, and R.L. Hayes. Depts. Neurosurgery, Rehab. Medicine, and Psychology, Virginia Commonwealth U., Medical College of Virginia, Richmond, VA 23298.

Memory deficits are a prominent and significant feature following human traumatic brain injury (TBI). While cognitive function following TBI is of great importance, tests of motor performance are the most common outcome measure used following experimental TBI. The development and validation of an animal model of cognitive function following TBI will allow the testing of the therapeutic efficacy of interventions designed to promote cognitive recovery following TBI.

The Morris water maze is a spatial memory task that has been shown to be dependent on hippocampal function. Therefore, we used the Morris maze to assess memory performance following contusional TBI. Rats were injured at moderate level (6 m/sec, 2.0 mm penetration, n=8) or received a sham-injury procedure (n=8). Morris water maze performance was assessed on days 11-16 after injury. Results revealed that the injured animals exhibited significant memory deficits over all test days.

The hippocampus is known to be a critical brain area for cognitive

humans and rats. The observation of Morris maze deficits following TBI supports the hypothesis that memory deficits following TBI are the result of hippocampal dysfunction. Future therapeutic interventions directed at preventing hippocampal dysfunction may attenuate the occurrence of memory deficits after TBI. Supported by NIH grant NS12587 and CDC grant R49/CCD303547.

THE SYSTEMIC PHYSIOLOGICAL RESPONSE OF ADULT AND AGED RATS TO TRAUMATIC BRAIN INJURY. R.J. Hamm, D. White, and A. Singha*. Depts. of Psychology and Neurosurgery, Virginia Commonwealth U., Medical School of Virginia, Richmond, VA 23298.

Age has been shown to be associated with an increase in mortality and morbidity following traumatic brain injury (TBI) in humans (J. Neurosurg., 68:409-416, 1988) and rats (Soc. Neurosci. Abstr., 14:1151, 1988). The mechanisms that are responsible for the age-related increase in vulnerability to TBI are unknown. As a first step in the investigation of this problem, we anesthetized (1.5% Halothane, 70% N₂O, 30% O₂) 3month-old Fischer 344 (adult, n=5) and 20-month-old (aged, n=4) rats. Rats were then subjected to a mild level (1.8 atm) of fluid percussion brain injury (J. Neurosurg., 67:110-119, 1987). For 60 min following injury we recorded blood gases, pH, glucose, blood pressure, heart rate, and body

Results revealed that there were no significant age-related differences in the systemic physiological response to mild TBI. As has been reported earlier (J. Neurosurg., 67:110-119, 1987), both age groups demonstrated mild hypertension for approximately 10 min following TBI. Similarly, all rats also exhibited increased plasma glucose levels at all time points following fluid percussion brain injury. These results indicate that the aged animal's higher mortality and morbidity following TBI are not the simple consequence of age-associated differences in the systemic physiological response to injury. The role of age-related changes in receptor-mediated neurotoxicity following TBI remains to be examined.

EPILEPSY: ANIMAL GENETIC MODELS

DECREASE IN SEIZURE SEVERITY IN THE GENETICALLY EPILEPSY-PRONE RAT (GEPR) FOLLOWING YOHIMBINE. M.L. Maring 1, R.W. Clough 1, P.K. Mishra 2, P.C. Jobe 2 and R.A. Browning 1. 1Sch. Med., So. Ill. Univ-Carbondale, IL 62901 and ²Univ. of Ill. Coll. of Med., Peoria, IL

GEPRs have an innate deficit in norepinephrine (NE) and display enhanced seizure susceptibility to a variety of seizure-evoking stimuli. White elevation in brain NE provides seizure protection and depletion produces seizure facilitation, little is known about the types of adrenoceptors involved. We have examined the effect of yohimbine, an alpha2 antagonist on audiogenic seizures (AGS) and intracerebral NE release in GEPRs. Fourteen male severe-seizure GEPRs (GEPR-9s) received either yohimbine (5mg/kg, i.p.) or vehicle one hour before AGS testing. Seizure severity was scored according to the scale of Jobe et al. *U. Pharmacol. Exp. Ther.* **184**: 1-10, 1973). A reduction in seizure severity was observed in 13 of 14 yohimbine-treated 1973). A reduction in sezizine severity was observed in 13 of 14 yonimonin-treated rats, while none of these animals displayed reduced seizure severity following treatment with vehicle. Moreover, in a separate study, one GEPR-9 rat whose seizure score was reduced from 9 to 5 following a graft of fetal locus coeruleus into the third ventricle, was completely protected from AGS (score = 0) following yohimbine (5mg/kg, i.p.) treatment. Although the mechanism by which yohimbine attenuates AGS is unknown, we have found that administration of a 50mM yohimbine solution through a microdialysis probe into the thalamus of GEPR-9s produced an elevation (approximately 2-fold) of NE in the extracellular fluid as compared to basal concentration. The present findings are at variance with the seizure-facilitating effects of yohimbine observed by others using seizure models that display facial & forelimb clonic convulsions (e.g. pentylenetetrazol and kindling), but are in agreement with the anticonvulsant effect observed using a tonic seizure model (e.g. maximal electroshock). Such findings suggest that yohimbine facilitates facial and forelimb clonic convulsions (forebrain, or limbic seizures) while inhibiting tonic convulsions forebrain, are the NPU entry NSC3673. (brainstem seizures). Supported in part by NIH grant NS22672.

NOREPINEPHRINE-STIMULATED INOSITOL PHOSPHATE ACCUMULATION IN CORTEX, AMYGDALA/PYRIFORM CORTEX AND HIPPOCAMPUS OF GENETICALLY EPILEPSY-PRONE AND KINDLED RATS. $\underline{D.L.\ Yourick}$, LaPlaca* and J.L. Meyerhoff. Dept. Med. Neurosci., Walter Reed Army Inst. Res., Washington, D.C. 20307-5100.

Genetically epilepsy-prone rats (GEPR-9) have a reduced number of noradrenergic nerve endings, and α_1 -adrenergic receptors, in cortex, amygdala and hippocampus and reductions in noradrenergic function may also exist in kindling. GEPR-9 respond to anticonvulsant therapy with norepinephrine (NE), NE uptake inhibitors or α -adrenergic receptor agonists. It was the purpose of the present study to evaluate NE-stimulated inositol phosphate (IP) accumulation (method of Maier and Rutledge, JPET 240:729-736, 1987) in genetic and kindled models of epilepsy. NEstimulated IP accumulation was reduced (P < 0.05) in cortex of GEPR-9 at 30 and 100 μ M when compared to control cortex. IP₂ accumulation was also reduced at 30, 100 and 300 μM NE the GEPR-9 when compared to epilepsy-resistant controls. Kindled rat cortical responses (28-30 days after last Stage 5 seizure) were similarly reduced when compared to unstimulated controls. No differences were noted in hippocampus or amygdala/pyriform cortex of either GEPR-9 or kindled rats when compared to their controls. These results support the hypothesis that cortical noradrenergic systems may represent endogenous anticonvulsant mechanisms and that these are impaired in epilepsy. Functional subregions of cortex are currently being examined.

DIMINISHED IN VIVO POTASSIUM (K+)-STIMULATED GABA RELEASE IN GENETICALLY EPILEPSY-PRONE RATS (GEPR). S.M. Lasley, Q-S. Yan* and R.L. Burger*. Dept. of Basic Sci., U. of III. Coll. of Med., Peoria, IL 61656. Previous studies in severe seizure GEPR (G-9) have

found decreased regional brain concentrations of GABA and increased levels of aspartic acid (ASP) compared to non-epileptic controls (Lasley et al., Soc. Neurosci. Abstr. 15:1215, 1989). The present work initiated the functional assessment of these changes by the use of microdialysis. assessment of these changes by the use of microdialysis. Five G-9 and 6 non-epileptic controls were implanted with guide cannulae under anesthesia, and for test sessions 7-10 days later dialysis probes were inserted unilaterally in rostral caudate. Each animal was perfused in the awake state with 100 and 150 mM K⁺ for 80 min in separate counterbalanced sessions spaced 5-10 days apart. 20-min fractions were collected, derivatized and analyzed for amino colde. Solutions contains bioth the proceed delivable and the second services of the second second services of the second services of the second services of the second s actids. Solutions containing high K⁺ increased dialyzable ASP and glutamic acid (GLU) by 3-7 times and GABA by 10-15 fold over the 80-min interval. At 150 mM K⁺ GABA release in G-9 was significantly less than in controls (p<0.01) throughout the stimulation period. In contrast, the increase of ASP and GLU in extracellular fluid after high K⁺ could not be distinguished statistically between G-9 and controls. These results suggest an important role for presynaptic GABAergic mechanisms in the seizure susceptibility observed in G-9.

NANGANESE-DEPENDENT ENZYMES IN GENETICALLY EPILEPSY PRONE AND CHRONICALLY

NONGHESE-DEPENDENT ENCITES IN BEREITHELT BYTEFSY YOURS AND LINGUILDED RATS. G.F.Carl, J.M.Critchfield,* F.Barnett,* L.Blackwell,* B.B.Gallagher, C.L.Keen*, Dept. Neurol., Med. Coll. Ga. and Med. Res. VA Med. Ctr., Augusta, GA 30910 and Dept. Nutr., Univ. Calif., Davis CA. 95616

It has been suggested that seizures cause a tissue redistribution of Manganese (Mm). It has also been suggested that a genetic predisposition to seizures may be marked by low blood Mn concentrations. It has been shown that seizures cause an increase in liver Mn levels but have no significant effect on brain Mn levels. Brain Mn, on the other hand, is lower in genetically epilepsy prone rats (BEPR) than in the parent strain but liver Mn is not different between these strains. Since Mn concentration differences are observed in genetically prome and chronically seizured animals, it is possible that Mn levels are affected by both seizure mechanisms and genetic mechanisms. In brain, where genetic associations are seen, the primary Mn binding protein is glutamine synthase. In liver, where the seizure effects are observed, the primary Mn binding protein is arginase. To examine the relationship between tissue levels of Mn and the activities of these enzymes we compared the arginase activity in livers and the glutamine synthase activity in the brains of chronically seizured animals and found that arginase activity was higher in the seizured animals but seizures did not have a significant effect on brain glutamine synthase. We also compared the activities of these enzymes in the same tissues from GEPR and age matched parent strain controls and found that glutamine synthase activity in brain was lower in the GEPR but arginase activity in liver showed no difference. We conclude that the differences in Mn levels in the tissues of chronically seizured and GEPR animals are a reflection of the amount of Mn bound to the primary binding protein in that tissue and in liver and brain that binding is reflected in differences in the activities of arginase and glutamine synthase, respectively.

EFFECT OF 6-OHDA-INDUCED LESIONS OF THE MEDIAL FOREBRAIN BUNDLE (MFB) ON AUDIOGENIC SEIZURES IN GENETICALLY EPILEPSY-PRONE RATS (GEPR-3s). C. Wang*, P.C. Jobe and R. A. Browning. Southern II. Univ. Sch. Med., Carbondale, IL 62901, and Univ. IL. Coll. Med., Peoria, IL 61656.

Widespread depletion of CNS norepinephrine (NE) produced by infusion of 6-hydroxydopamine (6-OHDA) into the locus coeruleus (LC) has been shown to increase the severity of audiogenic seizures (AGS) in moderate seizure GEPRs (GEPR-3s) (Browning et al., Epilepsia 30: 651, 1989). The present study was designed to determine whether depletions 379. The present study was designed to determine whether depictions of NE restricted to the forebrain could alter the severity of AGS. GEPR-3s (which display clonic convulsions only) were infused with either 6-OHDA (4 μ g/2 μ l) or vehicle in the MFB bilaterally. Ten to 14 days after 6-OHDA treatment rats were subjected to the AGS test and seizures were scored according to the scale of Jobe et al. (J. Pharmacol. Exp. Ther. 184:1-10, 1973). Subsequently, brains were assayed for NE. No increase in seizure severity was observed in the treated group (i.e. no increase in the incidence of tonic seizures) despite significant forebrain NE depletion (expressed as % of control: cortex, 26%; hippocampus, 21%; amygdala, 33%; thalamus, 54%, and hypothalamus, 47%). No significant depletion of brainstem or spinal cord NE was observed. Of interest, 3 of 10 GEPRs depleted of forebrain NE displayed facial and forelimb clonus with rearing (prior to generalized clonus) in response to audiogenic stimulation, whereas no rats in the vehicle group exhibited facial and forelimb clonus. These findings suggest that depletion of forebrain NE is not responsible for the increase in seizure severity following LC lesions and are consistent with the hypothesis that brainstem NE is more important in regulating AGS severity.

THE WAG/RIJ STRAIN: A RAT MODEL FOR ABSENCE EPILEPSY WITH PREDICTIVE VALIDITY. E.L.J.M., van Luijtelaar*, J.M.H. Vossen*, A.A. Ellenbroek and A.M.L. Coenen*, Dept. of Psychol., ¹Dept. of Pharmacol., Nijmegen

Ellenbrock and A.M.L. Coeners. Dept. of Psychol., 'Dept. of Pharmacol., Nijmegen Univ., P.O. Box 9104, 6500 HE Nijmegen The Netherlands. During the last years genetic animal models in which the seizures are not induced by sensory stimulation have become the focus of interest. It appeared that several types of rats, e.g. the WAG/Rij strain, exhibit spontaneous EEG and behavioral manifestations: chronically recurring 7-10 Hz spike-wave discharges (SWD's) accompanied by accelerated breathing and facial myoclonic movements closely resembling features of human absences. In addition, there is agreement between the states of vigilance in which the SWD's in man and rat occur, mainly at unstable vigilance periods. Also similar are the effects of the anticonvulsant actions of ethosuximide and trimethadion and of the proconvulsants carbamazepine and hydantoin, the involvement of GABA-ergic and submingrice agents and the dominant mode of inheritance. A final and most important

proconvulsants carbamazepine and hydantoin, the involvement of GABA-ergic and glutaminergic agents and the dominant mode of inheritance. A final and most important characteristic of absence epilepsy in man are the cognitive impairments during the presence of SWD's. Until now, cognitive impairments during SWD's have not been described in this model. The length of the post-reinforcement pause in a fixed interval (FI) task was used as an index for the accuracy of estimation of a time interval.

Eleven rats, previously trained on a FI 60 schedule of reinforcement, were provided with chronic EEG electrodes. During five sessions and in addition pre- and post training, the EEG was continuously recorded. It was found that during trials with SWD's, the post-reinforcement pause was enhanced compared to trials without SWD's suggesting that the capability of the animals to estimate a time period was disrupted. Furthermore, there were less SWD's during the task compared to the preceding and following rest hour. Based on these results, it was predicted that children with absence epilepsy should show similar impairments on FI responding. Under continuous EEG registration a FI task of one hour was presented to five children with absences. It appeared that after short (<3 sec.) SWD's the post-reinforcement pause was longer compared to trials without aberrant EEG signs of epilepsy. Considering the similarity of the influence of SWD's on FI responding between rat and man it is concluded that the proposed animal model has predictive validity. model has predictive validity.

SINGLE UNIT ACTIVITY IN THE INFERIOR COLLICULUS (IC) OF RATS DURING ETHANOL (ET) INTOXICATION AND WITHDRAWAL ASSOCIATED WITH AUDIOGENIC SEIZURES (AGS). A.Riaz and C.L.Faingold. Dept. Pharmacol. So. IL. Univ. Sch. Med. Springfield, IL.62794. Normal rats undergoing ET withdrawal (ETX) become susceptible to AGS.

C.L. Faingold. Dept. Pharmacol. So. IL. Univ. Sch. Med. Springfield, IL. 62794. Normal rats undergoing ET withdrawal (ETX) become susceptible to AGS. The IC plays a crucial role in initiation in many AGS models. The present study examined if changes in IC neuronal responses occur during ET administration and ETX. Under anesthesia microwire electrodes were implanted into IC of normal rats. To produce dependence, ET was given intragastrically (9-15g/kg) daily and was withdrawn at the end of day 4. Single-unit responses and behavior to AGS-inducing stimulus (12 kHz tone) were recorded in control, during ethanol treatment (ET+) and during ETX. At high stimulus intensities, which precipitate AGS, the rate-intensity functions of evoked unit firing in 61% of IC neurons (N=13) in the ET+ group showed a plateau or a decrease. All of the ETX group showed increased IC neuronal firing. A significant decrease in evoked unit firing occurred in the ET+ group as compared to control at highest but not at lower intensities. The evoked unit firing in ETX was significantly greater than control at all intensities. Spontaneous unit firing was decreased in ET+ (23.6% of control) and greatly increased (552.5% of control) during ETX. GABA is implicated in the effects of ET and in acoustically-evoked inhibition in normal rats. Evidence supporting a reduced efficacy of GABA-mediated inhibition in the IC has been observed in genetically epilepsy-prone rats (GEPRs) that exhibit AGS. Microinjections of GABA-ergic agents into IC block AGS during ethanol withdrawal. CONCLUSION: In light of previous findings the response pattern alterations observed in the present study might be mediated through ET-induced increases in GABA-ergic transmission during intoxication and rebound hyper-excitability involving reduced GABA-ergic function during ETX. This suggests that decreased GABA-mediated inhibition in IC could be a common factor in AGS initiation both in GEPRs and during ETX in normal rats.

320.6

EVIDENCE OF TRANSIENT NEONATAL HYPOTHYROIDISM IN THE MODERATE SEIZURE GENETICALLY EPILEPSY-PRONE (GEPR-3) RAT. S. Razani-Boroujerdi and DD Savage, Department of Pharmacology, University of New Mexico School of Medicine, Albuquerque, NM, 87131.

Previous studies from our laboratory have shown that severe seizure Genetically-Epilepsy Prone (GEPR-9) rats exhibit a moderate degree of hypothyroidism throughout life. Among the consequences of neonatal hypothyroidism (NH) in rats is the development of audiogenic seizure susceptibility (AGS). Given the morphological and neurobiological similarities among the moderate seizure GEPR-3, GEPR-9 and experimentally-induced NH rats, we hypothesized that GEPR-3 rats are functionally hypothyroid. Serum thyroxine (T4), triiodothyronine (T3) and thyrotropin (T5H) levels were measured in GEPR-3 and euthyroid non-epileptic Sprague-Dawley control rats at eleven different ages from day 5 up to one year. Like GEPR-9 rats, GEPR-3 rats had decreased serum total and free T4 levels and elevated T5H levels from day 5 through day 22 of age. However, unlike GEPR-9 rats, GEPR-3 rats had increased T4 levels and persistently high T5H levels as adults and normal serum T3 levels throughout life. The GEPR-3 rat thyroid hormone data suggest that: 1) the thyroid gland is not responding appropriately to elevations in T5H during the neonatal period, 2) feedback regulation of T5H production by T4 is impaired and 3) feedback regulation of peripheral 5'-monodeiodinase activity is intact, since normal serum T3 levels are maintained irrespective of low or high serum T4 levels.

These data indicate that GEPR-3 rats experience a transient T4 deficiency on brain function coupled with the development of AGS by GEPR-3 rats during the neonatal period. The critical impact of neonatal T4 deficiency on brain function coupled with the development of the seizure-prone state in GEPR-3 rats. Further, the differences in GEPR-3 and GEPR-9 rat thyroid hormone status after 22 days of age provide one explanation for d

SEIZURE SUSCEPTIBILITY IN MICE GENETICALLY SELECTED TO BE ETHANOL WITHDRAWAL SEIZURE-PRONE (WSP) OR -RESISTANT (WSR). J.C. Crabbe, T.J. Phillips, J.K. Belknap, and C.D. Merrill*. VA Med. Ctr. and Dept. Med. Psychol., Ore. Hlth. Sci. U., Portland, OR 97201

WSP mice have severe, and WSR mice mild, handling induced convulsions (HIC) after withdrawal from chronic ethanol (EtOH). Previous studies had found no differences between WSP and WSR mice in threshold sensitivity to seizures elicited by a number of convulsants. We examined the effects of low doses of several convulsants on basal HIC, reasoning that this would be a more sensitive assay. All convulsant drugs exacerbated HIC in WSP mice, but only three affected WSR mice. These were picrotoxin, pentylenetetrazole, and TBPS, agonists at the picrotoxin site of the GABA-gated chloride ion channel. Thus, the GABA system does not modulate the genetic difference between WSP and WSR mice. Acute EtOH injection is followed by elevated HIC 8-10 hr later in WSP mice, a state of acute withdrawal. NMDA had no effect on HIC in naive WSP mice, but exacerbated acute ethanol withdrawal HIC. NMDA had no effects in WSR mice, and kainic acid exacerbated both basal and acute withdrawal HIC in WSP mice. Thus, NMDA receptor function may underlie the EtOH HIC severity differences between WSP and WSR mice. Studies supported by Grants AA05828, AA06243, AA06498, and DA05228.

KANAMYCIN-INDUCED AUDIOGENIC SEIZURE (AGS) SUSCEPTIBILITY REQUIRES MONOAMINE DEPLETION IN SPRAGUE-DAWLEY (SD) RATS. C.E. Reigel and W.M. Aldrich*. Dept. of Basic Sci., Univ. of Ill. Col. of Med. Peoria, IL 61656.

Numerous studies in adult and developing GEPRs suggest AGS susceptibility is due to a combination of developmental hearing impairment and deficits in central noradrenergic and serotonergic inhibitory function. The necessity of both hearing impairment and monoaminergic deficits for the expression of AGS is supported by a recent observation of endogenously hearing impaired SD rats becoming AGS susceptible following monoamine (MA) depletion [Reigel et al. FASEB J. 2: A1069]. This report is in contrast to that of Pierson and Swann [Hearing Res. 32: 1-10, 1988] in which a kanamycin-induced hearing loss alone was capable of inducing a 100 percent incidence of AGS in Wistar rats. The purpose of the present study was to determine if it is possible to induce AGS susceptibility in SD rats through the production of a kanamycin-induced hearing loss alone or if monoaminergic depletion was required in addition to the kanamycin-induced hearing loss (as hypothesized to be the case in the GEPR). SD pups received 100 mg/kg/day kanamycin monosulfate or saline, given in one daily IP injection on postnatal days 9-12, the optimal parameters of the Wistar study. Kanamycin and saline groups were split, with half of each group receiving a SC injection of 10 mg/kg Ro4-1284 or saline at 30 days of age. Forty-five minutes following this injection, the time of maximal Ro4-1284 induced MA depletion, each subject was tested for AGS susceptibility. Kanamycin treatment alone or MA depletion alone (Ro4-1284) failed to induce AGS. The combination of kanamycin on postpartum days 9-12 and MA depletion at the age of AGS testing induced a 66.7 percent incidence of AGS. These results demonstrate that both hearing impairment and monoaminergic deficits are necessary for the induction of AGS susceptibility in SD rats.

QUANTITATIVE COMPARISON OF THE LATERAL

A QUANTITATIVE COMPARISON OF THE LATERAL CEREBELLUM BETWEEN NORMAL AND GENETICALLY EPILEPTIC MICE (tg/tg and tg/la). K. Isaacs and L. Abbott. Neuroscience Program and Dept. of Vet. BioSci. U. of Illinois, Urbana, IL 61801.

The lateral folia (L. paramedianus) of the posterior cerebellum of the mutant mouse tottering (tg/tg, n=3, 115 days old) and compound heterozygous mutants (tg/la, n=3, 137 days old) were compared to age-matched control mice (±/±, n=5) for changes in size of Purkinje cell somas and nuclei, and molecular layer thickness. tg/tg mice first exhibit signs of neurological disorder at 3-4 weeks, beginning with an ataxic gait followed by development of stereospecific, intermittent seizure activity. tg/la mice develop the same symptoms, but at an accelerated rate and with more severity and longer seizure duration. Semi-thin plastic sections were sectioned and stained with toluidine blue. Somas in tg/tg and tg/la mice were 8% and 9% smaller in diameter than controls (p<0.02). tg/tg nuclei were the same size as control mice, but tg/la were 8.6% smaller than tg/tg mice (p<0.01). The molecular layer was drawn with a camera lucida at 20x and perpendicular lines were made from the pia to the middle of the Purkinje cell layer. When the tg/tg and tg/la mice were compared to wild type mice, there was a noticeable 15% drop in thickness of the molecular layer (p<0.03).

320.13

ALTERATIONS IN CENTRAL BENZODIAZEPINE RECEPTOR SUBTYPES IN THE CEREBRAL CORTEX OF THE MUTANT MOUSE TOTTERING. E.M. Barnes, Jr. and M.H. Jalilian Tehrani. Baylor Col. of Barnes, Jr. and M.H. J Med., Houston, TX 77030.

The single locus mutant mouse tottering (tg/tg) displays spontaneous cortical discharges which resemble those found in petit mal epilepsy. In order to study possible alterations in GABAergic transmission in $\underline{\mathsf{tg}}$ runsmission in $\underline{\mathsf{tg}}$ mice, we measured the clonazepam-displaceable binding of [3H]flunitrazepam to GABA/benzodiazepine receptors on cortical membranes. Scatchard analysis of [3H]flu binding to membranes. Seatchard analysis of [-n] it binding to membranes from $\underline{tg/tg}$ and co-isogenic controls (+/+) revealed a single binding site with similar densities but different affinities ($\underline{tg/tg}$, Kd = 1.8 nM; +/+, Kd = 4.7 nM). The pharmacological profile of benzodiazepine receptors was determined by displacement of [3H]flu by clonazepam, CL 218872, and ethyl β -carboline-3-carboxylate (β -CCE). Clonazepam competition produced Hill numbers near white the Hill values for CL 218872 and $\frac{tg/tg}{s}$, while the Hill values for CL 218872 and $\frac{tg/tg}{s}$, while the Hill values for CL 218872 and $\frac{tg/tg}{s}$ and $\frac{tg/tg}{s}$ and $\frac{tg/tg}{s}$ or multiplicity. The net IC₅₀ values for CL 218872 were 170 nM in +/+ and 530 nM in $\frac{tg/tg}{s}$ cortex. The displacement curves indicate that nearly equal numbers of type I and type II benzodiazepine receptors are present or type I and type II benzodiazepine receptors are present in +/+, while tg/tg cortex has a higher proportion of type II receptors. The results suggest that the tottering mutation leads to a switching of GABA/benzodiazepine receptor isoforms. (Supported by NIH grant NS 11535.)

GENETIC DIFFERENCES IN NEOCORTICAL HIGH VOLTAGE SPIKE AND WAVE SPINDLE (HVS) PATTERNS: PARALLEL VARIATIONS IN BRAIN DOPAMINE (DA) SYSTEMS. <u>I.Laszlovszky, G.Buzsaki¹, A.Lajtha, G.Vadasz.</u> Nathan S. Kline Inst., Orangeburg, NY 10962 & ¹Dept. Neurosci. Univ. California at San Diego, La Jolla, CA 92093
Neocortical HVS episodes in the rat are similar to EEG

patterns characteristic of the human petit mal epilepsy Thus, neocortical HVS in the rat is regarded as an animal model for the latter. Recent EEG studies (Buzsaki, G. et al., in press, 1990) demonstrated age- and Neurosci., antagonist-dependent differences in the expression of HVS episodes. Here we report genetically based associations between brain DA systems and the expression of cortical HVS in the Fischer 344 (F344) and Buffalo (BUF) inbred rat strains. Activity of tyrosine hydroxylase (TH) was 15%-59% higher in the F344 strain in the corpus striatum (CS), tuberculum olfactorium (TUO), substantia nigra A8-A1O area and hypothalamus (HT), but not in pons-medulla. The 3Hspiperone receptor-binding studies evinced significantly lower (17%) D-2 DA receptor binding in CS and TUO of the BUF strain. Moreover, marked sexual dimorphism (with 50% higher TH activity in females) was found in the HT, in contrast to other brain regions. The findings that the HVS phenotype is expressed far more frequently in F344 than in the BUF and that there is a several-fold increase in the incidence of HVS after DA antagonist treatment in F344, but not in BUF, suggest that HVS in rats is under genetic control and that the genetic variations in the DA system might significantly affect the expression of HVS.

EPILEPSY: ANTI-CONVULSANT DRUGS

321.1

BLOCKADE OF 4-AP-INDUCED AFTERDISCHARGES BY U-54494A, A NOVEL ANTICONVULSANT, IN THE HIPPOCAMPAL SLICE OF RAT. M.Camacho-Ochoa, P.F. VonVoigtlander, W.E.Hoffmann and M.F.Piercey.
CNS Diseases Research, The Upjohn Company, Kalamazoo, MI 49001.
U-54494A, a 1,2-diamine structurally related to the opiate kappa receptor

agonist U-50488H, antagonized convulsions induced by excitatory amino acid agonists (EAAA: kainic, N-methyl-aspartic, and quisqualic acids) and the Ca** channel agonist BAY K 8644 (J. Pharmacol. Exp. Ther. 243:542, 1987) and antagonized glutamate excitation of cortical neurons (Soc. Neurosci. Abst. 14:1034, 1988). The anticonvulsant activity of U-54494A was studied on a 4-aminopyridine (4-AP) epilepsy model using extracellular recordings in in vitro hippocampal slices in the rat brain. Field potentials were evoked by stimulation of Schaffer collaterals and recorded from the CA1 region of the hippocampus after perfusion of 4-AP in the absence and presence of U-54494A. The number of afterdischarges was significantly decreased by increasing doses of U-54494A. In contrast, U-54494A did not significantly change the latency, duration, and area of the evoked PS, either in the presence or absence of 4-AP. Thus, by itself, U-54494A does not affect normal neuronal transmission in the hippocampal slice. This effect is in agreement with the results seen in vivo in the rat hippocampus where only mild depression of firing rates of pyramidal cells was observed, and in vitro where no effect on axonal conduction was found for U-54494A on an isolated sciatic nerve preparation (Soc. Neurosci. Abst. 14:1034, 1988). By contrast, U-54494A effects are observed on altered physiological systems such as the in vivo models of epilepsy (excitatory amino acids and Ca** agonist epilepsy models). These results provide more evidence that U-54494A is an effective anticonvulsant that may be useful in the treatment of paroxysmal neuronal activity, without having generalized depressant effects.

321.2

THE NEUROPROTECTIVE ANTICONVULSANT U-54494A BLOCKS KAINIC ACID INDUCED GLUTAMATE RELEASE. M. M. Payson, B. A. Donzanti and P. F. VonVoigtlander, NEOUCOM, Rootstown, OH 44272 and The Upjohn Company, Kalamazoo, MI 49001.

U-54494A, an analogue of the kappa agonist U-50488H, is a unique anticonvulsant in that it lacks the sedative, analgesic, and diuretic effects typical of selective kappa opioid agonists (VonVoigtlander et al, J. Pharmacol. Exp. Ther. 243:542, 1987). In an attempt to understand its mechanism of action, U-54494A was tested in vivo for its ability to alter spontaneous and evoked glutamate release from the CA₃ region of the rat hippocampus. Studies were performed in the urethane anesthetized animal by placing a 0.5 mm exposed dialysis membrane (210 μ o.d.) into the left hippocampal CA, region and perfusing the probe with artificial CSF at a flow rate of 1.5 µl/min. Twenty minute dialysate samples were collected and analyzed for glutamate content using HPLC-ECD following precolumn derivatization with o-pthalaldehyde and B-mercaptoethanol. U-54494A (50 mg/kg, s.c.) did not alter spontaneous glutamate efflux. Similarly, high K* (80 mM) perfusion evoked glutamate release was not altered following a 1 hr pretreatment with U-54494A. In contrast, kainic acid (3 mM) perfusion-induced glutamate release was significantly inhibited by 1 hr pretreatment with U-54494A (1-15 mg/kg, s.c.). These data suggest that U-54494A selectively inhibits kainic acid-induced glutamate release at nonsedating, anticonvulsant doses. Furthermore, these data may be mechanistically related to previous studies which showed U-54494A to protect against kainic acid-induced convulsions and CA_a neurotoxicity.

EFFECTS OF INTRANIGRAL INFUSION OF AP7 AND KETAMINE ON PENTYLENETETRAZOLE SEIZURES IN ADULT AND IMMATURE RATS. John ND Wurpel and Luisa M Milevoj*. Department of Pharmaceutical Sciences, St. John's University, Jamaica, NY 11439

AP7 and ketamine are reported to suppress seizures induced by a variety of models, our data support the hypothesis that the anticonvulsant effects of AP7 and ketamine may be mediated, in part, by the substantia nigra (SN). Further, these effects appear to be age-related. Animals were anesthetized with a mixture of ketamine and xylazine, and bilateral guide cannulae were implanted into the SN of adult & immature (16 day old) rats. After 2 days recovery, rats received AP7, ketamine or saline in a volume of 0.2 ul infused into both SN. AP7 (22.5-2250pg) and ketamine (25-250ng) reduced the incidence of pentylenetetrazole (PTZ; 80mg/kg, s.c.)-induced seizures of adult rats in a dose-dependent manner, without reducing seizure severity of those animals which demonstrated a clonic convulsion. AP7 infused into the SN of immature rats did not reduce the incidence of PTZ-

the SN of limitature rats did not reduce the incidence of P12-induced seizures, while ketamine infusions into the SN increased the occurrence of tonic seizures following PTZ.

Both AP7 and ketamine appear to exert an age-specific effect on seizure activity when infused into the SN. AP7 or ketamine are anticonvulsant when infused into the SN of adult rats whereas, AP7 or ketamine do not exert enticonvulsant effects whereas, AP7 or ketamine do not exert anticonvulsant effects when infused into the SN of immature rats.

D-SERINE POTENTIATES PHENYTOIN, PHENOBARBITAL, DIAZEPAM AND CARBAMAZEPINE IN MAXIMAL ELECTROSHOCK SEIZURES OF RATS. S.L. Peterson Dept. of Medical Pharmacology and Toxicology, Texas A & M University, College Station, Texas 77843.

Previous studies in this laboratory have shown glycine to potentiate the activity of anticonvulsant drugs in maximal electroshock seizures (MES). The purpose of this study was to determine if D-serine, an agonist of N-methyl-D-aspartic acid linked glycine receptors, also potentiates anticonvulsant drugs in MES.

MES was induced in male Wistar rats by passing a 60 Hz, 150 mA and 0.2 second duration current through saline soaked corneal Seizure severity was quantified by tonic hindlimb extension. Statistical significance between groups of anticonvulsant treated rats with or without D-serine were determined by maximum likelihood logistic regression analysis.

D-serine (20 mM/kg,p.o.) administered 1, 2 or 4 hours before the seizure test did not prevent tonic hindlimb extension in any rat tested. However, 20 mM/kg D-serine (4 hours before seizure test) significantly enhanced the anticonvulsant effect induced by 20 mg/kg phenytoin, 7.5 mg/kg phenobarbital, 7.5 mg/kg diazepam and 7.5 mg/kg carbamazepine. As D-serine is metabolically inactive, this data suggests a select action of glycine agonists to potentiate anticonvulsant drugs in MES. (Supported by NIH Grant 24566)

MK-801 AND MK-801+DIAZEPAM IN STATUS EPILEP-TICUS: MOTOR SEIZURES, EEG AND CORTICAL GABA
CONCENTRATION. N.Y. Walton, S. Gunawan* and
D.M. Treiman. Neurology and Research Services,
Wadsworth VAMC and Department of Neurology,
UCLA School of Medicine, Los Angeles, CA 90024.
Status epilepticus (SE) induced by lithium
and pilocarpine produces a progressive increase

and pilocarpine produces a progressive increase in cortical GABA concentrations which are first apparent at the time continuous, high-amplitude, rapid spiking is established on EEG (Exp. Neurol. 1990, 108:61-70). In this study SE induced by lithium and pilocarpine was treated with one of the following regimens when continuous spiking had been present on EEG for 10 minutes: 2 mg/kg MK-801; an equal volume of vehicle only; or 2 mg/kg MK-801 followed in 10 minutes by 20 mg/kg diazepam (DZP).

MK-801 alone stopped overt motor seizures but not electrographic seizure activity. MK-

but not electrographic seizure activity. MK-801+DZP stopped all manifestations of SE within 5 minutes of DZP injection. Cortical GABA concentrations were less elevated 30 minutes after treatment in the rats receiving MK-801+DZP than either of the other treatments. By two hours either of the other treatments. By two hours after treatment, GABA levels were lower in rats treated with MK-801 alone than vehicle-treated rats, and lower still in MK-801+DZP rats.

321.4

SELECTIVE ANTICONVULSANT PROPERTIES OF GLYCINE RECEPTOR ANTAGONIST, 7-CHLORO-KYNURENIC ACID (7CK). S. Hoshino, D.W. Bonhaus and J.O. McNamara. Duke and V.A. Med. Ctr., Durham, N.C. 27705

NMDA receptor antagonists inhibit seizures in a diversity of models. Activation of NMDA receptors requires the presence of agonists for a glycine binding site. We therefore hypothesized that glycine antagonists would exhibit anticonvulsant properties. To test this idea, we examined the effects of glycine antagonists in two seizure models, electroshock (ES) and electrically-induced hippocampal afterdischarge (AD). Injection of 7CK (3.35 μg or 10.06 μg in 5 μl saline) into the right lateral ventricle (ICV) produced ataxia and sedation reversible with D- but not L-serine. Surprisingly, ICV 7CK failed to reduce the duration of ES evoked tonic hindlimb extension (THE) (Vehicle $12.5\pm1.3,\ 3.35\ \mu g$ $13.4\pm1.4,\ 10.06\ \mu g$ 10.1 ± 1.4 sec). ICV injection a second glycine receptor antagonist, 5F-indole-2-carboxylic acid (179 or 537 μg in 5 μ l), also failed to inhibit ES whereas ICV injection of the uncompetitive NMDA antagonist, MK-801 (45 μ g in 5 μ l) abolished THE. The effects of ICV 7CK on AD and wet dog shakes (WDS) induced by left hippocampal stimulation were also examined. 7CK reduced the duration of recurrent discharge (RD) in the right hippocampus (Vehicle 23.1 ± 2.9 , 7CK 7.3 ± 4.6 sec; p<0.02) and the number of WDS (Vehicle 17.6 ± 2.1 , 7CK 7.4 ± 2.8 ; p<0.03), but not the duration of AD (Vehicle 41.7 ± 6.3 , 7CK 39.3 ± 9.7 sec). Thus ICV injection of 7CK produced behavioral evidence of glycine receptor antagonism and inhibited hippocampal epileptiform activity but not ES seizures. The effects of 7CK on hippocampal RD and WDS suggest that glycine receptor antagonists may provide a new class of anticonvulsants. The lack of effect against ES seizures may be due to inadequate access of 7CK to the responsible pathways. Alternatively, the effectiveness of MK-801 but not 7CK raises the interesting

321.6

THE ANTICONVULSANT ACTION OF GABAPENTIN
INVOLVES THE GLYCINE/NMDA RECEPTOR.
R J Oles*, L Singh*, JHughes and G N Woodruff
Parke-Davis Research Unit, Cambridge, England
Recent clinical trials have shown that
gabapentin is effective in medically refractory

possibility that not all NMDA receptors are coupled to glycine receptors.

patients with partial or generalised epilepsy. However, its mechanism of action is unknown. We have examined the involvement of the glycine/NMDA receptor.

glycine/NMDA receptor.

Intraperitoneal administration of gabapentin or the competitive NMDA receptor antagonist CPP in mice, 30 min before pentylenetetrazol (120mg/kg, s.c.) antagonised tonice seizures with ED₅₀ values of 139.3 and 7.9mg/kg respectively. The anticonvulsant effect of a submaximal dose of gabapentin (200mg/kg) was dose-dependently antagonised by i.c.v. administration of the glycine receptor agonist, D-serine (30ug completely antagonised the D-serine (30µg completely antagonised the effect of gabapentin). In contrast, up to 30µg of D-serine, did not antagonise a similar anticonvulsant effect of a submaximal dose of

CPP (10mg/kg).

These results may suggest an involvement of the glycine/NMDA receptor in the anticonvulsant action of gabapentin.

DEXTROMETHORPHAN(DM) AND CARBETAPENTANE (CBP) ANALOGS BIND TO DM AND SIGMA SITES IN THE GUINEA PIG BRAIN. M. Klein*, J.M. Musacchio, A.H. Newman¹, S.N. Calderon* and F.C. Tortella 1. Dept. Pharmacol.,

NYU Med. Ctr., New York, NY, 10016 and ¹Walter Reed Army Inst. of Res., Washington D.C. 20307-5100.

DM and (+)-3-PPP bind to a common high-affinity site that is allosterically modulated by phenytoin (PHT) and ropizine (Musacchio et al., Mol. Pharmacol. 35:1, 1989). DM, CBP and (Musacchio et al., Mol. Pharmacol. 35:1, 1989). DM, CBP and caramiphen, which displace [³H]DM in the nM range, protect rats and mice against MES seizures and potentiate the effect of PHT. However, several sigma ligands, which bind to the common DM/sigma site with nM affinities have no anticonvulsant activity (Tortella et al., TIPS 10:501, 1989). Since DM binds to an additional high- and to a low-affinity site, for which (+)-3-PPP has respectively low and intermediate affinity, it is not clear which site mediates the anticonvulsant activity. To elucidate this question, several DM- and CBP- analogs with/without anticonvulsant activity were texted in competition studies against (AUD) and (CM). were tested in competition studies against [3H]DM and (+)-[3H]3-PPP. Most analogs tested bind to the common high-affinity DM/(+)-3-PPP site with K_i values from 2 to 500 nM. Several CBP analogs bind also to the low-affinity DM/medium-affinity (+)-3-PPP site. Preliminary results have not shown a clear correlation between binding and anticonvulsant activity. Supported in part by USPHS grants DA-02013, MH-17785 and NS-23926.

SYNTHESIS AND ANTICONVULSANT ACTIVITY OF DEXTROMETHORPHAN AND CARBETAPENTANE ANALOGS. S.N. Calderon 1*, A.H.Newman 1, M. Klein 2*, J.M.Musacchio 2, F.C. Tortella 1· 1 Walter Reed Army Institute of Research, Washington D.C., 20307-5100 2NYU Medical Center, NY, NY, 10016

The non-opioid cough suppressants, dextromethorphan (DM) and carbetapentane (CBP), show anticonvulsant activity. The mechanism of anticonvulsant action of these drugs is not known. High and low affinity binding sites labeled with [3H]DM have been described for DM and CBP in brain, leading to the speculation that the anticonvulsant action of these drugs may be mediated at DM binding sites. Analogs of each of these parent compounds have been synthesized to determine structural requirements for anticonvulsant activity as well as to attempt to correlate anticonvulsant activity as well as to attempt to correlate anticonvulsant activity of metabolism to dextrorphan, the primary metabolite of DM, which is anticonvulsant but also produces undesirable behavioral side effects, a series of analogs with bioisosteric replacement of the 3-position methoxy group were prepared. Chemical modification at the ester function in CBP was explored to determine whether this group was necessary for anticonvulsant activity and to determine how these changes effected receptor binding. Preliminary testing in the supramaximal electroshock test in rats showed at least one compound in each series to be anticonvulsant.

321.11

SEROTONIN (5-HT) DEPLETION PREVENTS THE ANTICONVULSANT EFFECT OF CARBAMAZEPINE IN SEVERE SEIZURE GENETICALLY EPILEPSY-PRONE RATS (GEPRS). J.W. Dailey, A.F. Bettendorf*, R. Burger*, and P.C. Jobe. Dept of Basic Sci, Univ of IL Col of Med, Peoria, IL 61656.

Considerable evidence suggests that previously documented widespread deficits in CNS norepinephrine and serotonin (5-HT) are integral components of the seizure predisposition characteristic of GEPRs. Other results are compatible with the concept that carbamazepine (CBZ) produces its anticonvulsant effects in GEPRs at least in part through release of CNS 5-HT (Neurosci Abs 15: 24.8, 1989). To further evaluate this concept, 29 severe seizure GEPRs (GEPR-9s) had their phenotypic seizure expression (fore and hind limb tonic extension) confirmed by three separate tests of audiogenic seizure severity at weekly intervals. The 29 GEPR-9s then received a challenge dose of CBZ (6 mg/kg i.p.- 2 x ED₅₀ dose) to confirm its anticonvulsant effect. All 29 rats experienced the anticonvulsant effect (i.e., prevention of hindlimb tonic extension in audiogenic seizure test). The next week, 14 rats received 3 daily injections (150 mg/kg/day) of the 5-HT depleter, p-chlorophenylalanine (PCPA) methyl ester. The remaining 15 rats received 3 daily vehicle injections. On the day after the last injection, each animal was again challenged with 6 mg/kg of CBZ. Hindlimb extension was prevented in 12/15 vehicle treated animals and in 3/14 PCPA treated animals (p=0.003, Fisher's Exact Probability Test). Thus, 5-HT depletion prevented the anticonvulsant effect of CBZ in GEPR-9s. This finding further supports a role for 5-HT neurons in the CBZ anticonvulsant effect.

321.13

ETHOSUXIMIDE BLOCKADE OF THE EXCITATORY EFFECT OF GAMMA HYDROXYBUTYRATE ON MOUSE CENTRAL NEURONS IN CELL CULTURE. A.W. Wamil* and M.J. McLean. Dept. of Neurology, Vanderbilt Univ. Med. Ctr., Nashville, TN 37212.

Gamma hydroxybutyrate (GHB) is a naturally occurring metabolite of GABA in the mammalian brain which produces a trance-like state and EEG changes in animals which resemble generalized absence seizures in man. The effects of GHB were reversed by ethosuximide (ES; O.C. Snead, Neurology 28:636-642 and 1173-1178, 1978). We used conventional intracellular electrophysiological recording techniques to study effects of GHB on mouse spinal cord neurons in monolayer cell culture. Experiments were performed at 37°C during superfusion with protein-free phosphate buffer (pH 7.4) containing 7 mM kgT to suppress spontaneous activity. Application of 10 M GHB by pressure ejection from a blunt-tipped micropipette positioned nearby resulted in depolarization and burst firing of action potentials. Co-application of a therapeutically relevant concentration of ES (7 x 10 M, 100 ug/ml) resulted in use-dependent block of the response to GHB. These results suggest that the therapeutic efficacy of ES may depend on post-synaptic blockade of GHB-mediated excitation. (Supported by a Mallinckrodt Scholarship and grant NS 00817 from the U.S. National Institutes of Health to MJM and a post-doctoral fellowship from the Cissy Patterson Trust to AWW.)

321.10

ANTICONVULSANT PROPERTIES OF DIFFERENT CLASSES OF Ca⁺⁺-CHANNEL ANTAGONISTS ON AMYGDALA KINDLED SEIZURES, <u>CM Mack ME GILBERT</u> & <u>DB PEELE</u>, NSI Technology Services, RTP, NC, and N.C. State Univ., Raleioh, NC.

N-methyl-D-aspartate (NMDA) channel activation permits an Influx of extracellular Ca⁺⁺ and can produce epileptiform activity. NMDA antagonists protect against seizures induced by electrical kindling of the amygdala in rats. However, other voltage sensitive Ca⁺⁺-channels exist and may also contribute to seizure induction. The anticonvulsant efficacy of drugs from 3 classes of Ca⁺⁺-channel antagonists (phenyialkylamines, diphenyialkylamines, and dihydropytdlines) was assessed in the kindled amygdala model. Male rats (n=12) were kindled to stage 5 seizures (GS), then a threshold intensity required to evoke a GS was determined. The Ca⁺⁺-channel antagonists (nimodipine 0.5,25,50 mg/kg; nitrendipine 0.25,50,100 mg/kg; verapamil 0,10,20.40 mg/kg and flunarizine 0,20,40,80 mg/kg) were administered po 60-90 min prior to amygdala stimulation at the established threshold. One to two weeks intervened between drugs, and thresholds were redetermined during that time. The phenyialkylamine verapamil, and the dihydropyridines nimodipine and nitrendipine, did not protect against amygdala kindled seizures. Although not statistically significant, the high dose of nitrendipine did appear to suppress the afferdischarge (AD) duration and the duration of clonic activity. The diphenyialkylamine flunarizine (80 mg/kg) did significantly reduce seizure severity (25%). AD duration (46%), and duration of clonic activity (50%), relative to vehicle control. Thus voltage sensitive, non-NMDA, Ca⁺⁺-channels, may contribute to epileptiform activity induced by kindling.

321.12

PARENTERAL CARBAMAZEPINE: EFFECT ON CONVULSIONS AND ON DIALYZABLE HIPPOCAMPAL SEROTONIN (5-HT) IN GENETICALLY EPILEPSY-PRONE RATS (GEPRs). O-S, Yan*, P.C. Jobe and J.W. Dailey, Dept. of Basic Sci, Univ of Illinois Col of Med, Peoria, IL 61656.

Carbamazepine (CBZ) is a widely used antiepileptic drug which is virtually insoluble in traditional parenteral vehicles.

Carbamazepine (CBZ) is a widely used antiepileptic drug which is virtually insoluble in traditional parenteral vehicles. For experimental and perhaps medical reasons, an intravenous (i.v.) use of this drug is desirable. CBZ can be solubilized for i.v. use through complexing with beta-cyclodextrin (Molecusol^{Im}, Pharmatec, Inc.). This solubilized CBZ (provided by K. Estes, Pharmatec) was used in studies of the anticonvulsant mechanism of CBZ in GEPRs. Tail vein injections of a range of CBZ doses (up to 30 mg/kg) produced rapid (as little as 2 min.) and significant anticonvulsant effects in both moderate (GEPR-3s) and severe seizure animals (GEPR-9s), animals in which seizures are regulated, at least in part, by 5-HT. To determine the effect of i.v. CBZ on dialyzable serotonin, GEPR-3s were implanted with a jugular cannula and had a guide cannula stereotaxically placed in the skull over the hippocampus. After 10 days, the microdialysis probe was inserted and the hippocampus was dialyzed with artificial CSF for 3 hrs after which vehicle and CBZ were given i.v. Within minutes after drug, dialyzable 5-HJ increased about 3 fold. Vehicle had no effect. Dialyzable 5-HJdroxyindoleacetic acid, the major 5-HT metabolite, was not affected by vehicle or CBZ. This result confirms and extends our earlier observation (Neurosci. Abs. 15: 24.8, 1989) that the peak anticonvulsant effect with CBZ and the peak increase in dialyzable 5-HT occur simultaneously. These results are consistent with a role for 5-HT in the anticonvulsant effect of CBZ (Supported in part by a grant from Tsumura Juntendo Fdn).

321.14

DIFFERENTIAL EFFECTS OF HALOPERIDOL AND SCH 23390 IN A MODEL OF EPILEPSY IN THE RABBIT. P. Bo*\(\frac{1}{2}\) E. Ongini\(\frac{2}{2}\) and F. Savoldi*\(\frac{1}{2}\) Inst. of Neurology "Mondino", Univ. Pavia, I-27100 Pavia, and Research Labs, Schering-Plough S.p.A., Comazzo (Milan), Italy

Dopamine antagonist neuroleptics can induce EEG discharge patterns and increase susceptibility to seizures in epileptic patients. Using a model of epilepsy in the rabbit, we examined the effects of two neuroleptics which differ in selectivity for DA receptors, haloperidol (D-2) and SCH 23390 (D-1). The EEG pattern of after-discharge (AD) induced by electrical stimulation of hippocampus (Cornu Ammonis dorsale) or amygdala was studied before and after drug administration. Haloperidol (1 mg/kg iv) increased significantly duration of AD upon stimulation of either hippocampus or amygdala. The drug also lowered threshold of the AD. SCH 23390 (0.3 mg/kg iv) produced no change upon stimulation of amygdala and reduced duration of AD when the hippocampus was stimulated. Unlike haloperidol, SCH 23390 induced either no effect or protective action in a model of experimental epilepsy. The data suggest that the D-1 and D-2 receptor subtypes have different function in mechanisms underlying convulsions.

IN VITRO HIGH INTENSITY TETANUS (HIT) INCREASES KINDLING

IN <u>VITRO</u> HIGH INTENSITY TETANUS (HIT) INCREASES KINDLING THRESHOLD IN HIPPOCAMPAL SLICES. <u>L.S.Jones</u> Dept. of Anat., USC Sch. of Med., Columbia, SC 29208.

Electroconvulsive seizures (ECS) interfere with kindling in animals (<u>Exp. Neur. 78</u>:483, 492; <u>Epilepsia</u> 25:234) and elevate seizure thresholds in humans; the effect may be related to antidepressant properties (<u>Biol. Psych. 18</u>:1301). The anticonvulsant mechanism is unknown, but opioids have been implicated (<u>Science</u> 228:1106; <u>Brn. Res. 17</u>:273: Mol. Brn. Res. 6:11)

Res. 177:273; Mol. Brn. Res. 6:11).

Hippocampal slices from young rats were used to develop a model to allow in vitro monitoring of effects that may accompany ECS and the early seizure-resistant period following ECS in whole animal. 625 µM slices received a HIT either through the Schaffer collaterals (SCs) or the mossy fiber (MF) pathway prior to being "kindled" 45 min later through the same or the untreated pathway using the stimulus train induced bursting paradigm of interictalstimulus train induced bursting paradigm of interictal-like burst induction (<u>Brn. Res.</u> 344:296). A HIT via the SCs delayed kindling via the same fibers as measured by the appearance of after-discharges (ADs) in CA1 and spontaneous bursts (SBs) in CA3, and also delayed kindling via the MFs. A HIT via the MFs substantially delayed kindling via either the MFs or the SCs as measured by the appearance of spontaneous bursts in CA3, but had no effect on CA1 ADs. A HIT was not effective in arresting SBs established by earlier kindling or removing Mg+

EFFECTS OF NMDA ANTAGONISTS ON INFERIOR COLLICULUS (IC) NEURONAL RESPONSES AND AUDIOGENIC SEIZURES (AGS) IN BEHAVING NORMAL AND GENETICALLY EPILEPSY-PRONE RATS (GEPRs). C.A. Boersma Anderson and C.L. Faingold, Dept. Pharmacol., So. IL. Univ. Sch. Med., Springfield, IL. 62794.

Systemic administration of the competitive NMDA antagonist, CPP, or the noncompetitive NMDA antagonist, MK-801, blocks AGS in GEPRs. The IC is noncompeture IVIDA antagonist, MA-801, DIOCKS AGS in GEPRS. The IC is vital for initiation of AGS in the GEPR, and abnormal acoustically-evoked IC neuronal firing occurs in GEPRs, leading to AGS. The present study examined the effects of systemic administration of CPP and MK-801 on IC neuronal firing of behaving GEPR-9s and normal rats. Microwire electrodes were implanted into of behaving GEPR-9s and normal rats. Microwire electrodes were implanted into IC of normal rats and GEPRs anesthetized with ketamine/xylazine. Unit activity and behavior were examined in freely moving animals. CPP (5 mg/kg l.p.) or MK-801 (.05 mg/kg l.p.) was administered, and acoustic stimuli (12 kHz tone bursts, 100 msec duration) at 2/sec were presented. Neuronal responses were evaluated to stepwise increases in sound level up to 105 dB SPL. Responses were recorded before and 30-240 min after drug administration. CPP greatly inhibited IC neuronal firing (mean inhibited inc mean, 29.8% ± 9.1 SEM, N=13), while MK-801 inhibited firing to a small extent (mean, 29.8% ± 10.0, N=6) in normal rats and GEPRs (SPL 20-30 dB above 12 kHz tone threshold). With each drug the reduction in IC neuronal firing was significant at a time (60 min post injection) when both agents were effectively anticonvulsant. However, the degree of firing reduction was significantly greater with CPP than with MK-801. Previous studies indicate that CPP bilaterally microinjected into the IC is very potent and effective in blocking AGS, but microinjection of MK-801 is considerably less effective. However, MK-801 is the most potent agent systemically. CONCLUSION: CPP appears to be producing its anticonvulsant effect, in large part, on the brainstem auditory pathway. However, actions of MK-801 on additional and more rostral parts of the AGS network may be required for the complete anticonvulsant effects of this agent. (Support NIH NS 21281; 13849).

EFFECTS OF GLYCINE AND MILACEMIDE, A GLYCINE PRODRUG, ON AUDIOGENIC SEIZURES IN THE GENETICALLY EPILEPSY-PRONE RAT (GEPR-9). D.K. Naritoku, L.B. Mecozzi*, M.E. Randall*, C.L. Faingold. Div. of Neurol. and Dept. of Pharmacol., So. IL. Univ. Sch. Med., Springfield, IL. Glycine (GLY) is a putative inhibitory neurotransmitter in the brainstem

Glycine (GLY) is a putative inhibitory neurotransmitter in the brainstem auditory system, but may also enhance excitation via the NMDA receptor complex. Its role in audiogenic scizures (AGS) is unknown. Studies have implicated the inferior colliculus (IC) as important during AGS genesis, and we observed the effects of increasing brain glycine by systemic administration on milacemide (MIL), a glycine prodrug, and microinfusions of GLY or MIL into bilateral IC. In systemic studies, MIL (200 or 400 mg/kg) was given i.p. At various intervals the animals were exposed to bell stimulus (120 dB SPL) for 1 min or until AGS onset. The resulting selzures were scored using the scale of Jobe (1981). Systemic administration of MIL at 200 mg/kg did not affect AGS, whereas a dose of 400 mg/kg reduced the median AGS severity score to 3 at 30 min and 1 hr (p < .001). For microinfusion studies, cannula guides were placed over IC. After one week of recuperation, GLY $(0.5 - 1 \, \mu g)$ side) or MIL (200 or AMD $(0.6 \, 1 \, \mu g)$ and tested at various and tested at various and tested at various and tested at various 400 μ g/side) were infused into bilateral IC (0.5 μ l, 2 min) and tested at various intervals. Microinfusions of GLY (1 $\mu g/side$) reduced the mean severity score to 1 at 2 hrs (p < .001). No signific: at reduction occurred with a dose of 200 μ g/side of MIL, and 400 μ g/side infusions reduced the median severity score to 7 at 4 hrs (p < .01). There was a prolonged reduction of the severity score (p \leq .05) from 1 to 5 hrs after the MIL infusions. CONCLUSION: The data suggest GLY plays a role in the neuronal network which subserves AGS in the GEPR-9. The relatively large amounts of GLY or MIL required at IC to reduce AGS severity suggest that GLY may exert its antiepileptic effect at a site different from IC during AGS, or alternatively, the ability of GLY to facilitate excitatory transmission may partially offset its inhibitory effects. INFLUENCE OF ACTH AND ACTH FRAGMENTS ON (3H)MK-801 BINDING TO RAT HIPPOCAMPAL NMDA RECEPTORS. R.R.

Triflietti and M.R. Pranzatelli. Dept. of Pediatrics and Neurology, Columbia-Presbyterian College of Physicians and Surgeons, New York, NY 10032.

Adrenocorticotropic hormone (ACTH) is widely used in the treatment of infantile spasms. The anticonvulsant mechanism of action of ACTH remains unknown. Its mechanism of action is felt to be independent of cortisol release in that it is equally efficacious in adrenally-surpressed infants. We explored the possibility of a direct influence of ACTH upon rat brain N-methyl D-aspartate (NMDA) receptors labelled with the synthetic NMDA antagonist (3H)MK-801.

We found that ACTH(1-39) competitively inhibits binding of (3H)MK-801 to rat hippocampal membranes with a K₁ of 2.7 uM. The potencies of ACTH fragments at inhibiting (3H)MK-801 binding varies in the order ACTH(1-39) > ACTH(1-24) > ACTH(1-17) > ACTH(4-10). The known potencies of ACTH fragments at treating infantile spasms also varies in this order. This suggests that glutamatergic mechanisms might play a role in the anticonvulsant action of ACTH.

SENSITIVITY DIFFERENCES TO BLOCKADE OF AUDIOGENIC SEIZURES (AGS) IN THYROID DEFICIENT (THX) OR GENETICALLY EPILEPSY-PRONE RATS (GEPRs): MICROINJECTION INTO BRAINSTEM AUDITORY READING RAID (MEERS); MILKUINJELTION INTO BRAINSTEM AUDITORY NUCLEI. <u>D.L. Patrick and C.L. Faingold</u>. Dept. Pharmacol. So. IL. Univ. Sch. Med., Springfield, IL 62794.

Neonatally THX rats and GEPRs exhibit cochlear damage and are susceptible to AGS. GEPRs are also THX during development. Excitant amino acids (EEAs) and GABA in the inferior colliculus (IC) are critically involved in initiation of and GABA in the inferior colliculus (IC) are critically involved in initiation of AGS in GEPRs, while EAA action in cochlear nucleus (CN) appears to be relatively less important to epileptogenesis. This study examined the effects of microinjection into IC or CN of the EEA (NMDA) antagonists, AP7 and Mk 80), or the GABA agonists, THIP (GABA-A) and baclofen (BAC, GABA-B). Comparisons were made between effects in THX rats and GEPRs. THX rats were depleted of thyroid hormone using propythiouracil (PTU) (0.0075% postnatal day 0-19). AGS severity was tested using a bell (122 dB SPL, for 60 sec or until AGS onset). Bilateral infusion of MK-801 (in 0.5 μl, 2 min) into IC or until AGS onset). Bilateral infusion of MK-801 (in 0.5 μ l, 2 min) into IC completely blocked AGS at 50 (THX) vs. 40 nmol (GEPR). Microinjection of THIP completely blocked AGS at 68 (THX) vs. 13.6 nmol (GEPR). Microinjection of BAC completely blocked AGS at 28 (THX) vs. 1 nmol (GEPR). Relative doses of AF7 in CN were 50 (THX) vs. 5 nmol (GEPR) for reduction of AGS severity. CONCLUSION: These data suggest the sensitivity for blockade of AGS in IC and CN is considerably less in THX rats than in GEPRs. Cochlear damage may be more important in AGS of THX rats as compared to GEPRs wherein the IC may be abstituted from properties in AGS control. The additional properties of the properties wherein the IC may be relatively more critical in AGS control. The reduced sensitivity in THX rats may be due to consistent changes in receptor properties in CN and IC induced by the extensive neonatal deficiency of thyroid hormone in PTU-treated rats. Although GEPRs exhibit some degree of thyroid deficiency, the deficiency in PTU-treated rats may be more extensive than that observed in GEPRs. (Support: NIH NS 21281, NS 13849)

ALU REPEAT FAMILY (ARF) - AND AMYLOID PRECURSOR PROTEIN (APP) - RNA EXPRESSION IN ALZHEIMER AND CONTROL FIBROBLASTS. N.P. Dooley*, H.D. Durham, J. Nalbantoglu*, S. Gauthier and N.R. Cashman. MNI, McGill University, Montreal, and N.R. Cashman. Canada H3A 2B4

We have investigated ARF- and APP-RNA in unstimulated, non-transformed fibroblasts grown from primary cultures. ARF, which is transcribed by RNA polymerase III predominantly in brain, has been implicated in the regulation of neuronal genes during postnatal neural development. postulated that abnormalities in ARF may account for decreased mRNA in brains from patients with Alzheimer's disease(AD). Skin biopsies were obtained from AD patients and neurologically normal spouses. Total RNA was extracted using the guanidinium thiocyanate-phenol-chloroform method from cultures of the same low generation. Northern blots were probed for ARF RNA using the BC200 probe (Watson, J.B., Mol Cell Biol 7(9):3324-27, 1987) at high stringency. As a control for lane loading and signal intensity, these blots were stripped and rehybridized using a human actin probe (Gunning, P. Mol Cell Biol 3(5):787-95, 1983). ARF transcripts were detectable in all primary fibroblast cultures; preliminary results suggest decreased expression in 4 AD patients versus 6 controls (0.20 > p > 0.10).

APP deposition is believed to be a seminal event in AD pathogenesis and has been demonstrated in non-neuronal tissue. Northern blots were hybridized with a 3' APP cDNA probe followed by the actin probe. No significant difference between AD and control mRNA levels was observed.

Immunocytochemical Localization of A4 Amyloid Epitope in Plastic-Embedded Brain Tissue from Alzheimer's Disease Patients. R.A. Brumback, C.A. Marotta, R.E. Majocha, D.L. Feeback, * R.W. Leech, J.L. Ketring, * L.K. Benning-field, * G.D. Miner. Univ. of Oklahoma and VA Medical Center, Oklahoma City, OK, Harvard Program in Neurosciences, Massachusetts General Hosp./McLean Hosp., Boston, MA, The Alzheimer's Foundation, Tulsa, OK. Previously, we described improved histologic resolution of large brain specimens (without shrinkage and distortion artifacts of paraffin-embedding) using the technique of plastic embedding with methyl methacrylate (Ann Neurol 26:301, 1989). Cases of Alzheimer's disease studied with this technique show improved morphologic and spatial resolution

technique show improved morphologic and spatial resolution of characteristic plaques and tangles in Bielschowskystained sections. However, since greater sensitivity in detection of the Alzheimer's disease-associated amyloid plaque protein is possible utilizing monoclonal antibodies developed to the A4 amyloid epitope (J Geriatr Psychiatry Neurol 1:65, 1988; PNAS 55:6182, 1988), we have applied these antibodies to plastic embedded tissue. Tissue sections (2 µm thick) mounted on glass slides, dried, and subsequently xylene immersed (to remove the plastic) were incubated with antibody to the A4 amyloid epitope. Positive immunostaining (standard avidin-biotin-HRP method) for the amyloid protein was readily identifiable in plaques and technique show improved morphologic and spatial resolution amyloid protein was readily identifiable in plaques and neurons and detailed localization was possible. [Supported in part by NIH AG02126 and Metropolitan Life Foundation (CAM); and Founders of Doctor's Hospital (GDM)]

A 35KD FRAGMENT OF AMYLOID β/A4-PROTEIN PRECURSOR IN ALZHEIMER'S DISEASE AND CULTURED CELLS. L.A. Flanagan¹, G.M. Cole¹, E.R. Shelton^{*2}, H.W. Chan², and T. Saitoh¹. University of California, San Diego, Dept. of Neurosciences, M-024, La Jolla, CA 92093, ²Syntex Res. lnst. of Bio-Organic Chem., Palo Alto, CA 94304

4Syntex Res. Inst. of Bio-Organic Chem., Palo Alto, CA 94304.

A 35Kd fragment of the amyloid β/A4-protein precursor (ABPP) has been recognized by antisera directed to the N-terminal portion of the precursor and found at higher concentrations in Alzheimer cortex than in control cortex (Cole et al., Neurosci. Lett., 100: 340-346, 1989). To identify this 35Kd fragment (ABPP-35K) and discover its significance we have undertaken a systematic analysis of this peptide. ABPP-35K is soluble at 60% saturated ammonium sulfate whereas the majority of other ABPP species precipitate. Immunostaining of Western blots suggests the presence of a doublet at 35K rather than a single band, and both bands appear to contain the Kunitz-type protease inhibitor region of the precursor protein. An antibody directed to amino acids 175–186 of ABPP has higher affinity for the lower band while other antibodies directed toward the N-terminal portion of ABPP detect both bands equally well.

other antibodies directed toward the N-terminal portion of ABPP detect bout bands equally well.

We have previously suggested that degradation of ABPP occurs through lysosomal pathways (Cole et al., Neurochem. Res., 14: 933-939, 1989). We now have evidence that ABPP-35K may be generated by blocking lysosomal degradation of ABPP. Treatment of PC12 cells with leupeptin and ammonium chloride results in an increase in ABPP-35K. Further studies are underway to determine the C-terminal sequence of ABPP-35K and the pathways involved in its generation and degradation which may be altered in Alzheimers disease.

BETA-AMYLOID PROTEIN INCREASES NEURONAL VULNERABILITY TO EXCITOTOXINS IN CORTICAL CULTURE. J. Koh, L.L. Yang*, and C.W. Cotman, Dept. of Pyschobiology., Univ. of Cal., Irvine, CA92717.

Glutamate neurotoxicity has been proposed as a pathologic mechanism contributing to neuronal degeneration in a variety of diseases including Alzhemier's disease (AD). In addition to effects on extracellular glutamate levels, a particular disease may increase neuronal vulnerability to excitotoxins. In this study, we examined the possibility that β -amyloid protein found in plaques of AD acts in such a manner.

Mature mouse cortical cultures were exposed for 2 days to β-amyloid protein (β1-42, 100 μg/ml) in serum-free defined media and subsequently exposed for 5 min to 100 μM glutamate. Morphological observations and lactate dehydrogenase assay indicated that the pre-exposure to \$1-42 significantly increased the glutamate neurotoxicity compared with control sister cultures. Similar potentiation by β 1-42 was observed after 5 min exposure to 30 μ M N-methyl-D-aspartate observed after 5 min exposure to 30 μ M N-methyl-D-aspartate (NMDA) or 500 μ M kainate. The potentiation of NMDA neurotoxicity was dependent on β 1-42 concentration and exposure duration. Additionally, a shorter fragment of β -amyloid (β 1-28) also potentiated excitotoxicity.

The present results demonstrate that prolonged exposure to β -amyloid protein enhances neuronal vulnerability to excitotoxic damage. We speculate that this toxicity-

potentiating effect of β-amyloid protein could contribute to accelerated neuronal degeneration in AD.

322.4

EXPRESSION OF AMYLOID PRECURSOR PROTEIN mRNAS IN ENDOTHELIAL AND NEURONAL CELLS.
G.L.Forloni, S., Giorgi*, C., Bendotti, N. Angeretti* and S. Consolo. Istituto di Ricerche Farmacologiche "Mario Negri", 20157 Milano, Italy. The origin of the ß/A4 amyloid protein deposited in the neuritic plaque of Alzheimer disease (AD) is unknown. It has been demonstrated that the amyloid precursor protein (APP) gene encoding the precursor of the β/A4 amylod protein can be expressed as APP695 and/or APP751/770 depending on the presence of a Kunitz family protease inhibitor sequence. We investigated *in vitro* the expression of APP gene in endothelial and neuronal cells, by using two different probes recognizing the total APP mRNA or the APP751/770 mRNA. Total RNA was extracted from endothelial cells isolated from human umbelical cord grown to confluency and from rat cortical neurons dissociated at E17 and cultured *in vitro* for two weeks. The Northern blot analysis was performed using the APP ³²P-cDNA probe to detect the general APP sequence and with a 32P-labelled oligonucleotide (40 mer) complementary to the sequence of the protease inhibitor. The APP mRNA transcripts were abundant in both cell types. APP751/770 mRNA was found in endothelial as well as in the neuronal cells, however in the neuronal cells the ratio APP751/770 mRNA/total APP mRNA was much lower than in the endothelial cells. We observed in the endothelial cells, similar increase of total APP mRNA or APP751/770 mRNA after interleukin-1 (100ng/ml) treatment. The present results demonstrate some differences in the APP expression between neuronal and endothelial cells and identify these primary cell cultures as a useful model to investigate the mechanisms related to the β/A4 amyloid protein deposition in AD.

EFFECT OF NGF ON THE ALTERNATIVELY SPLICED BAPP MRNAS AND SECRETED BAPP DERIVATIVES IN PC12 CELLS. S. Estus. T. Golde, G. Landreth, and S. Younkin, Case Western Reserve University, Cleveland, OH

44106
The factors regulating the extracellular accumulation of the soluble derivatives of BAPP₆₉₅, BAPP₇₅₁, and BAPP₇₇₀ are unclear. These proteins could be secreted in direct proportion to the level of the corresponding mRNAs. Alternatively, regulation of the secreted forms could occur at the level of posttranslational processing. We have employed PC12 cells to examine this question because this cell line manifests a neural phenotype when stimulated by NGF and because our initial experiments showed that these cells express BAPP₆₉₅ mRNA, a form found primarily in neurons that lacks the Kunitiz protease inhibitor (KPI) insert, as well as BAPP₇₅₁ and lacks the Kunitiz protease inhibitor (KPI) insert, as well as BAPP₇₅₁ and BAPP₇₇₀ mRNAs, forms that contain the KPI insert and are found in all types of cells. Analysis of the BAPP derivatives secreted from PC12 cells on immunoblots labeled with anti-APP₄₅₋₆₂ revealed three large secreted forms: two proteins of ~ 134 and ~128 kDa that were also labeled with an antiserum specific for the KPI domain, and a protein at ~ 114 kDa that was not labeled with the KPI antiserum. To evaluate the changes induced by NGF, BAPP mRNAS were analyzed using a sensitive PCR based method and secreted BAPP derivatives were analyzed using 1251-protein A to quantitate anti-BAPP₄₅₋₆₂ immunoblots. As reported by others, NGF treatment produces a marked absolute and relative increase in the level of the secreted ~114 kDa KPI-free form. Moreover, our data indicate that this increase is due, at least in part, to an NGF-induced increase in the absolute and relative amount of APP₆₉₅ mRNA. Additional studies are underway to characterize the posttranslational processing of the BAPP in NGF and control PC12 cells to determine whether changes in posttranslational processing also contribute to the NGF-induced change in secreted BAPP derivatives.

B AMYLOID PROTEIN PRECURSOR DERIVATIVES IN AD . M. Palmert. T.

Cheung* M. Cohen* V. Frazzin*, T. Kunishita*, J. Pasternack, M. Usiak*, and S. Younkin, Case Western Reserve University, Cleveland, OH 44106
Previously, we (i) identified ~125, ~105, and ~25 kDa soluble aminoterminal derivatives of the full-length, membrane-associated 8 amyloid protein precursor (8APP) by purifying these proteins from human cerebrospinal fluid (CSF) and sequencing their amino termini, (ii) showed that the ~125 kDa form (CSF) and sequencing their amino termini, (ii) showed that the ~125 kDa form contains and the ~105 kDa form lacks the alternatively spliced Kunitz protease inhibitor domain, and (iii) demonstrated that the carboxyl-terminal region of both the ~125 and ~105 kDa forms contains at least part of the β amyloid protein (βAP). To determine if any of the ~125 or ~105 kDa derivatives in the AD or control brain are potentially amyloidogenic forms that contain full length βAP, we are analyzing their carboxyl termini and have adapted our purification procedure to isolate the requisite large amounts of these proteins from human brain tissue. To identify quantitative changes in βAPP derivatives that could reflect abnormal βAPP processing that leads to amyloid deposition, we have analyzed CSF samples from 24 AD patients and 12 controls. Our results show (i) that in eldery (68 + 3 year) as compared to amyloid deposition, we have analyzed CSF samples from 24 AD patients and 12 controls. Our results show (i) that in elderly (68 ± 3 year) as compared to young (45 ± 4 year) non-demented controls there is a significant increase in the relative amount of the ~25 kDa form, a corresponding significant decrease in the percentage of the ~105 kDa form, and significant increases in the absolute amounts of the ~25 kDa, ~105 kDa, and total 6APP derivatives, (ii) that the age-dependent shift toward a higher percentage of the ~25 kDa form is significantly enhanced in AD cases as compared to age-matched controls, and (iii) that the changes in AD are correlated with mental status. To identify proteases that may be involved in normal or abnormal 6APP processing, we are using substrate gel analysis (also called enzymography) to evaluate AD and control CSF. We have identified seven proteases between 45 and 155 kDa as well as several larger proteases in both AD and control CSF, and we are analyzing them to determine where they cleave the 6APP.

322.9

THE β-AMYLOID PRECURSOR PROTEIN, A COLLAGEN BINDING PROTEIN, MEDIATES NEURAL CELL ADHESION.

Kieran C. Breen. Dept. of Pharmacology, University College, Belfield, Dublin 4, Ireland. (SPON: Brain Research Association)

The β-amyloid precursor protein (APP) is a glycoprotein which consists of at least four isoforms derived from a single gene by a process of alternative splicing. The 42 amino acid β-A4 region is located at the carboxy terminal of the protein, and is partially embedded in the membrane. Two isoforms, APP751 and APP770 contain an extra domain homologous with the kunitz-type protease inhibitor.

As a membrane-bound glycoprotein, APP has been suggested to have possible adhesive properties and to mediate neural cell adhesion. Purified APP from transfected cell lines has been demonstrated to be capable of mediating cell-substrate adhesion.

Fab' fragments of antibodies to different domains of the molecule were prepared These were demonstrated to inhibit neural cell adhesion to a collagen substrate. APP was further shown to bind specifically to type IV collagen-bound sepharose. Fab' fragments of the antibodies also inhibited neuron-neuron and neuron-glial cell adhesion, but did not influence glialalial cell interaction.

These data suggest that APP plays a role in both cell-cell and cellsubstrate adhesion in neural cells

322.11

CLIPSIN, A POSSIBLE β-AMYLOID GENERATING PROTEASE, IN HUMAN BRAIN. R. Siman. R.B. Nelson J. M. Iqbal*, & J.C. Kauer, Cephalon, Inc., West Chester, PA. 19380, and ¹Dept. Neurobiology, Harvard Medical School, Boston, MA. 02115.

Proteolytic processing of the β-amyloid precursor proteins is required for deposition of the β-protein into neuritic plaques. We have designed chromogenic protease substrates with which to examine human brain fractions for activities capable of generating plaque β-amyloid. Here, we describe one such activity. Like the serine protease clipsin, previously described in rat brain, the human protease was detergent- and low ionic strength-insoluble, but could be extracted by high salt. The strength-insoluble, but could be extracted by high salt. The protease was found post-mortem in both Alzheimer's disease and normal brain. The human brain protease co-purified with authentic clipsin upon heparin-Sepharose and substrate affinity chromatographies. The protease, purified to homogeneity, had an apparent Mr~26 kDa and co-migrated with rat clipsin. The activity also co-migrated with authentic clipsin on substrate-containing enzymographic gels and, like clipsin, was inhibited by α 1-antichymotrypsin. We therefore refer to the human brain protease as clipsin. Both human and rat brain clipsin readily hydrolyzed peptide substrates that two other chymotrypsin-like proteases, chymotrypsin and cathepsin G, did not degrade. These results indicate that not all members of the chymotrypsin family of serine proteases are capable of liberating the N-terminal of β -amyloid. Clipsin, on the other hand, is a candidate for such a role. hand, is a candidate for such a role.

EXPRESSION OF NORMAL AND VARIANT ALZHEIMER'S B-PROTEIN
GENES IN VASCULAR AMYLOID OF HEREDITARY CEREBRAL HEMORRHAGE WITH AMYLOIDOSIS DUTCH TYPE. F. Prelli,* E. Levy,* S.G. van Duinen,* G.Th.A.M. Bots,* W. Luyendijk,* and B. Frangione NYU Med. Cent, NYC 10016; Univ. Med. Cent, Leiden, Holland Amyloid fibrils deposited in cerebral vessel walls in

Dutch patients with hereditary cerebral hemorrhage with amyloidosis (HCHWA-D) are formed by an amyloid protein simamyloidosis (MCHWA-D) are formed by an amyloid protein similar to the amyloid B-protein of Alzheimer's disease (AD) and Down syndrome (DS). Sequence analysis of the genomic DNA isolated from 4 Dutch patients revealed a point mutation, cytosine for guanine, at position 1852 of the precursor B-protein gene. The HCHWA-Ds had 1 normal allele. The mutation was not detected in 5 AD, 2 DS patients and 11 normals. To ascertain whether the amyloid fibrils in HCHWA-D are composed of normal and variant B-protein, fibrils were isolated from brain tissue of 2 Dutch patients.

HPLC fractionation of the tryptic digest of a fraction containing monomers yielded 4 peptides T1-T4; two peaks, T3a and T3b, had amino acid compositions identical to positions 17-28. Sequence analysis confirmed their identity, but T3a had GLN and T3b had GLU at position 22. Although GLN and ASN may undergo deamination, recovering GLN and ASN exclusively at positions 15 and 17, respectively, suggests that the GLU at position 22 expresses the normal β -protein allele rather than deamination of GLN. Thus both the normal and variant Alzheimer B-protein genes are expressed in the vascular amyloid of HCHWA-D.

MOLECULAR MODELING OF THE PROTEASE INHIBITOR INSERT OF THE AMYLOID PRECURSOR PROTEIN. R.J. McClure, W.E. Klunk and J.W. Pettegrew. Laboratory of Neurophysics, Dept. of Psychiatry, Western Psych. Inst. & Clinic, Univ. of Pittsburgh, Pittsburgh, PA

Recent studies have demonstrated that the 751 amino acid form of amyloid precursor protein (APP-751) contains a 56 amino acid residue insert with sequence homology to the Kunitz family of serine protease inhibitors. Purified secreted APP-751 inhibits trypsin with high affinity (Oltersdorf, T. et al., Nature, 341:144, 1989). The present study examines the 3-dimensional structure of this amyloid protease inhibitor (API) domain in order to help determine the role of a protease inhibitor in the increased deposition of β -amyloid in Alzheimer's disease (AD). The amino acids of API were modeled onto the molecular framework of bovine pancreatic trypsin inhibitor using the computer program FRODO and minimized using AMBER. This 3-dimensional model shows that API could adopt a conformation consistent with a high affinity inhibitor-trypsin complex. We postulate that AD may be a disease of protease dysregulation and that study of the tertiary structure of API may give insights into the molecular structure of this protease/protease inhibitor system which can be pharmacologically exploited.

SELECTIVE ELEVATION IN ACTIVITY OF THE PROTEASE CLIPSIN IN ALZHEIMER'S DISEASE. M. J. Savage and R. Siman, Cephalon, Inc., West Chester, PA.

Abnormal activity of a chymotrypsin-like protease has been hypothesized to play a key role in the pathogenesis of neuritic plaques in Alzheimer's disease (AD). Recently, we identified a chymotrypsin-like protease present in both rat (J. Biol. Chem. 265:3638, 1990) and human brain (this volume), termed clipsin. 265:3638, 1990) and human brain (this volume), termed clipsin. To examine the hypothesis that aberrant clipsin activity might underlie \(\textit{B}\)-amyloid deposition into plaques in AD, we quantified the activities of clipsin and several other proteases using selective synthetic substrates. In parietal cortex grey matter, clipsin activity was significantly elevated by two-fold compared with age-matched controls (n=17). In preliminary analysis, this increase holds for other brain areas as well. Activity levels in this present a second controls of the control of the c white matter were about three-fold less than in grey matter, and were also significantly elevated in AD. The clips in increase was selective, in that activity of the cytosolic enzyme prolyl endopeptidase was reduced by two-fold in AD, while that of the lysosomal enzyme cathepsin B was unchanged. Within the AD Isosomal enzyme cancepsin B was unchanged. Within the AD samples, clipsin activity did not correlate with the density of \(\textit{B}\)-amyloid deposits stained by Congo Red, but in control brains, clipsin activity was significantly lower along with the virtual absence of Congo Red staining. These results suggest that an aberrant increase in clipsin activity may contribute to the generation of \(\textit{B}\)-amyloid in AD.

PURIFICATION OF CLIPSIN, AN $\alpha_1\text{-}ANTICHYMOTRYPSINBINDING PROTEASE WHICH CLEAVES THE <math display="inline">\beta\text{-}PROTEIN$

PURIFICATION OF CLIPSIN, AN α1-ANTICHYMOTRYPSIN-BINDING PROTEASE WHICH CLEAVES THE β-PROTEIN PRECURSOR. B. B. Nelson¹, B. Siman², and H. Potter¹.¹ Department of Neurobiology, Harvard Medical School, Boston, MA 02115 and ²Cephalon, Inc., 145 Brandywine Pkwy., West Chester, PA 19380.
Independent lines of evidence suggest that a chymotrypsin-like protease is involved in depositing β-protein into the amyloid plaque cores which form in Alzheimer's disease and Down's syndrome. First, a chymotrypsin-like protease is predicted to cleave at the site which generates the amino terminus of the β-protein from the β-protein precursor. Second, an α1-antichymotrypsin-like protein (ACT) is an integral component of amyloid plaque cores. Third, the β-protein precursor includes a protease inhibitor domain having a high affinity for chymotrypsin. The discovery of clipsin, a chymotrypsin-like protease in rat brain which binds to ACT in an SDS-stable manner and preferentially degrades membrane-associated β-protein precursor, has recently been reported (*J. Biol. Chem.* 265:3836). We report here the purification of clipsin to homogeneity. Detergent-extracted membranes from 6-day-old rat forebrains were treated with 1.0 M MG2 to solubilize clipsin activity. Clipsin was then precipitated by dialysis against a low-ionic strength buffer, eluted at high salt from a heparin-agarose column, and finally purified to homogeneity using a custom-made substrate column (Ala-Pro-Phe-Sepharose 4B). Purified clipsin is a 25 kDa doublet which binds to ACT in an SDS-stable manner and demonstrates protease activity as measured in vitro and by enzymography. To obtain clipsin in a form suitable for microsequencing, the purified protease was exchanged into a volatile buffer on a Sephadex G-25 column. Internal protein sequence information from tryptic digests of clipsin is currently being obtained. Kinetic comparisons to other known chymotrypsin-like proteases already suggest that clipsin will be a novel enzyme. Partial sequences of clipsin will be used to

322.14

ANALYSIS OF THE HUMAN APP PROMOTER: 96 BASE PAIRS UPSTREAM OF THE TRANSCRIPTIONAL START SITE ARE SUFFICIENT FOR FULL PROMOTER ACTIVITY. W.W. Quitschke and D.Y. Goldgaber. Department of Psychiatry, State University of New York at Stony Brook, Stony Brook, NY 11794

The extracellular deposition of amyloid beta protein in cores of neuritic plaques The extracellular deposition of amyloid beta protein in cores of neuritic plaques and walls of blood vessels in brain and leptomeninges is a neuropathological manifestation of aging, Alzheimer's disease, Down syndrome, and hereditary cerebral hemorrhage with amyloidosis (Dutch type). The amyloid beta protein is derived from a larger amyloid beta protein precursor (APP). The gene encoding this protein is located on human chromosome 21. The APP gene encodes multiple transcripts for a family of secreted proteins that are generated by differential splicing. The APP gene is differentially expressed in all major tissues. In brain it is expressed primarily for a lamily of secretical proteins that are generated by differentials splicing. The APP gene is differentially expressed in all major tissues. In brain it is expressed primarily in neurons. The apparent overexpression of the APP gene in Down syndrome and in certain areas of the brain in Alzheimer's disease suggests that abnormalities in gene regulation might be a critical factor in the neuropathology associated with these conditions. We analyzed the promoter for the APP gene with the goal of identifying cis- and trans-acting factors that affect the expression of the APP gene. The promoter was analyzed by transfecting the mouse myogenic cell line C2C12 with APP promoter constructs fused to the chloramphenicol acetyl transferase gene (CAT). This cell line expresses the endogenous APP gene constitutively at moderate levels. The longest promoter fragment analyzed included 2.8 kb of sequence upstream of the transcriptional start site. Subsequent 5' deletions were introduced at positions -488, -308, -204, and -96. The results from transient transfection experiments suggest that full promoter activity is retained in a promoter fragment containing only 96 base pairs upstream of the transcriptional start site. Experiments are currently in progress to identify potential trans-acting factors that bind to this region. In addition, the promoter and its deletions are analyzed by stable transfection of additional cell lines of different origins that show varying levels of expression of the endogenous APP gene. the endogenous APP gene.

DISORDERS OF THE NERVOUS SYSTEM: DEVELOPMENTAL MODELS

323.1

TRYPTOPHAN (Trp), QUINOLINATE (QUIN) AND SEROTONIN (5-HT): I. ALTERATIONS IN CHILDREN WITH HYPERAMMONEMIA (HA). M. L. Batshaw, M. Heyes, S. Djali*, L. Rorke*, M.B. Robinson. Children's Seashore House, Depts. Pediatrics Phila., PA 19104 and NIH, Bethesda, MD.

Marked elevations in plasma ammonium levels in children can result in coma and subsequent mental retardation. Previous studies have demonstrated alterations in Trp and its metabolites in children and in animal models of HA. In this and the accompanying abstract (Robinson et al.), we report the effects of HA on Trp, 5-HT, 5-hydroxy-indoleacetic acid (5-HIAA), QUIN, and 5-HT receptors in children with congenital HA and 3 animal models of HA. Of the 13 children with congenital HA and 3 animal models of HA. Of the 13 children with urea cycle disorders and organic acidemias studied, three were neonates in coma, aged 3-7 d, with plasma ammonium levels >1000 μ M (normal 20-40 μ M). They had markedly elevated CSF levels of both QUIN and 5-HIAA: QUIN 252, 988, 672 nM (nl <35); 5-HIAA 1.55,1.17, and 9.19 μ M (nl<23). Ten were aged 2-22 yrs who had only modest elevations of plasma ammonium (30-71 μ M). CSF QUIN levels were significantly elevated ranging from 24-71 nM (54±18, p<0.01) as were 5-HIAA levels, 110-680 nM (309±164, p<0.0005), compared to non-HA control children Plasma ammonium levels were correlated with 5-HIAA levels, 110-680 nM (305±164, p<0.0005), compared to non-HA control children. Plasma ammonium levels were correlated with CSF Trp (r=0.72, p<.05) and 5-HIAA levels (r=0.84, p<0.001), but not with QUIN (r=0.4, p>.05). CSF Trp correlated with both 5-HIAA and QUIN (r=0.48, p<0.05; and r=0.68, p<0.001 respectively). Autopsy of the child with the highest levels of QUIN and ammonium revealed widely dispersed spongiform changes with neuronal necrosis and gliosis. These data suggest that alterations in 5-HT and QUIN may be factors in the neurologic alterations in children with HA.

TRYPTOPHAN (Trp), QUINOLINATE (QUIN) AND SEROTONIN (5-HT): II. ALTERATIONS IN ANIMAL MODELS OF HYPERAMMONEMIA (HA). M.B. Robinson, M. Heyes, E. Gorry*, N.J. Anegawa*, S. Djali*, I. Lucki, and M.L. Batshaw, Children's Seashore House, Depts. Pediatrics and Pharmacology, Univ. of PA, Philadelphia, PA. 19104 and NIH, Bethesda, MD.

The effect of HA on Trp and its metabolites was studied in 3 animal models; the appropriate acceptance of the proposition of the control of the proposition acceptance injected are traverse influenced at a not the season.

models: the ammonium acetate injected rat, urease infused rat, and the chronically hyperammonemic ornithine transcarbamylase deficient sparse fur (spl/y) mouse. In ammonium acetate injected rats, there was a 69% increase in cortical 5-HIAA levels compared to sodium acetate controls (p<0.05) with no alterations in CSF QUIN 1 h after injection. In these (p<0.05) with no alterations in CSF QUIN 1 h after injection. In these animals, cortical Trp significantly correlated with 5-HT (p<0.02). Cortical 5-HT correlated with both cortical 5-HIAA and CSF QUIN (p<0.02). To extend the duration of HA, rats were implanted with urease-containing mini-osmotic pumps. Urease infusion resulted in increased brain Trp and 5-HIAA (p<0.05) 12, 24 and 48 h after implant. Despite greater than two-fold elevations in brain Trp, no alterations in QUIN were observed in five brain regions, CSF, or plasma. In this model, plasma ammonium correlated with both brain Trp and 5-HIAA (p<0.01). Higher levels of 5-HIAA have also been observed in brain of (p<0.001). Higher levels of 5-HIAA have also been observed in brain of the spf/y mouse compared to controls. Decreases in cortical ketanserin (-19%, p<0.005) but not 8-hydroxy-di-n-propylaminotetralin binding sites were found in the spf/y mouse. Spf/y mice also demonstrated a decreased 5-HT2 mediated, quipazine induced head twitch response (p<0.005). These data provide further support for altered serotonin metabolism in HA and also suggest that the pathways from Trp to QUIN and 5-HT may be differentially regulated in rats and children.

323.3

CUMULATIVE LEARNING DEFICIT IN NEONATALLY HYPERPHENYL ALANINEMIC RATS: A RODENT MODEL OF MENTAL RETARDATION.
B.J. Strupp, M. Bunsey, D.A. Levitsky* and K. Hamberger*.
Div. of Nutritional Sci. and Dept. of Psychology, Cornell University, Ithaca, NY 14853.

University, Ithaca, NY 14853.

Based on an analysis of the human mental retardation (MR) literature, we proposed an animal model that focuses on cumulative learning deficits (Strupp, B.J. and Levitsky, D.A., Adv. Infancy Res., 6:1990). The model proposes that the difference in problem-solving ability between "retarded" rats and controls will increase with successive problem presentations. The present study tested this hypothesis, using pre- and postnatal hyperphenylalaninemia (HP) (models of maternal and classic PKU, respectively) as exemplary mental retardation models. The results confirmed the predicted cumulative learning deficit in neonatally HP rats, suggesting that the relatively small deficits generally observed in animal models of MR syndromes may be due to the use of a single task rather syndromes may be due to the use of a single task rather than a series of related problems. Also discussed will be (1) the types of errors and response style that characterizes these groups, (2) the attentional dysfunction of the experimental animals, and (3) the points of correspondence between the pattern of intact and impaired cognitive processes in these animals and the pattern observed in

323.4

DISTURBED MYELINOGENESIS AND RECOVERY IN HYPERPHENYLALA-NINEMIA: BIOCHEMICAL AND IMMUNOHISTOCHEMICAL RESULTS.
R. Burri*a, R. Reynolds*b, L. Bologaa, N. Herschkowitz*a.
aUniv. Berne, Dept. Pediatrics, Switzerland; and bImperial

Coll., Dept. Biochemistry, London Univ. UK.

To study myelinogenesis in hyperphenylalaninemia, rats were injected with phenylalanine (Phe)/alpha-methylPhe from days 3-17, and then allowed to recover until day 59. The developmental pattern of cerebroside sulfotransferase (CST), 2',3'-cyclic nucleotide 3'-phosphohydrolase (CNP), body weight, brain weight, brain protein and DNA were determined at 9 time points. CST and CNP activities (per mg brain) were reduced between days 10-17. CST recovered to normal values between days 17-24, CNP between days 35-59. However, brain weight was still significantly reduced at day 59. CNP and myelin basic protein immunostaining demonstrate a reduction in myelin in the corpus callosum (CC) by day 17 in test rats. Neurofilament protein (NF) positive axons were reduced in white and grey matter (GM). However, numbers of oligodendrocytes (ONP+, GalC+) and glial progenitors (GD3+, ganglioside+) appeared normal throughout development. There was no obvious deficit in myelin in the CC at 59 days. The number of strongly NF+ myelinated axons in the cortical GM was still reduced at 59 days. Our results suggest that axonal and not oligodendroglial maturation may be primarily affected by hyperphenylalaninemia.

323 5

PURSUIT EYE MOVEMENTS IN CEREBRAL PALSIED ADULTS.

M.LeGare, J.Coltellaro* and J.Terdiman*. Dept. of Psychology and Biomedical Engineering Program, California State
University, Sacramento 95819; Neuro-optometry Clinic, U.C.
Berkeley 94720.

Pursuit movements of the left eye were measured in response to triangle wave stimuli (0.3 Hz, $\pm 10~{\rm deg.~10}$ sec) presented to 5 moderate-severe cerebral palsied (CP) and 5 motorically normal (N) adult men using a monocular, noncontact videobased system (Micromeasurements S1200). Artifacts and quantization noise were removed from the raw signals by a rule-driven process followed by interpolation and 2-point averaging which provided movement signals comparable to those obtained simultaneously from a normal subject using an analog eye movement measurement device.

Plots of eye position superimposed on stimulus position showed more asymmetric hypo- and hypermetria, fixations and high velocity saccadic intrusions in CP as compared to N. Preliminary spectral analyses showed high spectral coherency between eye and stimulus positions (CP, N) with greater ranges of frequencies, power spectra and phase discrepancies for CP than for N in eye position. These data indicate good directionality with poor ramp pursuit control in CP at 0.3 Hz.

323.7

DALMATIAN CONGENITAL DEAFNESS: INCIDENCE AND PHENOTYPE CORRELATIONS. G.M. Strain, M.T. Kearney, 'I.J. Gignac,' D.C. Levesque,' H.J. Nelson,' B.L. Tedford' and L.G. Remsen,' Vet. Physiol., Pharmacol., & Toxicol., Sch. Vet. Med., Louisiana State Univ., Baton Rouge, LA 70803.

Congenital deafness in the Dalmatian results from cochleo-saccular end organ degeneration. Deafness in most breeds is associated with the merle gene, which is absent in the Dalmatian. The apparent high incidence of unilateral and bilateral deafness in this breed suggests the potential for its use in studies of human hearing disorders, such as Waardenburg syndrome, while at the same time leading breeders to seek means for reducing its incidence. To assess deafness we performed brainstem auditory evoked potential (BAEP) measurements on 1,031 Dalmatians from three geographically separated testing locales (Louisiana/Texas, Arizona, northern California). Phenotypic markers were also assessed to determine possible markers correlated with deafness, including sex, hair coat color (black, liver, lemon, tricolor), completeness of eye rim and nose pigmentation, ear pigmentation, patch, spot size and marking, sire and dam BAEP status, and presence of iris and retina pigmentation. Combined data from all sites revealed 8.1% bilateral deafness (83/1031) and 21.6% unilateral deafness (223/1031), or an overall 29.7% incidence of hearing disorder. Significant (P<0.05) correlations with deafness for the combined sites were seen for patch, sire and dam BAEP, iris pigment, and retina pigment. Dogs with patches were less likely to be deaf, while dogs without iris pigmentation (blue eyes, heterochromia iridis) or retinal pigmentation were more likely to be deaf. Unilateral sires or dams produced greater numbers of unilateral or deaf offspring. However, individual site significance levels differed for several phenotypic markers, showing no significance where grouped data were significant, suggesting the existence of multiple populations of deafness patterns. Insufficient data is currently available to determine if the genetic smission of deafness follows the pattern of a dominant gene with incomplete penetrance seen with Waardenburg syndrome and blue-eyed deaf white cats.

323.9

QUANTITATIVE NEUROANATOMIC ANALYSES OF CEREBRAL CORTEX IN RHESUS MONKEYS FROM DIFFERENT REARING CONDITIONS. J.H. Morrison, P.R. Hof, W. Janssen*, J.L. Bassent¹, S.L. Foote¹, G.W. Kraemer²*, and W.T. McKinney². Fishberg Res Ctr and Dept of Geriatrics, Mt Sinai Sch Med, New York, NY 10029, ¹Dept of Psychiatry, UCSD, La Jolla, CA 92093, ²Dept of Psychiatry, Univ of Wisconsin Sch Med, Madison, WI 53792.

Behavioral studies have demonstrated that early maternal and peer deprivation causes long-lasting psychopathology in monkeys. The neuroanatomic substrates of this syndrome have not been elucidated. We have initiated a detailed anatomic analysis of several chemically-defined systems within the cortex of monkeys reared either in isolation (I) or a nuclear family (NF). Preliminary results with antisera to neurofilament protein (SMI32) and Ca²⁺-binding proteins suggest that the density of SMI32-ir pyramidal cells and putatively GABAergic interneurons in several cortical areas is equivalent in the I and NF subjects. In contrast, initial counts of dopaminergic (DA) and serotonergic (5HT) varicosities by conventional microscopy suggested that dramatic differences existed between I and NF subjects in monoamine innervation density of cingulate, prefrontal and entorhinal cortex. However, more precise varicosity density measurements using a confocal laser scanning microscope demonstrated that the I subjects had a lower density of both DA and 5HT varicosities, but the differences were less dramatic than suggested by the conventional analysis. Further studies are in progress with the confocal microscope to determine the degree to which these differences are biologically and statistically significant. In addition, the analysis will be expanded to the amygdala and hypothalamus. Supported by the MacArthur Foundation.

323.6

MYOTATIC REFLEX DEVELOPMENT IN NORMAL INFANTS AND CHILDREN WITH CEREBRAL PALSY. C.T. Leonard, T. Moritani, H. Hirschfeld and H. Forsberg. Depts. of Neurophysiology and Pediatrics, Karolinska Institute, Stockholm, Sweden and Physical Therapy Dept., Univ. of Montana, Missoula, MT 59812

Many neonatal neural projections are more diffuse than those in the adult animal. Neural exuberance and its retraction during post-natal life has been shown to exist in several species but not in humans. Damaging CNS structures during neonatal stages results in retention of some exuberant projections from functionally related but undamaged structures. The present study was undertaken to determine whether there was any evidence of neonatal neural exuberance and its retention following damage to the CNS in the human. Electromyographic (EMG) recordings were obtained from 6 lower extremity (LE) muscles following patellar and achilles tendon percussions in 20 normal children (ages 13 days to 16 years) and 14 children with spastic type cerebral palsy (CP) (ages 1 to 15 years). Previous studies have shown that normal adults and individuals with adult onset cerebral vascular accidents (CVA) exhibit electromyographic potentials govly in the muscle being stimulated.

clear through the Central recordings were obtained from 1 other extremity (LE) muscles following patellar and achilles tendon percussions in 20 normal children (ages 13 days to 16 years) and 14 children with spastic type cerebral palsy (CP) (ages 1 to 15 years). Previous studies have shown that normal adults and individuals with adult onset cerebral vascular accidents (CVA) exhibit electromyographic potentials only in the muscle being stimulated. Results show that normal infants under the age of 2 often have reflex overflow into adjacent muscles following a tendon tap. Children with CP, regardless of age, consistently exhibit reflex overflow into adjacent musculature. This reflex abnormality seen in children with CP, therefore, does not appear to be aberrant but rather a retention of an earlier phase of reflex development. The reflex overflow is most likely the result of either: a) group Ia or alpha motor neuron projection exuberance or b) the absence of a tonic inhibitory effects which, in the normal adult, may block reflex transmissions to other muscles. The fact that individuals with an adult-onset CVA do not exhibit reflex overflow provides support for the hypothesis that the overflow seen In normal infants and children with CP is the result of projection exuberance.

INTERHEMISPHERIC MECHANISMS FOR VERTICAL MIDLINE STEREO-PSIS: POSSIBLE SOURCES OF VISUAL CONFUSION IN DYSLEXIA. K.Brady. Dept. Psyc. Geo. Wash. U., Wash.,D.C. 20052. Two mechanisms may accomplish stereopsis on the verti-

Two mechanisms may accomplish stereopsis on the vertical midline:(a) convergence of monocular images via striatal callosal connections (b) a narrower nasotemporal overlap zone of intermingled ipsi— and contralaterally projecting fibers. These 2 pathways were compared in dyslexic and control adults using Poffenberger simple manual key-press RT to 50 ms light flashes at .5, 2, or 10 to right or left of fixation. The difference between crossed VF/hand RT, which requires callosal transfer of the stimulus, and uncrossed RT is considered a measure of interhemispheric transmission time. Abolition of the crossed—uncrossed difference (CUD) is interpreted as evidence that input is available to both hemispheres simultaneously. Controls demonstrated a CUD at all eccentricities consistent with previous literature. Dyslexics, however, showed no CUD at .5°, consistent with the hypothesis of functional nasotemporal overlap. Retention of CUD at .5° in controls may reflect either absence or inhibition of overlap. At 2° dyslexics had both faster crossed and slower uncrossed RTs (after correction for overall slower RT). Net abolition of CUD at 2° may reflect group differences in the developmental processes of interhemispheric "pruning" and intrahemispheric proliferation of primary callosal fibers. CUD at 10° did not differ between groups.

323.10

A DEVELOPMENTAL MODEL OF CHOLINERGIC HYPOFUNCTION.

T.J. Walsh, R.W. Stackman and G. Woertwein*. Rutgers University, Department of Psychology, New Brunswick, NJ 08903.

The cholinergic innervation of the hippocampus (HPC) and the cortex (CX) appears to be an essential neurobiological substrate of memory processes. This neurotransmitter system is susceptible to a wide variety of insults during the early post-natal period. For example anoxia, alterations in carbohydrate metabolism or hormonal status, vitamin deficiencies, and exposure to heavy metals, all produce impairments in the maturation or function of the cholinergic system as well as a persistent mental retardation. In previous studies we have used AF64A and colchicine to develop animal models of dementia and cholinergic hypofunction in adult rats (Chrobak et al., *Brain Res.*, 1988; Emerich and Walsh, *Brain Res.* in press). We are now evaluating whether these compounds will be useful tools in developmental studies of the cholinergic system and its behavioral properties. The present study examined the behavioral and neurochemical effects induced by intraventricular injection of either 175ng = 1.5nmoles/1µl of AF64A, 3.5µg/1µl of colchicine, or 1µl of artificial CSF into 21 day old weanling rats. Neither treatment altered body weight or the growth curve at any time point following surgery. Both treatments produced a 25-60% increase in locomotor activity that peaked 7 days following surgery and resolved by 45 days after surgery. Both groups were also impaired in the aquisition and retention of a spatial memory task in the Morris water maze. AF64A decreased ChAT activity in the HPC and frontal CX by approximately 40% while colchicine decreased ChAT activity only in the HPC by 16%. These initial studies suggest that AF64A and colchicine might be useful to produce developmental models of cholinergic hypofunction that will help to elucidate the biology of memory and memory disorders.

EARLY PRENATAL EXPOSURE TO SINGLE DOSE ETHANOL ALTERS OPEN FIELD ACTIVITY IN C57 MICE. R. Dumas*, A. Rabe, E. Sersen*, S. Delia* and A. Lidsky. NYS Institute for Basic Research in Developmental Disabilities, Staten Island, NY 10314 Our previous work has shown that early prenatal exposure to a single maternal oral dose of ethanol has resulted in craniofacial and brain malformations in the mouse fetus. These resemble those found in the fetal alcohol syndrome (FAS) child. Since functional impairment after early alcohol exposure has been reported in the absence of the typical FAS stigmata, our recent work has been concerned with extension of our mouse model to include the postnatal development of pups from alcohol treated dams that appear normal at birth. As an indicator of functioning, activity levels were measured in an automated open field apparatus at different ages in 3 groups of mice. At weaning (days 23 thru 25) we tested one male and one female from each of 60 litters: 17 untreated (C), 20 ethanol-exposed (E) and 23 isocaloric-dextrose-fed (D). A different pair of offspring from each of the litters was tested at a later age (day 37). Preliminary analysis of the data shows that the E mice spent significantly less time in ambulation and travelled a shorter distance than the C animals, but they reared more often. The D animals were between the C and E groups; they did not differ significantly from either. The lack of hyperactivity is in contrast to the reported hyperactivity in human FAS. This may reflect a species difference. (Supported in part by NIAAA grant 1R01-AA07060.)

TRANSPLACENTALLY INDUCED MICRENCEPHALY HAS NO EFFECT ON TEMPORAL REGULATION OF BEHAVIOR. A.Rabe, M.Lee, and A. Heaney. NY State Institute for Basic Research in Developmental Disabilities, Staten Island NY 10314.

The micrencephalic rat has been used as a model for congenital brain defects as well as generalized cognitive impairment. Although it has been conclusively shown that it is hyperactive and poor at learning mazes, the nature of its defect(s) still remains to be characterized. We therefore studied its behavior on tasks that have rarely been used with this model. Severe cerebral hypoplasia was induced in all offspring (M group) by injecting the pregnant dam with 30mg/kg of methylazoxymethanol on GD 14. The controls (NC group) were from dams injected with saline. As adults, all offspring (N=62) were tested on 4 tasks with the following results: (1) Acquisition and retention of a step-down passive avoidance response; 3 baseline trials were followed by one footshock and retention tests 1 min, 1, 3, 7 d later. The M rats showed less avoidance at 1 min (36% vs 70%, p<.025) and at 1 d (26% vs 50%, p<.05). (2) Spontaneous alternation in a T-maze, one pair of trials daily for 3 d. The M rats alternated less (66% vs 81%, p<.025). (3) FI schedule with a 60 s delay; (4) DRL schedule with a 20 s delay. Training on both was for water, 30 min/d for 15 d each, followed by 3 d of extinction. On both timing schedules, the M rats had normal response rates, interresponse times and distribution of responses; the number of extinction responses were also the same for both groups. This pattern of results fits the hypothesis that the deficit in micrencephalic rats is cognitive and manifests itself primarily on tasks with spatial components.

MUSCARINIC CHOLINERGIC RECEPTOR CHANGES IN PRENATALLY INDUCED MICRENCEPHALIC RAT BRAIN. M.H. Lee, E.Alter*, A.Rabe, T. Lidsky and S.P. Banerjee. NY State Institute for Basic Research in Developmental Disabilities, Staten Island, NY 10314; Dept. of Pharmacology, CUNY Sch of Med, New York, NY 10031

The rat with methylazoxymethanol acetate-induced micrencephaly is a useful animal model of congenital brain defects. Born with severe forebrain hypoplasia, it consistently displays hyperactivity and impaired maze learning. Neurochemical bases for such behavioral changes have not been established. A recent study in our laboratory indicated hypersensitivity of maze learning. Neurochemical bases for such behavioral changes have not been established. A recent study in our laboratory indicated hypersensitivity of the micrencephalic (M) rat to atropine: As compared to normal (C) rats, the magnitude of deficits in learning the Morris water maze increased in M rats as a function of dose (0, 10, 50 mg/kg), suggesting that the impaired learning and memory may be related to changes in the number and/or function of muscarinic cholinergic receptors (MCR). In order to further elucidate this potential relationship, we measured the density and apparent affinity of MCR in the cerebral cortex and basal ganglia of M and C rats, using [³H]quinuclidinyl benzilate. In the M cortex, the densities of MCR binding sites decreased by 35%, while the affinity increased by about 50%. In contrast, there was a significant increase in the binding of QNB to MCR in the basal ganglia. Such region-specific changes in MCR may provide neurochemical explanation for the behavioral disorders of the M rats.

323.14

VITAMIN A-INDUCED NEURAL TUBE DEFECT WITH CHIARI II MALFORMATION IN MICE. S. Nakahara*, W. Goossens*, R.G. Higbee, T. Inagaki* D.G. McLone and P.A. Knepper. Division of Neurosurgery, Children's Memorial Hospital and Northwestern University Medical School, Chicago, IL 60614.

Vitamin A induces phenotypic and biochemical alterations in vivo. In this study, we examined the effects of vitamin A on the process of neurulation and determined whether a neural tube defect (NTD) was associated with herniation of the contents of the posterior fossa, a Chiari II malformation. Pregnant C-57 BL/6J mice were given IP injections of 5000 IU of vitamin A at the start (gestation day 8.0 and 8.5 [group A]) and during the process of neurulation (day 8.5 and 9.0 [group B]). On gestation day 14 and 16, embryos were processed for SEM and for fluorescence microscopy using FITC-lectins.

The early administration of vitamin A (group A) resulted in a high percentage of NTD, a primary neurulation defect and intrauterine resorption. administration (group B) resulted in a low percentage of NTD (<5%) and a high percentage of tail defects (>80%), a secondary neurulation defect. In both groups, the presence of a caudal NTD was always associated a Chiari II. In embryos with only a tail defect, there was no Chiari II. These results indicate that vitamin A-induced NTDs in mice relate to the time of administration and a Chiari II occurred only if there is a primary neurulation (Supported in part by the Kiwanis International)

Expression of the activated c-Harvey ras oncogene in most cell types
studied results in ingressed cell preliferation and a tunorization happens to

Expression of the activated c-Harvey ras oncogene in most cell types studied results in increased cell proliferation and a tumorigenic phenotype. In neuroendocrine cell lines, however, the response to ras oncogene expression appears to be more closely related to a terminal differentiation event. In this study we have investigated the consequences of introducing the human EJ-ras oncogene into the mouse anterior pituitary cell line AtT20. We previously reported that the tetrodotoxin-resistant component of the voltage-dependent sodium current in normal AtT20 cells is extinguished following ras oncogene transformation (Flamm, R.E. et al., European Journal of Physiology, (1990) in press). We have found that expression of the ras oncogene induces a number of profound changes in cell morphology, hormone secretion and biosynthesis, and electrophysiology. We report here that secretion of the pituitary hormone ACTH and transcription of the gene encoding its precursor polypeptide, pronoinelanogy. We report here that secretarion the primary nonlinois ACTI and transcription of the gene encoding its precursor polypeptide, proopiomelan-ocortin, are markedly downregulated in EJ-ras transformed clones. Further, ras oncogene expression in AtT20 cells induces a change in the shape and duration of evoked action potentials and a significant increase in the density of voltage-dependent potassium channels. The cell line AtT20 has been a model system for the study of hormone biosynthesis and secretion, posttranslational processing and electrophysiology in a neuro-endocrine cell line. The alteration of the differentiated phenotype of AtT20 cells following ras oncogene transformation makes this a valuable system for the study of the regulation of differentiation by ras oncogenes in a neurosecretory cell type.

328.3

SOMATOMAMMOTROPIC TUMOR CELLS POSSESS A NEUROENDOCRINE-TYPE ACTIVE TRANSPORT SYSTEM FOR ASCORBIC ACID. E.I. Cullen, W. Huo *, and F. Mesaros *. Dept. of Pharma-cology, New York Medical College, Valhalla, NY 10595. Ascorbic acid (AH2) is a co-substrate in the amidation

of peptides catalyzed by peptidyl-glycine α -amidating monooxygenase (PAM). Cells expressing PAM often possess a Na-dependent active transport system for AH2. PAM is expressed in rat somatomammotropic tumor cells (GH cells), and the cells can amidate peptides derived from transfected POMC cDNA (Cullen & Mains, '89 Endo 125: 1774). To determine if GH cells also possess an active transport system for AH2, they were incubated in 50 μ M [14C]AH2. Cellular content of AH2 reached levels of 2.9 mM after 6 hr (using experimentally determined cell volumes). Substitution of choline chloride for NaCl diminished uptake by more than 90%. The initial rate of AH2 uptake was saturable and displayed a Km of 35 \pm 3 μ M and a Vmax of 1.4 \pm 0.2 nmol/10(6) cell/hr. Efflux of AH2 was slow; the principle kinetic component was linear with time and represented a loss of 6%/hr of the initial cellular content. Growth for 7 days in 5 \(\textit{M} \) cortisol diminished cellular AH2 uptake and had the expected effects on GH and PRL (NIDDK RIA materials from Dr. Raiti, NHPP, U.Md.). These results reflect a previously unrecognized capability of GH cells, and support the hypothesis that the cells can amidate peptides. Supported by the Pharmaceutical Manuf. Assn. Found'n, Castle-Krob Res. Endowment, and NIH BRSG RR5398.

328.5

DISCOVERY AND COMPLETE CHARACTERIZATION OF A NOVEL PYROGLUTAMYL PEPTIDE DERIVED FROM CHROMOGRANIN B IN BOVINE ADRENOMEDULLARY CHROMAFFIN VESICLES. T. Flanagan, L. Taylor, O.H. Viverog and E.J. Dillberto, Jr. Div. Medicinal Biochem. and Organic Chem., Wellcome Res. Lab., 3030 Cornwallis Road, Research Triangle Park, NC 27709.

We recently demonstrated the exclusive localization of a glutaminyl cyclase to the chromaffin vesicle of the bovine adrenal medulla. Thus, pyroglutamyl peptides are likely to be found within this subcellular compartment. While no pyroglutamyl peptide has yet been isolated and fully characterized from the bovine adrenal medulla, the presence of neurotensin immunoreactivity has been reported. Therefore, we developed an assay to isolate and characterize pyroglutamyl peptides in extracts of chromaffin vesicles. This assay consists of a spectrometric comparison of the mass of peptide molecular ions before and after the specific removal of pyroglutamyl residues with pyroglutamate aninopeptidase. We used this assay system to guide extraction, chromatographic isolation and the complete structural characterization of a novel pyroglutamyl secretory peptide from the bovine adrenal medulla (BAM-1745). Oligonucleotide probes deduced from backtranslation of BAM-1745 were used in a separate study to identify the peptide Precursor as chromogranin B.

BAM-1745 is more abundant than enkephalins within the bovine adrenal medulla, and thus is a major secretory peptide. A Comparison of bovine, human, sheep, and rat chromogranin B sequence data, and the direct isolation and characterization of BAM-1745 homologs from bovine, human, sheep, and rat chromogranin B sequence is both well conserved and also consistently processed into a pyroglutamyl adrenal secretory peptide among mammalian species. BAM-1745 is likely to serve a biological function, however, that function is currently unknown.

A NOVEL ENZYME FROM NEUROINTERMEDIATE PITUITARY CATALYZES DEALKYLATION OF $\alpha\textsc{-Hydroxyglycine}$ derivatives, thereby functioning sequentially with peptidylglycine $\alpha\textsc{-Amidating}$ monooxygenase in peptide amidation. Andrea G. Katopodis*, Dongsheng Ping* and Sheldon W. May. School of Chemistry and Biochemistry, Georgia Institute of Technology, Atlanta, GA 30332.

We report the isolation of a novel enzyme from boyine neurointermediate

pituitary which catalyzes the conversion of α -hydroxybenzoy[g]ycine to benzamide. This enzyme, termed HGAD (α -HydroxyG]ycine Amidating Dealkylase), is a soluble protein with an apparent molecular mass of 47 kD, and no apparent cofactor requirement. Addition of HGAD to purified neurointermediate pituitary PAM requirement. Addition of HGAD to purified neurointermediate pituitary PAM (Peptidylglycine ca-Amidating Monoxygenase EC 1.14.17.3) increases the rate of formation of amide products by an order of magnitude. Sequential additions of PAM and HGAD gave results consistent with PAM first catalyzing the formation of an intermediate which is subsequently, in a separate reaction, converted by HGAD to the final amide product. Purified neurointermediate PAM incubated with N-benzoylglycine produces a HPLC peak which co-elutes with authentic chydroxybenzoylglycine. Experiments with rans-benzoylacytic acid and 4-phenyl-3-butenoic acid which are turnover-dependent inactivators of PAM, demonstrate that 3-butenoic acid which are turnover-dependent inactivators of PAM, demonstrate that HGAD is not inactivation of PAM, and, correspondingly, that HGAD activity is not affected by inactivators of PAM. As expected, HGAD has no effect on the rate of PAM catalyzed sulfoxidation of (4-nitrobenzy)!thioacetic acid, where a reaction analogous to that occurring during amidation of glycine-extended substrates is not possible. On the basis of these results, we propose that peptide C-terminal amidation is a two step process, with PAM first catalyzing the conversion of a glycine extended peptide to the a-hydroxyglycine derivative, which is in turn converted to the final amide product by HGAD.

EVIDENCE FOR THE ENZYMATIC DEGRADATION OF CRF IN CORTEX, HYPOTHALAMUS AND PLASMA. J.C. Ritchie, C.E. Nemeroff, D. Knight, M.J. Owens. Dept. of Psychiatry and Pharmacology, Duke Univ. Durham, NC 27710.

Little is known concerning the ultimate fate of Corticotropin Releasing Factor (CRF) in the CNS, neuroendocrine

pin Releasing ractor (CRF) in the CNS, heuroendoctile complex, or the periphery. In order to investigate this area we have established and characterized a 2 step gradient HPLC scheme for the fractionation of rat/human CRF₁₋₄₁, its available synthetic fragments, analogues, and other neuropeptides. In this system "I-tyr°-CRF elutes as a single peak. In an attempt to determine the degradation products of CRF1. In an attempt to determine the degradation products of CRF₁. In rat cortex (prefrontal/somatosensory), hypothalamus, and plasma both soluble and 10,000 x G particulate extracts were prepared. Extracts were incubated at 37°C for 120 mins. with iodinated tyr⁰-CRF and excess noniodinated r/h CRF_{1.41}. Fractionation of the soluble enzyme digests showed a diminution of the CRF peak and 2 early eluting peaks. The particulate extracts gave a similar but diminished pattern of activity. The plasma preps exhibited a decrease in the CRF but no early eluting peaks.

These results indicate a similar pattern of CRF degrada-

tion in both the CNS and the neuroendocrine complex. Additionally, the enzyme/s responsible for CRF degradation appear to be of a soluble nature.

AND ELECTRON MICROSCOPIC LOCALIZATION OF NEUROTENSIN DEGRADING ENZYME, NEUTRAL METALLOPEPTIDASE 24-16 IN RAT BRAIN. J. Woulfe, F. Checler* and A. Beaudet. Montreal Neurol. Inst., McGill Univ., Montreal, Que. H3A 2B4.

The neutral metallopeptidase 24-16 (NM 24-16) is an endopeptidase implicated in the biological inactivation of neurotensin (NT) through cleavage between pro and tyr in positions 10 and 11. In the present study, the regional and cellular distribution of NM 24-16 was examined by immunocytochemistry in rat CNS using a highly specific polyclonal antiserum generated against the purified enzyme. On light microscopic examination, immunoreactivity for NM 24-16 was ubiquitously distributed throughout all regions of the CNS. Areas of prominent labeling corresponded, in comparison with adjacent nissl-stained sections, to those of enriched neuronal density. On electron microscopic examination of ultrathin sections through the ventral tegmental area and substantia nigra, two areas which receive a substantial NT afferent input and exhibit high densities of NT binding sites, immunoreactivity for the peptidase was associated with both neurons and glia. In neurons, the labeling was restricted primarily to the plasma membrane and to multivesicular bodies. In glia, immunoreactivity for NM 24-16 was identified throughout the cytoplasm of astrocytic cell bodies and processes. The latter surrounded synapses established by axon terminals on dendritic shafts. These results provide anatomical support for NM 24-16's role in the endogenous metabolism and functional inactivation of NT.

EVIDENCE FOR REGIONAL SPECIFICITY OF NEUROTENSIN METABOLISM BY INTACT BRAIN SLICES. <u>T.J. Gillespie* and T.P. Davis.</u> Dept. of Pharmacology, Univ. of Arizona, Coll. Med Tucson, AZ 85724.

Our laboratory previously examined neurotensin (NT) metabolism by p SPM. This study examines regional differences in NT metabolism by rat brain micro slices, and describes specific peptidases involved. Male S.D. rats (280-360g) were sacrificed. Brains were sliced into 2mm coronal slabs, and caudate putamen (CPu) and nucleus accumbens (Acb) were micropunched (2mm). Hypothalamus (H) and hippocampus (Hi) were also punched. Slices (240g) were incubated for 0 or 120 min. with 100gM NT in the absence or presence of specific peptidase inhibitors. After HPLC analysis NT fragments were collected and identified by amino acid analysis. NT loss after 120 min. incubation was Acb 50% \pm 1.7, CPu 47% \pm 2.0, H 45% \pm 3.1, and Hi 38% \pm 2.7, with significant (p< .05) differences between Hi and Acb or CPu. In the presence of 20gM phosphoramidon (PAM) and 100gM CPP-Ala-Ala-Phe-PAB, neurotensin did not significantly decrease in any region studied indicating that most of NT metabolism is due to neutral endopeptidase 3.4.24.11, and metalloendopeptidases including 3.4.24.15. NT loss was decreased 33% in CPu after 20gM PAM only (p < 01). In Hi, NT loss decreased 11% with PAM only. Therefore, 24.11 activity is much higher in CPu than Hi. Captopril (20gM) did not significantly change % loss of NT in CPu or Hi, however, a shift in NT fragment levels was evident. NT-(1-10) increased from 0.50 to 3.85 moles (p < .01) in CPu and NT-(1-8) decreased in both regions. This indicates that NT-(1-10) serves as a substrate for angiotensin converting enzyme (ACE), with ACE much higher in CPu than Hi. Since brain slices retain a greater degree of morphology and metabolic properties than homogenates, these data provide evidence for a regional specificity of NT metabolism dependent on the expression of specific endopeptidases. (Supp. NIH-MH 42600, DK 36289 and DA 06284).

Cloning of cDNAs encoding amphibian bombesin: evidence for the relationship between bombesin and gastrin-releasing peptide (GRP). Eliot R. Spindel, Bradford W. Gibson*, Joseph R. Reeve, Jr.* and Michele Kelly*. Div of Neuroscience, Oregon Regional Primate Res Ctr, Beaverton, OR 97006, Dept of Pharmaceutical Chemistry, UCSF, San Francisco, CA 94143 and Ctr for Ulcer Res and Education, VA Wadsworth and UCLA School of Med, CA 90073 Bombesin is a tetradecapeptide originally isolated from frog skin; its mammalian homologue is the 27-amino acid peptide, GRP. Bombesin and GRP have important functions as neurotransmitters, growth factors and as paracrine regulators of GI function. cDNAs encoding GRP have been cloned from diverse species, but no cDNAs encoding amphibian bombesin have previously been characterized. Mass spectrometry was performed to demonstrate the existence of authentic bombesin in the skin of Bombina orientalis. Next a cDNA library was prepared from B. orientaiis skin and mixed oligonucleotide probes were used to isolate cDNAs encoding bombesin. Sequence analysis revealed a 119 amino acid prohormone with two basic amino acids flanking the C-terminus of bombesin. The N-terminus of bombesin is not flanked by basic amino acids but RNA blot analysis is flanked by a chymotryptic-like cleavage site. RNA blot analysis demonstrated similarly sized bombesin mRNAs in frog skin, brain and stomach. Polymerase chain reaction and DNA sequence analysis demonstrated that the same bombesin prohormone is encoded in both skin and gut. Prohormone processing however differs between skin and gut. Chromatography of skin extracts showed only bombesin while chromatography of gut showed two peaks of bombesin immunoreactivity, one consistent in size with bombesin, and one closer in size to mammalian GRP. Thus the same bombesin prohormone is processed in skin to bombesin, but in stomach is processed to both a peptide similar in size to bombesin and to a peptide similar in size to mammalian GRP.

EXPRESSION OF PROENKEPHALIN A AND PRODYNORPHIN GENES IN RAT BRAIN CELL CULTURES. R. Simantov and V. Höllt*. Dept. Mol. Gen. Weizmann Inst., Israel and NIDA Addiction Research Center, Baltimore, MD and Dept. Phy. U. of Munich, Germany.

The regulation of proenkephalin A (PEA) gene was studied extensively in adrenal chromaffin cells, but little is known about the control of this gene in nerve cells. Aggregating rat brain cell cultrues were used therefore to analyze the mechanism of PEA mRNA expression and translation to enkephalin. Depolarization of these cultures with potassium chloride or veratridine increase PEA mRNA levels in a time-dependent fashion, with a maximal effect of six folds. The same treatments, however, did not increase prodynorphin expression. PEA mRNA expression was also increased upon treatment with 8-Br-cAMP, phorbol 12-myristate-13-acetate (TPA) or the glucocorticoid hormone dexamethasone. Yet, neither of these agents increase the amount of enkephalin. The potent opioid agonist etorphine and the antagonist nattrexone did not alter PEA gene expression, suggestion that there is no feedback control of opioids on enkephalin biosynthesis. The aggregating brain cell cultures are useful therefore to investigate the mechanisms that regulate PEA and prodynorphin mRNA expression in neurons.

CHOLECYSTOKININ ACTIVATION: EVIDENCE FOR AN ORDERED REACTION MECHANISM FOR THE TYROSYL SULFOTRANSFERASE RESPONSIBLE FOR THE PEPTIDE SULFATION. F. Vargas and O. Frerot. Unité de Neurobiologie et Pharmacologie, Centre Paul Broca de l'INSERM. 75014 Paris. France.

Frerot. Unite de Neurobiologie et Pharmacologie, Centre Paul Broca de l'INSERM, 75014 Paris, France.

The kinetics of the forward tyrosylsulfot ansferase reaction were examined using an assay based on the $^{35}\mathrm{SQ}_4$ transfer from 3'-phosphoadenosine 5'-phosphol $^{135}\mathrm{S}$]sulfate ($^{135}\mathrm{S}$]PAPS) to tyrosyl residues of the non sulfated cholecystokinin derivate, BocCCK-8(ns). Tyrosyl sulfotransferase present in the microsomal membranes from rat cerebral cortex, was used for these studies. Initial velocity measurements performed over a wide range of PAPS and BocCCK-8(ns) concentrations, indicated that, the reaction follows an ordered mechanistic pathway. Thus, $K_{\rm M}$ value determined for BocCCK-8(ns) was $160 \pm 18~\mu{\rm M}$, and that for $1^{35}\mathrm{S}$]PAPS 0.15 \pm 0.03 $\mu{\rm M}$. 3'-Phosphoadenosine 5'-phosphate (3'-PAP) was found to be a strong product inhibitor with a Ki = 0.30 \pm 0.02 $\mu{\rm M}$. Adenosine 5'-phosphosulfate (APS) behaved as a dead-end inhibitor with a Ki = 3.0 \pm 0.3 $\mu{\rm M}$. ATP inhibited competitively the reaction when PAPS was the varied substrate with a Ki = 3.6 \pm 0.5 $\mu{\rm M}$. The results of product and substrate inhibition studies and the patterns of dead end inhibition obtained with APS are best fit by a steady state ordered Bi-Bi kinetic mechanism with PAPS and BocCCK-8(ns) as substrates. These results are of particular interest in view of the elucidation of sulfation reaction processes in the Golgi apparatus and Golgi membrane permeability.

INFLUENCE OF NMDA RECEPTOR BLOCKADE ON THE LEVEL OF PREPROTACHYKININ AND PREPROENKEPHALIN mRNA IN THE RAT BASAL GANGLIA. D.L. Somers* and R.M. Beckstead. Dept. of Anatomy and Cell Biology, Medical University of South Carolina, Charleston, SC 29425

The influence of chronic (7 day) icv administration of APV, an NMDA receptor antagonist, on the level of striatal preprotachykinin (PPT) and preproenkephalin (PPE) mRNA was examined by in situ hybridization of [35S]cDNA probes followed by autoradiography. Five rats received the drug via cannulas attached to osmotic minipumps loaded with 40mM APV in artificial CSF. The levels of message in the caudatoputamen on the side of influsion in the drug recipient rats were compared to those measured in 5 control rats that received CSF alone. Optical density measurements were taken from film autoradiograms of frontal tissue sections through the rostral, middle and caudal thirds of the caudatoputamen. The level of PPT mRNA was reduced by 34% in the rostral third, 22% in the middle third, and not at all in the caudal third of the striatum (p < 0.025). The level of PPE mRNA was reduced by 26% (p < 0.01) only in the rostral third of the striatum. Further analysis of the rostral levels revealed a gradient of PPT mRNA reduction ranging from 42% near the ventricle to 25% in the ventrolateral quadrant (p < 0.025). Experiments with the non-NMDA receptor antagonist, DNQX, revealed no such reduction in the level of either peptide message. The present findings are consistent with earlier studies of peptide message changes following the depletion of synaptosomal ASP and GLU levels, and provide further evidence for the role of excitatory amino acids as signals for the regulation of neuroactive peptide gene transcription. The data indicate further that the NMDA receptor subtype mediates this effect. Supported by NIH Grant NS24971.

REGULATION OF CCK mRNA IN THE DOPAMINERGIC NIGRO-STRIATAL SYSTEM. X.Z. Ding*, E. Costa and I. Mocchetti'. Fidia-Georgetown Institute for the Neurosciences and ^Department of Anatomy and Cell Biology, Georgetown University, 3900 Reservoir Rd., N.W., Washington, D.C., 20007. Although the coexistence of dopamine (DA) and cholecystokinin (CCK) in neurons of the substantia nigra (SN) is well documented, little is known about the interaction between these two putative neurotransmitters at the postsynaptic receptors. To shed some light on this interaction, we tested the hypothesis that DA could regulate CCK synthesis in the nigro-striatal system. Northern blot hybridization analysis was used to measure CCK mRNA, as an index of CCK synthesis. The induced release of DA evoked in rats by a single injection of cocaine (15 mg/kg s.c.), elicited, 8 hours later, a 50% increase in CCK mRNA content in striatum but not in SN. Seven daily injection of cocaine induced (3 fold) CCK mRNA in both SN and striatum but not in other brain regions. To gain insight of the dopaminergic nature of cocaine action we used haloperidol, a DA receptor blocker. Haloperidol, which decreased CCK mRNA by 50% in striatum, blocked the increase of striatal CCK mRNA elicited by cocaine. However, unlike cocaine, the effect of haloperidol was confined to the striatum suggesting that in striatum dopamine might regulate tonically CCK synthesis through a dopaminergic receptor mediated mechanism which is different from that operative in the SN. The mechanism of this interaction is currently under investigation in primary cultures of striatal and mesencephalic neurons.

G-PROTEIN REGULATION OF ω-CONOTOXIN BINDING SITES ON A NEURONAL CELL LINE. S. Bergamaschi*~. S. Govoni*, S. Del Monaco*^, F. Battaini~ and M. Parenti^, Dept. Pharmacobiol., Univ. Bari; ^Dept. Exp. Med. and Biochem. Sci., Univ. Rome; ^ Dept. Pharmacol., Univ. Milan, Italy.

G-proteins have been shown to modulate calcium currents (Hescheler, J., Nature, 325: 445, 1987) and the conformation of the binding site for dihydropyridines both in rat brain synaptic membranes and cultured cells (Bergamaschi S., Eur. Neurol. 30S2: 16, 1990). The present study investigates whether G proteins modulate the recognition site for ω-Conotoxin GVIA (CgTx), a peptide labelling high voltage-activated calcium channels. Both undifferentiated and differentiated (1 mM dibutyryl cAMP) neuroblastoma x glioma NG 108-15 cells were used. The specific binding of [125]]-CgTx is higher in differentiated cells (undiff.: Bmax 2.3±1.2 fmol/mg prot., Kd 9±2.2 pM; diff.: Bmax 16.2±3.8 fmol/mg prot., Kd 16±2.8 pM). Addition of 10 μM GMP-PNP, a stable GTP analogue, to membranes prepared from differentiated cells decreases by 30-40% the binding of CgTx. This effect can also be observed in undifferentiated cells. Other nucleotides such as ATP and GDP-β-S were inactive. Pretreatment of the cells with Pertussis Toxin (PTx; 100 ng/ml medium for 20 hours) greatly reduces the effect of GMP-PNP (control: -32%; PTx: -14%). The results suggest that G protein activation decreases the labelling of calcium channels by CgTx, possibly through a conformational change in the binding site.

ANALYSIS OF PRESYNAPTIC INHIBITION AND REDUCTION OF CALCIUM CURRENTS INDUCED BY BACLOFEN IN PYRAMIDAL AND NON-PYRAMIDAL NEURONS CULTURED FROM RAT HIPPOCAMPUS. K. P. Scholz, W. K. Scholz and R. J. Miller Dept. of Pharm. and Physiol. Univ. of Chicago, 60637.

The mechanisms underlying presynaptic inhibition produced by activation of GABAb receptors at excitatory and inhibitory synapses in the bispressions.

The mechanisms underlying presynaptic inhibition produced by activation of GABAb receptors at excitatory and inhibitory synapses in the hippocampus were studied using whole-cell patch clamp techniques in cultured hippocampal neurons. We have characterized the differential developmental appearance of pyramidal neurons and GABA-ergic interneurons in the hippocampus and have taken advantage of these results to study the physiological properties of these different cell types. Baclofen inhibited two components of ICA in pyramidal neurons that showed different kinetics and differential sensitivity to nimodipine. The EC50 for this action was near 0.5 uM. This action was sensitive to block by phaclofen and 2-OH-saclofen. In addition, inhibition of ICA was enhanced and rendered irreversible by inclusion of GTP-\(\tau\)S in the pipette and abolished by pretreatment with PTX. In GABA-ergic interneurons, baclofen inhibited a single nimodipine insensitive ICA. Baclofen reduced both EPSCs and IPSCs by a presynaptic mechanism that was abolished by PTX pretreatment in both cases. Although 0.5 uM baclofen strongly inhibited ICA, effects on synaptic transmission required higher concentrations. Although both EPSCs and IPSCs were reduced by baclofen, EPSCs were sensitive to dihydropyridine agonists and antagonists whereas IPSCs were sensitive to dihydropyridine agonists and antagonists whereas IPSCs were sensitive to dihydropyridine agonists and antagonists whereas IPSCs were not. We are investigating the possibility that these synapses may use different calcium channels at the vesicle release site, and further examining the role these channels play in presynaptic inhibition induced by baclofen.

MODULATION OF CALCIUM AND POTASSIUM CHANNELS BY RAS ONCOGENE PROTEINS IN HERMISSENDA NEURONS. C. Collin, A.G. Papageorge and D.L. Alkon. LMCN-NINDS and 'Laboratory of Cellular Oncology-NCI, NIH, Bethesda, MD 20892.

The early changes in excitability after iontophoretic injections of the protooncogenic (C) and oncogenic (V) forms of ras gene products, which are 20
KD G proteins, were studied on fully differentiated neurons (LP₁) of the snail
Hermissenda, in two microelectrode voltage clamp experiments. C and V
Harvey ras were expressed in E. Coli, purified and solubilized in a buffer
containing (mM) EDTA, 1; MgCl₂, 5; Tris pH 7.8, 20. A third electrode
containing 1 M KAc and 350 µg/ml of C and 150 µg/ml of V ras proteins was
used for intracellular injections. Voltage clamp steps from V_{I+}60 to 20 mV
under 0 Na* and 100 TEA ASW, elicited two voltage sensitive outward
potassium currents (I_A and I_C) and a voltage sensitive inward current carried
by Ca²⁺. Ten minutes after V and 20 min. after C ras injections small
increases in the inward currents were observed. After 40 to 60 min.,
progressive reductions of 15 to 30% in I_A and later I_C became clear. C ras but
not V ras effects were reversible. Inward currents were isolated in other
experiments using 3M CsCl₂ electrodes and (mM) 10 Ba* 5 4-AP and 100
TEA ASW. This sustained inward current, which activates at high thresholds
and is blocked by 10 µM Nifedipine, was increased by 40% after ras
injections. V ras effects were faster and more prolonged than C ras. Similar
experiments on Type B photoreceptors showed no effects on Ca** currents,
but significant reductions on both potassium currents. Heat inactivated ras
injections had no effect. Finally, previous exposure to 10 µM Sphingosine
prevented ras effects on potassium currents, but not Calcium currents in LP.,
This modulation of cell excitability by ras, and related G proteins (e.g. ep20,
Nelson, T.J. et al., Science, 247:1470, 1990) may be a critical initial step for the
cellular transformations of development, oncogenesis and memory storage.

329.2

MUSCARINIC AND α-ADRENERGIC SUPPRESSIONS OF CALCIUM CURRENT (I_{Ca}) ARE BLOCKED ONLY PARTIALLY BY PERTUSSIS TOXIN IN RAT SYMPATHETIC NEURONS. L. Bernheim*, D.J. Beech* and B. Hille. Univ. of Washington Sch. of Med., Seattle WA 98195.

Neurons were acutely dissociated from adult rat superior cervical control of the proceedings of the processing statements of the processing statements.

Neurons were acutely dissociated from adult rat superior cervical ganglia and current through voltage-gated Ca channels recorded under whole-cell voltage-clamp (CsCl pipette solution containing 0.1 mM BAPTA). In the bath was a 5 mM CaCl₂ Ringer solution with 10 mM TEA, 1 μM propranolol and 0.5 μM TTX. 100 μM oxotremorine-M (oxo-M) or 10 μM noradrenaline (NA) suppressed I_{Ca} by 83±3% (n=12) and 39±7% (n=10) respectively (mean±SEM). Increasing the pipette BAPTA to 20 mM reduced the suppression of I_{Ca} by oxo-M to 45±5% (n=7), but left unaffected the response to NA (37±10%, n=6). By measuring [Ca]_{ij} with fura-2 we showed that this effect of BAPTA was unrelated to Ca-chelating. Pertussis toxin (PTX) treatment divided both oxo-M and NA suppressions of I_{Ca} into two components. After neurons had been incubated with 50 ng/ml of PTX, either active (test) or boiled for 10 min (control), for 19-31 hrs at 37°C, oxo-M and NA suppressions of I_{Ca} fell from 89±3% to 47±5% and from 50±7% to 23±2% respectively. 9 PTX-treated and 9 control cells were tested for each agonist. Similar results were found using 150 ng/ml (n=8) or 500 ng/ml (n=19) PTX. Suppression of I_{Ca} by 0.5 μM somatostatin was assessed in the same cells. 50 ng/ml of PTX decreased the somatostatin response from 49±9% to 13±2%. (NIH NS08174, McKnight Research Award, Fond. Suisse Bourses Méd. Biol.)

SINGLE POTASSIUM CHANNELS OF HERMISSENDA TYPE B PHOTO-RECEPTORS: SELECTIVE EFFECT OF PHORBOL-12-13-DIBUTYRATE (PDBU). R. Etcheberrigaray and D.L. Alkon. LMCN-NINDS, National Institutes of Health, Bethesda, MD 20892.

Conditioning-induced reduction of two macroscopic currents (I_A & I_O) of Hermissenda type B-photoreceptors can be mimicked by protein kinase C (PKC) activation (Alkon, D.L., Sci. Amer., 1989). At the level of single channels, we have recently described two different potassium channels, characterized by conductances of 65 pS (large) and 42 pS (medium), (R. Etcheberrigaray et al., submitted to Biophys. J.J. In this study cell-attached (CA) and inside-out (IO) patch clamp modes were used to explore the effect of PDBU at the single channel level. Isolated eyes were incubated in PDBU JMM for 30 to 90 min. before patch clamp experiments. Measurements of percentage open time (OP) in CA at resting potential showed a profound effect of PDBU on the large K-channel. OP decreased from 15.5 (control) to 5.0 (Mann-Whitmey p<0.005). When a patch was ripped off a cell preincubated in PDBU, it remained almost completely silent. Occasional openings, nevertheless, allowed identification of the channel. When a patch was ripped off a cell preincubated in ASW channel activity remained very high (OP = 80). H-7 (50 µM) added before PDBU to the bath, prevented PDBU-mediated OP decrease of the large K-channel. CA and IO experiments revealed no differences in medium channel behavior after PDBU incubation (CA OP: control 16.0, 985 4.7 PDBU 12.6, 98 1.3; IO OP: control 48, 98 6.3, PDBU 57.8 8.5 1.4; P plus PDBU also had no effect, and PDBU application to an IO patch was without effects. In summary, we have found selective effects of a PKC activator on a particular class of B-photoreceptor potassium channels. Preliminary evidence suggests that the same channels are regulated by classical conditioning.

329.6

FMRFamide REDUCES A DELAYED OUTWARD CURRENT IN LEECH HEART INTERNEURONS. <u>T.W. Simon & R.L. Calabrese</u>, Department of Biology, Emory University, Atlanta, GA 30322

FMRFamide can accelerate the leech heartbeat central pattern generator in concentrations as low as 10-9M (Kuhlman, Li & Calabrese *J. Neurosci.* 5:2310-2317, 1985). In voltage clamp conditions, FMRFamide reversibly reduces a voltage dependent outward current, I_F, in leech heart interneurons. I_F activates at -20mV and appears fully activated at +10mV

The panel at the left shows I_F as a difference current in response to a range of depolarizing steps with and without 10-6M FMRFamide in the bath. The saline contained in mM: 0 Na+, 0 Ca++, 1.8 Co++. The activation time constant of I_F decreases from about 60 ms to 15 ms with depolarization. I_F inactivates

with a time constant of 0.5 to 1s over this same voltage range. The steady state activation and inactivation levels of I_F are also voltage dependent. Pharmacologically, I_F is blocked by internal TEA and by 1 μIM methohexital, a barbiturate, which blocks both I_A and the delayed I_K+ in leech heart interneurons. We are currently engaged in experiments to specify further the kinetic and pharmacologic properties of I_F , and its ionic dependence.

INTERPLAY OF 5-HT AND FMRFA CASCADES ON THE S-K+ CURRENT IN APLYSIA R.Shi and F.Belardetti. Dept. of Pharmacology, UT Southwestern, Dallas, TX 75235.

In aplysia mechanosensory cells (SNs) FMRFa has a dual action on the S-K+ channel: it increases its opening through the 12-lipoxygenase pathway of arachidonic acid (a.a.), and it "re-opens" channels closed by 5-HT or cAMP. We investigated the mechanism of the "re-opening" by voltage-clamping SNs at -35 mV and measuring the response to various agonists in the presence and absence of 5-HT (1-1000 nM). 1. Puff-applied a.a. (2-5 µM, 7 out of 9 experiments) or 12-HPETE (10-25 µM, 5/5) produced "re-opening", suggesting that a common pathway mediates both actions of FMRFa. 2. By constructing dose/response curves for each transmitter, we found that each transmitter non-competitively inhibits the other's action on the S-current. This rules out protein-phosphatase (PP) activation as a mechanism for "re-opening", unless PP is also inhibited by 5-HT. 3. High concentrations of 5-HT depressed also the response to a.a., indicating that this action is not primarily mediated by inhibition of the a.a. release. A 12-lipoxygenase metabolite might down-regulate a kinase, or alternatively act on the S-channel to make it a worse substrate for the kinase and/or a better substrate for PP. In the latter case, the channel might have a single receptor for a 12-lipoxygenase metabolite that mediates both effects of FMRFa, increased opening through a non-covalent change, and "re-opening" through de-phosphorylation.

ROLE OF 5-LIPOXYGENASE METABOLITES IN MODULATING K*-CHANNELS IN BRAIN NEURONS. K.Koyano, J.J.Grigg, S.Nakajima and Y.Nakajima. Dept. of Anat. and Cell Biol. and Dept. of Pharmacol., Univ. of Illinois, College of Medicine at Chicago, Chicago, IL 60612.

The role of arachidonic acid metabolism on somatostatin-and substance P-induced responses in cultured locus coeruleus and nucleus basalis neurons of the rat was studied using the wholecell clamp technique. The somatostatin-induced inwardly rectifying K'-conductance was reduced by phospholipase A_2 inhibitors (quinacrine, 50 μ M; 4BPB, 5-20 μ M), lipoxygenase inhibitors (NDGA, 3-5 μ M; ETYA, 20 μ M) and 5-lipoxygenase inhibitors (AA-861, Takeda, 50 μ M; A63162, Abbott, 50 μ M). In contrast, a cyclooxygenase inhibitor (indomethacin, 50 μ M) and a 12-lipoxygenase inhibitor (baicalein, 50 μM) were ineffective. Furthermore, 5(S)HPETE (5 μ M, a 5-lipoxygenase metabolite) enhanced the somatostatin-induced response as well as resting K'-conductance. The substance P-induced decrease in the K' conductance was also suppressed by AA-861 but not by baicalein. These results suggest that 5-lipoxygenase metabolites are not directly involved in the signal transduction of the somatostatin or the substance P effects. Perhaps 5-lipoxygenase metabolites act to maintain or to enhance the functional state of the K*-channels. Supported by NIH grants, AG06093, NS24711.

DISTRIBUTION OF PROTEIN KINASE C (PKC) ISOZYMES PREDICTS THE ATTENUATION OF VOLTAGE-GATED K CURRENTS BY TWO CLASSES OF PKC ACTIVATOR IN CULTURED CEREBELLAR NEURONS. <u>D.J. Linden, S.C. Sun, and J.A. Connor.</u> Dept. Neuroscience, Roche Inst. of Mol. Biol., Nutley, NJ 07110.

A striking example of the differential distribution of PKC isozymes is found in the cerebellum, where Purkinje cells express PKCI, an isozyme which is strongly stimulated by both the classical activators (CA) such as diacyl-glycerols and phorbol esters, and the cis-unsaturated fatty acids (c-UFA), while granule cells express only PKC isozymes which are strongly stimulated by CA, but not by c-UFA (Shearman et al., 1989, FEBS Lett. 243:177). We hypothesized that voltage-gated K currents would be attenuated by both classes of PKC activator in Purkinje cells, but only by CA in granule cells. This hypothesis was confirmed in whole-cell perforated-patch recordings of cultured rat cerebellar neurons. Voltage-gated K currents were measured with depolarizing steps from a holding potential of -90 mV in TTX. The sustained component of the K current was measured 100 msec after the start of the depolarizing step. The following table shows the % attenuation (mean ± SEM) of this current at +30mV in the presence of PKC activators. Similar results were seen in measures of the inactivating component of the K current. Treatment (N=5 for all groups) Granule cells. Purkinje cells (% atten.)

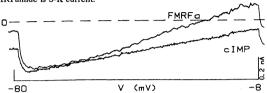

PDAc, 20nM	45.2±3.8	37.1±2.6

FMRFamide and cGMP ACTIVATE INWARD CURRENT IN APLYSIA SENSORY NEURONS. N. Buttner & S.A. Siegelbaum. Ctr. for Neurobiol. & Behav., Columbia Univ., New York, NY 10032.

FMRFamide modulates several ionic currents in Aplysia sensory neurons, including Ca current, S-K current, and Ca-activated K current. We now report that FMRFamide also elicits a Na-dependent inward current. Normally, the increase in S-K current masks the inward current. Inward current is preferentially activated: 1. At low concentrations of FMRFamide (500 nM), 2. After whole-cell dialysis, and 3. In response to YGGFMRFamide. Application of 8-bromo-cGMP to sensory cells elicits the inward current (n=9), but occasionally also elicits outward current (n=2). 8-bromo-cIMP, a cGMP analog that activates cGMP-dependent phosphodiesterase, selectively activates the inward current (n=7). cIMP and cGMP occlude the inward current response to FMRFamide. The figure shows FMRFamide (500 nM) and 8-bromo-cIMP (1 mM) difference currents in response to voltage ramps. The additional outward current with FMRFamide is S-K current.

329.10

ARACHIDONIC ACID-INDUCED DEPRESSION OF HIPPOCAMPAL POTASSIUM CURRENT IS MEDIATED VIA PROTEIN KINASE C AND OXYGEN FREE RADICALS. D.O. Keyser and B.E. Alger. Dept. of Physiology, Sch. of Med., Univ. of MD, Baltimore, MD 21201. We have reported that arachidonic acid (AA) depresses whole-cell

We have reported that arachidonic acid (AA) depresses whole-cell calcium current via protein kinase C (PKC) activation and oxygen free radical generation. We have now investigated outward currents including transient (I_A), steady-state (I_{SS}) and tail (I_{Tail}) currents and have tested the hypothesis that AA reduces both tail current and I_{SS} , by PKC activation and free radical generation.

Using acutely isolated adult guinea pig and primary cultured rat fetal hippocampal pyramidal cells we investigated outward currents under whole-cell voltage-clamp in control saline and 5 min following extracellular application of AA, 50 μ M (n=37). I_{SS} and I_{Tail} (V_H=-50 mV; V_{STEP}=-10 mV), were reduced by over 50%. Robust effects were also observed when AA was administered intracellularly. Palmitate, an unsaturated fatty acid that does not activate PKC or generate free radicals, had no effect. Pretreatment with the peptide seedosubstrate PKC inhibitor (19-36) or H-7 blocked the AA-induced current reduction by about 80%. Superoxide dismutase or a cocktail of free radical scavengers blocked the response by about 87%. I_A, (V_H=-110 mV; V_{STEP}=-10 mV), was not significantly depressed after 5 min in 50 μ M AA. Our results show that AA preferentially depresses non-inactivating outward currents via activation of PKC and generation of oxygen free radicals.

MODULATION OF ELECTRICAL SYNAPSES BETWEEN CULTURED APLYSIA NEURONS: DEPENDENCE UPON PROTEIN SYNTHESIS. G.M. Carrow, M.P. Wilson*, and I.B. Levitan. Graduate Department of Biochemistry, Brandeis University, Waltham, MA 02254.

The efficacy of electrical synapses between weakly coupled pairs of cultured neurons from juvenile Aphsia californica is increased upon exposure to nanomolar concentrations of the lectin Concanavalin A (Con A). This change results from a two- to ten-fold increase in the junctional conductance between pairs of cells as determined directly by dual voltage clamp (Carrow and Levitan, J. Neurosci. 9:3657, 1989). The modulation of junctional conductance by Con A is dependent upon protein synthesis since it is reversibly blocked by 10 uM anisomycin; this concentration of anisomycin inhibits 95% of protein synthesis in Aphsia nervous tissue. It is unlikely that the anisomycin block of modulation is due simply to interference with gap junction formation or maintenance since (1) pairs of neurons are capable of de novo formation of electrical synapses when cultured in the presence of anisomycin and (2) long-term exposure (up to 1 day) of electrically coupled pairs of neurons to anisomycin does not reduce coupling. Instead, the block by anisomycin of the Con A-induced modulation of junctional conductance appears to be specific since incubation of nervous tissue from juvenile Aphsia with Con A does not lead to a general increase in protein synthesis but rather to changes in the synthesis of particular proteins as determined by SDS PAGE. Moreover, 10 uM anisomycin does not block the Con A-induced increase of a glutamate-sensitive inward current in these neurons. These data suggest that Con A may specifically regulate the synthesis of gap junction channels or proteins that, in turn, regulate the channels. [Supported by NIH grant NS25366 to IBL]

MUSCIMOL DISRUPTS TEMPORAL DISCRIMINATION BY THE FM-FM AREA OF THE MUSTACHED BAT'S AUDITORY CORTEX. H. Riquimaroux, S. J. Gaioni* and N. Suga. Dept. of Biology, Washington Univ., St. Louis, MO 63130.

Neurons in the FM-FM area of the mustached bat's (Pteronotus parnellii) auditory cortex specifically respond to the combination of the FM sweep from the first harmonic of the emitted pulse (FM1) and a higher harmonic of the echo (FM2-4). They are tuned to particular echo delays. The best delay for these neurons systematically varies across the FM-FM area, suggesting that this area is important for processing echo delays, i.e., target ranging (Suga, 1984). We tested this function of the FM-FM area using reversible ablation with muscimol, a GABA agonist (Riquimaroux et al., 1989). Bats were trained on a discriminated shock avoidance task requiring a leg flexion. The stimuli were trains of artificial pulse FM1 - echo FM2 (P-E) pairs (e.g., 31→21 kHz and 62→46 kHz). For S+, echo delays were always the same (e.g., 4 ms), while for S- they were jittered between successive P-E pairs (e.g., 4 ms and 6 ms). Following baseline training, we applied 0.1-0.2 µg of muscimol in saline bilaterally to the FM-FM area. The bats failed on previously successful discriminations (1-20 ms of jitter). Performance returned to baseline levels within 24 h. The FM-FM area is necessary for echo-delay discriminations, i.e., target ranging. (Supported by AFOSR grant #87-0250.)

NMDA RECEPTORS ARE ESSENTIAL FOR DELAY-DEPENDENT FACILITATION IN FM-FM NEURONS IN THE MUSTACHED BAT.

J. A. Butman and N. Suga, Department of Biology, Washington University, St. Louis MO 63130

FM-FM neurons in the medial geniculate body of the mustached bat respond maximally to the combination of two signal elements, the biosonar pulse FM₁ and the echo FM_n, separated by a specific echo delay. The response at best delay consists of (1) a fast component due to a fixed latency initial spike followed by (2) a slow component due to a facilitative burst of

To investigate the synaptic mechanisms of this delay-dependent facilitation, the selective NMDA antagonist, APV, was iontophoresed onto thalamic FM-FM neurons while delay tuning curves were monitored. In 11/16 neurons, the burst (slow component) was eliminated, but the initial spike was little affected. This fast component still exhibited delay tuning, indicating that coincidence detection was unaffected. Kynurenic acid or non-specific doses of APV abolished this initial spike in some cases.

These data support the following model: Pulse and echo stimuli evoke fast EPSPs mediated by non-NMDA receptors. With NMDA receptors antagonized by APV, summation of these fast EPSPs depolarize the cell antagonized by APV, summation of these tast EPSPs depolarize the cell above spike threshold evoking only the initial spike. Normally, NMDA receptors are available, so that the summation of fast EPSPs at best delay depolarizes the cell sufficiently to unblock a slow NMDA mediated EPSP responsible for the facilitative burst. Delay tuning is thus the result of coincidence detection by fast EPSPs followed by a nonlinear multiplication of this response by the voltage-dependent NMDA receptor.

FM NEURONS BECOME DELAY-SENSITIVE IN AUDITORY CORTEX OF THE MYOTIS BAT. Maekawa and D. Wong, Anatomy Dept., Indiana Univ. School of Medicine, Indianapolis, IN 46202.
Cortical neurons sensitive to single FM

sounds are found throughout the auditory cortex of Myotis lucifugus, presumably to process the or Myotis lucifugus, presumably to process the bat's emitted echolocation sounds. Delaysensitive cortical neurons are also found in this FM bat, probably to provide target-distance information for echolocating bats in general. Our neurophysiological studies reveal that neurons sensitive to single FM sounds and to FM-FM sound pairs at specific time delays are not sensitive to paragraphs probabilities. Bather cortical neurons rm sound pairs at specific time delays are not separate populations. Rather, cortical neurons exhibit brisk responses to single FMs at low stimulation rates, but become delay-sensitive to FM-FM pairs at higher stimulation rates. Responses to single FMs drop dramatically facilitative responses emerge at specific delays. These stimulus conditions are analogous to the sound pattern that a bat hears when its sonar emission and echo return increase during echolocation. The change in the response properties suggests that individual neurons in Myotis cortex have the capacity for multidimensional analysis of target during auditory perception. (Supported by NIH grant DC00600).

330.2

MULTI-COMBINATION-SENSITIVE NEURONS IN THE FM-FM AREA OF THE AUDITORY CORTEX OF THE MUSTACHED BAT N. Suga and H. Dept. of Biology, Washington Univ. St. Louis MO 63130

In amphibians, avians, and mammals (bats), the auditory system creates combination-sensitive neurons for processing species-specific complex sounds. These neurons are tuned to combinations of two signal elements. In the mustached bat, a small population of neurons in the FM-FM area of the auditory cortex is tuned to combinations of more than two signal elements. An interesting question is how high the specialization of single neurons is for the processing of biologically important complex sounds. The aim of the present studies is to characterize the response properties of "multi-combination-sensitive (MCS)" neurons and their distributions within the FM-FM area. Out of 765 FM-FM neurons recorded, 156 were MCS neurons (80 FM1-FM2,4, 56 FM1-FM3,4, 6 FM1-FM2,3, and 14 FM1-FM2,3,4). They form two elongated 100 µm-wide bands along the boundary between the FM1-FM3 and FM1-FM4 subdivisions, and also along the boundary between the FM1-FM2 and FM1-FM4 subdivisions. A pulse FM1 is always one of the essential signal elements for the facilitative responses of MCS neurons. The best delays of MCS neurons are the same for different echo FM harmonics combined with the pulse FM1. When two echo components are combined with the pulse FM1 ("multi"-combination), the responses of an MCS neuron are either summation or facilitation of the responses to two "single" combinations. (Supported by PHS research grant NS 17333)

330.4

THE SIZE AND NUMBER OF CORTICAL COLUMNS IN THE MUSTACHED BAT'S AUDITORY CORTEX. D. C. Fitzpatrick and N. Suga. Washington Univ., St. Louis, MO 63130.

The cerebral cortex is organized as arrays of modular elements

(columns) with linear dimensions on the order of 0.5 mm. In most systems studied, the columns within a functional area are too numerous for detailed studies of identified columns to be possible. Here we report measurements that suggest that within the auditory cortex (AC) of the mustached bat, <u>Pteronotus p. parnellii</u>, each functional area contains sufficiently few columns for homologous columns in different animals to be mapped and studied. To determine the size of columns in the mustached bat's AC, injections of WGA-HRP or PHA-L were made in the AC of 4 bats. These injections labeled 21 cortico-cortical columns. The mean diameter of the columns was 368 \pm 33.4 μ m, after correcting for shrinkage. Sizes of individual functional areas were determined through multiunit mapping in 4 bats (39-51 penetrations/hemisphere). These areal sizes were then divided by the columnar size (described as closely packed hexagons, area = 0.102 sq. mm), yielding an estimate of the number of columns/functional area.

DSCF FM-FM CF/CF Alp Ala DF DM VA VF VP AC Area: 4 17 18 3 4 12 128 23 11 12

Since no injection (sizes 600-1200 µm) labeled more than 10 columns and 3 of the 4 injections labeled 5 columns or fewer, the connections between columns appear to be limited and specific. small number of columns/area and their restricted connections suggest that it should be possible to map interactions between identified columns in this specialized cortex.

330.6

ENCODING OF STIMULUS INTENSITY BY INFERIOR COLLICULAR NEURONS OF THE BIG BROWN BAT, EPTESICUS FUSCUS. M. Wu* and P.H.-S. Jen. Div. of Bio. Sci., University of Missouri, Columbia, MO 65211.

Using bats as a model system, we studied the isointensity and isofrequency discharge rate functions of inferior collicular (IC) neurons under free field stimulation conditions. For each IC neuron, the best frequency (BF), minimum threshold (MT), tuning curve and intensity rate function for the BF were first determined. Then at each of several chosen stimulus intensites, the number of impulses was measured for several frequencies which were incrementally chosen across the entire range of the neuron's tuning curve. A series of isofrequency discharge rate functions were also obtained by determining the intensity rate function for each of several frequencies chosen. Among 110 intensity rate functions measured at the BF of each IC neuron, 98 (89%) were nonmonotonic and 12 (11%) were monotonic. However, within the same series of isofrequency intensity rate functions, a neuron might show both monotonic and non-monotonic functions when measured at different frequencies. Similarly, the profile of each intensity rate curve within a series of isointensity rate functions might also vary with stimulus intensity. Isointensity discharge rate functions of most IC neurons (62 neurons, 61%) were triangular shaped reaching a peak value when stimulated with BF. The remaining (39 neurons, 39%) IC neurons had isointensity functions in which different curves peaked at different stimulus frequencies. In some extreme cases, some curves had two peaks or fluctuated within a moderate range of discharge rate throughout the whole range of stimulus frequency. Such a variation is presumably due to the different dynamic ranges of a neuron when measured at different frequencies. Our studies suggest that encoding of a wide range of stimulus intensity involves more than the discharge rate of any one individual neuron. Different populations of neurons with different BFs have to work coordinately to overcome the limitation of the dynamic range of individual neurons and to solve the ambiguity created by the same discharge rate of each individual neuron to different combinations of frequency and intensity within its auditory response area.

PLASTICITY IN THE EFFERENT INNERVATION OF THE COCHLEA INDUCED BY NEONATAL DESTRUCTION OF THE OPPOSITE INNER EAR. <u>A.F. Ryan and N.K. Woolf.</u> Division of Otolaryngology, UCSD, La Jolla, CA 92093.

Unilateral cochlear ablations were performed on gerbils at 0 to 6 days after birth. In adulthood, retrograde transport of horseradish peroxidase or tritiated amino acids was employed to assess efferent innervation of the surviving cochlea. The numbers and distributions of lateral olivocochlear (OC) neurons were essentially normal. In contrast, only 45% of the normal numbers of medial OC neurons were observed. Most of these neurons were located ipsilateral to the surviving cochlea.

We found no evidence that OC neurons associated with the lesioned cochlea formed new projections to the surviving cochlea. Rather, many medial OC neurons degenerated or failed to develop projections, even those which normally project to the intact cochlea. This suggests that the OC neurons which degenerated received sustaining projections from the ablated cochlea. Lateral OC neurons of the surviving cochlea, unaffected by neonatal lesions, presumably do not receive sustaining projections from the contralateral cochlea. This implies that the lateral OC system is primarily an ipsilateral loop, with inputs deriving from the cochlea to which it projects, in contrast to the medial OC system which receives major input from the contralateral cochlea.

330.9

TOPOGRAPHIC ORGANIZATION OF THE PROJECTIONS OF THE COCHLEAR SPIRAL GANGLION TO THE VENTRAL COCHLEAR NUCLEUS IN CATS. P.A. Leake and R.L. Snyder* Epstein and Coleman Laboratories, Dept. of Otolaryngology, U494, Univ. of California San Francisco, CA 94143-0732

The morphological organization of inputs from restricted sectors of the cat cochlear

spiral ganglion into the cochlear nucleus has been investigated previously by making focal extracellular injections of horseradish peroxidase (HRP) into the ganglion. Large injections intensely label sectors of the spiral ganglion which project into narrow "isofrequency laminae" extending across the entire lateral to medial dimension of the ventral cochlear nucleus (VCN). High frequency laminae are situated dorsally in the VCN and lower frequencies are found progressively more ventrally. Small injections label only part of an isofrequency lamina. Cells in the scala tympani portion of the spiral ganglion project to the lateral portion of VCN isofrequency laminae, and cells in the scala vestibuli portion of the ganglion project to the medial portion of the laminae.

In a corollary exeriment, restricted lesions of the anteroventral cochlear nucleus (AVCN) induced selective degeneration of spiral ganglion cells. Ablation of the lateral portion of AVCN isofrequency laminae results in degeneration of cells in the scala tympani portion of the ganglion, and medial lesions induce degeneration of the scala vestibuli portion of the ganglion for the frequencies effected by the lesion site. Since almost all cochlear nerve fibers bifurcate upon entering the brainstem, it is noteworthy that selective damage to the ascending branch is sufficient to induce degeneration of the

ganglion. The distal axons display a similar selective pattern of degeneration.

The data indicate a topographic organization of the spiral ganglion and isofrequency laminae orthogonal to the frequency domain. That is, in addition to the spiral dimension of the ganglion (corresponding to the dorsal to ventral frequency map in the VCN), there is also an orderly, sequential topographic projection of inputs from the scala tympani to scala vestibuli dimension of the spiral ganglion across the lateral to medial dimension of the VCN. (Supported by NIH Grant DC00160.)

330.11

THE GABAERGIC NEURONS IN CAT PRIMARY AUDITORY CORTEX (AI). J.J. Prieto.

THE GABAERGIC NEURONS IN CAT PRIMARY AUDITORY CORTEX (AI). J.J. Prieto. B.A. Peterson. and J.A. Winer. Department of Molecular and Cell Biolology, University of California, Berkeley, California 94720-2097.

The distribution, form, and number of GABA- or GAD-immunoreactive neurons in AI were studied in adult animals in 25 μm-thick sections. With one exception (see layers V and VI) all the cell types are non-pyramidal, and each was related to the neurons in Golgi material. The cells are: in layer_II, horizontal, tufled, bitufted (vertical) and multipolar cells; in layer_III, four kinds of multipolar neurons and bitufted cells; in layer_III, two types of stellate cells, tufled and bitufted cells; in layer_IV, three kinds of multipolar cells, inplayer and double bouquet cells; in layer_IV, three kinds of multipolar cells, in layer IV, three kinds of multipolar cells, inplayer and double bouquet cells, in layer_IV, three kinds of multipolar cells, invokinds of tufted neuron, bipolar cells, and inverted pyramidal cells. Thus, the common GABAergic cell types are: tufled, bitufted, multipolar, and bipolar cells, horizontal cells are found in layer I, and inverted pyramidal cells occur only in layers V and VI. Comparable cell types contain GABAergic members in other cortical sensory areas. GABA-immunopositive puncta were often found on the soma and dendrites of some GABAergic medium-sized stellate cells (layer III), medium-sized and large tufted cells (layer III), and large multipolar cells (layers IV and V) (see Peterson et al. [1990]: this volume).

The number and proportion of GABAergic cells were determined in 1 μm-thick plastic

[1990]: this volume).

The number and proportion of GABAergic cells were determined in 1 μm-thick plastic sections, counterstained with toluidine blue. In 500 μm-wide samples at systematic intervals along the rostrocaudal and the dorsoventral extent of Al, GABAergic cells were 21.75±1.57% of the total, a value comparable to other cortical areas. The highest proportion of GABAergic cells (73%) is between 0-200 μm deep (layer I), falling to 20.3-23.7% between 200 to 1600 μm, and to 14.3-17.3% from 1600 μm to the white matter. The number and proportion of such cells within Al were not significantly different, suggesting that these values may be uniform across frequency or aural dominance regions.

This research was supported by United States Public Health Service Grant RO1 NS16832-10, and by a personal fellowship (JJ.P.) from the Conselleria de Cultruz Educacion y Ciencia (Generalitat Valenciana). 330.8

SINGLE-UNIT RESPONSES IN THE COCHLEAR NUCLEUS OF YOUNG AND AGED RATS. E.M. Keithley, Division of Otolaryngology, UCSD, La Jolla CA 92093

Aging in mammalian cochleas is associated with loss of spiral ganglion cells in the base and apex. Thus, responses to acoustic stimuli of cells in the ventral cochlear nucleus (VCN) may reflect this loss of afferent input. Neural responses were recorded from the VCN of 2 month old (MO) and 24-26 MO Sprague Dawley rats with glass microelectrodes. Two aged animals had spontaneously active units (1-10 spikes/s), but no stimulus evoked activity. Three other aged animals had units with thresholds at least 30 dB above the most sensitive units from the young The characteristic frequencies of units from young animals extended from 0.4-55 kHz, while those from old animals ranged from only 0.9 -30 kHz. All classically described VCN unittypes were seen in both age groups. While the initial spike latency at 20 dB above threshold of most units from old animals latency at 20 dB above threshold of most units from old animals was within the range of times for young animals, there were a few units with longer response times. Timing variability and paucity of units at low and high frequencies could contribute to a decrease in the accuracy of stimulus coding and thereby degrade the clarity of the acoustic message in the elderly.

330.10

3-D ANALYSIS OF AUDITORY EVOKED POTENTIALS IN RAT NEOCORTEX. <u>DANIEL S. BARTH</u> and <u>SHI DI</u> Departments of Neurology and Psychology, Univ. of California, Los Angeles,

A 8x8 channel microelectrode array was used to map epicortical field potentials, evoked by bilaterally presented click stimuli, from a 8x8 mm² area in the right parieto-temporal neocortex of 4 rats. In two rats, a 16 channel microelectrode array was also inserted into primary auditory cortex to record the laminar profile of auditory evoked potentials

potentials.

The epicortical responses began with a positive-negative fast wave followed by a positive-negative slow wave, similar to the previously reported P1, N1, P2, N2 complex. Topographical distributions of the potentials for each of these components were distinct, suggesting that they were produced by separate but overlapping populations of cells. Laminar recording revealed the asynchronous participation of supragranular and infragranular pyramidal cells in the generation of the evoked response complex. The surface recorded P1 was primarily produced by supragranular cells and the N1, by infragranular cells. The P2 and N2 were produced by temporally overlapping contributions from both cell groups.

We conclude that middle latency components of the auditory evoked potential complex reflect both sequential and parallel activation of subpopulations of pyramidal cells in primary auditory cortex.

330.12

GABA-IMMUNOREACTIVE AXON TERMINALS IN CAT PRIMARY AUDITORY CORTEX (AI). B.A. Peterson, J.J. Prieto, and J.A. Winer. Department of Molecular and Cell Biology, University of California, Berkeley, California 94720-2097.

University of California, Berkeley, California 94/20-2097.

GABA is a major necordical neurotransmitter but its distribution in primary auditory cortex (AI) has not been described. Since many cortical cells are GABAergic, knowledge of them (see Prieto et al. [1990]: this volume) would be useful in understanding how GABA influences the cortex. We studied the laminar distribution of axon terminals in plastic embedded, 1 µm-thick sections processed with GABA antiserum, and in 25 µm-thick frozen sections processed with

GAD amiserum.

GABAergic axon terminals are found in all layers of AI but there are significant laminar differences in the form and locus of axon terminals. The main results are: (i) there is conspicuous immunoreactivity in the upper part of layer I and in layers III and IV that is related to both the density and size of axon terminals; (ii) layer I has the highest density (25-30 puncta/100 μm²) of GABAergic axon terminals; (ii) layers II, III, and IV have about half as many terminals; (iv) layers V and VI have still fewer terminals (5-8/100 μm²); (v) each layer has immunonegative cells with immunopositive axosomatic endings; and (vi) layers III and IV have axon proprogramatid immunopositive that require immunopositive expenses portions while many non-pyramidal immunopositive cells that receive immunopositive axosomatic endings, while layers I, II, V and VI have few.

layers I, II, Vand VI have few.

The size and density of axon terminals in the thalamic recipient zones (layers IV and IIIb) is consistent with the idea that, in AI as well as primary visual cortex and somatosensory cortex, there are intrinsic inhibitory influences on or near geniculorecipient neurons. The soma and apical dendrite of pyramidal neurons are frequently covered with immunopositive axon terminals, suggesting significant influences on commissural and corticofugal pathways. Both immunopositive and immunonegative non-pyramidal cells, which may project in corticocortical pathways or intrinsic circuits, receive GABAergic axon terminals. It is likely that GABAergic cells and axon terminals have a different role in each layer, and participate in every cortical respective.

Projection.

This research was supported by a United States Public Health Service Grant RO1 NS16832-10. We thank D.T. Larue for technical assistance and Drs. E. Mugnaini, D.E. Schmechel and R.J. Wenthold for the antisera and technical advice.

APPEARANCE OF FUNCTIONAL VOLTAGE AND AMINO ACID GATED CHANNELS ON EMBRYONIC NEOCORTICAL NEURONS. J.J.LoTurco, M.G.Bianton and A.R.Kriegstein. Dept. of Neurology and Neurological Sciences, Stanford Univ. Sch. of Med., Stanford, CA, 94305.

The compliment of voltage and ligand gated channels present on immature neurons will constrain the possible activity-dependent mechanisms that can influence their differentiation. In order to determine which voltage and amino acid gated channels are present on necortical neurons at different stages of development, we have made both whole-cell and outsideout patch-clamp recordings from different laminae of slices prepared from embryonic rat neocortex.

Cells in the ventricular zone had voltage activated sodium currents that

were blocked by TTX. The predominant potassium current showed voltage-dependent activation and slow inactivation. Outside-out patch recordings indicated that these ventricular zone cells had GABAa receptor/channels on their membranes, however lacked NMDA receptor/channels. Cells in the cortical plate had sodium and potassium currents that were larger than those in ventricular zone cells. In addition, a faster inactivating potassium current that was blocked by 4-AP became apparent in cortical plate cells. Calcium currents, both low threshold and high threshold, were also first detectable in cortical plate cells. Another apparent difference between the ventricular zone cells and cortical plate cells was that outside-out patches from the latter contained both GABAa receptor/channels and NMDA

These differences reveal the early assembly of neuronal properties, and indicate that embryonic cortical neurons at different stages of development will distinctively respond to extra- and intra- cellular signals.

DISSOCIATED TECTAL NEURONS FROM RANA PIPIENS EXHIBIT A CALCIUM INFLUX IN RESPONSE TO EXCITATORY AMINO ACIDS. H.T. Cline and R.W. Tsien. Dept Physiol & Biophys. Univ Iowa. Iowa City, IA 52242 and Dept Mol. Cell. Physiol. Stanford Univ Medical School. Stanford, CA. 94305

NMDA receptor activation is required for normal development of the retinotectal projection in frogs. We have suggested that the NMDA receptor detects the correlated

projection in frogs. We have suggested that the NMDA receptor detects the correlated electrical activity of retinal ganglion cells with overlapping receptive fields and that the Ca influx through the NMDA channel initiates the stabilization of the coactive retinal inputs (Cline & Constantine-Paton '89 Neuron 3:413). Although retinotectal synaptic transmission has been shown to be glutamatergic, a Ca influx in the tectal neurons in response to glutamate has not yet been demonstrated.

We have used calcium imaging with Fura-2 to assay the responses of dissociated tectal neurons (Steen et al. '89 J. Comp. Neurol. 289: 467.) to depolarizing [K] and excitatory amino acids (EAAs). Tectal cells exhibit a resting [Ca] of 50-200 nM, which rises rapidly to 0.5-2 µM in response to 56 mM K or EAAs. The magnitude of the Ca rise and the % of responsive cells increases over the first 2 d in culture and remains constant over the next 3 d. In cultures where about 70% of the cells respond to high K, 70% of the excitable cells (50% of the total) respond to NMDA (10-100 µM) or glutamate Glu: 1-10 µM). The NMDA-induced Ca transient is respond to high K, 70% of the excitable cells (50% of the total) respond to NMDA (10-100 µM) or glutamate (Glu; 1-10 µM). The NMDA-induced Ca transient is abolished in Ca-free Ringer, blocked by NMDA receptor/channel blockers, APV, Mg or MK801; and partially inhibited by Cd (0-50%) at concentrations that abolish the K response. The glu-induced Ca rise is completely blocked in Ca-free Ringer and partially blocked by APV. Quisqualate (up to 1 mM) did not cause a Ca rise, whereas kainate (10-100 µM) causes a small Ca rise of 100-300nM. Recovery from the Glu-induced Ca rise was slower (50% recovery at 7-10 min) than the recovery from the NMDA response (50% recovery at 1-2 min). These results indicate that dissociated tectal neurons respond to NMDA with a Ca influx through the NMDA channels, with a relatively small contribution from voltage-dependent calcium channels (VDCCs). Furthermore, Glu stimulation results in a Ca rise due to an influx through NMDA channels and VDCCs. Activation of the glutamate recentor influx through NMDA channels and VDCCs. Activation of the glutamate receptor does not appear to cause the release of Ca from intracellular stores.

331.5

NIMODIPINE SELECTIVELY BLOCKS CA²⁺ INFLUX THROUGH VOLTAGE-GATED CA²⁺ CHANNELS IN CORTICAL NEURONS. I.M. Nerbonne and L.C. Katz, Pharmacology Dept., Washington Univ. Med. Sch. St. Louis, MO 63110, and Lab. Neurobiology, The Rockefeller Univ., New York, NY 10021.

To examine the contributions of different types of voltage-gated Ca²⁺ channels to depolarization-induced Ca²⁺ influx in isolated callosal-projecting (CP) and superior colliculus-projecting (SCP) visual cortical neurons, we combined in vivo fluorescent retrograde labelling to identify these distinct cortical cell types, with in vitro Ca²⁺; imaging of dissociated cells loaded with fura-2. Resting Ca²⁺; in isolated CP and SCP cells ranged between 25 and 50 nM. K⁺-induced depolarizations (to \approx -25 mV) resulted in rapid, reversible increases in $Ca^{2^{+}}$; in both cell types. Although the magnitude of the responses varied, $Ca^{2^{+}}$; increased in all cells by at least 3 fold, and returned to control levels within minutes of washing with normal medium. These K^* -induced increases in somal and dendritic Ca^{2*} , were reduced 50-80 We in the presence of 2 μ M nimodipine. The putative "T" channel blocker, ethosuximide (10-50 μ M), in contrast, did not measurably attenuate K*-dependent increases in Ca²⁺₁.

We conclude that depolarization-induced Ca²⁺ entry into both CP

and SCP visual cortical neurons is predominantly through "L" type Ca²⁺ channels, and that these channels are effectively blocked by nimodipine. Because Ca²⁺ influx plays a critical role in excitotoxicity, these results suggest that nimodipine, which can cross the blood brain barrier, may be a useful therapeutic agent to prevent neuronal damage associated with cerebral ischemia. Supported by NSF #BNS-8809823, and the L. P. Markey Charitable Trust.

331.2

ENDOGENOUS ACTIVATION OF NMDA RECEPTORS DIFFERENTIATING NEURONS IN EMBRYONIC NEOCORTEX. Blanton, J.J. LoTurco and A.R. Kriegstein. Dept. of Neurology and Neurological Sciences, Stanford Univ. Sch. of Med., Stanford, CA, 94305.

N-methyl-D-aspartate (NMDA) receptors may play an important role in the control of neuronal growth and differentiation. To determine when these receptors are expressed and activated in differentiating neocortex, we made whole-cell voltage-clamp recordings from neurons in slices of embryonic rat neocortex.

Focal application of glutamate (1 mM) activated a current that was sensitive to the NMDA receptor antagonist D-2-amino-5-phosphonovalerate (D-APV); fluctuation analysis of the evoked current revealed an underlying mean channel open time of 5.0 msec, typical of NMDA receptors. In the absence of exogenously applied agonists, similar spontaneous currents were recorded from neurons in the contical plate beginning at embryonic day 15 (E15). The tonic currents were blocked by D-APV and the glycine site antagonist 7-chlorokynurenic acid. In addition the current was blocked in a voltage-dependent manner by magnesium. Analysis of single channels and fluctuation analysis of current noise in young cells revealed a conductance of 50 pS and a mean open time resembling that activated by exogenous glutamate. The currents were clearly distinct from spontaneous, discrete non-NMDA-mediated synaptic events that were detected later in embryonic

life.

The activation in situ of NMDA channels prior to synaptic differentiation provides a physiological substrate for the control of early neuronal differentiation by NMDA receptors.

331.4

NMDA RECEPTOR ACTIVATION DOMINATES SYNAPTICALLY-INDUCED CALCIUM INFLUX IN DEVELOPING RAT VISUAL CORTEX. Yuste and L.C. Katz. Laboratory of Neurobiology, The Rockefeller University, New York, NY 10021.

The entry of calcium through the NMDA receptor is considered a critical signal in models of developmental plasticity in the mammalian cortex. Using the calciumsensitive indicator fura-2, we analyzed calcium influx mediated by excitatory amino acids and synaptic transmission in cortical neurons in rat visual cortex slices during the first postnatal week.

A single brief shock (100 µsec) applied to the cortical white matter induced a large increase in $[Ca^{2+}]_i$ of postsynaptic neurons in the upper cortical layers that lasted >10 sec. This synaptically mediated increase in $[Ca^{2+}]_i$ was due primarily to activation of NMDA receptors: AP5 (50 µM), a competitive NMDA antagon blocked 75±6% of the signal. The remainder of the signal was completely blocked by DNQX (5 µM), a selective quisqualate receptor antagonist. The peak of the DNQX-sensitive component occurred about 400 msec prior to the peak of the AP5-

sensitive component. Similarly, approximately 95% of the increase in $[Ca^{2+}]_i$ induced by bath-applied glutamate (50 μ M) was blocked by AP5. NMDA and glutamate-induced increases in $[Ca^{2+}]_i$ could result either from Ca^{2+} entry directly through the NMDA channel, or indirectly via voltage-sensitive Ca^{2+} channels. To distinguish between these possibilities, we studied NMDA-induced responses in the presence of nimodipine, an antagonist of "L" type voltage-sensitive Ca^{2+} channels. Nimodipine (2.5-10 μ M) attenuated the increase in $[Ca^{2+}]_i$ elicited by 5 μ M quisqualate and 50 mM KCl by 40-60%, but had no effect on the response to 50 μ M NMDA. Thus, in the developing cortex, most of the synaptically induced Ca²⁺ influx probably results from activation of the NMDA receptor and Ca²⁺ entry directly through the NMDA channel. EFFECTS OF AP3 ON EAA-STIMULATED PI TURNOVER AND OCULAR DOMINANCE PLASTICITY IN THE KITTEN VISUAL CORTEX. S. M. Dudek, A. P. Bohner, and M. F. Bear. Center for Neural Science, Brown University, Providence, RI 02912.

It is now well known that certain excitatory amino acids (EAAs) can stimulate the hydrolysis of phosphoinositides (PI) in neurons. Potent agonists include glutamate, ibotenate, quisqualate, and ACPD. EAA-stimulated PI turnover is age dependent; in kitten visual cortex ibotenate-stimulated PI turnover correlates precisely with the critical period for ocular dominance (OD) plasticity (Dudek & Bear; Science 246: 673). Recently, it has been reported that the compound 2-amino 3-

246: 673). Recently, it has been reported that the compound 2-amino 3-phosphonopropionate (AP3) selectively antagonizes EAA-stimulated PI turnover (Schoepp & Johnson; J. Neurochem. 53: 273). The aim of this study was to investigate the effects of AP3 on PI turnover in vitro, and on OD plasticity in vivo.

The ability of AP3 to inhibit ibotenate- and quisqualate-stimulated PI turnover was assayed in two different preparations: synaptoneurosomes and slices of kitten striate cortex. A striking difference was observed between the two systems; AP3 potently inhibited EAA-stimulated PI turnover in synaptoneurosomes, but had no effect in clipse years at MA concentrations. Thus the precharges of series to AP3 effect in slices even at mM concentrations. Thus, the mechanism of action by AP3 is complex and appears to depend on factors differentially expressed by synaptoneurosomes and slices.

In the second part of this study, 50 mM AP3 was infused into striate cortex at 1 µl/hr at the same time that the kitten was monocularly deprived by lid suture. AP3 infusion appears to interfere with the ocular dominance shift after 7 d. of MD, but the effect is age dependent. The shift contralateral to the deprived eye was nearly of the effect is age dependent. The shift contralateral to the deprived eye was nearly completely blocked by AP3 when MD was initiated between 50 and 60 days of age (n= 3); however, AP3 appears to be largely ineffective in blocking the OD shift in younger kittens. Taken together, these results suggest that AP3 may not be potent enough an inhibitor to block EAA-stimulated PI turnover, and consequently OD plasticity, at the height of the critical period. (Supported by NIH grant EY06929)

VISUAL ACTIVITY AND OCULAR DOMINANCE PLASTICITY IN CAT VISUAL CORTEX PERSIST FOLLOWING SPECIFIC BLOCKADE OF NON-NMDA GLUTAMATE RECEPTORS J. B. DeFreitas* and M. P. Stryker. Neuroscience Graduate Program and Dept. of Physiology, Univ. of Calif. San Francisco, CA 94143-0444.

Previous studies have shown that specific blockade of the NMDA subtype of Previous studies have shown that specific blockade of the NMDA subtype of glutamate receptor in cat visual cortex profoundly depresses neuronal activity and reduces ocular dominance plasticity following monocular deprivation (MD). We now investigate the effects of specifically blocking non-NMDA glutamate receptors on the activity and plasticity of cells in visual cortex. Cannulae attached to osmotic minipumps infused 0.5 µl/hr 4mM CNQX into area 17 of the right hemisphere of 4 week old cats. On the following day (in 2 animals) recordings of neuronal responses to iontophoresis of quisqualate (QA) and NMDA from multi-barrel pipettes were used to delineate the regions of cortex in which receptors were blocked, and visual responses were studied. In

cortex in which receptors were blocked, and visual responses were studied. In 4 additional animals, the left eyelid was closed 2 days after implanting the infusion cannula, and similar recordings were made 5-12 days later. Close (<600µm) to the infusion cannula, both QA and NMDA iontophoretic thresholds were elevated, suggesting that CNQX was present in sufficient concentration to exert non-specific effects on NMDA receptors; and neural activity was profoundly depressed. Farther from the cannula, QA responses were selectively elevated, suggesting a specific blockade of non-NMDA receptors. In this region of cortex, visual responses were always evident and were commonly robust, while spontaneous activity was dramatically reduced in comparison to untreated cortex. The effects of MD were as pronounced in this region as in control cortex. While a reduction of ocular dominance plasticity was not evident under these conditions and is evident with infusion of NMDA-receptor blocker APV, these results do not provide support for a special role for NMDA receptors in ocular dominance plasticity, since visual responses were robust with CNQX but suppressed by APV. INPUT-DEPENDENT TRANSIENT EXPRESSION OF RECEPTOR POPULA-TIONS IN KITTEN VISUAL CORTEX DEVELOPMENT. M.S. Cynader, V. Booth, Y.L. Liu, R. Dyck, and W.G. Jia, Dept. of Ophth., Univ. of British Columbia, Vancouver, B.C. Can. We have previously found that over a dozen different

classes of neurotransmitter receptors are transiently expressed in cells of certain layers of the kitten visual cortex during early postnatal development. These receptors alter their distribution during the critical period and may disappear or may be expressed by cells in different cortical layers, depending on the specific receptor under study. Here we show that receptor redistribution under study. Here we show that recept depends on thalamic input early in life.

Posterior thalamus, including lateral geniculate nucleus was removed in kittens 10-25 days of age. After 3 to 12 weeks, the kittens were perfused and examined with receptor autoradiography. We examined the following binding sites: NMDA, Kainate, GABA B, 5-HT₁A, 5-HT₁C, Beta and Alpha Adrenergic, Muscarinic M1, M2, Adenosine A₁. Most receptors failed to undergo their normal agedependent redistribution in the operated dependent redistribution in the operated nemisphere. Instead receptors continued to be expressed in the same layers as they had been in young kittens. Adult lesions had no comparable effects. Despite the lesions, a few of the populations examined did undergo age-dependent redistribution. The implications for cortical plasticity of the differential responsivity of various receptor populalations will be considered.

331.11

CORTICAL ORGANIZATION OF ORIENTATION SELECTIVITY EMERGES FROM INTERACTIONS BETWEEN ON- AND OFF-CENTER INPUTS.

K.D. Miller, Dept. of Physiology, UCSF, San Francisco, CA 94143.

Last year I reported that Hebbian or similar synaptic plasticity mechanisms can yield orientation-selective cortical cells through interactions between

nisms can yield orientation-selective cortical cells through interactions between ON- and OFF-center inputs. The resulting receptive fields consist of alternate bands of ON- and OFF-center inputs. This can occur if, during the time that orientation-selective cells are developing, ON- (OFF-) center inputs are better correlated in activity with other ON- (OFF-) center inputs at retinotopic separations smaller than a receptive field center diameter, but best correlated with OFF- (ON-) center inputs at larger retinotopic separations.

Here I report further studies of the cortical organization of orientation that emerges under this model. A locally continuous and periodic arrangement of orientation arises that resembles that seen experimentally. Dependence of this organization on biologically measurable quantities (the correlations among inputs.

ganization on biologically measurable quantities (the correlations among inputs, the geniculcortical connectivity, and the intracortical connectivity) is studied both through simulation and analysis. Analytically, simple Hebbian mechanisms produce an outcome in which cortical cell activity is correlated over distances at produce an outcome in which cortical cell activity is correlated over distances at which tootical synaptic interactions are excitatory, and anticorrelated over distances at which those interactions are inhibitory. The correlation between two cortical cells depends on their preferred orientations, the retinotopic separation of their receptive field centers, and the spatial phase and frequency of their receptive field arrangements of ON- and OFF- regions. These considerations allow analysis of the spatial arrangements of receptive fields that should emerge under a Hebbian model. Previous models have not considered the role of spatial phase or frequency, which substantially alter predictions for the cortical organization of orientation. Experimentally, it will be important to study the simultaneous variation of all of these receptive field parameters in visual cortex. Supported by an NEI Fellowship and a Human Frontiers Science Program Grant to M. P. Stryker (T. Tsumoto, Coordinator).

DARK-REARING KITTENS DELAYS THE DEVELOPMENTAL DECREASE IN CORTICAL NMDA RECEPTOR EFFICACY. K.FOX, N.DAW, D.CZEPITA Dept. Cell Biology, Wash. U. Med Sch, St. Louis, MO 63110 We have previously reported that APV becomes gradually less effective in antagonizing visual responses (VRS) in layers IV,V and VI of visual cortex as the animal develops from 3 to 4 weeks. This implies that NMDA-receptors contribute less to the VRs as the animal matures. We now report that the functional distribution of NMDA-receptors reaches an adult stage by 6 weeks for animals reared in the light but remains at the 3-week immature stage if reared in the dark. The NMDA component of the VR was estimated by iontophoresis of APV using a standard drug trial of 10nA for 3 minutes for each cell. Four groups of animals were studied. In animals dark-reared for 6 weeks VRS were substantially supressed by APV in all layers. In 6 week light-reared animals only VRs of layer II and III cells were antagonized by APV; adult animals were indistinguishable from them in this respect. VRs of layer IV cells showed the greatest divergence from age-matched cells showed the greatest divergence from age-matched light-reared animals. Animals dark-reared for 6 weeks then exposed to visual experience developed the adult insensitiexposed to Visual experience developed the addit insensitivity to APV in layers IV,V and VI by 10 days but only partially by 4 days. CNQX attenuated VR in layers IV,V and VI in cases where APV only affected spontaneous activity. The effectiveness of APV was independent of the magnitude of the control response. We conclude that visual experience leads to a decrease in the NMDA component of visual transmission in deep cortical layers during days layers. mission in deep cortical layers during development.

POSTSYNAPTIC MEMBRANE POTENTIAL REGULATES SYNAPTIC POTENTIATION AND DEPRESSION IN VISUAL CORTICAL NEURONS. Y. Frégnac, D. Smith*, M.J. Friedlander, Neurobiology Res. Center, UAB, AL 35 294.

It has been suggested from in vivo recordings in cat visual cortex that changes in covariance between pre- and postsynaptic activity can potentiate or depress synaptic efficacy (Frégnac et al. Nature 333: 367, 1988). We have directly tested the

in covariance between pre- and postsynaptic activity can potentiate or depress synaptic efficacy (Frégnac et al. Nature 333: 367, 1988). We have directly tested the role of membrane potential of the postsynaptic neuron for inducing such synaptic plasticity, by comparing, in vitro, the effects of paired afferent stimulation with concomitant depolarizing or hyperpolarizing current injection in the target cell.

450 µm thick frontal slices of primary visual cortex (VC) were taken from 4-5 week old kittens and adult guinea-pigs, and maintained in standard bicuculline free ACSF, 38 stable intracellular records were made in VC, mainly in granular and supragranular layers, using K+methyl-sulfate and biocytin filled micropipettes. Bipolar electrical microstimulation (STIM) was applied in white matter (WM) or at the layer VI /WM border. Evoked compound PSP's were studied in most cells (34/38) as a function of the stimulus intensity and/or of the postsynaptic membrane potential. Low frequency (0.1 to 1.0 Hz) pairing of STIM with a short depolarizing pulse (+4 to +7 nA, 50ms) resulted, in 2/4 cells, in a long lasting increase of the compound PSP, affecting mainly its peak amplitude and its decay rate. Pairing with a hyperpolarizing pulse (-2 to -4 nA, 50 ms, delayed by -10 ms) resulted in 8/11 cells in a transient depression of both early and late components of the PSP. Input resistance and resting potential were usually unchanged. No effect was observed for current values less than +/-1 nA. Temporal associativity was demonstrated by the lack of changes (0/6 cells) produced when imposed current pulses were applied out of phase (delayed from STIM by 140 ms) or uncorrelated with the PSP's occurence.

Similar changes were obtained in kitten and adult guinea-pig VC. These results demonstrate that the same compound PSP (involving mono- and polysynaptic excitatory and inhibitory pathways) can be potentiated or depressed by the temporal association of afferent stimulation with a local control of the polarization state of the pos

331.12

A MODEL OF VISUAL CORTICAL PLASTICITY WITH A SLIDING MODIFICATION THRESHOLD: COMPARISON OF THEORY WITH EXPERIMENT. E.E. Clothiaux*, M.F. Bear and L.N Cooper, Dept. of Physics and Center for Neural

Science, Brown University, Providence, RI 02912

The response properties of neurons in striate cortex depend on the visual environment experienced during a critical period of postnatal development. For example, prolonged binocular deprivation broadens orientation selectivity, and binocular connections are modified after brief periods of monocular deprivation, strabismus, and reverse suture. The results of more recent experiments in which the cortical activity in one area of visual cortex is chronically recorded (Mioche and Singer, 1989) have provided detailed descriptions of the changes in binocular connections during periods of monocular deprivation and reverse suture. For example, Mioche and Singer found that during a reverse suture many neurons went through a "blind" period where they did not respond to stimulation of either eye. We have made a detailed investigation of the cortical plasticity model of Bienenstock, Cooper, and Munro (1982) with special attention to the fixing of parameters by comparison with experiment. Computer simulations capture the important features of the new monocular deprivation and reverse suture experimental results, while continuing to provide correct descriptions for normal rearing after monocular deprivation, binocular deprivation and strabismus. INHIBITION OF EPINEPHRINE BIOSYNTHESIS. ENANTIOSELECTIV-ITY IN THE BINDING OF BENZYLAMINE INHIBITORS RELATED TO LY-134046 AND OF CONFORMATIONALLY-DEFINED PHENYL-ETHYLAMINE INHIBITORS TO THE ACTIVE SITE OF PHENYL-ETHANOLAMINE N-METHYLTRANSFERASE (PNMT). Gary L. Grunewald, Vidyadhar M. Paradkar*, Vilas Dahanukar*, Duane M. Stillions*, Feei Ching*, and Kevin R. Criscione*. Department of Medicinal Chemistry, University of Kansas, Lawrence, KS 66045.

In order to elucidate the role played by epinephrine in CNS function, a selective inhibitor of PNMT has been sought. Most currently available inhibitors of the enzyme also show high binding affinity toward other sites, most notably the α2-adrenoceptor. To exploit as much as possible any subtle binding differences that may exist between ligands toward the active site of PNMT and to the α_2 adrenoceptor, we have prepared and evaluated binding affinities for enantiomers of inhibitors of the benzylamine class (typified by analogues of LY-134046) and of phenylethylamines (typified by conformationally-defined ligands in which the ethylamine side chain is held in an optimal fully extended conformation such as 8-amino-6,7,8,9-tetrahydro-5,8-methano-5*H*-benzocycloheptene and *anti*-10-amino-5,6,7,8-tetrahydro-5,8-methano-9*H*-benzocycloheptene). Where appro-Where appropriate, X-ray crystal structures have been determined to establish absolute stereochemistry. A comparison of the binding modes of ligands of these two structural types to PNMT and to the ₂-adrenoceptor will be described and illustrated in terms of a computer graphics model of the active site of PNMT. Supported by HL 34193.

LY274614, AN ANTAGONIST OF N-METHYL-D-ASPARTATE (NMDA) RECEPTORS, PROTECTS AGAINST AMPHETAMINE-INDUCED NEURO-TOXICITY TOWARD STRIATAL DOPAMINE NEURONS IN RATS. R. W. Fuller, S. K. Hemrick-Luecke* and P. L. Ornstein. Lilly Research Laboratories, Eli Lilly and Company, Lilly Corporate Center, Indianapolis, IN 46285.

In rats treated with iprindole to block the usually rapid metabolism of amphetamine by para-hydroxylation, one dose of amphetamine depletes striatal dopamine and its metabolites for weeks (Fuller and Hemrick-Luecke, Science 209:305, 1980; Steranka, Brain Res. 234:123, 1982) and causes histologic evidence of neurotoxicity (Ricaurte et al, Brain Res. 291:378, 1984). In male Sprague-Dawley al, brain Res. 291:376, 1964). In male Sprague-Dawley rats treated with iprindole (10 mg/kg i.p.), (±)-amphetamine sulfate (0.1 mmole/kg i.p.) caused about 40% depletion of striatal dopamine at one week. LY274614, (±)decahydro-6-(phosphonomethyl)-3-isoquinolinecarboxylic acid (an NMDA receptor antagonist), dose-dependently antagonized this loss of striatal dopamine when injected i.p. at doses of 1-10 mg/kg 1 hr before amphetamine. LY274614 (10 mg/kg i.p.) protected against striatal dopamine depletion when it was injected during an 8 hr period <u>preceding</u> amphetamine or during a 4 hr period <u>after</u> amphetamine.

LY274614 also antagonized methamphetamine-induced neurotoxicity in mice, consistent with findings of Sonsalla et al (Science 243:398, 1989) on other NMDA receptor antagonists. The NMDA receptor apparently plays a role in the nigrostriatal dopaminergic damage induced by amphetamines.

332.5

SEROTONIN ACTS AT 5-HT_{1A} RECEPTORS TO SELECTIVELY ATTENUATE GLUTAMATE-EVOKED RESPONSES OF LOCUS COERULEUS NEURONS. G. Aston-Jones¹, P. Charlety. H. Akaoka¹, R. Shiekhattar¹ & G. Chouvet, INSERM U 171/CNRS URA1195, CHLS, Pierre-Bénite, France; ¹Div. Behav. Neurobiol., Dept. Mental Health Sci., Hahnemann U., Philadelphia, PA, USA. Extracellular recordings were obtained from individual LC neurons in halothane-anesthetized rats using an 8-barrel micropipette assembly (recording tip extending 12-18 µm). Iontophoretic Glu or acetylcholine (ACh) potently activated, and NE consistently inhibited, LC cells. In contrast, 5-HT had no consistent effect on LC spontaneous activity, but reliably suppressed responses of LC neurons to Glu (by 58 ± 3% overall) in 83% of 201 neurons. This effect was specific for Glu, as 5-HT did not reduce ACh responses in 10 of 11 neurons. Also, NE did not attenuate Glu-evoked responses of LC neurons.

In seried was specific for aid, as 5-H1 did not reduce ACH responses in 10 of 11 neurons. Also, NE did not attenuate Glu-evoked responses of LC neurons. Iontophoretic methysergide or methiothepin antagonized 5-HT's attenuation of Glu-evoked responses (11/15 & 4/5 neurons, respectively). Iontophoresis of the the 5-HT, agonist RIU24969 mimicked the effects of 5-HT (10/13 cells), as did application of the 5-HT1A agonists 8-OHDPAT, PAPP and buspirone (18/25, 13/22 and 3/4 cases, respectively). Agonists at the 5-HT_{1B} site, TFMPP and CGS 12066B, were less effective. The 5-HT₂ antagonist

site, TFMPP and CGS 12066B, were less effective. The 5-HT₂ antagonist ketanserin did not attenuate (n=8), and the 5-HT₂ agonist DOI failed to mimic (n=6), 5-HT effects. Thus, a 5-HT₁A receptor may be most involved. Activation of LC neurons by sciatic nerve stimulation is mediated by excitatory amino acids (EAAs). After depletion of brain 5-HT with PCPA, LC neurons exhibited heightened sciatic responses (by 64%; n=32). However, microirfusion of 5-HT onto LC somata in intact rats did not reliably attenuate these responses. Thus, modulation of LC sensory responses by 5-HT may take place outside the LC, and 5-HT's attenuation of Glu responses may reflect an interaction with EAA receptor(s) that do not convey sensory responses of LC neurons. Support: CNRS, INSERM, the Phillippe Foundation, the Simone del Duca Foundation, and PHS grants NS24698 & DA06214.

KINETIC MODELING OF 6-FLUORODOPA TIME COURSES IN PRIMATE BRAIN. J.E. Holden, B.D. Pate*, K.A. Hewitt*, W.R.W. Martin*, T.J. Ruth*, B.J. Snow*, and D.B. Calne*. UBC/TRIUMF PET Program, Vancouver, B.C. V6T 2A3, and Dept. of Medical Physics, U. of Wisconsin, Madison, WI 53705

Our previously reported graphical analysis of the kinetics of 6-fluoro-L-dopa (6FD) measured by dynamic PET (Martin et al., Ann. Neurol., 26:535-542, 1989) has been extended by fitting tissue time-course data to first-order kinetic models. A sequence of PET images was collected following bolus injection of 6FD into rhesus or cynomolgus monkeys, and time course data generated from both striatal and occipito-parietal cortical regions of interest. Plasma concentrations of 6FD and its chief circulating metabolite 3-O-methyl fluorodopa were determined at 25 time points during the 2 hour studies. The striatal and cortical time courses were fitted simultaneously, and the model parameters describing exchange of labeled compounds between tissue and plasma were assumed to be identical for both compounds and both anatomical regions. A third model parameter described the first-order irreversible trapping of striatal 6FD. Studies with cerebral decarboxylase inhibitors or elevated plasma amino acid demonstrated the ability of the model analysis to distinguish the transport and trapping processes. A model accounting for the slow loss of the trapped component was used to fit a preliminary series of 4 hour studies. The mean loss rate of 0.0034/min is consistent with literature values for striatal dopamine turnover rates.

332.4

BOLE OF ANESTHESIA, BOUTE OF ADMINISTRATION AND CHRONIC TREATMENT WITH NICOTINE (NIC) ON THE NIC-INDUCED RELEASE OF DOPAMINE (DA) FROM RAT STRIATUM (St) AND NUCLEUS ACCUMBENS (NA) USING MICRODIALYSIS. Thomas C. Westfall and Lillian E. Vickery, Dept. of Pharmacology, St. Louis Univ. School of Medicine, St. Louis, MO 63104.

We have previously observed that the administration of NIC into microdialysis cannulae of freely moving conscious rats causes a release of endogenous DA and ³H-DA newly synthesized from ³H-tyrosine in the striatum (St). The present studies were designed to examine the role of anesthesia as well as the route of administration (i.v. or microdialysis cannula) on the NICinduced release of DA, DA metabolites (DOPAC and HVA) and 5-hydroxyindole acetic acid (5HIAA) from two brain regions (St and NA) before and after chronic treatment of rats with NIC (1 mg/kg/day for 14 days). For studies on chloral hydrate anesthetized rats guide cannulae were implanted and microdialysis probes immediately introduced. For studies in conscious animals, rats were anesthetized with ketamine/acepromazine and a guide cannula stereotaxically implanted into the St or NA. The microdialysis probe was introduced into the guide cannula after 5-7 days. In both cases the microdialysis probe was perfused with Ringers solution (2 μ /min). Fractions were collected at 20 min intervals for analysis of DA and metabolites by HPLC-EC detection. NIC was administered i.v. (300 μ g/kg) or into the microdialysis cannula (1 mM) 120 min after the start of perfusion. Basal release of DA from St was greater in anesthetized rats while there was an attenuation in the NIC induced release in these rats compared to conscious freely moving anim Chronic treatment with NIC often resulted in an increase in basal levels of DA and a decrease in evoked DA release from both brain regions. Basal releas of DA was lower in the NA compared to St while there was generally a greater NIC-induced release of DA from NA compared to St. (Supported by DA 02668).

ENHANCEMENT OF SENSORY-EVOKED RESPONSES IN RAT LOCUS COERULEUS (LC) BY THE 5-HT2 AGONIST 1-(2,5-DIMETHOXY-4-IODOPHENYL)-2-AMINOPROPANE (DOI). \underline{C} Chiang, B. Shiekhattar, and G. Aston-Jones. Div. Behav. Neurobiol., Dept. Mental Health Sci., Hahnemann Univ., Philadelphia, PA 19102
Hallucinogens, acting at 5-HT2 receptors, decrease LC firing while

Mental Health Sci., Hahnemann Univ., Philadelphia, PA 19102
Hallucinogens, acting at 5-HT2 receptors, decrease LC firing while increasing these cells' response to sensory stimuli (Aghajanian, 1980). Here, we systematically examined the effects of 5-HT2 receptor activation on LC responses to noxious or non-noxious stimuli using systemic or local pressure application of the potent agonist, DOI.

In chloral hydrate-anesthetized rats, (±)DOI (50 μg/kg, i.v.) decreased LC spontaneous activity in all cells tested; it also markedly potentiated air puff-evoked responses in 7710 cells (p=0.001; mean onset = 44 msec). Moreover, at this dose systemic DOI enhanced LC activation by subcutaneous electrical stimulation of the contralateral footpad (FS; 15/16 cells, mean increase = 53%, p<0.001). This enhancement was primarily the result of the induction of a second, late component of the FS response (onset approx. 64 msec, duration approx. 48 msec; mean increase of second component = 547% following DOI; p<0.001). After DOI pretreatment, local infusion of the non-NMDA antagonist, CNOX (50 μM, 60 nl), into LC reliably attenuated the first FS response component more than the second component (mean decrease = 7.15% and 11.5%, respectively). Similar infusion of the NMDA antagonist, AP5 (50 μM, 120-180 nl), attenuated the second response component but not the first in the one cell tested. Local pressure microhipection of DOI (0.5 μM or 20 μM, 30-240 nl) directly into LC had no effect on either spontaneous discharge or FS response of 13/13 LC cells. These results 1) show that, as with other 5-HT2 response after systemic injection of DOI may be mediated by an input to LC indirectly. Supported by PHS grants NS24698 and DA06214.

GENERALIZED OCCURENCE OF IMMUNOREACTIVITY TOWARDS A PEC-60 ANTISERUM IN CATECHOLAMINE NEURONS OF THE RAT. K. Fuxe, A. B. Tinner*, D.J. Morassutti, W. Staines, L.F. Agnatí*, C.-G. Östensson, S. Efendic, B. Agerberth, M. Goldstein & V. Mutt. Dept of Histology and Neurobiology, Dept of Endocrin and Biochem, Karolinska Inst, Stockholm, Sweden; Dept of Human Physiol, Univ of Modena, Modena, Italy; Dept of Anatomy, Univ of Ottawa, Ottawa, Ontario, Canada, Neurochem Res Unit, NY Univ Med Center, NY, USA.

A peptide with a partial but distinct sequence homology to pancreatic secretory trypsin inhibitor (PSTI) has recently been isolated from the pig intestine and named PEC-60 (peptide with N terminal glutamic acid, C-terminal cysteine and a total of 60 residues). Using a standard formaldehyde picric acid fixation protocol it was possible to demonstrate immunoreactivity using a PEC-60 rebbit antiserum (2510) exclusively and within all central dopamine (DA), noradrenaline (NA) and adrenaline (A) neurons, (cell bodies, dendrites, axons, terminals) and within peripheral NAergic neurons and NA gland cells of the adrenal medulla using two colour immunofluorescence procedures. Absorption with PEC-60 but not PSTI (50 µg/ml) abolished the specific staining. Genetically modified TH-expressing cells failed to show IR against the PEC-60 antiserum and immunohistochemical controls run on Western blots showed that the high molecular weight PEC-60 immunoreactive protein was not a catecholamine synthetic enzyme. The IR, probably, is due to a peptide, or protein, with a fundamental role in CA transmission, since it is present in every single neuron of the CA nerve cell family.

COORDINATED REGULATION OF CATECHOLAMINE SYNTHESIZING ENZYMES IN THE CNS AND ADRENAL GLAND. T.H. Joh, D.M. Stone, K.T. Kim, D.H. Park, J.M. Carroll, C. Carver, H. Baker, K.S. Kim and T. Wessel.

Cornell Univ. Med. College, The Burke Rehab. Center, White Plains, NY 10605. Reserpine has been used extensively to study changes in catecholamine (CA) systems. The biosynthetic pathway consists of four enzymes: tyrosine hydroxylase (TH), aromatic L-amino acid decarboxylase (AADC), dopamine β -hydroxylase (DBH) and phenylethanolamine N-methyltransferase (PNMT). Previous biochemical studies demonstrated differences in the magnitude of changes in enzyme activity in response to reserpine in locus ceruleus (LC), adrenal gland (AG) and substantia nigra (SN). Recent studies have shown that the increase in TH activity can be attributed to increased gene transcription for this enzyme. In this investigation we combined immunohistochemistry, in situ hybridization and Northern blot analyses to investigate possible coordinate regulation of this pathway. Sprague-Dawley rats were treated with a single injection of reserpine (10 mg/kg SQ). Northern blots of AG mRNA 24h post injection showed clear increases in all four CA synthesizing enzymes: TH had the greatest up-regulation followed by PNMT and DBH while AADC showed a modest increase. In situ hybridization corroborated these results. Immunohistochemical staining at 96 h confirmed elevated protein. Similar results were obtained for the LC while the SN showed no changes. To investigate the role that the proto-oncogenes c-fos and c-jun may play in the regulation of the CA synthesizing enzymes, rats were reserpinized and perfused 1h post injection. In sinu hybridization with DNA probes for c-fos and c-jun resulted in strong hybridization signal in the adrenal medulla and in LC while no signal could be detected in the SN or in controls. This interesting correlation suggests that AP-1 consensus sites in the 5-upstream region of the TH gene and possibly the other CA synthesizing enzyme genes have functional significance in the living animal. Supported by MH 44043.

DOPAMINERGIC REGULATION OF TRANSCRIPTION FACTOR mRNAS IN

DOPAMINERGIC REGULATION OF TRANSCRIPTION FACTOR MENNAS IN STRIATAL NEURONS IN VIVO. A.J. Cole, P.F. Worley and J.M. Baraban. Depts. of Neurology, Neuroscience and Psychiatry, Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205.

Recent studies have shown that D₁-dopamine receptor agonists induce expression of the transcription regulatory factor (TF) protein c-Fos in deafferented rat striatal neurons (Robertson et al., Brain Res., (1989) 503:346-9). In light of receiving findings that TR mWNAs are differentially light of previous findings that TF mRNAs are differentially regulated by neuronal stimulation in vivo, we have examined the effect of amphetamine on mRNA levels of several proven or putative TF genes using <u>in situ</u> hybridization. Amphetamine (2.5-10 mg/kg i.p.) causes a rapid but transient dose-dependent increase in <u>zif/268</u> and <u>jun-B</u> mRNA levels in striatum and cortex. Striatal mRNA responses are blocked by pretreatment with the specific D_1 receptor antagonist SCH-23390 (0.2 mg/kg), but not by mianserin (1 mg/kg), a 5-HT receptor antagonist, suggesting that they are mediated by the dopamine releasing action of amphetamine. Paradoxically, several chemically distinct selective D_2 antagonists, eticlopride (0.lmg/kg), haloperidol or pimozide (lmg/kg) increase striatal mRNA levels for both of these TFs. Taken together, these results suggest that zif/268 and jun-B mRNA levels in the intact striatum are regulated by a complex interaction between D1-and D2-dopamine receptor subtypes.

STRESS INCREASES c-FOS EXPRESSION IN BOTH DOPAMINERGIC AND NON-DOPAMINERGIC NEURONS IN THE VENTRAL TEGMENTAL AREA. A. Y. Deutch 1, M. J. Jadarola², and M. Goldstein³ ¹Departments of Psychiatry and Pharmacology, Yale University School of Medicine, New Haven, CT, 06510; ²NIDR, Bethesda, MD, 20892; and ³New York University Medical School, NY, NY 10016.

We have previously reported that mild stress increases dopamine (DA) metabolism in the ventral tegmental area (VTA) but not substantia nigra (SN). We now report that stress increases expression of the proto-oncogene c-fos in both DA and non-DA VTA neurons, but not neurons of the SN.

Rats were subjected to 30 min restraint stress or 30 min restraint in the cold (4°C). Animals subjected to restraint stress had an increased number of DA and non-DA neurons in the VTA (but not SN) which exhibited c-fos-like immunoreactivity (li). Cold restraint further increased c-fos expression in both VTA cell populations but not in the SN. The increased number of VTA c-fos-li DA neurons was most marked in the central linear nucleus and DA neurons in the dorsal raphe, and less marked in the nucleus parabrachialis pigmentosus. Stress also increased the number of c-fos-li cells in pontine nuclei innervating the VTA. These data indicate that stress increases c-fos in VTA DA and non-DA neurons. The stress-induced activation of VTA DA neurons my involve activation of excitatory pontine afferents to the VTA, and may also involve local circuit interactions with non-dopaminergic VTA neurons

STRIATAL PATCH/MATRIX DISTRIBUTION OF FOS, SUBSTRIATAL PAND DYNORPHIN INDUCED BY APOMORPHINE IN INTACT AND 6-0HDA-LESIONED RATS. L.M. GRIMES, X. PING*, H.-K. JIANG*, AND J.-S. HONG. Bio Sci. Res. Cent., UNC-CH, Chapel Hill, NC 27599 and Lab. Mol. Int. Neurosci., NIEHS, RTP, NC 27709. To determine the codistributions of immunoreactivity for fos, dynorphin (DYN), substance P (SP), 28 kD calcium binding protein (CaBP), and tyrosine hydroxylase (TH) in striatum, rats were injected intracisternally as neonates with 6-0HDA or vehicle and as adults were treated with apomorphine (AP) (5mg/kg, 7 days, bid). Twenty-four hours later, rats were given a final injection of APO or saline and perfused with 4% paraformaldehyde plus 0.2% glutaraldehyde after 1.5 hr. Immunocytochemical stainwith 4% paraformaldehyde plus 0.2% glutaraldehyde after 1.5 hr. Immunocytochemical staining of 30 um Vibratome sections revealed that, in intact rats, fos, SP and DVN were restricted to striatal patches devoid of CaBP. In 6-OHDAlesioned rats, areas depleted of TH showed expression of fos, SP and DVN in both patch and matrix compartments. These studies suggest that lesions of the striatal dopamine (DA) system cause alterations in matrix neurons to allow DA agonist-induced expression of fos, SP, and DVN gene products. Colocalization studies and DYN gene products. Colocalization studies are in progress.

332.12

DEVELOPMENTAL REGULATION OF THE ADRENERGIC PHENOTYPE. D.L. Wong. S.A. White and C.L. Bildstein*. Dept. of Psychiatry and Behavioral Sciences, Starford University School of Medicine, Starford, CA 94305. Phenylethanolamine N-methyltransferase (PNMT), the final enzyme in epinephrine synthesis, is a marker of the adrenergic phenotype. In the rate details and the second inclined with the control of the second inclined with the control of the second inclined with the second inclined and the second inclined with the second inclined and the second inclined with the second inclined and the second inclined an

epinephine synthesis, is a marker of the adrenergic phenotype. In the rat adrenal gland, glucocorticoids regulate this enzyme and adrenergic expression in three ways. Initially, PNMT is steroid independent as it always appears on ~E17.5 irrespective of fetal steroid levels. Steroids subsequently become inductive, and can induce overexpression of PNMT. Finally, steroids become permissive, restoring PNMT to basal levels following depletion.

To determine the mechanisms for these various modes of steroidal regulation, we are examining a spectrum of PNMT indices, enzyme activity, protein and mRNA. From birth (P0) through P15, PNMT increases while adrenal weight changes insignificantly, consistent with adrenergic development. Up until ~P10, steroids are inductive. During this inductive phase, ACTH administration (1.I.U.) for 7 days, starting on P0 or P4, increases PNMT activity up to 35%. Similarly, conticosterone administration (10-100 mg) for 1 week elevates the enzyme up to 50%. Immunochemical data suggest for 1 week elevates the enzyme up to 50%. Immunochemical data suggest that steroid-induced protein may be structurally different as the equivalence that steroid-induced protein may be structurally different as the equivalence points and slopes of the immunotitration curves change. Between P10-12, glucocordicoids become permissive. PNMT activity cannot be hormonally elevated above basal levels. Hormones now regulate enzyme degradation. Hypophysectomy markedly depletes PNMT activity and protein. ACTH administration reverses these events. Simultaneously, PNMT mRNA changes insignificantly. Around P10, transsynaptic mechanisms become operant, which complement adult steroidal control of PNMT. Hormones, however, seem to be primary in adrenergic development. They appear critical to the expression and establishment of the adrenergic phenotype. Once the phenotype is established, steroids then subsume a permissive regulatory role working in conjunction with neural mechanisms to modulate adrenergic function.

THE DEVELOPMENT OF A RADIOIMMUNOASSAY AND AUTORADIOGRAPHIC DISTRIBUTION STUDIES WITH CI-977, A NOVEL ANALGESIC KAPPA OPIOID RECEPTOR ACONIST. C.M. Barksdale, W.P. McNally, G.D. Nordblom*, M.J. Coon*, P.D. DeHart*, T. Chang*, and D.S. Wright*. Pharmacokinetics/Drug Metabolism Department Parke-Davis Pharmaceutical Research Division, Warner-Lambert Company, Ann Arbor, Michigan 48105-2430.

CI-977, a novel kappa opioid receptor agonist currently undergoing clinical evaluation in humans, has high in vitro affinity for the κ opioid receptor in guinea-pig forebrain preparations: the Kd for the κ receptor is 0.11 \pm 0.02 nM, while the Kd is 99.6 \pm 4.3 nM for the μ receptor and 1036 \pm 77 nM for the δ receptor. This results in a μ/κ selectivity ratio of 905 and a δ/κ selectivity ratio of 9418. We now report the development of a radioimmunoassay procedure for CI-977 and the autoradiographic distribution of $[^{7}{\rm H}]$ -CI-977 in rats. Male rats given 40 $\mu{\rm g/kg}$ of $[^{3}{\rm H}]$ -CI-977 (31 $\mu{\rm Ci/\mu g})$ by

Male rats given 40 µg/kg of [H]-CI-977 (31 µCi/µg) by IM injection were sacrificed at intervals from 10 minutes to 24 hours for whole body autoradiography. Autoradiograms showed activity widely distributed to tissues following IM dose, with highest levels seen in kidney, lung, spleen, salivaries, and liver at early time points. Activity was evenly distributed to areas of gray matter in brain and spinal cord, with higher concentrations in the choriod plexus, pituitary, cortex and hippocampal CA3 regions, previously reported to have significantly elevated kappa opioid receptor concentrations.

333.3

PHARMACOLOGICAL CHARACTERIZATION OF NALORPHINE, A KAPPA3 ANALGESIC. D. Paul. C.G. Pick. L.A. Tive and G.W. Pasternak. The Cotzias Lab. of Neuro-Oncology, Memorial Sloan-Kettering Cancer Center and Depts. of Neurology and Neuroscience and Pharmacology Cornell Univ. Medical College, New York NY 10021.

The observation that nalorphine antagonizes morphine analgesia, but itself produces analgesia led to the theory of Receptor Dualism and multiple opioid receptor types. Nalorphine binds with nanomolar affinity to the novel kappa3 opioid receptor, as well as mu and kappa1 receptors. We have now identified the receptor type that mediates nalorphine analgesia in the mouse tail-filick assay. Low nalorphine doses antagonized morphine analgesia, but at higher doses produced analgesia, replicating the original studies in man. Although it was blocked by naloxone, nalorphine analgesia was insensitive to the mu antagonist &-funaltrexamine, the delta antagonist naltrindole, and the kappa1 antagonist nor-binaltorphimine. Nalorphine was cross-tolerant with the kappa3 agonist, naloxone benzoylhydrazone (NalBzoH), but not with the kappa1 agonist, U50,488-H. In addition, nalorphine analgesia was 1000-fold more sensitive to antagonism by i.c.v. than i.t. administration of the opiate antagonist, WIN44,441, a pattern also seen with NalBzoH. These results support the conclusion that nalorphine produces its analgesic effect through supraspinal kappa3 receptors.

333.5

AUTORADIOGRAPHIC DISTRIBUTION OF [³H](+)-PENTAZOCINE BINDING SITES IN GUINEA PIG BRAIN J.M.Walker, W.D.Bowen, A.H. Roberts, B.deCosta, and K.C.Rice, Brown University, Providence, RI 02912 and National Institutes of Health, Bethesda, MD 20892

There has been a need for a selective (+)-opiate sigma ligand because evidence suggests differential binding of opiate and nonopiate-related sigma compounds. We now describe the autoradiographic distribution of specific binding of the selective sigma ligand $[^3H](+)$ -pentazocine in guinea pig brain.

in guinea pig brain.

Alternate sections were incubated with either [\$^3\text{H}\$](+)-pentazocine or [\$^3\text{H}\$]-DTG. Blanks were determined with 10 \$\mu M\$ haloperidol. After 8-11 week exposure, autoradiographs were quantified using a computer. Specific binding of 85% of the total occurred for both radioligands.

[\$^3\text{H}\$]-(+)-Pentazocine binding is concentrated sigma-rich areas including cingulate cortex, septum, ventromedial

 $[^3\mathrm{H}]$ -(+)-Pentazocine binding is concentrated sigma-rich areas including cingulate cortex, septum, ventromedial hypothalamus, periaqueductal gray, red nucleus, cerebellum and various cranial nerve nuclei. Binding was low in the caudate-putamen, ventral posterior nucleus of the thalamus, and most cortical areas. $[^3\mathrm{H}]$ (+)-Pentazocine binding across brain areas correlated highly with the amount of $[^3\mathrm{H}]$ (+)-DTG bound (r=0.88, p<0.0001), suggesting that it binds to sigma receptors. However, the ratios of the binding of the two ligands ranged from 0.8 to 3.4, suggesting that different populations of sites may be labelled by these two ligands.

333.2

CHARACTERISTICS AND DISTRIBUTION OF CENTRAL KAPPA OPIOID RECEPTORS IN A SONGBIRD SPECIES (dark-eyed junco, Junco hyemalis). P. Deviche. Inst. Arctic Biology, Univ. Alaska Fairbanks, Fairbanks, AK 99775-0180.

The characteristics of the binding of ³H-ethylketocyclazocine

The characteristics of the binding of 3H -ethylketocyclazocine (3H -EKC) to whole brain homogenates obtained from juncos were studied to identify and to characterize the central κ opioid receptors of this species. In the presence of DAGO and DPDPE (100 nM), 3H -EKC binds to brain homogenates specifically, in a time-related fashion, and with a high affinity (Kd: 1.3 nM). Specific 3H -EKC binding sites are present at a low concentration (Bmax: 35 fmoles/mg protein). Unlabelled ligands that have a high selective affinity either for μ or for δ opioid receptors have a low affinity for 3H -EKC binding sites (IC ${}^50 \ge {}^3\mu$ M). Using in vitro autoradiography, we found that κ receptors are present at the highest density in the forebrain (olfactory bulb, ventral neostriatum, hyperstriatum), and at a lower density in mid- and hindbrain regions. They are virtually absent from the cerebellum. These results will be compared with those obtained for mammals and for domestic pigeons, the only other avian species in which the brain distribution of κ receptors has been determined so far.

333.4

QUANTITATIVE AUTORADIOGRAPHY OF OPIOID RECEPTORS IN BRAINS OF SUICIDE VICTIMS. A. Biegon and R. Gross-Isserof*. Dept. Neurobiol., Weizmann Inst. of Science, Rehovot, Israel.

Indirect behavioral and pharmacological data suggest the involvement of opioids in the pathophysiology of depression, but there are no direct studies of human brain opioid systems in this context. We have examined μ and δ opioid receptors in the brains of 12 suicide victims and 12 age and sex matched controls postmortem, using quantitative in vitro autoradiography. Drug- and neuropathology-free brains were frozen and sectioned in a whole body cryostat. μ and δ receptors were labeled with $^3\text{H-DAGO}$ and $^3\text{H-DPDPE}$. Non specific binding was measured in the presence of naloxone. Computerized image analysis of the autoradiograms revealed large, statistically significant increases in μ receptor binding in several cortical regions of the suicide victims, especially temporal gyri. δ receptor binding was significantly reduced in the same brains, with the most pronounced differences in prefrontal cortical regions. These data suggest endogenous opioid systems play a role in depression and suicide via different recentor subtypes in specific brain regions.

333.6

SIGMA RECEPTORS IN IMMUNE AND ENDOCRINE TISSUES: DICHOTOMY BETWEEN BINDING AND FUNCTION. S.A. Wolfe. Jr., L.G. Aguayo and E.B. De Souza. Neurobiology Laboratory, NIDA ARC, Baltimore, MD 21224, and Section of Electrophysiology, Laboratory of Physiologic and Pharmacologic Studies, NIAAA, Rockville, MD 20852.

PCP and the prototypic o agonist N-allylnormetazocine (NANM) alter neuroendocrine and immune functions. We have previously described high densities of σ receptors (and the absence of PCP receptors) in human peripheral blood leukocytes and rat spleen, pituitary, adrenal, testis, ovary, and pineal. Since the pineal gland modulates CNS, endocrine and immune functions, we carried out electrophysiological studies to determine whether o receptors are physiologically active in the rat pineal. In addition, we examined the functional nature of σ binding sites in the immune system. In whole-cell patch clamp recordings, PCP suppressed the delayed voltageactivated K+ outward current in acutely dissociated rat pineal cells. The o ligands butaclamol and 3-PPP were more potent than PCP in this regard. However, these electrophysiological studies failed to show the stereoselectivity for enantiomers of butaclamol and 3-PPP which is characteristic of $\boldsymbol{\sigma}$ receptors in binding and autoradiographic systems. In the immune system, PCP and other σ ligands suppressed in vitro functional immune responses, but the pharmacological profile of immunosuppression was unlike that of σ receptors in binding assays. Recent data from several laboratories support the existence of multiple binding sites for σ ligands. Therefore the findings of the present study suggest that, although σ receptors appear to be present in high densities in pineal and immune cells, other receptor types in these cells may modulate the measured biological responses to σ ligands.

HETEROLOGOUS DOWN-REGULATION OF CHOLINERGIC RECEPTORS BY SIGMA RECEPTOR ACTIVATION. W.D. Bowen and P.J. Tolentino. Sect. Biochem., Div. Biol. and Med., Brown Univ., P.J. Tolentino. Sect Providence, RI 02912

We have previously shown that sigma ligands attenuate the ability of carbachol and oxotremorine-M (Oxo-M) to stimulate phosphoinositide carbachol and oxotremorine-M (Oxo-M) to stimulate phosphoinositide (PPI) turnover in rat brain synaptoneurosomes (Bowen et al. Eur. J. Pharmacol. 149:399; Bowen et al, NIDA Research Monograph Series, in press). The inhibitory potency correlated highly to sigma receptor binding affinity (r e 0.92; with oxotremorine-M as agonist). The major effect of sigma ligands is to reduce the maximal stimulation, without markedly affecting the EDSO of the cholinergic agonist.

We have investigated the effect of sigma ligands on cholinergic receptors. Pretreatment of membrane fragments with 50 uM (+)-pentazocine in Krebs-Henseleit/Hepes buffer had no effect on the binding of [3H]Oxo-M (assayed in same buffer). However, pretreatment of intact

(assayed in same buffer). However, pretreatment of intact synaptoneurosomes with (+)-pentazocine resulted in a marked decrease in the number of [3H]Oxo-M binding sites, with no effect on the binding affinity. (+)-Pentazocine pretreatment had no effect on the binding affinity. (+)-Pentazocine pretreatment had no effect on the binding parameters of the membrane permeant cholinergic ligand, [3H]QNB. These data suggest sigma-induced internalization of cholinergic receptors. In addition, when intact synaptoneurosomes were pretreated with (+)-pentazocine and then lysed in hypotonic buffer prior to Scatchard analysis of [3H]Oxo-M binding, an increase in Kd was observed, with no change in Bmax. The difference in results obtained when intracellular receptors are accessed with [3H]QNB (antagonist) and [3H]Oxo-M (agonist) may suggest that sigma activation also produces uncoupling of cholinergic receptors from G-proteins. Thus, sigma ligands appear to inhibit the cholinergic PPI response by heterologous desensitization. (Supported by PHS Grant NS-26746)

333.9

AUTORADIOGRAPHY OF 1251-B-ENDORPHIN BOUND TO

AUTORADIOGRAPHY OF ¹²⁵1-B-ENDORPHIN BOUND TO OPIOID AND NON-OPIOID SITES IN TISSUE CULTURE. R.I. CONE, J. LAMEH* AND W. SADEE*. Dept. Pharmacy & Pharmaceutical Chemistry, UCSF, San Francisco, CA 994143-0446. Detection of opioid binding sites on intact cells in culture is useful in monitoring the regulation of surface receptor affinity and density in human neuroblastoma cells, and in screening cDNA libraries for expression of genes encoding intact receptors following transfection in mammalian target cells. The presence of both μ and ∂ opioid receptors in the human neuroblastoma cell line, SK-N-SH, and its neuroblast subclone. SH-SY5Y have been demonstrated in this laboratory, and subclone, SH-SY5Y have been demonstrated in this laboratory, and opioid receptor regulation in SH-SY5Y cells has been studied.

We have developed an autoradiographic method using 1251-β-endorphin (β-E) for studying opioid receptor internalization in human neuroblastoma cell lines, and for screening a pCDM8 cDNA expression cloning library from SK-N-SH-SY5Y cells, complexity 2 x 107, after transfection into COS-7 cells for opioid expression.

Our results indicate that a large portion of β -E binding in SK-N-SH, NG108-15 and COS-7 Cells is non-opioid. However, in the presence of blocking concentrations of β -E (6-31), a fragment with intact c-terminus which binds only to non-opioid sites, 125I- β -E specifically labels μ and

The K_d of β -E binding to μ and ∂ opioid sites on intact neuroblastoma cells is between 0.2 to 1 µM, thereby allowing for sensitive detection of opioid receptors, either by filtration or by autoradiography. The ability of the tracer to cross the cell membrane or to internalize with the receptor will be investigated. Supported by NIDA grant DA 04166.

SIGMA (SR) AND OPIOID RECEPTORS (OR) IN HUMAN CANCERS. C.J. Coscia, W.T. Bem*, G.E. Thomas*, J.Y. Mamone*, B.K. Levy*, M. Szücs* and F.E. Johnson. St. Louis University

School of Medicine, St. Louis MO 63104

SR and OR interact with cell signalling pathways which contain proto-oncogene products and regulate cell proliferation. OR modulate growth of developing brain and been based on binding assays using $(\pm)^3H$ -ethylketocyclarocine (EKC). Since (\pm) EKC can bind to SR, we investigated SR and OR distribution in diverse tumors. Fresh specimens SR and OR distribution in diverse tumors. Fresh specimens were obtained from 28 human neoplasms (19 brain tumors and 9 others) and 7 normal tissues. Binding parameters were determined by homologous displacement assays using $^3H\text{-}1,3\text{-}$ di- $\varrho\text{-}\text{tolylguanidine}$ for SR and either $^3H\text{-}U\text{-}69,593$ or (-) $^3H\text{-}\text{EKC}$ with unlabeled μ and δ suppressors for OR. Data were analyzed with the LIGAND program. SR were detected in OR (κ) were found only in gliomas (4/4). OR were detected in desipramine-treated C6 rat glioma and 2 human glioma cell lines, but not in human neuroblastoma line SK-N-MC (which express SR). Bmax values for SR in renal, colorectal and meningeal tumors were greater than that of corresponding normal tissues. Intra-tumoral variability (ITV) in SR was compared with ITV in histology (assessed by computerized quantitative morphometry). was modest for SR Bmax values but marked for histologic parameters. On the basis of these and previous studies, SR and OR differ in stereochemistry, subcellular distribution, and pattern of expression in tumors.

333.10

THE BIOSYNTHESIS OF MAMMALIAN MORPHINE: THE ROLE OF THE BIOSYNTHESIS OF MAMMALIAN MORPHINE: THE HOLE OF ENZYMATIC O- METHYLATION OF (R)- AND (S)-ENANTIOMERS OF NORCOCLAURINE, AND 3-DEMETHYLNORRETICULINE IN THE FORMATION OF (S)-RETICULINE. C. R. CREVELING, M. E. BELL*, Y. SEKINE, D. TADIC, AND A. BROSSI, Labs. of Bioorganic and Analytical Chemistry, NIDDK, NIH, Bethesda, MD 20892.

Small amounts of the opioid alkaloids, morphine and codeine have been indentified in mammalian brain, adrenal glands, and skin, both as free alkaloids and as sulfate conjugates. The non-morphinan, reticuline, is converted in rat liver to the morphinan, salutaridine. The administration of salutaridine, thebaine, or codeine to rat results in increased levels of morphine in brain, liver, and intestine. These observations strongly suggest an endogenous biosynthetic rather than a dietary origin for mamma morphine. Zenk et al. (1985) clearly demonstrated that in poppy plant, (S)-norcoclaurine, derived from an enzymatic and stereospecific condensation of dopamine with (4-hydroxyphenyl) acetaldehyde, is the first isoquinoline in the biosynthesis of the critical intermediate, reticuline. We have examined the O-methylation, catalyzed by mammalian catechol-O-methyltransferase, of the (S)- and (R)-enantiomers of norcoclaurine and demethylnorrecticuline. In both cases, the O-methylation was stereoselective, affording almost exclusively the 6-O-methylethers from the (S)-enantiomers, an obligatory pathway for the biosynthesis of (S)-reticuline. When the (R)-enantiomers were substrates the 7-O-methylethers were the major products. These results suggest that the putative pathway for the mammalian biosynthesis of

(S)-reticuline may be identical to the pathway in poppy plants. Zenk, M. H., Rueffer, M., Amann, M., Deus-Neumann, B., Nakagura, N. J. Natural Products, 48, 725.

CELLULAR AND MOLECULAR STUDIES II

334.1

VITAL DYE ANALYSIS AND CONFOCAL IMAGING OF CRANIAL NEURAL CREST CELLS IN MICE. George N. Serbedzija, Scott E. Fraser and Marianne Bronner-Fraser. Developmental Biology Center, U.C. Irvine. Ca. 92717.

Analysis of cranial neural crest cell migration and differentiation in the mouse has been hampered by both the lack of a reliable cell marker and by the difficulty of manipulating the embryo in vivo at the stage of neural crest development. We recently have demonstrated that mouse truncal neural crest cells could be labelled successfully using the vital dye, Dil (Serbedzija, et al., 1990 Develop. 108:605-612). Here we have a this approach in combination with an experiment rechains the chains and the second of the combination with a complex to the combination of the combination with a combination with the differential at the property of the p 239:239-295) to describe crantal neural crest cen imgration painways and sites of differentiation. On the eighth day of pregnancy, 1-4 somite stage embryos were exposed in the uterus and labeled with Dil. The mothers were then closed, and the embryos allowed to develop for an additional 24-48 hours. Embryos were analyzed both in whole mount using a confocal microscope and in serial sections using an epifluorescence microscope. After 24 hours, metameric streams of labeled cells were observed extending from the neural tube into the developing branchial arches, and single labeled cells could be seen at the levels of the forebrain and midbrain regions. After 48 hours, labeled cells also appeared in the cranio-facial ganglia, in the heart, and throughout the head (e.g. in the maxillary process, and around the eye and the olfactory pit). These results demonstrate the feasibility of using the exo utero technique to perform an in situ study of the timing and pattern of murine cranial neural crest migration and differentiation. DEVELOPMENT OF PERISYNAPTIC CELLS IN SKELETAL MUSCLES OF TRANSGENIC MICE. J. Weis. S. Fine*, and J. R. Sanes, Dept. Anat. & Neurobiol., Washington Univ. Sch. Med., St. Louis, MO 63110. The adhesion molecules tenascin, N-CAM, and fibronectin accumulate

The adhesion molecules tenascin, N-CAM, and fibronectin accumulate near motor endplates in denervated skeletal muscle. Fibroblasts near synaptic sites selectively proliferate after denervation and are likely to be the cellular source of these molecules (Gatchalian et al., <u>I. Cell Biol.</u>, 108, 1873-1890, 1989). This biosynthetic specialization could reflect distinct features of the perisynaptic environment that arise upon denervation and/or intrinsic differences between perisynaptic and extrasynaptic fibroblasts. We now report results that favor the latter possibility.

DNA constructs containing 2 kilobases of the MHC class I gene promoter, the coding portion of the E. coli B-galactosidase gene (lacZ), and a 3' splicing and polyadenylation signal from SV40 were microinjected into the pronuclei of mouse embryos. Transgenic animals were identified by Southern blot analysis and PCR, and lacZ expression was detected histochemically. Surprisingly, the MHC promoter appeared inactive in this context and the transgene was apparently controlled by genomic regulatory elements near the integration site. Due to this control, the transgene was expressed in a distinct subset of cells in each line.

In one of nine mouse lines produced, cells close to neuromuscular

expressed in a distinct subset of cells in each line.

In one of nine mouse lines produced, cells close to neuromuscular junctions were lacZ-positive, whereas cells in extrasynaptic portions of muscle did not stain. Expression of lacZ was strong at birth and disappeared by 3 weeks postnatally. Electron microscopy revealed that some of the perisynaptic cells that expressed the transgene were fibroblasts. Other cells near synapses were also lacZ-positive; these may include Schwann, endothelial, and perineurial cells. However, no intramuscular cells (fibroblasts or others) located far from synaptic sites were lacZ-positive. These results support the notion that "perisynaptic" fibroblasts differ in their genetic program from "extrasynaptic" fibroblasts in muscle. MIGRATION OF CLONALLY RELATED CELLS IN THE DEVELOPING CHICK SPINAL CORD. S.M. Leber and J.R. Sanes. Dept. Anatomy & Neurobiology and Pediatrics, Washington University School of Medicine, St. Louis, MO 63110.

To study the lineage and migration of chick spinal motoneurons, we infect progenitors with a β-galactosidase-bearing retrovirus, then identify their progeny histochemically. We previously found that individual progenitors are pluripotent with respect to phenotype but that their progeny are restricted spatially along both the rostrocaudal (RC) and dorsoventral (DV) axes (Leber et al., J. Neurosci., in press). Here, we ask how this restricted distribution arises. First, we analyzed cell mixing in the ventricular zone (VZ). Some clones labeled at st. 8 spanned the entire DV extent of the VZ and up to 1½ segments along the RC axis. However, clones labeled at st. 12-14 were restricted to <½ segment length and to narrow DV sectors. These results imply that displacement of cells within the VZ becomes restricted between st. 8 and 12-14. Second, we studied the migration of cells out of the VZ by infecting embryos at st. 12-14 and varying the time of analysis. At st. 20-21, most clones consisted of radial arrays of cells, suggesting that the 20-21, most clones consisted of radial arrays of cells, suggesting that the initial migration is predominantly radial. However, by st. 25, neurons initial migration is predominantly radial. However, by st. 25, neurons in many clones turned orthogonally from their parent radial arrays and migrated along circumferentially oriented axons. By stage 34, clonally related cells were usually distributed in narrow transverse slabs in single quadrants of the spinal cord. Between st. 30 and 38, some white matter glia migrated up to several segments along longitudinal axons. We conclude that the distribution of clonally related cells results from: 1) limited mixing within the VZ that confines clonal relatives to the same RC position and, often, to either the alar or basal plate; 2) migration of cells from the VZ in spoke-like radial routes; 3) a secondary neuronal migration along circumferential axons; and 4) a late longitudinal migration of glia along white matter tracts.

DEVELOPING CHAT-IMMUNOREACTIVE SPINAL CORD NEURONS MAY USE COMMISSURAL FIBERS AS MIGRATORY GUIDES. P. E. Phelps and J. E. Vaughn. Division of Neurosciences, Beckman Research Institute of the City of Hope,

Duarte, CA 91010.

A "U"-shaped group of ChAT-immunoreactive (ChAT-IR) neurons was detected initially on embryonic day 16 (E16) directly adjacent to the <u>ventral</u> ventricular zone in rat cervical spinal cord. Since no cholinergic cells are observed dorsally at this or previous stages, we have hypothesized that the ChAT-IR neurons located in the dorsal and central spinal cord at later developmental times, and in adults, are derived from this E16 group of neurons (Phelps et al., ICN, 291:9, 1990). Closely spaced transitional stages suggest that some of these primitive cholinergic neurons that display short processes oriented dorsal-ventrally may follow the commissural pathway to reach their more dorsallylocated, final positions. This pathway is formed by the early developing located, final positions. This pathway is formed by the early developing axons of commissural neurons that transiently express the cell surface glycoprotein TAG-1 (Yamamoto et al., *INeurosci.*, 6:3576, 1986; Dodd et al., *Neuron*, 1:105, 1988). The coincidence of the distribution patterns of both the "U"-shaped group of ChAT-IR cells and the TAG-1-IR commissural fibers suggests the possibility that cholinergic cells could utilize such fibers as migratory guides. In addition, double-labeled immunocytochemical experiments provide preliminary evidence that some of these ChAT-IR neurons are associated with TAG-1-IR commissural fibers during the embryonic period (E16-17) when we propose that these neurons migrate from the ventral ventricular zone to their adult positions. *Supported by NIH grant NS 18858*.

PRENATAL ASSEMBLY OF STRIATAL COMPARTMENTS IN THE MOUSE. M.A. Edwards and C.R. Gerfen. Developmental Neurobiology Dept., Shriver Center, Waltham, MA 02554, and Laboratory of Cell Biology, NIMH, Bethesda, MD 20892.

Previous studies have suggested that the patch-matrix organization of the rodent striatum emerges in the perinatal period. In the present study, the fetal development of striatal modules was studied using [3H]thymidine autoradiography and immunocytochemistry with monoclonal antibody RC2, which stains radial glia and immature astrocytes, and with an antibody to calbindin, known to stain predominantly neurons of the matrix zone. Results from variable survival periods after maternal [3H]thymidine exposure indicate that patch neurons arise largely between embryonic days E11 to E13 and initially become distributed uniformly to the striatal intermediate zone by E15. This distribution changes subsequently as laterborn cells labelled on E14 and E15 migrate out to attain a matrix-like distribution between E17 and P0. Correspondingly, results with calbindin staining indicate that the neurons which express it become distributed in a matrix pattern in the period between E17 and E18. In the transition period between E14 and E17, RC2 staining reveals that radial glial fibers in the striatum changes from a uniform distribution into a pattern characterized by streams interposed by zones containing immature astroctyes. Sections double-labelled with RC2 immunostaining and autoradiography or with RC2 and anti-calbindin staining suggest that migratory columns of matrix neurons follow radial glial streams but earlier-born, patch neurons occupy the zones where immature astrocytes accumulate. These results suggest that radial glia organization may contribute to the migration of matrix neurons into zones which break up the initially uniform field of patch neurons. (Supported by HD21018).

VISUAL CALLOSAL DEVELOPMENT IN NEONATAL RATS: DO MIGRATING OR UNDIFFERENTIATED CELLS HAVE AN INTERHEMISPHERIC AXON? C.S. Hernit. R.C. Van Sluyters, and K.M. Murphy, Dept. of Molecular and Cell Biology and School of Optometry, Univ. of California, Berkeley, CA 94720, Dept. of Psychology, McGill University, Montreal, Canada H3A 1B1.

At birth (PND1) lamination in the visual cortex of the rat is incomplete. Neurons destined for layers II-III are undifferentiated and complete. Neurons destined for layers II-III are undifferentiated and either still en route or newly arrived at the immature cortical plate! In order to determine whether these cells have a callosal projection, the posterior neocortex of animals aged PND1 was injected with either Rhodamine Conjugated Latex Microspheres (RLM), Fast Blue (FB) or Fluorogold (FG). The radial positions of callosally labelled cells were examined on PND12, an age at which cortical lamination is complete.

In mature brains callosal cells are found in layers II-VI. Cells callosally labelled with RLM on PND1 were found only in lower layer IV and layers V-VI. A similar distribution of callosal cells was intensely labelled with FB and FG. Cells faintly labelled with FB were also labelled with FB and FG. Cells faintly labelled with FB were also found throughout cortical layers II-III and IV, as well as in the lateral geniculate nucleus contralateral to the injection. This faint labelling was likely due to leakage of FB from callosally labeled cortical cells. Some cells faintly labelled with FG were also visible in a region extending into lower layer II-III, and evidence indicates that they too were secondarily-labelled. The absence of supragranular cells intensely labelled with RLM, FB or FG suggests that at birth migrating or undifferentiated layer II-III cells do not possess a callosal axon.

LATERAL MIGRATION OF CELLS IN EMBRYONIC NEOCORTEX. S. A. Bayer, J. Altman, and R. Russo*. Dept. of Biology, Indiana-Purdue Univ. Indianapolis, IN 46205.

The embryonic (E) neocortex in rat brains from days E15 through E21 were three dimensionally reconstructed with a computer software package (SKANDHA, Univ. of Wash., Seattle). A prominent medial shift in the neocortical germinal matrix indicated that cells destined for the germinal matrix indicated that cells destined for the superficial layers (IV-II) in lateral cortical areas are generated in a medial position. Correlated [³H]thymidine autoradiographic studies tracking the migratory pathways of young neurons indicated a "lateral migratory stream" in the intermediate zone. In addition, medial vs. lateral cortical cells have differential times of arrival in the cortical plate: dorsal cells are there in two days, lateral cells in three days, and ventrolateral cells in four days. TUMOR NECROSIS FACTOR (TNF) SELECTIVELY INHIBITS MITOSIS OF CULTURED BRAIN NEUROBLASTS. L.E. Chen. E. DiCicco-Bloom, and I. B. Black, Div. Dev. Neurol., Cornell Univ. Med. Coll., NY, NY 10021, and Dept. Neurosci. and Cell Biol. UMDNJ-Robert Wood Johnson Med. Sch., Piscataway, NJ.

Neurosci. and Cell Biol. UMDNJ-Robert Wood Johnson Med. Sch., Piscataway, NJ.
During brain development, proliferation of neuronal precursors is highly
reproducible spatially and temporally, suggesting precise regulation. Little is
known, however, about mechanisms governing neuroblast mitosis. Previous studies
in this lab have demonstrated that traditional growth factors as well as
neurotransmitters stimulate neuroblast mitosis. We now report that TNF selectively

neurotransmitters stimulate neuroblast mitosis. We now report that TNF selectively and specifically inhibited the mitotic cycle of cultured brain neuroblasts.

A highly enriched population of granule neurons and dividing precursors derived from 7 day rat cerebella was cultured in fully defined medium, and assayed for mitotic activity, neurite outgrowth and cell survival. Exposure to recombinant murine TNF (rMuTNF) evoked a 40% decrease in 3H-thymidine incorporation. In contrast, TNF did not affect survival, neurite outgrowth or protein synthesis, indicating that TNF selectively inhibited DNA synthesis. Moreover, inhibition reflected a decreased proportion of neuroblasts entering the mitotic cycle in culture and not simply diminished incorporation by a pre-existing mitotic population.

To define specificity, we examined a number of closely related cytokines. Although recombinant human TNF and lymphotoxin had similar effects on DNA synthesis, ED₅₀s were 10-fold higher than that of rMuTNF, consistent with previously defined species specificity. In contrast, interleukin-6 had no effect, suggesting that TNF is a highly specific inhibitor of neuroblast mitosis.

previously defined species specificity. In contrast, interieuxin-o had no effect, suggesting that TNF is a highly specific inhibitor of neuroblast mitosis.

To characterize cellular specificity, the effect of TNF on cultured sympathetic neuroblasts was examined. TNF had no effect on DNA synthesis of sympathetic neuroblasts, suggesting that TNF may serve to regulate mitosis of

specific populations of neuronal precursors.

In sum, TNF specifically inhibited neuroblast mitosis. Combined with previous evidence of mitogenic <u>stimulation</u> by growth factors and neurotransmitter, our observations suggest that both positive and negative epigenetic signals regulate neuroblast proliferation.

EGF AND FGF REGULATE MITOSIS OF CULTURED CEREBELLAR GRANULE CELL PRECURSORS. R.N. Cohen, E. DiCicco-Bloom, and I.B. Black. Div. of Developmental Neurology, Cornell Univ. Med. Coll. NY, NY 10021 and Dept. Neurosci. and Cell Biol., UMDNJ/ Robert Wood Johnson Medical School, Piscataway, NJ

Neurogenesis proceeds through a well-delineated sequence of events, yet underlying regulation remains undefined. Recent studies of the peripheral nervous system indicate that epigenetic signals regulate neuroblast mitosis. In contrast, numerous technical and theoretical constraints have impeded study of central neuroblasts. To overcome these limitations, we developed a fully-defined neuronal culture system in which central precursors undergo division. We found that physiologic concentrations of insulin promote cell survival, whereas insulin-like growth factor-I (IGF-I) additionally stimulates mitosis. We now report that both epidermal (EGF) and fibroblast (FGF) growth factors regulate DNA synthesis of central neuroblasts, but that multiple other factors are ineffective.

A highly enriched population of granule cells and precursors was obtained from postnatal day 7 rat cerebella (Hatten, J. Cell Biol., 1985); cells were cultured in fully-defined medium. To define potential growth factors for granule precursors, cells were cultured under varying conditions and were assayed for [3H]thymidine ([3H]dT) incorporation (Inc.) and survival. EGF increased Inc. 3-fold, with an EG50 of 1 ng/ml. To define the cellular basis for increased Inc., the proportion of cells that synthesized DNA (the "labeling index") was assessed by [3H]dT autoradiography. A suprasaturating dose of EGF (100 ng/ml) increased the labeling index 50%. This concentration, however, did not promote survival, suggesting that EGF specifically functioned as a mitogen. In contrast, bFGF increased both Inc. and survival (EC50 = 1 ng/ml), thereby exhibiting both trophic and mitogenic activity. The mitogenic effects appear to be highly specific. Both NGF and TGF-B, which appear to regulate nervous system development, failed to stimulate Inc. Furthermore, depolarization, a mitogenic signal for peripheral neuroblasts, did not stimulate DNA synthesis of granule precursors. In sum, mechanisms regulating proliferation of central neuroblasts are apparently distinct from those operating in the periphery.

A METALLOPROTEASE SECRETED BY SCHWANN CELLS CLEAVES FIBRONECTIN INTO FRAGMENTS THAT INHIBIT PROLIFERATION. D. Muir. S. Varon and M. Manthorpe. Dept. of Biology, University of California at San Diego, La Jolla, CA 92093.
Rat sciatic nerve Schwann cell conditioned medium contains protein that inhibits the proliferation of mitogen-stimulated Schwann cell

Rat sciatic nerve Schwann cell conditioned medium contains protein that inhibits the proliferation of mitogen-stimulated Schwann cell cultures. This antiproliferative protein can exist in 55 kD and >1000 kD forms and the 55 kD form can be dissociated from the >1000 kD form. During fractionation of the conditioned medium, a protease activity was found to copurify with the antiproliferative activity. In zymographic gels the purified 55 kD protease degraded gelatin and casein and was inhibited by EDTA and phenanthroline, indicating that it is a metalloprotease. When the 55 kD metalloprotease was tested for an ability to degrade rat laminin, fibronectin and native collagens only a limited proteolysis of fibronectin was observed. The resulting fibronectin fragments were separated by heparin-affinity chromatography and tested for the ability to affect Schwann cell proliferation. Results showed that a heparin-binding fraction (containing several fibronectin fragments with Mr=120-160 kD) possessed potent antiproliferative activity for mitogen-stimulated Schwann cells. Similar antiproliferative heparin-binding fibronectin fragments were found in serum-containing Schwann cell conditioned medium. These findings suggest that autocrine regulation of Schwann cell proliferation might involve an activation of fibronectin resulting from proteolysis by a secreted metalloprotease. CELL KINETICS IN THE SUBEPENDYMAL LAYER OF THE MOUSE BRAIN N. B. Manley, E. H. Lo, K. A. Frankel', M. H. Phillips' and J. I. Fabrikant', Research Medicine and Radiation Biophysics, Lawrence Berkeley Laboratory, Berkeley, CA 94720.

The subependymal layer of the mouse brain is an actively prolif-

The subependymal layer of the mouse brain is an actively proliferating cell population with morphologically distinct subpopulations. Pulse labelling techniques with DNA precursors combined with high-resolution autoradiography demonstrate consistent regional differences in cellular kinetic parameters, such as labelling index (LI), growth fraction (GF), and mitotic index (MI), in different regions of the subependymal layer. These regional differences in brain cell kinetics may reflect locally specialized functions in the cytoarchitecture of the developing brain. Pulse-labelling methods provide useful techniques for studying the spatiotemporal patterns of cellular proliferation, differentiation, and migration in neural development. Focal charged particle radiation beams are used as non-invasive probes to perturb cell kinetics in the subependymal layer of the developing brain. Local changes in LI, GF, and MI are observed following irradiation with helium and neon ion beams. This research was supported by the Office of Health and Environmental Research, U.S. Department of Energy Contract DE-AC03-76SF00098.

GABAA RECEPTORS IV

335.1

DIFFERENCES IN RECEPTOR STRUCTURE REQUIREMENT FOR NEUROSTEROID AND BENZODIAZEPINE FACILITATION OF GABA-GATED CI CURRENTS. G.Puia*, M.R.Santi, S.Vicini, P.H.Seeburg*§, and E.Costa. FGIN, Georgetown University, Washington, D.C. 20007 and §ZMBH, Heidelberg, FRG.

Using the whole cell voltage-clamp recording technique, we investigated the modulation of GABA-gated Cl channels by THDOC $(3\alpha,21dihydroxy-5a-pregnan-20-one)$, $3\alpha-OH-DHP$ $(3\alpha-hydroxy-5\alpha-6)$ pregnan-20-one) and PS (pregnenolone sulfate) on various GABA, receptor subtypes assembled in a mammalian cell line after transfection with cDNAs encoding for different GABA, receptor subunits. We also compared the activity of these modulators on primary neuronal cultures of newborn rats. Nanomolar concentrations of 3α -OH-DHP and THDOC potentiated GABA- activated CI currents; micromolar concentrations of steroids elicited bicuculline- sensitive Cl currents. In these cultures micromolar concentration of PS negatively modulated GABA activated Cl' currents. The interactions between 3\alpha-OH-DHP and PS modulation will be discussed. Steroids facilitated GABA-gating equally well in artificially assembled homooligomeric and heterooligomeric channels, and in channels naturally expressed in primary neuronal cultures. Conversely, the γ and α subunits are required to optimize benzodiazepines (Bz) and imidazopyridines (Ip) positive modulation. However, variation in the molecular form of α and γ subunits may change efficacy and potency of Bz and Ip.

335.2

A NOVEL GABAA RECEPTOR SUBTYPE EXPRESSED IN CULTURED CEREBELLAR GRANULE CELLS. P.H. Seeburg¹, H. Monyer¹, K. Keinänen¹, F. L.A. Verdoorn², B. Sommer¹, Center for Molecular Biology, University of Heidelberg and ² Max-Planck-Institut für medizinische Forschung, 6900 Heidelberg, FRG.

A novel GABAA receptor subunit, $\alpha_{\textrm{6}},$ was isolated from bovine and rat cerebellar cDNA libraries. Northern analysis and in situ hybridization demonstrate that the α_6 mRNA is expressed only in the cerebellum and, within this structure, predominantly by the granule cells. When this subunit is coexpressed with β_2 and γ_2 subunits in mammalian cells, a GABAA receptor is formed with a unique benzodiazepine recognition site. The only benzodiazepine ligands which bind to this site are Ro 15-1788 and Ro 15-4513. It is possible that this receptor mediates alcohol induced motor incoordination. To further investigate the functional properties of this receptor we analyzed the expression of α subunits in cultered cerebellar granule cells and studied electrophysiologically GABAA receptor properties in these cells. Amplification by PCR of cDNA constructed from cerebellar granule cell RNA revealed that α_6 is also expressed in vitro. Single channel currents in outside-out patches (-50mV) from these cells had a mean conductance of 25 +/-3.0 pS (n=3, 5µM GABA). Comparisons of these channel characteristics with channel currents from cells transfected with DNA encoding subunit combinations including $\alpha 6$ will be discussed.

PATCH-CLAMP STUDY OF GABA-EVOKED CI CURRENTS IN DOPAMINE (DA) VERSUS NON-DA NEURONS IN SLICE. G.Mereu and S.Vicini. FGIN, Georgetown University, Washington,

DA neurons were identified by their location and their electrophysiological characteristics in cell attached or current clamp (CC) mode. DA cells exhibited highly regular spontaneous firing (pacemaker like) of 0.5 - 5.0 Hz (more often observed at RP \leq 56 mV) and spike duration ≥ 3.5 msec. In CC mode action potentials had high threshold (-38 mV), low frequency (< 8.0 Hz) repetitive firing, followed by huge (\geq 10 mV) after hyperpolarization (AH) and spike duration \geq 2.5 msec. On the other hand non DA, putative GABA, cells displayed modest AH, capability of high rate (≥ 10 Hz) non rhythmic (rarely spontaneous) firing, and spike duration ≤ 2.5 msec. GABA-evoked Cl currents in DA neurons were compared to that of non-DA neurons by monitoring these currents in rat thin slices by patch-clamp technique (Edwards et al., 1989, Pflugers Arch. 414:600). Interesting, in whole-cell voltage-clamp (VC) mode, the majority of cells (46/54) exhibited spontaneous synaptic currents both excitatory and inhibitory. By application of GABA in whole-cell VC mode, both DA and non-DA neurons generated Cl currents which were modified by various benzodiazepine (BDZ) receptor ligands. The positive modulation elicited by diazepam, flunitrazepam, and zolpidem was about twofold more efficacious in non-DA than in DA

335.5

CALCIUM MEDIATES THE HALOTHANE-INDUCED PROLONGATION OF SPONTANEOUS INHIBITORY POSTSYNAPTIC CURRENTS (sIPSCs) IN HIPPOCAMPAL NEURONS. I. Mody', M. B. MacIver² and D. L. Tanelian², Depts. of 'Neurology & ²Anesthesia, Stanford Univ. Sch. of Med., Stanford, CA.

The decay time constant (TAUD) of sIPSCs is prolonged by anesthetic agents. Recently, volatile anesthetics have been shown to produce elevations in intramuscular and synaptosomal Ca2+ levels presumably through release of Ca2+ from intracellular storage sites. We have investigated the possibility that rises in intraneuronal Ca^{2+} may be responsible for the prolongation of sIPSCs by volatile anesthetics. Using whole-cell patch clamp recordings in hippocampal slices maintained at $34\pm1^{\circ}C$ we found halothane (1.2vol%) and pentobarbital (50 μ M) to prolong the TAU_D of TTX-resistant GABA_A receptor mediated sIPSCs by 275% and 230% respectively. When increases in intraneuronal Ca²⁺ were prevented by intracellular administration of the Ca²⁺ chelator BAPTA or the sarcoplasmic Ca2+ release inhibitor dantrolene, halothane's (but not pentobarbital's) effect was reduced by 70% (p<0.005, ANOVA). The contribution of GABAergic inhibition to the depression of field potentials by halothane was investigated in extracellular recordings. With inhibition intact or excitation enhanced by lowering extracellular Mg2+, halothane depressed population spike amplitudes by 80-100%. When GABA mediated inhibition was blocked by bicuculline (100 µM), halothane reduced the population spike amplitude by only 21%.

These findings demonstrate: 1) Transient elevations in intraneuronal Ca2+ enhance the function of $GABA_A$ receptor/channels; 2) Anesthetics which prolong sIPSCs do so via different mechanisms (unlike halothane, pentobarbital does not require an elevation of intraneuronal Ca2+); 3) The foremost action of halothane is to enhance GABA, mediated inhibition rather than to depress neuronal excitability as previously thought.

335.7

MODULATION OF [35S]-t-BUTYLBICYCLOPHOSPHOROTHIONATE BINDING TO INTACT CEREBELLAR GRANULE CELLS BY THE TYPE II PYRETHROID DELTAMETHRIN. T.E. Murray and T.R. Jacobsen*. College of Pharmacy, Oregon State Univ., Corvallis, OR 97331.

An involvement of GABA_A receptors in pyrethroid neurotoxicity has been posited. We have investigated the binding of [35]TBPS in intact cultured cerebellar granule cells to characterize the regulation of GABA_A receptors in a defined neuronal population and to assess the interaction of deliamethrin with this recognition site. The binding of [35]TBPS at equilibrium was saturable with a Kd value of 60 nM and a Bmax value of approximately 650 fmol/mg protein. The specific binding of [35S]TBPS was inhibited approximately 55-60% by the GABA receptor antagonist bicuculline methiodide (10 μM). The bicuculline methiodide-induced inhibition of [35S]TBPS binding was reversed by muscimol in a concentration-dependent manner (0.01-1.0 μM). These results suggest that GABA_A receptor activation effects a positive modulation of [35S]TBPS binding presumably through an opening of the chloride channel. In contrast higher concentrations of muscimol in the range of 1-100 μM elicit an inhibition of [35S]TBPS binding possibly reflecting an agonist-induced desensitization of the GABA_A receptor complex. The pyrethroid insecticide deltamethrin modulated the equilibrium saturation binding of [35S]TBPS in a complex manner. Concentrations of 1 and 10 μM deltamethrin reduced the [35S]TBPS Bmax by 22 and 32%, respectively. In addition these concentrations of deltamethrin increased the affinity of [35S]TBPS for the remaining sites. These results suggest that deltamethrin may act as both a noncompetitive antagonist and a positive allosteric modulator of [35S]TBPS binding to the chloride channel domain of the GABA_A receptor. (Supported by HHS Grant ES04891

MEDIATED ZOLPIDEM MEDIATED POTENTIATION OF GABAA RECEPTOR RESPONSE IN RAT CEREBELLAR GRANULE CELLS. P. Vanderheyden, M. Desarmenien, P. Feltz and Ghandour, S., Lab de Neuroendocrinologie, Strasbourg, France.

The imidazopyridines zolpidem and alpidem were compared with the benzodiazepines diazepam and alprazolam for their action on GABA_A receptor responses. For this, GABA-mediated currents were measured from rat cerebellar granule cells in primary culture (3-5 days) using the patch clamp technique in the whole-cell configuration. Both benzodiazepines, applied at 1 μ M, increased the response to 5 μ M GABA. Alprazolam was more potent than diazepam, causing a 96 % potentiation, versus 32 % for diazepam.

The BZD1 selective compound zolpidem caused a dosedependent and reversible potentiation of GABA responses as well. The maximal effects were 63 and 34 % for 5 and 50 μM GABA applications respectively. This potentiation was reversibly blocked by the benzodiazepine antagonist Ro 15reversibly blocked by the benzodiazepine antagonist Ro 15-1788 (0.5 $\mu\rm M)$, suggesting that zolpidem interacts at or near the benzodiazepine recognition sites. On the other hand, alpidem, a ligand that selectively binds to peripheral benzodiazepine sites, only slightly potentiated GABA responses in the cerebellar granule cells. Our results confirm, on physiological grounds, the presence of a benzodiazepine1/GABA_A receptor complex on cerebellar granule cells and the efficacy of zolpidem as a benzodiazepine receptor agonist.

335.6

ISOLATED CNS OF THE NEWBORN OPOSSUM (MONODELPHIS DOMESTICA) MAINTAINED IN VITRO: RESPONSES TO GABA, GLYCINE, GLUTAMATE AND NMDA. R.R. Stewart, D.J. Zou*, J.G. Nicholls and N.S. Saunders* Dept. Pharmacol. Biocenter, 4056 Basel, Switzerland and Dept. Physiol. & Pharmacol., Southampton Univ. Med. Sch., Southampton, England The isolated CNS of the newborn opossum offers certain advantages

for studying transmitter action. It survives for up to 4 days in medium as deficient as Krebs's fluid, and agents, such as TTX and Mg2+, exert their effects rapidly and reversibly. In the present experiments we show that amino-acid transmitters such as GABA, glycine, glutamate, NMDA and their antagonists have rapid, reversible and reliable effects on spontaneous and evoked activity. For example, bicuculline, as expected, reversibly blocks GABA-A receptors but not the GABA-B receptors activated by baclofen; bicuculline can also cause synchronized bursts of activity in the CNS. In more suitable medium (BME), survival of the CNS has now been extended to over a week. Dose-response curves of the various transmitters at the end of a week remain unchanged. It is now possible to expose the CNS to TTX and other drugs for prolonged periods. For example, after 7 days in TTX, the CNS begins conducting compound action potentials (CAPs) within minutes after rinsing; in addition, the sensitivity of CAPs to GABA remains unchanged. By contrast, chronic exposure to low concentrations of certain amino acids markedly alters the sensitivity of evoked CAPs to GABA. These results suggest that the long-term regulation of receptor properties can be analyzed in detail in this CNS in vitro.

GABA, RECEPTOR SUBTYPES AS A SITE OF ACTION FOR THE ANTICONFLICT AND ANTIPROCONFLICT ACTION OF BENZODIAZEPINE (BZ) LIGANDS. P.Giusti, A. Guidotti, and E. Costa. FGIN, Georgetown University, Washington, D.C. 20007.

The conditioned suppression of drinking in rats (Vogel test) - both in its conflict and proconflict paradigm - was used as a behavioral model to determine whether clinically effective BZ drugs with a preferential antipanic action produce different behavioral effects by acting on the allosteric modulatory sites of a class of heteropolymeric GABA, receptor subtype. Pentylenetetrazole, a drug known to decrease GABA, receptor subtype. Pentylenetetrazole, a drug known to decrease GABA, receptor subtype. Pentylenetetrazole, a drug known to decrease GABA, receptor subtype. The produce panic-like syndrome in animals and man, was used to facilitate punished suppressed behavior in the proconflict paradigm. The anxiolytic drugs diazepam and chlordiazepoxide, which do not show a preferential potency in the treatment of panic disorders, presented similar anticonflict (AC) and antiproconflict (AP) potency in the Vogel test. The ED₅₀ AC/AP ratio was close to 1. On the other hand, the 1-4 BZ clonazepam, the 1-4 triazolo BZ alprazolam and the 1-5 imidazo BZ bretazenil (Ro 16-6028), which have a preferential potency as anti-panic disorder agents, exhibited a higher AC/AP ratio as compared to diazepam. A further increase in the ratio was seen when animals that had received alprazolam were treated with Cl-966. Flumazenil abolished either the AC or the AP activity of the high-affinity binding sites of ³H-clonazepam, *H-alprazolam, and ³H-bretazenil was significantly lower than that for ³H-diazepam. Thus, BZ ligands with clinical efficacy in the symptomatic treatment of panic disorders exhibited in rats an unexpected behavioral profile and a selective binding distribution as compared to the anxiolytic BZs, suggesting that they interact with a different population GABA_A receptors.

NATURALLY OCCURRING ENDOGENOUS BENZODIAZEPINES: PURIFICATION, SYNTHESIS, AND PHYSIOLOGY. Rothstein JD, Garland W. Puia G. Guidotti A. Costa, E. Johns Hopkins Univ, Dept. Neurology, Baltimore MD, 21205; FGIN-Georgetown Univ, Washington D.C., 20007; Hoffman-La Roche,

Endogenous benzodiazepine-like substances are naturally present in the CNS. These substances are present in tissue from man and animal, and in plants and fungi. Using selective extraction protocols and HPLC purification, receptor binding displacement studies, and selective anti-benzodiazepine antibodies, we have identified 6 benzodiazepine-like substances in rat and human brain. All material could displace [3H]-flunitrazepam binding to central benzodiazepine receptors. One peak demonstrated greater activity at the "peripheral" benzodiazepine receptor. Electrophysiologically, some peaks potentiated GABA gated Cl channel opening, monitored in patch clamped cultured cortical neurons. Preliminary mass-spectroscopic analysis identified small amounts of diazepam (DZ) and desmethyldiazepam (DDZ) in purified peaks. However, the amount of DZ and DDZ in these peaks was a small fraction of the biological activity based on radioreceptor and electrophysiological analysis. Human CSF contained 3 pmole/ml of total BZ-like material, while human brain contained up to 150 pmole/gm. There was up to a 4 fold variation in regional human and rat brain content of BZ-like material. Cultured cerebellar granule cells, but not glial cells, could release the material in a calcium dependant, potassium stimulated fashion. The source of these substances may be endogenous synthesis or by dietary consumption. Furthermore, the ubiquitous fungus Penicillium aurantiogriseum synthesized BZ-like substances that appear to be similar to those purified from animals. Their synthesis is being studied. In conclusion, naturally occurring benzodiazepines exist in the CNS and may be active physiologically.

STATE-SELECTIVE MODULATION OF GABA CURRENTS BY 7-BUTYROLACTONES. K. D. Holland*. K.-W. Yoon. J. A. Ferrendelli. D. F. Covey*. and S. M. Rothman. Depts of Pharmacology, Neurology and Anatomy and Neurobiology, Washington Univ. School of Medicine, St. Louis, MO 63110.

γ-Butyrolactones (GBLs) and γ-thiobutyrolactones are compounds which act at γ-Butyrolactones (GBLs) and γ-thiobutyrolactones are compounds which act at the picrotoxin receptor as either agonists or inverse agonists depending on the nature of the alkyl substituents. We examined the effects of two GBLs, α -ethyl- α -methyl-GBL (α -HMGBL), and α -isopropyl- α -methyl-GBL (α -HMGBL), on GABA currents and inhibitory postsynaptic currents (IPSCs) in cultured, voltage-clamped rat hippocampal neurons. α -EMGBL potentiated responses to low (0.5 μM) but not high (\geq 10 μM) GABA. α -EMGBL also decreased the rate of IPSC decay without altering IPSC peak amplitude. In the presence of higher GABA concentrations (30 μM) α -EMGBL acts as a mixed agonist/inverse agonists and inverse agonists. Thus, α -EMGBL acts as a mixed agonist/inverse agonist. In contrast to α -EMGBL, α -IMGBL had no effect on responses to either 0.5 μM or 30 μM GABA, or on IPSCs. α -IMGBL was able to block the effects of picrotoxin receptor agonists and inverse agonists. Thus, α -IMGBL acts as a pure antagonist at the picrotoxin receptor.

The main conductance state of the GABA-gated channel probably has two or more open states; an early, short monoliganded one and a diliganded open state. more open states; an early, short monoliganded one and a diliganded open state. Using a computer model based on the single channel data of Weiss and Magleby (J. Neurosci., 1989) we were able to simulate our data by assuming that α-EMGBL altered only the opening and closing rate constants for the monoliganded open channel of the GABA receptor. These results suggest that some compounds may be "state" as well as site specific modulators of liganded channels. Supported by the Seay Neuropharmacology Research Fellowship and NIH grants NS14834 and GM07805.

LOCALIZATION OF PERIPHERAL-TYPE BENZODIAZEPINE RECEPTORAND DIAZEPAM BINDING INHIBITOR-LIKE IMMUNOREACTIVITY IN HUMAN BRAIN AND CEREBRAL TUMORS. H. Alho-, P. Helen-, T. Harjuntausta A. Hervonen and K. Krueger. Dept. of Biomed. Sci., Dept. of Neurosurg., Univ. of Tampere BOX 607, 33101 Tampere, Finland; Fidia—Georgetown Institute for the Neurosci., Washington DC 20007, USA.

The polypeptide diazepam binding inhibitor (DBI) inhibits benzodiazepine (BZ) ligand binding to both central benzodiazepine receptors (CBZR) and to so-called peripheral benzodiazepine receptors (PBZR). We studied the expression and distribution of DBI-like immunoreactivity (LI) and PKBS-LI (PK-11195 binding site, peripheral benzodiazepine receptor) in normal human brain

and cerebral tumors by immunocytohistochemistry.

The immunohistochemistry was performed with routine
PAP-method using human-DBI and rabbit-PKBS-antisera. In the normal cerebellum DBI and PKBS-LI was observed in astrocytes, no staining was identified in neurons. In astrocytomas the DBI- and PKBS-LI was identified in some of the astrocyte-like-cells in the tumors. In glioblastomas the numbers of DBI and PKBS immunoreactive cells were higher, large multinuclear anaplastic cells particular showed intense immunoreactivity. The role of PKBS and DBI in glia and in gliomas is unknown. DBI may modulate the function of CBZ- and PBZ-receptors, which are also found gliomas, either by acting directly via these receptors indirectly via neurosteroids regulated by the PKBS.

SPECIFICITY AND ENHANCEMENT OF REGENERATION

336.1

TOPOGRAPHIC SPECIFICITY OF PERIPHERAL AXON REGENERATION ACROSS ENCLOSED GAPS. T.M.E. Brushart. Departments of Orthopaedics and Neurology, Johns Hopkins Hospital, and The Raymond M. Curtis Hand Center, Baltimore, MD 21218.

These experiments evaluate the specificity of muscle reinnervation by sensory and motor neurons after entubated repair of a proximal nerve trunk. Both proximal sciatic nerves of nine female Sprague-Dawley rats were divided and the ends separated by 8 mms. within mesothelial tubes. Eighteen months were allowed for regeneration. The peroneal muscles were then injected with horseradish peroxidase to identify the sensory and motor neurons responsible for their reinnervation. Normal peroneal muscles were innervated by a mean of 386 motor neurons and 2897 sensory neurons. In experimental animals, these muscles were reinnervated by a mean of 210 motor neurons and 1982 sensory neurons. However, there was no return of motor function, with fixed ankle flexion and claw toe deformities. A mea of 53% of reinnervating motor neurons previously served the tibial muscles. The normal sensory innervation was from L2-4, centered on L3; neurons from L2-6 participated in reinnervation with random predominance of levels. Muscle was reinnervated by adequate numbers of neurons, but half of the motor neurons reinnervating the peroneal muscles had previously served the antagonistic tibial muscles and sen-sory levels were radically altered. Regenerating sensory and motor axons thus reinnervated muscle on a topographically random basis.

336.2

PERMANENT LABELING OF MOTONEURON POOLS: ACCU-RACY OF REGENERATION ANALYZED AT THE SINGLE NEU-RON LEVEL. R.D. Madison, S.J. Archibald, and S. Meadows. Departments of Surgery and Neurobiology, Duke University Med. Ctr., and Research Service, V.A. Hospital, Durham, N.C. 27710.

The motoneuron pool to the quadriceps muscle in the rat was labeled by exposing the terminal motor branch of the femoral nerve to the fluorescent dye DiI for 60 mins., and then repairing the motor branch by direct suture. Two weeks later, 5 of 14 animals had the parent nerve to the quadriceps muscle (femoral nerve) transected and repaired by direct suture, the other 9 animals served as non-transection controls. Four weeks later all 14 animals had the terminal motor branch re-exposed, a second tracer applied (Fluoro-gold) for 60 mins., and the nerve stump sealed into an empty polyethylene tube. Five days later animals were perfused and spinal cords were dissected and processed to display fluorescent cells. Corrected cell counts, mean+std. dev., were: (1) control animals, N=9, 396+37 double-labeled, 2+2 DiI alone; (2) femoral nerve transection, N=5, 351+62 double-labeled, 103+67 Dil alone. These results show that it is possible to permanently label a motoneuron pool with greater than 99% accuracy, and, in this model system the significant differences in DiI alone cells (p<.001) indicates many regenerating motor axons have been misrouted into the terminal sensory branch of the femoral nerve. Supported by NS 22404 and VA MR-Merit Review Program (RDM).

TRANSPLANTATION AND FUNCTIONAL INTEGRATION OF AN IDENTIFIED INTERNEURON THAT CONTROLS RESPIRATORY BEHAVIOR IN LYMNAEA. N.I. Sved, R.L. Ridgway, A.G.M. Bulloch and K. Lukowiak. Department of Medical Physiology, HSC, University of Calgary, Calgary, Alberta, Canada, T2N 4N1.

An identified interneuron, Visceral Dorsal 4 (V.D4), of the pond snail <u>Lymnaea stagnalis</u> is involved in the control of respiratory behavior. Semi-intact preparations in which V.D4 was ablated have suggested that this neuron in preparations in which V.D4 was ablated have suggested that this neuron in necessary for respiratory behavior to occur. In the present study we made critical tests of the importance of this neuron through transplantation experiments. We selectively removed or destroyed interneuron V.D4 from the visceral ganglion of an animal. Using in <u>vitro</u> culture techniques, neuron V.D4 from another animal was then transplanted into this ganglion, in the same position where the original V.D4 had been located. Within 3 - 5 days, the transplanted V.D4 extended neurites and restored the functional circuitry underlying the respiratory behavior. Interestingly, when a V.D4 was implanted into a ganglion in which the host V.D4 had not been ablated earlier, the second (implanted) V.D4 displayed an aberrant morphology and failed to make appropriate synaptic connections: it did, however. nad not been ablated earlier, the second (implanted) v.D4 displayed an aberrant morphology and failed to make appropriate synaptic connections; it did, however, make inappropriate connections. This result suggests that transplanted interneurons have the capacity to extend neurities and to form synaptic connections. Additionally, these neurons can re-establish connections, with appropriate targets, but these do not occur in the presence of the host

LOW ENERGY LASER IRRADIATION AT DIFFERENT WAVELENGTHS ALTERS PHOTOSTIMULATION EFFECTS ON THE RATE OF RAT FACIAL NERVE REGENERATION. $\underline{\mathbf{J}}.\underline{\mathbf{J}}.$ Anders, S. Woolery*, R. Borke and W. Vandemerwe*.

Dept. of Anatomy and Laser Biophysics Center,
USUHS, Bethesda, MD 20814.

Low energy laser irradiation (8.5mW, 90 min,
632nm) increases the rate of rat facial nerve

regeneration after crush injury (Anders, J.J., Neurosci., 15:316, 1989). The purpose of this study was to establish the wavelength with the study was to establish the wavelength with the greatest photostimulatory effect on the rate of facial nerve regeneration. The facial nerve was crushed unilaterally in anesthetized rats for 90 secs. The wound was sutured and transcutaneously irradiated daily with a tunable dye or ND-YAG laser at 8.5 mW for 90 min for 7, 8 and 9 days at various wavelengths (1060, 720, 632, 514, 457 and 361nm). HRP was injected subcutaneously, on the side of the face supplied by the injured nerve, before aldehyde perfusion. The number of HRP-labeled neurons in the facial motor nucleus was used as an assay of the degree of regeneration. Laser irradiation at all wavelengths examined caused an increase in the rate of regeneration as compared to the non-irradiated controls. 632nm had the greatest effect on the rate of regenerahad the greatest effect on the rate of regenera-tion and increasing or decreasing the wavelength from 632nm decreased the stimulatory effect.

WALLERIAN DEGENERATION OF NERVE ALLOGRAFTS AND IMMUNOSUPPRESSION. T.E. Trumble, Orthopaedic Research Lab., Univ. of

Washington Sch. of Med., Seattle, WA 98195
The transplantation of Wallerian degenerated grafts were investigated as a means of decreasing the immunogenicity of the grafts and therefore the requirement for systemic immunosuppression. Short-term immunosuppression has been shown to decrease the host rejection in previous studies. This study evaluated the functional recovery in the animal with Wallerian predegenerated grafts, both alone and in combination with short-term immunosuppression with cyclosporin-A (CyA). Eight groups of animals were used and included allografted groups (grafts transplanted from Brown-Norway to Lewis rats), control groups with isografts with and without predegeneration, and a separate group that was not grafted. CyA concentrations were evaluated by radioimseparate group that was not grafted. CyA concentrations were evaluated by radioimmunoassay one month following transplantation. Recovery of neurologic function
was evaluated using sensory testing, gait analysis (de Medinaceli sciatic function
index, or SFI), hind limb flexion contractures, tibialis anterior (TA) muscle weight,
and hydroxyproline concentration, as well as axonal counts. Three months after surgery the CyA was terminated and the animals were observed for another month to
allow for signs of rejection to occur.

Results: All the animals receiving CyA had therapeutic serum levels. The animals receiving allowable along hed therapeuter flaving a contractures (A(2), 129) which

Results: All the animals receiving CyA had therapeutic serum levels. The animals receiving allografts alone had the greatest flexion contractures (44°±13°) which was significantly higher than the animals with the predegenerated allografts without CyA (36°±7°, p<.01). Both of these groups were higher than allografted animals that receive CyA or the isografted animals (p<.01). The muscle weight ratios revealed that all grafted groups received some reinnervation, with the allograft-only group having the smallest return of muscle weight. The hydroxyproline concentrations revealed a significant difference between the allograft-only group and the allograft group with predegenerated grafts but without CyA (p<.01). The allografted groups without CyA did better than those without CyA whether or not they had predegenerated grafts (p<.01). Axonal counts did not reveal a significant difference between the grafted groups. In sum, predegenerated allografts allowed a better functional result when cyclosporin was not used.

ADULT RAT RETINAL GANGLION CELL AXONS ESTABLISH CONNECTIONS WITH COCULTURED VISUAL MIDBRAIN TARGETS. M. Bähr and G.W. Eschweiler* Dept.Neurology, University Tübingen D-7400 Max-Planck-Institut für Entwicklungsbiologie,

Tübingen, F.R.G.

The ability of adult rat retinal ganglion cells (RGC) to regrow axons into appropriate target regions was investigated in vitro. Retinal explants were obtained from adult rats 5 days after optic nerve crush and cultured with organotypic midbrain cultures including the primary visual target area (colliculus superior) from 15 day old (E15) rat embryos. Explant cultures were placed at a distance of 200-500 µm and cocultured for 10-14 days. The origin and cellular morphology of different RGC types proorigin and cellular morphology of different RGC types projecting to the midbrain cultures could be determined by placing small crystals of Di-I (Molecular Probes) into the explants. RGC axons were anterogradely labeled inside the cocultured explant, but no midbrain neurons were labeled retrogradely, suggesting that midbrain axons avoided to grow into adult retinal explants. The projections which were established with midbrain targets by adult RGC showed some similarity to those seen in vivo. In electrophysiological experiments neuronal activity could be recorded in the adult retina and in the midbrain explants suggesting that a functional reconnection of adult rat RGC with target neurons might be observed in our tissue with target neurons might be observed in our tissue culture system.

NERVE GROWTH FACTOR (NGF) PROMOTES CHOLINERGIC AXONAL REGENERATION INTO THE DENERVATED ADULT RAT HIPPOCAMPAL FORMATION. T. Hagg, H.L. Vahlsing*, C. Portera-Cailliau*, M. Manthorpe and S. Varon, Dept. Biol., M-001, UCSD, La Jolla, CA 92093

Cholinergic axons of the adult rat regenerate vigorously into peripheral nerve grafts placed between the disconnected septum and hippocampal nerve grains placed between the disconnected septum and hippocampal formation (HF) but do not regenerate well beyond the end of the nerve bridge into the hippocampal tissue. Since cholinergic septal neurons are known to be supported by NGF we tested whether NGF administration would promote their regeneration into the HF. Adult female Sprague-Dawley rats received bilateral aspirative fimbria-fornix transections, fresh septo-hippocampal nerve autografts and a concurrent one month unilateral infusion with 75 NGF or autograss and a concurrent one month unitated mission with 7s NGP vehicle i) into the lateral ventricle proximal to the graft or ii) into the hippocampal tissue 2 mm (dorsal HF) or 7 mm (ventral HF) distal to the graft. With intraventricular NGF the number of ChAT-positive septal neurons which axotomy reduced to 35% was increased to 85% of normal, but the number of AChE-positive axons in the nerve graft and HF was significantly decreased. Intraventricular NGF also induced the appearance of a cholinergic plexus in the septal region facing the ventricle and away from the fimbria-fornix region. This suggests that NGF promotes and directs axonal regeneration toward the site of infusion. A one month <a href="intra-https://intra-https: and to a lesser degree into the ventral regions dramatically enhanced and and to a lesser degree into the ventral regions dramatically enhanced and accelerated the entry and penetration of cholinergic axons into the dorsal HF. The improved regeneration occurred without a concomitant increase in the number of ChAT-positive neurons in the septum or of AChE-positive axons in the nerve graft, suggesting that hippocampal NGF infusion promoted regeneration by improving tissue penetration and not by recruiting additional neurons or axons. Support: NINCDS grants NS-16349, NS-25011 and NSF grants BNS-88-08285, BNS-86-17034.

MORPHOLOGY OF REGENERATED DORSAL ROOTS IN SEMIPERMEABLE TUBES IS ALTERED BY TUBE INNER SURFACE COMPOSITION. J.H.
Lustgarten*, M. Proctor*, A.M. Avellino* and M. Kliot.
Dept. of Neurosurgery, Columbia Univ., New York, NY 1003
Centrally-directed fibers of lesioned dorsal roots in

the adult rat regenerate up to the PNS/CNS interface but not across it. Providing a permissive local environment, e.g. an implant coated with embryonic astrocytes, enhances their outgrowth [Kliot et al., 1990]. Semipermeable acrylic polymer tubes in combination with biological substrates provide a defined microenvironment in which to clarify con-ditions influencing dorsal root regeneration. Centrallydirected processes of transected dorsal roots were placed in blind-ended tubes. The extent and pattern of axon outgrowth was studied using 1 µm plastic sections. Tubes having a smooth inner surface and impregnated with laminin support outgrowth of a discrete central cable of myelinated axons across a 2.7 mm gap. At 4 weeks regenerated axons represent <5% of the total root axons placed in the tube; this increased three-fold by 8 weeks. Tubes having a rough inner surface support more modest outgrowth of myelinated axons splayed within a diffuse cellular infiltrate. Rough tubes impregnated with dexamethasone suppressed this cellular infiltrate and axonal regeneration. We conclude that limited regeneration of dorsal roots can occur in semipermeable conduits even in the absence of a distal stump; and that morphology of the regenerated root is highly dependent on the tube inner surface composition.

THE EFFICACY OF MODIFIED ACELLULAR NERVE ALLOGRAFTS IN THE REPAIR OF PERIPHERAL NERVES. A.K. Gulati. Department of

Anatomy, Medical College of Georgia, Augusta, GA 30912. Genetically different nerve allografts are unable to support host axonal regeneration as they are immunologically rejected. The present study describes the ability of experimentally prepared nerve allografts in the repair of rat peripheral nerves. Nerve allografts were prepared by first freezing and thawing a six week in situ degenerated rat peripheral nerve. This procedure removed the degenerated myelin and killed the cellular elements within the nerve. The Schwann cell basal lamina was however preserved. Prior to transplanting these nerves to repair nerve gaps, as was done in a recent study (Gulati and Cole, J. Neurosurg. 72:114-122, 1990), these nerves were passaged through an intermediate host or cocultured with macrophages to rid the grafts of dead cell debris. After each of these procedures the nerves were harvested and used to repair surgically created nerve gap in the host rat. Appropriate control cellular allografts (i.e. not frozen and thawed) and genetically identical isografts were performed for comparison. The graft length was 2cm in all cases. Grafts were evaluated morphologically at 1, 2, 4 and 12 weeks. The control cellular isografts supported the axonal regeneration best. The cellular allografts were rejected and were unable to support axonal regeneration. The acellular allografts after passage through an intermediate host or after culture were successful in supporting axonal regeneration through its entire length, as were acellular isografts. It is concluded that experimentally modified acellular allografts are capable of supporting axonal regeneration and exhibit reduced immunogenicity.

336.11

EFFECT OF SERINE PROTEASE AND SERINE PROTEASE EFFECT OF SERINE PROTEASE AND SERINE PROTEASE INHIBITOR ON NERVE REGENERATION IN VIVO. P. Leg1, R.H. Soriano. J.G. Spector¹ and D.G. Roufa, ¹Dept. of Otolaryngology, Washington University and CNS Diseases Research, Searle R&D, St. Louis, MO 63198.

Serine proteases (e.g., thrombin) and serine protease inhibitors (e.g., Protease Nexin-1) have been implicated in neurite outgrowth activity. We have examined the activities of thrombin and protease nexin-1(PN-1) in a rat sciatic nerve regeneration model

regeneration model.

regeneration model.

A 4-5mm sciatic nerve segment was removed and the nerve ends were implanted in a 10mm silastic tube to create an 8mm gap. Each tube was prefilled with either 1.5IU thrombin, 50ug/ml or 1mg/ml of PN-1, or saline. Thrombin, at day 1 and 4 after implantation, reduced the length of the blood clot propagating from both the proximal and distal nerve stumps. PN-1 at 50ug/ml did not interfere with clot progression at day 1 and day 4. At day 17, the number of nerve regenerates containing myelinated axons in the middle of the tube was 1/6 for thrombin, 6/9 for PN-1 (50ug/ml), and 6/10 for saline. Nerve regenerates had no statistically of the tube was 1/6 for thrombin, 6/9 for 1/4-1 (Soughil), and 6/10 for saline. Nerve regenerates had no statistically significant increase in the number of myelinated axons at day 21, with a higher dose of PN-1 (1mg/ml).

In conclusion, we demonstrated that thrombin interfered

with clot progression and reduced the number of myelinated axons. PN-1 did not affect clot progression nor did it affect the number of myelinated axons.

336.10

FIBRONECTIN-LAMININ COMBINATION ENHANCES PERIPHERAL NERVE REGENERATION ACROSS LONG GAPS. A.L. Woolley*, J.P. Hollowell*, and K.M. Rich. Dept. of Otolaryngology, Dept. of Neurosurgery, and Dept. of Neurobiology, Washington Univ. School of Medicine, St. Louis, MO 63110.

An exogenous fibronectin-laminin (FN-LAM) solution was added into a silicone chamber to determine the effects on peripheral nerve regeneration across 18 mm long gaps. The sciatic nerves of adult rats were sutured into silicone tubes 20 mm in length, creating a 18 mm gap between the proximal and distal nerve stumps. The tubes were filled with either a mixture of fibronectin and laminin (500 µg/ml each) or a solution of cytochrome C (1 mg/ml) as the control. After six weeks, the animals were sacrificed and the chambers were examined for regeneration. Seventy animals were sacrificed and the chambers were examined for regeneration. Seventy percent of the animals from the FN-LAM group demonstrated regeneration across the 18 mm gaps, compared to only thirty percent in the control group. The combination of FN-LAM significantly increased the number of axons that grew into the distal end of the chamber (FN-LAM, 1325 \pm 442; cytochrome C, 153 \pm 51; P < 0.05). Examination of the distal tributary nerves revealed axons only in the FN-LAM group; none were found in the control group. Quantitative analysis of horseradish peroxidase labeling of the distal sciatic nerve through the regene segment revealed a greater number of sensory and motor neurons in the FN-LAM group had extended axons across the 18 mm gap compared to the control group.

Morphometric studies revealed that the mean area of the regenerated segment in the FN-LAM group was 37% larger than the controls, and ultrastructural analysis demonstrated a more mature nerve. This is the first in vivo demonstration that this combination of fibronectin and laminin significantly enhances the regeneration of myelinated axons across a long nerve gap in the rat sciatic nerve. Supported by NIH grant 5T32NS07057-11.

DEGENERATIVE DISEASE-PARKINSON'S

337.1

ABSOLUTE NUMBER OF NEURONS IN THE SUSTANTIA NIGRA IN PARKINSON'S DISEASE. A. Møller, B. Pakkenberg, H.J.G. Gundersen, A.M. Dam* & H. Pakkenberg*. Neurological Research Laboratory, Hvidovre University Hospital, Copenhagen and Stereological Research Laboratory, Aarhus University, Denmark

Using an unbiased stereological technique, the total number of pigmented and non-pigmented neurons was estimated in the substantia nigra of seven patients and seven controls. In the control group the average total number of pigmented neurons was 550.000 and nonpigmented was 260,000 with a variation of about 20%. There was a large reduction in the neuron number for both the pigmented neurons, 66%, and the non-pigmented neurons, 24%, in the Parkinson's diseased patients with no overlap in the figures between the two groups. A significant correlation (r = 0.81, 2p = 0.028) existed between the total number of pigmented and non-pigmented neurons in the controls, whereas a similar correlation in the patients fell just short of significance (r = 0.27, 2p = 0.069). The unbiased stereological method is a few orders of magnitudes more efficient than the previously used conventional and biased methods. The amount of time used to count each substantia nigra was approximately one hour.

337.2

IRON AND ALUMINUM INCREASE IN THE SUBSTANTIA NIGRA OF PATIENTS WITH PARKINSON'S DISEASE: AN X-RAY MICROANALYSIS Hirsch E.C., Brandel J.P.', Galle P.', Javoy-Agid F, and Agid Y. INSERM U289, Hôpital de la Salpêtrière, 47 Bd de l'hôpital, 75013 Paris and INSERM SC27, 94010 Créteil, France.

Parkinson's disease is characterized by the degeneration of melanized dopaminergic neurons in the substantia nigra and the presence of Lewy bodies. In order to analyze the putative role of trace metal in nigral cell death we analyzed the level of different elements by X-ray microanalysis in the substantia nigra and the central grey substance of patients with Parkinson's disease, progressive supranuclear palsy and matched controls. In control brains, only iron, potassium, silicium, sodium, sulfur and zinc were within the detection limit of the technique. The elements were present at similar concentrations and distributed professive in the two regions except sulfur leaves which were higher even uniformly in the two regions except sulfur levels which were higher on neuromelanin aggregates in the substantia nigra than in nigral regions lacking neuromelanin or in the central grey substance. The concentrations of the other elements were similar in both structures. In Parkinson's disease, but not in progressive supranuclear palsy, nigral iron levels increased in regions devoid of neuromelanin and decreased on neuromelanin aggregates and were unchanged neuromelanin and decreased on neuromelanin aggregates and were unchanged in the central grey substance, when compared to control values. Concentrations of the other elements in the central grey substance and substantia nigra were not different from controls in brains from patients with Parkinson's disease and progressive supranuclear palsy. Analysis of Lewy bodies in the parkinsonian substantia nigra, revealed high levels of iron and the presence of aluminum. Trace metal abundance was not affected in progressive supranuclear palsy, in spite of the nigral cell death. This suggests that the increased iron levels and the detection of aluminum observed in the substantia nigra of patients with Parkinson's disease are not solely the consequence of the neuronal degeneration.

SPECIFIC DOPAMINERGIC CYTOTOXICITY IN SERA OF IDIOPATHIC PARKINSONIAN PATIENTS. R. Dal Toso, G. De Fazio* D. Benvegnù*, Minozzi M.C.*, A. Cananzi^{1*} and A. Leon. Fidia Research Laboratories, 35031 Abano Terme, Italy and Dept. of Neurology, Vicenza Hospital, 36100 Vicenza, Italy

We here provide evidence, that sera from patients affected by Parkinson's Disease (PD) contain complement-dependent cytotoxic activity specific for dopaminergic (DA) neurons in vitro, and mainly present in sera of idiopathic PD patients. In particular, heat inactivated serum from PD patients or neurological controls were added to serum-free mesencephalic-striatal co-cultures on day 4 "in vitro". After 24 hrs, reconstituted rabbit complement was added for 30 min and DA and GABA uptake thereafter assessed. We found that 14 out of 16 sera of idiopathic PD patients produced a complement-dependent reduction of DA uptake without affecting GABA uptake. This reduction was correlated with an equivalent loss of tyrosine-hydroxilase immunoreactive neurons, thereby indicating specific cytotoxicity for DA neurons. No inhibitory activity was observed in 12 out of 14 non-idiopathic PD and all neurological control sera. The correlation between this cytotoxic activity in serum and that reported in CSF (McRae et al., Neurochem. Res., 13: 679, 1988) as well as its relevance in pathophysiology of PD remain to be elucidated.

337.5

A STRIATAL-DERIVED NEUROTROPHIC FACTOR (NTF):
RELATIONSHIP TO PARKINSON'S DISEASE (PD).
E.S. Lo, L.R. Ptak*, S.T. Nath*, E.J. Mufson
Note of the control of PD is associated with dopamine (DA) receptor proliferation and increased DA synthesis as compensatory mechanisms. Extracts of the caudate (Cau), putamen (Put), and cerebellum (Cb) of 4 Lewy body positive PD patients were evaluated for their growth effect in an E13 rat mesencephalic culture growth effect in an E13 rat mesencephalic culture system to determine if enhanced NTF production also represents a DA cell loss compensatory mechanism. Number of cells in a low density culture system or DA uptake and number of tyrosine hydroxylase (TH) positive neurons in a high density system were used as indices of growth. Put and Cau extracts from PD patients rescued more cells than extracts from pD patients rescued more cells than extracts from Dp patients rescued more cells than extracts from Dp atients rescued more neurons relative to PD Cau and control extracts, although this effect was not seen in all PD patients. Cb extracts from all patients had low level effects. These data suggest that physical denervation scondary to PD leads to an enhanced production of a target-derived NTF which is similar to that seen following pharmacologic denervation (Carvey, this meeting). Enhanced NTF production may represent a compensatory mechanism for loss of striatal DA tone. Since chronic DA agonism reduces this NTF, levodopa therapy in these PD patients may account for the inconsistent increases observed.

HEMIPARKINSONISM IN MONKEYS AFTER UNILATERAL STRIATUM INFUSION OF MPTP: CAUDATE NUCLEUS VS PUTAMEN. H.IMAI, T.NAKAMURA*, K.ENDO*, and H.NARABAYASHI*, Dept.of Neurology, Juntendo Univ. Sch. of Med., Tokyo 113, Japan.

In an attempt to clarify the role of the dopamien nerve terminal and cell body in MPTP toxicity and construct a model for pure hemiparkinsonism, we first administered 4 mg of MPTP HCl directly into the unilateral caudate nucleus of crab-eating monkeys via an Alzet 200 μl osmotic minipump for 14 days. The monkeys exhibited a persistent flexed posture and hypokinesia of the contralateral limbs, and spontaneous circling toward the MPTP-treated side. After treatment with apomorphine the circling motion was reversed. Almost total nigral dopamine cell loss was produced in the MPTP-treated side. After infusion of 4 mg of MPTP into the unilateral putamen the monkey exhibited a clear hemiparkinsonism behaviorally and histologically, virtually the same as seen in those animals given 4 mg of MPTP into the caudate nucleus. Infusion of 0.4 mg of MPTP into the caudate nucleus exhibited no clear hemiparkinsonism except apomorphine-induced circling away from the MPTP-treated side, and produced a partial nigral cell loss mainly rostrally and clusters of spared cells were seen. Infusion of 0.4 mg of MPTP into the putamen exhibited a mild hemiparkinsonism but no apomorphine-induced circling, and produced a partial nigral cell loss mainly caudally and ventrolaterally.

MICROSTIMULATION OF VENTRAL INTERMEDIUS NUCLEUS OF THALAMUS IN HUMAN PATIENTS WITH PARKINSONIAN TREMOR. A.L. Benabid , D.M. Gao*, D. Hoffman * and P. Pollak*, INSERM U. 318, Department of Neuroscience, Grenoble University, 38043 Grenoble - France.

Chronic stimulation of the thalamus has been demonstrated to suppress the parkinsonian tremor in human patients. The effects of the stimulation of various sites and the stimulation parameters were investigated in 41 patients with parkinsonian tremor or other sorts of tremors during stereotaxic surgery and were used for precise location of the chronic stimulating electrode. The optimal stimulation point was identified in the presumed nucleus ventralis intermedius (Vim) of the thalamus by multi-unit recording and microstimulation and compared with the determination of Vim from ventriculographic landmarks. The threshold intensity in Vim required to suppression of the tremor was minimal $(0.39 \pm 0.095 \text{ mA})$ at 130 Hz), where the relatively higher neural noises were recorded, and stimulation intensities higher than the threshold intensity could induce paresthesias in the contralateral side of the body, which was considered to be caused by the diffusion the stimulation current to the somatosensory nuclei of the thalamus (VPL or VPM). At sites which were 1 or 2 mm posterior to the optimal stimulation, multi-unit responses to the superficial stimulation of the contralateral body were often recorded. This tremor suppression effect was frequency-dependent and stimulations with a frequency from 60 to 1000 Hz were effective, but the optimal stimulation frequency was about 130 to 150 Hz. The function and the possible mechanism of action of the presumed Vim nucleus are discussed in the scope of a feed-back loop model.

A UNIFORM RATING SCALE FOR PARKINSONIAN FEATURES IN NON-HUMAN PRIMATES.

D.M. Gash 1, M.H. Kim*1 and R. Kurlan*2. Departments of Neurobiology and Anatomy 1 and Neurology 2, University of Rochester, Rochester, NY 14642.

Many laboratories are now using primates with MPTP-induced nigrostriatal lesions as a model of human Parkinson's disease (PD). While parkinsonian monkeys are proving valuable for evaluating new therapeutic approaches for the treatment of PD, the behavioral tests employed for assessing the motor impairments and recovery of function following treatment vary widely. This has made the comparison of results between laboratories difficult and to some comparison or results between laboratories diricult and to some extent impeded progress in this field. It is important that the research community using primates agree upon and utilize standardized tests to overcome this problem. As one step in this direction, we have developed a 24 item rating scale based on the direction, we have developed a 24 item rating scale based on the human clinical PD rating scales for assessing parkinsonian features (e.g. bradykinesia, tremor), general behavioral features (e.g. social interaction, grooming behavior, defense reactions) and treatment related side effects (e.g. dyskinesias, vomitting) in Rhesus monkeys. This rating scale has proven to be quite sensitive in detecting L-dopa induced improvements in our unilateral and bilateral parkinsonian monkeys. In order to improve interrater reliability and consistency, specific definitions for scoring have been developed and are illustrated on videotape.

been developed and are illustrated on videotape.

DELAYED AND ACUTE STEREOTACTIC CO-GRAFTING IN THE TREATMENT OF HEMIPARKINSON MONKEYS. R.A.E. Bakay, C. Herring, R. Watts, and L. Byrd. VA Medical Center, Yerkes Primate Center of Emory Univ., Atlanta, GA 30322.

A delayed stereotactic technique has been developed that has the potential for improving graft survivability by increasing the availability of neurotrophic factors at the time of grafting, and by the creation of a cavity for implantation of solid tissue. The delayed technique consists of x-ray confirmed stereotactic implantation of catheters into targets in the caudate and putamen one week prior to grafting. At the time of grafting, the catheters are removed and the tissue placed in the tract developed by the catheters.

Nine male M mulatta (2-4 years old) were rendered hemiparkinsonian by an intracarotid injection of MPTP. After stabilization of the lesion over a 2-4 month period, the subjects were randomized to either an acute stereotactic grafting of adrenal medullary tissue and sural nerve or a delayed technique with or without co-graft tissue. Apomorphine-induced rotation was decreased at three months by 45% in the acutely grafted monkeys and by 81% in the monkeys in which a delayed technique was used. Follow-up demonstrated that this decrease in drug-induced behavior

was maintained over a six-month period.

RELATIONSHIP BETWEEN EXCESS S-ADENOSYLMETHIONINE (SAM) DEPENDENT METHYLATION AND PARKINSON'S DISEASE (PD). C. G. Charlton, B. Crowell, Jr. and R. Benson*. Department of Physiology, Meharry

Medical College, Nashville, TN 37208.

The primary symptoms of PD are tremor, hypokinesia and rigidity due to degeneration in the nigrostriatal pathway. Tyrosine hydroxylase (TH), dopamine (DA) and melanin are depleted, and the relative concentration of methylated metabolites of DA are increased. During therapy, I-dopa is methylated, accompanied by a depletion of SAM. The cause of PD is still unknown. Any proposed cause should embrace both the etiology and the therapy of PD. An excess of SAM may embrace both, since an increase in SAM-dependent methylation can cause similar changes to those occurring in PD, and SAM seems to be involved in the action of I-dopa. We tested the proposal by injecting SAM into the brains of rats and by administering I-dopa and quantifying its effects on SAM. Acute icv injection of SAM caused tremors, hypokinesia, abnormal posture, etc. and DA depletion in the caudate nucleus (49.1% ipsilateral and 9.5% contralateral). Chronic treatment caused neurodegeneration localized damage to the CN, hippocampus and septum; and remotely, in the substantia nigra (SN), a reduction in size, cell loss and gliosis occurred accompanied by a reduction in TH and disruption in its cellular compartments. Chronic I-dopa increased the activity of methionine adenosyl transferase (MAT), the synthesis enzyme for SAM, by 32%. Most of the motor deficits cause by SAM are similar to those occurring in PD. The depletion of DA and TH and the remote degeneration that occurred in the SN also parallel the neurological findings in PD. It is known that I-dopa depletes SAM, therefore, our finding that chronic I-dopa can increase MAT is an indication that a rebound increase in SAM may contribute to the reduced efficacy of I-dopa during long term I-dopa therapy. UNC-116, A GENE INVOLVED IN PROVIDING POSITIONAL INFORMATION FOR AXONAL GUIDANCE DURING C.

ELEGANS NEURAL DEVELOPMENT. N.Patel and J.R. Mancillas. UCLA, Los Angeles, CA, 90024.

Unc-116 is a genetic locus identified by mutation during a screen for genes involved in axonal guidance. Unc-116 (e2312) mutants display abnormal locomotion, primarily during backward movement. Anatomical abnormalities involve the misplacement of axons normally occupying a lateral position to more dorsal positions and abnormal hypodermal nuclear migrations along the circumferential axis (Thierry-Mieg and Mancillas, in preparation), suggesting that unc-116 plays a role in a system signaling position along the circumferential axis. Genetic analysis placing unc-116 chromosomes over deficiencies spanning the locus reveals that e2312 is a hypomorph. This app to be due to transcription of the transposon This appears (TC5) whose insertion caused the mutation in (TC5) whose insertion caused the mutation in e2312. We have isolated cDNAs of various sizes from 2 cDNA libraries and identified genomic fragments covering the entire coding region. Its temporal pattern of expression is currently being analyzed by probing blots of C. elegans poly A+ mRNA isolated from distinct developmental stages.

NEURITIC OUTGROWTH PATTERNS FROM SEVERED GIANT AXONS IN LUMBRICUS TERRESTRIS. A.W. Lyckman, S.M. Thomas* as Bittner. Dept. of Zoology, Univ. of Texas, Austin, Texas 78712.

We have previously shown that severed giant axons in the We have previously shown that severed giant axons in the earthworm Lumbricus terrestris regenerate functional connections that restore electrical coupling and impulse propagation across the lesion site. This functional restoration is specific in that medial giant axons (MGAs) reconnect only with MGAs, and lateral giant axons (LGAs) reconnect only with LGAs (Balter et al., J. Exp. Neurol. 211: 395, 1980; Birse & Bittner, J. Neurophysiol. 45: 724, 1981). We have now examined the pattern of neuritic outgrowth of MGAs and LGAs severed by transection of the ventral nerve cord (VNC). After various postoperative intervals, severed giant axons were injected with Lucifer yellow and prepared for epifluorescence microscopy.

severed giant axons were injected with Lucifer yellow and prepared for epifluorescence microscopy.

The probability of producing at least one neurite from a severed MGA or LGA averaged 57% for the 1st through 7th postoperative weeks (POW). Severed MGAs and LGAs produced 1.2 ± 0.2 S.E.M. (n = 74) neurites which emerged from the cut end of the axon. The number of neurites showed little dependence on POW, except that outgrowth was minimal in the 1st POW. For severed MGAs or LGAs, proximal stumps produced significantly (p=0.01) more neurites than distal stumps (which may have catonlesmic content with neulested except.) produced significantly (p<0.01) more neurites than distal stumps (which may have cytoplasmic contact with nucleated axons). Severed earthworm giant axons grew very straight for most of their length. The initial and final angles of growth were typically less than 30° from the longitudinal axis. On average, neurites encountered appropriate giant axons for 37±7% of their total length, inappropriate giant axons for 7±3%, while spending 18±5% in the lesion site and 40±7% in other regions of the VNC. 86% of the severed axons had some contact with an appropriate giant axon, while 46% had some inappropriate contact. Supported by grants TAT #194 and NSF ECS 8915178 to GDB.

PIONEER NEURON GUIDANCE CUES IN GRASSHOPPER LIMB BUDS. J. S. Duerr and M. L. Condic. Dept. of Mol. and Cell Biology, Univ. of Calif., Berkeley, CA 94720. In the grasshopper limb bud, the Ti1 pioneer neurons extend their

axons from their origin in the periphery along a stereotyped pathway to the central nervous system. In a semi-intact preparation, the behavior of DiI-labeled growth cones of these identified pioneer neurons can be observed at the level of resolution of single filopodia with computer-enhanced video microscopy. Along their normal pathway, the cells encounter several possible sources of navigational information, including immature neurons and different regions of limb epithelium. Recent experiments have indicated that a single filopodium in contact with an immature neuron can recrient the extension of the growth cone. In the experiments reported here, sensory neurons of an identified type (femoral chordotonal organ) are taken from donor limbs and placed on the epithelium near the normal pathway of DiI-labeled pioneer neuron growth cones. The behavior of the pioneer neurons' growth cones as they approach and pass or touch these cells is observed with fluorescent video microscopy. In addition, the behavior of the transplanted sensory neurons in their new environment is monitored to see if they respond to general cues present in the limb epithelium.

CELL-SPECIFIC CONTACT SELECTS THE RESPONSE TO 5-HT DURING REINNERVATION OF AN IDENTIFIED LEECH NEURON. D. Merz* and P. Drapeau. McGill Univ. Centre for Research in the Neurosciences, Montreal, Canada. When serotonergic Retzius neurons of the leech

When serotonergic Retzius neurons of the leech contact pressure sensitive (P) neurons in culture, they selectively reduce a cationic response to 5-HT by uncoupling protein kinase C activation and reform the inhibitory, Cl-dependent synapse seen in vivo.

Retzius cells fixed in a mild aldehyde solution prior to pairing still reduce the cation response of the P cell (Drapeau et al, J Neurosci 9(7):2502-2508, 1989). Treatment of the Retzius cell with trypsin prior to fixation and pairing prevents the loss of the cationic response of the P cell.

To examine the cellular specificity of this

To examine the cellular specificity of this interaction, P cells were paired in culture with other identified leech neurons. Contact with other sensory neurons (T or N cells), or with a motor neuron (AE) had

neurons (T or N cells), or with a motor neuron (AE) had no effect on 5-HT responses of the P cell.

We conclude that the selection of responses may be mediated by surface proteins with a restricted cellular distribution. The early clearing of the non-synaptic (excitatory) response to transmitter appears to be a prelude to (inhibitory) synapse formation.

EXPRESSION DURING DEVELOPMENT OF A NEURAL ANTIGEN SHARED BY GRASSHOPPER AND DROSOPHILA. .. von Bernhardi and M. J. Bastiani. Dept. of Biology, University of Utah, Salt Lake City UT 84112.

During development most growing neurons extend their axons along the surface of established axon bundles. Molecules expressed in the axolemma may be specific cues for pathway choice or may be related to the extension of growth cones.

We have characterized the expression of an antigen (Ag) recognized by the monoclonal antibody (MAb) 5Clusing immunofluorescence and immunoperoxidase labeling techniques, both with light and electron microscopy. In grasshoppers 5C1 begins to recognize the nervous system at approximately 30% of development. Initially the label is on cell processes in the CNS axon pathways and the major nerves. After 40% of development, labeling becomes prominent around neuronal somata. This pattern persists through embryonic development and into adulthood, always with a conspicuous granular appearance.

Live labeling indicates that the MAb recognizes a surface Ag and

electron microscopy shows expression with a granular pattern on axons and filopodia. Finally, this MAt also recognizes an epitope expressed in the CNS of *Drosophila* embryos making it possible in the future to address the question of its physiological function using genetic

The spatial pattern of expression and its relative abundance on filopodia suggest that this molecule could participate in the recognition, affinity, or extension of a developing axon. We are currently assaying the effect of the Ab on axon growth and pathfinding.

A NOVEL SUBSET OF AXON PATHWAYS IN GRASSHOPPER EMBRYOS IS LABELED BY THE 10E6 MAB M. J. Bastiani and E. M. Carpenter, Dept. of Biology, University of Utah, Salt Lake City, UT 84112

The 10E6 MAb was generated by immunosuppression of mice (Hockfield, Science 237, 1987) with body wall tissue from 50% grasshopper embryos followed by

237, 1987) with body wall tissue from 50% grasshopper embryos followed by immunization with adult nerve cord. Labeling using this antibody is first seen at 33% of development on a pair of cells that pioneers a pathway in the anterior commissure and on the midline cells that pioneer the median fiber tract. As axonogenesis begins in these neurons their cell bodies, growth cones, and filopodia all label with the MAb. However as their axons extend, the labeling fades from the cell bodies but remains on the axons, growth cones, and filopodia. At 40% of embryonic development the 10E6 MAb labels all sensory neurons and their associated peripheral nerves, a single ventral pathway in the CNS connectives, and 3 CNS commissural pathways. At this stage approximately 10 CNS neurons are labeled. The ventral connective pathway is quite interesting in that it is pioneered by a pair of CNS neurons and then followed by the processes of sensory neurons which had been waiting in the ventral sensory neuropil region. By 70% of development, labeling of the commissural pathways appears to fade and is not seen at later stages of development or in cryostat sections of the adult, while the ventral sensory pathway is very prominent and remains prominent in the adult. All the peripheral sensory very prominent and remains prominent in the adult. All the peripheral sensory neurons seem to label while less than 1% of the CNS neuronal somata and axonal processes label in the adult. Incubation of live embryos with the MAb results in the same pattern of labeling suggesting that the MAb binds to a surface epitope. Immuno EM examination confirms the surface membrane localization of the antigen. We are currently attempting to characterize the antigen recognized by the 10E6 and determine what effects the MAb may have on normal neuronal development.

STEREOTYPY AND VARIABILITY IN THE PATTERN OF DYE COUPLING BETWEEN NEURONS IN THE GRASSHOPPER EMBRYO. Paul Z. Myers and Michael J. Bastiani. Dept. of Biology, University of Utah, Salt Lake City, UT 84112.

We have examined quantitatively the strength and frequency of dyecoupling between a set of early neurons in the embryonic grasshopper.

couping between a set of early neurons in the embryonic grassnopper. The Q1 neuron, which pioneers a fascicle in the posterior commissure, initially extends its growth cone anteriorly along the longitudinal pathway pioneered by the MP1 neuron. After growing past the anterior and posterior corner cells, the Q1 growth cone turns medially to grow over the MP1 soma to the midline, where it contacts the growth cone of its contralateral homolog. Very shortly after axogenesis begins and for 10% or more of development, Q1 and the corner cells are robustly and consistently dye-coupled to one another. Q1 and MP1, however, are only observed to be dye-coupled approximately 50% of the time overall, although there is a likelihood of roughly 85% of observing strong dyecoupling when or shortly after their growth cones contact each other's somata.

somata.

Our observations suggest that there is a transient period of strong dyecoupling between MP1 and Q1 that occurs when growth cones contact cell bodies, and that this dye-coupling persists only weakly or for a variable length of time. In contrast, dye-coupling between Q1 and the corner cells is maintained at a uniformly vigorous level over a substantial portion of embryonic development. We are currently investigating the significance of these different temporal patterns of intercellular communication by ablating neurons before they become dye-coupled. Supported by \$T32 CA09602, NIH NS08656 and NS25378, and the McKnight Foundation.

A CHROMOSOMAL DEFICIENCY IN DROSOPHILA ALTERS NEURITIC PROJECTIONS IN AN IDENTIFIED MOTONEURON. G.P. Swain. R.J. Wyman and M.D. Egger. Dept. of Neuroscience & Cell Biology, UMDNJ-Robert Wood Johnson Medical School, Piscataway, NJ 08854; † Dept. of Biology, Yale University, New Haven, CT 06511.

Baird (1988) noted that in Df(1)16-3-22/FM6 Drosophila, which are heterozygous for a deficiency at the base of the X-chromosome, a branch of the medial neurite of the motoneuron innervating the tergotrochanteral (TTM) muscle invariably crossed the midline, whereas in wildtype strains this midline crossing occurred rarely. Earlier, however, Koto (1983) had reported that in Df(1)16-3-22/C-S flies, the medial neurites of the TTM motoneuron did not cross the midline. We reinvestigated the influence of Df(1)16-3-22 on TTM motoneuron morphology. HRP was applied to the TTM muscles of wildtype (C-S, n=32; O-R, n=17) strains, as well as to Df(1)16-3-22/C-S (n=31) or Df(1)16-3-22/O-R (n=40). Reaction product could be seen in at least one TTM cell body in 80-100% of the flies in each of the four groups. Of those flies in which at least one cell body was labelled, one or both medial neurites were well filled in 65% of the C-S flies, 50% of the O-R, 39% of Df(1)16-3-22/C-S, and 55% of Df(1)16-3-22/O-R. Rates of midline crossing were then assessed in these flies. No midline crossings were observed in the C-S flies. However, in contrast to Koto's observations, a neuritic branch crossed the midline in 58% (7/12) contrast to Koto so observations, a neutrino trainer trosset the mindle in 36% (1/12) of D[(1)16-3-22/C-S flies, some extending $25-30 \,\mu$ m from the parent neutrie. In 2/8 O-R flies, neurites crossed the midline, but in only one of these was this a major projection, contrasting strikingly with the D[(1)16-3-22/C-R flies, in which a branching process of the medial TTM neurite extended beyond the midline in 82% (18/22) of our sample. In more than half of these flies, the midline-crossing neurite extended 30-45 μ m from the parent neurite. In summary, the deficiency, 16-3-22, promotes midline crossings of branches of the medial neurite of the TTM motoneuron. These midline crossings occurred with greater frequency and magnitude than in control wildtype strains.

PROCESS OUTGROWTH. GROWTH CONES AND GUIDANCE MECHANISMS VII

EFFECTS OF MANIPULATION OF GAP-43 EXPRESSION ON MORPHOLOGY IN PC12 CELLS AND CULTURED HIPPOCAMPAL NEURONS. S.A. Fidel, L.R. Dawes, K.A. Neve, R.L. Neve. Dept. of Psychobiology, Univ. of California, Irvine, CA 92717 and V.A. Medical Center, Portland, OR 97207.

To analyze the role of the neuronal protein GAP-43 in neurite outgrowth and regeneration, we designed oligonucle-otides and recombinant constructions of GAP-43 that allow otides and recombinant constructions of GAP-43 that allow us to alter the levels of GAP-43 within neuronal cells. Recombinant sense and antisense GAP-43 clones were transfected into PC12 cells and recombinant GAP-43 RNA levels in each were analyzed by PCR amplification of cDNA synthesized using vector-specific primers. Immunoblot analysis of stable transfectants revealed that cells expressing high levels of RNA from the sense construct contained higher levels of GAP-43 protein than controls; these cells displayed more and longer processes than control undifferential played more and longer processes than control undifferentiated cells. The cells expressing antisense GAP-43 mRNA contained lower levels of GAP-43 protein than controls, and displayed a morphology similar to that of PC12 cells treated with glucocorticoid. HPLC analysis of dopamine levels

in medium conditioned by these cells is underway.

Antisense oligonucleotides complementary to GAP-43 mRNA were added to primary hippocampal neuronal cultures. Antisense, but not sense, oligonucleotides inhibited process outgrowth from these neurons. The extent of inhibition of outgrowth was dependent on the concentration of antisense oligonucleotide that was added to the culture.

EXPRESSION OF GAP-43 mrna and protein in the chick embryo L Baizer, G. Ciment, and K. Stocker* Neurological Sciences Institute, Good Samaritan Hospital, and Department of Cell Biology and Anatomy, Oregon

Health Sciences University Portland, Oregon 97209
Growth-associated protein-(GAP)-43 is a neuron-specific phosphoprotein expressed at elevated levels during periods of axonal growth and regeneration. To begin to analyze the expression of GAP-43 in the early stages of neuronal development we recently isolated a cDNA for chicken GAP - 43 (Mol. Brain Res. 7:61 - 68 (1990). We have used this cDNA as a probe in Northern blot and in situ hybridization analysis to investigate the time-course and location of GAP - 43 mRNA expression in the chick embryo. We have also performed immunocytochemical analysis of GAP-43 protein expression.

Results indicate that GAP-43 mRNA and protein expression are first detectable on embryonic day 2 (e2) in the chick brain, neural tube, and neuroctodermal placodes. Northern blot analysis demonstrates that GAP-43 mRNA levels in brain reach peak levels at e13 and diminish rapidly thereafter. On e7 and e10, GAP-43 mRNA is detectable by in situ hybridization analysis in the brain and craniel ganglia, spinal cord, and sympathetic, dorsal root, and nodose ganglia. Thus, GAP-43 is expressed by tissues derived from neurectoderm, neural crest, and ectodermal placodes and is among the first neuron-specific gene products to be expressed in the

developing nervous system.

In situ hybridization analysis reveals that GAP-43 mRNA is also expressed. in the distal regions of the limbs on e7. This result is substantiated by Northern blot analysis, which indicates that GAP-43 mRNA is expressed in the limbs transiently, from e5 to e9. Our results thus suggest a possible role for GAP-43 in limb development.

THE GROWTH ASSOCIATED PROTEIN, GAP-43, IS PRESENT IN DENDRITIC PROCESSES AND GROWTH CONES. M.I.Johnson and S.M.Schuh. Univ. of Ariz. Col. of Med., Tucson, AZ 85724 and Wash. Univ. Sch. of Med., St. Louis, MO 63110.

The membrane bound phosphoprotein, GAP-43, is elevated in axons and axonal growth cones during neuronal development and regeneration. In this study an in vitro model is utilized to determine whether GAP-43 is present in developing dendrites. Dissociated embryonic rat superior cervical ganglion neurons, maintained in serum free medium in the absence of nonneuronal cells elaborate primarily axonal processes (Bruckenstein and Higgins, 1988). After 3-7 days dendrite development was induced by addition of 25-50 µg/ml of Matrigel to the medium. Cultures were double stained immunocytochemically to simultaneously detect GAP-43 and dephosphorylated neurofilament proteins. Whenever a process was identified as dendritic by the presence of dephosphorylated neurofilament proteins, GAP-43 was also present. The fluorescence in dendrites was decreased in intensity compared to axons. As dendrites developed, neurofilament bundles were observed to fill the broad proximal segments of the dendrites, taper, and end at the base of the growth cone. GAP-43 was found in the entire dendrite including the growth cone. The difference in these results from those reported in hippocampal neurons (Goslin et. al., 1988) may be secondary to the different neuronal system. reported in hippocampal neurons (Goslin et. al., 1988) may be secondary to the different neuronal system, antibody, or antibody concentrations used.

339.5

ANTISENSE B-50 (GAP-43) PREVENTS NEURITE OUTGROWTH IN PC12 CELLS. P. Schotman*, E.R.A. Jap Tjoen San, M. Schmidt-Michels* and W.H. Gispen*, (SPON: European Neuroscience Association) Div. of Molec. Neurobiol. IMB, Dept. of Physiol. Chem., Rudolf Magnus Institute, University of Utrecht, Padualaan 8, 3584 CH Utrecht, The Netherlands.

It has become clear, that B-50 expression and its (trans)location into growth cone membranes correlate well with neuronal development, but

whether this is a prerequisite for neurite outgrowth, is still unknown. NGF-induced neuritogenesis was studied in PC12 cells. After 24 hrs of culture B-50 immune reactivity (B-50 IR) was determined with an B-50 ELISA and average neurite length of the same cells was determined

by video image analysis.

Using a small, antisense oligomer to B-50, we were able to specifically block the NGF-induced enhancement of B-50 IR. This treatment also prevented the NGF-induced neuritogenesis of the PC12 cells completely.

prevented the NGF-induced neuritogenesis of the PC12 cells completely. It has been reported that dexamethasone interferes with B-50 expression at the transcriptional level. Pretreatment of PC12 cells with dexamethasone interfered with the NGF-induced increase of B-50 IR and neurite outgrowth in a similar way as the antisense oligomer to B-50 IIR and neurite outgrowth in the NGF-induced B-50 expression in PC12 cells, either at the transcriptional level by dexamethasone or at the translational level by an antisense oligomer prohibited the NGF-induced neurite outgrowth of these cells.

We conclude that enhanced B-50 expression is a prerequiette for NGF.

We conclude that enhanced B-50 expression is a prerequisite for NGF-induced neurite outgrowth in PC12 cells. (Supported by The Centre for Developmental Biology, Utrecht NL).

PC12 CELLS DEVOID OF GAP-43 PROTEIN SYNTHESIZE A TRUNCATED FORM OF GAP-43 mRNA E.E Baetge 1, C.M.Sampson 1 J.P.Hammang 2 1CNS Molecular Biology, Bristol-Myers Squibb Pharm. Res. Inst. Wallingford, Ct 06492. 2 Univ. Wisconsin-Mad., Pathobio. Sci. Madison, WI. 53706. We have characterized a PC12 cell line, (PC12B), that is devoid of GAP-43 protein and mRNA as determined by immunocytochemical, westers and portbars blot analysis.

western and northern blot analysis.

western and northern blot analysis.

GAP-43 probed northern blots containing 10ug of Poly A+-mRNA isolated from PC12(B) cells revealed a diffuse mRNA hybridization signal that was more than 3 orders of magnitude lower than an equivalent amount of PC12(A)(GAP-43 containing) Poly A+-mRNA. In addition, the size was shorter by 100-200 nt. To further characterize these findings, RNA from PC12(A) and PC12(B) cells was reverse transcribed using random primers and PCR-amplified using oligonucleotides flanking the entire coding region of rat GAP-43. The predicted 708 bp GAP-43 coding sequence was amplified from both cells and both were identical to the published rat cDNA as determined by complete DNA sequence analysis. In contrast, when RNA was oligo-dt primed and amplified as above, the 708 bp coding fragment could only be amplified from PC12(A) RNA. Further analysis of PC12(B) RNA using a 3' PCR-oligo complementary to the last 24 nt of the 3'UT region of GAP-43 mRNA, did not produce the expected 1207 bp DNA fragment suggesting that these cells express a truncated mRNA missing a portion of the 3 UT region and lacking a poly A tail. The missing 3' end may predispose the truncated GAP-43 mRNA to rapid nuclear/cytoplasmic degradation thus preventing functional translation and expression of the GAP-43 protein.

NEURITE INITIATION AND THE ESTABLISHMENT OF POLARITY BY NEURONS *IN VITRO*. C.L. Smith and E.M. Munro*, Laboratory of Neural Control, NINDS, NIH, Bethesda, MD 20892.

Neurite formation signals the initiation of a neuron's differentiation and the establishment of its functional polarity. We are studying neurite formation by embryonic chick neurons grown *in vitro* in order to understand how the shapes and polarities of neurons are determined. Cultures of dissociated neurons are examined with video microscopy on an inverted microscope neutions are examined with video interestry of an inverted interestry.

The enclosed in an incubator. Our initial studies focused on regenerating dorsal root ganglion neurons. Although these neurons often retain a remnant of their original axon during dissociation, their axons usually disappear within 1 hour after plating. The neurons extend a flat, veil-like lamellipodium arround their anter planing. The heurous extented a riar, verlank attain planing around the entire circumference. Filopodia protrude from the lamellipodium. The first filopodium that contacts another cell often develops into a neurite. The filopodium develops a thickening at its base which moves centrifugally toward the tip. The thickened area often sprouts new filopodia as it moves. After the thickening reaches the tip, the process begins to elongate. Immunocytochemical staining of filopodia undergoing this transformation. Immunocytochemical staining of filopodia undergoing this transformation showed that the thickened area contained actin, microtubules and GAP 43, a protein known to be enriched in growth cones. Most sensory neurons developed only one or two neurites, but some became multipolar. Although sensory neurons appeared polarized prior to neurite formation, with eccentric nuclei and centrally-located centrosomes, the positions at which they formed neurites did not bear a consistent relationship to their initial polarities. However, if a neurite formed on the same side of the cell as the nucleus, then the cell body rotated so as to move the nucleus to the opposite side. Thus, the polarities of regenerating sensory neurons in vitro can be influenced by extrinsic factors. Preliminary observations on the initial outgrowth of processes from sympathetic ganglion neurons generated in vitro from dividing precursor cells indicate that the polarities of newly-generated neurons also can be influenced by their contacts with other cells.

DIFFERENTIAL EFFECTS OF ANTIBODIES TO PKC SUBSTRATE B-50 (GAP-43) AND KINASE INHIBITORS ON CALCIUM- AND PHORBOL ESTER-INDUCED NA RELEASE FROM PERMEATED SYNAPTOSOMES. P.N.E. DeGraan, J.J.H. Hens*, L.V. Dekker*, M. De Wit, A.B. Oestreicher* and W.H. Gispen*. Div. Mol. Neurobiol., Rudolf Magnus Inst. and Inst. Mol. Biol. and Med. Biotechnol., Univ. of Utrecht, Padualaan 8, 3584 CH Utrecht, NL.

Antibodies raised against the neuron-specific growth-associated protein B-50 (GAP-43) inhibit protein kinase C (PKC)-mediated phosphorylation of B-50 and Ca²⁺-induced ³H-noradrenalin (NA) release from Streptolysin-O permeated Ca⁻-induced normal (NA) release from surprovising permeated synaptosomes (Dekker et al., <u>Nature</u>, 342: 74, 1989). The present study was designed to characterize Ca⁺- and phorbol ester-induced NA release from highly purified permeated synaptosomes and to study possible differences between the two secretagogues using anti-B-50 antibodies and kinase inhibitors. Both secretagogues induce a concentration-dependent release of NA; their stimulatory effects are not additive. Anti-B-50 IgG completely inhibits Ca²⁺-induced release, but has only minor effects on phorbol ester-induced release. The kinase inhibitors but has only finited release in the finish the first but has been made infinited by the first but and polymyxin B, which inhibit B-50 phosphorylation, inhibit phorbol ester-induced release, but only polymyxin B attenuates Ca²⁺-induced release. Our data indicate that Ca²⁺ and phorbol esters stimulate NA release through different mechanisms. Alternatively, besides phosphorylation, other properties of B-50, such as calmodulin binding, may also be important for the regulation of NA release from permeated synaptosomes. To investigate this latter possibility we studied B-50/calmodulin binding. With homobifunctional crosslinkers we identified a 70 kDa B-50/calmodulin complex in vitro and in synaptosomal plasmamembranes. The complex is only formed in the absence of Ca²⁺ and is not found after prephosphorylation with PKC. Our data are in line with the hypothesis that both B-50 phosphorylation and calmodulin-binding are regulatory factors in NA release.

THE C6 GLIOMA CELL LINE EXPRESSES THE GROWTH-ASSOCIATED PROTEIN GAP-43 IN A DEVELOPMENTALLY REGULATED FASHION.

J.P. Hammang, A. Messing and E.E. Baetge.

University of Wisconsin-Madison, School of Veterinary Medicine,
Madison, Wi. 53706 and CNS Molecular Biology, Bristol-Myers

Squibb Pharmaceutical Research Institute, Wallingford, Ct. 06492.

The growth-associated protein, GAP-43, is expressed in developing neurons during axonal outgrowth and in peripheral neurons during regeneration. This membrane-associated phosphoprotein is particularly concentrated in the axonal growth cones and is involved in various aspects of synaptogenesis and synaptic function. Until recently, this protein was considered neuron-specific. However, new evidence suggests that the GAP-43 protein is expressed in primary cultures of neonatal rat cortical astrocytes (Vitković et al., <u>PNAS</u> 85 1988). As these astrocytes differentiate in culture, GAP-43

The C6 glioma cell line has been studied extensively as a model system for glial differentiation. This differentiation can be induced with the addition of dBcAMP to the culture medium. We report that monolayer cultures of C6 glioma cells (35-45th passages) express GAP-43 mRNA and protein and low levels of GFAP. When the cells are treated with 1 mM dBcAMP, GAP-43 protein levels fall as GFAP levels rise. The C6 line should prove to be a valuable model system for investigating the role of the GAP-43 protein in glial development.

Electrophysiological Properties of GAP-43-Containing and GAP-43-Negative PCl2 Cells Exposed to NGF. Valentin K. Gribkoff¹, E. Edward Baetge², and Joseph P. Hammang³. CNS Pharmacology¹ and Molecular Biology², Bristol-Myers Squibb Pharm. Res. Institute, 5 Research Parkway, Wallingford, CT 06492, and Pathobiol. Sciences³, Sch. Veterinary Med., Univ. of Wisconsin-Madison, Madison, WI 53706.

PC12 cells differentiate into neurons when exposed to NGF. During the process of differentiation, neurites are formed and the cells become capable of forming functional synaptic contacts. PC12A cells contain GAP-43, and it has been shown that levels of this protein are elevated by NGF, leading to the conclusion that GAP-43 plays an important role in the response to NGF. Recently, a mutant cell line (PC12B) was characterized that does not contain GAP-43 or functional GAP-43 mRNA, yet which responds to NGF with neurite extension and by expressing other neuronal characteristics (see abstract by Baetge et al.). Using intracellular recording techniques, we have begun to characterize these cell lines electrophysiologically. PC12A cells (n=26) had Vm $(\bar{x}\pm sem)$ = -51.4 \pm 2.8 mV; PC12B cells (n=25) had Vm ($\bar{x}\pm$ sem)=-51.5 \pm 2.2 mV. The input resistance of all cells exceeded 100 M Ω . No cells exhibited spontaneous action potentials, and clearly-defined postsynaptic potentials were not observed. In response to depolarizing intracellular current injection most PC12A cells (23/26) responded with a well developed action potential; fewer PC12B cells (10/25) displayed current-evoked action potentials under these conditions.

339.11

EVIDENCE THAT NEUROMODULIN (GAP-43, B-50, pp46, F1) IS NOT ESSENTIAL FOR EARLY NEURITOGENESIS. J.T. Megerian, W.L.Klein Evanston IL. 60208

Neuromodulin is a calmodulin binding protein found in developing neurites and the presynaptic endings of certain adult brain regions. Its role is unclear, having been implicated in axon outgrowth, neurotransmitter release, and plasticity of adult synapses. We report here evidence against a adult synapses. We report here evidence against a requirement for neuromodulin in neurite outgrowth. Mouse and human neuroblastoma cells were cultured in conditions promoting and inhibiting neurite growth and examined for the presence of neuromodulin using a monoclonal antibody (courtesy of J.H.P. Skene) capable of recognizing four known isoforms. Immunoblots and cell fluorescence showed neuromodulin was present equally in neurite promoting and inhibiting cultures. In cultures lacking neurites, neuromodulin appeared in a halo around the periphery of the cell. suggesting appeared in a halo around the periphery of the cell, suggesting association with the plasma membrane. A second study looked at the production of neuromodulin in 1 day old cultures of E15 rat basal forebrain cells. These cultures contained cells undergoing a neuroblast- neuron transition and sprouting neurites de novo. Immunofluorescence showed that 80% of the cells that had neurites lacked neuromodulin. Double labeling showed that neurofilament was present in many of the neurite-positive, neuromodulin-negative cells. The two studies are consistent with the hypothesis that neuromodulin is neither sufficient nor necessary for early neurite outgrowth.

RELATIVE DISTRIBUTIONS OF KINASE C-PHOSPHORYLATED AND NON-PHOSPHORYLATED FORMS OF GAP-43 IN THE ADULT NERVOUS SYSTEM. J.E.Schwob & K.F.Meiri. Depts. Anatomy & Cell Biology and

Pharmacology, SUNY Health Science Center, Syracuse NY 13210.

The neuron-specific protein GAP-43, which is highly enriched in the membrane skeletons of growth cones, is also found in the pre-synaptic terminal in parts of the adult nervous system where it is a substrate for protein kinase C. While information about the distribution of GAP-43 is available from studies utilizing polyclonal antisera, nothing is known of the relative distribution of phosphorylated vs. non-phosphorylated forms. To address this issue we have used the monoclonal antibodies 2G12, which is specific for the kinase C phosphorylated form of GAP-43, and 10E8, which recognizes both phosphorylated and nonphosphorylated forms (Meiri and Schwob, presented at this meeting). While the distribution of 10E8 immunoreactivity resembles that described previously using antisera, the relative amount and distribution of the kinase C phosphorylated form varies between neuronal types. For example, the spatial distributions of kinase C phosphorylated and unphosphorlyated GAP-43 are similar in the neuropil of the adult cerebral cortex, (in contrast with the differences seen in the developing cerebral cortex, Meiri and Schwob, this meeting), although the intensity of the 2G12 immunoreactivity is consistently less. Conversely, in both sympathetic and parasympathetic postganglionic axons of the adult autonomic nervous system, little if any 2G12 immunoreactivity is detectable under normal conditions, despite the presence of 2G12 immunoreactivity during the initial innervation of the target organs in the embryo. These results demonstrate that in the adult nervous system, as during axonogenesis, the regulation of GAP-43 by kinase C phosphorylation s under complex control.

LOCALIZATION OF GAP-43 mRNA IN RAT CEREBELLUM AND IN BRAINSTEM NUCLEI PROJECTING TO THE CEREBELLAR CORTEX: A DEVELOPMENTAL STUDY. Linda Console-Bram. 1 James G. McElligott. 2 1 Temple University, Dept. of Pharmacology Phila PA.

Distribution of GAP-43 within the cerebellum has been shown to coincide with early postnatal development and synaptogenesis. Within the first two weeks after early postnatal development and synaptogenesis. Within the first two weeks after birth, rat cerebellar cortex undergoes extensive remodeling leading to the formation of three distinct layers. Our study was designed to determine the location of GAP-43 mRNA, employing an 35S-labeled oligonucleotide probe, in the cerebellum and brainstem nuclei projecting to the cerebellum in both immature and adult rats. At postnatal day (PD) 6-7, the GAP probe was found to hybridize strongly in the molecular layer (ML) and moderately in the internal granule cell layer (IGL). Expression of GAP-43 mRNA in the ML during this time period corresponds to the descent of granule cells from the premigratory zone to the IGL. The olivary nuclear complex in the brainstem, the source of cerebellar climbing fibers (CF), also exhibited intense hybridization. Both the external germinal cell layer and Prukinje cells were devoid of GAP message. By PD 21, GAP-43 message was confined to the granule cell layer of the cerebellum. The olive remained positive for GAP-43 mRNA but with a reduction in hybridization in comparison to that of the first postnatal but with a reduction in hybridization in comparison to that of the first postnatal week. In the adult rat, hybridization patterns were similar to those found at PD 21. Previous studies demonstrated the presence of GAP-43 protein in the ML of both immature and adult rats and GAP-43 mRNA in granule cells of adult rats. Since this study is the first to demonstrate GAP-43 mRNA in both granule and olivary cells of immature and adult animals, GAP-43 protein in the ML is most likely derived from two sources: parallel fibers (PF) and CF. This study supports developmental regulation of GAP-43 expression in the central nervous system as the most intense hybridization was observed during periods of axonal outgrowth and synaptic organization within the cerebellum. Because GAP-43 is also thought to be associated with synaptic plasticity, the presence of GAP-43 mRNA in the adult rat suggests that the PF and CF synapses may continue to be plastic in adults.

MONOCLONAL ANTIBODIES DEMONSTRATE THE REGULATION OF GAP-43 AMOUNT AND PHOSPHORYLATION BY KINASE C DURING AXONOGENESIS IN VIVO. K.F. Meiri & J.E. Schwob. Depts. Pharmacology & Anatomy & Cell Biology, SUNY Health Science Center, Syracuse NY 13210.

The neuron-specific protein GAP-43 is highly enriched in the membrane skeletons of growth cones and is a substrate for protein kinase C. Initial studies in vivo determined that GAP-43 synthesis is induced during axonogenesis but did not provide a precise temporal correlation with the onset of axon out- growth, nor did they investigate the role of kinase C phosphorylation in this process. We have generated a panel of monoclonal antibodies monospecific for GAP-43 that are able to discriminate between GAP-43 that has been phos- phorylated by kinase C (exemplified by 2G12) and GAP-43 that has not (exemplified by 10E8). We have used these antibodies to study early axon outgrowth in vivo and have obtained two major results.

First, with regard to kinase C phosphorylation of GAP-43, the phosphorylated form is spatially restricted to the distal axon and growing tip; it is never seen in either cell bodies or dendrites, even those that contain unphosphorylated GAP-43. Kinase C phosphorylation of GAP-43 is also temporally restricted and occurs subsequent to the onset of axonogenesis. Furthermore, the lag between the onset of axon outgrowth and the appearance of phosphorylated GAP-43 in different types of neurons is variable

Second, with regard to the amount of GAP-43 present during axonogenesis, 10E8 immunoreactivity is present at the onset of axonal growth in those types of neurons that we have examined. Taken together these results indicate that the regulation of GAP-43 and hence its role in axon outgrowth is more complex than previously appreciated, and emphasize that the process of axon outgrowth is likely to have multiple components.

DEPENDANCE OF AXONAL BRANCHING AND GROWTH CONE STRUCTURE ON THE TARGET CELL. S.A. Berman and S. Bursztajn. Baylor College of Medicine and M.D. Anderson Cancer Center. Houston, Tx 77030

The growth cone is a crucial structure which guides neuronal growth in response to environmental cues and appropriate targets. It has been shown that GAP43, a neuron specific growth-associated phosphoprotein, is selectively distributed in axons of growing neurons and their growth cones, but is absent from dendrites. We have utilized an antibody to GAP43 and immunofluorescent microscopy to determine the changes in growth pattern and polarity the growing neurons undergo when they contact a "proper" target. We have used ciliary neurons, cocultured with myotubes or plated alone, since these neurons form functional synapses with myotubes. Our results show that ciliary neurons plated alone have bipolar or tripolar axons, but when cocultured most cells have 4 or 5 axons showing GAP43 immunoreactivity. The mean number of axons per cell soma was 1.9 ± 0.1 (SEM) when ciliary neurons were plated alone, and 3.4 ± 0.1 when ciliary neurons were cocultured with myotubes. Differences in growth cone behavior was readily apparent in these two types of cultures. The size occupied by the neuronal growth cone lamelopodia showed significant differences. The majority of growth cone lameiopodia in coculture were 20-30 µm² with an average area of $25.0\pm2.3\mu\text{m}^2$ (SEM), whereas those neurons plated alone occupied an average area of $56.3\mu\text{m}^2$. The number of filopodia of the growth cones depended on culture conditions. In neuronal occultures, the average number of filopodia per growth cone was 3.6+ 0.2(SEM), whereas in ciliary cultures the number of filopodia was 6.8 ± 0.4 (SEM). These results suggest that muscle cells or the factors they release can regulate the growth and topography of axons and their

ELEVATED LEVELS OF EXPRESSION OF GAP-43 AND CALCYCLIN mrnas during tra-induced differentiation of a human NEUROBLASTOMA CELL LINE. G. Allan, * J.M. Moerschbaecher, III and N.G.

Bazan. LSU Eye Center and Neuroscience Center, New Orleans, IA 70112.
The cell line SH-SY5Y undergoes morphological differentiation in response to 13-O-tetradecanoyl-12-phorbol acetate (TPA) as characterized by neurite extension. Maximal neurite extension is achieved after 7-8 d exposure. In the present study, however, we show that the mRNA coding for GAP-43, a protein associated with growth cones and nerve endings undergoing remodeling, dramatically increases in SH-SY5Y cells exposed to 10ng/ml TPA for 24 h and does not rise above these levels over an interval of 8 d. We also note that there is a low but significant level of GAP-43 mRNA in the untreated cells. While this expression can be explained by the low level of spontaneous neurite extension observed, we also observe a similar level of GAP-43 mRNA in the retinoblastoma cell line Y79, which exhibits no overt signs of neurite extension. TPA treatment of the neuroblastoma line also elevates levels of the mRNA coding for calcyclin, a putative calcium-binding protein specific for the G_1 phase of the cell cycle. This suggests that the increase in GAP-43 mRNA in these cells is accompanied by significant alterations in cell-cycle kinetics. By contrast, levels of cyclophilin mRNA, which encodes a constitutive 'house-keeping' protein, do not change over this time course. We have previously shown that the lipid mediator platelet-activating factor (PAF) elevates calcyclin mRNA expression in the same cell line, and that TPA and PAF activate c-fos expression in an additive manner. Thus it may be that there are convergent pathways acting in response to differentiating signals and signals of cell damage, which trigger neuronal regeneration (some neuroblastoma cell lines respond to PAF osure with a differentiation response). We are currently studying the effects of factors on the differentiation/regeneration response of this system. Supported by NIH grant NS23002.

POSTTRANSCRIPTIONAL REGULATION OF GAP-43 mRNA LEVELS DURING PROCESS OUTGROWTH. N. I. Perrone-Bizzozero, N. Irwin*, S. E. Lewis, I. Fischer*, R. L. Neve and L. I. Benowitz McLean Hosp. (Belmont, MA, 02178), Harvard Med. Sch., E. K. Shriver Center and U.C. Irvine

The expression of GAP-43 is a well-characterized correlate of the growth and reorganization of neural connections. Although the expression of the protein is known to depend on the mRNA levels, the mechanisms that control the latter are poorly understood. Using Northern blots and nuclear run-on assays, we analyzed the synthesis and accumulation of GAP-43 mRNA in (a) developing rat cortical neurons, (b) the regenerating goldfish optic nerve, and (c) NGF-induced PC12 cells. In all of these instances, significant levels of the nascent transcript were detected even when cells were not growing, and this changed little during differentiation. These data suggested that GAP-43 mRNA levels are regulated via a transcription-independent pathway. To begin to study the nature of the mechanism(s) involved, we examined the half-life of the mRNA in naive and NGF-treated PC12 cells. Experiments using pulse-chase labeling or actinomycin D treatment both showed that NGF induced a 3-fold increase in the stability of the mRNA. Thus, changes in the rate of degradation of the mRNA seem to be the key control mechanism that regulates GAP-43 levels during neurite outgrowth. The presence of putative instability-conferring sequences in the 3' untranslated region of GAP-43 mRNA lends further support to this possibility. PEPTIDE-IMMUNOREACTIVE FIBERS IN HIPPOCAMPUS FOLLOWING SEPTAL LESIONS. R. Loy, D. Heyer* and M. Johnson. Dept. Neurology, Univ. Rochester Sch. Med., Rochester, NY 14642 and Dept. Neurobiology, Harvard Med. Sch., Boston, MA 02115.

Septal deafferentation of the rat hippocampus leads to ingrowth of noradrenaline (NA)-containing collaterals of vascular sympathetic fibers. In normal cerebral vascular afferents, neuropeptide Y (NPY) is co-localized with NA. We have investigated whether or not NPY immunoreactivity (NPYir) is also present within putative sympathetic fibers in the hippocampus following septal lesions. In addition, we have evaluated adjacent sections for substance P (SPir), as this peptide nave evaluated adjacent sections for substance P (SPIT), as this peptide is present in sensory fibers innervating the cerebral vasculature. Rats received aspiration lesions of the medial septum 4 days after birth and were allowed to survive 3-10 weeks. Sections from normal and lesioned brains were stained free-floating in NPY (Incstar, 1:1000), SP (Incstar, 1:500), or in nerve growth factor receptor (NGFR, 192-IgG, 1 µg/ml, courtesy of P.S. DiStefano). In lesioned brains, both NPYir and SPir fibers are associated with penetrating and fine collateral blood vessels adjacent to the hippocampal fissure and within the parenchyma. These are not as numerous, however, as fibers immunoreactive for NGFR, which are present in a characteristic pattern along the granule and pyramidal cell layers, as well as adjacent to blood vessels. While it remains to be determined if the SP- and NPY-containing fibers are in remains to be determined it the SP- and NPT-containing fibers are in fact peripheral in origin, or if all sympathohippocampal fibers contain both NA and NPY, it appears likely that reorganization of pathways containing these peptides occurs following septal deafferentation.

ALTERED PHOSPHORYLATION OF A GROWTH-ASSOCIATED PROTEIN (GAP-43) IS ASSOCIATED WITH LESION-INDUCED TERMINAL SPROUTING IN THE CNS. L. H. Lin*, B. Costello*, and J. J. Norden.

Dept. of Cell Biology, Vanderbilt University, Nashville, TN 37232.

Reactive synaptogenesis, a widely used model of synaptic plasticity known to involve axon growth, was induced in the hippocampus by lesioning the ipsilateral entorhinal cortex in rats. Decreased in vitro phosphorylation of GAP-43 was observed in ipsilateral dorsal hippocampal tissue from animals sacrificed at 4 days(when terminal proliferation begins), 6 days (maximal terminal proliferation) and 30 days (synaptogenesis ends) following entorhinal cortex lesions, as compared to that of the contralateral dorsal hippocampi of the same animals. The amount of GAP-43 in the hippocampus also was determined since a change in the observed incorporation of 32P may represent a change in the amount of substrate protein available for phosphorylation. A significant decrease in GAP-43 levels in the ipsilateral hippocampus was seen 2-3 days following lesion. Levels of GAP-43 in ipsilateral hippocampi were lower but not significantly different from that of contralateral sides at 4, 6, 15, 30, 60, and 120 days following lesion. When the phosphorylation of GAP-43 was expressed as incorporation of ³²P per unit of GAP-43, a significant expressed as incorporation of ³⁴P per unit of GAP-43, a significant decrease was observed in the ipsilateral hippocampi of animals sacrificed 6 days following lesion, but not at 4, 15, 30, 60, and 120 days post lesion. This decrease in *in vitro* phosphorylation coincides with the period of maximal proliferation of presynaptic terminals. These data suggest that GAP-43 phosphorylation state is associated with lesion-induced axonal growth in the CNS of adult mammals. (Supported by NIH Grant NS25150 to JJN)

ASTROCYTES MAY BE INVOLVED IN THE HOMOTYPIC SPROUTING OF S-HT FIBERS IN THE HIPPOCAMPUS, F.C. Zhou, and S. Bledsoe. Department of Anatomy, Indiana University School of Medicine, Indianapolis, IN 46202 We have previously reported that partially removing 5-HT fibers in the hippocampus induced a homotypic sprouting (Zhou & Azmitia, Brain Res, 1984, 1986). Extract from partially denervated hippocampus increased the survival, fiber growth and transmitter level of fetal 5-HT neurons when grafted in adult brain for bioassay (Zhou et al., J. Neurosci. Res. 1987; Zhou & Azmitia, Brain Res., 1990). A sprouting factor, SNTF, is being proposed in this experimental model. We currently report that the sprouting of 5-HT fibers can be induced directly by removing neurons in the hippocampus. The role of astrocytes on release of SNTF and sprouting of 5-HT fibers are hypothesized. Ibotenic acid (IB) injected into hippocampus of Sprague-Dawley rats removes the intrinsic neurons. Three days after IB-lesion, the intrinsic neurons in the hippocampus had degenerated in the injection site as shown by Nissi staining, Immunocytochemistry showed that two patterns of laminin immunostaining were increased, small punctiform in the granular layer, and the sheath form on the vessel; neo-microvessels were observed; reactive astrocytes elevated glial fibrillary acidic protein (GFAP) level; double immunostaining of laminin and GFAP showed that the small punctiform laminin was produced by astrocytes; mearmythle, the 5-HT fibers retained similar fiber density. At 8-day stage, both patterns of laminin continued at elevated levels, Astrocytes expressed high activity of GFAP, and 5-HT fiber density was highly increased in the hippocampus with a similar innervation pattern. The hyperinnervation reduce to a less degree but sustained above normal scale at the stage 24 days after lesion. The 5-HT inneravation pattern maintained in the same manner of normal without the local target nervons. A number of important result were observed in this study (a) astro

Axonal Sprouting Induced by Striatal Implants of Genetically Modified Fibroblasts that Produce Nerve Growth Factor in vitro. M.D. Kawaja¹, M.B. Rosenberg², K. Yoshida¹, T. Friedmann^{2*}, and F.H. Gage¹. Depts. of Neurosciences 1 and Pediatrics 2, University of California, San Diego, La Jolla, CA 92093

Dolla, CA 92093

Cultured skin fibroblasts of Fischer 344 rats were infected with a retroviral vector containing the cDNA for mouse nerve growth factro (NGF). These cells synthesized and released NGF in vitro. The purpose of this study was to assess the biological effects NGF-producing fibroblasts have in the adult rat nervous system. Female Fischer rats received implants of genetically modified (NGF-producing) primary fibroblasts into the right striatum; uninfected primary fibroblasts or those infected with a retroviral vector containing the cDNA for E. coli 6-galactosidase were implanted into the left striatum. At 1, 2, 3, and 8 weeks after grafting, the rats were perfused, and sections of their brains were processed for immunocytochemistry and electron microscopy. At 1, 2, and 3 weeks, a modest to robust aberrant plexus of NGF receptor-positive axons was found adjacent to the right striatal grafts. NGF receptor-positive axons were not observed adjacent to or within left striatal fibroblast grafts. Also, aberrant monoaminergic striatal inputs were not seen near the right or left striatal grafts. Ultrastructural data revealed that all grafts were composed of fibroblasts and collagen, and possessed numerous capillaries. Small, unmyelinated axons were evident near the grafts in the right striatum only. Axonic profiles within these grafts were surrounded by astrocytic processes and/or Small, unmyelmated axons were evident near the gratts in the right striatum only. Axonic profiles within these grafts were surrounded by astrocytic processes and/or basal lamina. These results reveal aberrant sprouting of NGF receptor-positive axons in response to NGF, putatively released from genetically modified fibroblasts grafted into the striatum. These axonic profiles later penetrate the grafts within host-derived astrocytic sheaths. Our data provide evidence for NGF-induced tropism in vivo and new insight into the substrates that promote axonal sprouting in the adult rodent central nervous system. (Supported by the N.I.A.)

PRUNING AND REGENERATIVE CAPACITY IN THE CNS IS ALTERED IN PERINATALLY MORPHINE-EXPOSED RATS.A.Gorio, Giulio, B.Tenconi*, M.L.Malosio*, M.L.Donadoni*, S.De Biasi* and F.Cattabeni.Dept. of Med.Pharmacol., Inst. of Pharmacol. Sci.; Dept. of General Phisiol. and Biochem.; Univ. of Milano, Italy.

The major aim of this laboratory in the past several years has been centered upon neuronal plasticity and regeneration both in normal and pathological conditions. More recently we have focused our attention on brain plasticity in rats perinatally exposed to morphine. The most striking effects of the treatment were confined to the development of the striatal innervation, with reduced dopaminergic innervation and hyperinnervation by metenkephalinergic neurons. No traces of morphine were ever found in the brain of treated animals. Following neonatal lesions by the neurotoxin 5,7-HT the serotoninergic neurons of morphine-exposed rats did not show any pruning capacity, while the rate of regeneration was slightly reduced. In addition, these animals showed a higher susceptibility to neurotoxic lesions compared to control animals. Our hypothesis is that some permissive factor is present in insufficient

CHANGES IN DORSAL AND MEDIAN RAPHE NEURONS DURING LESION-INDUCED REORGANIZATION OF THE AREA DENTATA SEROTONERGIC PLEXUS. J.H. Haring, J. Young*, A. Bartoli* &

Bergeron*. Dept. Anat. & Neurobiol., St. Louis Univ., St. Louis, MO 63104. Six weeks after partial lesions of the median raphe (MRN) a proliferation and reorganization of serotonergic (5HT) axons is seen in the area dentata (AD) using nocytochemistry (Haring, Soc. Neurosci. Abstr. 1595, '88). This re mediates the recovery of 5HT content to low normal levels (Marshall & Haring, Soc. Neurosci. Abstr. 15:90, 89). The purpose of this study was to determine what, if any, changes were occurring in the dorsal raphe (DRN) and MRN during the 6 weeks following partial MRN lesion.

Adult, male, Sprague-Dawley rats were anesthetized with nembutal and injected with 5,7 DHT (3ug in 250nl artificial CSF) in the caudal MRN. Control rats were injected with vehicle. The status of MRN and DRN neurons with projections to the dorsal AD was studied by fluorescent retrograde tracing at 2 and 6 weeks post-lesion. The cross-sectional area of MRN and DRN 5HT-immunopositive neurons was studied at 2, 4 and 6 weeks. No significant change has been detected in either numbers or distribution of MRN and DRN neurons with projections to dorsal AD 2 and 6 weeks post-lesion except for the MRN cell loss. A few cases appeared to have a rostral shift in the distribution of DRN neurons, but tracer spread into overlying cortex accounts for this result. A significant increase in the area of 5HT neurons of both MRN and DRN was seen at 2 weeks. AT 4 and 6 weeks MRN and DRN cell areas were in the normal range. These data suggest that recovery of the AD 5HT plexus is mediated only by AD-projecting cells that survive the lesion. Changes in MRN and DRN cells correspond to the time of increased cell activity following the lesion, but the cells are normal at the time when sprouting is most evident in the AD. Support: NS25752.

INCREASE OF THE PRIMARY AFFERENT INPUT TO AUTONOMIC AREAS OF THE RAT SACRAL CORD AFTER NEONATAL SPINAL TRANSECTION. K.Chung. School of Allied Health Sciences & Marine Biomedical Institute, Univ. of Texas Medical Branch, Galveston, TX 77550.

The present study examines the plasticity of the primary afferent input to the lumbosacral spinal cord of the rat after neonatal spinal transection. The antibody against calcitonin gene-related peptide (CGRP) is used as a primary afferent marker. In neonatal rats, spinal transection is performed under hypothermic anesthesia. Controls are litter mates subjected to a sham operation. All operated rats are returned to the mother and then raised to adulthood. Three-four months after operation, the animals are perfused with 3% paraformaldehyde, 3% glutaraldehyde in 0.1M phosphate buffer. The L6 and SI segments are removed, vibratome sectioned, and immunostained for CGRP by peroxidase-antiperoxidase method. CGRP immunoreactivity in the sacral autonomic areas of the cord in the neonatal spinal transected rats is greatly increased compared to that of the control litter mates. Data suggest that many more primary afferent terminals led in the autonomic areas of the spinal cord. (supported by NS11255)

A STRIATAL-DERIVED NEURONOTROPHIC FACTOR: ENHANCEMENT BY CHRONIC HALOPERIDOL TREATMENT.

P.M. Carvey, L.R. Ptak J.M. Kerns, D.K.
Sierens*, H.L. klawans*. Rush Medical college,
Crude extracts of rat striatal tissue, contain a neuronotrophic factor (NTF) which induces dopamine (DA) neuron growth, as well as functional activity (DA uptake), in a dose-dependent fashion when added to rat E-13 mesencephalic cultures. Boiling the extract removes this activity. Extracts from animals with unilateral kainic acid lesions of the striatum produce significantly less growth in culture than extracts from the contralateral striatum. We therefore examined the effects of chronic halpoperidol (HAL) or amphetamine (AMPH) treatment on the growth effect extracts have in culture to apmonorphine by 1 month chronic HAL (1.25 mg/kg) treatment, enhanced growth and DA uptake in culture relative to saline treated controls. Extracts from chronic AMPH (2.5 mg/kg) treated animals had the opposite effect. The growth effect therefore appears to be inversely related to chronic DA tohe. Electron microscopic examination of the striatum (dorsolateral) in 4 of these animals revealed that HAL treatment led to an 18% increase in the overall number of perforated synapses suggesting alterations in heuronal cytoarchitecture. This data suggests that HAL induced increases of a striatal-derived DA NTF and its subsequent effect on synaptic plasticity may, in part, be responsible for the development of DA hypersensitivity behaviors.

METAMORPHIC REORGANIZATION OF TRIGEMINAL MOTONEURONS IN RANA PIPIENS. F.F. Omerza* and K.E. Alley. Ohio State University, Columbus, OH 43210.

During metamorphosis trigeminal motoneurons of R. pipiens larvae are redeployed from degenerating larval myofibers to newly formed adult myotubes. The objectives of this study were to describe: 1) the ontogeny of neuromuscular junctions (NMJs) and 2) the transfer of axonal processes from larva to adult. Ag/AChE histochemistry was used to identify NMJs. The morphometric analysis of NMJs consisted of an assessment of the following parameters: synaptic length, synaptic density and the number of polyinnervated NMJs. Examination of 647 synapses on 101 myofibers from 24 animals demonstrated that both synaptic length and density expanded during early and mid-larval stages reaching a plateau in late larval and metamorphic stages. In contrast, NMJs containing multiple axons peaked during the late larval period and then declined. A striking feature, evident on observation of the staining patterns of larval and adult muscles, was the redistribution of the synapses. In the larva NMJs were diffusely distributed, whereas in early juveniles the banded adult pattern was already evident. In order to examine axonal transition we followed the cellular features of the trigeminal motor terminals during myofiber turnover. In an analysis of 725 adult NMJs, a vast majority of innervation (91%) occurred by means of nerve sprouts that arose from the neighboring larval junctions while only a small contingent (09%) arose as collateral branches off the preterminal axon. These observations demonstrate that new adult NMJs received innervation from axons previously distributed to larval myofibers and suggest that the premetamorphic elevation of synaptic length, density and polyinnervation may ready the motor axons for the rapid redeployment to new adult fibers.

MK-801 INDUCES AN INCREASE IN CENTRAL AND PERIPHERAL CGRP IMMUNOSTAINING WITHOUT ALTERING PERIPHERAL CGRP IMMUNOSTAINING WITHOUT ALLERING PRIMARY AFFERENT NEURONAL NUMBERS. <u>D.L. McNeill, K.A. Sharkey, R.E. Papka, J.M. Galbraith</u>, and R.L. Shew. Dept. of Anat. Sci., Univ. of Oklahoma, Oklahoma City, OK 73190 and Dept. of Med. Physiol., Univ. of Calgary, Calgary, AB, Canada MK-801 induces an increase in the density and distribution of CGRP

immunoreactive (IR) fibers in the rat dorsal spinal cord. In the present study, the increase in CGRP-IR following MK-801 treatment was quantified in the dorsal spinal cord and dorsal root ganglia (DRG). In addition, the stomach and distal ileum were examined to determine if a similar increase in CGRP-IR occurred in peripheral processes of DRG neurons. Five Sprague-Dawley rats received 1.0 mg/kg/day of MK-801 for 30 days. Four additional untreated rats served as controls. On day 30, 30 days. Four auditional untreated rats served as controls. On day 30, rats were perfused and the L5 DRG, L5 spinal cord, stomach and ileum were removed and immunostained for CGRP. Image analysis revealed a significant increase in CGRP-IR in the dorsal grey commissure (p < 0.05) and deep dorsal horn laminae (p < 0.01) in MK-801 treated rats. the number of CGRP-IR neurons in the DRG was not significantly different between the two groups. Furthermore, there was an apparent increase in the number of CGRP-IR nerves in the stomach of MK-801 treated animals, but no difference in CGRP-IR in the ileum. These data indicate that MK-801 induces an increase in CGRP-IR processes of DRG neurons, both central and peripheral, without a concomitant change in the number of CGRP-IR perikarya. SYNAPTIC PLASTICITY IN LAMINA II OF DEAFFERENTED SPINAL CORD. B.Zhang , M.E.Goldberger, L.-F.Wu*, and M.Murray. Dept. Anatony, Medical College of Pennsylvania, Phila., PA 19129 and Dept. Histology, West China University of Medical Sciences, Chengdu, Sichuan, PRC

Projections to the dorsal horn change in adult mammals after complete or partial deafferentation. We are using quantitative EM to study the related changes in specific classes of terminals in the dorsal horn. We first examined complex terminals (CT) which originate from dorsal roots. The CT and the post-synaptic densities (PSD) associated with CT were measured in lamina II of L5 and L6 in cats subjected to unilateral spared root (L6) dorsal rhizotomies and compared to CT in the control side. After acute partial deafferentation, the number of CT decreased but the length of their PSD increased. Later the number of CT was restored and both the number and length of PSD were number of C1 was restored and both the number and length of PSD were increased. The changes in CT suggest reactive reinnervation (sprouting) from the spared dorsal root fibers. Spared root deafferentation thus elicits compensatory changes in presynaptic terminals of the spared root and also in post-synaptic neurons. After complete lumbosacral deafferentation, the number of synaptic terminals remains constant, indicating replacement of lost dorsal root terminals by newly formed terminals from spared intrinsic systems. Quantitative LM immunocytochemistry has shown marked changes in densities of SP and 5HT projections which may permit identification of the replacement terminals with EM immunocytochemistry.

DIRECTIONAL SPROUTING AT ENDPLATE SITES ON INTACT MUSCLE FIBERS IN RESPONSE TO DAMAGE OF NEARBY MUSCLE FIBERS IN LIVING MICE. P. van Mier and J.W. Lichtman, Dept. Anat. & Neurobiol., Washington Univ. Sch. Med., St. Louis, MO 63110.

In muscles in which some fibers had unintentionally been injured, we

& Neurobiol., Washington Univ. Sch. Med., St. Louis, MO 63110.

In muscles in which some fibers had unintentionally been injured, we were surprised to observe sprouts originating from nerve terminals on healthy muscle fibers. To determine more precisely what the sprouting stimulus was, we used a laser ablation technique to destroy single muscle fibers in living mice. In each sternomastoid muscle (N=26) one vitally stained muscle fiber was damaged by exposing it to 1-15 laser pulses (3 nsec, 503 nm), focussed through the microscope (spot diameter < 1 \mum.) The sites of laser damage were at least 300 \mum from the endplate band to avoid axonal or nerve terminal injury. Seconds after laser irradiation evidence of striations began to disappear in the treated fiber, and by 2 d. such muscle fibers had completely degenerated. Typically, the nerve terminal on the damaged muscle fiber retracted within 2 d. after ablation (see Rich & Lichtman 1989, Neuron 3:677-688). Within 3-4 d. a new muscle fiber was generated within the original basal lamina ghost. In 15 muscles (57%), at the time the new muscle fiber was being generated, nerve terminals on the muscle fibers immediately adjacent to the ablated muscle observed over time sprouts rarely occurred (<1 per 100 endplates). In 14 of the laser damaged muscles (93%), the sprouts were either directed towards or already growing on the newly forming muscle fiber. In 2 of these muscles, nerve terminals on nearby but not adjacent muscle fibers also extended sprouts towards the young muscle fiber. The results of our experiments show that nerve terminals nearby damaged and regenerating muscle fibers are induced to sprout, and that newly formed muscle fibers seem to present a favorable substrate for these sprouts. We are presently testing, by repeated laser ablation, whether sprouting of nearby nerve terminals is caused by muscle fiber degeneration or regeneration.

SPROUTING OF ATYPICAL, NEUROPEPTIDE Y-IMMUNO-REACTIVE SYMPATHETIC NERVES INTO NEONATALLY DENERVATED CONTRALATERAL TARGET. P.G. Smith, T.L. Hoffman* and H. Reddy*. Dept. of Physiology, University of Kansas Medical Center, Kansas City, KS 66103

Sympathetic innervation to lateral cranial targets normally is distributed strictly ipsilaterally. However, unilateral superior cervical ganglionectomy of neonatal but not older rats results in formation of projections from the contralateral ganglion to denervated targets. This study was conducted to determine if differences in neuropeptide phenotype exist in sympathetic neurons providing ipsilateral and contralateral innervation.

Superior tarsal smooth muscle (STM) of the ipsilateral or contralateral orbit was injected with Fluoro-Gold (1 µl, 2%) and Neuropepide Y-immunoreactivity (NPY-ir) of labelled ganglion neurons quantified. 21:3% of somata labelled by ipsilateral injections displayed NPY-ir; in contrast, 85,3% of the contralaterally projecting cells were NPY-ir (p<0.001). Examination of ipsilaterally innervated STM revealed infrequent NPY-ir nerves; after contralateral reinnervation, NPY-ir nerves were observed It is concluded that sympathetic outgrowth throughout the muscle. following neonatal unilateral superior cervical ganglionectomy results in establishment of an atypical NPY-ir pathway to non-vascular orbital smooth muscle. The presence of this non-native neuropeptide in the contralateral pathway may contribute to the slower time course for STM contraction and relaxation which occurs with electrical stimulation of sympathetic nerves. Supported by NIH NS23502.

SINGLE SUBLETHAL DOSE OF IRREVERSIBLE CHOLINESTERASE INHIBITOR PRODUCES ULTRATERMINAL AND NODAL NERVE SPROUTING IN MAMMALIAN MUSCLE. W.M.Cintra, M.Kawabuchi*, S.S.Deshpande* and E.X.Albuquerque. Dept. Pharmacol. Exp. Ther., Univ. Maryland Sch. of Med., Baltimore, MD 21210.

A single sublethal dose of the irreversible anticholinesterase agent sarin produced severe damage of the post-junctional membrane of rat muscle (Kawabuchi et al., Synapse 2:139-147,1988). To study the effects on the presynaptic terminal, young female Wistar rats were injected s.c. with a sublethal dose of sarin and their soleus (SOL) muscle was examined with a combined cholinesterase (ChE)-silver staining for light microscopy on 1, 3 and 6 days after injection. By day 1 neural degeneration affecting the motor nerve with selective retraction of distal motor nerve was seen in 22% of endplates. Recovery from sarin injury was evidenced by restoration of the size and density of ChE sites, retraction of distal motor nerve was seen in 22% of endplates. Recovery from sarin injury was evidenced by restoration of the size and density of ChE sites, decreased extent of neural degeneration and enhanced sprouting. At 6 days 18% of the endplates showed nodal sprouting and 3% showed ultraterminal sprouting. Membrane depolarization was observed, being more pronounced at the endplate region of the SOL muscle (-73±3 mV (n=25)1 for control and -53±10 mV (n=10) at 1.5-2.0 days after sarin injection; -57±7 mV (n=24) at 5 days after sarin injection) than on the extra-junctional regions (-59±11 mV (n=19) and -67±7 mV (n=30) for 1.5-2.0 days and 5 days after dug injection, respectively). The depolarizing and morphological changes were more pronounced on the SOL than on the extensor digitorum longus (EDL) muscles. 3-6 days after one dose of sarin injection, miniature endplate potentials (menos) were recorded on the SOL on the extensor digitorum longus (EDL) muscles. 3-6 days after one dose of sarin injection, miniature endplate potentials (mepps) were recorded on the SOL muscle fibers 800-1500 μm from the endplate region. These mepps, some quite abnormal in shape, had smaller amplitudes and lower frequency than those recorded from the endplate region in the same fibers. Thus, after initial nerve retraction and reduction of terminal branches due to sarin, nerve sprouting was observed on rat SOL muscles, and the presence of mepps suggests that these newly formed ectopic nerve-muscle contacts were functional. PLASTICITY OF DORSAL ROOTS IS ASSOCIATED WITH A PLASTICITY OF DORSAL ROOTS IS ASSOCIATED WITH A TRANSIENT INCREASE IN GAP-43 FOLLOWING SPINAL CORD HEMISECTION IN THE ADULT CAT. ME. Helgren and M.E. Goldberger. Regeneron Inc. Tarrytown, NY. and Dept. of Anatomy, Medical College of Pennsylvania, Philadelphia, PA. High basal levels of GAP-43 immunoreactivity are observed in the superficial laminae of the adult cat spinal cord. The protein is localized in the terminals of primary affectent fibers pressynatic to superictal raintage of the adult cat spinar out. The protein is localized in the terminals of primary afferent fibers presynaptic to dorsal horn neurons (Skene,J.H.P, 1989). The area occupied by GAPdorsal norn neurons (Skene,J.H.P., 1989). The area occupied by GAP-43 staining in the dorsal horn is significantly increased unilaterally following low thoracic hemisection sparing the dorsal columns. A moderate increase is seen 8 days post-operatively (dpo), peaks by 14 dpo and then gradually returns to basal levels. The region of GAP-43 staining in the spinal cord overlaps with the projection areas of dorsal root fibers mapped with MAb RAT-102 and the descending serotoninergic projections. Following hemisection there is a 4-5 fold increase in the density of Rat-102 immunoreactivity on the lesioned side along with a permanent decrease in the density of 5-HT staining. The increase in GAP-43 immunoreactivity may indicate a growth phenomenon of dorsal root projections in response to hemisection. These results suggest that a process of reactive reinnervation by primary afferent systems occurs in response to a loss of descending projections. This response may be one mechanism mediating recovery of motor control. It is consistent with behavioral studies using the hemisected spinal cord model which shows increases in reflex activity.

MAJOR CYTOSKELETAL CHANGES PRECEDE DENDRITIC SPROUTING MAJOR CYTOSKELETAL CHANGES PRECEDE DENDRITIC SPROUTING FOLLOWING CLOSE AXOTOMY OF LAMPREY GIANT CENTRAL NEURONS. G.F. Hall+, V.M.-Y. Lee+ and K.S. Kosik+. +Harvard Med. Sch. Brigham and Women's Hosp., Boston, MA 02115 and +Dept. of Pathology, Univ. Penn., Sch. Med., Philadelphia, PA 19104.

Close axotomy of giant central neurons (ABCs) in the lamprey within 500 µm of their somata results in axonal regeneration from the dendritic tips (dendritic sprouting), while distant axotomy results in sprouting from the axon stump. We show that mAbs recognizing highly phosphorylated (RM034) and dephosphorylated (RM015) epitopes on lamprey neurofilaments and total neurofilament protein (RM0270) reveal a large increase in the number and degree of phosphorylation of neurofilaments in the somata and dendrites of ABCs by 4-6 days following close axotomy. This is paralleled by a large increase in staining for tyrosinated tubulin. These changes occur well before dendritic sprouting begins at 10-15 days post axotomy. After distant axotomy, such changes do not appear until after the onset of sprouting.

Dendritic sprouts have higher levels of RMO34 and RMO270 staining than do dendrites following close axotomy, and unlike dendrites, have generally low levels of tubulin. Dendrites which give rise to sprouts resemble sprouts rather than dendrites in these characteristics.

These early changes may thus be an important preliminary to dendritic sprouting in ABCs, and may therefore have a role in the maintenance of normal polarity in injured neurons.

SPROUTING OF IDENTIFIED MOLLUSCAN NEURONS IN <u>VITRO</u>: PROMOTION BY MURINE NERVE GROWTH FACTOR (\$\beta\$-NGF). R.L. Ridgway, N.I. Syed, Y. Fujito, K. Lukowiak, and A.G.M. Bulloch. Dept. of Med. Physiol., Univ. of Calgary, Alberta, Canada T2N 4N1.

Physiol., Univ. of Calgary, Alberta, Canada T2N 4N1.

Sprouting by adult neurons of the pond snails Lynnaea stagnalis and Helisoma trivolvis normally requires the presence of "conditioning factor(s)" produced and released by brains. Since the actions of these as yet unidentified endogenous factors resemble those of known vertebrate neurotrophic factors, we examined whether murine β-NGF could elicit sprouting in molluscan neurons. Identified Lynnaea and Helisoma neurons cultured in vitro in defined medium plus β-NGF extended neurites within 18-24 h of plating on poly-L-lysine substrate. The sprouting was dose-dependent, but the response varied with cell type. For most cell types the threshold concentration of β-NGF was 50-100 ng/mL; the optimum was 300-400 ng/mL. Motor neurons (e.g., Ce-A and Pe-A Cluster Cells) and certain interneurons (e.g., R.Pe.D1 and V.D4) exhibited the most extensive outgrowth, whereas known neurosecretory cells (e.g., Ce-LIGCs, Ce-CDCs, V.YCs, and Pa-YGCs) were unresponsive to β-NGF. In contrast, virtually all identified Lynnaea and Helisoma neurons sprouted when cultured in brain-conditioned medium. Adsorption of defined medium containing β-NGF with an affinity purified polyclonal antiserum (to murine β-NGF) blocked sprouting by ordinarily responsive neurons. Interestingly, sprouting by these neurons was also inhibited when brain-conditioned medium was absorbed with the same antiserum; nonimmune serum had no effect. This suggests that an endogenous NGF-like neurotrophic substance may be present in molluses.

GLUTAMATE MODULATES SPROUTING OF ADULT HELISOMA NEURONS BY ENHANCING CONDITIONED MEDIUM. A.G.M. Bulloch. R. L. Ridgway and G. Hauser. Department of Medical Physiology, University of Calgary, 3330 Hospital Dr. N.W., Calgary, Alberta, T2N 4N1 Canada A primary goal of our laboratory is to identify molluscan neurotrophic factors and mechanisms by which they are regulated. A number of our recent studies have indicated that the amino acid, L-glutamate, can enhance sprouting by both intact and isolated Helisoma neurons. Specifically, glutamate enhances the conditioning of medium by ganglionic rings of Helisoma. Such medium is effective in evoking sprouts from undamaged neurons in a semi-intact preparation, as well as from cultures of isolated neurons. Previous studies have indicated that glutamate does not exert a direct effect on neurons, rather its effect appears to be mediated via macromolecular trophic factors. macromolecular trophic factors.

macromolecular trophic factors.

We are attempting to isolate and characterize the neurotrophic factors present in conditioned medium, particularly those that are enhanced by glutamate. To this end, we have analyzed conditioned medium by SDS-PAGE and have shown the presence of a number of polypeptides. Two of these molecules, which have nominal molecular weights (under reducing conditions) of approximately 16 and 25 kD, are enhanced by glutamate. It therefore appears that the action of glutamate on sprouting is by enhancement of specific polypeptides, presumably acting either to increase their synthesis and/or release. The precise mechanism by which glutamate acts, and also the nature of the trophic factors, are currently under investigation. In this context, preliminary Western Blots indicate that the 25kD molecule is immunoreactive for NGF.

PROENKEPHALIN mRNA IS EXPRESSED BY DIFFERENT SUBPOPULATIONS OF DEVELOPING MURINE ASTROCYTES IN CULTURE: COMBINED IN SITU HYBRIDIZATION AND GFAP IMMUNOCYTOCHEMISTRY. A. Stiene-Martin, J.G. Osborne and K.F. Hauser. Dept. of Anat. and Neurobiol., Univ. of Kentucky College of Med. Lexington, KY 40536-0084.

Different studies have shown that confluent, astrocyte-enriched cultures produce proenkephalin mRNA; and, that Met-enkephalin suppresses astrocyte growth in primary, mixed-glial cultures isolated from 1 day old mouse cerebral hemispheres after 5 or 6 days in vitro. We were therefore interested in ascertaining whether cultured astrocytes produce proenkephalin mRNA after 5 days in vitro when approximately 50-60% of the cells are astrocytes. A method was developed to double label cells by colocalizing proenkephalin mRNA by in situ hybridization using a cRNA probe and the immunocytochemical identification of glial fibrillary acidic protein (GFAP). GFAP-positive cells could be separated into 3 morphologic categories: flat (type I), bipolar, and multipolar process-bearing (type II) astrocytes. Astrocytes were classified according to morphology and evaluated based on the presence or absence of mRNA for proenkephalin. Between 60% and 70% of type I astrocytes contained mRNA for proenkephalin, whereas virtually all bipolar astrocytes and essentially none of the multipolar astrocytes contained mRNA for proenkephalin. The heterogeneous expression of proenkephalin mRNA by astrocyte subpopulations suggests that there are age- and/or region-dependent differences in opioid expression by these cells. Moreover, a subset of astrocytes may act as critical intermediaries in opioid-dependent regulation of neural maturation through the local synthesis of proenkephalin peptides. Supported by NIDA grant DA 06204 and NIH grant RR-05374.

SOLUBLE AXOLEMMA STIMULATES PROLIFERATION OF CELLS OF THE OLIGODENDROGLIAL LINEAGE. J.B. Grinspan, B.Q. Kreider, J.L. Stern. M.L. Williams and D. Pleasure, Neurology Research, Children's Hospital of Philadelphia, Philadelphia, PA 19104

The importance of contact with neurons in regulating glial cell

proliferation has been demonstrated in both PNS and CNS. Chen and DeVries (<u>J Neurochem.</u>, 52:325, 1989) showed that particulate axolemma has a mitogenic effect on GC+ oligodendroglia, and that this effect could be inactivated by heat or trypsin. We have extended their observations using soluble axolemma derived from the brains of three day old rats by a modification of the method of Ratner et al (<u>PNAS USA</u>, Soluble axolemma was added to cerebral white matter cultures from 6 day old rats. Using immunofluorescence, we found that the number of oligodendroglial-precursor cells and of GC+ oligodendroglia increased more than three fold after three days of treatment and more than 6 fold after a week of treatment. The mitotic index of both the O2A cells and oligodendroglia was more than doubled with either 24 or 48 hours of treatment. Axolemma had no effect on the proliferation of astrocytes in these cultures. Platelet-derived growth factor (PDGF) added in combination with axolemma further augmented recruitment of both O2A cells and oligodendroglia. Incubation of soluble axolemma-treated cells with anti-PDGF antibodies causes a 50% inhibition of the axolemma-induced cell increase, suggesting either that soluble axolemma contains PDGF activity or that endogenously secreted PDGF is a necessary cofactor for the axolemmal mitogen.

341.2

LOCALIZATION OF ENKEPHALIN IMMUNOREACTIVITY AND PROENKEPHALIN mRNA BY IN SITU HYBRIDIZATION IN PURKINJE CELLS OF THE DEVELOPING RAT CEREBELLUM. J.G. Osborne¹, M.S. Kindy²* and K.F. Hauser¹. Depts. of ¹Anat. and Neurobiol., and ²Biochemistry, Univ. of Kentucky College of Med., Lexington, KY 40536-0084.

Enkephalins have been reported to transiently appear in neuronal progenitor cells of the cerebellar external granule layer (EGL) both in vivo and in vitro, and have been implicated in the regulation of EGL cell growth. Moreover, by manipulating opioid systems (opioids and their receptors) it is possible to alter the rate and pattern of dendritic growth, and spine number in Purkinje cells of developing rat cerebella. To identify potential sources of endogenous opioid production in the developing cerebellum, immunocytochemistry and in situ hybridization was performed on coronal and sagittal sections of cerebella from pre-weaning male Sprague-Dawley rats. Briefly, the pups were anesthetized and perfused with 4% paraformaldehyde in phosphate buffer (pH 7.25). Enkephalin immunoreactivity was examined on frozen sections (10 µm) using previously characterized antisera specific for met- and, to a lesser extent, leu-enkephali (donated by Dr. B.E. Maley). In situ hybridization was performed using a [35S] labeled cRNA probe specific for proenkephalin mRNA. We have previously described proenkephalin gene products in Golgi cells and some glia. We now additionally report the localization of these products as being confined to a subpopulation of Purkinje cells which varies with age as well as region of cerebellum sampled. The local production of proenkephalin by developing Purkinje cells might be a mechanism by which opioids modulate cerebellar proveth including the rate of EGL cell production. Supported by NIDA grant DA 06204 and NIH grant RR-05374.

341.4

TARGET HIPPOCAMPUS REGULATES LOCUS COERULEUS NEURON SURVIVAL IN DISSOCIATED CELL CULTURE. L.J. Robinson*, I.B. Black and C.F. Dreyfus, Div. Devel. Neurol., Cornell Univ. Med. Coll., NY, NY 10021 and Dept. Neurosci. and Cell Biol., UMDNJ Robert Wood Johnson Medical School, Piscataway, NJ 08854

Increasing evidence suggests that environmental signals regulate development and function of neurons in the brain. For example, recent studies of the noradrenergic (NA) locus coeruleus (Ic) indicate that depolarizing influences increase tyrosine hydroxylase (TH), the rate-limiting enzyme in NA biosynthesis. We have extended this work to determine whether the target hippocampus (hi) also regulates development of this diffusely projecting begin puchas. ment of this diffusely projecting brain nucleus. Dissociated le was grown alone, or co-cultured with hi cells in a serum-free, fully-defined medium that limited non-neuronal growth. Le grown with target hi exhibited a 2-fold increase in TH activity after 6 days. Moreover, TH+ cells increased 2-fold, suggesting that hi enhanced lc survival. Increased cell number was that hi enhanced lc survival. Increased cell number was accompanied by a striking increase in neurite length and branching. The target effects were apparently selective, since total neuron number, estimated with neuron specific enolase or total protein, was unaffected by hi. To approach the issue of survival more directly, hi cells were added to lc dissociates at zero time, or after 2 days. TH+ cell number was increased only by hi cells added initially, suggesting that the target does, indeed, foster neuron survival. Our observations suggest that hi regulates survival and neurite elaboration of affected lc neurons. regulates survival and neurite elaboration of afferent lc neurons. IN VITRO DEVELOPMENT OF CHICKEN EMBRYONIC MOTOR NEURONS IN MEDIA CONDITIONED BY VARIOUS CELL TYPES. S.J. Jeong, T.H. Oh, G.J. Markelonis and M.B. Clark. Dept Anatomy, Univ of Maryland School of Medicine, Baltimore, MD, 21201 In vivo studies suggest that cell-cell interactions may influence naturally occurring spinal motor neuron (MN) death observed early in embryonic development. To mimic these interactions, media conditioned by various cells (conditioned media; CM) were collected and tested for their trophic activities on MN. Purified chicken embryonic MNs were cultured for 6 days in media conditioned by skeletal muscle (SKM-CM), heart muscle (HM-CM), dorsal root ganglia (DRG-CM). Schwann cells (SC-CM) and astrocytes (AS-CM). All CMs supported the survival and outgrowth of neurites from MNs. Survival of MNs grown in the presence of SKM-CM, SC-CM or AS-CM was higher than that of MNs grown in HM-CM or DRG-CM. Choline acetyltransferase activity of MNs was enhanced by SKM-CM, AS-CM and DRG-CM but not by SC-CM or HM-CM. Interestingly, certain CMs induced distinct patterns of neuritic arborizations produced by cultured MNs. MNs grown in SKM-CM, DRG-CM or SC-CM had extremely complex branches at the end of a relatively long process containing a prominent growth cone. MNs grown in AS-CM or HM-CM had large numbers of simple, rather straight primary or secondary processes. This study suggests that various supporting cells have qualitatively different effects on motor neuron survival and neuritic outgrowth and appear to influence neuronal morphology and cholinergic differentiation. GLIAL-MEDIATED EFFECTS OF 5-HT AND NIALAMIDE IN VITRO DEVELOPMENT OF RAPHE AND SUBSTAN NIGRA NEURONS. J.Liu*, M.B.Wilkie*

J.M.Lauder, Dept.of Cell Biol.& Anat. Un N.C.Sch. Med., Chapel Hill, NC 27599 USA

The importance of neurotransmitters embryonic neuronal-glial interactions

___, NC 27599 USA Octuance of neurotransmitters neuronal-glial interaction cell culture embryonic embryonic neuronal-glial interactions was studied in cell cultures from the embryonic day (E)14 rat brain containing rostral raphe (RR) 5-HT neurons, substantia nigra (SN) tyrosine hydroxylase (TH) neurons, RR or SN radial glia/astrocytes (RG/A). 1) 5-HT and/or nialamide added to the medium promoted survival and growth of 5-HT neurons, with minimal effects on TH neurons. 2) When co-cultured with RR or SN RG/A and treated in the same way, or 3) exposed to conditioned medium from treated glial cultures (GCM), survival and growth of 5-HT neurons was (GCM), survival and growth of 5-HT neurons (GCM), survival and growth of 5-HT neurons was enhanced, but some inhibitory effects of 5-HT were seen, especially in co-cultures where the numbers of RG/A were greatly increased. In both types of glial experiments, TH neurons were much less affected suggesting that they respond differently to the same glial signals. Regional differences in treatment effects on 5-HT and TH course indicate that resultations of comparisons. neurons indicate that populations of embryonic glia may produce different trophic factors in response to the same neuroactive substances.

GRAFTS OF FETAL CNS TISSUE RESCUE AXOTOMIZED CLARKE'S NUCLEUS NEURONS IN ADULT AND NEONATAL OPERATES. B.T. Himes¹, M.E. Goldberger¹, and A.Tessler^{1,2}. ¹Dept. of Anatomy, Medical College of PA and ²VA

Medical Center, Philadelphia, PA.
Why CNS neurons die following injury is still incompletely understood. Many elements are thought to be involved, including maturity of the cell at the time of injury, ability to re-establish or maintain target contact and dependence upon trophic factors produced by targets. We have therefore studied axotomized Clarke's nucleus (CN) neurons after thoracic hemisection in neonatal and adult rats and compared cell loss following hemisection to that following the same lesion with insertion of a fetal CNS transplant.

In the rat, hemisection axotomizes many CN neurons and causes extensive cell death. Neonatal T8-T9 hemisection causes a 40-50% loss of neurons in CN at L1 ipsilateral to the lesion. Similar surgery in the adult causes a 20-30% cell loss. In both groups it is primarily the larger neurons that either die or atrophy. Cell death is complete within one month of axotomy in neonates and 2-3 months in adults. A transplant of embryonic (E14) cerebellum or spinal cord prevents the death of most axotomized neurons. In both neonates and adults only 10% of CN neurons at L1 die when a transplant is placed in a hemisection cavity at T8-T9. Transplants rescue axotomized CN neurons by providing trophic support. Supported by grants NIH grant NS 24707, USAMRDC-51930002, and The VA Medical Research Service.

DISSOCIATION OF FOS ONCOGENE EXPRESSION FROM CELL PROLIFERATION AND DELTA-OPIOID RECEPTOR EXPRESSION IN NUTGI NEUROBLASTAMA CELLS. W.X. Lu* and K.-J. Chang. Division of Cell Biology, Burroughs Wellcome Co., Research Triangle Park, NC 27709

Effects of fibroblast growth factor (FGF), insulinlike growth factor-1 (IGF-1) and others on fos oncogene expression, cell proliferation and delta-opioid receptor activity were studied in NUTG1 neuroblastama cells. Using Northern Blot, FGF was found to stimulate dose-dependently and transciently fos oncogene expression. Both subtypes of FGF, acidic and basic FGF, possessed a similar effect. Cycloheximide, a protein synthesis inhibitor, potentiated and prolonged the effect of FGF on fos expression, but IGF-1, other growth factors, neuropeptides and neurotransmitters did not significantly change fos expression. When 3H-thymidine incorporation was used to measure proliferation, IGF-1 and insulin dose-dependently increased thymidine incorporation at 24 h after administration, but FGF, other growth factors, neuropeptides and neurotransmitters did not. NUTG1 cell has a high density of delta-opioid receptor. IGF-1, insulin and dibutyryl cAMP (BtgcAMP), but not FGF and other growth factors, decreased opioid receptor binding activity after at least 1 day treatment. After 2 days treatment of BtgcAMP on the third day induced partial recovery of opioid receptor synthesis. Results suggest that fos expression is independent from or insufficient for cell proliferation and opioid receptor expression in N4TG1 cells.

OUTGROWTH OF STATOACOUSTIC GANGLIA EXPLANTS IN RESPONSE TO COCHLEAR-DERIVED CONDITIONING FACTORS. L.M. Bianchi, R.J. Salvi, and C.S. Cohan, Departments of Communicative Disorders and Anatomical Sciences, SUNY at Buffalo, Buffalo, N.Y. 14214

Previous studies have suggested the presence of cochlear-derived conditioning factors which are necessary for guiding the growth of acoustic nerve fibers. The present experiments evaluated the existence of such factors in the embryonic chick auditory system and the period in which these factors were active.

Otocysts and statoacoustic ganglia (SAG) were removed from chick embryos at various stages of development. Three to four otocysts were cocultured with two to three ganglia in a serum-containing medium on plastic tissue culture dishes. Control conditions consisted of SAG explants in the absence of otocysts. Neurite outgrowth occurred at stages 22-24 (preinnervation stages) and 27-29 (early innervation stages) in the co-culture conditions. Neurites extended within 24-72 hours and continued to grow for up to ten days. Degeneration of neurites became visible within 14-20 days. The majority of control explants did not extend neurites. In a few control explants a brief period of neurite outgrowth was followed by neurite retraction within 24-48 hours. Thus, a cochlear-derived conditioning factor promotes neurite outgrowth at early stages of SAG development.

GASTRIC TRANSPLANTS RESCUE NEURONS IN THE DORSAL MOTOR NUCLEUS OF THE VAGUS AFTER AXOTOMY. L. Rinaman and P. Lavitt, Dept. of Anatomy, Med. Coll. of Pennsylvania, Phila. PA 19129.

Death of axotomized neurons is more rapid and complete in the dorsal motor nucleus of the vagus (DMV) than in any other motoneuronal population. Axotomized DMV motoneurons may degenerate because they are deprived of factors normally supplied by their gastrointestinal enteric targets. To test this, we compared DMV degeneration following cervical vagotomy in rat neonates to that in animals which first received an implant of gastric tissue at the site of to that in animals which first received an implant of gastric tissue at the site of vagal lesion. A 1 mm² piece of the stomach wall was dissected from E17 donors and implanted next to the carotid artery at the level of the omohyoid muscle in P0 hosts. Control animals received no transplant or received a transplant of uterus, bladder, or heart tissue. Unilateral vagotomy was performed below the nodose ganglion of all animals 24 hr later. Animals were sacrificed 1-25 days subsequent to the lesion and the DMV examined in Nissistained sections. In some animals, CT-HRP was injected into the transplant (or into the area of nerve lesion in non-transplant controls) 48 hrs prior to sacrifice. DMV motoneuronal loss was first evident 3-5 days post-vagotomy, and appeared complete by 8-10 days in control animals, including those that contained healthy, non-gastric transplants. CT-HRP labeled DMV motoneurons were rarely observed on the lesioned side in control animals. In contrast, animals that received gastric implants had DMV motoneurons on the motoneurons were rarely observed on the lesioned side in control animals. In contrast, animals that received gastric implants had DMV motoneurons on the lesioned side as long as 25 days post-vagotomy, although their number was reduced as compared to non-lesion controls. Injections of CT-HRP into gastric transplants routinely labeled surviving neurons in the lesioned DMV. Examination of gastric transplants revealed a well-developed mucosa, enteric neurons, and intramural nerve fibers. These results suggest that the survival of axotomized DMV motoneurons during early postnatal development depends on their access to gastric tissue, and that other peripheral tissues are ineffective. Whether this involves neuronal or non-neuronal gastric components remains to be determined. Supported by NIMH Grant MH45507.

MITOTIC SYMPATHETIC NEUROBLASTS REQUIRE TROPHIC SUPPORT. Emanuel DiCicco-Bloom. David W. Pincus. and Ira B. Black. Div. of Devel. Neurol., Cornell Univ. Med. College, NY, NY 10021. Dept. Neurosci. and Cell Biol., UMDNJ-Robert Wood Johnson Med. Sch., Piscataway, NJ 08854.

While targets govern neuronal survival after innervation, the role of trophic support earlier in development is largely unexplored. Specifically, when do developing neurons acquire dependence on exogenous molecules for

when do developing neurons acquire dependence on consuming a survival?

To examine trophic chronology, we employed a previously defined sympathetic neuroblast culture system containing a virtually pure population of neurons and dividing precursors. Superior cervical ganglia from gestational day 15.5 rat embryos were dissociated and cultured at low density in serum-free medium. In the presence of mitogenic concentrations of insulin (10µg/ml), approximately one-third of plated cells divide *in vitro*. The fate of dividing cells was documented by serial time-lapse photomicrography.

Observation of newly-born cells revealed that 20% died within 24 h of

plating, whereas 75% were lost by 48 h. In contrast, addition of two sympathetic trophic molecules, VIP and NGF, rescued virtually all mitotic cells. Remarkably, treatment with either factor alone failed to reproduce these effects, suggesting that multiple factors interact to generate stable neuronal populations. Indeed, combined factor treatment allowed multiple rounds of division by single neuroblasts in vitro.

division by single neuroblasts in vitro.

In aggregate, our observations suggest that trophic molecules play a major role in survival of mitotic neurons. Consequently, trophic mechanisms may govern neuronal ontogeny at times earlier than previously considered, during neuroblast division or immediately thereafter. Since the majority of neurons at this developmental stage have not established target connections, trophic molecules may be elaborated locally, from ganglionic sources. COMBINATORIAL EFFECTS OF INSULIN-LIKE GROWTH FACTOR I AND NERVE GROWTH FACTOR ON CULTURED

FACTOR I AND NERVE GROWTH FACTOR ON CULTURED SEPTAL CHOLINERGIC NEURONS. N.T. Neff and C.A.H. Friedman*. Cephalon, Inc., West Chester, PA 19380.

Nerve growth factor (NGF) and insulin-like growth factor-1 (IGF-1) each enhance choline acetyltransferase (ChAT) activity in cultured embryonic rat neurons (J. Neurosci 8: 2967, 1988; J. Neurosci, 10:558, 1990). To determine potential differential critical fields these factors on chellingratin purpose, their effects on actions of these factors on cholinergic neurons, their effects on ChAT activity and cholinergic cell survival were investigated in embryonic age (E17) rat septal cultures. Saturating concentrations of NGF (20 pM) or IGF-1 (50 nM) enhance ChAT activity by 40-60% when added separately to cultures at plating. When added together, their effect on ChAT activity is additive and results in a 2-fold increase in ChAT activity were unjoined 5 day cultures. fold increase in ChAT activity over uninduced 5 day cultures. A greater than additive effect on ChAT activity is observed in the continual presence of IGF-1 when NGF is added 3 days after seeding. To discriminate between the effects of these factors on enzyme regulation or cholinergic neuron survival, acetylcholinesterase (AChE) cytochemistry, which is a reliable marker for ChAT positive neurons in rat septal cultures, was marker for ChAT positive neurons in rat septal cultures, was performed. IGF-1 increases the number of AChE positive neurons by 3 to 4-fold, whereas NGF results in no increase. The number of AChE positive cells increased by the joint presence of the factors is the same as that elicited by IGF-1 alone. These results suggest that under the culture conditions employed, IGF-1 has a greater effect on cholinergic cell survival, while NGF regulates (increases) ChAT activity in existing cholinergic neurons.

NGF REGULATES THE DEVELOPMENT OF RAT CEREBELLAR PURKINJE CELLS IN CULTURE. S. Cohen-Cory. C.F. Dreyfus and I.B. Black. Lab. of Neurobiol., Rockefeller Univ., Div. of Dev. Neurol., Cornell Univ. Med. Coll., New York, N.Y. 10021, and Dept. Neurosci. and Cell Biol. UMDNJ-Robert Wood Johnson Med. Sch., Piscataway, N.J.

In the cerebellum, Nerve Growth Factor (NGF) and NGF receptors are highly expressed during early development in several species. The localization of biologically active, high-affinity receptors to developing Purkinje cells suggests that NGF may play an important role in the ontogeny of this cell type.

To begin defining the mechanisms by which NGF may regulate development, we have studied the effects of several epigenetic signals on the survival and maturation of Purkinje cells. Responses to NGF and excitatory neurotransmitters were analyzed in dissociated cell culture. Purkinje cells were identified immunocytochemically with anti-Calbindin D28K antibodies (a gift of Dr. S. Christakos). NGF markedly increased the survival and morphological maturation of Purkinje cells grown in the presence of general depolarizing agents, such as potassium or veratridine. Furthermore, NGF together with the excitatory neurotransmitters, aspartate or glutamate, promoted a 2-fold increase in survival of Purkinje cells. The combination of agents also elicited a marked increase in neurite branching. Effects on survival or neurite elaboration were not evoked by exposure either to trophic factor or transmitters alone. Our results suggest that the trophic factor, NGF, and excitatory amino acid transmitters act in concert to regulate survival and differentiation of cerebellar Purkinje cells. MULTIPLE FACTORS REGULATE CULTURED BASAL FOREBRAIN (BF) NEURONS THROUGH DIFFERENT MECHANISMS. M. Yokoyama, R.S. Morrison, I.B. Black, & C.F. Dreyfus, Comell U. Med. Coll., NY, UMDNJ/Robert Wood Johnson Med.

Dreyfus, Cornell U. Med. Coll., NY, UMDNJ/Robert Wood Johnson Med. Sch., NJ, and R.S. Dow Neurol. Sci. Inst., OR Numerous studies suggest that Nerve Growth Factor (NGF) plays a critical role in regulation of BF function. We sought to determine whether BF neurons are responsive to NGF exclusively, or whether other known factors also govern function directly or indirectly. Initially, we defined the effects of NGF, basic Fibroblast Growth Factor (bFGF; Synergen), Epidermal Growth Factor (EGF) and Transforming Growth Factor-α (TGF-α; Oncogen Inc.) on BF cholinergic cells in culture. All factors elevated activity of the acetylcholine synthetic enzyme, choline acetyltransferase (CAT). To determine whether non-neuronal cells mediated the observed effects, a mitotic inhibitor, 5-fluorodeoxyuridine (FDUR), was added to the cultures to eliminate dividing support cells. The actions of EGF and TGF-α were inhibitor, 5-fluorodeoxyuridine (FDUR), was added to the cultures to eliminate dividing support cells. The actions of EGF and TGF- α were completely blocked by the addition of FDUR. However, NGF and bFGF continued to elevate CAT activity in the presence of FDUR. Consequently, NGF and bFGF may regulate forebrain cholinergic function directly, whereas EGF and TGF- α may affect cholinergic cells indirectly through support cells. NGF influences both cholinergic and GABA populations in the BF. To determine whether FGF regulates the same neuronal populations, the activity of glutamic acid decarboxylase (GAD), a GABA synthetic enzyme, was monitored. FGF elicited a significant increase in GAD activity: the effect was completly abolished by addition of FDUR. Thus, FGF may act directly on cholinergic neurons and indirectly on GABA cells. Our study suggests that multiple factors potentially regulate cell function through different mechanisms. The multiplicity of factors and mechanisms, and apparent redundancy, may play a critical role in normal ontogeny. (Support: NINDS, NICHD, March of Dimes, Mc Knight fellowship & Bristol Meyers)

Effects of Estrogen and Fimbria/Fornix Transection on NGF Receptor Immunoreactivity in the Rat Basal Forebrain. R.B. Gibbs and D.W. Plaff. Lab of Neurobiology & Behavior, Rockefeller University, New York, N.Y. 10021. Effects of estrogen on expression of the nerve growth factor (NGF) receptor in the medial septum (MS) and horizontal limb of the diagonal band (HDB) of normal and injured animals were examined using immunocyto-chemical (ICC) techniques. Thirty adult, ovariectomized, Sprague Dawley rats were used. Silastic capsules (5 mm) containing 17-β-estradiol crystals (E) were implanted subcutaneously into 16 animals. Two days later, 6 animals with implants and 6 animals without implants received a bilateral transection of the fimbria/fornix. Ten animals (5 with implants and 5 without implants) received sham surgery. Two weeks later, these 22 animals were sacrificed. Their brains were removed, sections through the MS and HDB were cut and processed for ICC detection of the NGF receptor protein using the mouse monoclonal antibody 192 IgG (Dr. E. Johnson). Remaining animals had their implants removed and were allowed to survive an additional 2 weeks prior to sacrifice.

As expected, transection of the fimbria/fornix resulted in a significant decrease (45.8%) in the number of NGF receptor-IR cells observed in the MS. Interestingly, E-treatment alone also resulted in a significant decrease (22.8%, p-0.01) in the number of NGF receptor-IR cells observed in the MS. Animals in which E-treatment and fimbria/fornix transection were combined showed the same degree of cell loss (47.6%) as the non-E-treated animals, suggesting that E-treatment influences NGF receptor-IR cells in animals from which E-capsules had been removed were not significantly different from non-E-treated controls. No effects of estrogen and/or fimbria transection on the

E-capsules had been removed were not significantly different from non-E-treated controls. No effects of estrogen and/or fimbria transection on the number of NGF receptor IR cells in the HDB were observed. These data demonstrate that (1) NGF receptor expression in the rat basal forebrain can be influenced by estrogen, and (2) the effects of estrogen are region specific. Supported by NIH grant #HD05751.

VIP AND NGF SUPPORT SYMPATHETIC NEURONAL SURVIVAL AT DIFFERENT DEVELOPMENTAL STAGES. David W. Pincus. Emanuel DiCicco-Bloom, and Ira B. Black. Cornell Univ. Med. College, NY, NY 10021, UMDNJ-Robert Wood Johnson Med. Sch., Piscataway, NJ 08554.

Current models of trophic factor action suggest that developing neurons are initially independent of survival factors and develop requirements for target-derived trophic support with maturity. We recently found that vasoactive intestinal peptide (VIP) regulated multiple ontogenetic processes of cultured rat sympathetic neuroblasts, including survival. This putative transmitter was localized to the developing superior cervical ganglion (SCG), reflecting presynaptic and/or perikaryal sources. Thus, transmitter molecules of local origin may provide trophic support to developing neurons prior to target

origin may prior to target innervation.

The present study defines the trophic actions of VIP on SCG neurons at different ages. We compared VIP to nerve growth factor (NGF), since sympathetics develop absolute dependence on the factor with maturation. In fact, at gestational age 15.5 (E15.5), either VIP or NGF rescued -90% of cells initially plated. In the absence of either factor, 50% of cells survived. At older ages, VIP rescued fewer cells, while NGF dependence increased. By birth, all SCG neurons required NGF for survival. Further, the time course of VIP effects on neuronal survival correlated with expression of peptide in the SCG. While total VIP levels/ganglion increased with maturity, VIP concentration/ug protein decreased with age from a peak at E15.5. This developmental profile was unique when compared to VIP expression in other neuronal populations. In sum, our findings indicate that sympathetic neurons may derive trophic support from VIP or NGF as a function of embryonic age. Since the temporal profile of VIP responsivity parallels the ontogenetic expression of VIP in the SCG, these results may reflect in vivo mechanisms. Consequently, young neuronal populations that have not yet reached targets may derive trophic support from presynaptic or local factors.

EFFECTS OF BASIC FIBROBLAST GROWTH FACTOR AND HEPARIN ON TRANSPLANTED FETAL DOPAMINERGIC NEURONS AND ASTROCYTES IN THE DENERVATED RAT CAUDATE-PUTAMEN. <u>H.W.M.STEINBUSCH, M.J.DOLLEMAN- VAN DER WEEL, A.NIJSSEN and F.FULLER', Dept. Pharmacology, Vrije Universiteit, Amsterdam, The Netherlands and 'California Biotechnology, Mountain View, CA, U.S.A. Neurotrophic factors appear to be essential for the growth, maintenance, and</u>

Neurotrophic factors appear to be essential for the growth, maintenance, and repair of neurons. Basic fibroblast growth factor (bFGF) has been recognized as a trophic factor for fetal CNS cells in vitro. It has been shown to exert a positive effect on the survival of fetal astrocytes and in vivo a preserving effect on damaged adult septal cells. The aim of this study was to investigate the morphological and functional effects of heparin with or without bFGF on grafted dopaminergic neurons. The experimental design consisted of rats with an unilateral 6-OHDA lesion, grafting of a fetal (E 15) dopaminergic cellsuspension in the caudate-putamen and various behavioral tests using rotation turning behavior with amphetamine and apomorphine. The cellsuspension was mixed either with vehicle, heparin or a combination of bFGF with heparin. All rats were processed for DA- and GFAP-immunocytochemistry. All groups showed surviving dopaminergic transplants. A difference was observed with regard to the fiber outgrowth, the heparin group alone showed the highest fiber outgrowth. No differences were noted in diameter of the transplants or the number of surviving dopaminergic cells. The behavioral data revealed that the heparin group resulted in a marked decrease in apomorphine-induced rotation, while the bFGF/heparin group was not different from the control group. The amphetamine-induced ipsilateral rotation did not differ between groups. The comparison of both the amphetamine conditions with the pretransplant or lesion condition revealed no differences in recovery. Heparin alone had a positive effect on morphology and behavior, while the combination bFGF/heparin showed a positive tendency towards behavior.

MUSCARINIC ACETYLCHOLINE RECEPTOR BINDING IN PARASYMPATHETICALLY ANEURAL CHICK ATRIA. T. L. Creazzo. Dept. of Anatomy, Medical College of Georgia, Augusta, GA 30912-2000.

Chick hearts were made cholinergically aneural by bilateral ablation of the nodose placodes and the neural crest which seeds pharyngeal arches 1-3, prior to cell migration (Kirby, 1988, J Neurosci, 8:1089-1095). Hearts with this lesion do not have postganglionic parasympathetic intracardiac ganglion cells. were sacrificed on day 11, the atria separated from the ventricles and stored in liquid nitrogen until used. The atria were pooled (approx. 15 per determination) and assayed for muscarinic receptors (MAChR) with [3H]-QNB as previously described (Creazzo TL, Hartzell HC, 1985, J Neurochem, 45:710-718). Scatchard analysis showed no significant difference in the number of MAChRs in aneural atria compared to sham-operated controls (sham: 221±34 fmol/mg \pm S.D., n=3; aneural: 241 \pm 47, n=3). In competition with carbachol, approx. 30% & 70% of MAChRs were in lowand high-affinity states, respectively, and in 50 μM GPP(NH)P, essentially all of the MAChRs were in the lowaffinity state for both sham-operated and aneural (sham: $K_{\rm I}$ =7.1±3.7 μ M, n=2; aneural: $K_{\rm I}$ =4.4±1.1 μ M, n=2). The results show that, unlike nicotinic ACh receptors in skeletal muscle, MAChR development in chick atria does not depend on cholinergic innervation. Supported by NIH HL 36059 & HL 39039.

TWO-DIMENSIONAL ELECTROPHORETIC ANALYSIS OF GLIAL PROTEINS RELEASED BY VIP. D.E. Brenneman. Laboratory of Dev. Neurobiology, NICHD, NIH, Bethesda, Maryland 20892

Previous studies indicated that nonneuronal cells mediate the

Previous studies indicated that nonneuronal cells mediate the neurotrophic action of VIP (J. Cell Biol. 104:1603, 1987). To investigate the glial proteins which may participate in this action, the release of S³⁵ methionine-labeled proteins was measured in astroglial cultures treated with VIP. Conditioned medium was collected from rat cortical astrocyte cultures during one hour incubations. A 2-fold increase in labeled proteins was detected in the medium after treatment with 0.1 nM VIP. A similar stimulation of secreted proteins was observed after treatment with an active phorbol ester; however, the addition of 8-Br cAMP or forskalin increased protein efflux by < 40% as compared to controls. Two-dimensional polyacrylamide gel electrophoresis combined with quantitative image analysis revealed an increase (> 50% of control) in 15 out of the 333 medium protein spots after VIP treatment. These proteins had molecular weights estimated to be from 17 to 117 kDaltons and all had acidic pl's. By optical density of the autoradiograms, the VIP-stimulated proteins comprised 18-22% of the total protein released from the glial cultures. The three proteins showing greatest (9-25 fold) increase from controls were between 45 and 52 kDaltons. PHI-27, a closely homologous peptide to VIP, had no detectible effect on any of the VIP-stimulated proteins. These data indicate that low concentrations of VIP release a complex mixture of acidic proteins of high molecular weight from glial cultures and suggest that VIP-mediated secretion of glial proteins may not exclusively involve cAMP-linked actions.

MANNOSE-6-PHOSPHATE POTENTIATES IGF-II STIMULATED NEURONAL CELL DIVISION BUT NOT NEURITE OUTGROWTH. E.L. Feldman and A.E. Randolph. Department of Neurology, University of Michigan Medical Center, Ann Arbor, MI 48109.

Mannose-6-phosphate (M6P) and insulin-like growth factor II (IGF-II) bind to separate sites on the same cell surface receptor. M6P is known to increase the affinity of the shared receptor for IGF-II, potentiate the effects of IGF-II on phosphotidylinositol turnover in kidney cells and increase IGF-II endocytosis in IM9 cells. We postulated that M6P might modulate the known effects of IGF-II on neuroblastoma cells. We report that M6P alone increases neuronal cell doubling when compared to serum-free media, and in the presence of IGF-II, M6P potentiates IGF-II induced neuronal cell doubling, but has no effect on IGF-II enhanced neurite outgrowth.

neurona ceir doubning wene compared to serume-iree media, and in the presence of IGF-II, M6P potentiates IGF-II induced neuronal cell doubling, but has no effect on IGF-II enhanced neurite outgrowth.

SH-SY5Y neuroblastoma cells were grown in 6 well plates in either serum free DMEM (SF DMEM), or with the addition of 5 mM M6P, 10 nM IGF-II, or a combination of M6P and IGF-II. Cell number was determined on days 2, 3, and 7 with corresponding DNA assays. Compared to SF DMEM cell counts on days 2, 3, and 7, M6P increased cell number by 7, 17 and 43%, IGF-II by 73, 116 and 110%, and IGF-II/M6P by 90, 135 and 235%, respectively. This same pattern was observed with quantitative DNA assays. In a separate set of experiments, under the same conditions, neurite outgrowth was assayed by the method of Sonnefeld and Ishii (1982). On days 1 through 7, there was no difference in neurite outgrowth between SF DMEM or SF DMEM with M6P. IGF-II alone stimulated outgrowth by 70% over SF DMEM by day 3; the addition of M6P to IGF-II did not alter this stimulation. We speculate that M6P can potentiate selective effects of IGF-II on neuronal cells. (Supported by grant NS01381 to ELF)

Ca^{*2}-INDUCED VESICULATION IN DIALYZED SQUID GIANT AXON.

<u>Harvey M. Fishman and Kirti P. Tewari*</u> Department of
Physiology and Biophysics, University of Texas Medical
Branch, Galveston, TX 77550-2779

Formation of vesicles within cut ends of squid giant

Formation of vesicles within cut ends of squid giant axons following transection in divalent cation (DC)-containing artificial sea water (ASW) was recently reported (BBA, <u>Biomemb</u>. 1023:421, 1990). Internal dialysis of axons was implemented to determine whether vesiculation is caused by entry of Ca*2 or by the injury. A technique for dialysis of axons was modified so that continuous DIC video microscopy was possible during dialysis. Control solution consisted of (mM) 440 K glutamate + 2.5 EGTA + 5 TrisCl adjusted to 989 mOsm by adding glycine. Control solution in the bath and as dialysate produced minimal vesiculation after 1 hr of dialysis. Replacing glutamate by Cl⁻ in the dialysate produced a slight increase in vesiculation compared to that of control. Dialysis with DC-free ASW (430 Na*) produced a further increase in vesiculation. Vesicle production was greatest when Ca*2 was added to the DC-free ASW. Ca*2-induced vesicles were evident at dialysate [Ca*2] of 100 µM and axosomes (50 µM dia., fused vesicles) formed at dialysate [Ca*2] above 1 mM. No vesiculation was apparent beyond the porous region of the dialysis tubing within axons. These data show that a rise in axoplasmic [Ca*2] to 100 µM or more without axonal injury is sufficient to induce axonal vesiculation and that Na* and Cl⁻ enhance the induced vesiculation effect of Ca*2. Supported by ONR Grant N00014-90-J-1137.

NGF RECEPTOR EXPRESSION IN RAT CIRCUMVENTRICULAR ORGANS (CVO) HB Clark, Q Yan, EM Johnson, Jr. and WF Hickey*. Pathology, So. Ill. Univ., Springfield, IL 62781 and Pharmacology & Pathology, Washington Univ., St. Louis, MO 63110 Previously we have shown that in the neurohypophysis (NH) NGF receptors (NGFR) are localized on cells with the ultrastructural appearance of "perivascular microglia" (PVM). Presently we have examined NGFR expression in other CVO using immunostaning with monoclonal antibody 192-166 (PVM). Presently we have examined NGFR expression in other CVO using immunostaining with monoclonal antibody 192-IgG by light microscopy (LM) and electron microscopy (EM). NGFR immunoreactivity (NGFRI) and immunostaining for other cellular markers, CD45 for bone marrow-derived monocytes and GFAP for fibrillary glia, were compared by LM and EM. In median eminence the LM staining pattern for NGFR and GFAP was similar, and by EM the NGFRI was primarily on tany was similar, and by EM the NGFRI was primarily on tany-cytes. In choroid plexus the LM staining for NGFR and CD45 corresponded and by EM was localized to PVM. In NH and area postrema (AP) the staining for NGFR, CD45 and GFAP did not correlate well by LM. EM showed NGFR and CD45 on PVM in both NH and AP. In AP occasional cells with neuronal morphology had NGFRI and in NH some cells resembling pituicytes had NGFRI. Cells and processes reactive for CD45 were cytes had NGFRI. Cells and processes reactive for CD45 were seen in the neuropil of the AP and NH. In summary, CVO have NGFR localized to PVM but also to other cells that differ among the CVO and include neurons and glia. Some "microglial" cells with NGFR may be present in the neuropil of AP and NH. The function of NGFR on these various types of cells in CVO is unclear.

342.3

DISTRIBUTION AND QUANTIFICATION OF BRAIN-DERIVED NEUROTROPHIC FACTOR MRNA IN THE CENTRAL NERVOUS SYSTEM

M. M. HOFER* and Y.-A. BARDE
Dept. of Neurochemistry, Max-Planck Institute
for Psychiatry, Martinsried, FRG.

for Psychiatry, Martinsried, FRG. Brain-derived neurotrophic factor (BDNF) is a protein that is both functionally and structurally related to nerve growth factor (NGF). The BDNF gene is strongly expressed in the adult central nervous system, from which BDNF was originally isolated. The distribution of BDNF mRNA in the adult mouse brain was examined by quantitative Northern blot analysis. All brain regions studied were found to contain two transcripts, 1.5 and 4.2 Kb in length. The highest levels of both transcripts were found in the hippocampus followed by the were found in the hippocampus followed by the cerebral cortex. Quantitative determinations indicated that in the hippocampus, which is also the site of highest NGF gene expression in the central nervous system, there is about 50-fold more BDNF mRNA than NGF mRNA. In other brain regions, such as the cerebellum, the difference between the levels of BDNF and NGF mRNAs are even more pronounced. These data suggest that BDNF may play an important role in the CNS for a wide variety of adult neurons.

CILIARY NEURONOTROPHIC FACTOR (CNTF) IMMUNOREACTIVITY IN RAT CNS. S. Varon, T. Hagg, O. Prospero-Garcia, J.M. Conner and M. Manthorpe Dept. Biol., M-001, UCSD, La Jolla, CA 92093

A peptide corresponding to the carboxy terminal residue Nos. 181-200 of rat nerve CNTF (Stöckli et al., Nature 342:920, 1989) was synthesized and coupled to keyhole limpet hemocyanin and the complex used to immunize rabbits. The resulting anti-peptide antibodies were affinity-purified with sepharose-immobilized peptide. Anti-peptide antibodies reacted with purified rat sciatic nerve CNTF protein by ELISA and by immunosequestration of CNTF neurotrophic activity toward 8 day chick ciliary ganglionic neurons. Adult and neonatal rats were transcardially perfused with 4% paraformaldehyde and 30 µm sections cut from the brain and spinal cord on a freezing microtome. Immunostaining for CNTF-peptide was carried out on selected sections using a sensitive ABC-peroxidase method. In normal neonatal and adult rat, anti-peptide immunoreactivity appeared in most neuronal and glial cell bodies of the brain and spinal cord as a perinuclear vesicular staining. This staining pattern appeared to be associated with the perinuclear Golgi system. Electron microscopy is being undertaken to determine the exact intracellular location of brain CNTF. The widespread staining pattern detected in the CNS is in contrast to the selective staining of Schwann cells in the PNS (Rende et al., Soc. Neurosci. Abstr., 16, 1990). The above results suggest that central nervous system CNTF is more widely distributed than might be expected for a specific target-derived neuronotrophic factor. Support: NINCDS NS-16349, NS-25011 and NSF BNS-88-08285, BNS-86-17034.

NERVE GROWTH FACTOR (NGF) RECEPTOR EXPRESSION IN THE BRAIN AND RETINA OF CHICK EMBRYOS. C.S. von Bartheld, J.G. Heuer*, M. Bothwell. Depts. of Otolaryngology Washington, Seattle, WA 98195.

Expression of NGF receptors was investigated in chicks from 5

days of incubation to 14 days posthatch with in situ hybridization. NGF receptor mRNA is expressed transiently in hippocampus, neostriatum, habenula, optic tectum (layers 3, 10), all nuclei of the isthmic complex, all motor nuclei, cerebellum (Purkinje cells, Golgi cells), inferior olive, and retina (inner plexiform layer, ganglion cell layer). High levels of NGF receptor mRNA persist in nucleus subrotundus, mesencephalic nucleus of the trigeminal nerve, locus

NGF receptors are expressed predominantly, but not exclusively in cholinergic neurons and always precede the onset of cholineacetyltransferase immunoreactivity. Levels of NGF receptor mRNA are high during periods of target dependence and cell death (e.g., isthmo-optic nucleus, retina, optic tectum, cerebellum, motor nuclei), suggesting a role of NGF receptors in cell survival. High levels of NGF receptor transcripts in locus coeruleus are remarkable because rat locus coeruleus normally lacks NGF receptors. Surprisingly, NGF receptors are not expressed in cholinergic neurons of the basal forebrain, instead, these neurons express high levels of The type of growth factor (FGF) receptors (Heuer et al., submitted). forebrain neurons (FGF, but not NGF) thus differs from that in mammais, possibly reflecting differences in the embryonic origin of the targets. Supported by NIH grants DC0019, GM07270, NS23343.

342.4

LOCALIZATION OF BDNF mRNA IN AGED RAT BRAINS Denton, TL, Johnson, SA, and Hefti, F University of Southern California, Andrus Gerontology Center, Los Angeles, CA 90089 Brain Derived Neurotrophic Factor (BDNF) is a neurotrophic

factor, related to NGF, for which the sequence has recently been determined. We wanted to determine if there were any changes in BDNF concentrations in the aging brain. For initial studies of regional distribution young (21 days) Fisher 344 rats were decapitated and the brains dissected into regions. Tissue pieces decapitated and the brains dissected into regions. Itssue pieces were frozen on dry ice and the RNA was isolated using acid guanidinium. Northern blots were hybridized to an ³²P-labeled antisense 460 bp partial rat BDNF riboprobe overnight and exposed to X-ray film. Exposures were quantitated by densitometry. Two species of mRNA hybridized with the probe, one at 4.5 and one at 1.7 kilobases. BDNF mRNA was found to be widespread in rat brain. Concentrations in dorsal and ventral mesencephalon were intermediate. These findings suggest a role for BDNF in the function of a number of neuronal populations. The highest concentration was found in the hippocampus and the lowest concentration in the striatum. Results will be presented comparing the concentration of BDNF mRNA in various regions of young adult (6 months) and old (26 months) rat brains. SAJ was supported by NIA AG07909.

342.6

Survival effect of ciliary neurotrophic factor (CNTF) and other factors on embryonic motoneurons in culture Arakawa, Y., M. Sendtner and H. Thoenen, Max-Planck-Institute for Psychiatry, D-8033 Martinsried, FRG. CNTF has a potent survival effect on various embryonic neurons in culture, such as ciliary, dorsal root sensory and sympathetic neurons. Recent investigations showed that CNTF prevents the degeneration of motoneurons in new-born rats after lesion (M. Sendtner et al., Nature, 1990, in press). The question arose as to whether CNTF also has a survival effect on embryonic chick motoneurons at the developmental stage where physiological cell death occurs. To study this, we improved the culture method for chick embryonic motoneurons using metrizamide gradient centrifugation, which provided a high purity (more than 80% demonstrated by retrograde labelling) and a high survival rate of motoneurons (virtually 100% after 3 days in culture in the presence of muscle extract). Unde these conditions, CNTF (1.5ng/ml) supported 64% of initially plated motoneurons (EC₅₀ 0.023ng/ml). NGF, brain derived neurotrophic factor (BDNF) and neurotrophin-3 (NT-3) had no survival effect. Basic FGF supported maximally 51% of motoneurons (EC50 0.28ng/ml) and acidic FGF supported 35% of motoneurons in the presence of 1 μ g/ml heparin. Small effects at high concentrations were observed by insulin (16%) and insulin-like growth factors I and II (both at 15%) (basal survival rate was 5%). Many other mitogens and cytokines had no survival activity. The effect of CNTF and basic FGF was additive, resulting in a 100% survival even after 6 days. Thus, CNTF also supports embryonic motoneurons and, together with basic FGF, results in a 100% survival even after 6 days.

LOCALIZATION OF BRAIN-DERIVED NEUROTROPHIC FACTOR mRNA AND PROTEIN. C. Wetmore, P. Emforst, H. Perssont, L. Olson, Dept. of Histology & Neurobiology, and Department of Medical Chemistry†, Karolinska Institute, 104 01 Stockholm, Sweden.

Institute, 104 Of Stockholm, Sweden.

For many years, nerve growth factor (NGF) was the only trophic factor known to exert specific effects upon the growth and differentiation of neurons. In the past year, two new neurotrophic factors with striking homology to NGF have been purified and cloned: brain-derived neurotrophic factor (BDNF) and neurotrophin 3 (NT3). While all three factors show extensive similarities in amino acid sequence, molecular weight, conservation of six cysteine residues and of the intraprotein disulphide bonds, these factors effect neurotrophic responses from somewhat overlapping yet distinct populations of neurons. BDNF, unlike NGF, appears not to promote the growth of sympathetic neurons in culture, yet does support fiber outgrowth of placode-derived

In the present study, we have used oligonucleotide probes to study the distribution of BDNF in the adult pig and rat brain. The oligonucleotide, derived from a stretch of porcine BDNF sequence, was labeled at the 3' end with $[^{35}S]$ -dATP, applied to slide-mounted, $14\mu m$ sectioned brain tissue, and allowed to hybridize for 6 weeks at $-20^{\circ}C$. Measurements of grain densities were carried out at high magnification using bright field illumination and clustering over specifically labeled cells was well over (20-40

field illumination and clustering over specifically tabeled cells was well over (20-40 fold) background levels as evaluated by computer-assisted image analysis.

BDNF mRNA shows a distribution in the brains of both species similar in several respects to that known for NGF mRNA, with strong labeling in granule cells of the dentate gyrus, as well as pyramidal and hilar cells in the hippocampus. Additionally, BDNF mRNA was detected in small cells around the subependymal area of the pig, and in scattered neurons of cortex cerebri, and claustrum of both pig and rat. These results indicate that in the brain, BDNF, like NGF, has neuronal rather than glial sites of synthesis. Immuno-histochemical localization of the BDNF protein with antibodies raised against BDNF peptides in rabbits shows a distribution similar to that of BDNF mRNA as detected with in situ hybridization.

A DOPAMINERGIC NEUROTROPHIC FACTOR (DNTF) IS SECRETED BY SCHWANN CELLS GROWN IN CULTURE. J.E. Springer, L. Jacovitti, B.A. Maguire,* and T.J. Collier. Center for Neurological Research and the Hahnemann Institute for Neuroscience, Hahnemann University, Philadelphia, PA 19102, and Dept. of Neurobiology and Anatomy, University of Rochester Medical Center, Rochester, New York, 14642 (TJC).

Specific polypeptide molecules termed neurotrophic factors may be required for the Specific polypepide molecules termed neurotrophic factors may be required for the development, survival, and normal function of certain neuronal populations in the central nervous system (CNS). We have previously shown that a soluble factor(s), designated as dopaminergic neurotrophic factor (DNTP), is secreted from sciatic nerve and exhibits trophic actions on embryonic midbrain dopamine neurons. In the present study we have determined that Schwann cells grown in culture may be a potential source of DNTF. Ventral midbrain tissue containing the substantia nigra was isolated from rate at 15 days gestation, dissociated and pelated at a density of 300,000 cells per culture well. These cultures were grown in culture medium containing 10% fetal cell serum (FCS) for at 15 days gestand, dissociated and plated at a density of 30,000 dens per clinical references cultures were grown in culture medium containing 10% fetal calf serum (FCS) for 48 hours. The cultures were then incubated in conditioned medium from an immortalized Schwann cell line (kindly provided by G. Owens, Washington University) diluted with culture medium containing 1% FCS. For comparison, additional cultures were grown in the presence of known growth factors including basic fibroblast growth factor (BGF), insulin-like growth factor, IGGF-1), and nerve growth factor (NGF). The cultures were maintained in the low serum/growth factor conditions for 3-5 days and processed for the immunocytochemical localization of tyrosine hydroxylase (TH). Cultures grown in the presence of Schwann cell conditioned medium (SCCM) exhibited a concentration-dependent increase (150-200%) in the number and neurite outgrowth of TH-positive neurons. Cultures treated with bFGF showed a similar, but less robust effect compared to SCCM treated cultures (38%). None of the other growth factors tested showed any effect with the exception of IGF-1, which decreased the number of TH-positive neurons by 20%. These results demonstrate that one of the factors secreted by Schwann cells exhibits trophic activity on dopaminergic neurons in vitro (see also Collier and Springer, this volume). Supported by NIH grants AG-08969 (JES) and AG-08133 (TJC).

VASOPRESSIN PROMOTES HIPPOCAMPAL NERVE CELL GROWTH IN CULTURE. R.E. Brinton, Sch. of Pharmacy and Depart of Biology, Univ. of Southern California, 1985 Zonal Ave, Los Angeles, CA 90033.

The present study seeks to address the hypothesis that if memory formation is subserved by structural changes in nerve cell morphology, then factors which in-fluence memory formation should influence neuronal growth. Vasopressin (AVP) has been shown to enhance memory formation (DeWied, 1971; 1984) through a NE dependent mechanism (Kovacs et al., 1979). AVP also acts as a neuromodulator to potentiate NE-induced cAMP formation in the hippocampus (Brinton and McEwen, 1989). In an initial test of the above stated hypothesis we found AVP to act as a neurotrophic factor in cultured embryonic Xenopus nerve cells (Brinton and Gruener, 1987). Because the site of behavioral and neuromodulatory effects of AVP involve the hippocampus, the influence of AVP upon hippocampal nerve cell growth in culture was determined. Hippocampal nerve cells from E18 rat pups were cultured in serum containing media and allowed to attach to polylysine coated coverslips whereupon the media was changed to serum free. Thirty min exposure to 10 uM AVP resulted in a significant increase in the length of filopodial extensions when compared to the change in filopodial length during the control period of observation (control = -0.89 ± 0.51 um, n = 102; AVP treated = 1.76 ± 0.37 um, n=102). The significant increase in filopodial length persisted for 20 minutes and returned to control values at 30 min. Exposure for 18 hr to 100 nM AVP in serum free medium resulted in a significant increase in the # of neurites (c=0.13 \pm 0.06; AVP=0.64 \pm 0.13, n=66 cells, p <.0001) and # of filopodia (c=1.0 \pm 0.27; AVP=6.23 \pm 1.1, n=66 cells, p <.0001). Exposure for 48 hin, to 100 nM AVP in serum free medium resulted in loss of neuritic extensions suggesting that prolonged exposure to AVP is toxic to nerve cells. Experiments to determine calcium dependency of AVP effects are in progress. This work supported by NIH grant MH-46036 to R.E.B.

PROTEIN KINASE INHIBITORS K-252A AND K-252B INHIBIT THE TROPHIC ACTION OF NGF, BUT NOT bFGF AND INSULIN ON CNS NEURONS IN CULTURE. F. Hefti and B. Knusel. Andrus Gerontology Center, Univ. of Southern California, Los Angeles, CA 90089.

The protein kinase inhibitor K-252a has been shown to inhibit NGF induced neurite growth in PC12 cells and in primary cultures of dorsal root ganglion cells (Matsuda, Y. and Fukuda, J., Neurosci. Letts. 87:11, 1988; Hashimoto, S., J. Cell Biol., 107:1531, 1988). We studied actions of K-252a and the structurally depend of the State in the structurally depend (S. S.) in primary cultures of perhapsings (S. C.). hashindto, 3, veri biot., 107.1331, 1395, We studied actions to N-222a affective the structurally closely related K-252b in primary cultures of embryonic rat CNS cells in presence and absence of growth factors. Treatment for 5 days with 10 to 200 nM K-252a depressed ChAT activity and dopamine uptake in cultures of medial septum and ventral mesencephalon, respectively, to 10 - 40 % of to 200 nM R-252a depressed ChA1 activity and oppamine uptake in cultures of medial septum and ventral mesencephalon, respectively, to 10 - 40 % of control. 300 to 1000 nM K-252a restored both parameters to control values or higher. K-252b, up to 2500 nM, slightly depressed ChAT activity and dopamine uptake in a dose-dependent manner. No stimulatory effect was observed with this compound. Protein content was only mildly decreased with either compound, but the cultures showed signs of toxicity of K-252a (a >30nM) in phase-contrast observation. Tested with growth factors, both, K-252a and K-252b completely abolished the action of NGF on septal cholinergic neurons. High concentrations of the two compounds did not diminish the stimulatory actions of bFGF and insulin on septal cholinergic and mesencephalic dopaminergic neurons. Insulin, however, exacerbated the deleterious effect of low concentrations of K-252a on ChAT activity in septal cultures.

We conclude from our findings, that the actions of K-252a and possibly also K-252b in the CNS are twofold: (i) selective inhibition of the action of NGF on basal forebrain; (ii) non-selective inhibitory and stimulatory actions on different transmitter-specific populations of neurons. Since the two compounds inhibit various protein kinases with different selectivity (Kase, H., et al., Biochem. Biophys. Res. Comm., 142:436, 1987), our results are suggestive of multiple roles of protein kinases in biochemical differentiation of CNS neurons.

342.10

A PERIPHERAL NERVE GROWTH FACTOR AUGMENTS THE BEHAVIORAL AND MORPHOLOGICAL EFFECTS OF CO-GRAFTED DOPAMINE NEURONS. T.J. Collier and J.E. Springer, Dept of Neurobiology and Anatomy, Univ. of Rochester Sch. of Med., Rochester, NY 14642; and Dept of Neurology, Hahnemann Univ. Sch. of Med., Philadelphia, PA 19102.

Neurobiology and Anatomy, Univ. of Rochester Sch. of Med., Rochester, NY 14642; and Dept of Neurology, Hahnemann Univ. Sch. of Med., Philadelphia, PA 19102. We have demonstrated that explanted segments of adult rat sciatic nerve placed in co-culture with embryonic rat mesencephalic dopamine (DA) neurons increase the number of tyrosine hydroxylase (TH) positive neurons and enhance their neurite outgrowth (Soc. Neurosci. Abst. 15:1354, 1989). The current study examined whether intraventricular implants of sciatic nerve could serve as a source of potential DA neuron growth-promoting factor, and would augment the behavioral and morphological recovery produced by embryonic rat ventral mesencephalic tissue grafted into the denervated striatum of unilateral 6-hydroxydopamine (6OHDA) lesioned rats. One week following lesion, rats were tested for baseline rotational behavior in response to intraperitoneal injection of 5mg/kg amphetamine. Subjects then received simultaneous implantation of a single block graft of E15 rat ventral mesencephalon into the DA-depleted striatum, combined with a hollow fiber implant into the ipsilateral lateral ventricle. Controls (n=6) received an empty fiber, cografted subjects (n=10) received a fiber containing a 5mm segment of adult rat sciatic nerve. Amphetamine rotation was retested 1,3,5,7,10 and 12 weeks after grafting. Co-grafted rats exhibited enhanced recovery of rotational behavior: 8 of 10 co-grafts showed complete recovery of rotation over the 12 week interval, while only 1 of 6 controls recovered. Co-grafted rats also exhibited an average 86% increase in the number of surviving grafted TH neurons in the striatum, combined with a prominent increase in neurite outgrowth, such that a larger proportion of the striatum was reinnervated in co-graft subjects and behavioral recovery was achieved even by small grafts that were behaviorally ineffective in control rats. These results support the view that peripheral nerve produces a factor with growth-promoting properties for central DA neu

BRAIN-DERIVED NEUROTROPHIC FACTOR IS EXPRESSED IN CENTRAL OLFACTORY REGIONS AND BY TARGET AREAS OF BASAL FOREBRAIN CHOLINERGIC NEURONS. H.S. Phillips. J.M. Hains*, G.R. Laramee*, K. Nikolics, and J.W. Winslow. Dept Dev. Biology, Genentech, 460 Point San Bruno Blvd., South San Francisco, CA 94080.

Brain-derived neurotrophic factor (BDNF) is a homolog of NGF which exhibits a different pattern of target specificity in the peripheral nervous system and which appears to be expressed in brain at higher levels than NGF (1). We report here the distribution in rat forebrain of messenger RNA (mRNA) for BDNF as determined by in situ hybridization. Sense and anti-sense 35-S labelled RNA probes were employed for hybridizations which were analyzed with a combination of sheet film and emulsion autoradiography. Cells hybridizing intensely for BDNF message were located within the major targets of the basal forebrain cholinergic system, i.e., hippocampus, neocortex and amygdala. High concentrations of strongly hybridizing cells were also observed in several structures associated with the olfactory system, including the anterior olfactory neucleus, piriform cortex, tenia tecta, and endopiriform nucleus. These findings suggest that trophic activity of BDNF may not be restricted to primary sensory neurons, and point to basal forebrain cholinergic cells and olfactory pathways as potential central targets for BDNF.

HUMAN BASIC FIBROBLAST GROWTH FACTOR AND TRANSPLANTATION OF HUMAN AND RAT FETAL MESENCEPHALIC DOPAMINE CELLS. C.R. Freed, Y.B. Zhang, D. Bhaskaran, and C.A. Kruse, Depts. of Med., Pharm., and Surg., Univ. of Colo. Health Sci. Ctr., Denver, CO 80262.

To improve survival of fetal mesencephalic dopamine cells during transplantation to adult brain, we have studied the effect of human basic fibroblast growth factor (bFGF, Amgen) on fetal human and rat cells in culture and after transplant. Human fetal dopamine cells were acquired from therapeutic abortion as previously described (Arch. Neurol. 47:505-512, 1990). Rat mesencephalon was obtained from embryonic day 15 to 16 Sprague-Dawley fetal rat. Tissue was preserved in high potassium, calcium and magnesium free media at 10 degrees. On the day following acquisition, fetal cells were placed in culture. Rat and human tissue was cultured in N5 media with NSF as previously described (Brain Res. 384:84-93, 1986). Human bFGF 10 ng/ml and heparin 1 ug/ml were added. Tissue was harvested after one week in culture and assayed for dopamine. Dopamine concentration from bFGF/heparin treated cultures was compared to untreated cell cultures. In addition, some cultured tissue was directly transplanted into rats with unilateral striatal dopamine depletion. Rats receiving human fetal tissue were immunosuppressed with daily injections of cyclosporine (10 mg/kg i.p.).

FATE OF INTRACEREBRALLY INJECTED ¹²⁵I-FIBROBLAST GROWTH FACTOR. L.S. Carman, A.M. Gonzalez*#, F.H. Gage, M. Buscaglia*#, C.W. Shults and A. Baird*#. Dept. of Neuroscience, U.C. San Diego and #The Whittier Institute for Diabetes and Endocrinology. La Jolla, CA 92037.

Institute for Diabetes and Endocrinology, La Jolla, CA 92037.

Basic fibroblast growth factor (bFGF) is a member of the FGF family that shows multifunctional biological activity. It is localized and synthesized in several different tissues and particularly in the brain. It is a potent neurite-promoting agent for a variety of CNS cell types in vitro. In addition, infusion of bFGF in vivo has been shown to enhance survival of septal cholinergic neurons following axotomy. In an effort to understand the fate of bFGF following intracerebral injection, we injected 1251-bFGF into striatum or ventricle of normal or lesioned rats and measured activity in dissected tissue or processed tissue for autoradiography. Thus, we hope to determine (1) how much bFGF remains in brain, (2) whether it is stable, and (3) where it binds

By 4 hours after injection into striatal parenchyma, 62% of injected radioactivity remained at the injection site. By 2 days and 7 days, this decreased to 36% and 6%, respectively. There were no differences in diffusion or binding between normal and previously-lesioned rats. Western blot analysis showed that after 2 days, the bFGF present in the tissue corresponded to the 18-kD molecular form. Tissue autoradiography showed that injected ¹²⁵1-bFGF remained mainly bound to cells and matrix at the site of injection. Following injection into the ventricle, most ¹²⁵1-bFGF bound to ependymal cells, lining the ventricle and very little of it diffused into adjacent parenchyma.

These observations suggest that, as in other tissues, injected bFGF binds locally in the brain. The biological significance of this binding and potential exploitation of this characteristic is in progress. DK-18811.

NEUROTROPHIC ACTIVITY CONTAINED IN RAT HIPPOCAMPUS IS REDUCED BY CHRONIC EXPOSURE TO ETHANOL. D.W. Walker, M.B. Heaton, M.A. King, B.E. Hunter, Veterans Administration Medical Center and University of Florida College of Medicine, Gainesville, Florida, U.S.A. 32610.

The objective of this research is to determine if chronic ethanol treatment (CET) reduces the NGF-like neurotrophic activity contained in the rat hippocampus (HPC). A bioassay performed in cultures of dissociated dorsal root ganglion cells (DRG cells) from E7-8 chick embryos was used to determine the relative NGF-like neurite-promoting activity contained in the HPC of rats exposed to CET or control diets for 20-24 weeks. We compared the effect of the following four culture media conditions on the survival and neurite outgrowth of DRG cells after 24 and 48 hrs in culture: 1) control medium, 2) control medium + NGF (20 ng/ml) as positive control, 3) medium containing HPC extract (5% w/v) from a CET rat and 4) medium containing HPC extract (5% w/v) from a pair-fed control rat. The most dramatic difference in neurotrophic activity observed was a 40-50% decrease in both the total extent and average length of neuronal processes extended in the cultures maintained in medium containing HPC extract from CET rats as compared to HPC control extract or NGF control conditions. These data support the hypothesis that CET reduces the neurotrophic activity contained in the HPC which may compromise the structural and functional integrity of the septohippocampal system due to chronic deprivation of normal neurotrophic influence. We are currently conducting experiments to determine what proportion of the neurotrophic activity contained in the HPC extract is NGF-like, and what proportion may be due to other neurotrophic factors

(Supported by the Veterans Administration, NIAAA grant AA00200 and NIH Grant NS 20387).

EXPRESSION OF C-SIS ONCOGENE-RELATED PROTEINS IN DEVELOPING AND ADULT RAT CENTRAL NERVOUS SYSTEM.

A. Simonati*, R. S. Cameron*, M. Solimena and P. Rakic Section of Neuroanatomy, and Department of Cell Biology, Yale University School of Medicine, New Haven, CT 06510

The expression and distribution of the c-sis/PDGF-B gene product within the mammalian CNS is still controversial (Oberdick et al., Neuron, 1988; Johnston and

The expression and distribution of the c-sis/PDGF-B gene product within the mammalian CNS is still controversial (Oberdick et al., Neuron, 1988; Johnston and van der Kooy, PNAS, 1989; Pringle et al., EMBO J, 1989). In order to address this issue we have used three monoclonal antibodies (mabs) for morphological and biochemical analysis of rat CNS: one mab was directed to residues 1-18 (Microbiol. Assoc.) and two mabs (C-1975 and C-3893) were developed against residues 22-38 (from C. Hart, Zymogenetics Inc.) of the PDGF-B chain. Detergent solubilized polypeptide fractions of human platelets, developing and adult rat cerebellum and forebrain were reduced, alkylated and processed for 1-D Western Blotting. On immunoblots of platelets all mabs recognize a 28 Kd band, the molecular weight (m.w.) of the c-sis gene product. A band of the same m. w. is seen for cerebellar fractions when using the two mabs to residues 22-38; the mab to 1-18 residues recognizes a 18 Kd band (corresponding to the PDGF-B chain m.w.) and a 33-35 Kd doublet on both the developing cerebellum and forebrain. Immunostaining of neural antigens on tissue sections is obtained by the latter mab. During prenatal development, regions corresponding to the main fibre pathways of the neural tube and forebrain are labelled. The developing fibre tracts of the postnatal cerebellum are also immunoreactive. However, in adult CNS fibre pathways are not immunolabelled, while dendrites of pyramidal neurons and Purkinje cells are well stained. We are carrying out analyses of cultured glial cells, prepared from prenatal rac cortex and preliminary data show cytoplasmic staining of the astrocytes with the C-3893 mab. The present study confirms that PDGF is expressed in the rat CNS and suggests that different post-translational products of the c-sis oncogene can be detected in the developing CNS in locations that are different from adult.

TYROSINE PHOSPHORYLATION OF A 70 kDa PROTEIN BY INSULIN AND INSULIN-LIKE GROWTH FACTORS IN CULTURED FETAL CHICK NEURONS. K.A. Kenner* and K.A. Heidenreich. Dept. of Medicine, UCSD, La Jolla, CA 92093
Insulin and insulin-like growth factors have been

Insulin and insulin-like growth factors have been implicated in neuronal growth and differentiation. Previous studies in our laboratory showed that cultured neurons derived from embryonic day 7 chick forebrain have both insulin and IGF-I receptors (5.7 X 10³ and 4.5 X 10⁴ high affinity sites/cell, respectively), which undergo autophosphorylation in response to ligand binding. Tyrosine phosphorylation of other proteins by the activated receptor kinases was not detected in neurons cultured for 5 days. In this study we examined neurons cultured for less time, using immunoblot analysis with antiphosphotyrosine antibodies. Neurons cultured 3-5 hrs contained a predominant protein M_T 70,000 (pp70) that was phosphorylated on tyrosine in response to insulin, IGF-I, or IGF-II. Ligand-stimulated phosphorylation of pp70 was not detected in neurons cultured longer than 24 hrs. Phosphorylation of pp70 was detected within 30 sec of ligand exposure and was maximal by 5 min. All 3 growth factors stimulated phosphorylation of pp70 to a similar extent at concentrations ranging from 1-50 nM. The time course and dose-response of pp70 phosphorylation paralleled that of insulin and IGF-I receptor autophosphorylation, suggesting that this protein represents an endogenous substrate for these receptor kinases in neurons.

TGF-BETA ISOFORMS IN THE CENTRAL AND PERIPHERAL NERVOUS SYSTEM. K. Unsicker, K.C. Flanders*, D.S. Cissel*, S. Marascalco*, R. Lafyatis*, A.B. Roberts* and M.B. Sporn*. Dept. Anatomy and Cell Biology, University of Marburg, F.R.G., and Lab. Chemoprevention, NIH, NCI, Bethesda, MD 20892.

TGF-Bs are multifunctional growth factors with a wide tissue distribution. We have studied the localization of the TGF-B1, 2 and 3 proteins and TGF-B3mRNA in the adult rat and embryonic chick nervous systems using immunohistochemistry, Northern blot analysis and in situ hybridization. TGF-B2 and 3 immunoreactivities are strictly colocalized and occur in neurons, radial glial cells, white matter astrocytes and Schwann cells. TGF-B1 is confined to meninges and choroid plexus. In the rat brain, highest densities of TGF-B immunoreactive neuronal cell bodies are found in brainstem motor nuclei, cerebral cortical laminae 2, 3 and 5, hippocampus, hypothalamus and amygdala. In other areas, like spinal cord dorsal horn, periaqueductal gray and thalamic nuclei, neuronal perikarya containing TGF-Bs are very scarce. Northern blots reveal approximately equal levels of TGF-B3mRNA in cerebral cortex, hippocampus, striatum and cerebellum. In situ hybridizations suggest synthesis of TGF-B3 in neurons and glial cells.

SUBSEIZURE AFFERENT STIMULATION INCREASES NGF MRNA IN RAT DENTATE GYRUS GRANULE CELLS.

M.W. Oliver, P.J. Isackson and C.M. Gall, Department of Anatomy and Neurobiology, University of California, Irvine CA 92717.

Previous work in our laboratories demonstrated that recurrent seizures increases NGF mRNA expression in the dentate gyrus granule cells. In the present study in situ hybridization techniques, using 35S-cRNA probes complementary to the full rat preproNGF and c-Fos mRNA sequences, were used to evaluate whether subseizure stimulation of the perforant path is sufficient to alter NGF and c-Fos mRNA expression in GC.

In anesthetized Sprague-Dawley rats, either high frequency (HFS; 100-400Hz, 5 pulses ,repeated 10x) or low-frequency (LFS; 10Hz, 15-20 pulses, repeated 2-4x) stimulation was delivered to the angular bundle; continuous recordings from the dentate gyrus verified orthodromic activation and the absence of epileptiform activity. In only 2 of 18 cases, HFS dramatically increased (>7-fold) hybridization of the NGF cRNA probe within GC. LFS was more effective: in 3 of 6 cases hybridization of the NGF cRNA probe was increased 3-fold or more. In all cases, hybridization was only increased ipsilateral to stimulation. In control rats, with electrodes lowered but no stimulation, NGF cRNA hybridization was only slightly increased (<50%) within ipsilateral GC and olfactory cortex. Increases in hybridization to c-Fos mRNA correlated with NGF cRNA labeling in GC of stimulated rats. These data demonstrate that subseizure activity regulates the expression of neural trophic factors and immediate-early genes by adult forebrain neurons. (Supported by PEW Foundation & NS26748 to C.G. and NS24747 to P.i.)

BRAIN DERIVED NEUROTROPHIC FACTOR MRNA EXPRESSION IS INCREASED IN ADULT RAT HIPPOCAMPAL NEURONS AFTER SEIZURE INDUCTION. P.J. Isackson, M.M. Huntsman*, K.D. Murray*, and C.M. Gall. Department of Anatomy and Neurobiology and Department of Biological Chemistry, University of California, Irvine, CA 2274.7

92717.
Brain derived neurotrophic factor (BDNF) and nerve growth factor (NGF) are homologous target-derived neurotrophic factors that affect different neuronal populations. We have previously shown that the induction of limbic seizures results in a rapid, transient increase in NGF mRNA expression in hippocampal dentate granule cells. We have used in situ hybridization and S1 nuclease protection assays with an RNA probe prepared from a PCR-generated cDNA clone for rat BDNF to demonstrate that BDNF is regulated by a similar mechanism in the adult rat hippocampus. The level of BDNF mRNA is dramatically increased in the dentate gyrus granule cells, bilaterally, following recurrent limbic seizures induced by unilateral electolytic lesion of the dentate hilar region as well as following one hippocampal discharge (30-45 sec duration) induced by 10 Hz stimulation of the discharge (30-45 sec duration) induced by 10 Hz stimulation of the perforant path. Hybridization is increased greater than 10-fold above perforant path. Hybridization is increased greater than 10-fold above normal levels in the hilus lesion rats. In contrast to NGF, BDNF mRNA is increased in pyramidal cells of the CA1 and CA3 regions of the hippocampus in addition to the dentate gyrus granule cell layer. These results suggest that homologous members of the NGF neurotrophic family are regulated similarly by physiological stimulation and may play an important role in activity-dependent plasticity in the adult CNS. (Supported by NS24747 to P.I. and NS26748 to C.G.).

bfgf undergoes receptor-mediated retrograde transport in

bFGF UNDERGOES RECEPTOR-MEDIATED RETROGRADE TRANSPORT IN CNS NEURONS. <u>Ian A. Ferguson</u>. Akio Wanaka, and E.M. <u>Johnson</u>, <u>Jr</u>. Dept. of Pharmacology, Washington University School of Medicine, St. Louis, MO 63110

Neurons in the adult rat CNS which respond to bFGF by internalizing and retrogradely accumulating the growth factor were identified by autoradiography following injections of ¹²⁵I-bFGF. Neuronal populations which showed specific (saturable) retrograde accumulation of ¹²⁵I-bFGF included the pyramidal cell neurons of the hippocampus, neurons in the subiculum, paracentral thalamic and central medial thalamic nuclei, parafascicular nucleus, the lateral hypothalamus, supramammilliary nucleus, substantia nigra compacta, pedonuclopontine and laterodorsal tegmental nuclei. Basal pedonuclopontine and laterodorsal tegmental nuclei. Basal forebrain cholinergic neurons, which retrogradely accumulated $^{125}\mathrm{I-NGF},$ did not accumulate $^{125}\mathrm{I-bFGF}.$ Neurons which retrogradely accumulated $^{125}\mathrm{I-bFGF}$ also expressed mRNA for the bFGF receptor as shown by <u>in situ</u> hybridization studies. The retrograde accumulation of $^{125}\mathrm{I-bFGF}$ in neurons was specific as co-injection of excess unlabeled bFGF or co-injection of WGA (which nonspecifically blocks the binding of bFGF to its receptor) abolished the retrograde labeling. The time course of labeling was consistent with labeling being a retrograde transport-mediated phenomenon. The analogy with NGF is striking and strengthens the possibility that bFGF may be a neurotrophic factor for some CNS neuronal populations.

343.2

SEIZURES INDUCE INCREASES IN NGF mRNA THROUGHOUT CEREBRAL CORTEX.

J.C. Lauterborn, P.J. Isackson, and C.M. Gall, Department of Anatomy & Neurobiology, University of California, Irvine CA 92717.

Nerve growth factor (NGF) application has been demonstrated to affect the levels of both choline-O-acetyltranferase and NGF receptor expression within the basal forebrain. These observations are intriguing in that they suggest that changes in the amount of endogenous NGF may be of consequence to specific neuronal circuitries. Recently, our laboratories have reported that hilus lesion (HL) induced limbic seizures lead to a rapid and dramatic increase in the expression of NGF mRNA in neurons within hippocampus followed by increases in NGF mRNA throughout broad fields of neocortex (Science, 1989). In the present study, the full distribution of seizure-induced increases in NGF mRNA within rat forebrain was examined by in situ hybridization using a 35S labeled riboprobe complementary to the full rat preproNGF sequence and autoradiographic techniques. By 24 hrs following HL, hybridization to NGF mRNA was observed throughout the entire rostral to caudal extent of the neocortex as well as the entorhinal and piriform cortices, anterior offactory nucleus, amygdaloid complex, and endoprinform nucleus. Increases in hybridization to NGF mRNA within neocortex were most prominent within layers II, III, and VI. In one case, densiometric analysis of the increased cRNA hybridization within lateral neocortex analysis of the increased critical newtones and a 30-fold increase in the HL animal as compared to control. These data demonstrate that physiological activity can stimulate the expression of NGF mRNA in a variety of cortical neurons. (Supported by NS26748 to C.G. & NS24747 to P.I.).

343.4

IN SITU LOCALIZATION OF bFGF RECEPTOR mRNA IN THE ADULT RAT CNS. A. Wanaka, E.M. Johnson, Jr., and J.D. Milbrandt.
Departments of Pharmacology and Pathology, Washington
University School of Medicine, St. Louis, MO 63110. Washington

Basic FGF receptor (bFGF-R) mRNA expression in the adult rat CNS was examined with Northern blot analysis and in situ hybridization histochemistry with the use of cRNA probes for rat and human bFGF-R. Northern analysis showed a probes for rat and human bFGF-R. Northern analysis showed a distinct 4.3 Kb transcript in the various regions of the CNS. In situ hybridization revealed widely distributed, but specific, populations of the cells that express bFGF-R mRNA. The most intense hybridization signals were observed in the hippocampus and in the pedunculopontine and laterodorsal tegmental nuclei. The amygdala central nucleus, supraoptic nucleus, median eminence, substantia nigra pars compacta, locus coelureus, motor nuclei and cochlear nucleus showed robust labeling. Cerebellar granule cells were labeled intensely. Various types of neurons in the spinal cord were positive for bFGF-R mRNA. We did not find any signals in the basal forebrain cholinersic the spinal cord were positive for bFGF-R mRNA. We did not find any signals in the basal forebrain cholinergic neurons. These results are generally consistent with retrograde transport studies using ¹²⁵I-bFGF (Ferguson et al.). The distribution of bFGF-R mRNA significantly differed from that of NGF-R mRNA with a little overlap. The present study strongly suggests that FGF may act as neurotrophic or modulating factors on specific neuronal populations in the mature CNS. bFGF-R mRNA expression in the injured CNS is now under investigation.

DIFFERENTIAL INHIBITION OF EARLY NGF-INDUCED mRNAS BY PURINE ANALOGUES. A. Balistatou. C. Volonté. L.A. Greene*. Department of Pathology and Center for Neurobiology and Behavior, College of Physicians and Surgeons, Columbia University, New York, N.Y. 10032.

Purine analogues [exemplified by 2-aminopurine (2-AP) and 6-thioguanine (6-TG)] inhibit some of the actions of NGF when applied to PC12 cells, but not others. We have extended our studies to the effects of purine analogues on the NGF induction of several early mRNAs in PC12 cells. Our data suggest that NGF induces early genomic effects via at least three distinct pathways. One pathway is sensitive to 2-AP but not to 6-TG and includes the NGF-induced increases of c-myc, cfos, c-jun and TIS11 mRNAs. A second pathway is sensitive to both 2-AP and 6-TG; 2-AP delays the NGF-induced increase of TIS1 (also designated as NGFI-B or nur77) mRNA, while 6-TG inhibits this increase. A third pathway is insensitive to both 2-AP and 6-TG; neither of these compounds decrease the NGF-induced increase of TIS8 (also designated as NGFI-A or egr-1) mRNA. Prior studies indicate that these compounds inhibit protein kinases. Both 2-AP and 6-TG block PKN, an NGF-regulated serine protein kinase (Volonté, C. et al., J. Cell Biol., 109:2395, 1989) at concentrations similar to those used in these experiments. Thus far 6-TG appears to be specific for PKN. 2-AP affects other kinases as well and this may explain its wider action. These data support the hypothesis that multiple distinct kinase pathways are involved in the NGF-mediated increase of early gene expression and argue for the requirement of PKN in one of these pathways.

MOLECULAR CHARACTERISTICS OF AN NGF-ACTIVATED MOLECULAR CHARACTERISTICS OF AN NGF-ACTIVATED PROTEIN KINASE (PKN). C. Volonté and L.A. Greene*. Department of Pathology, Columbia University, New York · N.Y., 10032.

Past work established a cell-free assay for the detection of an NGF-activated protein kinase activity designated protein kinase N (PKN). PKN is a serine kinase which is activated by NGF and other factors in PC12 cells and other cell lines. Through the use of purine analogs which inhibit PKN, we have been able to suggest a role for PKN in certain, but not other, of the multiple pathways of the NGF mechanism of action. The aim of this work is to further characterize the blochemical properties of PKN. We now have found a new purine analog, 6-methylmercaptopurine riboside (6-MMPR), which is very potent (IC 50 ~ 5nM in vitro) and apparently specific for PKN inhibition . The structure of 6-MMPR is important for PKN inhibition : similar compounds which lack the methyl or riboside for PKN inhibition . The structure of 6-MMPR is important for PKN inhibition : similar compounds which lack the methyl or riboside groups are not as active in inhibiting the kinase. 6-MMPR also prevents some of the biological actions of NGF in PC12 cells, including neurite regeneration and ODC induction, again suggesting a role for PKN in certain NGF pathways. Preparations highly enriched for PKN have been prepared with good recovery of activity by ion exchange chromatography on Mono S and Q resins and by elution from Mono S with ATP. By density gradient centrifugation the kinase exhibits a Svedberg coefficient of 4.6. On a Superose12 FPLC column PKN elutes as major peak at 40-50kD and minor peak at 100-130kD. PKN can be affinity labelled with 8-azido-(³P)ATP and shows apparent mol wt of about 47kD by SDS-PAGE. The affinity labelling of PKN is inhibited by purine analogs and shows competition with ATP and GTP, both phospate donors for PKN.

INCREASED NERVE GROWTH FACTOR RECEPTOR mRNA IN CONTUSED RAT SPINAL CORD. M. Revnolds. N. Brunello, J.R. Wrathall and I. Mocchetti. Department of Anatomy and Cell Biology, Georgetown University, Washington, D.C. 20007.

Sciatic nerve transection has been shown to increase the expression of nerve growth factor receptor (NGFR) mRNA in spinal cord motoneurons (Enfors et al., Neuron 2:1605, 1989). To test whether a similar increase occurs after injury to the spinal cord, NGFR mRNA content was determined in spinal cords of adult rats after a standardized mild contusive injury (Wrathall et al., Exp. Neurol. 88:108, 1985). A cRNA probe for NGFR mRNA was synthesized from the p5B plasmid (Buck et al., Develop, Brain Res. 44:259, 1988) and used in Northern blot analysis of total RNA. By 4 days after contusion NGFR mRNA was significantly increased in thoracic segments of the cord that contained the injury site. The induction was maximal at 7 days, about 5-7 times the level of uninjured controls, and remained about 4-fold control level at 14 and 28 days after contusion. The cellular localization of this increased NGFR mRNA is currently unknown but in situ hybridization studies should allow us to identify the sites. The increase in NGFR mRNA after contusive injury suggests that axotomy in the CNS may trigger the molecular mechanism(s) leading to up-regulation of NGFR gene expression. One possibility is that the receptor mRNA may increase in response to the higher levels of NGF protein that we find in the spinal cord after contusive injury. (Supported by NIH-BRSG RR05360 and Genentech, Inc.).

QUANTITATIVE ANALYSIS OF NGF-RECEPTOR GENE EXPRESSION IN THE DEVELOPING RAT CNS. B. Zhao. S. Koh. and G.A. Higgins. Univ. Rochester. Med Ctr., Rochester, NY 14642, and Gerontology Res. Ctr., NIA/NIH, Baltimore, MD 21224.

During the first 3 weeks of postnatal development, NGF-responsive basal forebrain neurons undergo a program of differentiation, including profuse dendritic growth and cellular hypertrophy. In situ hybridization shows that levels of NGF-receptor mRNA appear to peak within basal forebrain neurons at postnatal day (PD) 15 in the rat. In order to better understand the developmental profile of NGF-R gene expression, we have quantified NGF-receptor mRNA levels at PD 1, 5, 10, 15, 22, 30 and adult rat brain, using a combination of densitometric measures of in situ hybridization and the competitive reverse transcription - polymerase chain reaction (RT-PCR). For RT-PCR, the same oligonucleotide primers are being used to amplify endogenous NGF-receptor mRNA, as well as known amounts of exogenously added control NGF-receptor RNA. The control RNA was synthesized from a plasmid which was engineered to produce a different-sized product after RT-PCR. These studies should provide a more detailed quantitative measure of changes in NGF-receptor mRNA levels during rat brain development.

REGULATION OF NERVE GROWTH FACTOR MRNA BY INTERLEUKIN-1 IN THE RAT CENTRAL NERVOUS SYSTEM R. P. Hellendall. D. Casper, C. Lackner, F. Berkenbosch, and M. Blum. Fishberg Ctr. for Neurobiology,

Lacking ...r. Bernelhosson, and M. Blum, Fishberg Ctr. for Neurobiology, Mt. Sinai Sch. of Med., New York, NY 10029 Interleukin-1 (IL-1), a cytokine released by activated macrophages and microglia, has been shown to induce the synthesis of nerve growth factor (NGF) mRNA in explant cultures of rat sciatic nerve (Lindholm, D., et. al., Nature 330:658, 1987). We are studying the regulation of NGF mRNA by Nature 330:658, 1987). We are studying the regulation of NGF mRNA by IL-1 in the CNS to examine if a similar regulation occurs. Astrocytes, purified from PN2 Sprague-Dawley right hippocampus, showed significantly increased levels of NGF mRNA in non-confluent cultures following exposure to IL-18 (10U, 3 hours; Genzyme Corp.). To determine if there are regional differences in the astroglial regulation of NGF mRNA by IL-18, we compared the response to IL-18 in astroglia cultured from the hippocampus, hypothalamus and cortex. Astroglia from all of these areas produced significantly incresed levels of NGF mRNA in response to IL-18. In contrast, preliminary experiments with cultured neurons isolated from E18 rat hippocampi gave no NGF mRNA induction subsequent to IL-1 application. Since it has been demonstrated that the degree of NGF release can be growth-phase dependent, we hypothesize that the ability of application. Since it has been demonstrated that the degree of NGF release can be growth-phase dependent, we hypothesize that the ability of NGF gene expression to be induced by IL-1 may also be correlated to the proliferative state of the cell. Consistant with this idea, injection of 10U of IL-18 (ICV, 3 hr. survival) into adult Fisher 344 rats, where NGF mRNA has been localized to neuronal perikarya, gave no NGF mRNA induction. Thus satroglia may be susceptible to IL-1 induced NGF gene expression during periods of growth and cell division; these periods may include development of the CNS and proliferative responses following injury. Current experiments are examining the effect of the stage of astrocyte proliferation on this inducibility. We are also further clarifying the differences between the glial and neuronal cultures.

INCREASE IN NERVE GROWTH FACTOR (NGF) AND DECREASE IN CHOLINE ACETYLTRANSFERASE (ChAT) ACTIVITY FOLLOWING MILD CONTUSIVE INJURY. J.R. Wrathall, M. Armanini, G.L. Bennett*, W-L. T. Wong* and C. Bakhit. Dept. of Anatomy and Cell Biology, Georgetown Univ., Washington, DC, 20007 and Genentech, Inc., South San Francisco, CA 2010

Washington, DC, 20007 and Genentech, Inc., South San Francisco, CA, 94080.

A standardized mild contusive spinal cord injury can be produced in rats using a weight-drop technique (Wrathall, et al., Exp. Neurol. 88:108, 1985). Initially there is a severe functional deficit that is attenuated over time to reveal by three weeks the mild chronic deficits characteristic of this degree of trauma. As cholinergic neurons are widely distributed and functionally important in the spinal cord, we measured ChAT activity in different segments of the spinal cord before and after injury. We also determined the levels of NGF, a trophic factor for some CNS cholinergic neurons, using a specific two-site ELISA. In normal spinal cord we found a significant correlation (r = .74) between ChAT activity and NGF levels at different segmental levels of the cord. Mild contusive injury resulted in a significant decrease in ChAT activity which reached a nadir at 1 week then partially rebounded at 2 and 4 weeks after injury. The changes in ChAT activity were mirrored by changes in NGF levels that increased dramatically to reach a maximum of about ten-fold greater than normal at 1 week, then declined at 2 and 4 weeks as ChAT activity rebounded. These results suggest the possibility of a role for NGF in promoting the recovery of cholinergic function after spinal cord injury. (Supported by Genentech, Inc.)

RECOMBINANT HUMAN NGF LABELS NOVEL HIGH AFFINITY BINDING SITES IN RAT BRAIN. M. Dugich-Djordjevic. L. E. Burton++, G. L. Bennett*, and C. A. Altar. Developmental Biology, ++Recovery Process R & D, and *Immunology Res. and Assay Tech. Genentech, Inc., South San Francisco, CA 94080.

Francisco, CA 94080.

Iodinated recombinant human nerve growth factor ([125]]rhNGF) was used to characterize displaceable, high affinity NGF binding sites throughout rat brain. [125]]rhNGF stimulated neurite formation in PC12 cell systems with an EC50 of 49 pg/ml in two studies, compared with 39-52 pg/ml for rhNGF. Using quantitative ligand autoradiography, the *in vitro* equilibrium binding of [125]]rhNGF was saturable, reversible, and displaced by up to 74% with rhNGF or muNGF, but not by 100 nM bFGF, EDF, rhGH, cytochrome c or IGF-1. [125]]rhNGF bound to these sites with high affinity (Kd = 52-85 pM) and low [143]]rhNGF bound to these sites with high affinity (K_d = 52-85 pM) and low capacity (B_{max} values ≤ 13.2 fmol/mg protein). Displaceable [125]]rhNGF binding varied by 10-fold throughout the brain and labelled areas not identified previously with [125]]muNGF or with antibodies to the murine NGF receptor. These novel areas include the nucleus accumbens, olfactory tubercle, subticulum, pineal gland, medial geniculate nucleus, dorsal hippocampus, dentate gyrus, amygdala, paraventricular thalamus, and frontal, parietal, occipital, and cingulate cortices. Most brain binding sites for 125 in the caudite put grant which also contained a 2 to 3.404. parietal, occipital, and cingulate cortices. Most brain binding sites for [¹²⁵]|rhNGF are in the caudate-putamen, which also contained a 2 to 3-fold medial-lateral gradient of increasing NGF binding density in rat and rabbit. The nucleus accumbens contained a two-fold lateral-medial gradient, [¹²⁵]|rhNGF binding sites were also found in most areas labeled by [¹²⁵]|muNGF. [¹²⁵]|rhNGF binding sites were absent in the pedunculopontine and parabrachial cholinergic nuclei and their thalamic, hypothalamic, and tectal projections, and in areas replete with low affinity NGF binding sites, including the offactory bulb, circumventricular organs, myelinated fiber bundles, and the choroid olevus. choroid plexus.

SURFACE PROTEIN PHOSPHORYLATION IN PC12 CELLS: INTERACTION WITH NGF. Z. Pawlowska*, M.V. Hogan* and Y.H.Ehrlich. CSI/IBR Center for Developmental Neuroscience, City University of New York, Staten Island, NY 10301.

The regulation of neuronal function by extracellular ATP may involve the activity of ecto-protein kinases that phosphorylate proteins located at the cell surface. To investigate the role of ecto-protein kinase (ePK) in neuronal growth and differentiation, we have identified and characterized the surface phosphoproteins in PC12 cells, a cloned cell line used extensively in studies on the action of nerve growth factor (NGF). Cells were assayed in 48-well plates, attached to collagen, in Krebs-Ringer Hepes buffer. 0.1 μ M of γ -32P-ATP were used in ePK reactions and intracellular ATP pools were labeled by incubating cells with 32Pi. Ectoprotein kinase activity in PC12 cells was very rapid; phosphorylation of proteins with apparent MW of approx. 20K, 40K and 105K was detected within 10 seconds of the addition of AT32P to the extracellular medium. Surface phosphorylation of proteins with MW of approx. 97K, 116K and 125K was observed after longer incubations. In contrast, the early substrate for intracellular phosphorylation in cells labeled with 32p was a protein with MW of 56K. Addition of NGF (50 ng/ml) to the ePK reaction medium 5 min before the $AT^{32}P$ stimulated selectively the phosphorylation a 20K protein. Furtheremore, in PC12 cells treated for 3 days with NGF there was a significant increase in the phosphorylation of the 20K protein by ePK. The surface phosphorylation of this specific protein by extracellular ATP may play an important role in the functional consequences of the interaction of NGF with neurons. Supported by AFOSR.

THE USE OF XENOPUS OOCYTES FOR DETECTION AND CLONING OF NEUROTROPHIC FACTORS. A.Lam*, F.Fuller, J.Kloss, B.Cordell, S.Varon and M.Manthorpe. California Biotechnology Inc. 2450 Bayshore Pkwy, Mountain View, CA 94043; Dept. Biology, UCSD, La Jolla, CA 92093. The rat glioma cell line, C6, produces several

neurotrophic factors (Westermann, R., et al. J Neurochem., 50:1747, 1988). We have developed a highly sensitive assay capable of detecting responses of E8 chick ciliary neurons to polypeptide hormones. At least two factors present in extracts of C6 cells elicited a response in this assay - basic FGF, and a distinct ciliary neurotrophic factor (CNTF). Injection of Xenopus occytes with C6 mRNA elicited only the non-FGF CNTF activity. The physical behavior of this expressed CNTF was identical to that of rat sciatic nerve CNTF. A cDNA library was prepared from C6 cell mRNA using a transcription vector. Injection of oocytes with synthetic mRNA prepared from this library revealed the presence of a clone encoding a functional, rat CNTF molecule. Further characterization indicated that a C6 cell contains only about 1-5 copies of CNTF mRNA. Thus, oocyte injection represents an extremely sensitive method for the detection and cloning of neurotrophic factors.

NGF INDUCES A DIFFERENTIAL INCREASE IN THE MULTIPLE mRNA'S FOR CALMODULIN IN PC12 CELLS G. Bai* and B. Weiss, Department of Pharmacology, Medical College of Pennsylvania, Philadelphia, PA 19129 We previously reported (Soc. Neurosci. 15:501, 1989) that nerve growth factor (NGF) increases the activity of calmodulin (CM) and the amount of CM mRNA in PC12 cells and that these changes are coincident with cellular differentiation. Recently, it has been shown that in rat tissue CM is encoded by 3 distinct genes which transcribe five different mRNA's (0.9, 1.4, 1.7, 2.3 and by 3 distinct genes which transcribe five different mRNA's (0.9, 1.4, 1.7, 2.3 and 4.1 kb). In this study, we examined whether the multiple mRNA's for CM also exist in PC12 cells and what effect NGF has on the expression as well as the turnover of these mRNA's. RNA was isolated from PC12 cells incubated with NGF for 30 min to 16 days. The CM mRNA's were analyzed by Northern Blot using a cRNA probe, which is able to reveal all the CM mRNA's when used at conditions of moderate stringency, and oligonucleotide probes designed to detect the calmodulin mRNA's for each of the calmodulin genes. Densitometric measurements of the developed autoradiograms were calibrated using cyclophilin mRNA as a standard. The results showed that PC12 cells have all the mRNA's not calmodulin; the relative abundance of the calmodulin mRNA's was 1.7 > 1.4 > 4.1 > 2.3 > 0.9 kb. Treatment of the PC12 cells with NGF caused a differential increase in the mRNA's; the 1.4 kb transcript was increased earlier and to a greater extent than any of the other mRNA's. No NGF caused a differential increase in the mRNA's; the 1.4 kb transcript was increased earlier and to a greater extent than any of the other mRNA's. No significant changes in the CM mRNA's were seen in the cells not treated with NGF. The half-lives (t1/2) of the mRNA's were estimated by adding actinomycin D (1 ug/ml) after treating the cells for two days with NGF, then measuring their rate of decline. These studies showed that there were no significant effects of NGF on the t1/2 of any of the CM mRNA's. However, the t1/2 of the CM mRNA's were different from each other; the t1/2 for the 1.4, 1.7, 2.3 and 4.1 kb transcripts were 12, 17, 20 and 26 hr, respectively. We conclude that NGF-induced cellular differentiation may involve the selective induction of certain types of CM mRNA's.

217c, A TUMOR-ASSOCIATED ANTIGEN MONOCLONAL ANTIBODY RECOGNIZES THE RAT NGF RECEPTOR. M.G. Fiori, G. Ferrari, M. Fabris*, S.D. Skaper, P. Polato* and Q. Yan (1). Fidia Research Labs., Abano Terme (PD), Italy and (1) Genentech Inc., South San Francisco, CA.

The monoclonal antibody 217c, has been shown to be a marker for Schwann cells in culture. We now report that the antigen recognized by 217c is the rat NGF receptor. The distribution of 217c immunoreactivity closely paralleled that observed for NGF receptors using 192-IgG, with both cultured Schwann cells and NGF-primed PC12 cells as well as a number of central nervous system neurons in vivo. 217c immunoprecipitated an 1251-NGF/receptor complex having a major band at 90 kDa, as reported for 192 IgG. However, 217c recognized an epitope on the rat NGF receptor different from 192-IgG because: a) the two monoclonal antibodies differed in their catwo monoclonal antibodies differed in their capacity to increase NGF binding to PC12 cells at 4C°; b) a combination of 192-IgG and 217c stained more strongly NGF receptor-positive neurons than did either antibody alone; and, most importantly, c) 217c did not compete with $12^5\text{I}-192\text{-IgG}$ binding to PC12 cells. Thus, the 217c antibody can now be considered an important tool in the study of NGF receptors.

COMPARISON OF EXPRESSION AND FOLDING OF MOUSE RECOMBINANT B-NERVE GROWTH FACTOR (NGF) IN BACTERIAL SYSTEMS. G.-L. Hu* Y. Luo*, D. E. Timm*, and K.E. Neet. Department of Biochemistry, Case Western Reserve University, Cleveland OH.

We have examined three plasmid vectors for high level expression of recombinant mouse β-NGF in E. coli. Biologically active NGF has been produced in each system with varying yields and varying biological specific activity. Our original pAS1 system produced mature NGF in a soluble form at a low level of about 50 µg/L culture of which 0.1% was biologically active; these results were attributed to problems of both folding and proteolysis [Gene 70, 57 (1988)]. The pRIT2T system produced a Protein A-NGF fusion protein that accumulated in insoluble inclusion bodies with a yield after purification of about 5 mg/L culture; after cleavage about 600 µg of pure NGF could be obtained that contained about 10-20% biologically active NGF before further refolding. The pT7-7 plasmid system yielded about 4 mg/L culture of mature NGF in inclusion bodies that had low biological activity but could be readily purified. From these data we conclude that this small protein can be protected against bacterial degradation in inclusion bodies with or without fusion to another protein. A protocol has been developed for refolding recombinant or authentic mouse NGF from guanidine hydrochloride under controlled redox conditions that yields NGF with high specific activity. The disulfide formation and secondary structure of these proteins are being characterized. (Supported by an NIH grant, NS24380)

EXPRESSION OF NERVE GROWTH FACTOR RECEPTOR (NGFR) mRNA IN THE RAT RETINA IS DEVELOPMEN-

EXPRESSION OF NERVE GROWTH FACTOR RECEPTOR (NGFR) mRNA IN THE RAT RETINA IS DEVELOPMENTALLY REGULATED AND INCREASED AFTER OPTIC NERVE SECTION. M.C. Comelli*, L. Bonfanti*1, A. Merighi*1, G. Carmignoto and L. Maffei*2. Fidia Research Laboratories, Abano Terme (PD), 1 Dept. of Morphophysiology, University of Turin, Turin and 2 Institute of Neurophysiology, CNR, Pisa, Italy.

Using RNA blot analysis, NGFR mRNA in the rat retina was found to be expressed at its highest levels on postnatal day 2 sustained at a somewhat lower level throughout development and in adulthood. Optic nerve section in the adult rat resulted in a 2 to 7 fold increase in NGFR mRNA levels in the lesioned retina compared with the unlesioned control, consistent with an increased need for trophic support to damaged retinal ganglion cells. We previously showed that NGFR in the retina is localized on ganglion cells and Müller cells. Immunocytochemical studies using the monoclonal antibody 1921gG for NGFR are in progress to investigate whether an increase in NGFR mRNA is paralleled by an increase in NGFR protein on Müller cells and/or ganglion cells.

EXPRESSION OF NERVE GROWTH FACTOR RECEPTOR (NGFR) ON ADULT RAT RETINAL GANGLION CELL (RGC) TERMINALS. G. Carmignoto, P. Candeo*, C. Comelli*, G. Calderini and L. Maffei*. Fidia Research Labs, Abano Terme (PD) and linstitute of Neurophysiology, CNR, 56100 Pisa, Italy.

of Neurophysiology, CNR, 56100 Pisa, Italy.

A recent immunohistochemical study using the monoclonal antibody 192-IgG for rat NGFR demonstrated the presence of NGFR immunopositive fibers at the level of the Superior Colliculi (SC) and Lateral Geniculate Nuclei (LGN), the main targets of RGC projections (Yan and Johnson, J. Comp. Neurol., 290:585, 1989). After optic nerve section we found that immunopositive fibers contralateral to the lesion site practically disappeared in the LGN and were reduced in the SC, demonstrating that the NGFR is clearly associated with RGC axonal terminals. Preliminary results indicate that following ligation of the optic nerve, 125I-NGF injected into the target regions of RGC projections accumulates at the site of ligation. Axonal terminals of RGCs appear to bind, internalize and retrogradely transport NGF to the cell bodies, supporting the hypothesized role of NGF as a target derived factor for rat RGCs.

SENSORY SYSTEMS-DEVELOPMENT AND PLASTICITY II

PRESYNAPTIC SITES PERSIST FOLLOWING DEGENERATION OF THEIR POSTSYNAPTIC PARTNERS AT PHOTORECEPTOR SYNAPSES OF THE FLY'S LAMINA. I.A. Meinertzhagen, I.H. Brandstätter and H.S. Seyan. Life Sciences Centre, Dalhousie University, Halifax, N. S. CANADA B3H 411. Terminals of photoreceptor cells in the first optic neuropile, or lamina, beneath the fly's (Muzac domestica), compound eye lose afferent synaptic sites as part of normal adult development. At each site a presynaptic ribbon abuts a postsynaptic tetrad invariably comprising processes of two monopolar interneurons, L1 and L2, unique occupants of each lamina module, or cartridge. To study the effects of degenerating these postsynaptic elements at the photoreceptor synapses, we severed the axons of L1, 2 in the chiasma, the output tract of the lamina, and examined the structure and frequency of synapses by single-section EM. The head of 7d-adult flies was opened and a lesion made with a fine tungsten needle, then closed and the animals left to recover in a moist chamber from 0.5 to 48hr. Control animals received only a stab wound. After the lesion, L1, 2 degenerated extremely rapidly, shrinking, becoming dark and exhibiting other signs of electron-dense degeneration, even by 0.5hr. post-lesion. Despite the rapidity of this degeneration we found no difference after 0.5hr in the tetrad synaptic frequencies between receptor terminals with L1, 2 degenerated and controls, only a moderate (ca.16%) decrease after 1 - 4hr post-lesion, and around a 30% decrease after 18hr, following which the frequency then increased slightly up to 48hr. Thus, many presynaptic ribbons outlive their postsynaptic elements, and although L1, 2 were heavily degenerated their spines preserved contact with the presynaptic site as long as a ribbon was present. We found no detached presynaptic ribbons, as occur in L2 following that the tetrads' presynaptic ribbons outlive their postsynaptic elements, and although L1, 2 were heavily degenerated their spines preserved contact with the presynaptic sit

AUDITORY INPUT TO THE SUPERIOR COLLICULUS (SC)
OF ALBINO GUINEA-PIGS: INDICATION OF AN ANOMALY
OF THE 'ACOUSTIC CHIASM'. S. Grant* & K. E. Binns*
(Spon: BRA). National Institute for Medical
Research, London NW7 1AA, UK.

In pigmented guinea-pigs auditory neurons of
the SC respond to sounds from restricted spatial

In pigmented guinea-pigs auditory neurons of the SC respond to sounds from restricted spatial locations. At threshold sound intensities for these neurons this location-sensitivity is monaural, based upon excitatory drive from the contralateral ear, but at 15-20dB above threshold requires inhibitory input from the ipsilateral ear (Palmer & King, 1985). We have compared the contributions of the two ears to the spatial sensitivity of auditory SC neurons in pigmented versus albino guinea-pigs, using (i) plugs to (reversibly) occlude an ear and (ii) unilateral cochlea ablation. We found that the ipsilateral ear exerts less influence upon neurons of the albino SC than in pigmented animals: they can maintain appropriate location-sensitivity at suprathreshold sound intensities when this ear is plugged or its cochlea destroyed. Albinism has long been associated with anomaly of the optic chiasm, whereby the ipsilateral eye gains little access to centers of vision. Our results are consistent with an analogous anomaly of the 'acoustic chiasm' in this mutation.

344.2

SENSORY EXPERIENCE AND THE CONSTRUCTION AND LATER MAINTENANCE OF THE SUPERIOR COLLICULAR MAP OF AUDITORY SPACE IN THE GUINEA PIG. M.J. Keating, K.E. Binns and D.J. Withington-Wray, National Institute for Medical Research, Mill Hill London NW7 1AA UK

Hall, London NW7 1AA, UK.

Topographic order in the superior collicular map of auditory space in the guinea pig appears about 32 days after birth (DAB). The 4 day period 26-30 DAB constitutes an experience-dependent crucial period for the normal emergence of the map. Visual or auditory deprivation limited to this period prevents the normal emergence of the map. Bimodality auditory and visual experience limited to this period is sufficient for map emergence. The experience-dependence of the auditory space map is not, however, limited to this single developmental crucial period. Visual or auditory deprivation from 32 DAB disrupts an already established map. Conversely, animals deprived of a normal map by sensory deprivation until 34 DAB generate an ordered map if permitted subsequent visual and auditory experience. The map's responsivity to normal or abnormal sensory experience appears to have an upper time limit. Animals visually-deprived until 100 DAB are unable to generate a map even if permitted subsequent normal experience.

344.4

TRAJECTORY PATTERNS AND MULTIPLE ENDINGS: IMPLICATIONS FOR DEVELOPMENT OF CALYCIFEROUS AXONS IN AUDITORY BRAINSTEM J.M.Zook and N.Kuwabara Dept. of Zool. & Biomed. Sci. & Basic Sci., COM, Ohio Univ., Athens, OH 45701

We have classified calyciferous axons in the auditory brainstem by intraaxonal dye-labeling in a tissue slice preparation. Slices were taken from gerbils, Meriones unguiculatus, and mice, Mus musculus, of different ages as well as from adult bats, Eptesicus fuscus. Each calyciferous axon originates from a globular-bushy cell of the ventral cochlear nucleus, crosses the brainstem in the trapezoid body, and gives rise to a single, large, perisomatic ending (a calyx of Held) within the contralateral medial nucleus of the trapezoid body (MNTB). Each of these axons is characterized by an abrupt change in trajectory just prior to calyx formation. We will discuss this trajectory change in terms of the development of topographic maps in the MNTB. In tissue slices from mature animals (greater than four weeks old),

In tissue slices from mature animals (greater than four weeks old), labeled calyciferous axons usually terminated with a single calyx. In slices taken from young animals (less than two weeks old), around 5 % of the labeled calyciferous axons formed multiple calyces. These axons commonly branched two or even three times, with each branch terminating as a calyx of Held upon a different target cell. Calyx-forming branches usually diverged from the main axons at widely different points, but almost always formed calyces on either two neighboring cells or two distant, but vertically aligned cells. These patterns will be discussed in terms of possible age-related pruning and map refinement in the auditory brainstem. (Supported by NIH Grants NS 26304, NS 01394 and the OUCOM)

VISION INSTRUCTS THE AUDITORY SPATIAL TUNING OF NEURONS IN THE OPTIC TECTUM OF DEVELOPING BARN OWLS. E.I. Knudsen and M.S. Brainard. Dept. Neurobiology, Stanford University, Stanford, CA 94305.

The optic tectum (superior colliculus) contains auditory and visual maps The optic tectum (superior colliculus) contains auditory and visual maps of space that are mutually aligned: neurons in the tectum respond to auditory and visual stimuli originating from the same restricted region of space and are organized according to the locations of their auditory and visual receptive fields to form a multimodal map of space. The alignment of auditory with visual spatial tuning indicates that tectal neurons are tuned for the values of sound localization cues arising from sound sources at the location of their visual receptive fields.

We have found that the tuning of tectal units for sound localization cues is guided by vision. Barn owls were raised from the day of eyelid opening (14d) viewing the world through displacing prisms that shifted the visual field 23' to the left or right. Once the owls were older than 60 days, they were prepared for extracellular tectal recording. Auditory receptive fields were measured with a movable free field speaker in a sound isolation chamber; visual receptive fields were plotted on a hemispheric screen. Tectal units with visual receptive fields that were hemispheric screen. Tectal units with visual receptive fields that were located within the optically displaced field of the prisms had auditory receptive fields that tended to be shifted in the direction and, in most cases, by an amount equal to the optical displacement of their visual receptive fields. In contrast, units with visual receptive fields located in areas that were blocked by the spectacle frames exhibited little if any systematic shift in auditory spatial tuning.

The data demonstrate that different portions of the auditory space map are calibrated independently by vision and suggest that the underlying mechanism depends on coincident auditory and visual stimulation from restricted portions of space.

344.7

AUDITORY EXPERIENCE MODIFIES THE TUNING FOR SOUND LOCALIZATION CUES OF NEURONS IN THE BARN OWL'S OPTIC TECTUM AND INFERIOR COLLICULUS. J. Mogdans and E.I. Knudsen, Dept.

Neurobiology, Stanford University, Stanford, CA 94305.

Neurons in the barn owl's optic tectum (OT) and external nucleus of the inferior colliculus (ICx) have restricted spatial fields as a consequence of their tuning for both interaural intensity differences (IID) and interaural time differences (ITD). Experiments in which barn owls were raised with monaural earplugs have shown that experience with abnormal interaural difference cues during early development leads to an adaptive change in the spatial tuning of tectal neurons.

In the present study we used dichotic stimulation to measure the tuning for IID and ITD of neurons in the OT and ICx in normal birds and in birds raised with monaural earplugs. We found that in earplugged birds the tuning of neurons in both the tectum and the ICx was altered so as to compensate for the monaural impairment: IID tuning was shifted by up to 10 dB and ITD tuning was shifted by up to 50 μs towards the unplugged ear compared with the tuning of neurons at comparable sites in normal animals. These adaptive changes to abnormal auditory cues that occur during early development must therefore be implemented prior to the formation of the auditory space map in the ICx, possibly at the first stages of binaural interaction in the brainstem. We are currently attempting to identify the site in the auditory pathway where these experience-dependent changes take

NEURONAL ACTIVITY REGULATES ASTROCYTIC PROCESSES IN A BRAIN SLICE PREPARATION OF THE AVIAN AUDITORY SYSTEM. R.L. Hyson, K.S. Canady, E.W Rubel, Hearing Development Laboratories, Univ. of Washington, Seattle, WA 98195.

Afferent activity regulates the structure and metabolic activity of both neurons and glial cells in the second-order auditory nucleus, nucleus magnocellularis (NM) of the chick. Within hours of eliminating afferent activity, NM neurons have altered metabolic activities, and glial cell processes proliferate. Previous evidence from an in $\it vitro$ brain slice preparation indicates that activity-dependent regulation of NM $\it neurons$ requires Ca⁺²-dependent release of some "trophic substance" from presynaptic auditory nerve terminals. In the present experiment, we determined whether activity-dependent regulation of glial processes has similar requirements.

Brain stem slices containing portions of the auditory nerve and NM bilaterally were maintained in vitro. In different groups of slices, NM on one side of the slice was unstimulated while NM on the other side was either: 1) Orthodromically stimulated, via electrical activation of the ipsilateral auditory nerve, 2) Antidromically stimulated, via electrical activation of NM neuron axons, or 3) Orthodromically stimulated in a medium containing low Ca^{+2} and high Mg^{+2} concentrations. Control slices were unstimulated on both sides. After receiving one of these treatments for 3 hrs, the slice was fixed, sectioned and processed using GFAP immunocytochemistry. The amount of immunoreactivity was compared in NM on the two sides of the same tissue sections. Just as in vivo, less GFAP immunoreactivity was observed on the stimulated side of the slice. This difference occurred under all three stimulation conditions. Thus, GFAP expression can be regulated in vitro by neuronal activity. Unlike neurons, the glial cells respond to local changes in neuronal activity without requiring Ca+2-dependent synaptic release of neurotransmitter or trophic substances. This suggests that glial cell processes respond to local changes in the ionic environment resulting from altered neuronal activity. (Supported by PHS grant DC00393)

344 6

THE INFERIOR COLLICULUS IS A SITE OF PLASTICITY IN THE VISUAL CALIBRATION OF AUDITORY SPATIAL TUNING IN DEVELOPING BARN OWLS. M.S. Brainard and E.I. Knudsen. Dept. Neurobiology, Stanford University, Stanford, CA 94305.
The optic tectum (superior colliculus) contains aligned auditory and visual maps

The optic tectum (superior colliculus) contains aligned auditory and visual maps of space. Barn owls raised with laterally displacing prisms which optically shift the visual map, develop an auditory map of space in which the representation of azimuth is shifted by an approximately equivalent amount (Knudsen and Brainard, Soc. Neurosci. Abstr., vol. 18, 1990). Because the azimuthal tuning of tectal neurons is largely due to their tuning for interaural time difference (ITD), this shift in auditory receptive fields corresponds to a shift in neuronal tuning for ITD. We have found that these vision dependent changes in tuning for ITD reflect changes courring the fixer the level of the online tectum; in the external nucleus of the occurring before the level of the optic tectum, in the external nucleus of the inferior colliculus.

Owls were raised with displacing prisms that shifted the visual field by 23° to the left. Extracellular unit recordings were used to compare the representations of the inthe central and external nuclei of the inferior colliculus (ICc and ICx) and in the tecta of normal and prism reared birds; ITD tuning was measured using dichotic stimuli delivered via earphones placed in the ear canals.

In normal owls, units at the rostral end of the tectum, ICx and ICc were tuned to

0 µsec ITD (corresponding to a sound source located on the midsagittal plane). In contrast, in prism reared owls, neurons at the rostral end of the tectum and ICx were tuned to 50 µsec right ear leading, indicating that the representation of ITD in both of these nuclei had been altered by prism rearing. However, neurons at the rostral end of the ICc, which provides input to the ICx, were still tuned to approximately 0 usec ITD. The data suggest that displaced vision alters the pattern of neural connectivity between the ICc and ICx, at the site where the auditory map of space is synthesized.

NEURONAL ACTIVITY REGULATES GROWTH AND

RETRACTION OF ASTROCYTIC PROCESSES

K. S. Canady and E. W Rubel, Hearing Development Laboratories, Univ. of Washington, Seattle, WA 98195

Previously we have shown that blockade of 8th nerve action potentials results in rapid growth of astrocytic processes in the ipsilateral cochlear nucleus. The increase in processes immunoreactive for glial fibrillary acidic protein (GFAP) is greater than two-fold within 3 hours of blocking 8th nerve activity. To assess the reversibility of two-rou within 5 nours of brocking our nerve activity. To assess the reversioning in this astrocytic reaction, we first blocked 8th nerve activity for a minimum of 31 you with a single intralabyrinthine injection of tetrodotoxin (TTX) and then allowed recovery of normal 8th nerve activity. We then measured the density of astrocytic processes immunoreactive for GFAP in nucleus magnocellularis (NM, the avian cochlear nucleus).

Subdermal electrodes were used to record the click-evoked auditory brainstem response (ABR) in 7 deeply anesthetized 8-10 day old chicks. Peak-to-peak amplitude of the ABR was measured before and after injection of 1 µl 0.3 mM TTX. Animals were re-anesthetized and re-tested 3 hours later to confirm that the duration of activity blockade was sufficient to produce an astrocytic reaction, and again on subsequent days to confirm full recovery of inner ear function. One week after TTX injection, the animals were sacrificed and tissue sections from the brain stem were prepared for

animals were sacrificed and ussue sections from the trial stells were prepared to GFAP immunocytochemistry.

Chicks sacrificed during the blockade of 8th nerve action potentials showed a mean increase in GFAP immunolabeling of 120% in the ipsilateral NM. This confirms that astrocytic processes proliferate during periods of prolonged neuronal inactivity. In contrast, chicks allowed to recover normal 8th nerve activity after TTX injection showed no difference in GFAP immunolabeling between the control and experimental NM. These results suggest that the regulation of astrocytic processes by neuronal activity is bidirectional: A loss of neuronal activity results in astrocytic process growth, while the return of neuronal activity causes a retraction of these reactive astrocytic processes. (Supported by PHS grant DC00393.)

344.10

Additive Functional Subcortical Changes Contribute to Cortical Alterations Following Sensory Training. <u>CL Hand, RL Craik, KG Gallo*, & PJ Hand.</u> Idaho St. U., Pocatello, ID 83209, Beaver Coll., Glenside, PA 19038, & Univ. of PA, Phila., PA 19104.

To complete analysis of functional CNS changes resulting from sensory enrichment training of a spared rat vibrissa analysis of subcortical vibrissal relays was undertaken. Bilateral vibrissa sparing/unilateral associatively-paired (AP) training was undertaken in 10 rats. Subtotal vibrissa deafferentation spared bilateral C3 vibrissae (SC3) before postnatal day 3. AP training (associatively pairing vibbrissa stroking with sugar water) of L or R SC3 (SC3/AP) was 5 min/ day x 60 days. Behavioral and 2DG metabolic analyses previously revealed significant alterations in exploratory behavior and an increase in SC3/AP cortical area of 34.9%.

Present analysis of functional SC3 representations within subcortical relays reveals additive subcortical contributions to the functional plasticity observed in cortex. Areal increases for AP trained SC3 representations (compared to controls) within trigeminal brainstem complex (principalis, oralis, interpolaris & caudalis) averaged 10.8%. In VBm thalamus, areal increases for AP/SC3 averaged 22.0%. While functional area was altered along the pathway, the absolute level of functional activity within the altered area remained relatively unchanged. Alterations in cortical area following vibrissal training are partly the result of a cortical phenomenon and partly an additive effect of NS22283-04. plasticity within the subcortical relays.

ELECTRON MICROSCOPIC ANALYSIS OF THE RAT INFRAORBITAL NERVE ONE WEEK FOLLOWING AXOTOMY AT BIRTH. J. Golden, D.S. Zahm and M.F. Jacquin. St. Louis Univ. Sch. Med., St. Louis, MO 63104.

A great deal is known about the central consequences of infraorbital nerve injury at birth in rodents. However, little is known regarding the short-term effects upon the organization of the infraorbital nerve. This information is fundamental to our understanding of injury responses in the developing trigeminal system. As a first step towards filling this void, 3 newborn rats were subjected to left infraorbital nerve section. They were perfused one week later and the 3 left infraorbital nerves were removed at a point proximal to the lesion, processed for EM analysis and counted at a final magnification of 4300X. The 3 nerves contained 16, 18, and 24 fascicles. These values do not differ significantly from the normal adult, but they are higher than the 8-15 fascicles observed in the newborn (Renehan and Rhoades, <u>Brain Res</u>. 322:369, '84). Axon counts revealed 594, 913, and 715 myelinated, 6,717, 9,317, and 7,852 unmyelinated, and 117, 207, and 111, degenerating myelinated axons, respectively. In total there were 7428, 10,437, and 8,678 axons in the 3 nerves. These totals are well below those reported for both the normal adult (19,740 myelinated, 13,319, unmyelinated) and newborn infraorbital nerves (168 myelinated, 42,051 unmyelinated). In an adult nerve counted after the same lesion at birth (Mooney et al., <u>Soc. Neurosci. Abstr.</u> 9:, '83), 5,260 myelinated and 2,747 unmyelinated fibers were observed. Most of the ganglion cell death occurs during the first postlesion day (Henderson and Jacquin, this volume) and cortical responses to peripheral stimuli cannot be recorded until 7 days after this lesion (Waite and Cragg, Proc. Roy. Soc. Lond. B 214:191, '82). The present data suggest that degeneration and remyelination are incomplete by postnatal day seven. Support: DE07734, DE07662, NS23805.

EARLY POSTNATAL DEVELOPMENT OF THE RAT CORTICOTRIGEMINAL TRACT. M.R. Wiegand & W.E. Renehan. Anatomical Sciences & Neurobiology, Univ. of Louisville School of Medicine, Louisville, KY 40292.

The carbocyanine dye, dil, was used to study the early postnatal development of the corticotrigeminal tract in the rat. Dil was placed in the presumptive barrel cortex of fixed brain tissue in neonatal rat pups on postnatal days (PND) 0-14. Descending corticotrigeminal fibers reached the level of the pyramidal decussation by PND 0, at which time sparse label could be seen along the medial aspect of ipsilateral principalis. Subsequent corticotrigeminal development proceeded in a rostral to caudal, ipsilateral to contralateral sequence. On PND 1, corticotrigeminal axons were labeled in all ipsilateral and the medial portion of rostral contralateral subnuclei. The density of the insilateral label began to decrease in all subnuclei with the exception of the medial portion of rostral contralateral subnuclei. The density of the ipsilateral label began to decrease in all subnuclei with the exception of principalis by PND 2-3, with a concomitant increase in contralateral rejections. Fibers were observed crossing to contralateral subnuclei at all levels by this age. By PND 4-5, contralateral corticotrigeminal projection morphology approached that of the adult, although persistent ipsilateral projections remained, especially in principalis. The adult-like pattern of corticotrigeminal fiber label was apparent by PND 6. Rat corticotrigeminal development follows a rostral to caudal, ipsilateral to contralateral sequence that appears to evolve after the establishment of previously documented afterent system connections. This pattern contrasts with the caudal to rostral developmental sequence described in the cat (Tolbert et al., JCN, 1984). Support: NIH DEO7734

THE EFFECTS OF COLD STRESS ON THE INDUCTION OF C-FOS IN DEVELOPING RATS. M.P. Joyce and G.A. Barr. Biopsycholog Doctoral Program, Dept. of Psychology, Hunter College, CUNY, New York, N.Y. 10021

As an animal matures, the nature of the behavioral and physiological responses to cold temperature changes. rat pups appear to rely predominantly on behavioral mechanisms, while internal thermoregulatory mechanisms predominate in older rats. The neural response to cold is mediated by several hypothalamic and extrahypothalamic nuclei. The response of these sites to decreased environ-mental temperatures changes as the animal develops. Recently, the induction of the oncogene c-fos has been shown to be a reliable indicator of cellular depolarization. The present study uses fos protein as a marker to examine changes in the neural response to cold in developing rats. Rats, 1-60 days of age, were exposed to an environmental temperature of 15°C for one hour and then sacrificed immediately or 1, 2, or 3 hours after removal from the cold. immediately or 1, 2, or 3 hours after removal from the cold. The biotin-avidin HRP method was used to label fos-like immunoreactivity. Fos-like nuclear labeling was observed in the POAH, posterior hypothalamus, PVN of the thalamus and hypothalamus, dorsomedial nucleus of the hypothalamus, lateral septal nuclei, nucleus of the diagonal band and the lateral habenula. In rats 28 days and older, fos-like labeling was observed in animals that were sacrificed immediately after removal from the cold. In younger pups, labeling was not apparent until 1 hour after removal from the cold.

NEONATAL INFRAORBITAL NERVE SECTION PRODUCES INCREASED CHOLECYSTOKININ (CCK) LEVELS IN RAT MEDULLA. M.C. Beinfeld, R.W. Rhoades, C.A. Bennett-Clarke, N.L. Chiaia & M.F. Jacquin. Dept. of Pharmacology and Dept. of Anat. & Neurobiol., St. Louis Univ. Sch. Med., St. Louis, MO 63104., Dept. of Anat., Med. Coll. of Ohio, Toledo, OH 43699.

Infraorbital nerve section at birth produces a profound deafferentation of the trigeminal brainstem complex that spares the innervation of laminae I and II of the medullary dorsal horn. Enfiejian et al. (Somatosens. Mot. Res. 6:537, '89) and Rhoades et al. (J. Neurosci. 8:2234, '88) have also demonstrated normal levels of substance P in the deafferented medulla by radioimmunoassay (RIA) and immunohisto- chemistry. Here, CCK-specific RIA and immunohistochemical methods were used to assess CCK levels in the medullary dorsal horn in adult rats subjected to left infraorbital nerve cut at birth. RIA showed that the left medulla contained 31% higher levels of CCK than the control right medulla (1.27 \pm 0.19 vs. 0.97 \pm 0.11 ng/mg protein). This increase was observed in 8 of 10 animals and was statistically reliable (N = 10: paired t-test, p < .05). Immunohistochemistry revealed a dense band of CCK-like staining in laminae I and II ipsi- and contralateral to the lesion (N = 7). Densitometric analysis showed a 7.5 ± 10^{-3} 2.8% increase in immunoreactivity from sections on the left side (P < .01). These results indicate that CCK immunoreactivity, most probably of primary afferent origin (Clements and Beitz, Neurosci. 20:427, '87), is selectively preserved after neonatal nerve transection. This finding differs from that we have previously obtained for SP in that CCK increased to significantly supranormal levels. Thus, CCK-containing primary afferents may respond differently to neonatal nerve damage than other V ganglion cells. Support: DE07734, DE07662, BNS8517357, NS18667.

THE ABILITY OF AXOTOMIZED AFFERENT FIBERS IN SURAL NERVE TO MODULATE THE FLEXION REFLEX. J.X. Bao. Dept. of Neuroscience, University of Florida, Galnesville, FL 32610. Intracellular studies have shown that axotomized myelinated afferent fibers

in the sural nerve elicit apparently normal postsynaptic potentials in triceps surae motoneurons (Nishimura et al., Soc. Neurosci. Abstr. 15: 920, 1989). Unmyelinated fibers in the normal sural nerve facilitate the flexion reflex (Wall et al., J. Physiol. 356: 443-458, 1984). The goal of this study was to determine whether there was still this facilitative effect of the unmyelinated fibers after axotomy.

fibers after axotomy.

In an initial procedure, the sural nerve was ligated and capped with Gore-Tex tube. After two to three weeks the animals were decerebrated and spinalized. The magnitude of the flexion reflex was recorded in filaments of biceps femoris and semitendinous nerve to pinches of the toes or electrical stimuli of sural nerve before and after 20 seconds high intensity C fiber conditioning stimulation (0.5ms, 4mA, 1 Hz).

The normal sural nerve facilitated the flexion reflex for approximately 30 seconds to 2 minutes (23/26 flexor motoneurons). The facilitation effect not controlled in the sural nearly the common paragraph appreciations.

seconds to 2 minutes (23/26 flexor motoneurons). The facilitation effect not only existed in the sural nerve: the common peroneal nerve could produce a similar action. After axotomy, no flexor motoneurons (11 motoneurons) showed this facilitation effect, in spite of the fact that the normal unmyelinated fibers in the common peroneal nerve could still induce this facilitation. This suggests that the facilitative ability of the unmyelinated fibers in the sural nerve depended on the intact target innervation, although the myelinated fibers in the sural nerve did not have this target dependency. DEVELOPMENT OF NERVES AND TEETH IN THE RAT MANDIBLE. Johansson* and C. Hildebrand. Dept. of Cell Biology, Faculty of Health Sciences, University of Linköping, 581 85 Linköping, Sweden.

The aim of this study is to provide a description of the anatomy of the inferior alveolar nerve (IAN) in the rat mandible and of the structural development of this nerve and mandible and of the structural development of this nerve and its dental targets. The first signs of mineralization occur in the incisor and molar 1. Molars 2 and 3 follow later. The incisor erupts during the first week after birth and the first and second molars erupt by 3 weeks, when the pups are being weaned. Shortly after entrance in the mandibular canal the IAN splits into the mental nerve and a common dental branch. The latter emits separate branches to each molar root and to the incisor. The length of the IAN increases 3 times between birth and adulthood. The total number of IAN axons is about 5,000 neonatally and reaches a maximum of 12,500 9 days after birth. From 2 weeks on the number of axons is about 9,000. birth. From 2 weeks on the number of axons is about 9,000. Myelination begins at birth, and the adult proportion of myelinated axons is established by 3 weeks. From a qualitative point of view the fine structure of the IAN undergoes a rapid development after birth, particularly during the first week. Signs of myelin sheath remodelling occur at the end of the first postnatal week. In the adult rat the size distribution of myelinated IAN fibres is bimodal and the largest fibres reach a diameter of 11 µm. Internodal length (L) increases slowly with increasing fibre diameter (D), reaching a maximal L-value of about 750 µm at D values expend 11 µm. about 750 µm at D values around 11 µm.

EFFECTS OF EARLY POSTNATAL RECEPTOR DAMAGE ON DENDRITIC DEVELOPMENT IN GUSTATORY RECIPIENT ZONES OF THE ROSTRAL NUCLEUS TRACTUS SOLITARIUS (NTS) IN RAT. P.S. Lasiter and D.L. Kachele. Florida Atlantic University, Boca Raton, FL. 33431 and Ohio State University, Columbus, OH, 43210.

University, Columbus, OH, 43210.

We have previously shown that damage induced to lingual gustatory receptors of the anterior tongue at postnatal day 2 (P2) specifically alters the developmental expansion of chorda tympani and greater superficial petrosal nerve (CT/GSP) axons within the rostral nucleus tractus solitarius (NTS). Receptor damage also decreases the planar distance between neurons in the CT/GSP terminal field that project axons to the second-order gustatory relay in the caudal parabrachial nucleus (PBN). These findings led us to speculate that, in addition to presynaptic effects, receptor damage may alter normal dendritic development in the CT/GSP terminal field. To examine this question Golgi impregnation studies were performed following unilateral receptor damage at P2. First, planar length of first- and second-order dendrites of multipolar neurons belonging to morphological classes associated with PBN projection neurons are significantly decreased following receptor damage. Second, the mean number of second-order dendritic branches/neuron is significantly reduced ipsilateral to damage, as compared to neurons mean number or second-order dendritic branches/neuron is significantly reduced ipsilateral to damage, as compared to neurons contralateral to damage. These results confirm that early receptor damage specifically alters the development of both pre- and postsynaptic structures in the CT/GSP terminal zone. ASSESSMENT OF SPIRAL GANGLION CELL DEVELOPMENT IN THE POSTNATAL HAMSTER. <u>D.D. Simmons</u>¹², L.K. Manson-Gieseke¹², M.S. Rogers¹, and P. Sahgal¹ Natural Science Division, Pepperdine University, Malibu, CA and ²Dept. of Biology, UCLA, Los

Angeles, CA.

The postnatal development of spiral ganglion cells (SGCs) in the hamster was studied from birth (postnatal day 0) until the young adult stage (> PND 21). Cochleae were processed using standard light and electron microscopic techniques and data were limited to the modiolar portion of the cochlear nerve and the basal 40% of the spiral ganglion. In the young adult hamster cochlea, two types of SGCs were easily discernible. The majority (92%) of SGCs had cytoplasmic-to-nuclear density (CND) ratios greater than 1, whereas the remaining 8% had CND ratios less than or equal to 1. The darkly staining SGCs were always found in the lower 30 percentile of cell areas measured, but there were no differences in cytoplasmic-to-nuclear area (CNA) ratios between the two cell types.

two cell types.
From PND 0 to 3, SGCs exhibited roughly equal CND and CNA ra-From PND 0 to 3, SGCs exhibited roughly equal CND and CNA ratios, cell areas between 34 - 53 µm², multiple nucleoli and no evidence of myelination. By PND 3, the cochlear nerve fibers exhibited several layers of myelin lamellae. From PND 3 to 7, SGCs increased in cell size by almost 65%. By PND 7, nearly all of the SGCs were myelinated and the number of cells with multiple nucleoli was reduced drastically. By PND 10, there were clearly two cell types present as in the young adult animal. Few morphological changes occurred after PND 13 in either SGCs or their nerve fibers. These results are discussed in relation to the morphological maturation of intervation patterns in the organ of Corti

morphological maturation of innervation patterns in the organ of Corti.

SENSORY SYSTEMS-DEVELOPMENT AND PLASTICITY III

MIGRATION OF CELLS FROM THE OLFACTORY EPITHELIUM OF ADULT INTACT RODENTS. A.G. Monti Graziadei, Dept. of Biological Science, Florida State Univ., Tallahassee, FL 32306.

Previous studies of partial and total olfactory bulb removal in adult rodents have shown that cells can exit from

moval in adult rodents have shown that cells can exit from the olfactory epithelial compartment, migrate along the olfactory nerve and reach, intracranially, the nerve layer of the olfactory bulb. It has also been reported that in adult unoperated mice, which had received one injection of tritiated thymidine from three days to 24 hours before sacrifice, clusters of autoradiographically labeled cells were present in the lamina propria of the olfactory mucosa.

present in the lamina propria of the olfactory mucosa. In order to ascertain if cell migration from the olfactory epithelium occurs in normal rodents, 5 weeks old rats and 4-5 months old mice, which did not undergo any sort of experimental manipulation, were sacrificed by perfusion with Bouin's fixative. The heads, embedded in paraffin, were serially sectioned and stained with hematoxylin. Migrating cells (MC) were present in both animal species, but differences were observed in regard to the areas of olfactory epithelium from which they migrated out. In rats, the MC formed cords originating from the olfactory epithelium covering the recesses of the olfactory cavity. The cords reached the nerve layer of the olfactory bulb. In mice, clusters of cells migrated out from the olfactory epithelium of the nasal septum and turbinates. These results suggest that the mechanism regulating cell migration in normal animals may be species-specific. NIH NS20699.

TIME COURSE OF UNILATERAL OLFACTORY DEPRIVATION EFFECTS ON OLFACTORY BULB

FUNCTION. D.A. Wilson. Developmental Psychobiology Laboratory, Dept. Psychology, U. of Oklahoma and J. Wood, Dept. Anatomical Sciences, Oklahoma U. Health Sciences

Olfactory deprivation effects on olfactory bulb neuroanatomy are dependent on the age at which the deprivation occurs. The present study examined the agedependent affects of deprivation on olfactory bulb physiology

and neurochemistry.

Rat pups were cold anesthetized at PN1 or anesthetized with Rat pups were cold anesthetized at PN1 or anesthetized with ketamine/xylazine on PN20 and had a single naris cauterized. Control pups were cauterized on the top of the snout. Ten, 20 or 40 days later, rats were anesthetized with urethane and evoked responses to single and paired shocks of either the lateral olfactory tract (LOT) or olfactory nerve (ON) were examined. The results suggest that paired-pulse inhibition induced by stimulation of the LOT is enhanced by early deprivation but not by deprivation occurring later. On the other hand, preliminary results suggest that inhibition induced by paired-pulse stimulation of the ON is enhanced after 40 days of deprivation, regardless of the age at onset. The relationship between these functional effects and levels of olfactory bulb dopamine will be presented.

UNILATERAL NARIS CLOSURE AND PROTEIN SYNTHESIS WITHIN THE OLFACTORY MUCOSA. <u>I.S.</u> Stewart, D.L. Korol, and P.C. Brunjes. University of Virginia, Charlottesville, VA 22903.

Blocking airflow through one side of the nasal cavity during early life produces dramatic changes in olfactory bulb growth including enhanced cell death and reductions in laminar volume. These structural changes appear to follow a long chain of cellular events, which include rapid (within 24 hours) alterations in glucose metabolism and protein synthesis. Structural changes have also been reported in the olfactory mucosa (Farbman, et al., J. Neurosci. 8, 1988), but these occur long after widespread alterations are seen in the bulb. In the present study we sought to determine if naris closure rapidly alters the cellular function of the olfactory receptor sheet. Rat pups underwent sham surgery or unilateral naris closure on postnatal Day 1. Twentyfour hrs later, rates of protein synthesis were examined by administering ³H-leucine (i.c., 30 min pulse), and processing tissue for standard emulsion autoradiography. Grain densities were determined at three dorsal/ventral locations on the caudal portion of the nasal septum. No left/right differences were found at any location. Therefore, the rapid protein synthetic changes occurring after naris closure in the bulb do not result from similar cellular changes in the mucosa. Supported by DC00338, HD18411, and HD07323.

UNILATERAL NARIS CLOSURE AND PROTEIN SYNTHESIS WITHIN THE OLFACTORY BULB. D.L. Korol, A. Rao, O. Steward and P.C. Brunjes. Univ. of Va., Charlottesville, VA 22903.

Closure of one external naris on postnatal day (P) 1 in the rat leads to a constellation of changes resulting in decreased ipsilateral olfactory bulb size. One of the earliest changes is a rapid reduction in protein synthesis across all bulb laminae (Korol & Brunjes, <u>Dev. Brain Res.</u> 52, 1990). The present study extends these findings by examining which protein classes are altered. We evaluated the extent of incorporation of ³⁵S-methionine into protein. Whole olfactory bulbs were removed 24 or 48 hours after occlusion on P1 and incubated with label in 24 or 48 hours atter occlusion on P1 and incubated with label in vitro. SDS-PAGE gels and their fluorograms were prepared for 1-d analysis, and used to examine the extent of amino acid incorporation into different protein classes. While the pattern of protein separation seen with Coomassie blue staining appeared similar for control and deprived bulbs, the amount of synthesis was reduced in deprived bulbs. Initial examination suggested that the affects were not limited to specific classes of proteins. that the effects were not limited to specific classes of proteins: decreases in precursor incorporation appeared across all molecular weight bands. These data suggest that the effects of deprivation on protein synthesis reflect general changes in "housekeeping" events. Perhaps these are primary events in the cascade of changes following deprivation.

A MORPHOLOGICAL AND QUANTITATIVE INVESTIGATION OF OLFACTORY BULB DEVELOPMENT IN THE CLAWED FROG. XENOPUS LAEVIS. C.A. Byrd and G.D. Burd. Depts. of Molecular & Cellular Biology and Anatomy, University of Arizona, Tucson, AZ 85721.

We analyzed the larval development of the olfactory bulb (OB) from stage 29 to 58. The axons of olfactory receptor cells (ORC) begin to contact the neural tube at stage 29 (Klein and Graziadei, 1983). At this stage, the neural tube only contained a few differentiating cells. By stage 33, ORC axons were visible at the surface of the neural tube, and mitral cells were present immediately below the axons. Glomerular neuropil was first observed at stage 39, and individual glomeruli were evident by stage 45. Also at stage 45, the neuropil in the mitral cell/external plexiform layer began to develop. By stage 48, the accessory olfactory bulb (AOB) was distinct, and all normal adult layers were present in the main olfactory

We also examined the quantitative relationship between the ORC axons and the neurons in the mitral cell/external plexiform layer (MCL/EPL) of the MOB and AOB of tadpoles between stages 50 to 58. The number of ORC axons was obtained from EM montages, and the number of neurons in the MCL/EPL was determined from serial sections through the OB. The number of mitral cells was correlated with the number of ORC axons throughout larval development (n=11, r=0.9935), and the ratio of ORC axons to mitral cells was 4.4 \pm 0.15. In conclusion, even though the OB continues to grow in size and neuron number, the relationship between the mitral cells and the sensory afferents remains constant.

RECEPTIVE FIELD PROPERTIES OF TRIGEMINAL GANGLION CELLS IN FETAL RATS. N.L. Chiaia, G.J. Macdonald and R.W. Rhoades. Dept. of Anatomy, Medical College of Ohio, Toledo, OH 43699.

The peripheral and central connections of trigeminal (V) ganglion cells guide the aggregation of neurons and axons characteristic of the rodent's central V neuraxis. As yet, however, no one has evaluated the peripheral projections of individual V ganglion cells at the time when central patterns corresponding to the periphery are beginning to develop. We mapped the receptive fields of single V ganglion cells on embryonic (E-) days 18 (44 cells), 19 (40 cells), and 20 (53 cells). The data from the 3 ages are generally the same so they will be considered together. The receptive fields of V ganglion cells in fetal rats E-18 and older were no larger than those in mature animals. Specifically, we tested 44 cells that responded to stimulation of vibrissa follicles and 95.4% were discharged by indentation of only a single follicle. In adult rats, all vibrissa-sensitive V ganglion cells respond to deflection of only a single whisker. Trigeminal ganglion cells from fetal rats differed from those in adult animals in that nearly all (97.0%) gave rapidly adapting responses. Only 9 of the V ganglion cells that we recorded had any spontaneous activity (invariably <0.1 spikes/s) and they were all recorded from E-18 fetuses. These results demonstrate that individual V ganglion cells have tightly focused peripheral projections well before central patterns characteristic of the mature V neuraxis can be detected. Supported by BNS 85 17537, DE 07734, DE 08971, and the State of Ohio Research Challenge.

NEURON MORPHOLOGY IN SOLITARY NUCLEUS DURING FUNCTIONAL DEVELOPMENT OF TASTE PATHWAYS. C. M. Mistretta and M. Womble. School of Dentistry, Univ. of Michigan, Ann Arbor, MI 48109.

To learn whether postsynaptic neuron morphology alters in association with developmental changes in taste response and receptive field properties, we are studying a functionally defined region of nucleus of solitary tract (NST) in sheep. Age groups include fetuses at 100, 110 and 130 days of gestation (term-147 days), perinatal animals, and postnatal lambs aged 30 to 50 days. Neural recordings identify the NST area with high frequency responses to NaCl and receptive fields on tongue tip, and an electrolytic lesion is made. Neurons are reconstructed from Golgi Cox preparations in an area around the lesion. In 100 day fetuses neurons are too immature to distinguish among types, but by 110 days elongate, multipolar and tufted cells are evident. Dendritic length and total branch points increase between 100 to 110 days, and subsequently. There is, however, an apparent dendritic reorientation in postnatal lambs. Neurons have large numbers of spines across all age groups. Thus, NST neurons acquire basic morphological features when peripheral responses to NaCl are still weak and in advance of a period of major afferent convergence. Subsequent changes in dendritic extent and orientation take place in association with functional alterations. (NIH Grant DC00456)

CORRELATED FIRING IN CLOSE AND DISTANT PAIRS OF MITRAL CELLS IN MOUSE OLFACTORY BULB. M. E. Lickey. Dept. of Anat. and Neurobiol., Wash. Univ. Sch. of Med., St. Louis. MO 63110

Neighboring sensory neurons, e.g. retinal ganglion cells, show positive temporal correlation of firing during periods of spontaneous activity. In brain development, correlated firing may be a cue for the formation of functional modules in the cortex, e.g. ocular dominance columns. Here I ask whether correlated firing can possibly help specify the morphology and connections of olfactory glomeruli. Using glass micropipets I recorded spontaneous extracellular spikes simultaneously from pairs of olfactory mitral cells that were either near neighbors (<100 microns apart) or far apart (>700 microns). A correlation coefficient was calculated for each pair based on spike frequencies during 20 to 50 activity samples spanning 3 to 30 minutes. While only a minority of pairs was positively correlated, near neighbors were more often positively correlated than widely separated cells. These results are consistent with the possibility that correlated firing of olfactory afferents is a cue for the formation of glomeruli. (USPHS NS 11699 to D. Purves and McDonnell Center for Cellular Neurobiology)

THALAMIC AND CORTICAL REORGANIZATION AFTER CHRONIC TRANSECTION OF THE MEDIAN AND ULNAR NERVES IN ADULT MONKEYS. P.E. Garraghty. R.D. Clower*. E.A. LaChica. and J.H. Kaas. Dept. Psychology, Vanderbilt Univ., Nashville, TN 37240.

Plastic changes are reliably observed in somatosensory cortex

of adult monkeys after peripheral nerve manipulations. remain, however, regarding: 1) the cortical distance across which somatotopic map reorganization can occur, 2) the extent to which earlier processing stations contribute to the reorganization, and 3) the characterization of the mechanism(s) underlying the reorganization. We have begun addressing these questions by studying the effects of chronic denervation of the entire volar surface of the hand in adult squirrel monkeys on the somatotopic maps in the ventroposterior lateral nucleus (VPL) of the thalamus and cortical areas 3b and 1. We have also employed antibodies against gamma-aminobutryic acid (GABA) to determine the role, any, of this transmitter system in the reorganization. two months of the transections, we found: 1) that the entire expanse of deprived cortex had regained somatotopically organized responsivity to cutaneous stimulation of the dorsal surface of the hand and digits; 2) that a parallel reorganization was present in VPL; and 3) that staining for GABA was substantially decreased throughout the deprived zone of cortex. Thus, under these conditions, the cortical distance limit for injury-induced reorganization is no less than 3-3.5 mm. Finally, the somatotopic reorganization evident at the level of cortex is accompanied by changes in thalamic somatotopy and cortical GABAergic activity. (Supported by N.I.H. NS16446.)

EFFECTS OF NEONATAL INFRAORBITAL NERVE SECTION ON THE CORTICOTRIGEMINAL PROJECTION (CTP) IN RAT.

Wiegand, S.S. Stansel & M.F. Jacquin, Anatomical Sciences & Neurobiology, University of Louisville School of Medicine, Louisville, KY 40292, and Anatomy & Neurobiology, St. Louis University School of Medicine, St. Louis, MO 63104.

The normal adult CTP is robust in contralateral trigeminal brainstem submided caudallis intermediate and preprinting and extensive work in

The normal adult CTP is robust in contralateral trigeminal brainstem subnuclel caudalis, interpolaris and principalis and relatively weak in contralateral oralis and all ipsilateral subnuclei. Few CTP fibers terminate in the substantia gelatinosa of caudalis, but the magnocellular portion of this subnucleus exhibits a dense projection that tends to surround each vibrissal "barrelette." In the present study, anterograde WGA-HRP tracing methods were used to study the CTP in adult rats subjected to unilateral infraorbital nerve section at birth. Adult animals received WGA-HRP injections in the posteromedial barrel subfield of the somatosensory cortex contralateral or instituted to the locinetic force that are received.

posteroriectal carrier submed of the somatosensory conex commanderal or insilateral to the lesioned infraorbital nerve.

Cortical injections contralateral to the lesion revealed the following changes: 1) An increase in the density of the CTP to the substantia gelatinosa ipsilateral to the lesion. 2) Absence of a vibrissae-related pattern in the trigeminal brainstern complex on the same side as the lesion. 3) An increase in the density of the projection to rostral trigeminal subnuclei on the side opposite the

Injections <u>ipsilateral</u> to the lesion revealed a deafferentation-induced maintenance of a substantial ipsilateral CTP (Wiegand and Renehan, this volume). These data suggest that both afferent instructions and target factors play a role in the development of the corticotrigeminal projection pattern. They also are consistent with a similar study in kittens (Westrum et.al. '83, Soc. Neurosci. Abs.). Support DE07734 and DE07662

NEUROGENIC PERIOD OF LONG ASCENDING PROPRIOSPINAL NEURONS (LAPNS) IN THE LUMBAR SPINAL CORD OF THE RAT. K.N. Nandi, D.S. Knight* and J.A. Beal. Dept. of Cellular Biology & Anatomy, LSU Medical Center, Shreveport, LA 71130.

The purpose of this study was to determine the neurogenic period of LAPNs in the rat which project from

The purpose of this study was to determine the neurogenic period of LAPNs in the rat which project from the upper lumbar spinal cord to the cervical enlargement. To determine neuronal birthdates, tritiated thymidine was administered to fetal rats on embryonic (E) days E12 thru E16 via i.p. injection of the dam. To label LAPNs in the lumbar cord, using 40 to 50 day old pups of tritiated thymidine treated dams, Fluoro-Gold (FG) was injected via a micropipette into the cervical (C6) gray matter. FG labeled LAPNs were observed in all laminae of the gray matter on both the side ipsilateral and the side contralateral to the injection site. LAPNs undergoing mitosis were doubled labeled, i.e. labeled with both FG and tritiated thymidine. On day E12, all LAPNs exhibited tritiated thymidine label in their nuclei. Less than 5% of LAPNs were found still proliferating late on day E15. These late proliferating LAPNs were confined mainly to laminae I-III of the dorsal horn on both the ipsi- and contra-lateral sides. Results show that in rats, LAPNs continue to proliferate throughout most of the neurogenic period for spinal neurons (E12-E16) and beyond the neurogenic period of long projection neurons of the ascending tracts (Nandi, et al., 1990). Supported by NSF grant #BNS-8908601.

TIME ANALYSIS OF RECEPTIVE FIELD(RF) REORGANIZAT-TION IN SI OF SPINAL KITTENS. <u>C.Chau and P. McKinley</u>. School of Physical and Occupational Therapy, McGill Univ., Montreal, Quebec, H3G 1Y5.

McKinley et al (J.Neuroscience, in press, 1990) showed that the reorganization of primary somatosensory cortex after T12 spinal cord transection at 2 weeks of age is robust. This study addresses the sequential nature of the re-shaping of the RF representation in this age group. Somatosensory cortex is mapped at either 3,6 or 9 weeks post-cordotomy (multiunit recording). The % non-cutaneous response among the three groups are comparable suggesting that somatotopically inappropriate RF representation is already present at 3 weeks post-cordotomy. As time progresses, there is an increase in representation of rostral body parts in hindlimb cortex suggesting that the more inappropriate the input, the longer it takes to drive a cortical area. Finally, the evolution of RF characteristics suggest that RF shaping is complex in the trunk. The final appearance of rostral-caudal RF orientation may result from an initial amalgamation of narrow dermatomal strips running dorsal-ventrally followed by a subsequent lateral inhibition (in a dorsal-ventral direction) of the amalgamated RF. sponsored by MRC.

ELECTROPHYSIOLOGICAL CONSEQUENCES OF DORSAL COLUMN DEMYELINATION. R.P. Yezierski, J.G. Broton, R.M. Devon* and J.P. Vicedomini, The Miami Project to Cure Paralysis, University of Miami School of Medicine, Miami, FL, and *Department of Oral Biology, University of Saskatchewan, Saskatoon.

Demyelination of central axons occurs clinically, and in animal models of spinal cord injury (SCI). Demyelinated axons that survive SCI display conduction abnormalities. Following demyelination, there can be spontaneous remyelination by endogenous oligodendrocytes and invading Schwann cells which may lead to functional restitution. The present research combines electrophysiological and anatomical approaches to determine if recovery of axonal conduction occurs within a time course related to that of remyelination. Adult male rats (n=12) received dorsal column (DC) lysolecithin injections (0.2µl, 1%, w/v) and were used in acute electrophysiological experiments 5, 10, 15, 25 and 50 days post-injection. DC conduction was evaluated from the tibial N. and lumbosacral enlargement, below thoracic DC lesions, to the dorsal column nuclei (DCN). Light and electron microscopic observations were made within the lesion zone at each survival time. DCN evoked response latencies were increased and their amplitudes decreased 5 days post-injection. Partial recovery of various response measures was observed as early as 10 days post-injection, however, conduction abnormalities persisted even at 50 days post-injection. Light microscopy showed that many demyelinated axons remained in continuity through the lesion 5-10 days post-hysolecithin. Electron microscopy demonstrated remyelination by endogenous oligodendrocytes and invading Schwann cells at 15 days post-injection. The time course and extent of remyelination paralleled the partial recovery of electrophysiological measures. Supported by The Miami Project to Cure Paralysis

DEVELOPMENT OF APICAL, BASAL, AND MIXED DENDRITES OF FUSIFORM CELLS IN THE DORSAL COCHLEAR NUCLEUS OF THE HAMSTER. L. Schweitzer. Anatomical Sciences and Neurobiology, University of Louisville School of Medicine, Louisville, KY 40222.

Fusiform cells in the dorsal cochlear nucleus of the adult hamster have apical and basal dendrites which emanate from opposite poles of the cell body, are located in separate layers, receive different inputs, and have distinct appearances. The development of the dendrites was assessed using morphometric analyses of Golgi-impregnated brains from hamsters of various ages. In addition, a third type of dendrite that exits the cell laterally was analyzed. The distal branches of the laterallyextending dendrites end either near the apical dendrites, near the basal dendrites, or near both the apical and basal dendrites. Branches of laterally-extending dendrites that end near apical dendrites are qualitatively and quantitatively identical to the other apical dendrites (that is they are long dendrites with many short, spine-laden branches) and the converse is true of the branches ending near basal dendrites. This is also true for the distal portions of mixed laterallyextending dendrites that split and extend both apically and basally. That is, branches near apical dendrites have apical-like features and branches near basal dendrites have basal-like features. While it is possible that signals originating in the cell body could be transported down a common dendritic trunk and direct differential maturation of the apical and basal dendrites, it seems more likely that during development the environment surrounding these disparate distal branches determines their length, branching pattern, and appearance. NS-20162

A MODEL OF DORSAL COLUMN FUNCTIONAL INTEGRITY IN THE RAT. J.P. Vicedomini, J.G. Broton and R.P. Yezierski, The Miami Project to Cure Paralysis, University of Miami School of Medicine, Miami, FL

Cure Paralysis, University of Miami School of Medicine, Miami, FL
Cord dorsum potentials evoked by peripheral (tibial N.) or dorsal column
(DC) stimulation were studied in the lumbosacral (LS) cord and dorsal column
nuclei (DCN) in urethane anesthetized rats. Orthodromic and antidromic
responses produced by applying stimuli at various voltages and repetition rates
were analyzed. Antidromic responses were obtained from the LS cord and
tibial N. following cervical cord (CI) stimulation. Reversible (DC lidocaine)
or irreversible (mechanical) lesions were made to identify pathways responsible for orthodromic or antidromic responses. Orthodromically evoked LS and
DCN potentials showed: (1) decreases in latency with increasing stimulus
intensity paralleled by increases in response strength and DCN response
duration; and (2) greater amplitude attenuation evoked by high frequency
stimulation in DCN vs. LS responses. Antidromic LS or tibial N. potentials:
(1) had nearly constant latencies at all stimulus intensities tested, but increased
in amplitude and strength with greater stimulus intensities; and (2) exhibited
different sensitivities to high frequency stimulation, with tibial N. potentials
following repetition rates ≥ 500 Hz, and LS potentials attenuating and failing
at about 200Hz. Lesioning techniques showed that orthodromic DCN
responses were abolished by DC plus dorsolateral funiculus transections; lesions
Confined to the DCs were sufficient to abolish antidromic tibial N. responses.
These electrophysiological results provide a framework for the development of
criteria useful in the assessment of DC functional integrity.

Supported by The Miami Project to Cure Paralysis.

THE MATURATION OF THE LATERAL SPINOTHALAMIC AND TRIGEMINOTHALAMIC TRACTS IN RATS. <u>D.Y. Miya and G.A. Barr.</u> Biopsychology Doctoral Program, Dept. of Psychology, Hunter College, CUNY, New York, N.Y. 10021

In order to identify the neurons of origin and to study the ontogeny of both the lateral spinothalamic tract (LSTT) and the trigeminothalamic tract, two retrograde labels, 5% WGA-HRP and green fluorescent latex microspheres were stereotaxically injected into neonatal rats. 1 and 10 day old rat pups were injected with either tracer into the ventral posterior lateral nucleus (VPL) of the ventrobasal complex (VB) of the thalamus unilaterally. Rats were sacrificed at several different times following injection (24, 48 & 72 hours). Labeling was found to be most intense at the 24 hour survival period. For the 1 and 10 day olds, both methods yielded densely labeled cells in the ventromedial aspect of the contralateral dorsal horn of the lumbar enlargement. Smaller cells were labeled laterally in more superficial layers of the dorsal horn (lamina IV). Labeled cells were not seen in the cervical or thoracic segments. Although the pattern and quantity of cells was the same in both age groups, the cells in the 10 day olds appeared more densely labeled. The trigeminothalamic tract and medial lemniscal tract were present also in both ages. In all animals, the ipsilateral medial lemniscus and the lateral most aspect of the contralateral principal sensory trigeminal nucleus were densely labeled following VPL injections. Results demonstrate that both sensory systems, the trigeminothalamic tract and LSTT are present at birth in the rat.

EFFECTS OF NEONATAL SEROTONIN REDUCTION ON THE DEVELOPMENT OF LAYER IV GRANULE CELLS OF RAT PRIMARY SOMATOSENSORY CORTEX. J.A. Daughtery¹, N.L Chiaia², C. Bennett-Clarke², R.W. Rhoades² & J.H. Haring¹. St. Louis Univ. Sch. Med., St. Louis, MO 63104 and Med. Coll. of Ohio, Toledo, OH 43699.

A dense, discontinuous serotonergic (5HT) projection to rat SmI present during the first 3 postnatal wks (D'Amato et al., PNAS 84:4322, '87), assumes the pattern of the SmI barrel fields (Rhoades et al., J.Comp.Neurol. 293:190, '90). We have reported alterations in layer V pyramidal cells & cytochrome oxidase (CO) patches in SmI of rats treated with p-chloroamphetamine (PCA) at birth (Daugherty & Haring, Soc. Neurosci. Abstr. 15:1050, '89). The purpose of this study was to determine the impact of 5HT reduction on the development of layer IV granule cells in SmI.

Neonatal rats received PCA injections (10mg/kg, SC) on either PND 0 & 1 or PND 3 & 4. Other neonatal rats had injections of 5,7 DHT into the raphe nuclei. The barrel fields were studied in all treatment categories at various postnatal times in Nissl-stained tangential sections. The morphology of layer IV granule cells was studied in rats injected on PND 0 & 1 with a combined cytochrome oxida Golgi method. The reduction of 5HT did not alter aggregation of layer IV granule cells into barrels. In each category, barrels were present at the earliest time studied. By contrast, qualitative assessments of granule cell morphology in PCAtreated rats suggest that the development of these neurons is altered by a postnatal reduction of 5HT. Quantative analyses will reveal the specific changes in these granule cells. These data suggest that the early 5HT innervation of SmI does not function to organize the granule cells of the barrel fields. However the subtle morphological changes imply a role for 5HT in cell differentiation & perhaps synaptogenic interactions between layer IV granule cells and the developing thalamocortical axons to SmI. SOURCE OF THE TRANSIENT SEROTONINERGIC IMMUNOREACTIVITY IN THE DEVELOPING SOMATOSENSORY AND VISUAL CORTICES IN THE RAT. C.A. Bennett-Clarke, N.L. Chiaia, G.J. Macdonald and R.W. Rhoades. Dept. of Anatomy, Medical College of Ohio, Toledo, OH

The visual and somatosensory cortices (area 17 and S-I, respectively) contain dense serotonin (5-HT) immunoreactivity (IR) during the first 2 weeks of life (D'Amato et al. P.N.A.S., 84:4322, 1987; Rhoades et al. J.Comp. Neurol.,293:190, 1990). To determine the origin of these projections we carried out 4 experiments. At ages (P-5 to P-7) when the cortical pattern of 5HT-IR was well established, rats received either electrolytic lesions of the thalamus or the medial forebrain bundle (MFB), or injection of the neurotoxin 5,7-DHT into either nucleus raphe dorsalis (NRD) or the cerebral cortex. Rats were killed 2 days after these treatments. Neither destruction of the thalamus nor injection of 5,7-DHT into cortex had significant effects upon the dense 5-HT-IR in area 17 and S-I. Transection of the MFB markedly reduced the density of 5-HT-IR in the ipsilateral cortex and injection of 5,7-DHT into NRD reduced 5-HT-IR in both cortices. Additional pups (P-6) were treated with fluoxitene, a specific inhibitor of 5-HT. This had no significant effect on the 5-HT-IR. These results indicate the dense 5-HT-IR in developing S-I and area 17 arises from NRD and is contained in the axons of these cells. EXPRESSION OF GLUTAMIC ACID DECARBOXYLASE (GAD) RNA DURING THE DEVELOPMENT OF GRAFTED FETAL THALAMIC NEURONS IN THE EXCITATOXICALLY LESIONED ADULT THALAMUS. F. Nothias P. Salin M. Peschanski and M.F. Chesselet²: ¹ INSERM U.161, 2 rue d'Alésia 75014 Paris; Dept. of Pharmacology, U. of Pennsylvania ,PA 19104 Homotypic fetal neurons (E15), dissected from dorsolateral diencephalon containing both primordia of ventrobasal complex (VB) and reticular thalamic nucleus (RT), were implanted as cell suspension into the kainic-acid-lesioned adult rat thalamus. GAD mRNA was detected by *in-situ* hybridization histochemistry using 35S cRNA probes (A. Tobin) and emulsion autoradiography. Compared to the contralateral intact adult RT, emulsion autoradiography. Compared to the contralateral intact adult R1, very low labeling, but higher than the background signal obtained with sense-GAD RNA, was seen in the transplant at 7 days post-grafting (pg; no labeling was observed in the lesioned area). The hybridization signal increased during the second week pg and at 10 days pg, individual labeled cells were well distinguished, intermingled with unlabeled neurons and scatered in the whole transplant. At the third week pg, when the transplant became morphologically mature (Nothias et al., Neurosci. 33:605-616 '90), and later (4 months) the level of labeling in individual grafted neurons was comparable to that in the intact adult RT. The results show that GAD gene expression in RT neurons is preserved when they are removed from their normal embryonic environment. In addition, preliminary results showed that the time course of GAD gene expression in fetal grafted RT neurons is comparable to that occurring during the normal ontogeny of the RT nucleus. GLUTAMATE AND ASPARTATE IN FETAL RAT FRONTAL CORTICAL GRAFTS AS DETERMINED BY IN VIVO MICRODIALYSIS. T.J. Tevler, B.W. Chooko, B.A. Donzanti, T.J. Yoneida, Dept. of Neurobiology, NE Ohio Univ. College of Medicine, Rootstown, OH 44272.

ragments of frontal cortical tissue obtained from 15 day fetal rats Fragments of frontal cortical tissue obtained from 15 day fetal rats were transplanted into 3 adult rats immediately after the production of a transcortical lesion cavity in the rostral sensorimotor cortex. After a postoperative (PO) survival of 2 weeks (PO2W), 7 months (PO7M), or 8 months (PO8M), the hosts were anesthetized and prepared for in vivo microdialysis of the graft and of contralateral sensorimotor cortex. Basal levels of aspartate (asp) and glutamate (glu) and the response to a 30 minute infusion of 80 mM high-K were assessed with HPLC and electrochemical detection. In the PO2W graft, high-K resulted in bilateral increases in both asp and glu. The increase in graft asp was large (423% baseline) and sustained until 2 hours after washout of the high-K. Contralateral asp increased to a lesser extent (168%) and dropped below baseline within 1 hour after washout of high-K. The magnitude and pattern of glu levels in the PO2W rat were similar in both graft and contralateral cortex. In the PO3M graft, glu and asp levels fluctuated widely, with high-K tresulted in a large and sustained increase in both asp (338%) and glu (281%). In contralateral PO8M cortex, high-K resulted in only a small increase in asp and a small decrease in glu. Fetal frontal cortical grafts release asp and glu in response to stimulation with high-K. Dissimilarities between graft and contralateral cortex suggest the possibility of differences in amino acid release, utilization, or removal. (Supported by OBR Research Challenge Grant.) were transplanted into 3 adult rats immediately after the production of

DOPAC IN FETAL RAT FRONTAL CORTICAL GRAFTS AS DETERMINED BY IN VIVO MICRODIALYSIS. B.W. Chooko. B.A. Donzanti. T.J. Yoneida. Dept. of Neurobiology, NE Ohio Univ. College of Medicine, Rootstown, OH. 44272.

Fragments of frontal cortical tissue obtained from fifteen day fetal rats were transplanted into 3 adult rats immediately after the production of a transcortical lesion cavity in the rostral sensorimotor cortex. After a postoperative (PO) survival of 2 weeks (PO2W), 7 months (PO7M), or 8 months (PO8M), the hosts were anesthetized and prepared for in vivo microdialysis of the graft and of contralateral sensorimotor cortex. Basal levels of DOPAC and the response to a 30 minute infusion of 80 mM high-K were assessed with HPLC and electrochemical detection. In the PO2W graft, the response to high-K was an increase in DOPAC levels to high-K were assessed with HPLC and electrochemical detection. In the PO2W graft, the response to high-K was an increase in DOPAC levels to 267% baseline; DOPAC gradually decreased to 164% baseline by 4 hours after washout of the high-K. In the contralateral PO2W cortex, DOPAC levels diminished to 35% baseline after high-K treatment, and remained low thereafter. In the PO7M and PO8M grafts, the averaged response to high-K was a decrease in DOPAC to 58% baseline; baseline was reestablished within 1.5 hours after washout of high-K. In the PO8M contralateral cortex, DOPAC levels were undetectable throughout the experiment. In all grafts, dopamine levels were not consistently detectable. Fetal rat frontal cortical grafts appear to possess the ability to synthesize and metabolize dopamine. The observed differences between young and old grafts may reflect maturation of graft dopamine metabolism. (Supported by OBR Research Challenge Grant.)

INCREASED OPIOID PEPTIDE AND CATECHOLAMINE PRODUCTION IN HUMAN ADRENAL MEDULLARY EXPLANTS. J. Sagen and G.D. Pappas. Dept. Anat. and Cell Biol., Univ. II at Chicago, Chicago, IL 60612.

Our laboratory has been concerned with the potential for adrenal medullary transplants in CNS pain modulatory regions to reduce nociception by providing a local source of both oploid peptides and catecholamines, substances which independently, and perhaps synergistically, reduce pain sensitivity. Rodent studies in our laboratory have indicated that adrenal medullary transplants in the spinal cord subarachonid space reduce pain sensitivity as assessed by both acute and chronic analgesiometric tests. Furthermore, recent work has indicated that rat adrenal medullary tissue maintained in culture may be a better source of graft tissue for reducing nociception. The purpose of the present study was to determine whether human adrenal medullary explants may be a viable source of graft tissue for pain reduction. Human adrenal glands were obtained from the Regional Organ Donor Branch of Illinois, and medullary tissue was dissected from cortical tissue and placed in explant culture for various time periods, ranging from 0 - 45 days. Basal oploid peptide and catecholamine release, and release following nicotinic stimulation was determined at several time intervals following placement in culture using RIA and HPLC, respectively. Explanted adrenal medullary tissue was also analyzed morphologically using immunocytochemistry and electron microscopy at various intervals. Results indicate that human adrenal medullary explants can survive in culture for at least 45 days. At early time points (0 - 3 days), the number of cells staining for tyrosine hydroxylase is small, but the number of stained cells increases dramatically after 7 days in culture curse of the study, atthough the cells tend cells tend cells and cells are found throughout the time course of the study, atthough the cells tend tyrosine hydroxylase is small, but the number of stained cells increases dramatically after 7 days in culture. Cuboidally shaped catecholamine producing cells are found throughout the time course of the study, although the cells tend to become more pleomorphic following longer culture times. In addition, both met-enkephalin and catecholamine levels are significantly increased from 7 - 21 days in culture. These results indicate that human adrenal medullary explants may be a good source of graft tissue for the reduction of clinical pain. (Supported by NIH grants NS25054 and NS28931)

RELEASE OF ENDOGENOUS OPIOIDS FROM RAT BRAIN SLICES CONTAINING BOVINE CHROMAFFIN CELL TRANSPLANTS. Ortega. J.D.; Sagen. J.; Dept. Anat. and Cell Biol. Univ. II at Chicago, Chicago II, 60612.

Work in our laboratory has indicated that the transplantation of adrenal medullary chromaffin cells into CNS pain modulatory regions can reduce pain sensitivity by locally increasing opioid peptide levels. The analgesia produced by the transplanted cells is increased by nicotine, most likely via the stimulation of nicotinic receptors on the transplanted chromaffin cells. Previous studies have demonstrated that isolated bovine chromaffin cells survive for prolonged periods when transplanted into the rat periagual used area? (PAG) and continue have demonstrated that isolated bovine chromaffin cells survive for prolonged periods when transplanted into the rat periaqueductal gray (PAG), and continue to stain immunocytochemically for met-enkephalin, as well as catecholamine synthetic enzymes. The purpose of the present study was to assess whether transplanted bovine chromaffin cells release opioid peptides pharmacologically in response to nicotinic stimulation, as they do in situ. Adult male rats were stereotaxically injected with either 2/µl of a bovine chromaffin cell suspension or equal volumes of vehicle. Following a 4-12 week period, brain slices (300 µm) containing the transplant and PAG were sectioned using a vibratome, and superfused continuously (2-3 ml/min) with oxygenated artificial CSF maintained at physiological temperature. Following a one hour stabilization period, perfusion samples before and after stimulation with several doses of nicotine (15-120 µM) were collected and analyzed for opioid peptide content using RIA. Each stimulation period was followed by a 10 min washout phase with artificial CSF. A dose-related increase in met-enkephalin release following nicotine Each stimulation period was followed by a 10 min washout phase with artificial CSF. A dose-related increase in met-enkephalin release following nicotine administration was observed from slices with bovine chromaffin cell transplants. At pharmacologic concentrations, nicotine produced 20-40 fold increases in met-enkephalin levels. Met-enkephalin release returned to basal levels following each washout. At the highest nicotine doses, met-enkephalin levels were decreased, suggesting a depolarization block. Similar responses are found in cultured bovine chromaffin cells. Results of this study indicate that bovine chromaffin cells are pharmacologically responsive, and can release high levels of opioid peptides. (Supported by NIH grants NS25054)

FETAL DOPAMINE CELL IMPLANTS INTO INTACT STRIATUM: EFFECT ON TRANSPLANT SURVIVAL. J.X. Qi*, P. Patino, C. Hutt*, E. Kriek, and C.R. Freed. Depts. of Med. and Pharm., Univ. of Colorado Health Sci. Ctr., Denver, CO 80262.

As fetal neural implants become a therapeutic option for human Parkinson's disease, there is concern that L-

dopa therapy may inhibit transplant growth. Since the intact striatum is a dopamine rich environment which mimics maximal dopamine replacement, we have compared the survival, growth and behavioral effects of fetal survival, growth and behavioral effects of fetal mesencephalic dopamine cells implanted into intact and lesioned striatum. Male Sprague-Dawley rats 250-350 g were implanted unilaterally in striatum with a coarse suspension of fetal mesencephalic dopamine cells from embryonic day 15-16 fetuses (n=14). The tissue was allowed to grow $\underline{\text{in situ}}$ for four weeks, then half of the rats were lesioned with 6-hydroxydopamine (G-OHDA) in the nigrostriatal bundle. Another group not transplanted with showed that animals transplanted then lesioned Results circled after methamphetamine 5 mg/kg (METH) than less after methamphetamine > mg/kg (MEIH) than animals with lesion alone. Unlesioned, transplanted animals did not circle after METH. After sacrifice, tyrosine hydroxylase (TH) positive cells were found in rats which were transplanted then lesioned but not in transplanted, unlesioned animals. Thus, intact striatal dopamine prevents the expression of graft TH activity but fetal cell implants can express TH after 6-0HDA lesion.

FETAL STRIATAL, CORTICAL OR VENTRAL MESENCEPHALIC TISSUE GRAFTS INTO INTACT STRIATUM. S.Y. Lu, M.T. Shipley, A.B. Norman, E.M. Zubrycki and P.R. Sanberg. Div. of Neuroscience, Depts. Psychiatry, Physiology and Anatomy. Univ. of Cincinnati College of Medicine, Cincinnati, OH 45267-0559

Intrastriatal grafting of fetal striatal (STR), cortical (CTX) or ventral mesencephalic (VM) tissue into the normal striatum produces behavioral deficits. We examined the cellular elements of the graft and their conectivity with the host using histochemistry for cytochrome oxidase (CO) and AChE, and immunocytochemistry for glial fibrillary acidic protein(GFAP), OX-42, tyrosine hydroxylase(TH), dopamine-B-decarboxylase(DBH) and 5-HT 5-15 months after transplantation. CO staining showed that the grafts were metabolically active. AChE staining within the STR grafts was patchy and contained AChE positive neurons and fibers. The CTX grafts exhibited AChE terminals with similar appearance to that of the host cortex. The VM grafts showed light AChE staining. 5-HT, TH and DBH immunoreactive(-IR) fibers were found in the STR and CTX grafts shich presumably originated from the host brain. The density of these fibers varied graftly for different grafts. In one of four CTX grafts, many TH-IR neurons were found. The VM grafts developed TH-IR, 5-HT-IR, DBH-IR neurons and fibers. Fibers crossed the transplant and host border. GFAP and OX-42 stainings showed intermittent heavy staining along the border of the next found in and fibers. Fibers crossed the transplant and host border. GFAP and OX-42 stainings showed intermittent heavy staining along the border of the graft and the host, OX-42 stained macrophages were found in many grafts. Intrastriatal grafts in the intact normal brain were innervated by afferents from the host, and neurons in the graft can innervate host tissue. The glial barrier may be a factor limiting the integration between the graft and the host. The TH-IR neurons found in the CTX graft may be due to induced expression of TH as reported in previous studies. Supported by NINDS, HDSA, TSA.

POTASSIUM-EVOKED OVERFLOW AND DIFFUSION OF DOPAMINE IN DOPAMINE DENERVATED STRIATUM REINNERVATED WITH GRAFTS OF FETAL HUMAN VENTRAL MESENCEPHALIC TISSUE. G. A. Gerhard^{1,2}, I. Stromberg³, C. van Horne², M.N. Friedemann^{1,2} and B.J. Hoffgr. Depts. of Psychiatry¹ & Pharmacology², Univ. of Colorado H.S.C., Denver, CO 80262 & Dept. of Histology³, Karolinska Inst., Stockholm, Sweden. The mechanisms by which grafts of fetal ventral mesencephalic tissue reinnervate and improve the functional properties of dopamine (DA)-denervated host striatum remain unclear. In order to explore the dynamic properties of graft derived DA-containing nerve endings, we employed the technique of high-speed chronoamperometry to study potassium (K ⁺)-evoked overflow of DA and diffusion of DA in graft-reinnervated brain issue. Human fetal mesencephalic fragments (Ist trimester) were transplanted into the ventrole adjacent to the lesioned striatum of unilateral into the ventricle adjacent to the lesioned striatum of unilateral 6-0HDA-lesioned Sprague-Dawley rats; rats were treated with cyclosporin-A daily. Lesioned non-grafted rats, which rotated more than 500 turns/hour following apomorphine injection (0.05 mg/kg), exhibited greatly decreased K^+ -evoked overflow of DA as compared to control. Locally-applied DA K⁺-evoked overflow of DA as compared to control. Locally-applied DA signals had temporal dynamics that were slower compared to control striatum. In contrast, lesioned/grafted animals had reduced rotations compared to pre-grafting rates and showed increased K⁺-evoked overflow of DA in areas within the graft. In addition, locally-applied DA signals had temporal dynamics analogous to control striatum. However, in areas at the periphery of the graft, adjacent to the host lesioned striatum, K⁺- evoked responses were diminished in amplitude and exhibited longer time dynamics as compared to control. In addition, the diffusion properties of locally-applied DA in these brain regions were similar to that of 6-OHDA-lesioned striatum. These data suggest that there are areas at the periphery of DA- containing brain grafts where DA can more readily diffuse, and also suggest that small brain grafts may influence a relatively larger volume of the host brain because of changes in the host brain. relatively larger volume of the host brain because of changes in the host brain. Supported by USPHS AG06434, AG00441 and NS09199.

DEVELOPMENT OF EMBRYONIC DOPAMINERGIC NEURONS TRANSPLANTED TO THE STRIATUM OF RAT PUPS AND EFFECTS ON THE POST-LESION INCREASE OF STRIATAL ENKEPHALINERGIC IMMUNOSTAINING AND SEROTONINERGIC SPROUTING. J.P. Herman, M. Manier*, N. Abrous*, C.Feuerstein*, and M. Le Moal. Lab. Psychobiologie Comportements Adaptatifs INSERM. U259, Univ. Bordeaux II. 33077 Bordeaux Cedex-France. INSERM U318, CHU Grenoble 38043 Grenoble, France.

The ascending dopaminergic (DA) pathway of rat pups (PD3) was unilaterally destroyed by 6-OHDA (6μ g) injected into the lateral hypothalamus. Three days later a cell suspension containing embryonic DA neurons was implanted into the denervated striatum. Tyrosine hydroxylase (TH), met-enkephalin (ME) and serotonin (5HT) immunohistochemistry were performed nine months later and quantified by image analyzer (Peretti-Renucci et al., J. Neurosci, Res., 1990).

Transplanted TH+ neurons developed and reinnervated the host striatum. In comparison to the development observed after adult-stage transplantation (Abrous et al., J. Comp. Neurol., 1988) several differences could, however, be noted. 1) Survival of transplanted DA neurons was lower, 2) Surviving cells migrated over long distances and did not form a compact graft tissue disorganizing the host parenchyma as seen in adult hosts, 3) Preferential migration routes could be shed, e.g., under the corpus callosum and towards the subependymal zone.

The lesion of the ascending DA pathways provoked an increase in ME immunostaining in the denervated striatum. This increase was inhomogeneous, more pronounced in the dorsal and lateral aspects of the striatum. The presence of the graft totally reversed this increase in the zones where, and only where, a TH+ reinnervation was present. Lesion-induced sprouting of striatal 5HT afferents was untouched by the grafts. These results suggest that morphological reorganizations induced by DA lesion are less easily reversed by intracerebral neural grafts than physiological types of modifications.

CEREBELLAR SEROTONIN FIBER INNERVATION IN NORMAL AND pcd MUTANT MICE AND HOST AFFERENTS INTO INTRA-AND FCA MOTANT MICE AND HOST AFFERENTS INTO INTRA-PARENCHYMAL CEREBELLAR GRAFTS. L.C. Triarhou, W.C. Low and B. Ghetti. Dept. of Pathol., Physiol.-Biophys., and Prog. in Med. Neurobiol., Indiana Univ. Sch. Med., Indianapolis, IN 46202. One aspect of integration of implanted neurons into the neuro-

nal circuitry of a defective host brain is the re-establishment of a host-to-graft afferent innervation. We addressed this issue by using the adult cerebellum (CB) of pcd mutant mice, which lack virtually all Purkinje cells (Pc) after P45. Pc constitute one of the CB cell types being innervated by axons of raphé serotonin (5HT) neurons. In normal mice, varicose 5HT-immunoreactive (ir) fibers are distributed to all CB folia with an anteroposterior (AP) density gradient. Following Pc loss in pcd mice, CB 5HT concentration is increased due to the accompanying parenchymal atrophy; 5HT-ir fiber density is higher than normal, but the AP gradient is preserved. Grafts of E12 CB cell suspensions were implanted into the CB of pcd mutants. The state of grafted Pc and host 5HT axons was monitored by calbindin and 5HT immunocytochemistry. Numerous host-derived 5HT-ir axons are present in the graft within 5 days; at 30 days the overall 5HT fiber density in the graft is somewhat higher than the surrounding host CB tissue. These findings offer an anatomical correlate of the biochemical state of 5HT in pcd mice and provide evidence for afferent inner-vation of donor CB tissue by 5HT fibers of host origin. It remains to be established whether this effect is related to a se-lective attraction of host fibers by grafted neurons or to a nonspecific invasive property of 5HT systems. (PHS RO1-NS14426).

AN ULTRASTRUCTURAL IMMUNOCYTOCHEMICAL ANALYSIS OF SEROTONIN (5-HT) NEURONS GRAFTED TO ADULT RAT HIPPOCAMPUS. G. Chazal. A. Daszula*. S. Garcia*. S. Oleskevich and L. Descarries. INSERM U6 and CNRS LNF 4, Marseille, France, and CRSN, Université de Montréal, Montréal (Québec), Canada.

5-HT-immunocytochemistry was used at the EM level to examine the ultrastructural features of 5-HT neurons that had reinnervated adult rat hippocampus, 4 to 5 months after a 5-HT denervation (5,7-DHT) and subsequent graft of embryonic raphe cells. Immunostained cell bodies and dendrites in the core of grafts were compared to their in situ counterparts in the dendrites in the core of graits were compared to their in stu counterparts in the nucleus raphe dorsalis, and axon terminals (varicosities) in a CA3 and a dentate gyrus (DG) outgrowth zone to the normal 5-HT innervation of hippocampus (Oleskevich et al., *Soc. Neurosci. Abstr.*, this volume). The shape, size and synaptic investment of grafted somata and their dendrites resembled those of in situ raphe neurons. Some of these dendrites contained clusters of small clear vesicles, and a few others were contacted by immunostained varicosities. In both the core and two outgrowth zones, the varicosities (n = 500) were also indistinguishable from their normal counterparts, with respect to shape, size, content, and frequency of synaptic contacts and juxtaposed elements. In single sections, only 7.4% of these profiles exhibited a junctional complex, yielding a stereologically extrapolated synaptic incidence of 16% for whole varicosities. These contacts were asymmetrical and mostly made on dendritic shafts, except in the molecular layer of DG where a few axo-spinous synapses were also seen. The microenvironment of immunostained varicosities was similar in the neuropil layers of both CA3 and DG, comprising mostly other axonal varicosities, neurites and dendritic shafts. Thus, in spite of their transplantation and growth into an abnormal milieu, and the fact that they hyperinnervated the host tissue, grafted embryonic 5-HT neurons appeared committed to express a particular set of intrinsic and relational features resembling their normal characteristics.

VASOPRESSIN-NEUROPHYSIN (VP-NP) AND CORTICOTROPIN-RELEASING FACTOR (CRF) ARE CO-LOCALIZED IN PARVICELLULAR NEURONS OF THE TRANSPLANTED PARAVENTRICULAR NUCLEUS. <u>S.J. Wiegand, J.A. Olschowka and D.M. Gash.</u> Dept. of Neurobiology and Anatomy, University of Rochester Medical Center. Rochester, NY 14642.

Rochester Medical Center, Rochester, NY 14642.

Grafts of the fetal paraventricular nucleus (PVN) characteristically contain neurons immunoreactive for a number of neuropeptides, including CRF and VP. The parvicellular VP-immunoreactive (VPir) neurons in PVN grafts are morphologically indistinguishable from the CRFir neurons, and are similarly distributed within the transplanted tissue. The objective of the present study was to determine the extent to which CRF and VP might be collectived within the classified within cells of the transplanted EVN.

parvicellular VP-immunoreactive (VPI) neurons in VPN grafts are morphologically indistinguishable from the CRFir neurons, and are similarly distributed within the transplanted tissue. The objective of the present study was to determine the extent to which CRF and VP might be co-localized within cells of the transplanted PVN. Blocks of tissue containing the developing PVN were obtained from normal Long-Evans rat fetuses (E15-17) and transplanted to the periventricular hypothalamus of adult, male, Long-Evans or VP-deficient Brattleboro rats. Developing neocortex or SCN served as control tissues. Animals were sacrificed 6-12 weeks after transplantation and the grafts were stained using a double-immunofluorescence procedure employing a mouse monoclonal antibody against VP-NP and a rabbit polyclonal antiserum against CRF. Alternate series of sections were double-stained for CRF and oxytocin(OT)-NP. CRF and VP-NP were co-localized in 70-90% of immunoreactive parvicellular neurons, with the remaining cells containing one or the other peptide. A relatively small number of magnocellular neurons were found to contain OT- or VP-NP, but these cells did not stain for CRF. Nor were CRF and VP-NP co-localized in the cells of cortical or SCN grafts. The extensive co-localization of VP-NP and CRF in the PVN grafts was particularly striking, and somewhat unexpected, as the graft recipients were neither adrenalectomized nor injected with colchicine prior to sacrifice. Consequently, neurons in the medial parvicellular PVN of Long-Evans host animals stained only moderately for CRF, and not at all for VP-NP. This strongly suggests a differential regulation of peptide expression in the grafted neurons and the homologous population of cells in the bost brain, notwithstanding their exposure to identical titers of circulating glucocorticoids.

RESTORATION OF STRIATAL SP-mRNA EXPRESSION BY DOPAMINERGIC FETAL SUBSTANTIA NIGRA GRAFTS. B.A. Flumerfelt, I. Mendez, K. Elisevich and C.C.G. Naus. Depts. of Anatomy and Clinical Neurological Sciences, University of Western Ontario, London, Canada, N6A 5C1.

Evidence for survival and growth of fetal nigral grafts and reversal of behavioural and biochemical deficits in the donamine (DA) depleted striatum is well documented. Restoration of a synaptic DA input on host neurons has also been demonstrated. One of the postsynaptic targets of graft-derived DA terminals is the substance P (SP) neuronal population within the striatum (Mendez et al., Restor. Neurol. and Neurosci. Suppl., 1989). In this study, the SP-mRNA expression in the striatum was analysed before and after the grafting procedure. Fetal nigral cell suspensions were stereotaxically implanted into the deafferented neostriatum of Wistar rats two weeks after inducing an ipsilateral nigral lesion with 6-hydroxydopamine. Striatal SP-mRNA expression was assessed using an SP ³⁵S-radiolabelled antisense oligonucleotide probe. DA depletion was accompanied by a corrresponding decrease in SP-mRNA in the striatum ipsilateral to the lesion. Restoration of SP-mRNA levels was observed in grafted animals that exhibited normalization of rotational behaviour and viable grafts as demonstrated by TH immunocytochemistry. This study thus suggests that reestablishment of the DA input on host SP neurons has a direct effect on the gene expression for SP production.

NEURONAL DEATH: DEAFFERENTATION AND PRENATAL STUDIES

347.1

AXON NUMBERS IN DEEP VIBRISSAL NERVES OF NEONATAL AND ADULT RATS: A QUANTITATIVE ELECTRON MICROSCOPIC STUDY. X. Huang. R.S. Crissman, M.F. Jacquin, W.E. Renehan, B.G. Klein, and R.W. Rhoades. Dept. of Anatomy, Medical College of Ohio, Toledo, OH 43699.

It has been suggested on the basis of light microscopic data that the deep nerves innervating the vibrissa follicles in newborn rats contain only 70% of the fibers that they will in adulthood (Munger, B.L. and F.L. Rice, J. Comp. Neurol., 252:404, 1986). This result is surprising since axon number decreases postnatally in several peripheral nerves (e.g. Renehan, W.E. and R.W. Rhoades, Brain Res., 322:369, 1984; Jenq, C-B. et al., J. Comp. Neurol., 244:445, 1986). We attempted to resolve this issue by using the electron microscope to count axons in the deep vibrissal nerves supplying the C-1 and C-4 follicles in both newborn and adult rats. In newborns, the average number of fibers supplying the C-1 follicle (N=5) was 287 ± 30.9 (s.d.); for adults, the average number was 324 ± 30.5 (p>0.5). In neonates, nerves to the C-4 follicle (N=6) contained 236 ± 28.4 axons; for adult follicles (N=4), this value was 217 ± 29.4 (p>0.10). Almost all of the axons in the neonates were unmyelinated. Thus, deep vibrissal nerve fiber number does not increase with postnatal age. However, adult numbers of axons exist in these infraorbital (ION) branches when the parent nerve still contains about 25% more fibers than will be the case in adulthood. Thus, if axonal loss occurs in vibrissal nerves, it is complete prior to that for the ION as a whole. DE 07734, BNS 85 17537.

SEGMENT-SPECIFIC DEATH OF THORACIC INTERNEURONS IN THE MOTH, MANDUCA SEXTA. T.M. Amos * K.A. Mesce * and S.E. Fahrbach * * Graduate Program in Neuroscience and Dept. of Entomology, Univ. of Minnesota, St. Paul, MN 55108 and * Neuroscience Program and Dept. of Entomology. Univ. of Elilinois. Urbana. III. 61801.

Program and Dept. of Entomology, Univ. of Illinois, Urbana, Ill. 61801. During metamorphosis of the holometabolous insect, Manduca sexta, the larval meso- and metathoracic ganglia fuse with the first two abdominal ganglia (A1 and A2) to form the adult pterothoracic ganglion. A pair of identified intersegmental interneurons is located in both A1 and A2 of the pterothoracic ganglion. These are the only interneurons present in the pterothoracic ganglion that project posteriorly through more than two ganglia. These neurons may be involved in generating ecdysis behavior since, in the adult, intracellular stimulation of the neurons in A2 produces the adult-specific phase of ecdysis.

Our studies show that these intersegmental interneurons are conserved larval interneurons. Pairs of intersegmental interneurons analogous to those in the adult are present in the larval thoracic ganglia as well as the first two abdominal ganglia. We present evidence suggesting that these larval thoracic interneurons die in a segment specific fashion during the first few days after pupal ecdysis. The thoracic neurons can no longer be backfilled with cobalt at the same time that light microscopic sections of thoracic ganglia show a small number of degenerating neurons, some of which are located in positions similar to the larval thoracic intersegmental interneurons.

Preliminary results suggest that new, adult-specific neurons may regulate this death. We have found, in 20% of animals treated with hydroxyurea (a DNA synthesis inhibitor which selectively ablates adult-specific neurons), that the thoracic intersegmental interneurons appear to be saved.

DUAL FATE OF SUBPLATE NEURONS IN THE RODENT. T.U. Woo, J.M. Beale* and B.L. Finlay. Biopsychology Laboratory, Cornell University, Ithaca, NY 14853. While subplate neurons (layer VIb or VII) are lost during the

While subplate neurons (layer VIb or VII) are lost during the development of the cat cortex, in rodents the subplate persists to adulthood, at least in part. Using tritiated thymidine, we traced the developmental course of the suplate in the golden hamster, comparing the amount of cell loss in this earliest generated layer with layer VI and LGN.

Tritiated thymidine injections in pregnant hamsters on embryonic day 10 (E10) and E11 labeled cells of the subplate, layer VI, and LGN. Animals were examined prior to cell death and at adulthood. Absolute number of silver grains was counted. At all criteria, a greater proportion of cell loss occurred in the subplate, as compared with layer VI and LGN. However, a substantial population of subplate cells remains, forming an intact layer in adult animals. adult animals.

Since cats and hamsters differ in timing of neurogenesis, axonal innervation of cortex, and fate of subplate cells, comparative information can constrain our hypotheses on the function of this developmentally transitory population.

DEVELOPMENTAL NEURON DEATH IN TARGET-SPECIFIC SYMPATHETIC GANGLION NEURONS. <u>L.L. Wright, and A.F. Elshaar.</u> Dept. Anatomy, Boston Univ. Sch. Med., Boston, MA 02118.

Since target tissues are known to play a large role in regulating developmental neuron death, we compared the time course and magnitude of neuron death in rat superior cervical ganglion (SCG) neurons innervating the submandibular gland with those projecting to the eye in the rat. These target-specific subpopulations of SCG neurons were identified with retrogradely transported fluorogold, and the number of fluorogold labelled neurons, pyknotic neurons, and pyknotic-fluorogold-labelled neurons were tallied directly from the microscope at P3,5, and 8, during the normal period of neuron death. Results are expressed as the percentage of fluorogoid-

labelled neurons that are pyknotic.

In <u>females</u>, the peak neuron degeneration among SMG-projecting neurons occurred at P5, with significantly less degeneration at P8. Neuron degeneration in eye-projecting neurons remained constant over the 3 ages. In males, the peak degeneration in SMG-projecting neurons occurred at P3, while the peak degeneration in eye-projecting neurons occurred on P8. In both males and females a significantly greater percentage of eye-projecting neurons than SMG-projecting neurons were degenerating on P8. Cumulative percent loss of SCG neurons was statistically greater in females than in males in the SMG-projecting population, but not in the eye-projecting population.

These data indicate that there are differences in the magnitude and time course of neuron death between males and females, and between SCG neurons innervating different target tissues

Supported in part by NIH grant NS21577 to LLW.

TIME COURSE OF POSTSYNAPTIC CELL DEATH FOLLOWING INFRAORBITAL NERVE SECTION AT BIRTH IN RAT. T.A. Henderson and M.F. Jacquin. Dept. of Anatomy & Neurobiology, St. Louis University School of Medicine, St. Louis, MO 63104.

It is well established that afferent inputs are necessary for the normal development of sensory systems. Neonatal deafferentation produces extensive transneuronal cell loss whithin 2 days in the gerbil auditory system (Hashisaki and Rubel, JCN 283:465, '89), yet no cell loss was detected at postnatal day (PND) 5 in the mouse lateral geniculate following enucleation at birth (Heumann and Rabinowicz, Exp. Brain Res. 38:75, '80). The "acute" effect of neonatal deafferentation upon cell numbers in the trigeminal (V) system is unknown. As a preliminary step in addressing that issue, 6 rats sustained left infraorbital nerve sections at birth and were sacrificed on either PND 1, 3, or 5. Brainstems and V ganglia were sectioned in paraffin and stained with cresyl violet. In each rat, all neuronal profiles containing nucleoli were counted in 5 sections through each of V brainstem subnuclei principalis and interpolaris. The average cell loss in principalis by PND 1, 3, and 5 was 26.1, 23.9, and 30.9%, respectively. Corresponding values in interpolaris were 9.2, 30.9, and 31.6% Corresponding values in interpolaris were 9.2, 30.9, and 31.6%, respectively. In V ganglia ipsilateral to the lesion, a 28.3% mean cell loss was observed by PND 1. Thus, deafferentation-induced cell death in the V brainstem complex occurs very rapidly. Inasmuch as a 30-40% cell loss has been reported in adult rats following the same lesion at birth (Choy et al., Soc. Neurosci, Abstr. 15:1332, '89), the present data suggest that the majority of V brainstem cells which will die do so during the first few posterical data. Suggest 15:07374, DE07362 postnatal days. Support: DE07734, DE07662.

CELL DEATH DURING THE EARLIEST STAGES OF SPINAL CORD DEVELOPMENT IN THE CHICK EMBRYO. S. Homma, H. Yaginuma and R. W. Oppenheim. Dept. of Neurobiology and and R. W. Oppenheim. Dept. of Neurobiology and Anatomy, Bowman Gray School of Medicine, Winston-Salem, NC 27103

Following neural tube closure, degenerating cells were observed in the neuroepithelium (NE) in virtually all areas of the presumptive spinal cord, including roof and floor plate regions. We have quantified the roof and floor plate regions. We have quantified the extent as well as the spatio-temporal distribution of dying cells in the NE of the brachial spinal cord beginning at stage (St) 15 (embryonic day 2, 50-55 hours of incubation). Brachial neural tubes were embedded in plastic, sectioned transversely at 2 μm and all pyknotic cells were counted in every fourth section through one segment. The number of dying cells was highest at St. 17 and 18 (approximately 60 dying cells per segment). Before St. 15 and after St. 22, dying cells were virtually absent. Although dying cells were most frequently observed in the floor plate, some were also found in most other regions of the neural tube. also found in most other regions of the neural tube. Debris from dying cells was phagocytized by adjacent NE cells. The period of cell death in the floor plate coincides with the projection of commissural axons across the ventral midline and thus may be associated with nathway formation. with pathway formation.

INVOLVEMENT OF AFFERENT SYNAPTIC INPUT IN TROCHLEAR MOTOR NEURON DEATH DURING DEVELOPMENT. S. Hirano*, K. Kumaresan* and G.S. Sohal. Department of Anatomy, Medical College of Georgia, Augusta, GA 30912.

About half of the trochlear motor neurons die during normal development in duck embryos. In order to understand the nature of factors controlling survival or

death of neurons we have begun to examine the involvement of afferent synaptic input in cell death. Brains of duck embryos before, during, and after the period of trochlear motor neuron death were processed for electron microscopy. Central afferent synapses on the trochlear motor neuron soma began to form before the onset of neuron death. This This finding suggests that afferent input may be involved in neuron survival. This possibility was examined by neuron survival. This possibility was examined by decreasing input to the trochlear motor neurons. Deafferentation was achieved by ablation of portions of medulla and pons giving rise to the medial longitudinal fasciculus, a major source of afferents to the trochlear motor neurons, before motor neuron death begins. Our preliminary results indicate that there is a significant decrease in the number of surviving trochlear motor neurons. Further, the neurons were considerably smaller in size. The decrease in neuron survival occurred even though the target muscle was not manipulated. These observations suggest that afferent input may be important in the control of neuron numbers during development. (Supported by NIH Grant HD17800).

DEAFFERENTATION OF CLARKE'S NEURONS PREVENTS RETROGRADE CELL DEATH AFTER AXOTOMY. C.A. Sanner, and M.E. Goldberger, Medical College of Pennsylvania, Philadelphia, PA. 19129

Factors determining the amount of cell death in Clarke's Nucleus (CN) after axotomy were assessed in cat L3 spinal cord.
Distance of lesion from the cell body effects cell death since T9 hemisection resulted in a greater cell loss than C2 animals. Age was also a factor since greater cell loss was seen after neonatal than after adult T9 hemisection. Afterents may also be a factor. L1-S2 dorsal rhizotomy 6 months prior to T9 hemisection resulted in total cell survival. Thus neurons that would have undergone retrograde cell death after axotomy were protected by the prior deafferentation. Though the cell population was composed almost entirely of smaller cells they stained positively for MAP2. This suggests that since total cell number is normal, the larger cells are most likely shrinking. Cell survival after combined lesions implies that there is an intrinsic balance between the influence of the target and that of the afferents upon CN neurons. Removal of one of these influences creates an imbalance while removal of both may create a new homeostasis that allows cell survival.

UNILATERAL OLFACTORY DEPRIVATION INCREASES CELL DEATH AMONG PRENATALLY PROLIFERATING GRANULE CELLS IN THE MOUSE

AMONG PRENATALLY PROLIFERATING GRANULE CELLS IN THE MOUSE MAIN OLFACTORY BULB. K.T. Spence*, LC. Skeen*, and B. Wolfson, University of Delaware, Newark, DE 19706. Olfactory bulb granule cells (GCs) are deleteriously affected by olfactory deprivation (Skeen, et al., Neurosci. Lett., 54:301, 1985), however, the degree to which deprivation affects the prenatally produced subset of these neurons is unknown. of these neurons is unknown.

of these neurons is unknown.

Pregnant dams were injected with ³H-thymidine on embryonic days 13 through 16 to radiolabel the earliest-produced GCs. Pups from these dams underwent unilateral naris occlusion on postnatal (P) day1 and were sacrificed on P15, P30 and P45 to compare the number of radiolabeled GCs in deprived and nondeprived olfactory bulbs (OBs).

Prenatal exposure to ³H-thymidine radiolabeled light and dark GCs, and both subtypes were affected by deprivation. There are 19% fewer light GCs (ANOVA, p< .005) and 26% fewer dark GCs (ANOVA, p< .003) in deprived versus nondeprived OBs. Deprivation-related death is apparent by P15 in light GCs and by P30 in dark GCs. These results indicate that among GCs early proliferation proresults indicate that among GCs early proliferation provides no insulation against the effects of early olfactory deprivation. The finding that dark GCs are affected by deprivation later than light GCs may reflect differences in the efferent connections of these cells.

347.11

IN VIVO LESIONING AND DII MARKING OF THE ENTORHINAL CORTEX IN THE FETAL MOUSE. D.C. Snyder, E. Bui*, B. W. Coltman*, and C.F. Ide Dept. of Cell and Molecular Biology, Tulane University, New Orleans, LA 70118.

We identified, using in vivo implantation of Dil crystals, the presumptive entorhinal cortex (EC) in the E15,16 mouse fetus. By term (E19), a prominent dye marked projection of the angular bundle into the CA1 region of the hippocampus was clearly evident. We then lesioned the lateral EC at E15,16 using suction or electrocautery methods; in some cases, Dil was placed in the lesion. Embryos were allowed to develop to term (E19) and then analyzed histologically. The consequences of the lesion were 1) removal of angular bundle innervation of CA1 during fetal development, 2) cell death anterior to the lesion site, presumably of cells which project into the lesioned area, and 3) little apparent cell death posterior to the lesion site, including CA1. Therefore, prenatal disruption of major cortical tract innervation of the developing hippocampus has little effect on its basic structure at birth.

NONGENETIC REGULATION OF PROLIFERATION AND CELL DEATH IN THE OLFACTORY EPITHELIUM (OE). V.McM. Carr and A.I.Farbman. Dept. Neurobiol.& Physiol., Northwestern Univ., Evanston, IL 60208.

Continued genesis and replacement of olfactory sensory neurons (SNs) occur throughout a vertebrate's life. Until recently SN longevity was thought to be genetically controlled, but recent studies now suggest that influences other than genetic may be important. To assess the role of target deprivation, quantitative [3H]-TdR, autoradiographic analysis of both SN genesis and degeneration was carried out in unilaterally bulbectomized (OB-Xd) rats.

Results show that [3H]-TdR incorporation was 3-4 times greater on the OB-Xd side than contra-

Results show that $[^3H]$ -TdR incorporation was 3-4 times greater on the OB-Xd side than contralaterally at 7-11 days post-op following a 1-day exposure to $[^3H]$ -TdR $(2\mu\text{Ci}/\text{gm}\ b.\text{wt.},\ 3x/24\ hr.)$ (p<<.001). Simultaneous analysis of degenerative activity shows not only OB-X-enhanced degeneration but also that a greater proportion of newly formed cells are dying precociously, especially in the basal and mid regions of the OE. These data indicate that proliferative activity and SN longevity may be environmentally controlled.

LONG-TERM POTENTIATION IV

348.1

LOW FREQUENCY DEPRESSION IS MODULATED BY LTP IN THE IN VIVO DENTATE GYRUS. P.C. Rinaldi and V.B. Nguyen*. Div. of Neurosurgery, School of Medicine, Univ. of California, Irvine, CA 92717.

Low frequency stimulation (LFS) of the medial perforant path (mpp) projecting from the entorhinal cortex to dentate gyrus of the hippocampal formation results in habituation—like decrements in response campal formation results in habituation—like decrements in response called low frequency depression (LFD). In contrast, brief trains of high frequency stimulation (HFS) of mpp produce a lasting increase in response known as long-term potentiation (LTP). Both phenomena have been implicated in information processing and memory/learning. This work assessed their interaction, specifically, whether LFD is modified in a potentiated network. Population spike and excitatory postsynaptic potentials produced by bipolar stimulation of mpp were monitored in 12 rats under urethane anesthesia and were recorded from the tored in 12 rats under uretrane anestresia and were recorded from the ss. granulosum of the dentate gyrus by microelectrodes. After establishing a 20 minute baseline with test stimulation (1/30 seconds), a 40 trial LFS series was delivered (0.5 Hz) to assess LFD. Following recovery, brief trains of HFS were employed to induce LTP. Post-LTP (30 minutes) a second LFS series was delivered for LFD assessment.

Comparison of computer averages of the population spike potential indicated that the relative amount of depression post-LTP was significantly less than pre-LTP (t=4.43, df 7, p<0.005). Analysis of population EPSP slope and spike amplitude showed that changes were located in the latter. Results suggest that changes in the potentiated network can significantly modulate the outcome of LFD and thus have the potential to modify processing or memory capabilities of the network. (Supported by NIH grant NS22980-01A1 to PCR.)

348.2

LTP-INDUCED EPSP/SPIKE DISSOCIATION IN THE DENTATE GYRUS IS BLOCKED BY LOCAL INFUSION OF BICUCULLINE. R.A.Tomasulo, W.B Levy. and O.Steward. Depts. of Neuroscience and Neurosurgery, Univ. of VA, Charlottesville, VA 22908.

The induction of long-term potentiation (LTP) in the dentate gyrus is accompanied by a change in the EPSP/spike (E-S) relationship. After inducing LTP, a given pEPSP evokes a larger population spike than previously. This phenomenon, termed the E-S dissociation, is seen in field potential studies as a shift to the left of the E-S curve, in which population spike amplitude is plotted against EPSP slope at various stimulus intensities. One possible cause of the E-S dissociation is a reduction in feed-forward (FF) inhibition. This hypothesis predicts that removing FF inhibition before inducing LTP will prevent the E-S curve shift with LTP. We blocked GABA_a neurotransmission in a circumscribed area of the dentate gyrus (DG) of urethane-anaesthetized rats by inserting a micropipette filled with 8mM bicuculline methiodide in saline, as previously described (Steward, Tomasulo, Levy. Brain Res. 1990 in press). Effective blockade of inhibition was indicated by multiple population spikes after a single perforant path stimulus, a lowered spike threshold, and absence of paired pulse inhibition. We recorded E-S curves from this electrode and a control electrode, containing saline only, before and after inducing LTP in the perforant path with 8-pulse, 400 Hz trains. In 6 of 7 experiments, the bicuculline prevented the left shift, and, unexpectedly, revealed a shift to the right, so that a given EPSP evoked a 10-20% smaller population spike after right, so triat a given EFSP evoked at 10-20% shalled population spike after inducing LTP. The control electrodes showed the expected left shift. We conclude that EPSP/spike dissociation in the DG reflects a reduction in GABA_a-mediated FF inhibition. The cause of the right shift remains to be determined. Supported by BNS8818766 to OS, NS15488 and MH0622 to WBL, and training grant NS07199 to RT.

PHENCYCLIDINE BLOCKS THE INDUCTION OF LONG-TERM DEPRESSION IN THE HIPPOCAMPAL DENTATE GYRUS IN VIVO. N. L Desmond, C. M. Colbert, D. X. Zhang, and W. B Levy. Dept. Neurosurgery, Univ. of Virginia Health Sciences Center, Charlottesville, VA 22908.

Long-term depression (LTD) of inactive synapses occurs in the entorhinal cortical (EC)-dentate gyrus (DG) system when LTP occurs at nearby, active synapses. Given that NMDA receptor antagonists block the induction of LTP and that strong postsynaptic depolarization is the permissive event for induction of both LTP and LTD in this system¹, we assessed the effect of phencyclidine (PCP), a noncompetitive NMDA receptor antagonist, on the induction of LTD in the EC-DG system. Adult, Sprague-Dawley rats were anesthetized with urethane. Recording pipets were placed bilaterally in the DG; stimulating electrodes were positioned bilaterally in the angular bundles. Either PCP (6 mg/kg body weight) or normal saline was administered i.v. via a lateral tail vein. Compared to the saline control group (N=5), PCP blocked the induction of both LTD of the converging contralateral EC-DG response and LTP of the ipsilateral response (N=5). Compared to the immediately preceding baseline, conditioning stimulation depressed the converging contralateral response 34.2% (SEM 1.0%) for the saline group but only 1.8% (SEM 0.5%) for the PCP-treated group (t=6.32, p<0.01). The unconditioned ipsilateral response was unchanged in both groups of animals. Activation of NMDA receptors is thus required for the induction of LTD in the EC-DG system. In addition, subsequent conditioning stimulation at supramaximal intensity in the presence of PCP did not consistently induce LTP or LTD. Therefore, brief but massive postsynaptic depolarization alone is probably not sufficient to induce LTD or LTP in the EC-DG system.

KETAMINE BUT NOT MK-801 INHIBITS THE INDUCTION OF LONG-TERM POTENTIATION (LTP) IN THE DENTATE GYRUS *IN VIVO*. S. Maren, T. J. Shors. M. Baudry, and R. F. Thompson. Neural, Informational, and Behavioral Sciences, University of Southern California, Los Angeles, CA 90089.

Activation of the *N*-methyl-*D*-aspartate (NMDA) receptor is essential for LTP induction in the dentate gyrus and hippocampal CA1 region. The present study examined the effects of the noncompetitive NMDA antagonists, ketamine and MK-801, on LTP induction in the perforant path-granule cell pathway of anesthetized rats. Dentate hilar field potentials evoked by perforant path stimulation were recorded in nembutal anesthetized Long-Evans rats. Input/output functions were generated immediately before drug injection and 30 minutes following high frequency perforant path stimulation (theta rhythm: 10 30 ms 400 Hz bursts at 5 Hz). LTP was quantified by calculating the percent change in population spike (PS) amplitude and excitatory postsynaptic potential (EPSP) slope for responses having an initial PS amplitude of approximately 6 mV. Fifteen minutes prior to delivery of the perforant path tetanus, animals were injected intraperitoneally with either saline (S; 1 mg/kg; *N*=6), ketamine (K; 30 mg/kg; *N*=6), or MK-801 (M; 1 mg/kg; *N*=10). The development of LTP in animals treated with ketamine was significantly attenuated (LSD, p<.01) relative to those injected with either saline or MK-801 (mean changes in PS amplitude SEM: S=121 ± 32%, K=1 ± 20%, M=71 ± 20%; and EPSP slope ± SEM: S=23 ± 6%, K=-10 ± 3%, M=18 ± 7%). These results are thus consistent with those of Abraham and Mason (Brain Research, 462, 1988) showing that MK-801 did not prevent LTP induction when administered 30 minutes before delivery of the tetanus. The contrasting modulation of LTP induction by ketamine and MK-801 may be related to the differential use-dependency of the two drugs as the pharmacological actions of MK-801, but not ketamine, are use-dependent *in vitro*. Supported by NIH McKnight Foundation.

348.7

LONG TERM POTENTIATION AND DEPRESSION IN THE RAT VISUAL CORTICAL-CALLOSAL SLICE PREPARATION. R.L.Berry, B.W. Chopko & T.J. Teyler, Neurobiology Dept, NE Ohio College of Medicine, Rootstown, OH 44272

In order to study interactive long term potentiation (LTP) and depression (LTD) in the rat visual cortex, we have developed a slice preparation in which both geniculate (GC) and callosal (CC) afferents to rat visual cortex are preserved. Slices were obtained from 16-25d rats and maintained in a perfusion system. A recording electrode was placed in layer II/III of OC1 (area 17), OC2 (area 18) or at the OC1/2 border (location verified by AChE histology). Stimulation of the CC pathway was followed (60 ms delay) by stimulation of the GC pathway. Field potentials were recorded for a 30 min baseline period, tetanic stimulation (20 pulses/5 s at 100 hz--10 min) given to the <u>CC pathway</u> alone, and field potentials recorded for a further 70 min.

The incidence of LTP and LTD of the field potential response to CC and GC test stimulation is shown below. LTP or LTD to at least one pathway was seen in 7/11 slices. The three slices that showed GC LTP did not show either LTP or LTD to CC stimulation. These results show that tetanic stimulation of the callosal projection to visual cortex can result in novel forms of LTP and LTD.

KETAMINE BLOCKS LTP AT LEC-DG SYNAPSES. <u>D.X. Zhang and W.B Levy.</u>
Dept. Neurosurgery, Hith. Sci. Ctr., Univ. of VA., Charlottesville, VA 22908.
The induction of long-term potentiation (LTP) is often controlled by the NMDA

receptor, e.g., NMDA receptor antagonists block the induction of LTP at medial entorhinal cortical (MEC) synapses on dentate gyrus (DG) granule cells. Some forms of LTP, however, do not require activation of the NMDA receptor, e.g., the DG-CA3 mossy fiber synapses. Whether or not the lateral (L) EC-DG synapses behave like the MEC-DG synapses or the DG-CA3 synapses is not known. In the region of LEC synapses there are NMDA receptors similar to the region of MEC-DG synapses. However, the region of LEC-DG synapses has a chemical similarity to the DG-CA3 synapses, including the presence of zinc and dynorphin. To elucidate the role of NMDA receptors in LTP of the LEC-DG synapses, we used ketamine in an LTP paradigm. The experiment used urethane-anesthetized albino rats with two stimulating electrodes (one in the LEC and the other in the MEC) and one DG recording electrode. response to each stimulating electrode was mapped through the DG to ascertain the suitability of the stimulating electrode placements. Responses were tested alternately every 30 sec. Once a baseline was established, 70mg/kg ketamine was administered i.p. over 1 hr. Brief, high-frequency trains were delivered separately to the LEC and then to the MEC electrodes. After 1 hr testing, these trains were repeated, and finally the LEC was conditioned two more times. Each set of conditioning trains was separated by at least 30 min. In all the animals in which ketamine blocked LTP of the MEC-DG response, it also blocked induction of LTP of the LEC-DG response. Thus, even though the LEC-DG synapses may biochemically resemble the DG-CA3 mossy fiber synapses, LEC-DG synapses probably depend on activation of NMDA receptors for the induction of LTP.

LONG-TERM POTENTIATION (LTP) INDUCES NOVEL POLYPEPTIDE IN AREA CAI OF RAT HIPPOCAMPUS. T.J. Shors. N. Uenishi, N.R. Nichols, C.E. Finch, R.F. Thompson Neurosciences Program, Univ. of Southern Calif., LA, CA 90089

In vitro induction of LTP in hippocampal slices followed by [358]methionine labeling and two-dimensional gel electrophoresis was used to identify changes in protein synthetic patterns. We found a polypeptide in the CAl region of the hippocampus that has a molecular weight of 48kD and an isoelectric point of 6.8. The rate of synthesis was increased 1-3 hours following the induction of LTP (56% increase in EPSP slope) using high-frequency (100 Hz) stimulation to the Schaffer collaterals. Relative to unstimulated slices, protein radioactive image was increased in 7/10 experiments using pooled slices; no change occurred in 3 experi-Low-frequency stimulation at 1 Hz did not induce a change in 4/6 experiments. The relative increase was evident only when CAl was separated from the dentate gyrus. The induction occurred in dentate samples re gardless of stimulation (12/13). This 48kD polypeptide does not appear to be any of those previously associated with the induction of LTP (i.e. phosphorylated proteins) since it is more basic and was detected during the maintenance phase. NEOCORTICAL SYNAPTIC LONG-TERM INDUCED BY TETANIC STIMULATION IN THE PRESENCE OF AN NMDA RECEPTOR ANTAGONIST. V.A.Aroniadou and T.J.Teyler. Dept. of Neurobiology, Northeastern Ohio College of Med., Rootstown, OH 44272.

In visual cortical slices of young rats, stimulation (3-5 V) of the subjacent white matter evoked a field potential consisting of two components (peak latency 5-7 ms and 13-16 ms, respectively) in layer II/III of area 17. The response was reversibly abolished by perfusion with Ca++ free medium indicating that it consisted of synaptic activity alone. The second component was of lower amplitude, was probably polysynaptic (it did not follow stimulations above 0.2 Hz), and was reversibly blocked by addition of the NMDA receptor antagonist DL-2-amino-5addition of the NMDA receptor antagonist phosphonovalerate (APV; $50\,\mathrm{uM}$) to the medium.

Tetanic stimulation (200 ms trains at 100 Hz every 5 sec for 10 min) in normal medium induced a 200 to 460 % potentiation of the first component (n = 9). The second component was either unaltered, reduced, or it fused with the first component which had a greater duration in the potentiated response. Long-term potentiation (LTP) started developing ~ 15 min post-tetanus, reached a peak at ~ 80 min, and remained at the peak level throughout the observation period (3 hours). Tetanization in the presence of APV resulted in long-term depression (LTD; n=4) or no change (n=2) after return to the normal medium. LTD started developing ~15 min post-tetanus reaching peak level (150-310%) at ~45 min. It appears that mechanisms activated during LTP-inducing tetanic stimulation may result in long-term depression if allowed to operate without concurrent activation of NMDA receptors (supported by the ONR).

EFFECTS OF DISINHIBITION ON LTP INDUCTION IN SLICES OF VISUAL CORTEX. W.A. Press* and M.F. Bear. Center for Neural

Science, Brown University, Providence, RI 02912.

One interest of this lab is the role of excitatory amino acid (EAA) One interest of this lab is the role of excitatory amino acid (EAA) receptors in the mechanisms of synaptic plasticity in the kitten visual cortex. In this study we have approached this question using visual cortical slices in vitro. Extracellular field potentials (FP's) as evoked by single shock stimuli applied to the white matter/layer VI border were recorded in layer III. These FP's usually were comprised of two components: a short latency $(2.7 \pm 0.2 \, \text{ms})$ nonsynaptic response and an early $(6.8 \pm 0.3 \, \text{ms})$ synaptic response. The synaptic response depended entirely on the activation of non-NMDA EAA receptors. Conditioning the inputs with patterned high frequency stimuli resulted in a long-term potentiation of the early synaptic responses in 2 out of 25 (8%) attempts. The presence of bicuculline methiodide (BMI) in concentrations greater than $0.6 \, \mu\text{M}$ revealed an additional late $(12.4 \pm 1.6 \, \text{ms})$ component of the FP which could be blocked by $10.4 \, \text{M}$ AFS. Merosian (BMI) in the truncation of LTP could be blocked by APS. Increasing (BMI) further usually led to epileptiform activity. In an effort to produce strong local disinhibition without seizures, the recording electrode was filled with concentrated BMI. Our results to date, using cortical slices from rats, suggest IAI LTP can be readily elicited using this method. It is apparent that layer III of neocortex can exhibit synaptic potentiation as robust as that seen in Ill of necortex can exhibit synaptic potentiation as robust as that seen in hippocampus provided that GABAergic inhibition is reduced. LONG-TERM DEPRESSION (LTD) OF ELECTROTONIC AND CHEMICAL COMPONENTS OF MIXED SYNAPSES ON THE MAUTHNER (M-) CELL. X.-D. Yang and D.S. Faber, Neurobiology. Lab, Dept. of Physiology, School of Medicine, SUNY at Buffalo, Buffalo, NY 14214.

LTP and LTD are synaptic phenomena often related to learning and memory. Previous work showed that suprathreshold tetanization of the 8th nerve potentiates both electrotonic coupling and glutaminergic chemical response at the mixed synapses between the glutaliniergic chemical response at the linked synapses between the nerve and the M-cell in goldfish. We report here that when weak subthreshold tetanization is paired with an antidromic (AD) spike, there can be long-term and reversible depressions of both synaptic responses. *In vivo* intracellular recordings were obtained from the Mcell lateral dendrite. The cell was stimulated antiformically via spinal cord, and orthodromically via 8th nerve. The depression protocol consisted of 210 trains of 5 pulses at 500 Hz with 2 sec intervals and paired with one AD spike at the beginning of each train. Both electrotonic and chemical responses could show depressions up to 50% (n=5), the longest lasted 45 min. The depression could be reversed by suprathreshold tetanization, which, if applied repeatedly, could potentiate the reponses further, but eventually reached a limit. Also, additional depression protocols could depress the synaptic reponses only to a certain minimum. Since AD spike is small on the dendrite, where the synapses are located, and produces a powerful collateral inhibition of the M-cell, we suggest that low level activation of the excitatory synapses and the simultaneous postsynaptic inhibition together caused the depression, though the mechanism is unknown. Also, synaptic efficacy has a finite range, beyond which usual methods for LTP or LTD cannot induce further changes.

ACTIVATION OF Ca2+/CALMODULIN-DEPENDENT PROTEIN KINASE II IN CEREBELLAR GRANULE CELLS BY N-METHYL-D-ASPARTATE RECEPTOR ACTIVATION.

1.2K. Fukunaga, 2E. Miyamoto* and of Mol. Physiol., Vanderbilt Univ. Med. Sch., Nashville, TN 37232-0615, USA, 2Dept. of Pharmacol., Kumamoto Univ. Med. Sch., Kumamoto 860, Japan

Recent studies have strongly suggested the involvement of protein kinase C or CaM kinase II in the induction of long-term potentiation (LTP) in the CAI region of hippocampus. Furthermore, during the induction of LTP, a protein kinase has been reported to be converted to a protein kinase has been reported to be converted to a Ca²⁺-independent form that is constitutively active. We have investigated generation of the Ca²⁺-independent form of CaM kinase II by the activation of the NMDA receptor in cerebellar granule cells. Glutamate did produced an elevation of Ca²⁺-independent CaM kinase II activity when granule cells were incubated in Mg²⁺-free buffer, and this response was potentiated by luM glycine. This response granule cells were incubated in Mg²⁺-free buffer, and this response was potentiated by luM glycine. This response required extracellular Ca²⁺ and was blocked by specific antagonists of the NMDA receptor. Phosphopeptide mapping of the ³²P-labeled 58-60kDa subunit of CaM kinase II revealed a correlation between generation of Ca²⁺-independent activity and ³²P-incorporation into peptide CBI which contains Thr 286/287. These results indicate that the excitatory neurotransmitter glutamate acting through the NMDA receptor can stimulate autophosphorylation of CaM kinase II to generate its Ca²⁺-independent form. form.

DIFFERENT VOLTAGE-DEPENDENT THRESHOLDS FOR THE INDUCTION OF

DIFFERENT VOLTAGE-DEPENDENT THRESHOLDS FOR THE INDUCTION OF LONG-TERM DEPRESSION AND LONG-TERM POTENTIATION IN SLICES OF RAT VISUAL CORTEX. A. Artola.*S. Bröcher*and W. Singer(SPON: European Neuroscience Association) Max Planck Institute for Brain Research, 6000 Frankfurt/M, F.R.G. We provide evidence for long-term depression (LTD) of synaptic responses (p.s.p.s) to white matter stimulation in layer II-III cells. In normal medium, low intensity tetani (tet., 50Hz) induce no modifications. However, when post-synaptic activation is raised during tet. by application of bicuculline (BIC), either LTD or long-term potentiation (LTP) are obtained depending on BIC concentration. LTD (B1.744.5% of control, n=7, mean±s.e.m.) occurs with 0.1-0.2µM BIC and LTP with 0.3µM BIC. Initial slopes of p.s.p.s change accordingly. LTD occurs also in normal medium (67.2±2.6%, n=13) if postsynaptic activation is increased by raising intensity of tet.. In that case LTD is prevented by hyperpolarizing (-40mV) the cell during tet. while LTP is induced with depolarization (+20mV). LTD can be reversed by stimulation conditions inducing LTP and vice versa. During LTD, a second, non-tetanized, intracortical pathway remains unchanged. Addition of the NMDA receptor-blocker APV (25µM) prevents induction of LTP but not of LTD. This suggests that 1) LTD and LTP both depend on post-synaptic activation and have different voltage-dependent thresholds, 2) LTP but not LTD requires NMDA receptor activation, 3) modified synapses are on the recorded neuron and 4) LTD is selective for the tetanized pathway.

A ROLE FOR INTRACELLULAR CALCIUM IN INITIATING CEREBELLAR LONG-TERM DEPRESSION. A. Konnerth. J. Dreessen & G.J. Augustine. MPI for Biophysical Chemistry, Goettingen, FRG. Thin-slice patch clamp and digital imaging methods were used to examine long-term depression (LTD) of synaptic transmission between parallel fibers (PF) and Purkinje cells in the rat cerebellum. Brief activation of the climbing fibers (CF) innervating the Purkinje cells caused a prompt and transient (< 5 min duration) elimination of synaptic currents (EPSCs) evoked by PF stimulation. This was followed by recovery of EPSC magnitude to its initial level (or even larger) and then by a pronounced depression of EPSCs which reached a maximum in 10-60 min and lasted up to 3 hours. This final phase apparently corresponds to LTD. We examined whether this LTD is caused by a rise in Ca concentration ([Ca]₁) in the Purkinje cell. CF stimulation produced a large and transient (10-100 s long) rise in [Ca]₁. This rise was most prominent in the dendrites and apparently was due to activation of voltage-gated Ca channels. Direct depolarization of Purkinje cells opened Ca channels, raised [Ca]₁, and caused changes in EPSC amplitude much like those produced by CF stimulation. The long-lasting depression caused by depolarization was blocked by intracellular application of EGTA (10 mM), indicating that the synaptic effects of depolarization were caused by changes in [Ca]₁. We conclude that CF stimulation initiates LTD of the PF synapse by transiently raising [Ca]₁ in the postsynaptic Purkinje cell. A ROLE FOR INTRACELLULAR CALCIUM IN INITIATING CEREBELLAR

EFFECTS OF AGING ON THE MESOSTRIATAL DOPAMINE SYSTEM: A BEHAVIORAL AND NEUROBIOLOGICAL STUDY. R. Burwell¹, L. Thai², Neurobiology, University of North Carolina, Chapel Hill, NC 27599.

Twenty male Long-Evans rats completed a longitudinal study of reaction-

time (RT) performance. Subjects were tested every six weeks from 14.5-25 mo of age. On average, RT latencies increased significantly with age. Some rats, however, maintained a stable performance throughout the study. At 25 mo of age, other behavioral tests were conducted. Compared to young rats tested at the same time, the 25 mo rats were impaired in learning a spatial task in the Morris water maze. Again, however, some aged rats learned this task as readily as the younger animals. Although no correlation was found between RT latencies at 25 mo and spatial learning performance within the aged group, a possible biomarker for the emergence of learning impairment was identified in the RT task. Compared to rats that maintained their learning ability at 25 mo of age, rats that were impaired in the spatial learning task were significantly less accurate on their RT performance at every assessment. Thus, even at 14.5 mo of age, RT accuracy was significantly related to the emergence of learning impairment at 25 mo.

Quantitative autoradiography in brain slices from these animals is currently being used to assess the integrity of pre- and post-synaptic neurons for the dopaminergic (DA) system. The status of markers for the mesostriatal DA system will be discussed in relation to RT performance and other behavioral data, i.e. spatial learning, spontaneous alternation, and locomotor activity.

HIPPOCAMPAL CHOLINE ACETYLTRANSFERASE ACTIVITY CORRELATES WITH SPATIAL LEARNING DEFICITS IN AGED RATS. G. L. Dunbar¹, R. J. Rylett², and L. R. Williams³. ¹Dept. of Psychol., Central Michigan Univ., Mt. Pleasant, MI 48859 (USA); 2Dept. of Physiol., Univ. of Western Ontario, London, Ontario, Canada N6A 5C1; 3CNS Diseases Res., The Upjohn Co., Kalamazoo, MI 49001 (USA). Since 24-month old rats show significant decreases in choline acetyltransferase (ChAT) and highaffinity choline uptake (HACU) when compared with 4month old rats (Williams & Rylett, J. Neurochem., in press), we investigated whether these reduced levels correlated with age-related learning deficits. Eighteen male, Fisher rats (24 months old) were tested for 10 days on a Morris water maze task. After behavioral testing, levels for ChAT and HACU were made in the hippocampus, frontal cortex, and striatum. Stepwise regressions for predicting total time and distance swum in the maze from all six biochemical measures showed only hippocampal ChAT as a significant predictor (both ps < .02). These results indicate that lower levels of hippocampal ChAT correlate with agerelated learning deficits.

MEMORY AND SENSORY-MOTOR SKILLS IN AGING RATS: NEURAL CORRELATES AND DIET RESTRICTION. D. S. Olton and A. L. Markowska Dept. of Psychology, The Johns Hopkins University, Baltimore, MD 21218.

The cognitive effects of aging were examined by testing rats in a battery of cognitive and sensory-motor tests. Two strains (Fisher-344, and a cross between Brown-Norway and Fisher-344) were tested at 10-12 mo, and 23-25 mo of age, with a few rats at 30 mo and 36 mo of age. The behavioral tests in a Morris water maze included spatial navigation, discrimination reversal, cue learning, and recent memory as assessed with a delayed match-to-sample task. Sensory-motor tests provided measures of different skills. The experiments were designed to answer questions about age-related impairments in different behavioral domains, and the effects of diet restriction: life-long, only during development, or only at the time of testing.

NORADRENERGIC, CHOLINERGIC AND OPIOID CORRELATES OF SPATIAL MEMORY IMPAIRMENT IN AGED RATS. T. D. Smith¹, M. Gallagher² and F. M. Leslie¹. ¹Dept. of Pharmacology, University of California, Irvine, Irvine, CA. 92717 and ²Dept. of Psychology, University of North Carolina at Chapel Hill, Chapel Hill, NC. 27599.

Hill, NC. 27599.

Spatial memory performance in young (6 mo) and aged (24 mo) male Long-Evans rats was assessed in the Morris water maze. A subpopulation of aged rats performed within the range of young rats and was designated the memory unimpaired (MU) group. The remaining aged rats displayed spatial learning deficits and were designated memory impaired (MI). Quantitative autoradiography in brain slices from these animals was used to assess the integrity of pre- and post-synaptic neurons for cholinergic, noradrenergic and opioid neurotransmitter systems. [3H]Hemicholinium binding to cholinergic pre-synaptic reuptake sites and [3H]pirenzepine binding to cholinergic M1 cholinergic pre-synaptic reuptake sites and [3H]pirenzepine binding to cholinergic M1 receptors decreased with age in olfactory tubercle and deep layers of frontal motor cortex, respectively, [3H]Pirenzepine displayed an increase in binding density in aged MU as compared to both young and MI rats in the superficial layers of frontal cortex and in olfactory tubercle, [3H]Desmethylimipramine labeling of noradrenergic presynaptic reuptake sites showed an increase with age in frontal and anterior cingulate cortices, and a memory-related increase in the aged MU rats in insular cortex and dentate gyrus. [3H]Idazoxan binding to noradrenergic alpha-2 receptors was densest in the aged MU and least dense in MI rats in many limbic regions, as well as in frontal cortex. This same memory-related nattern of labeling was also observed with [3H]DADLE. This same memory-related pattern of labeling was also observed with [3H]DADLE binding to delta opioid receptors. In contrast, [3H]diprenorphine binding to kappa opioid receptors was increased in the aged MI subpopulation in various limbic regions. optote receptors was increased in the aget with subplyination in various limitor regions. [341]DAGO binding to mu opioid receptors displayed mainly age-related, but not memory-related changes. These results suggest that selective cholinergic, noradrenergic and opioid receptor radioligands not only show age-related changes in binding densities but distinguish between memory impaired and unimpaired aged rats.

COMPLEX MAZE LEARNING IN AGED RATS IS RELATED TO BLOOD GLUCOSE LEVELS AND INSULIN RESPONSE BUT IS UNRESPONSIVE TO GLUCOSE TREATMENT. J. Long1, B. Davis2, P. Garofalo11, E. Spangler*1, D. Ingram1. 1Gerontol. Res. Ctr., NIA, NIH, Baltimore, MD 21224; ²Dept. Neurobiol. Anat., U. Roch. Sch. Med., Rochester, NY 14642.

In aged rats and humans, glucose regulation has been correlated with memory performance, and glucose treatment can result in improved performance (Gold P., & Stone W., *Neurobiol. Aging*, 9:709, 1988). We tested this glucose hypothesis with rats in a 14-unit T-maze that has provided robust evidence of age-related performance decline (Ingram D., Neurobiol. Aging, 9:475, 1988). Aged (24-25 mo) and young (6-7 mo) male F-344 rats were pretrained for 1-way active avoidance to a criterion (8 avoidances/10 trials) pretrained for 1-way active avoidance to a criterion (8 avoidances/10 trials) before receiving complex maze training (4 daily trials over 5 days) with the contingency of moving through each of 5 segments within 10 sec to avoid footshock (0.8 mA). Ten min before daily training, aged rats received either saline (n=7) or glucose in doses of 10 (n=7), 100 (n=6), or 500 (n=10) mg/kg i.p., while young rats received saline. Significant (ps<.05) age-related increases in errors, runtime, shock frequency and duration were observed, but the only significant (ps< 05) glucose effect was to reduce runtime and shock duration at the highest dose. About 4-6 wks later, all rats were fasted for 12-hr; injected i.p. with glucose (150 mg/kg); and bled at 0, 30, 60, and 120 min post-injection to obtain estimates of blood glucose and insulin levels. Significant correlations (ps<.05) were observed between maze errors and baseline glucose levels, r(21) = -62, and peak glucose response, r(19) = .49. However, within the aged group, significant correlations (ps < 0.01) with maze errors emerged only for baseline glucose, r(13) = .69, and peak insulin response, (r(13) = .65). Thus, regulation of insulin, but not glucose, appeared related to learning abilities among aged rats.

RELATIONSHIP OF AGE-RELATED BEHAVIORAL DEFICITS TO NEUROCHEMICAL MARKERS. G.L. Wenk, A.L. Markowska, L. Gorman, V.E. Koliatsos, D.L. Price, and D.S. Olton. Depts. of Psychology and Pathology, The Johns Hopkins University, Baltimore, MD 21218.

For rats of different ages, strains, and diets, correlations among different measures of behavior and brain function were determined. Fisher-344 (ages 4, 12 & 24 mo) and a cross between the Brown-Norway and Fisher-344 (ages 4, 12, 24, 30 & 36 mo) were given cognitive and sensorimotor tests, followed by neurochemical and immuno-cytochemical measurements of markers for various neurotransmitter systems in basal forebrain, locus coeruleus, neocortex, hippocampus and caudate/putamen. The variance of some of the behavioral and neurochemical measures was larger in the older rats than in the younger rats. The pattern of correlations among the different measures provides information about the differential effects of aging on selected neural systems. Supported by NIH NS 20471 and AG 05146.

AGE-RELATED ALTERATIONS IN MOTOR LEARNING ARE CORRELATED TO LOSS OF CEREBELLAR NORADRENERGIC FUNCTION. P.C. Bickford-Wimer, C. Heron and R. de la Garza Vet.Admin. Med. Ctr; and Dept. Pharm. UCHSC, Denver, CO 80262.

Motor learning is fundamental to normal execution of movement because continual adaptation to change is required. Age-related declines in motor function are well documented in the literature for both humans and animals. Alterations in the ability to learn new motor patterns, however, has not been studied extensively. In humans there is patterns, nowever, has not been studied extensively. In numans there is a decline in mirror tracking proficiency with advanced age suggesting that motor learning is altered. We investigated age-related alterations in the ability of F344 rats to learn novel motor skills. The behavioral paradigm was designed after that of Watson and McElligot (Br. Res.296:129-138, 1984). Performance on this task is dependent on cerebellar NE. Because we have previously demonstrated age-related cerebellar NE. Because we have previously demonstrated age-related changes in cerebellar noradrenergic function, it was our hypothesis that alterations in motor learning would correlate with this deficit. The animals were trained to run back and forth on pegs for a water reward. Two weeks after training the animals were tested on a novel peg pattern. Three groups of rats were tested: young, young treated with 6-hydroxydopamine (6OHDA) and 18-20 month old rats. Both the young 6OHDA lesioned and aged rats showed impairments in the acquisition of the novel locomotor task. Subsequent to behavioral testing, extracellular recording from cerebellar Purkinje cells demonstrated a correlation between performance and the ability of NE to modulate GABAergic transmission (r=.78; p<0.05). This supports our hypothesis of a role for cerebellar noradrenergic function in motor learning deficits associated with aging. (VAMRS and AG 04418).

AGE DIFFERENCES IN A 750 MSEC CS-US DELAY CLASSICAL CONDITIONING PARADIGM. <u>D K. Sasse and</u> D. S. Woodruff-Pak. Department of Psychology, Temple University, Philadelphia, PA. 19122.

Small but statistically significant age differences in eyeblink classical conditioning have been demonstrated in the delay paradigm with a 400 msec CS-US interval. Large age differences have been demonstrated in the trace paradigm when the CS and US were offset by 750 msec. The major aim of this study was to test for age differences in classical conditioning in a 750 msec delay paradigm. We also compared this long 750 msec delay interval with data collected in a 750 msec trace paradigm (Woodruff-Pak, Lavond, Logan, & Thompson, 1987). Criterion for learning was 8 CRs out of 9 consecutive trials. In the 750 msec delay paradigm, significant age differences were found in the rate of acquisition between 51-month-old (796 trials), 24-month-old (770 trials), and 4-month-old rabbits (535 trials) (F=5.00; p<.05). No significant differences were found between the trace and delay paradigms. The interaction between age and conditioning paradigm (trace versus delay) was not statistically significant. A hearing test (measuring CRs/block as the tone CS was systematically decreased at 5 dB intervals) revealed no age differences in hearing. Differences in rate of conditioning were not due to diminished hearing capacity in aged rabbits. Results suggest that large age differences in longer CS-US intervals may result from the long time period between CS onset and US onset. (Supported by NIH RR07115).

CYTOARCHITECTURAL CHANGES IN THE FRONTOPARIETAL CORTEX OF AGED AND BASAL FOREBRAIN LESIONED RATS. C.L. Wellman and D.R. Sengelaub. Program in Neural Science and Dept. of Psychology, Indiana University, Bloomington, IN 47405.

Alzheimer's disease (AD) is characterized by deficits in learning and memory and decreased cortical cholinergic activity. Lesions of basal forebrain nuclei have been used to model the behavioral and pharmacological deficits of AD. Because AD typically occurs in aged populations, the changes seen in AD could be due to neuropathology specific to AD, age, or an interaction. We are using basal forebrain lesions in rats to determine the contribution of these factors. Cellular changes in the frontoparietal cortex of 13-month-old intact (n=3) and basal forebrain lesioned (n=4) adult rats and intact, 22-month-old (n=5) aged rats were assessed in frozen sectioned, cresylecht violet stained material. Lesions did not affect neuron number, but significantly reduced soma size in particular cortical laminae, resulting in decreased laminar thickness relative to intact adult These effects were most pronounced in lamina II-III, where soma size was decreased by about 42%. In aged rats, neuronal loss was observed in several laminae and was most pronounced in laminae II-III and VI, averaging about 22%. Soma size in aged rats was decreased about 31% relative to intact adults, but this atrophy was not reflected in changes in laminar thickness. Decreases in soma size were seen in both superficial and deep laminae. Thus, the patterns of regressive change in the cortex differ in basal forebrain lesioned adults and intact aged rats. Basal forebrain lesions in aged rats should thus result in more extensive cortical neuronal changes, and these changes should correspond to more severe behavioral deficits than are seen after lesions of young adult rats. Basal forebrain lesions in aged rats may better model the neural and behavioral changes of AD.

AGE-RELATED DIFFERENCES IN LONG-TERM RETENTION OF DELAY CLASSICAL CONDITIONING IN RABBITS. J. M. Coffin & D. S. Woodruff-Pak. Department of Psychology, Temple University, Philadelphia, PA 19122

Age differences in acquisition of the NM/eyeblink response in rabbits in the delay paradigm (400 msec CS-US interval) are significant, but they are not as large as age differences in the trace paradigm. In the delay task older (O) rabbits perform as well as young (Y) by the 4th training day. We present here data from a 12-month and 18-month retest in Y and O rabbits on retention in the delay task. Y rabbits were 7 months old at acquisition and 19 and 25 months old at the 12- and 18-month follow-ups. O rabbits were 36 months old at acquisition and 48 and 54 months old at the follow-ups. An 85 dB, 1 KHz tone CS was paired with a 3 psi airpuff US in acquisition and subsequent retests. Daily sessions of 90 trials were run until rabbits achieved a criterion of 8 CRs in 9 trials. A test of rabbits' hearing sensitivity, assessed at the 18-month follow-up by reducing the tone by 5 dB intervals until no CRs were present, revealed no age differences. Rabbits retrained following 12and 18-month intervals showed no significant age differences. Mean trials to relearning at 12 months was 146 for Y and 161 for O rabbits. At the 18-month follow-up, O rabbits relearned in a mean of 55 trials, while Y rabbits took 90 trials. Age differences exist in acquisition, but there are no age effects on retention. (Supported by an Alzheimer's Association/NJAHCF Research Grant).

HUMAN ASSOCIATIVE LEARNING: ANALYSIS OF TRACE AND DELAY

HUMAN ASSOCIATIVE LEARNING: ANALYSIS OF TRACE AND DELAY EYE-BLINK CONDITIONING . R. A. Deyo, I. D. E. Gabrieli and I. F. Disterhoft. Dept. of Psychology Northwestern Univ. Evanston, II. 60208. In rabbits, acquisition of Trace and Delay eye-blink conditioning tasks involve unique combinations of neural systems. Acquisition of Trace conditioning, but not Delay conditioning, is blocked by hippocampal lesions. Analysis of Trace and Delay conditioning may reveal similar organization of associative learning in the human brain. There are, however, few studies of trace conditioning in human subjects, and no study of long-term retention of conditioned eye-blink responses. The purpose of the present study was to compare and evaluate acquisition and retention of delay and trace eye-blink conditioning tasks using healthy subjects.

In the first experiment, 24 college students (age = 18-22) received either

Delay or Trace conditioning that consisted of 50 acquisition trials. Trace conditioned subjects were trained using a paradigm employing a 100ms tone CS, a 500ms trace interval and a 100ms corneal air puff (UCS). Delay conditioned subjects were trained using a paradigm employing a 600ms tone CS that overlapped and coterminated with the UCS. Analysis of the percentage of conditioned responses (CRs) for each group indicated that Trace conditioned subjects made more conditioned responses than subjects in the Delay conditioned group. There were no group differences in CR amplitude or latency or in the size of the unconditioned response amplitude.

In Experiment 2, trace and delay conditioned subjects were trained using the

parameters described above. All subjects received 50 trials on Day 1 and were retested 24 h, 7 or 28 days later. Analysis of the percentage of CRs indicated that conditioning on both tasks is preserved for long periods.

Supported by the Alzheimer's Association (Award # IIRG-89-081).

LIFE-LONG FOOD RESTRICTION AND SPATIAL MEMORY: A LONGITUDINAL AND

CROSS-SECTIONAL STUDY IN THE RAT.

M. Gyger*, D. Muller and E.M. Rouiller. Nestlé Research Center,
Nestec Ltd., Vers-chez-les-Blanc, CH-1000 Lausanne 26, Switzerland;
Dept Pharmacology, Centre Médical Universitaire, CH-1206 Genève,
Switzerland; Dept Physiology, University of Fribourg, CH-1700
Fribourg, Switzerland.

Food restriction extends life-span and slows down age-related physiological deteriorations. Cognitive abilities seem also affected. We tested rats either repeatedly during their life (longitudinal study) or once at 24 months of age (cross-sectional study). Three food conditions were compared: ad libitum, 70 %

study). Inree rood conditions were compared: ad inditum, 70 % restriction and a two-day-a-week fasting schedule. Spatial memory was assessed using the Morris water maze.

No effect of food restriction is found during the learning (at 6 months) and the relearning of the task (at 12, 19 and 24 months). A retrieval test (the platform is removed) indicates that the searching pattern of one group only, the 70 % restricted rats, is still focussed on the platform location past 12 months of age. A removed test (the platform is removed to the quedent of the maxes. reversal test (the platform is moved to the quadrant of the maze diagonally opposite to the previous location) shows that the 70 % restricted rats perform better than ad libitum sujects during the first four trial block.

Hippocampal function was assessed by LTP of slices taken from 25 month old ad libitum and 70 % restricted rats. The results of the cross-sectional study currently in progress will be discussed in relation to the data of the longitudinal study.

EFFECTS OF AGE AND COGNITIVE STATUS ON RAT BRAIN INSULIN-LIKE GROWTH FACTOR-I BINDING SITE LEVELS. D. Seto, D. Diorio, W. Rowe, M.J. Meaney, R. Quirion and J.-G. Chabot. Douglas Hospital Research Centre, Department of Psychiatry, McGill University, Verdun, Quebec, Consideration. Canada.

Canada.

In recent years insulin-like growth factor-I (IGF-I) gene, protein expression and specific binding sites have been demonstrated in the mammalian (CNS). Additionally, some results have suggested that IGF-I may act as neurotrophic and/or neuromodulatory substance in the brain. During brain aging the densities of several neurotransmitter receptors are affected. In the present study, the levels of [120] IGF-I CNS binding sites in young adult (3, 6 and 9 month-old) and 24 month-old cognitively-unimpaired and cognitively-impaired Long Evans rats were determined. We observed that the densities of [120] IGF-I binding sites were similar in young and aged, cognitively-unimpaired rats. In the aged, cognitively-impaired animals receptor densities were similar, except in the CA1 region of the hippocampus where receptor density was slightly decreased. There was considerable (~50%) neuron loss in the CA1 region of the hippocampus in the aged, cognitively-impaired animals compared with both young and aged, cognitively-unimpaired animals, however, the same was true for the CA3 region where there was no change in IGF-I receptor density. Thus, the brain densities of IGF-I sites appear to be maintained throughout aging, with the possible exception of the CA1 area of the hippocampus.

349.15

NIMODIPINE MODULATION OF HIPPOCAMPAL NEUROPHYS-

NIMODIPINE MODULATION OF HIPPOCAMPAL NEUROPHYS-IOLOGY IN VIVO AND IN VITRO. M. Mazzanti. O. Thibault, D.S. Kerr. and P.W. Landfield. Department of Physiology & Pharmacology, Bowman Gray Sch. of Med., Wake Forest Univ., Winston-Salem, NC 27103.

Nimodipine, a dihydropyridine (DHP) that blocks L-type Calcium (Ca) channels, appears to exert significant actions on central nervous system function. In aged animals, learning, motor behaviors and recovery of function have been shown to be improved by nimodipine (Schuurman et al., Neurosci Res Comm, 1987; Gispen et al. In: The Calcium Channel, Springer, 1988; Deyo et al., Science, 1989; for review, see Scriabine et al. FASEB J, 1989). Such findings are consistent with growing evidence that Ca currents are increased in aged rat hippocampal neurons (e.g., Landfield, In: The Calcium Channel, Springer, 1988). Studies on the actions of DHP's indicate clearly that these agents affect Ca currents in isolated neurons, but much less is known about DHP effects on the physiology of relatively intact brain systems.

that these agents affect Ca currents in isolated neurons, but much less is known about DHP effects on the physiology of relatively intact brain systems. In the present study, we examined the effects of nimodipine (40 mg/kg, p.o.) on hippocampal frequency potentiation (FP) of the extracellular population spike, in intact, anesthetized rats. Frequency potentiation is impaired consistently in aged rats, apparently due to excess Ca, and this impairment is correlated with impaired memory functions. Thirty minutes after nimodipine administration, FP during a 4 min train of 7 Hz stimulation was significantly greater in nimodipine animals, in comparison to vehicle controls. In particular the spike was larger during the last 2 min of the train

was significantly greater in nimodipine animals, in comparison to vehicle controls. In particular, the spike was larger during the last 2 min of the train. Intracellular recordings in hippocampal slices were also conducted, to analyze the possible mechanisms underlying the nimodipine effects on spike FP. Nimodipine decreased, and BAY K 8644 (a DHP agonist) increased, the calcium-dependent, potassium-mediated afterhyperpolarization (AHP) in these neurons. This AHP is also increased in aged neurons.

Thus, the AHP may be modulated through L-type channels, and nimodipine may strengthen spike FP by blocking inhibitory effects of the AHP.

INTRACELLULAR RESPONSES OF NEOSTRIATAL NEURONS IN AGED RATS: EFFECTS OF N-METHYL-D-ASPARTATE. <u>M. S. Levine and</u> C. Cepeda. Mental Retardation Research Center, UCLA, Los Angeles, CA

Previous studies from our laboratory have demonstrated decreased excitation in neostriatal neurons in aged rats and cats. Results obtained from intracellular recording experiments in in vivo and in vitro preparations indicated that a population of cells were less capable of generating action potentials and displayed higher thresholds to evoke EPSPs by extracellular stimulation. The present study was designed to assess the responsiveness of aged neostriatal neurons in slices to application of excitatory and inhibitory amino acids by combining intracellular recordings with iontophoresis. Slices (400 μ m) were obtained by standard methods from young (3 month) and aged (>24 month) Fisher 344 rats. Intracellular recordings were obtained with K-Acetate filled microelectrodes (60-120 $M\Omega$). A five-barrelled pipette containing NMDA, AP-5, GABA, glutamate and saline was positioned close to the recording microelectrode (100-200 µm). In all young neurons (N=10), NMDA produced robust depolarizations accompanied by repetitive firing. In aged neurons NMDA produced less consistent responses. In about 50% of the tested cells (N=12) to date, NMDA depolarized the membrane but action potentials were not generated. The specific NMDA antagonist AP-5 blocked NMDA responses in cells obtained from young rats. However, antagonism of NMDA responses by AP-5 required higher currents in aged cells. In both aged and young cells, GABA decreased the amplitude of the EPSP, depolarized the membrane and greatly increased ionic conductance. The decrease in NMDA responsiveness in aged neostriatal neurons may account, in part, for the decreased ability of these cells to produce excitatory responses. Supported by USPHS AG 7462.

SYMPATHETIC AND CHOLINERGIC RESPONSES TO NERVE GROWTH FACTOR (NGF) INFUSION IN YOUNG AND AGED RATS. R.M. Booze, M.L. FACTOR (NGF) INFUSION IN YOUNG AND AGED RATS. R.M. Booze, M.L. Smith, R.D. Guarino*. Department of Physiology and Pharmacology, Bowman Gray School of Medicine, Wake Forest University, Winston-Salem, NC 27103.

Chronic infusion of NGF results in increased cholinergic cell survival in the medial septal nucleus after fimbria/fornix lesions. NGF administration also results in the pro-

liferation of sympathetic axons which innervate blood vessels (Saffran, Brain Res. 1989). We investigated 1) whether these cholinergic and sympathetic responses occurred following NGF infusion and 2) whether the responses were influenced by aging.

Bilateral electrolytic and sham lesions of the fimbria/fornix were performed on young

(3-4 months, n=12) and aged (22 month, n=12) male Fischer-344 rats. Vehicle (aCSF), 7S-NGF, and NGF antibodies were delivered by a subcutaneous Alzet osmotic mini-pump and a unilateral cannula placed in the dentate hilus of the dorsal hippocampus. Four weeks after surgery, serial cryostat sections through the septum and the dorsal hippocampus were collected for catecholamine histoflourescence, as well as for Nissl and AChE staining. NGF-infused young and aged brains displayed proliferation of the sympathetic innervation of cerebral blood vessels; however, only the aged brains showed sprouting into the surrounding parenchyma, most prominently in the forebrain contralateral to the infusion site. Lesioned animals of both ages displayed hippocampal sympathetic sprouting, although sprouting was less in aged animals. Infusion of NGF antibodies resulted in attenuated innervation of blood vessels in all rats, suggesting that the above effects are mediated by NGF. NGF-infused young and old brains showed a hypertrophy of cholinergic cell bodies in the medial septum.

These results confirm the responsiveness of sympathetic innervation and cholinergic neurons to NGF infusion in young and aged rats. Extrapolation of these data to aged humans suggests infusion of NGF as a cholinergic enhancing agent would induce a significant sympathetic response. AGE-DEPENDENT CHANGES IN HIPPOCAMPAL SLOW WAVE PERIODICITY IN THE AMESTHETIZED RABBIT. S.D. Berry and L.J. Dresh-field. Psychology Dept., Miami Univ., Oxford, OH 45056. Extracellular unit activity and slow waves were recor-

ded from young (6-11 mos.) and aged (48-50 mos) New Zealand white rabbits. Animals were anesthetized (Ketamine 50 mg/kg; Xylazine, 10 mg/kg; i.m.) and maintained in a stereotaxic headholder throughout recordings. Stainless steel microelectrodes (3-5 um. tip) were lowered into area CA1 of the dorsal hippocampus until cellular activity could be isolated in the pyramidal cell layer. Several minutes of free-running activity were recorded on a VCR-based instrumentation recorder (Vetter, Model 420C). At the end of recording, animals were euthanized with T-61 (Hoechst-Roussel) and electrode sites were marked with de Slow wave records were filtered (0.5-25 Hz) and digitized at 100 Hz. Autocorrelations of 5 sec samples indicated that aged rabbits had significant periodicity at approximately 3-4 Hz, whereas slow waves from younger animals were dominated by 2-2.5 Hz activity. Treatment with scopolamine hydrobromide (1.5 mg/kg, subcutaneous) was observed to shift the slow wave periodicity in younger rabbits toward the 3-4 Hz period seen in older subjects. Results indicated differences in hippocampal slow wav activity between young and old rabbits, and suggested a cholinergic basis for age-related differences. (Supported by research grant # AGO7014, NIH)

INTRACELLULAR RESPONSES OF NEOSTRIATAL NEURONS IN AGED RATS: DECREASED MODULATION BY DOPAMINE. M. Bertolucci-D'Angio, C. Cepeda, D. Birt, N.A. Buchwald and M.S.Levine. Mental Retardation Research Center, UCLA, Los Angeles, CA 90024.

Evidence indicates that alterations in neostriatal (NS) dopaminergic function occur during aging. We have demonstrated that in aged cats the ability of dopamine (DA) to modulate evoked cortical neuronal responses decreases. The present study used intracellular recording to assess DA's ability to modulate responses of NS neutrons. Recordings were obtained from cells in slices of young (3 months) and aged (>24 months) Fisher 344 rats. DA was bath applied at a series of ascending concentrations. The average resting membrane potential (RMP) and action potential amplitudes (AP) were similar in neurons recorded in each age group (67±3.2 (Mean±SD) vs 65±9.1 mV for RMP and 60±5.1 vs 62±11 mv AP for aged and young groups, respectively). Input resistance was slightly higher in neurons in aged rats $(29\pm8.2 \text{ vs } 25\pm9.2 \text{ M}\Omega)$. DA induced a dose-dependent depolarization of the RMP $(6.2\pm2.4 \text{ mV})$ at 10 μ M to 10±4.6 mV at 100 μ M) in both groups. As described previously, in virtually all neurons in young rats DA reduced the amplitude of a depolarizing postsynaptic potential evoked by local extracellular stimulation in a dose dependent and reversible manner. The magnitude of the change increased from 28% (10 μ M)to 46% (100 μ M). To date, in neurons obtained from slices in aged rats, DA produced no effect on extracellularly evoked depolarizations or effects occurred only at the highest concentrations (100 μ M). These results demonstrate that the ability of DA to modulate synaptic input to NS neurons is compromised during aging and are consistent with observations indicating a loss of DA receptors with age. Supported by USPHS AG 7462.

CHANGES IN ELECTROPHYSIOLOGICAL PROPERTIES OF AGED CAT LUMBAR MOTONEURONS FOLLOWING AXOTOMY. J.K. Engelhardt. J. Yamuy*. F.R. Morales and M.H. Chase. Brain Research Institute, Dept. of Physiology and Dept. of Anatomy & Cell Biology, UCLA Sch. of Med., Los Angeles, CA 90024.

The electrophysiological properties of normal adult motoneurons are dramatically altered following axotomy. The experiments reported here were undertaken to determine whether the aging process interferes with the ability of motoneurons to respond to axotomy. Selected hindlimb muscle nerves were cut in 5 cats (13-16 years old) and measures were taken to avoid reinnervation. After 4-6 weeks the animals were prepared for intracellular recording from identified hindlimb motoneurons. Various basic electrophysiological properties were measured and the data were analyzed within the framework of linear cable theory. Axotomized old motoneurons, when compared with unaxotomized control motoneurons from different nerves in the same animals, exhibited a 35% reduction in axonal conduction velocity, a 127% increase in cell input resistance and a 45% increase in membrane time constant. Estimates of total cell capacitance indicate that the increase in input resistance after axotomy is due to the combined effects of an increase in membrane resistance (reflected in the increase in membrane time constant) and a decrease in cell surface area, relative to the control, non-axotomized old motoneurons. We conclude that, in spite of the aging process, old motoneurons retain their ability to react to axotomy. (Supported by USPHS AGO 4307.)

VIBRATION-INDUCED CEREBRAL BLOOD FLOW RESPONSES: EFFECTS OF NORMAL AGING. <u>L.W. Tempel, J.S. Perlmutter</u>. Departments of Neurology and Radiology, Washington Univ. Sch. of Med., St. Louis, MO 63110.

The purpose of this study was to determine whether vibration-induced cerebral blood flow (CBF) responses change with normal aging. We measured CBF with PET and bolus-administered H₂ ¹⁵ Oin 14 *young* (mean 23 yr;range 20-27) and 12 *elderly* (mean 58 yr;range 40-72) subjects. Mean global CBF did not significantly change from resting-state to vibration in young or elderly. Furthermore, mean CBF did not significantly correlate with age. Regional CBF responses were identified in each individual by subtraction-image analysis. The responses in elderly and young subjects then were compared by construction of an image with each pixel representing a computed t statistic based upon regional values from the individual subtraction images from the 2 groups. The advantage of this approach is that it considers regional variance rather than assuming constant variance throughout the brain. No substantial differences between responses in young and elderly subjects were identified. In contrast, T images comparing rest and vibration scans show consistent responses in both young and elderly in contralateral primary sensorimotor area (PSA), supplementary motor area (SMA) and ipstateral cerebellum. Since cerebellum was often not included within the limited axial range of our studies, we only calculated the linear regression between age and the magnitude of blood flow responses in PSA and SMA. There were no substantial relationships between age and responses to either left or right hand vibration (PSA slope=-.02 and -.01,respectively). We conclude that the blood flow responses to bithoractile hand stimulation are both qualitatively and quantitatively similar in young and elderly normals.

EFFECT OF NORMAL AGING ON MEMBRANE PHOSPHOLIPID METABOLISM BY "P IN VIVO NMR SPECTROSCOPY. Panchalingam K, Pettegrew JW, Strychor S and Tretta M, Laboratory of Neurophysics, Dept. of Psychiatry, U. of Pittsburgh, Pittsburgh,

of Neurophysics, Dept. of Psychiatry, U. of Pittsburgh, Pittsburgh, Pa. 15261

TP In vivo nuclear magnetic resonance studies (NMR) were performed on normal controls. TP NMR spectroscopy provides a direct, non-invasive assessment of phosphomonoesters (PME), phosphodiesters (PDE), high energy phosphates phosphocreatine and adenosine triphosphate (ATP). The measurements were made in the dorsal prefrontal cortex of normal subjects (N-29) between the ages of 12 and 81 years. All subjects were screened for and determined to be free of medical, neurological and psychiatric disorders. The results demonstrate that the PME levels decrease linearly with age (p=0.01, r=0.52) and the PDE levels increase with age. This indicate a decreased synthesis and increased breakdown of membrane phospholipids with aging in human cerebral cortex. These measurements are compared with those measured in Alzhelmer's Disease (ADRDA-NINCDA criteria) patients and schizophrenia patients. In AD patients, the PME levels are elevated in the early stages of the disease and then decreased as the disease progresses. This would indicate an increased membrane phospholipid synthesis during the early stages of AD. The high energy phosphates are not attered in AD brains. In schizophrenics, the PME levels are decreased (p=0.005) and PDE levels are increased (p=0.01) indicating a abnormal breakdown of membrane phospholipids. There is no atteration in the high energy phosphates. These findings provide molecular insights into normal brain aging process and how it differs from AD and schizophrenia.

NEUROTRANSMITTER AND NEUROMODULATOR DEVELOPMENT

LYSOPHOSPHATIDYLSERINE ENHANCES THE TRANSFER OF 22:6n3 TO PHOSPHATIDIC ACID IN BRAIN MICROSOMES. Z-Y Hu', G. Y. Sun and P. Rhodes. Dept. Biochem. and Child Health, Univ. Missouri School of Medicine, Columbia, MO.

Phosphatidylserine (PS) in brain is known to contain a high proportion of docosahexaenoic acid (22:6n3) although exactly how this acyl group profile is attained is not understood. PS is important in many neuronal membrane functions. In this study, rat brain microsomes were incubated with ¹⁴C-22:6n3, ATP, and CoA in the presence and absence of LPS in order to test whether some 22:6n3 may be incorporated into PS through the lysophospholipid: acyl-CoA acyltransferase route. Similar incubations were carried out with other lysophospholipids (LPI, LPC, LPA) for a comparision. Results indicated that in spite of an active uptake of labeled 22:6n3 by PC, PI and PA in the presence of their respective lysophospholipids, LPS was a poor substrate for this reaction. Surprisingly, LPS (5-20 JuM) specifically enhanced the incorporation of labeled 22:6n3 into PA in microsomes by 2-3 fold. This effect of LPS is probably not due to an increase in LPA resulting from phospholipase A₂ action because incoporation activity was not affected by EGTA. On the other hand, addition of LPA to microsomes gave a corresponding increase in labeled PA, and LPS further increased this activity. Results seem to suggest that LPS enhanced PA synthesis by activating LPA acyltransferase through some kind of physical interaction with the enzyme.

FUNCTIONAL Na* CHANNELS AND ENDOGENOUS GABA PRECEDE FUNCTIONAL GABA, RECEPTORS IN EMBRYONIC RAT STRIATUM. M.L., Fiszman. G.D. Lange. N.S. Nadi, S.V. Smith. E.A. Novotny, and J.L. Barker. LNP and ICS, NINDS, NIH, Bethesda, MD, 20892, USA.

The development of excitability in embryonic CNS cells was examined by flow cytometry using oxonol, a fluorescent, voltage-sensitive, indicator dye. Cell suspensions were obtained from rat cerebral hemispheres at 13 days gestation (E13) and from striatum (STR) at E14, E15 and E17. As previously described (Fiszman et al, Dev. Brain Res. in press), cells stained with the supravital dye acridine orange (AO) fell into two populations. The high Forward Angle Light Scatter population (high FALS) was strongly stained with the dye and comprised 85% of scattering events. About 10% of the events collected scattered little light (low FALS) and accumulated less AO. Analysis of sorted material showed that the low FALS population contained flat, phase-dark cells which were neurofilament negative; subcellular fragments and phase-bright cells were neurofilament positive. Cell diameters ranged from 1 to 3µm. The high FALS population was 99% phase-bright, neurofilament-positive cells. Diameters ranged from 4 to 10µm. Exposure of E13 cells to veratridine depolarized the high FALS population. However, these cells did not respond to the GABAA agonist muscimol. In the E14 STR muscimol depolarized only the high FALS population Responses to both muscimol and veratridine were well developed in both populations at E17. Detectable amounts of GABA, determined by HPLC, were found in E13 cortex and at all ages in STR. Our results suggest that Na* channels are functionally operative before GABAA, receptors and that endogenous GABA is present before the appearance of the responses induced by GABAA agonists. The differences in responsiveness among populations during the development of the STR suggest heterogeneity in the distribution of Na* channels and GABAA receptors.

EXPRESSION OF GLUTAMATE-LIKE IMMUNOREACTIVITY IN DEVELOPING COCHLEAR AND VESTIBULAR GANGLIA OF THE QUAIL. M. Mujeeb, J. Represa and P. Bernd, Department of Anatomy and Cell Biology, SUNY Health Science Center, Brooklyn, NY 11203.

It is believed that glutamate and aspartate are the neurotransmitters released by cochlear and vestibular neurons in the adult. The purpose of the present study was to determine whether glutamate is present in developing cochlear and vestibular ganglia, and, if so, establish the timing of glutamate expression. Frozen sections (10 µm thick) of the temporal region of quail embryos aged 7, 9, 14, and 15 days were prepared and examined for glutamate-like immunoreactivity (Glu-LI). A mouse monoclonal anti-glutamate antibody (INCSTAR Corp.) was used at a dilution of 1:1000, in conjunction with an avidin-biotin immunoperoxidase technique. Glu-Ll was detected in embryonic cochlear and vestibular ganglia at all ages examined. In all cases, processes were darkly stained, while neuronal cell bodies became more intensely immunoreactive as development proceeded. It remains to be determined when Glu-LI first appears in cochlear and vestibular ganglia; ages prior to 7 days have not yet been examined. This study demonstrates that the putative neurotransmitter, glutamate, is present in cochlear and vestibular neurons during development. Supported by a grant from the Deafness Research Foundation

HISTOLOGIC ALTERATIONS OF THE CEREBRAL CORTEX IN ADULT MICE PRENATALLY TREATED WITH DIAZEPAM. Márquez-Orozco A., Márquez-Orozco, M.C. and Alcantara-Ortigoza, M.A. Dept. of Embriology, School of Medicine, UNAM, 04510 México,

Prenatally administered diazepam accumulates in the fetal cerebral and cerebellar cortices and mesencephalon. Posnatally until adult age, these mice present alterations in locomotor activity, swimming pattern, and long-term memory. We investigate if histologic alterations in motor cortex occur in adult mice prenatally treated with diazepam. Single daily doses (2.7 mg/kg) of diazepam were i.p. administered to female CD-1 strain mice, between the equivalent volumes of saline sol. The offsprings were wet-nursed by non-treated mice, weaned, and kept for 240 days. Their motor activity and swimming pattern, were periodically measured from the 6th day till the 8th month. Mice were deeply anesthetized, perfused with 10% formaline, and the brains were removed, fixed, and stained with current and a modified fast-Golgy thechniques. Forty um sections were observed under a photonic microscope. The experimental animals showed atypically distributed and more aboudant glia cells. The dendritic patterns and vascular distribution differed from those of the control animals. Locomotor activity and swimming patterns were altered, which could indicate motor cortex impairment.

HEMICHOLINIUM-3 BINDING SITE REGULATION IN VIVO DURING POSTNATAL DEVELOPMENT OF THE RAT. H.K. Happe and L.C. Murrin. Dept. of Pharmacology, University of Nebraska Medical Center, Omaha, NE 68198 High affinity choline transport is the rate limiting step in the synthesis of acetylcholine. [*H]Hemicholinium-3 (HC3) binds with high affinity and specificity to a site associated with the choline transporter and both choline transport and the apparent number of HC3 binding sites are regulated in vivo by drug treatments known to alter acetylcholine release and in vitro by depolarization. Previously we described the development of HC3 binding sites by autoradiography. Low levels are present during the early postnatal period, and then increase significantly by day 15 in striatum and by day 21 in cortex. In this study we examine the in vivo regulation of HC3 binding sites in adult rats and at postnatal days 5 and 15. Animals were administered drugs i.p. for 30-60 min. and striatal and cortical membrane fractions were prepared. HC3 binding was assayed at 10 nM [*H]HC3. Blanks were generated with 10 μM cold HC3. Nicotine (5 mg/kg) increased HC3 binding sites in adult striatum and cortex by 10-20% and produced even greater Blanks were generated with 10 µM cold HC3. Nicotine (5 mg/kg) increased HC3 binding sites in adult striatum and cortex by 10-20% and produced even greater increases at d15 and d5. Haloperiold (4 mg/kg) increased binding sites in striatum only, with the greater effect on d5 animals. Oxotremorine (1.1 mg/kg) greatly reduced binding in both adult cortex and striatum. The effects of oxotremorine in cortex were diminished at earlier ages. On the other hand atropine (20 mg/kg) did not significantly affect HC3 binding sites at any age. Pentobarbital (64 mg/kg) decreased HC3 binding in adult striatum but had no significant effect in cortex. The striatal effect of pentobarbital was more pronounced in day 5 animals. In summary, we report that acute nicotine treatment increases apparent HC3 binding site number, in addition to other drugs previously reported to alter HC3 binding. All drug treatments that were effective in adult animals were also effective as early as day 5, indicating that the small population of cholinergic terminals present during early postnatal development are regulated by similar muscarinic and nicotinic cholinergic, and dopaminergic mechanisms. It is not known if the changes in magnitude of drug effects are due to differences in drug metabolism or to developmental differences in regulation of cholinergic mechanisms. Supported by NS23975 and the McDonald Foundation.

DEVELOPMENTAL CHANGES IN APPARENT NMDA-ANTAGONIST EFFICACY IN HIPPOCAMPAL CA₃ PYRAMIDAL CELLS.

R.J.Brady and J.W.Swann, Wadsworth Ctr for Labs. & Res., NYS Dept. of Health, Albany, NY 12201.

Evidence exists for heterogeneity in the NMDA receptor population. We have shown a developmental change in the divalent cation sensitivity of the NMDA receptor-channel complex in the CA3 infrapyramidal zone (IPZ). In recent studies NMDA-induced depolarization of CA3 pyramidal cells was evoked by iontophoretic agonist application into the proximal portion of the basilar dendrites, the IPZ. Intracellular recordings of the responses were obtained under current-clamp in mature (PND>35) and immature (PND 10-15) hippocampal slices in which both synaptic activity and calcium currents were blocked. An iontophoretic dose-response relationship was constructed for each slice and the iontophoretic dose-response relationship was constructed for each stice and the current needed to produce a response that is 50% of maximum calculated. The EAA-receptor antagonists kynurenic acid (KYN) or D(-)2-amino-5-phosphonovaleric acid (D(-)AP5) were then added to the bathing media at different concentrations. Dose-response curves were obtained under each condition to assess the shift. This effect can be quantified for a single antagonist concentration by calculating the ratio of the currents needed to produce a response that is 50% of maximum, A^1 . In hippocampal slices taken from immature rats $100\mu M$ KYN yields an A^1 value of 2.41 ± 0.05 while in adult tissue, 1.55 ± 0.03 . A similar observation was seen with D(-)AP5. The greater antagonist efficacy in immature tissue is a further indication of developmental change in the IPZ NMDA receptor population. Perhaps an antagonistpreferring form of the receptor-channel complex predominates in the immature tissue. Supported by grants NS23071 to RJB and NS18309 to JWS from NINDS-

CHANGES IN CORTICAL MONOAMINE CONTENT AND NEURONAL RESPONSE IN RATS DURING EARLY ADULTHOOD. J. Goyer, A. Ferron and T.A. Reader. Departement de physiologie, Faculte de Medecine, Universite de Montreal, C.P. 6128 Succ. A, Montreal, P.Q., CANADA H3C 317.

Age-related alterations in the response of parietal cortex neurons to microionto-

phoretic applications of the three monoamines (MA) noradrenaline (NA), dopamine (DA) and serotonin (5-HT), and their agonists were investigated in relation to measurements of endogenous cortical MA levels. Single-unit cell recordings were made from 3, 6 and 12-month old male Sprague-Dawley rats under urethane anesthesia. Two response parameters were taken into account: the responsiveness (% of responsive cells), and the sensitivity, expressed as the charge (in nC) which caused a 50% reduction in the spontaneous firing rate. When compared with 3-month old rats, 6-month old rats showed a reduced sensitivity to MAs (NA 1944 vs 1502 nC; DA 2300 vs 1265 nC; 5-HT 2123 vs 970 nC) and HPLC assays showed very large increases in both NA and 5-HT content (NA 3.6 vs 1.8 ng/mg prot.; 5-HT 3.2 vs 1.3ng/mg prot.), while DA content showed a small but significant decrease (.01 vs.06 ng/mg prot.). The observed MA sensitivity changes were paralleled by corresponding changes in the sensitivity to amidephrine (a1 agonist), quinpirole (D2), and mCPP (5-HT1B) and DOI (5-HT2). In 12-month old rats, bothresponsiveness and sensitivity to all three amines were decreased (NA 53% vs 89% responsiveness, 2407 vs 1944 nC; DA 55 vs 83%, 3300 vs 2300 nC; 5-HT 50 vs 80%, 2526 vs 2123 nC), while MA content remained unchanged (NA 3.4 ng/mg prot.; DA 0.02 ng/mg prot.; 5-HT 2.7 ng/mg prot.), as compared to the 6-month old rats. These results indicate that neuronal sensitivity to NA, DA and 5-HT may be regulated by factors other than neurotransmitter availability. Furthermore, major developmental modifications of the cortical MA systems may still occur in rats as late as the age of 12 months.

KINESIN IS DEVELOPMENTALLY REGULATED IN RAT BRAIN. K.L. Moya, B. Tavitian and L. Di Giamberardino. S.H.F.J., C.E.A., INSERM U334, 91406 Orsay, France.

Kinesin mediates ATP-dependent movement along microtubules and is considered to be the "motor" for rapid anterograde axonal transport. We used a monoclonal antibody to the 120kD form of bovine brain kinesin to examine developing rat brain.

The antibody recognized a single protein (115kD, pI=6.5) on 2-D immunoblots of partially purified microtubule associated proteins. Quantification of 1-D immunoblots containing homogenates from E(mbryonic day)18, P(ostnatal day)0, P3, P7, P14, P21 and adult brains showed that relative levels of kinesin greatly decreased after P14. Partial subcellular fractionation revealed that soluble kinesin was more abundant than kinesin in the crude membrane fraction. than kinesin in the crude membrane fraction. Furthermore, the decrease of kinesin in the two fractions was markedly different. Soluble kinesin decreased sharply and constantly from E18 to P14, while levels in the particulate fraction remained similar from E18 to P14 then greatly diminished at P21. These results show that kinesin is more abundant in the brain early in development and that the subcellular localization appears to be differentially regulated.

FREE RADICAL GENERATION FROM DOPAMINE THROUGH THE ACTION OF

FREE RADICAL GENERATION FROM DOPAMINE THROUGH THE ACTION OF MONOAMINE OXIDASE (MAO). F.F.Ahmad. D.L.Cowan* and A.Y.Sun.Dept. Pharmacology and Dept. Physics*, University of Missouri, Columbia, MO 65212.

It is known that monoamine oxidase (MAO) catalyzes the oxidative deamination of catecholamines to aldehydes according to the following equation: $R-CH_2-NH_2+O_2+H_2O\longrightarrow R-CHO+H_2O_2+NH_3.$ Since free radical damage has been implicated in cellular degeneration in the brain, particularly the dopamine neurons in Parkinson's disease (PD), we used the ESR spin trapping technique to detect whether dopamine (DA) may serve as a substrate for free radical formation. Incubation of DA with mouse brain mitochondria resulted in the formation of free substrate for free radical formation. Incubation of DA with mouse brain mitochondria resulted in the formation of free radicals. The spin adduct of 5,5-dimethyl pyrrolidine-N-oxide (DMPO) of the hydroxyl radical and an unidentified carbon center radical were detected. The free radical formation was demonstrated with purified MAO and was inhibited by either pargyline or Clorgyline (MAO inhibitors). It is possible that under certain conditions, the abnormal metabolism of dopamine may lead to free radical generation, resulting in cell death and tissue injury. (Supported by AA7585.)

DEVELOPMENTAL CHANGES OF SYNAPTIC TYROSINE KINASE AND

DEVELOPMENTAL CHANGES OF SYNAPTIC TYROSINE KINASE AND pp60src IN RAT FOREBRAIN. S.B. Cudmore and J.W. Gurd Dept. of Biochemistry, Scarborough Campus, University of Toronto, Ontario, M1C 1A4.

The subcellular distribution of protein tyrosine kinase (PTK) and phosphotyrosinylated proteins in the developing rat forebrain has been studied. Subcellular fractions from rats ranging in postnatal age from 5 to 60 days were prepared and analyzed for i) PTK activity using polyglutamyltyrosine as substrate ii) endogenous PTK substrates using polyclonal antibodies specific to phosphotyrosine and iii) developmental changes in levels of pp60src. PTK activity was highest in homogenate of young brains (p10) and decreased 2.7-fold to adult levels by p60. Although PTK activity of all fractions underwent a generalized decrease during development, different fractions exhibited characteristic developmental profiles. PTK activity in P3 was maximal at p5 and decreased 44% to adult values by p60. Both cell and synaptosome soluble activity decreased 40-50% between p10 and p15 and an additional 20-25% by p60. PTK activity in the synaptosome particulate (SP) fraction exhibited a biphasic developmental profiles with maximal levels occurring at p10 and p20 and then underwent a 50% decrease by p60. Endogenous substrates for PTK were identified by incubating individual fractions with 2 mM ATP in the presence of Na-O-Vanadate and probing nitrocellulose blots with antiphosphotyrosine antibodies. Several PTK substrates were identified in SP and P3, including proteins of Mr 180K, 120K, 100K, 83K, 68K, 62K, 54K, 52K and 42K. Two major p-tyr containing proteins (Mr 54/52 and 120K) were identified in SP and P3, including proteins of Mr 180K 120K, 100K s8K, 68K, 62K, 54K, 52K and 42K. Two major p-tyr containing proteins (Mr 54/52 and 120K) were identified in SP and P3, including proteins of Mr 180K 120K, 100K s8K, 68K, 62K, 54K, 52K and 42K. Two major p-tyr containing proteins (Mr 54/52 and 120K) were identified in SP and P3, including proteins of Mr

EFFECT OF WATER TEMPERATURE ON SPATIAL LEARNING (MORRIS MAZE) IN INFANT RATS. K.L. ALTEMUS. N.J. LITTLE*. E.A. Foley* and C.R. Almli. Develop. Neuropsychobiol. Lab., Dept. Psych., Washington University.

St. Louis, MO 63130.

Previous work has dated the emergence of object localization abilities in a Morris water maze task to localization abilities in a Morris water maze task to postnatal day 18. This study determined the effect of water temperature (23°C vs 30°C) on the ontogeny of spatial abilities. Albino rats were tested in a water maze under proximal, distal, or random conditions for 3 consecutive days, with testing beginning on postnatal days 15, 16, 17, 18, or 19. Latencies to enter the escape quadrant and latencies to escape were recorded for each session of 12 1-min acquisition trials. Each daily session concluded with a 1-min probe trial, during which escape was impossible. Latencies to enter the quadrant previously containing the platform, and the total time within this quadrant, were recorded. Water temperature did not affect the age at which spatial behaviors emerged (postnatal day 18), but did enhance "performance" as early as postnatal day 19. (Conducted under NIH Guide for Care and Use of Laboratory Animals)

EFFECTS OF THE NMDA ANTAGONIST MK-801 ON BEHAVIOR, BODY WEIGHT AND DENTATE GRANULE CELL MORPHOLOGY IN DEVELOPING RAT PUPS. B.J. Claiborne & A.M. Felthauser*. Div. of Life Sciences, University of Texas, San Antonio, TX 78285. We are interested in the relationship between neuronal

We are interested in the relationship between neuronal activity and dendritic morphology in the hippocampus. Here we have examined the effects of MK-801, an antagonist of the NMDA subclass of glutamate receptors, on the concurrent dendritic growth and branch loss seen in developing dentate granule cells (Rihn & Claiborne, Dev. Brain Res., In Press). Rat pups were treated with MK-801 (1 mg/kg i.p.) or saline every 12 hours for 10 days beginning or restricted days beginning or restricted days. days, beginning on postnatal day 14. Animals (n=8) were sacrificed on PN day 25 and granule neurons (n=18) were filled with Lucifer Yellow in fixed hippocampal slices.

The MK-801-treated pups displayed marked behavioral effects beginning with sedation for the first two days, followed by hyperactivity for the remainder of the period and, on PN day 25, weighed 30% less than the littermate controls (41 \pm 1.6 vs. 63 \pm 3.3 gms; mean \pm S.D.; P < .001). However, dentate molecular layer width, number of dendritic branches per granule cell, transverse dendritic spread and percentage of branches reaching the top of the layer were similar for the two groups. These data show that although MK-801 treatment affected both activity patterns and weight gain in the pups, it did not influence developmental changes normally seen in dentate granule cells during this period. (Supported by NSF)

ADRENAL HORMONE EFFECTS ON HIPPOCAMPAL EXCITATORY

ADRENAL HORMONE EFFECTS ON HIPPOCAMPAL EXCITATORY
AMINO ACID RECEPTOR BINDING. A. S. Clark and C.W. Cotman.
Department of Psychobiology, University of California, Irvine, CA 92717.
Synaptic transmission in the hippocampus is primarily mediated by
excitatory amino acids (EAA). The hippocampus is also a major target for
adrenal steroids. To define whether adrenal hormones might influence the
plasticity of hippocampal neurons via modulation of EAA receptors, we
studied the effects of acute adrenalectomy and hormone replacement on EAA

binding in the rat hippocampus using quantitative autoradiography.

Adult male Sprague-Dawley rats were adrenalectomized (ADX) and given access to 0.9% saline. Corticosterone (CORT) was administered by injection (10 mg/day s.c.) or in the drinking water (25 µg/ml). Rats were killed after 5-7 days, the brain removed, frozen on dry ice and stored at -70 °C.

Quantitative autoradiography of glutamate receptor subtypes (NMDA, kainate and AMPA) was conducted on 6 µm cryostat sections through the hippocampus. Binding to the NMDA receptor was highest in the stratum radiatum of CA1 in animals of all treatment groups (1900 fm/mg protein). No marked changes in NMDA binding were observed in any hippocampal area although a small (10-15%) decrease in NMDA binding in ADX rats relative to controls was sometimes present in CA3 radiatum. Kainate binding was highest in stratum lucidum of CA3 (2200 fm/mg protein). A binding was highest in stratum fuctoum of CA3 (220 mm) mg protein). A small decrease in kainate binding after ADX was occasionally observed in CA3 radiatum. CORT replacement had no effect on EAA binding in any hippocampal region measured. Although adrenal hormones likely play some role in hippocampal function, their short-term manipulation appears to have a limited influence on the binding of EAA to their synaptic receptors. However, interactions between these two systems may modify events subsequent to receptor binding. Supported by the Pew Foundation.

MICRODIALYSIS OF SEPTOHIPPOCAMPAL LESIONED ANIMALS.

P. Maysinger. D.G. Herrera and A.C. Cuello; Dept. of Pharmacology & Therapeutics, McGill University, 3655 Drummond St., Montreal, Quebec, H3C 1V6, Canada.

Microdialysis probes (4mm) were implanted bilaterally into the hippocampi of adult male Wistar rats. Artificial cerebrospinal fluid (CSF) with and without KGI (100 M) was then delivered to the start of without KCl (100mM) was then delivered at a rate of 2ul/min into the hippocampi. Administration of K+ in high concentrations, but not CSF alone, led to behavioural alterations including manifestations typical of motor seizure. In some animals, the putative seizure reached stage 4 on the scale of Racine (Electroenceph. Clin. Neurophysiol. 32:281). Alterations were observed Clin. Neurophysiol. 32:281). Alterations were observed in neurotransmitter release and c-fos expression (assessed by immunostaining). Furthermore, animals bearing a unilateral fimbria-fornix lesion which underwent similar testing, showed comparable motor responses. Degenerative changes in the medial septum following fimbria-fornix lesion were assessed with ChAT and NGFr immunostaining. These alterations are being correlated with the changes in the release of various neurotransmitters into the extracellular space. Supported by M.R.C. (Canada) and Canadian Centers of Excellence Network for Neural Repair and Functional Recovery.

EFFECTS ON BASAL FOREBRAIN STRUCTURES FROM EXPERIMENTALLY INDUCED HYDROCEPHALUS. RM. Kriebel. J. Stella*, K.E. Miller and J.P. McAllister. Depts. Anatomy, Phila Col Osteopath Med, Temple Univ Sch Med, Phila PA 19131 and Searle/Monsanto Co., St. Louis MO 63198.

The neurological deficits found in infantile hydrocephalus have most often been explained by pathological changes in cerebral cortex. It has been the primary goal of our studies to provide a cellular basis for the residual neurological deficits observed even though surgical intervention may have relieved the effects of ventriculomegaly on the cerebral cortex. Our previous studies have shown decreases in ChAT labeled neurons and severe neuropil degeneration of the basal forebrain region, especially in septal nuclei. These studies suggested that basal forebrain as well as cortex should be considered in mechanistic explanation of neurological deficits seen with this disorder. In the present study we attempted to discern if on a macroscopic level specific regions within the basal forebrain were differentially affected in experimental hydrocephalus, and if ventriculoperitoneal (VP) shunt treatment reversed the effect. Kaolin injection induced hydrocephalus, aldehyde fixed brains were sectioned coronally with subsequent staining for cells and fibers. The basal forebrain was divided according to standard atlas designations and planimetrically analyzed with a Bioquant® system. Decrease in volume was observed in all areas of basal forebrain; these changes were only partially normalized in VP brains. NIH support HD21527:JPM.

DEVELOPMENT OF TH-POSITIVE AND DBH-POSITIVE FIBER INNERVATION OF THE RAT HIPPOCAMPUS. A.M. Moudy, D.D. Kunkel, A.T. Majouf & P.A. Schwartzkroin. Dept. Neurol. Surgery, Univ. Washington, Seattle, WA 98195

Development of noradrenergic innervation of rat hippocampus (HC) by locus coeruleus (LC) was examined histochemically in the roller tube cultured slice preparation and in fixed tissue from rats 4 to 21 days postnatal. The presence of tyrosine hydroxylase (TH)- and dopamine beta-hydroxylase (DBH)positive fibers was evaluated in sections of HC and LC. HC and LC slices (250 μ m) were obtained from brains of 4-day-old pups with a Vibratome tissue slicer and co-cultured in the roller-tube slice preparation. Large, multipolar TH- and DBH-positive cells were visible within LC, and positively stained fibers could be seen traversing the space between LC and HC. In sections from 21-day-old rats, the highest density of stained fibers was found in str. radiatum (SR) of CA3, and in the hillus. Beaded fibers could be seen traveling from the fimbria through the pyramidal cell layer, branching extensively in SR. Heavy fiber densities in the infragranular region of dentate gyrus (DG) were oriented parallel to the granule cell layer, but very few could be found among the cell bodies in str. granulosum. Intermediate densities of fibers were found in CA1 SR, lacunosum and oriens, and in the molecular layer of DG. Other areas of HC showed only low-density innervation. Tissue from 10-day-old rats showed fibers in CA3, not as dense as in adult, but in a similar pattern. Innervation was more evenly distributed within the hilus, without parallel organization into a dense band. In 4-day-old tissue, fibers were much more sparsely distributed. Very few fibers were seen in either CA3 or CA2. In CA1, fibers were far less dense than in adult, but more dense than in either CA2 or CA3. DG showed very few positive fibers, almost none in the infragranular band. The subicular area had the most dense distribution pattern at 4 days. Supported by NIH, NINDS fellowship NS08639, and grant NS15317.

ANTIBODIES TO LUCIFER YELLOW AND CASCADE BLUE: LIGHT AND ELECTRON MICROSCOPIC OBSERVATIONS OF DYE-FILLED NEURONS IN RAT HIPPOCAMPUS. D.L. Schmiege, D.D. Kunkel, A.T. Malouf, H.E. Scharfman & P.A. Schwartzkroin. Dept. Neurological Surgery, Univ. Washington, Seattle, WA 98195.

Intracellular injection of fluorescent markers, such as Lucifer Yellow, has been an important tool for morphological analysis of physiologically identified neurons. Although fluorescent dye injections and other fluorescent tracing techniques are widely used, long-term visualization of cellular morphology, and particularly ultrastructure, is often impossible. As a means of enhancing morphological characterization, we have used the recently introduced antibodies to Lucifer Yellow (LY) and Cascade Blue (CB) (Molecular Probes; rabbit anti-LY or -CB). Pyramidal and non-pyramidal neurons, in acute hippocampal slices or in hippocampal slice cultures, were physiologically identified and filled with LY or CB. Immunocytochemical techniques, for both light (LM) and electron microscopy (EM), were utilized to prepare fluorescent dye-filled cells for more stable visual examination. Slices with LY- or CB-filled neurons were fixed, cryoprotected and sectioned; tissue was then exposed to rabbit anti-LY or -CB antibody (1:500 dilution), then goat anti-rabbit IgG conjugated with HRP. At the LM level, specific neurons were identified by an optically dense HRP/DAB reaction product which was localized within somata, dendrites and axons. Dendritic spines and the axonal plexus were clearly visible; non-spe cific background staining was virtually absent in these preparations. At the EM level, a fine electron-dense granular reaction product could be seen within the soma and cell processes. The evenly distributed granular reaction product did not obscure cellular details significantly, thus allowing characterization of subcellular components and synaptic specializations. Supported by NINDS, NIH grants NS18895, NS15317, and NS20482.

THE EARLIEST AREAL DIFFERENTIATION OF THE HUMAN CEREBRAL CORTEX: ENTORHINAL AREA. I. Kostović, Z. Petanjek and M Judaš. Sect. of Neuroanatomy, Medical Faculty Zagreb, Y

We have used Golgi and Nissl method to identify neurons and architectonic laminae expressing the early areal specialization in the cerebral cortex of human postmortem fetuses (10-13 weeks of gestation - w.g.). The first area specific cells are large neurons ("organizers") with widely bifurcating apical dendrites, appearing at the outer margin of the cortical plate of the prospective entorhinal cortex (E.C.) of 10w.g. fetus. Concomitantly, multilaminated spread of the deep part of the cortical plate occurs. In a 10,5 w.g. fetus "organizer" neurons form magnocellular layer. At 13 w.g., characteristic fiber-rich dissecant and cell-dense principal laminae develop unevenly within the cortical plate of E.C., causing precocious subareal parcellation of E.C. In rostral entorhinal subareas cell . islands of the future layer II develop at the subpial depths where "organizer" neurons reside. In caudal entorhinal subareas well developed lamina dissecans stops abruptly at the border of neocortex while lamina principalis interna continues into upper subplate zone. In conclusion, both area-specific neurons ("organizers") and fiber-rich (afferent) strata develop synchronously during the earliest areal differentiation of the cerebral cortex. The precocious lamination of the cortical plate is crucial event in the histogenesis of the entorhinal cortex. Supp. by U.S.-Yugoslav Joint Board JF 855.

SYNAPTIC DEVELOPMENT AND REORGANIZATION IN CA1 OF RAT HIP-POCAMPAL SLICE CULTURES. D.D. Kunkel, D.L. Schmiege, A.T. Malouf & P.A. Schwartzkroin. Dept. Neurological Surgery, Univ. Washington, Seattle,

Hippocampal slice cultures combine the advantages of dissociated cell culture and acutely prepared brain slice preparations. They provide an organotypic preparation for studying a developing system which has lost extrinsic afferents. We used conventional light and electron microscopic techniques to provide quantitative information on cellular and synaptic features in developing rat hippocampal slice cultures. Three subfields of CA1 were examined: strata oriens, pyramidale, and radiatum (SO, SP, SR)
Rat hippocampal slices were prepared from 4-6-day-old rats, and cultured for 1-8 weeks using modifications of methods developed by Gähwiler. Hippocampal slice cultures maintained an intrinsic cellular and synaptic organization similar to that of the original hippocampal brain tissue Observations on synaptic organization, density and differences in asymmetric and symmetric synaptic densities were made. Total synaptic densities increased in all subfields from 1 week (6/100 μm^2) to 3 week $(14/100~\mu m^2)$; thereafter, the density slightly decreased $(12.5/100~\mu m^2)$. In SO and SR, both symmetric and asymmetric synapses increased to their greatest density between 3 and 4 weeks; a gradual decrease was seen after this period. After 1 week of development, the proportion of asymmetric versus symmetric synapses in SR and SO was constant at 70% and 20%, respectively. In SP, asymmetric and symmetric synaptic density increased gradually to 5 weeks, and then leveled off. Approximately 50% asymmetric

and 35% symmetric synapses were observed in SP. Supported by grants from NINDS, NIH NS18895, NS15317; and Epilepsy Foundation of America.

ELECTROPHYSIOLOGICAL COMPARISON OF RAT PYRAMIDAL AND NON-PYRAMIDAL HIPPOCAMPAL NEURONS IN VITRO. J. R. Buchhatter and M. A. Dichter. Dept. of Neurology, Univ. of Pennsylvania and Graduate Hosp., Philadelphia, PA 19146.

Differences in electrophysiological properties between pyramidal and non-pyramidal neurons have been demonstrated in the hippocampal slice urons have been demonstrated in the hippocampal slice We have examined these characteristics in dissociated rat hippocampus

Hippocampi were removed from E18-E19 embryos, incubated in a trypsin solution, dissociated by trituration and plated at a density of 600,000 viable cells in 35 mm Petri dishes containing poly-L-lysine coated glass coverslips. cells in 35 mm Petri dishes containing poly-L-lysine coated glass coverslips. Cultures were maintained for 3-4 weeks in a caff serum supplemented media before intracellular recordings were made with 3.5 M potassium acetate containing pipets. The extracellular solution contained (in mM): 145 NaCl, 3 KCl, 2 CaCl₂, 1 MgCl₂, 10 HEPES, 8 glucose. Recordings were made at room temperature (22-25°C) or with the bath heated (29-36°C). No significant differences were noted between pyramidal and non-pyramidal neurons with regard to action potential (AP) amplitude, rate of rise and fall, duration at half maximal amplitude, accommodation to steady state depolarization or resting membrane potential and input resistance. Expected differences in AP duration, and rates of rise and fall were observed when room and elevated temperature recordings were compared, independent of morphology.

room and elevated temperature recordings were compared, independent of morphology.

We conclude that the differences noted in the hippocampal slice preparation are not apparent in dissociated cell culture. This may be due to the absence in vitro of factors which control the development of ion channels in vivo. It is also possible that we have recorded from a population of non-pyramidal neurons with electrophysiological properties which overlap with those of pyramidal neurons. Partial overlap has been recorded in the slice preparation with non-pyramidal neurons from different layers (Lacaille J. et al, J Neurosci, 7:1779-93, 1987).

HIPPOCAMPECTOMY IN INFANT RHESUS MONKEYS FACILITATES OBJECT-REMARD ASSOCIATION LEARNING BUT NOT MEMORY FOR CONDITIONAL OBJECT-OBJECT ASSOCIATIONS. R. Killiany and H. Mahut, Psychol. Dept., Northeastern Univ., Boston, MA 02115

The performance of lyr old normal control (Gr.1, n=7), 5mos old normal control (Gr.2, n=4) and lyr old infants hippocampectomized at 2 mos of age (Gr.3, n=5) was compared to that of 6 young adults (Gr.4) on a task that, first, involved presentations of 4 object pairs and monkeys had to learn which pairings were rewarded and which were not. A given object appeared as a member of both rewarded and non-rewarded pairs. In the last stage, conditional retrieval, monkeys had to discriminate between three single objects depending on their past association with other objects (Saunders & Weiskrantz, 1989). We found that:

1. In learning associations, infants in groups 2 and 3 were as efficient as were adults while those in Gr.1 performed significantly worse than did those in the other three groups.

2. In the conditional retrieval stage, infants in groups 2 and 3 were significantly impaired compared to lyr old (Gr. 1) or adult (Gr. 4) monkeys.

Thus, though the hippocampal system may mediate ob-

Thus, though the hippocampal system may mediate object recognition memory at adult levels of efficiency as early as at 4.5 mos of age (Mahut & Killiany, Abstr. Soc. Neurosci., 1990), it is not sufficiently mature at 5 mos of age to mediate conditional retrieval at the same level of accuracy as that seen at either one or four years of age.

351 19

ONTOGENY OF OBJECT-REWARD ASSOCIATION LEARNING AND TRIAL-UNIQUE OBJECT RECOGNITION MEMORY - EFFECTS OF EARLY HIPP-OCAMPECTOMY ON THE TWO CAPACITIES IN RHESUS MACAQUES. H. Mahut and R. Killiany, Psychol. Dept., Northeastern Univ., Boston, MA 02115

The present study examined the ontogenetic development of the two capacities and the effects upon them of hippocampectomy at 2 mos of age on: 1. Learning of a concurrent object discrimination task (COD) with repeated trials in which one member of each of the 8 pairs of objects remained the positive stimulus. 2. Delayed matching to sample recognition task (DMS) with 3 groups of infants: Gr. A (n=4) normal, 6.7 mos old; Gr. B (n=8) normal, 3 mos old and Gr. C (n=10) 3 mos old operated infants. Four normal, 3-4 yr old adults with identical training history constituted an age control group (Gr. D).

On the COD task, the only significant difference was found with infants in Gr. B that performed better than did young adults. On the DMS task, no significant differences were found among the three age groups of normal control monkeys. However, operated infants were significantly impaired compared to the other three groups of monkeys.

These findings support our earlier suggestion (Mahut and Moss, The Hippocampus, 4:241, 1986) that there might be complex developmental interactions between brain systems that mediate associative learning (cf 'habit', Hirsh 1974) and a maturing hippocampal system.

mRNA REGULATION: TRANSCRIPTION FACTORS

352.1

INDUCTION OF IMMEDIATE EARLY GENE mRNAs BY CYCLOHEXIMIDE IN MOUSE SKELETAL MUSCLE IN VIVO. S.R. Abu-Shakra*, A.J. Cole. D.W. Saffen*, J.M. Baraban, P.F. Worley, and D.B. Drachman. Depts. of Neurology and Neuroscience, Johns Hopkins University, Baltimore, MD 21205.

Drachman. Depts. of Neurology and Neuroscience, Johns Hopkins University, Baltimore, MD 21205.

Recent studies have described a family of genes referred to as immediate early genes (IEG) that respond rapidly and transiently to growth factor stimulation in fibroblasts. The finding that several IEGs which encode transcription factors respond to nicotinic stimulation in PC12 cells (Bartel et al., Genes Dev., 1989, 3:304) raises the possibility that these transcription factor mRNAs play a role in skeletal muscle response to neuromuscular transmission. In initial studies, basal levels of several IEG mRNAs were undetectable by Northern blot analysis of total RNA from mouse gastrocnemius. Accordingly, we examined IEG mRNA levels after treatment with cycloheximide, a protein synthesis inhibitor that superinduces IEG mRNA levels in other cell types, by increasing IEG transcription and decreasing mRNA degradation. Four hrs. after cycloheximide treatment (40-80 mg/kg, i.p.), the following IEG mRNAs were readily detectable: zif/268, c-jun, and nur/77. Our results suggest that these known or putative transcription factors are expressed in myocytes and may play a role in regulating transcriptional responses to muscle stimulation.

COLOCALIZATION OF SPINAL OPIOID PEPTIDE mRNA AND FOS PROTEIN IN A RAT MODEL OF PERIPHERAL INFLAMMATION AND HYPERALGESIA.

K.Noguchi, M.J.Iadarola and M.A.Ruda Neurobiology and Anesthesiology Branch, NIDR, NIH, Bethesda, MD, 20892

Branch, NIDR, NIH, Bethesda, MD, 20892

The relationship of dorsal horn Fos proteins and opioid peptide precursor mRNAs for preprodynorphin (PPD) and preproenkephalin (PPE) was examined following peripheral inflammation and hyperalgesia. Rats received an injection of carrageenan (6mg/150 µl saline) into one hindpaw and were sacrificed 3d later by perfusion with 4% paraformaldehyde. The L-5 segment of the spinal cord was processed for in situ hybridization histochemistry using oligonucleotide probes labeled with 375 to identify PPD and PPE mRNA levels. The tissue was then processed using the PAP method with antisera against Fos-related nuclear proteins.

At 3d post-inflammation, a large ipsilateral increase in PPD mRNA and

At 3d post-inflammation, a large ipsilateral increase in PPD mRNA and Fos proteins was detected in a subpopulation of dorsal horn neurons, while a small increase in PPE mRNA was noted. In laminae 1 & II, more than 80% of the neurons exhibiting increased PPD mRNA colocalized Fos proteins, while only half of the PPE neurons had Fos nuclear labeling. In laminae V-VI, about half of the neurons exhibiting either PPD or PPE mRNA exhibited Fos immunoreactive proteins.

These data demonstrate that a subpopulation of dorsal horn neurons colocalize either PPD or PPE mRNA and Fos proteins. The activation of nuclear proteins such as Fos, may play a role in the transcription of PPD and PPE. However, the number of neurons displaying increased Fos proteins is greater than the number of neurons colocalizing PPD or PPE. This suggests that other transcriptional events are also involved in the response to peripheral inflammation and hyperalgesia and are regulated by Fos-related nuclear proteins.

352.3

ANATOMIC DISTRIBUTION OF C-FOS, C-JUN AND NGFI-A mRNA FOLLOWING A KINDLING AFTERDISCHARGE (AD). D. A. Hosford, M. Simonato*, Z. Cao*, C. Shin, L. Butler*, and J. O. McNamara, Epilepsy Res. Lab, Duke and V.A. Med. Ctrs., Durham, NC 27705.

Kindling development requires the production of a focal AD after electrical stimulation. The mechanism by which brief, periodic ADs produce the longlasting kindling phenomenon is unknown. Immediate-early genes (IEGs) may transduce brief stimuli into long term changes in cell phenotype by regulating gene expression. Importantly, the IEGs c-fos, c-jun, and NGFI-A are induced by chemoconvulsant seizures (Morgan et al., 1987; Saffen et al., 1988). To test the hypothesis that IEGs contribute to kindling development, it is first necessary to define their anatomic distribution after an AD.

Male Sprague-Dawley rats were killed 15 min after a single AD (mean duration = 41 sec) produced by an electrode implanted in the right angular bundle, or after sham stimulation. $[^{32}P]$ -labelled oligonucleotide probes (50-mers) for c-fos, c-jun and NGFI-A were allowed to hybridize to brain sections in situ. Optical densities of anatomic regions were measured using autoradiograms generated by apposition of film to the brain sections. C-fos mRNA was significantly induced (p < .01) in pyriform cortex, neocortex, dentate granule cell (DGC) layer, CA3, and CA1 pyramidal cell layers after a single AD. No significant induction was observed in basal ganglia, thalamus, or amygdaloid nuclei. The pattern of induction of c-jun and NGFI-A transcripts had an anatomic distribution similar to that for c-fos. The findings are noteworthy for 2 reasons. First, the breadth of this anatomic distribution is surprising, given the brief duration of the initial AD. Second, the similarity of the anatomic distribution to that of the N-methyl-D-aspartate (NMDA) subtype of excitatory amino acid receptors suggests that an NMDA receptor-mediated mechanism during an AD may induce these IEGs. (NIH and V.A. grant support)

352.4

C-FOS EXPRESSION IN DIRECTIONALLY SELECTIVE VISUAL SYSTEM NEURONS. Ximena Rojas*, Josh Wallman and John Leah*. Dept. of Biology, City College of CUNY, New York, NY 10031 and Griffith University, Brisbane, QLD, Australia.

Immediate early genes, such as c-fos, are transiently expressed in brain cells just after very strong stimulation and produce proteins that control transcription of other genes. To explore further the role of these genes under physiological conditions, we have studied the expression of c-fos in electrophysiologically well characterized neurons of the chick accessory optic system (AOS) during biologically relevant visual stimulation.

Chicks that had had a translucent occluder over one eye for 3-11 days were presented with unidirectional whole-field visual motion for 2 hr, with the other eye covered. The protein product of c-fos was detected by immunocytochemical methods. In the rostral and caudodorsal parts of the nucleus of the basal optic root of the AOS, in which all neurons are upward-sensitive, we found intense and widespread labeling only when the contralateral eye viewed upward motion. Label was entirely lacking both if the eye viewed horizontal motion and in the corresponding structures on the ipsilateral side. Similar specificity was found in regions known from electrophysiology to respond to other motion directions. In the pretectal lentiform nucleus, only horizontal visual stimulation of the contralateral eye produced labeling. Thus we find c-fos expression only in those directionally selective neurons tuned to the motion direction of the visual stimuli.

REGULATION OF C-FOS EXPRESSION BY BRADYKININ BUT NOT BY MUSCARINIC RECEPTOR STIMULATION IN NG108-15 CELLS. Trejo, D. Goldstein, E.A. Martinson, H. Abe and J.H. Brown. Department of Pharmacology M-036, U.C San Diego, La Jolla, CA 92093

We recently demonstrated that muscarinic receptor (mAChR) stimulation by carbachol leads to increased expression of c-fos mRNA in 1321N1 astrocytoma cells. In these cells, m3 mAChR activation stimulates phospholipid turnover, increases intracellular calcium (Ca^{2*}) and activates protein kinase C (PKC). To determine whether c-fos is induced by activation of m4 mAChR that regulate adenylate cyclase rather than phospholipid hydrolysis, we studied NG108-15 cells. We found no increase in c-fos mRNA in serum-deprived NG108-15 cells stimulated with carbachol for up to 2 hrs. In contrast, bradykinin (BK), which stimulates inositol phosphate generation and increases Ca2+, in NG108-15 cells, induces a 5-fold increases in c-fos mRNA within 30 min. In cells depleted of protein kinase C by overnight treatment with PMA, BK failed to increase c-fos mRNA above control levels suggesting that PKC is necessary for the BK-mediated c-fos induction. Forskolin and ionomycin also increase c-fos mRNA approximately 5-fold; further studies will determine whether BK interacts with these cAMP- and Ca2+ dependent pathways. In addition, we will use NG108-15 cells transfected with the gene encoding an mAChR subtype (m1) that couples to phospholipid metabolism to ask whether carbachol can activate c-fos expression by the same pathway used by BK. Supported by GM 36927.

352.7

NMDA INDUCTION OF C-FOS EXPRESSION IN INDIVIDUAL NEURONS ISOLATED FROM THE DENTATE GYRUS. L.S. Lerea and J.O. McNamara, Duke Univ. and V.A. Med. Cntr., Durham, NC, 27705

Seizures induce the dramatic and transient expression of the immediate early gene c-fos in discrete neuronal populations in rat brain. The mechanism by which seizures induce c-fos expression is unknown. Activation of the N-methyl-D-asparate (NMDA) receptor appears to be necessary for the full expression of seizure induced c-fos in dentate granule cells since NMDA receptor antagonists inhibit c-fos induction without inhibiting seizure induced granule cell firing (Labiner et al., this volume). We sought to determine whether NMDA receptor activation alone was sufficient to induce c-fos in dentate granule cells. The dentate gyrus was microdissected from the hippocampus of 4 day old rats and enzymatically dissociated to yield neuronal and non-neuronal cells. Neurons were identified immunocytochemically with a monoclonal antibody to neurofilament protein. c-fos mRNA expression was measured by in situ hybridization using ³²P-dATP incorporated into a 50 base pair oligonucleotide complementary to the coding region of rat c-fos (Curran, T., et al., Oncogene 2:74-87, 1987). NMDA treatment of dentate cells in vitro produced a dose and time dependent increase in c-fos mRNA localized to neuronal somata (10-15 fold compared with vehicle). Induction of c-fos was maximal at 30 uM NMDA and was blocked by the NMDA receptor antagonist APV (100 uM). Stimulation of dentate gyrus cells with NMDA also resulted in an increase in intracellular calcium as measured with the calcium sensitive dye fura-2. We conclude that NMDA receptor stimulation is sufficient to induce c-fos expression in neurons isolated from the dentate gyrus. Ongoing investigations are seeking to elucidate the mechanism(s) by which NMDA receptor activation triggers c-fos mRNA expression. Supported by NRSA GM12049.

EFFECTS OF N-METHYL D-ASPARTATE (NMDA) ANTAGONIST MK801 ON CORTICAL NEURAL FOS EXPRESSION FOLLOWING VARIOUS STIMULI IN SERUM-FREE CULTURE. K.Hisanaga, S.M.Sagar, K.J.Hicks* and F.R.Sharp. Depts.of Neurology and Physiology, UCSF and

VAMC, San Francisco, CA 94121

Expression of the c-fos proto-oncogene in cultured neurons derived from fetal rat cerebral cortex was examined using Northern blotting for c-fos mRNA and immunocytochemistry for Fos (and/or Fos related antigens). Induction of c-fos mRNA was observed after treatment with phorbol diester, dibutyryl-cyclic AMP, vasoactive phorbol diester, dibutyryl-cyclic AMP, vasoactive intestinal peptide, basic fibroblast growth factor (bFGF), fetal calf serum, high K^+ , Zn^{2^+} , and l-glutamate (10 μ M). Although all these stimulants increased Fos immunoreactivity in some neurons (7-24%), the Fos induction by all of these stimulants was inhibited by pretreatment with 1 μ M MK801. Moreover, MK801 inhibited the induction of Fos by kinate and quisqualate, agonists for other glutamate receptors. It is possible that some of these stimulants induced Fos in these neurons by NMDA receptor-mediated receptors. It is possible that some of these stimulants induced Fos in these neurons by NMDA receptor-mediated Ca^{2+} influx following glutamate release from other neurons in the culture. However, Zn^{2+} is known to act as a NMDA antagonist, and bFGF is believed to reduce glutamate induced— Ca^{2+} influx. The present results suggest that either Fos expression was affected by an unkown action of MK801, or that NMDA receptor might be associated with cortical neural c-fos expression via a non-glutamate as well as a glutamate mediated mechanism.

ANALYSIS OF c- fos AND c-fos-RELATED GENE FUNCTION IN THE MAMMALIAN NERVOUS SYSTEM. J.L.Sonnenberg*, R.Molinar-Rode. K.Schilling, T. Curran* and J.I.Morgan. Roche Institute of Molecular Biology, Roche Research Center, Nutley, NJ

Diverse forms of stimuli elicit a rapid and transient induction of socalled immediate-early genes, such as c-fos and c-jun, in the vertebrate CNS. Many of these genes encode transcription factors that are thought to mediate the long-term adaptive response of neurons to stimulation by altering the expression of other target genes (Trends in Neurosci. (1989) 12:459; Science (1989) 246:1622); Neuron (1989) 3:359). In the rodent CNS, the glutamate receptor plays a critical role in coupling excitatory stimuli to the transcriptional activation of c-fos, c-jun and jun-B, genes that encode proteins present in transcription factor AP-1. AP-1 is composed of heterodimeric protein complexes containing one Fos-like and one Jun-like protein. In the CNS following stimulation, the levels of the various Fos- and Jun-like proteins vary in a dynamic manner with time. We have investigated this phenomenon by isolating fos-related genes that are expressed following kainic acid treatment. The properties of these gene products have been assessed in gel shift, protein association and transfection assays. In addition we have analysed the coupling of the K-type glutamate receptor to c-fos both in vivo and in a neuronal cell line stably transfected with an inducible c-fos-β galactosidase fusion gene. Supported by the DFG (to KS, Schi 271/2-1).

DISSOCIATION OF NEURONAL ACTIVITY AND SEIZURE-INDUCED c-fos mRNA EXPRESSION BY NMDA RECEPTOR ANTAGONIST. D.M. Labiner. D.A. Hosford, C. Shin, Z. Cao', L.S. Butler', J.O. McNamara. VA and Duke Univerity Medical Center, Durham, NC 27705

Expression of c-fos has been used as a marker of neuronal activity in the mammalian nervous system, but the mechanisms regulating its expression in vivo are incompletely understood. We previously found that NMDA channel blockers decreased seizure-induced c-fos mRNA expression in the dentate granule cells (DGC) of hippocampus without affecting afterdischarge duration (ADD). This suggests that c-fox expression was decreased without decreasing neuronal activity. To test this suggestion, we used field potential recordings to measure the effect of the NMDA channel blocker, Mk-801, on DGC firing during kindled seizures.

Rats were kindled by stimulation of the dorsal hippocampus. DGC field potentials were recorded from a concentric bipolar electrode placed in the dentate hilus opposite the kindled hippocampus. Animals serving as their own controls were given either vehicle or Mk-801 (1.0 mg/kg, ip) 1 hr prior to receiving a stimulus-evoked seizure. Mk-801 did not inhibit ADD or clonic motor seizure duration. Unexpectedly, significantly **more** population spikes per seizure were recorded in each of the animals tested following Mk-801 (849 \pm 80) compared to vehicle (297 ± 114 ; p<0.05). In animals sacrificed 30 min after the last seizure, in situ hybridization with a ³²P-oligonucleotide probe was used to measure c-fos mRNA in the DGC of the recorded hippocampus. The dramatic seizure-induced increase in c-fos mRNA in the DGC was attenuated by Mk-801 (50%, p<0.01).

An NMDA channel blocker decreased seizure-induced c-fos mRNA expression in the DGC while increasing the seizure-induced firing of these cells, thereby dissociating neuronal activity from c-fos expression. We suspect that an NMDA receptor mediated rise in [Ca++], is required for full induction of c-fos. These data warrant caution in use of c-fos expression as a marker of neuronal activity.

ADRENALECTOMY-INDUCED C-FOS EXPRESSION IN CRF CONTAINING NEURONS IN THE PARAVENTRICULAR NUCLEUS. E. Robbins and F. Baldino, Jr. Cephalon, Inc., West Chester, PA 19380.

Corticotropin-releasing factor (CRF) neurons in the paraventricular nucleus of the hypothalamus (PVN) have been shown to be uniquely sensitive to alterations in the levels of adrenal steroids. CRF and arginine vasopressin (AVP) are markedly elevated in adrenalectomized rats. It has been established that CRF-containing neurons within in automacconnect rats. It has occur exactioned that CRT-containing neurons within the parvocellular subdivisions of the PVN are primarily responsible for the elevated CRF levels, and that AVP mRNA can be co-localized within these same neurons in

CRF levels, and that AVP mRNA can be co-localized within these same neurons in adrenalectomized animals. This phenotypic alteration is reversed by the administration of glucocorticoids. The purpose of this study was to investigate the role of c-fos in the plasticity of the CRF/AVP phenotype.

A c-fos cDNA (2200 bases) was used to generate a ³⁵S-labeled RNA probe for in situ hybridization histochemistry. Male Sprague-Dawley rats from Charles River Laboratores were adrenalectomized or sham-adrenalectomized under mild anesthesia and were sacrificed 4 days after surgery. Rats were kept in a temperature, humidity and light (12h on/off) controlled room and allowed food and water ad libitum. In situ hybridization was performed on 12um tissue sections according to previously published methods using 3.5ng probe per section with a detection time of 3 weeks after exposure to autoradiographic emulsion.

C-fos mRNA was detected within individual neurons in the medial parvocellular

c-tos mixNA was detected within individual neurons in the median parvocentuals subunit of the PVN and was co-distributed with CRF-immunoreactive neurons. At the single neuron level, c-fos mRNA was co-localized with CRF-immunoreactive material. These data suggest an important role for early genes in the plasticity of neuronal phenotypes in the adult CNS.

The authors gratefully acknowledge the critical evaluation of Dr. M.E. Lewis and Dr. Kobel for the generous gift of the c-fos cDNA.

C-FOS AND C-JUN EXPRESSION IN THE RAT BRAIN FOLLOWING TRANSIENT ISCHEMIA. T. Wessel, H. Baker, T.H. Joh and B.T. Volpe. The Burke Rehabilitation Center, Cornell University Medical College, White Plains, NY 10605

A variety of insults induce the early immediate genes c-fos and c-jun in the central nervous system. We examined the regional specificity and the time course of c-fos and c-jun expression in Wistar rats subjected to 20 minutes of forebrain ischemia by four- vessel occlusion. Transient ischemia typically produces severe neuronal loss in the CA1 region of the hippocampus and in the dorsolateral caudate nucleus. In situ hybridization with specific DNA probes revealed a striking temporal sequence of c-fos and c-jun expression 30 minutes after reperfusion: the most prominent response occurred in the dentate gyrus, cerebellum, medial habenula and pyriform cortex; more moderate hybridization signals were seen in the medial amygdala, several hypothalamic nuclei and the perimamillary region as well as in the ependyma of the lateral and third ventricles. These brain regions displayed synchronous c-fos and c-jun induction which diminished to different degrees at 1, 2, 3 hours after re-perfusion. Specifically, the dentate gyrus was still clearly outlined 3 hours after re-perfusion, when hybridization signal over the cerebellum had vanished. Uniquely, CA1 though CA4 in the hippocampus showed a <u>delayed response</u> that was most prominent 1 hour after re-perfusion. Expression of these proto-oncogenes was not detected at 6 hours or 1 week post ischemia. Sham-operated animals did not demonstrate c-fos and c-jun induction. These results in the postischemic brain indicate that transcription of c-fos and c-jun occurs early, evolves over hours and decays at different rates in various brain regions. While the pattern of c-fos and c-jun induction does not correspond solely to areas of selective vulnerability, the delayed response of the hippocampus may reflect a transsynaptic effect that contributes to selective neuronal injury. Supported by MH 44043 and MH 40090.

INDUCTION OF c-FOS mRNA IN CULTURED RAT ASTROCYTES BY CALCITONIN GENE-RELATED PEPTIDE C.A. Haas*. M. Reddington and G.W. Kreutzberg. Dep. of Neuromorphology, Max-Planck Inst. for Psychiatry, 8033 Martinsried,

FRG
Retrograde changes caused by peripheral nerve injury affect both neurons and their surrounding glial cells. The dramatic increase of the mRNA encoding the calcitonin gene-related peptide (CGRP) as early as 16 hours after axotomy represents one of the earliest molecular changes in facial motoneurons. CGRP has a variety of functions in the PNS and CNS. In order to gain information about its possible role in the cellular reactions accompanying neuronal regeneration its effect on astrocytes was studied in vitro. A strong and transient increase in c-fos mRNA was observed in cultured astrocytes after treatment with CGRP. Quantitative Northern blot analysis revealed an increase of c-fos mRNA within 15 min, a peak after 30 min and a subsequent decline. This CGRP effect was concentration dependent, half maximal stimulation of c-fos mRNA being obtained in the range of 100-300 nM. Calcitonin was found to mirnic the action of CGRP on cultured astrocytes. It transiently induced c-fos gene expression with a similar time course as CGRP, but its effect was somewhat weaker. These data provide the first evidence for an effect of CGRP/calcitonin on astrocytes and demonstrate the usefulness of measuring c-fos gene expression for studying receptor-mediated transcriptional activation mechanisms.

C-FOS GENE EXPRESSION AND GLUTAMATE CONTENT ARE INCREASED WHILE GLUTAMINE CONTENT IS DECREASED IN THE BRAIN OF DEVELOPING RATS AFTER TRANSIENT HYPOXIA. D. Krainc, K.P. Gudehithlu, A-M. Duchemin, M. Hadjiconstantinou and N.H. Neff. Departments of Pharmacology and of Psychiatry, The Ohio State University College of Medicine Columbus, Ohio 43210 USA

We have studied the relationship between neonatal hypoxia and c-fos expression. Seven days old rats were exposed to various periods of hypoxia (8% O₂ balance N₂) and c-fos mRNA, glutamate and glutamine content were assayed in hippocampus, frontal cortex and striatum. We found 3 hr of hypoxia resulted in the expression of c-fos in the hippocampus, frontal cortex and striatum. c-Fos mRNA of hippocampus was increased immediately after exposure to hypoxia and then gradually declined to basal content by about 2 hr. In the frontal cortex and striatum, c-fos mRNA increased immediately after hypoxic exposure and continued to increase for about one hr after hypoxia. About 3 hr are required for c-fos mRNA to return to basal values in both brain regions. There were concomitant increases of glutamate and a decrease of glutamine when c-fos expression increased in the three regions of brain. Within 1 hr after hypoxia, glutamate and glutamine returned to control values. However, glutamate then decreased while glutamine increased. At 6 hr the substrates returned to control values. Our studies suggest that the temporal pattern of c-fos mRNA changes in neonatal rats exposed to hypoxia might be correlated with glutamate and glutamine content.

IPR INDUCIBILITY OF C-FOS IS ONE DIFFERENCE BETWEEN EARLY AND LATE PASSAGE C6 GLIOMA CELLS. R.M. Gubits and H. Yu*. Dvsn. Ped. Neurol. Dent. Neurol. Columbia Univ. Coll. Phys. & Sufre. NY, NY.

Ped. Neurol., Dept. Neurol., Columbia Univ., Coll. Phys. & Surg., NY, NY. C6 glioma cells (Benda et al., Science 161:370,1968) are widely used as a model system for the study of glial cell function. Depending upon cell passage number and culturing conditions, C6 cells can express a predominantly astrocytic or oligodendroglial phenotype. During our studies on changes in gene expression after β-adrenergic receptor (BAR) activation, we noted a cell passage numberrelated difference in the response of C6 cells to treatment with 10 µM isoproterenol (IPR). A further comparison of <u>early</u> (E) and one population of <u>late</u> (L) passage C6 cells revealed the following: 1.) Morphological changes, 2.) Changes in generation time, and 3.) Numerous differences in gene expression, including: a.) IPR-inducible c-fos mRNA expression in E, but not L cells, b.) No difference between E and L cells in c-jun mRNA response to IPR treatment, c.) IPR-inducible preproenkephalin mRNA expression in both E and L cells, but from a basal level 5-fold higher in L cells, d.) IPR-inducible expression of NGF mRNA in E cells, compared with constitutive expression in L cells, e.) IPR-inducible changes in GFAP mRNA level in E cells, but undetectable GFAP mRNA expression in L cells, and f.) higher constitutive expression of tubulin mRNA in E than in L passage cells. Vernadakis et al., (Adv. in the Biosci. 61:371,1986) have suggested that the altered phenotype of late passage C6 cells may represent a model system for glial aging. Our results suggest that the aging process may include an altered response to BAR activation. (Supported by Giblin Foundation for Pediatric Neurological Research).

5HT RECEPTORS: BEHAVIOR AND PHARMACOLOGY

353.1

MODULATION OF 5-HT₂ RECEPTOR-INDUCED BEHAVIORAL MODELS VIA DIFFERENT 5HT₁ RECEPTOR SUBTYPES. R.A. Glennon*2, N.A. Darmani¹, U. Pandey*1 and B.R. Martin*1. Depts of Pharmacol/Toxicol¹. and Medicinal Chemistry², MCV/VCU, Richmond, VA 23298.

Receptor binding studies have identified several types of 5-HT receptor sites (5-HT₁, 5-HT₂, 5-HT₃ and 5-HT₄). 5-HT₁ sites are heterogeneous and appear to consist of a number of subtypes of which the 5-HT_{1A} and 5-HT_{1B} sites are best studied. One of the most often used models of 5-HT₂ receptor function is the head-twitch response (HTR) in rodents. Recently we characterized the ear-scratch response (ESR) induced in mice as a behavioral model for 5-HT₂-selective receptor agonists.

Recently we characterized the ear-scratch response (ESR) induced in mice as a behavioral model for 5-HT₂-selective receptor agonists.

Intraperitoneal injection of DOI induced both HTR and ESR in a dose-dependent manner (0.6-5.0 mg/kg, i.p.). For drug interaction studies a dose of 2.5 mg/kg DOI was used to induce both behaviors in mice. The DOI-induced behaviors were observed immediatly after injection for 30 minutes. The non-selective 5-HT agonist 5-MeO DMT (2-8 mg/kg, i.p.) and the 5-HT₂ antagonists ketanserin (0.06-1.0, s.c.) and spiperone (0.02-0.5 mg/kg, i.p) pretreatment dose dependently reduced both behaviors. However pretreatment with a selective 5-HT_{1A} agonist 8-OH DPAT (0.5-2.5 mg/kg, i.p.) only inhibited the HTR and had no significant effect on ESR. The 5-HT_{1B}/5-HT_{1C} agonist TFMPP (0.6-1.2 mg/kg, i.p.) and the 5-HT_{1B} agonist RU 24969 (0.25 mg/kg, i.p.) pretreatment inhibited ESR but not HTR. These results suggest that the 5-HT₁2 caceptor-induced HTR and ESR are selectively modulated by 5-HT_{1A} and 5-HT_{1B} sites respectively. Supported by NIDA grants DA-01642, DA-02396 and DA-05274.

SINGLE DOSE 8-OH-DPAT PRETREATMENT DOES NOT ALTER THE 5-HT RELEASE-INHIBITORY RESPONSE TO SUBSEQUENT 8-OH-DPAT CHALLENGE AS DETERMINED BY *IN VIVO* MICRODIALYSIS. <u>S. Hjorth</u>, Dept. of Pharmacology, Univ. of Göteborg, Box 33 031, S-400 33 Göteborg, SWEDEN

Brain 5-HT_{1A} receptors and -mechanisms have been implicated in anxiety and depression. Whereas there is an abundance of data on the acute effects of 5-HT_{1A} receptor agonists in different experimental models, very little is known about their subacute and chronic modes of action. The present study attempted to test the hypothesis that 5-HT_{1A} autoreceptors are desensitised by single pretreatment with 5-HT_{1A} agonists (Kennett *et al.* EJP 138, 53, 1987). Groups of rats were given a single injection of vehicle or the prototype 5-HT_{1A} agonist 8-OH-DPAT (0.025, 0.1 or 1.0 mg/kg, SC). About 24 h later an *in vivo* brain microdialysis probe was stereotaxically implanted (chloral hydrate anaesthesia) into the ventral hippocampus, which receives prominent 5-HT input from the brainstem raphé. Following a control period (2-3 h), to establish stable baseline output levels of 5-HT, the rats were challenged with 8-OH-DPAT at a sub-maximally effective, preferentially 5-HT_{1A} autoreceptor active, dose (0.025 mg/kg SC), and the measurements were continued for 2 h. The 8-OH-DPAT challenge decreased 5-HT release with a similar time-course in all of the pretreatment groups. Furthermore, there were no significant differences in the baseline output of 5-HT between the groups (60-70 fmoles/20 µl sample), neither was there any significant difference with regard to maximum release reduction (= 60 %), nor in the overall response to 8-OH-DPAT challenge (summed 5-HT output 0-2 h after drug). The data suggest that release-regulating 5-HT_{1A} autoreceptors remain responsive to agonist challenge 24 h after a single dose 8-OH-DPAT pretreatment.

ATTENUATED 5-HYDROXYTRYPTOPHAN (5-HTP) INDUCED RESPONSE SUPPRESSION FOLLOWING PRETREATMENT WITH A SELECTIVE 5-HT₂
RECEPTOR AGONIST (DOI) IN AN ANIMAL MODEL OF DEPRESSION.² RECEPTOR ACONIST (DOI) IN AN ANIMAL MODEL OF DEPRESSION.

E.A. Engleman, J.N. Hingtgen, J.M. Murphy, F.C. Zhou &
M.H. Aprison, Depts. Psychiat; Biochem; Psychol; & Anat;
Prog. Med. Neurobiol.; Inst. Psychiat. Res.; Indiana U.
Sch. Med. & Purdue Sch. Sci., Indianapolis, IN 46202
Integrating various types of neurobiological data with
clinical data, Aprison and Hingtgen formulated the
hypersensitive postsynaptic serotonin (5-HIT) theory of
depression. A behavioral model was developed in which
rats exhibit a period of coverant surpression after ID.

rats exhibit a period of operant suppression after IP administration of D,I-5-HTP. Subsequent studies suggest that this effect may be mediated through 5-HTP, receptor activation. Recently, IP injections of the 5-HTP, activation. Recently, IP injections of the 5-HI₂ agonist 1-(2,5-dimethoxy-4-iodophenyl)-2-aminopropane (DDI) have been shown to down regulate 5-HI₂ type receptors (Buckholtz et al., <u>Life Sci.</u>, 42:2439, 1988). In the current study, 24 hours after IP administration of 1.0 or 2.0 mg/kg DDI, mean 5-HIP (25 mg/kg) induced response suppression was reduced by 37 and 58%, response suppression was reduced by 37 and 58%, respectively, from baseline 5-HTP suppression values (p<0.05). In a related experiment, IP injection of DOI alone in small doses (0.5 mg/kg) induced response suppression similar to that observed with 25 mg/kg D,L-5-HTP. These results provide further evidence of 5-HT2 receptor involvement in 5-HTP induced behavioral suppression. (Indiana Dept. of Mental Health & AA03243).

353.5

EFFECTS OF SEROTONERGIC AGENTS ON THE SPONTANEOUS ACTIVITY OF NEURONS OF THE RAT DEEP CEREBELLAR NUCLEI. P.A. Cumming-Hood, J.C. Strahlendorf, and H.K. Strahlendorf. Depts. of Physiology and Neurology, Texas Tech University Health Sciences Center, Lubbock, TX 79430.

Superfusion and iontophoretic application of serotonin (5-HT) in the in-vitro cerebellar slice preparation from young adult male rats caused both excitation and inhibition of the spontaneous activity of neurons of the deep cerebellar nuclei (DCN). Selective agonists and antagonists for the 5-HT receptor subtypes known to exist in the DCN antagonists for the 5-HT receptor subtypes known to exist in the DCN (5-HT_{1A}, 5-HT_{1B} and 5-HT₂) were used to determine which subtype(s) might be mediating the effects noted. Iontophoretic application of 8-hydroxy-2-N-dipropylaminotetralin (8-OH-DPAT), a 5-HT_{1A} agonist, mimicked the inhibitory effect of iontophoretically applied 5-HT. This response, as well as 5-HT-induced inhibition, was blocked by superfusion of spipirone, a 5-HT_{1A} antagonist. 1-(2,5-dimethoxy-4-iodophenyl)-2-aminopropane (DOI), a 5-HT₂ agonist, caused inhibition of spontaneous activity when applied iontophoretically. Superfusion of ritanserin, a 5-HT₂ antagonist, attenuated this response. To test the hypothesis that the DOI-induced inhibition could be mediated through an interneuron, picrotoxin, a GABA (chorde chanpal) antagonist, applied iontophoretically and Inhibition could be mediated through an interneuton, piccoloxin, a GABA (chloride channel) antagonist, was applied iontophoretically and found to attenuate the response. These results indicate that the inhibitory response to 5-HT is mediated, in part, by the 5-HT_{1A} receptor and that DOI-induced inhibition may be mediated via a GABAergic Interneuron. Supported by NS 19296 and the Tx. Adv. Res. Prog. Grant 010674-020.

353.7

EFFECT OF GEPIRONE ON SOCIO-PSYCHOLOGICALLY INDUCED STOMACH LESIONS OF MICE IN THE COMMUNICATION BOX. C. Hara and N. Ogawa. Dept. of Pharmacology, Ehime Univ. Sch. of Med., Ehime 791-02, JAPAN.

791-02, JAPAN.

In the communication box, non-foot shocked mice (NFS) exposed to emotional responses of foot shocked mice (FS) 3-hr a day for 3 days (1.5 mA), developed stomach lesions with 100% incidence, and the stomach lesions were prevented by 5-HT1A related agents, bispirone (BSP), ipsapirone (IPS) and SM3997, similar to chlordiazepoxide (Hara, C., Jpn J. Pharmacol., 5(Suppl.):153P,1990). The present study examined effect of gepirone (GPR), a 5-HT1A partial agonist, on the stomach lesions. Male ICR mice (8 weeks old) were used. The experiment was started at 7:00 PM. GPR was daily given i.p. to the NFS mice for 3 days, 15 min before the experiment. The NFS mice were fasted after the experiment on the 2nd day. The FS mice were experiment. The NFS mice were lasted after the experiment on the 2nd day. The FS mice were exchanged to naive mice daily. After terminating the experiment, the NFS mice were sacrificed by ether and inspected for the stomach lesions by ether and hispected for the stomach restons visually. GPR (0.1-1.0 mg) prevented the stomach lesions. The preventing effects of GPR, BSP and IPS seemed to be more potent than SM3994. Therefore, the preventing effect may be based on the anxiolytic action.

MODIFICATION OF 8-OH-DPAT-INDUCED HYPOTHERMIA

MODIFICATION OF 8-OH-DPAT-INDUCED HYPOTHERMIA AFTER ACUTE OR SUBCHRONIC RITANSERIN TREATMENT. R. F. Kucharik*, S.M. White, J.A. Moyer. Wyeth-Ayerst Research, CN 8000, Princeton, NJ 08543-8000. The hypothermic response to 8-OH-DPAT is centrally mediated by 5-HT_{1A} receptors (Gudelsky, G.A., et al., Neuropharmacology 25:12, 1986) and is thought to be presynaptically mediated in the mouse (Goodwin et al., Neuropharmacology, 24:12, 1985). In this study the effects of acute and subchronic (3 days) administration of ritanserin a potent and selective 5-HT₂ receptor antagonist on ritanserin, a potent and selective 5-HT2 receptor antagonist, on 8-OH-DPAT-induced (0.5 mg/kg sc) hypothermia were studied in male CF-1 mice. Acute ritanserin (1 mg/kg ip) did not alter body temperature, but potentiated the hypothermic response elicited by 8-OH-DPAT. A higher dose of ritanserin (10 mg/kg ip) caused a is significant decrease in body temperature which was further decreased by 8-OH-DPAT. Twenty-four hours after a single dose treatment with ritanserin (1,3, 10,30 mg/kg ip), the magnitude of 8-OH-DPAT induced hypothermia was similar to controls in that ritanserin treatment neither potentiated nor attenuated 8-OH-DPAT-induced hypothermia. thermia. After subchronic administration of ritanserin (1,3,10, mg/kg ip), there was a significant attenuation of 8-OH-DPAT-induced hypothermia. The results of these studies suggest a possible interaction between 5-HT_{1A} and 5-HT₂ receptors. Additional studies will be conducted to characterize the selectivity of this interaction.

353.6

DISCRIMINATIVE STIMULUS EFFECTS OF THE 5-HT, AGONISTS RU DISCRIMINATIVE STIMULUS EFFECTS OF THE 5-HT₁ AGONISTS RU 24969 AND mCPP IN THE PIGEON. J.B. Hogan¹*. H.C. Holloway². and J.E. Barrett². ¹bept. of Psychology, Univ. of Maryland at College Park, College Park, MD 20742 and ²Dept. of Psychiatry, Uniformed Services Univ. of the Health Sciences, Bethesda, Maryland 20814-4799

The present study attempts to characterize the discriminative stimulus effects of RU 24969, a 5-HT_{IA/1B}

agonist and mCPP, a $5\text{-HT}_{1B/1C}$ agonist in the pigeon. White Carneau pigeons were trained to discriminate drug from saline in a 2 key operant paradigm, where responding on the right key was reinforced following drug administration, and responding on the left key was reinforced after saline administration. One group was trained to discriminate 1.7 mg/kg RU 24969 from saline, and a second group was trained mg/kg kU 24969 from saline, and a second group was trained to discriminate 3.0 mg/kg mCPP from saline. Generalization to the RU 24969 stimulus occurred with 8-OH-DPAT and with metergoline, but not with TFMPP, mCPP, pirenperone, or fenfluramine. Generalization to the mCPP stimulus occurred with MCPP stimulus o with TFMPP and ferfluramine, but not with RU 24969, 8-OH-DPAT, or pirenperone. In addition, the stimulus properties of RU 24969 were blocked by prior administration of the putative 5-HT antagonist NAN-190. In view of the apparent absence of 5-HT₁₈ receptors in pigeon brain (Waeber et al, N. Schmied., 1989 <u>340</u>: 486-494.) these findings suggest that pigeons respond to the stimulus effects of the 5-HT_{1A} component of RU 24969 and the 5-HT_{1C} component of mCPP.

SEROTONIN AND THYROTROPIN RELEASING HORMONE INTERACTIONS ON RAT SPINAL MOTONEURONS IN SITU. D.A.Jackson and S.R.White. Dept. of VCAPP, Washington State Univ., Pullman, WA 99164.

Responses of ventral horn cells to serotonin (5HT) are enhanced by prior application of thyrotropin releasing hormone (TRH) in the spinal cord slice preparation (Kow and Pfaff, Soc. Neurosci. Abst., 1989, 15:365.8). In this study we used microiontophoretic techniques to investigate 5HT/TRH interactions on spinal motoneurons in urethane-anesthetized control rats and in rats with chronic sciatic axotomies to test whether damaged motoneurons are more responsive to TRH than are controls.

Both short-term (3-7 day) and long-term (10-19 day) sciatic axotomy significantly prolonged the enhancing effect of TRH (5 mg/kg, i.v.) on MSR amplitude compared to control animals. Furthermore, long-term axotomy had a significantly greater effect than short-term axotomy. Glutamate-evoked motoneuron firing was enhanced by microiontophoretically applied 5HT for all motoneurons tested (axotomized and control rats). However, TRH applied microiontophoretically, either prior to or simultaneously with the 5HT application, failed to enhance the 5HT response in motoneurons from control or from chonic axotomized animals. These results suggest that responses of motoneurons to TRH in the slice preparation may be altered compared to in situ motoneurons. In addition, prolongation of TRH effects on MSR amplitude in chronic sciatic axotomized rats does not appear to be mediated by a direct effect of TRH on the motoneurons.

354.3

EFFECTS OF DOPAMINE DEPLETION ON GABA CONTENT IN THE PITUITARY PARS INTERMEDIA. H. Bouman, L. Bauce, B.A. MacVicar, O.J. Pittman. Neuroscience Research Group, University of Calgary, Calgary, Canada.

The pars intermedia (PI) of the rat pituitary consists of

melanotrophs that receive colocalized inhibitory dopaminergic and GABAergic inputs descending through the stalk from the hypothalamus. In order to determine the extent of dopamine (DA) and GABA colocalization, we have tried to selectively deplete pituitary DA stores and evaluate the consequences of this intervention on GABA concentrations. Rats received either two intracerebral ventricular (ICV) administrations, 24 hours apart, of 6-OHDA or 6-OHDA was directly injected into the pituitary. HPLC measurements of pituitary and hypothalamic DA and GABA levels were made 1 week later. ICV injections did not alter pituitary DA levels, while intra-pituitary injections depleted 96% of pituitary DA, and 61% of hypothalamic DA. There were no changes in GABA levels in either brain area. Therefore pituitary DA can be depleted following intra-pituitary 6-OHDA injections, but this is not accompanied by an equivalent drop in GABA. DA and GABA may not be significantly colocalized in the rat PI. Alternatively, large quantities of GABA in pituicytes or nerve fibers of the posterior pituitary may obscure possible changes in GABA levels in nerve fibers innervating the PI. Supported by MRC. H. Bouman is a PMAC student

EVALUATION OF THE INTERACTIONS OF SEROTONERGIC LIGANDS WITH MU, KAPPA, & DELTA OPIATE BINDING SITES. P.J. Monroe¹, S.E. Perschke^{*2}, T. Crisp², & D.J. Smith³, Nova Pharmaceutical Corporation¹, Baltimore, MD 21224, Northwestern Ohio Universities², Rootstown, Ohio 44272, and West Virginia University³, Morgantown, WV 26506.

Serotonergic receptor antagonists, e.g. methysergide and

Serotonergic receptor antagonists, e.g. methysergide and ritanserin, attenuate the analgesic effect of spinally administered opiates, suggesting an interaction between opiate and serotonergic neuronal components (Crisp and Smith, 1989). However, spiroxatrine, a serotonergic agent with partial agonist properties, has been shown to interact directly with opiate binding sites (Leysen, et al., 1977). The present study was undertaken to determine if the effect of these drugs on opiate-induced analgesia could be explained by a direct effect on opiate receptors.

Fourteen serotonergic agents were evaluated for their abilities to interact with opiate receptor subtypes labelled by [3H]-DAGO (mu), [3H]-DADLE (delta), and [3H]-U89593 (kappa). Consistent with previous results, spiroxatrine was found to interact equipotently with all three opiate subtypes, yielding Ki values of approx. 110 nM. Of the other compounds tested, only the 5HT2 selective agent, ritanserin, was found to interact with opiate sites, yielding Ki values of 10 (delta), 21 (mu), and 5 uM (kappa). These results suggest that spiroxatrine and ritanserin may act at opiate sites to inhibit opiate-induced analgesia.

RELATIONSHIP OF GABA NEURONS TO RETICULO—AND RAPHE-SPINAL NEURONS IN THE MEDULLARY RETICULAR FORMATION. E. Rodriguez-Veiga, C. Holmes and B.E. Jones. Fac. Veterinary Med., U. C. M., Madrid, Spain and Montreal Neurological Inst., McGill Univ., Montreal, Quebec, Canada H3A 2B4.

Multiple GABA neurons have been identified within the medullary reticular formation (Mugnaini & Oertel, 1985) but the projections of these cells have not been defined. In order to determine if GABA neurons, like reticular and serotonin raphe neurons, give rise to long projections to the spinal cord, wheat germ agglutinin conjugated to horseradish peroxidase (WGA-HRP) was injected into the cervical cord of the rat and the tissue processed for HRP histochemistry (with diaminobenzidine, DAB, and/or tetramethyl benzidine, TMB, enhanced with cobalt) and immunohistochemistry for glutamic acid decarboxylase (GAD) and serotonin by the peroxidase-antiperoxidase (PAP) technique (using DAB). Large numbers of large reticular neurons and serotonin raphe neurons were retrogradely labeled from the spinal cord. These neurons were commonly surrounded by prominent GAD-immunoreactive varicosities. Although GAD-immunoreactive neurons were interspersed among these cells, very few were retrogradely labeled from the cord. It was concluded that the CABA neurons in the medullary reticular formation lie in amongst reticular and serotonin raphe spinal projection neurons and may influence the spinal cord primarily by innervating these neurons.

SIMULTANEOUS MEASUREMENT OF GABA AND 5-HT RELEASE IN DORSAL RAPHE OF FREELY-MOVING RATS: PHYSIOLOGICAL AND PHARMACOLOGICAL STUDIES.

D.W. Gallager, T.D. Hernandez, G.M. Anderson and M.J. During Depts. of Psychiatry, Laboratory Medicine and Neurosurgery, Yale Univ. Sch. Med., New Haven, CT 06508.

Dorsal raphe neurons exhibit significant subsensitvity to GABA, but not 5-HT, following amygdala kindling (Hernandez et al, Brain Res., 1990). Indeed, this long term change persists for at least 3 months after the last kindled seizure (Hernandez et al., Neurosci. Abstr., 1990). The mechanism by which kindling results in this persistent change in GABA sensitivity remains unclear. It is possible that subsensitivity is due to increased release of GABA in response to kindled seizures, since serotonergic neurons of the dorsal raphe also exhibit significant subsensitivity to GABA following chronic exposure to diazepam, which potentiates the actions of GABA. We have therefore developed a microdialysis system to quantitate both GABA and 5-HT release in the dorsal raphe of unrestrained, awake rats. Basal GABA levels ranged from 2-10 nM and 5-HT levels ranged from 0.5-5.0 nM in the dialysate (1 ul/min). Both GABA and 5-HT increased 10 to 20 fold with 60 mM K+depolarization. During perfusion of this nucleus with the GABA uptake inhibitor, nipecotic acid, GABA levels increased approximately 8 fold, whereas 5-HT decreased to unmeasurable levels. We will present data on the characterization of basal and amygdala kindled seizure-induced release of several neurotransmitters (including GABA and 5-HT) and their interaction within dorsal raphe in response to pharmacological manipulations (K+depolarization, nipecotic acid and the 5-HT uptake inhibitor, fluoxetine).

INTERACTIONS OF ADRENERGIC LICANDS WITH MU, KAPPA, AND DELTA OPIATE BINDING SITES. S.E. Perschke*1, P.J. Monroe¹, and D.J. Smith². Nova Pharmaceutical Corp. ¹, Baltimore, MD 21224 and West Virginia Univ. ², Morgantown, WV 26506.

Adrenergic neuronal systems appear to play a modulatory

adrenergic hedronal systems appear to play a modulatory role in nociception in the spinal cord. Intrathecal adrenergic agonists produce analgesia which is inhibited by adrenergic antagonists. Futhermore, opiate-induced analgesia is sensitive to adrenergic antagonists, suggesting a noradrenergic-opiate neuronal interaction may also occur. On the other hand, adrenergic drugs may be capable of directly interacting at opiate sites. Thus, the present study was undertaken to examine the abilities of several adrenergic agents to interact with opiate receptor subtypes labelled by [3H]-DAGO (mu), [3H]-DADLE (delta), and [3H]-U69593 (kappa).

Prazosin and WB4101 (Alpha-1) were equipotent in competing for all three opiate subtypes, yielding Ki values near 10 uM. Clonidine and yohimbine (alpha-2) were approximately 4 fold less potent. Phentolamine (non-selective) was most potent, competing for binding at all three sites with Ki values near 1 uM. Beta adrenergic agents were ineffective. Effective spinal concentrations of adrenergic agents used in studies of pain modulation fall in the range of 1 to 100 uM, assuming equal distribution within the injected compartment. Thus, it may be important to reconsider the involvement of adrenergic systems in spinal or opiate-induced analgesia.

A MU AGONIST BUT NOT A KAPPA AGONIST SUBSTITUTES FOR A DOPAMINE D2 AGONIST IN A QUINPIROLE VS SALINE DRUG DISCRIMINATION. D.V. Widzowski, S.C. Johnson and D.A. Cory-Slechta. Environ. Health Sci. Center and Program in Neuroscience. School of Med. and Dent., Univ. of Rochester, Rochester, N.Y. 14642.

Neurotransmitter systems in the CNS are thought to interact with one another in a number of ways, both postsynaptically and presynaptically. In vivo and synaptosomal studies have shown that mu opioid agoniets enhance dopamine (DA) release, while kappa opioid agonists decrease it. If such interactions have functional properties, then mu agonists, but not kappa agonists would be expected to substitute for the D2 agonist quinpirole in a drug discrimination (DD) procedure. Rats were trained to discriminate between an LP. injection of 0.050 mg/kg of the DA D2 agonist quinpirole HCl and saline in a standard two lever DD. Baseline quinpirole responding under training conditions was > 90% following quinpirole injections and < 10% for saline injections. Quinpirole responding was clearly mediated by the D2 receptor since haloperidol, but not the D1 antagonist SCH 23399 blocked drug-lever responding. Moreover, drug responding generalized to apomorphine (0.25 mg/kg) but not to the selective D1 agonist SKF 38393 (6 mg/kg). Morphine (3 mg/kg) also engendered quinpirole responding, with the effect dependent on preinjection time, increasing from 40% drug-lever responding at 15" preinjection to 80% at 60". This time course data parallels in vivo dialysis studies of the time course of morphine-induced DA release. Naloxone completely blocked the morphine effect. Haloperidol partially blocked the effect, suggesting its mediation via DA D2 receptors. In contrast, the kappa agonist U-50.488 did not engender quinpirole responding at any of the doses (2 and 4 mg/kg) nor preinjection times (15 to 60 minutes) tested. These results support a role for mu agonists in modulating the behavioral functions of dopaminergic systems and suggest that d

EFFECTS OF NEUROTENSIN (NT) ON MIDBRAIN DOPAMINE (DA) NEURONS: ARE THEY MEDIATED BY NT-DA COMPLEXATION? W. -X, Shi and B.S. Bunney. Depts. of Psychiatry and Pharmacology, Yale Univ. Sch. of Med., New Haven, CT 06510.

Effects of NT on middrain DA cells were studied in brain slices containing the ventral tegmental area and the substantia nigra. The spontaneous activity of DA cells was recorded extracellularly. At low concentrations (0.2-10 nM), slice perfusion with NT attenuated the inhibition of DA cells induced by DA without a pertusion with N1 attenuated the inhibition of DA ceits induced by DA without a significant change in basal firing rate. At higher concentrations (>10 mM), NT consistently caused an increase in firing rate. At even higher concentrations (>100 nM), NT caused a cessation of activity. Whether this inhibitory effect of NT is due to depolarization inactivation or a toxic effect remains to be determined.

NT has been shown to bind with DA. To determine if the effects of NT are

NT has been shown to bind with DA. To determine if the effects of NT are mediated by the formation of a NT-DA complex, several NT analogues were studied. AT (8-13) which is active in binding with both NT receptors and DA, mimicked the effects of native NT. Neuromedin N, a peptide that competes with NT for the same receptor and does not binds with DA, also mimicked the effects of NT on DA cells. However, NT (1-11), a N-terminal fragment of NT which is inactive in competing for NT receptors but binds with DA, was found to be ineffective. In addition, it was found that the excitatory effect of NT on DA cells was largely unchanged in the presence of DA receptor blockade by sulpiride. These results suggest that formation of a NT-DA complex may not account for the effects of NT on DA cells. When combined with the fact that there is a high density of NT receptors on DA cells, our data support the suggestion that the observed effects of NT on DA neurons are most likely to be mediated by an activation of NT receptors on DA cells.

EFFECTS OF DOPAMINE AGONISTS ON EXCITATORY INPUTS TO NUCLEUS ACCUMBENS FROM THE AMYGDALA: MODULATORY ACTIONS Mogenson. Dept. of Physiology, Univ. of Western Ontario, London, Ontario, Canada N6A 5C1.

It has been demonstrated that dopamine (DA) reduces

excitatory responses of neurons of the nucleus accumbens to single-pulse stimulation of the basolateral awygdala (Yim & Mogenson, 1982). It was also reported that cholesytokinin (CCK) co-exists (Kalivas & Nemeroff, 1988) and interacts (Yim & Mogenson, 1990) with DA in accumbens neurons. In the present study the interaction of CCK and DA was investigated by using CCK and DA

The effects of iontophoretically application of CCK, DA, dopamine $\rm D_1$ and/or $\rm D_2$ receptor agonists (SKF-38393 and LY-171555 respectively) were compared. The application of DA, SKF-38393, LY-171555 and LY-171555 + SKF-38393 significantly attenuated the excitatory responses of accumbens neurons to electrical stimulation of basolateral amygdala whereas saline had little or no effect. The application of CCK reversed these attenuating effects of DA, LY-171555 and LY-171555 + SKF-38393.

These observations confirm and extend the results of recent experiments which demonstrated that CCK reduces the modulatory action of DA on excitatory inputs to $\,$ accumbens neurons. (Supported by MRC of Canada)

CENTRAL ANGIOTENSIN II. OCCURRENCE IN CATECHOLAMINE NEURONS OF THE MEDULLA OBLONGATA AND INTERACTIONS WITH NEUROPEPTIDE Y RECEPTORS IN CARDIOVASCULAR AREAS. <u>L.A.</u> Aguirre, K. Fuxe, R. Coveñas*, D. Ganten*, M. Goldstein and L.F. Agnait*. Dept. Histology and Neurobiology. Karolinska Institut. 104 01 Stockholm. Sweden.

High densities of angiotensin II (ANG II) immunoreactive (IR) nerve terminal networks codistribute with high densities of noradrenaline (NA), adrenaline (A) and networks Constitute with implications or inoradientamile (NA), auto-infinite (A) and neuropeptide Y (NPY) nerve terminal networks in cardiovascular areas. We have therefore studied the possible coexistence of ANG II/tyroxine hydroxylase (TH) immunoreactivities (IR) in the medulla oblongata. Double immunolabelling techniques using a standard immunofluorescence protocol (Rabbit-ANG II antiserum techniques using a standard immunoritubrescence protocol (Rabbit-Aino II antiserum) Denise and mouse monoclonal TH antibodies) were employed to demonstrated AnG II/catecholamines costoring neurons. In the receptor autoradiographical experiments coronal cryostate sections from the region of the dorsal medulla were used together with the radioligand 1251-NPY 1-36 (0.5 nM) (Amersham, U.K.), which was found to label NPY receptors of the Y1 type. Incubation with ANG II (10 nM) was made (Peninsula Lab., U.S.A). Functional (cardiovascular) studies were also performed (Peninsula Lab., U.S.A). Functional (cardiovascular) studies were also performed using intracisternal injections of ANG II (3 nmol/10 µl and 10 nmol/10 µl) and porcine NPY (pNPY) (Peninsula Lab., U.S.A.) (7.5 pmol/10 µl and 75 pmol/10 µl) in the α-chloralose anaesthetized rat. In the NA A1 area 20-30 % of the TH IR nerve cell bodies were ANG II IR and in the A C1 area 5-40 % of the TH IR nerve cell bodies displayed ANG II IR. The autoradiographical study showed that ANG II significantly increased the 125I-pNPY 1-36 binding within the dorsal strip (dorsal cardiovascular region of the nucleus tractus solitarius) with a trend for an increase of the 125I-pNPY 1-36 binding in the area postrema. A threshold dose of ANG II (3 nmol) not only counteracted the vasodepressor action of an ED50 dose of pNPY 1-36, but also led to the development of a highly significant vasopressor action of ANG II compared with the control group. These results can be explained in the basis of the existence of true ANG II/NPY Y1 receptor-receptor interaction, which may take place at the intravantic level. take place at the intrasynaptic level.

EFFECT OF AMFONELIC ACID ON INCREASED EXTRACELLULAR DOPAC IN THE NUCLEUS ACCUMBENS AND THE STRIATUM INDUCED BY TYPICAL AND ATYPICAL NEUROLEPTICS AND NEUROTENSIN. $\underline{\mathbf{R}}$. Rivest, F.B. Jolicoeur and C.A. Marsden 1*, Dept. of Psychiatry, Fac. of Med., Univ. of Sherbrooke, Canada JIH-5N4 and 1 Dept. of Physiol, and Pharmacol., Med. Sch., Queen's Medical Centre, Nottingham NG7 2UH, UK.

Many central effects produced by neurotensin (NT) resemble those of atypical neuroleptics (Jolicoeur et al., Hand. Neurochem., 8:95, 1985). A proposed model for discrimination between neuroleptics suggested that amfonelic acid potentiates the ex vivo increase of striatal DOPAC level induced by typical but not atypical neuroleptics (Waldmeir et al., Biochem. Pharm. 34:39, 1985). In the present study, we have examined whether amfonelic acid can be used to discriminate between both class of neuroleptics and NT in vivo by monitoring extracellular DOPAC in the nucleus accumbens and the striatum using differential pulse voltammetry with carbon fibre microelectrodes. Amfonelic acid potentiated the increase of extracellular level of DOPAC induced by typical neuroleptics in both the nucleus accumbens and the striatum but the effect was much greater in the striatum. However, while clozapine, thioridazine and NT also significantly increased the extracellular level of DOPAC in both regions, the administration of amfonelic acid 5 min before totally prevented the rise in DOPAC induced by the atypical neuroleptics and NT. In conclusion, the *in vivo* data confirm that amfonelic acid is a valuable tool to neurochemically differentiate potential typical from atypical neuroleptics. Using this model, it appears that the atypical neuroleptics and NT produced similar in vivo neurochemical effects. We thank the Wellcome Trust, MRC and FCAR for financial support.

GABAERGIC INNERVATION OF PEPTIDERGIC NEURONS IN T. Lantost, T.F. Freundt, and G. Szabo. *Institute of Biochemistry, Biological Research Center, Hungarian Academy of Sciences, Szeged, Hungary 6701, †Department of Functional Neuroanatomy, Institute of Experimental Medicine, H-1450 Budapest, Hungary; †Neuromorphology Laboratory, Semmelweis Medical University, Budapest, H-1094, Hungary.

Since the arcuate nucleus plays an important role in several neuroendocrine functions, our present aim was to elucidate the GABAergic afferentation of peptidergic (somatostatin, growth hormone releasing hormone, beta endorphin, neuropeptide Y and galanin) neurones using a new antiserum raised against a chemically modified 62 kd form of glutamic acid decarboxylase (GAD). Light and electron microscopic dual labeling immunocytochemical methods were used in this study. At the light microscopic level close apposition of GAD immunoreactive axons with the above mentioned peptidecontaining neurons were observed. At the ultrastructural level GADimmunoreactive axon terminals formed symmetric synaptic junctions with the peptidergic neurons. Based upon the present results a general GABAergic inhibition of peptidergic neurons of the arcuate nucleus may be assumed.

NEUROPEPTIDES MODULATE THE RELEASE OF ENDOGENOUS AMINO ACIDS FROM THE RAT SPINAL DORSAL HORN. I. Kangrga, G. Pavlaković and M. Randic. Dept. of Vet. Physiol. and Pharmacol., Iowa State University, Ames, IA 50011.

Paviagooic and M. Rangic. Dept. of Vet. Physiol. and Pharmacol., Iowa State University, Ames, IA 50011.

Although the co-existence of substance P (SP) and glutamate (Glut) in some small dorsal root ganglion (DRG) neurons has been reported, and also of SP, neurokinin A (NKA) and calcitonin gene-related peptide (CGRP) in a proportion of DRG cells, the significance of this phenomenon for primary afferent neurotransmission is not well understood. The effects of SP, NKA, CGRP and opioid peptide (Tyr-D-Ala-Gly-MePhe-Gly-ol-enkephalin, DAGO) on the dorsal root (DR) stimulation-evoked release of ten endogenous amino acids have been investigated using the rat spinal cord slice-DRG preparation and HPLC with fluorimetric detection. Activation of the low-threshold Primary afferent fibers (PAF) resulted in a 2-fold increase in the basal efflux of aspartate (Asp) and in a smaller increase in Glut and serine. Activation of low-and high-threshold PAF resulted in a 2 to 5-fold increase in the basal efflux of aspartate (Asp) and smaller increase of glycine, CABA, alanine and threonine. SP (0.1-1.0 µM) and CGRP (0.1 µM) increased the electrically-elicited release of Glut and Asp. Unlike the response to DR-electrical stimulation that was usually limited to the 5-min period, the SP-response was prolonged lasting 10-15 min. The CGRP-response was prolonged lasting 10-15 min. The CGRP-response was oscillatory in character and lasted up to 30 min. DAGO, reduced or abolished the electrically-evoked release of Glut and Asp. The modulation of the release of Glut and py tachykinins, CCRP and opioid peptides acting at the µ receptor subtype may have important physiological implications for regulating the strength of synaptic connnections in the spinal dorsal horn. (Supported by the NIH and NSF).

CHRONIC D1-DOPAMINE RECEPTOR BLOCKADE INCREASES D1 MEDIATED ACETYLCHOLINE (ACh) RELEASE FROM RAT STRIATAL (S) SLICES. P. Butkerait, H.Y. Wang and E. Friedman, Depts. of Pharmacology and Psychiatry, Med. Coll. of Pennsylvania, Philadelphia, PA, 19129.

The effects of D1-dopamine receptor agonists on S cholinergic neurons were studied by measuring K*-evoked [°H]ACh efflux from superfused rat striatal slices pre-loaded with [°H]choline. Three D1 receptor agonists including SKF38393 (1-phenyl-7,8-dihydroxy-2,3,4,5-tetrahydro-1H-3-benzazepine HCI), all produced dose dependent (0.1-10µM) increases (24-59%) in K*-evoked [°H]ACh release from rat S slices. The increase in evoked ACh release by SKF38393 was blocked by 1µM of the D1 antagonist SCH23390 (8-chloro-2,3,4,5-tetrahydro-3-methyl-5-phenyl-1H-3-benzazepin-7-ol hemimaleate). In contrast, quinpirole and carbachol produced dose dependent (0.1-10µM) decreases (31-60% and 15-50%, respectively) in evoked ACh release. To study the regulation of D1 receptors mediating S K*-evoked ACh release, rats were treated for 5 months with 0.1mg/kg/day SCH23390. This treatment selectively increased SKF38393 mediated S ACh release without altering quinpirole or carbachol mediated S ACh release. These results provide evidence that chronic SCH23390 treatment produces functional sensitization of D1 receptors mediating S K*-evoked ACh release.

DRUG-INDUCED MODIFICATION OF ETHANOL'S HYPOTHERMIC EFFECTS IN TWO LINES OF RATS DIFFERING IN CHOLINERGIC SENSITIVITY. Amir H. Rezvani, David H. Overstreet, and David S. Janowsky. Center for Alcohol Studies and the Dept. of Psychiatry Univ. of North Carolina School of Medicine, Chapel Hill, NC.

In an attempt to understand the mechanisms underlying the differential hypothermic effects of ethanol in the Flinders Sensitive (FSL) and Flinders Resistant (FRL) Lines of rats, animals were pretreated with drugs having relatively specific actions on particular neurotransmitters. Neither scopolamine (1 m/kg), bicuculline (2 mg/kg), haloperidol (1 mg/kg, pindolol (1 mg/kg), nor idazoxan (3 mg/kg), altered ethanol-induced hypothermia in either line. Calcium channel antagonists verapamil (10 mg/kg) potentiated hypothermia to a similar degree in both lines, while nicardipine (10 mg/kg) attenuated it. Mecamylamine (5 mg/kg), dramatically potentiated ethanol-induced hypothermia in FSL rats. However, this potentiation was not seen with hexamethonium (5 mg/kg). Consequently, central nicotinic mechanisms might be involved in the differential ethanol-induced hypothermia.

ne involved in the differential ethanol-induced hypothermia. In conclusion, although several drugs were able to modify the hypothermic effects of ethanol, no drug tested was able to reduce the differential hypothermic effects of ethanol in the FSL and FRL rats. Therefore, the mechanisms underlying the significantly greater hypothermia induced by ethanol in the FSL rats remain to be determined. Supported in part by Grant No. 8802 from NCARA to A.H.R.

MODULATION OF EXCITATORY AMINO ACID-INDUCED CURRENTS BY TACHYKININS AND OPIOID PEPTIDES IN RAT SPINAL CORD NEURONS. H. Hećimović, K. I. Rusin*, P. D. Ryu and M. Randić. Dept. of Vet. Physiol. Pharmacol., Iowa State University, Ames, IA 50011.

The whole-cell patch-clamp technique was used to examine the effects of substance P (SP) neurokinin A (NKA) and opioid peptides (D-Ala-, D-Leu-enkephalinamide, DALEA; Tyr-D-Ala-Gly-MePhe-Gly-ol-enkephalinamide, DALEA; Tyr-D-Ala-Gly-MePhe-Gly-ol-enkephalin DAGO) on excitatory amino acid-induced currents in acutely dissociated (enzymatically and/or mechanically) rat spinal dorsal horn neurons (L.I-IV). In about half of tested cells, SP (10-10-10-10) by itself induced an inward current frequently accompanied by an increase in membrane current noise. When applied simultaneously with, or prior to L.glutamate (Glut), SP and NKA enhanced Glut-induced current (184 ± 37%, n-23) in 65% of the cells. The inward currents induced by N-methyl-D-aspartate (NMDA, 30-300 µM) and quisqualate (QA, 0.3-10 µM) were also potentiated by tachykinins. Both transient and sustained components of the NMDA and QA responses were augmented and the effect lasted up to 1 hour. NMDA-induced current, however, was frequently depressed during application of SP (0.2-20 nM).
Furthermore the fast, but not the sustained component of the response to QA was enhanced by DALEA (2-200 nM) in 11 cells and reduced in 3 cells. The transient components of the inward currents induced by NNDA and Glut were decreased by DAGO (10-100 nM) in 6 cells and increased in 2 cells. These results suggest that post-synaptic mechanisms of action of tachykinins and opioid peptides may contribute to the regulation of the glutamate-mediated transmission in the rat spinal dorsal horn. (Support by the NIH and NSF).

EFFECTS OF ACETYLCHOLINE ON CORTICAL AND HYPOTHALAMIC RELEASE OF CORTICOTROPIN RELEASING HORMONE (CRH) IN-VITRO. Y. Tizabi and A.E. Calogero*. Howard Univ. Dept. of Pharm., Wash., D.C 20059 and DEB, NICHD, NIH, Bethesda, MD 20892.

Alzheimer's disease (AD) is associated with a

Alzheimer's disease (AD) is associated with a reduction in cholinergic markers and CRH levels, but an up-regulation of CRH receptors in the cerebral cortex. There are suggestions that central CRH and cholinergic systems interact. To gain an insight into this interaction, we measured the in-vitro release of immunoreactive CRH (iCRH) from frontal, parietal, temporal and occipital cortex and from the hypothalamus in response to a challenge with varying acetylcholine (ACh) concentrations or KCL. KCL-stimulated iCRH release from the hypothalamus was approxiately 3-fold higher than in cortical tissues. Both 1 or 10 nM concentrations of ACh significantly inhibited iCRH secretion from the frontal cortex (20-26%). InM ACh also significantly inhibited iCRH secretion from the parietal cortex (32%). Other cortical areas were not affected. In contrast, hypothalamic release of iCRH was significantly increased by both concentrations of ACh (26-36%). These data indicate differential regulation of CRH release from hypothalamic and cortical tissues under ACh stimulation. The inhibitory effect of ACh on cortical CRH release could have important implication in neurodegenerative disorders.

354.18

MODULATION OF TRANSMITTER RESPONSES BY VERY LOW CONCENTRATIONS OF ACETYLCHOLINE AND GABA. S. N. ALYKAPELYAM* and D. O. Carpenter, Wadsworth Labs, NYS Dept. of Health and School of Public Health, Albany, NY 12201.

We have found that extremely low concentrations of both acetylcholine and GABA alter the sensitivity of <u>Aplysia</u> neurons to these same substances applied at the much higher concentrations necessary to elicit voltage and conductance changes. We used acetylcholine at $10^{-5} \rm M$ and GABA at $10^{-4} \rm M$ to elicit Cl-dependent conductance increase responses. When acetylcholine was bath perfused at concentrations between 10⁻¹⁴ and 10⁻⁸M (concentrations at which there were no direct effects on electrical characteristics of the neurons), the responses to GABA were reduced in all of 53 neurons studied. The average reduction was about 30% but in 7 neurons the responses were abolished. A similar effect of low concentrations of acetylcholine was observed on responses to $10^{-5} \rm M$ acetylcholine. The effect required about 10 min of acetylcholine perfusion to reach maximum, and was abolished by cooling. The threshold concentration varied in different neurons. Low concentrations of GABA $(10^{-12}$ to 10-8M) caused an increase to an average of 130% of control in the response to both acetylcholine and GABA in approximately 65% of neurons studied. This effect had a similar time course. These observations suggest that these conventional neurotransmitters have modulatory as well as direct transmitter actions.

DIHYDROPYRIDINES ALTER THE INHIBITORY ACTION OF ADENOSINE IN THE RAT HIPPOCAMPAL SLICE.

J.T.Bartrup*and T.W.Stone. Department of Pharmacology, University of Glasgow, G12 8QQ. U.K.

An electrophysiological approach has been used to determine the effect of dihydropyridines (DHP) on adenosine inhibition of synapatic transmission.

Orthodromically evoked population potentials were recorded from the CA1 of rat hippocampal slices. The percentage change in potential size was determined from

chart records recorded via a digital storage oscilloscope. The inhibitory action of adenosine and its analogues was determined in the presence of a number of DHPs. Nifedipine $(1-10\mu\text{M})$ significantly potentiated the inhibition by adenosine (50 μM), increasing it from 58.4 \pm 4.87% to 93.1±2.89% at 10 μ M nifedipine (mean ± sem n=10) contrast the action of 2-chloroadenosine and other analogues was attenuated in a dose dependent manner, the percentage inhibition by 2-chloroadenosine (0.5µM) being reduced from 57.5±3.63% to 21.9±3.36% at 10µM nifedipine (n=16). Similar effects were shown by the DHP agonist Bay K8644 but not by nimodipine or nitrendipine. The DHPs on their own had no effect on the population potential

Dipyridamole (10 μM) reversed the potentiating effect of nifedipine on adenosine to an antagonism. The results are consistent with uptake and binding studies showing the ability of DHPs to displace ligands from the transporter and receptor sites.

IN VIVO ELECTROCHEMICAL INVESTIGATION OF ASCORBIC ACID DYNAMICS IN RAT BRAIN. Jon Cammack, Behnam Ghasemzadeh, and R.N. Adams. Dept. of Pharmacology, University of Kansas, Lawrence KS, 66045.

The function(s) of Ascorbic Acid (AA) in the CNS has been an enigma for years, though a variety of roles have been ascribed for this essential vitamin. to investigate specific release of AA in brain as a result of various pharmacological manipulations. In vivo electrochemistry, using carbon fiber electrodes with discrete parameters that allows selective detection of AA without any interferences from other oxidizable compounds, was used.

Ascorbic acid oxidase (AAO), was injected into different brain nuclei after attaining stable baselines, the difference between pre- and post-AAO representing basal values. These results, in different regions, are in contrast to reported microdialysis figures. Because of the facile auto-oxidation of AA in solution, we believe our values more accurately describe resting, basal concentra-tions. Also, various stimulations, such as glutamate infusions and amphetamine injections were performed. These gave rise to AA signals in established areas such as caudate nucleus, as well as regions not previously studied, such as thalamus. The amphetamine induced AA signal in the thalamus may point to a novel function of this agent. Further work in this area should help to elucidate ascorbate's role in the CNS.

TRANSMITTERS IN INVERTEBRATES IV

PROCTOLINERGIC AND DOPAMINERGIC MODULATION OF A CRUSTACEAN SEXUAL BEHAVIOR: IMMUNOCYTOCHEMICAL AND PHYSIOLOGICAL EVIDENCE Debbie Wood, Charles D. Derby, Georgia State University (SPON: M.-N. Girardot), M.-N. Girardot, BMD

The male blue crab produces a sterotyped posture and rhythmic behavior in response to a sex pheromone produced by the female. Bioassays of neuromodulators have shown the monoamine dopamine and the neuropeptide proctolin are capable of eliciting the postural and rhythmic behavioral components respectively. Proctolin-like and dopamine-like immunoreactivity has been shown in mature male and female crabs. Comparisons across gender, sexual maturity, and hormonal status groups reveal differential behavioral responses to these modulators. We are currently investiga-ting these differences anatomically and physiologically to localize elements of the motor system important to the production of the mature male behavior.

PROCTOLIN IMMUNOREACTIVITY IN CRAYFISH CNS OCCURS IN REGIONS THAT CONTAIN SWIMMERET COMMAND NEURONS. L.D. Acevedo, W.M. Hall* and B. Mulloney. Zoology Dept, Univ. of California, Davis, CA 95616.

Five command axons triggering swimmeret motor pattern generation in crayfish occur in specific locations in the crayfish abdominal connectives, and project to each abdominal ganglion (Wiersma, C.A.G., Ikeda, K., Comp. Biochem. Physiol., 12:509, 1964). The neuropeptide proctolin mimics stimulation of these command neurons (Mulloney, B. et al., J. Neurophysiol. 58:584, 1987; Acevedo, L., UCD Thesis, 1990). To test the hypothesis that these neurons use proctolin as a transmitter, we used a Neurophysiol. 58:584, 1987; Acevedo, L., UCD Thesis, 1990). To test the hypothesis that these neurons use proctolin as a transmitter, we used a new affinity-purified proctolin antiserum to trace the projections of proctolinergic neurons in abdominal connectives, and in the core of abdominal ganglia. After visualizing the antibody with an HRP-conjugated secondary antibody and DAB, abdominal ganglia were osmicated, embedded in plastic, and sectioned.

Transverse sections of connectives revealed proctolinerigic axons in regions where the command neurons are found. Horizontal sections of ganglia revealed proctolinergic axons in all longitudinal tracts. Because command neurons project in specific tracts, we traced the proctolinergic axons in these tracts to see whether they branched into the LN, the naired

command neurons project in specific tracts, we traced the proctolinergic axons in these tracts to see whether they branched into the LN, the paired neuropil containing the swimmeret motor centers. We found proctolinergic axons with trajectories that would be predicted for four of the five excitatory command neurons: E_A, E_B, E_C and E_E. These axons are found in the LDT, DLT, LVT, and MVT, respectively; they are intersegmental and project into the LN.

BEHAVIORAL AROUSAL IN THE CRAYFISH (PROCAMBARUS CLARKII) IS MODULATED BY SEROTONIN AND OCTOPAMINE. Nicholas C. Hunt* and Richard F. Olivo. Dept. Biol. Sciences, Smith College, Northampton, MA 01063.

Serotonin and octopamine modulate two behaviors that normally incre when a crayfish is aroused: the optokinetic response, and spontaneous walking (Arnesen & Olivo, 1988, Comp. Biochem. Physiol. 91C: 259-263). We show here that the amines alter the firing rates of optomotor units, indicating that their effects on eye movements are not through their known actions on muscles. We also confirm that serotonin suppresses episodes of walking and enhanced optomotor activity, and show that its threshold for action is at doses about a thousand-fold lower than those used in the earlier experiments.

Crayfish were clamped at the center of an oscillating striped drum that elicited continual optomotor responses. Their legs rested on a floating foam-rubber ball, on which they walked during episodes of spontaneous arousal; we monitored walking with a video-based motion detector. A bipolar electrode implanted in a lateral eye muscle recorded the firing of multiple optomotor units, and a cannula in the pericardial space let us inject amines without handling the crayfish. In each experiment, after a 40-minute control period, we injected serotonin-HCl or DL-octopamine in 0.1 ml saline, and monitored the effects on arousal for the next 60 minutes. For serotonin, 4 to 6 experiments at each of three doses showed that 10 ug suppressed arousal for 40 to 60 minutes, after which normal alternating episodes of arousal and quiesence returned. The optokinetic response also was depressed during non-aroused periods. Lower doses of serotonin had smaller (1 ug) or undetectable (0.1 ug) effects. Octopamine in doses from 20 to 500 ug was variable in its actions, but generally increased alking and optomotor activity; this is the opposite of serotonin's effects.

GLUTAMATE AND ACETYLCHOLINE RESPONSES FROM STOMATOGASTRIC NEURONS IN DISSOCIATED CELL CULTURE. Andrew A. Sharp, Jorge Golowasch and Eve Marder. Biology Department, Brandeis Univ., Waltham MA 02254.

The crustacean stomatogastric ganglion (STG) is a model system for the study of rhythmic pattern generation in neural networks. However, due to the complexity of the interactions between the neurons within the ganglion it is difficult to characterize their biophysical properties. To eliminate these difficulties, several laboratories have developed techniques to grow STG neurons in dissociated, primary tissue culture (Krenz and Fischer,1988, Neurosci. Abstr.14:295; Graf and Cooke,1990, J. Exp. Biol.149:521; Golowasch et al., Crustacean Systems in Neurobiology, in press). We are characterizing the responses to the Neurobiology,in press). We are characterizing the responses to the primary intraganglionic transmitters, glutamate and acetylcholine, in cultured STG neurons from <u>Cancer borealis</u> and <u>Panulirus interruptus</u>. Iontophoretic or bath applications of glutamate produces inhibitory responses that are blocked by picrotoxin. Acetylcholine produces a strong excitatory response. Most neurons respond to both transmitters after 3 to 7 days in culture and do not require new outgrowth. The responses seen to date represent only a subset of those seen in the intact ganglion, either due to sampling problems or because cultured cells produce only some of the responses seen in the intact ganglion. Supported by NS17813.

LOCALIZING NEUROPEPTIDE-IMMUNOREACTIVE NEURONS THAT PROJECT TO THE CRAB STOMATOGASTRIC GANGLION. MJ. Coleman and M.P. Nusbaum, Neurobiology Research Center/Dept. of Physiol. & Biophysics, Univ. of Alabama-Birmingham, Bhan. AL 35294.

Different exogenously-applied neuropeptides elicit different motor patterns from the pyloric network, in the stomatogastric ganglion (STG) of the crab, Cancer borealis (Marder & Nusbaum, Persp. Neural Sys. & Behav. pp.73-91, 1989, eds. TJ Carew & DB Kelley, AR Liss). Thus far, however, only one of the neurons responsible for these peptide-mediated effects has been identified (Nusbaum & Marder, J. Neurosci. 2:1600-1607, 1989). No STG somata contain these peptides, but many of them appear to originate in somata in the commissural ganglia (CGs). We have now localized several peptide-immunoreactive somata in the CGs that do indeed extend processes to the STG, using the following double-labeling technique. In in vitro preparations, the STG input nerve is cut and backfilled towards the CGs (approx. 15mm) with 5% biocytin (in 50mM NaHCO3) for 48 hours. The wholemount is then fixed and processed for biocytin visualization and immunocytochemistry, using different fluorophores to differentiate the two labels. Biocytin backfills routinely label 5-10 somata/CG. In contrast, Lucifer yellow backfills routinely label 5-10 somata/CG. In contrast, Lucifer yellow backfills routinely label 5-10 somata/CG. The contrast, Lucifer yellow backfills abel 0-4 somata/CG. We have found one biocytin-labeled neuron (approx. 30µm), located anteromedially in the CG, that shows proctolin-like immunolabeling (n=5CGs). Three others (approx. 30µm each), located posteromedially in the CG, show FMRFamide-like immunolabeling (n=5CGs). We are working to identify: (1) the transmitter(s) used by the other biocytin-labeled cells, and (2) these double-labeled neurons with dye-filled microelectrodes, to determine how they influence the pyloric motor pattern.

CHARACTERIZATION OF THE PEPTIDE-REGULATED MEMBRANE GUANYLATE CYCLASE OF THE AMERICAN LOBSTER M.F. Goy and C.A. Geary. Department of Physiology, University of North Carolina, Chapel Hill, NC 27599.

C.A. Geary. Department of Physiology, University of North Carolina, Chapel Hill, NC 27599.

In lobsters, and other crustaceans, a family of related peptides (two isoforms of Crustacean Hyperglycemic Hormone and a more-distantly related Molt Inhibiting Hormone) regulate cyclic GMP metabolism in multiple target tissues. These peptides (also called peptides G1, G2, and G3, for their cyclic GMP-promoting effects) are produced abundantly by the sinus gland and, to a lesser degree, by two other neurosecretory structures, the pericardial organs and the proximal secretory regions of thoracic second nerve roots. The peptides have recently been shown to selectively activate the membrane form of guanylate cyclase (M.F. Goy, J. Biol. Chem, in press), a reaction that can be studied in homogenized preparations.

We have used the advantageous properties of homogenates to characterize the peptide/cyclase interaction. (1) The peptide alters the V_{max} of the enzyme without changing the K_m for GTP. (2) Calcium ions may play an inhibitory role in the regulation of cyclase activity, but do not serve to couple or enhance the peptide response. (3) Cytoplasm contains a factor that, when added back to purified membranes, enhances peptide-induced cyclic GMP synthesis. Biochemical techniques have been used to characterize this factor. (4) Molecular cloning experiments, using probes against the membrane cyclases of other species, have been used to define the primary structure of the lobster membrane cyclase, and to compare it to the peptide-responsive cyclases of other species. Supported by NiH grants NS21290 and NS25915.

ELEVATED TEMPERATURE ALTERS THE IONIC DEPENDENCE OF AMINE-INDUCED OSCILLATIONS IN A CONDITIONAL BURSTER NEURON. B.R. Johnson, J.H. Peck and R.M. Harris-Warrick. Neurobiology and Behavior, Cornell Univ. and Dept. of Psychology, Ithaca College, Ithaca, NY 14853.

The AB neuron in the lobster stomatogastric ganglion is a conditional burster. The amines dopamine (DA, 10-4M), serotonin (5HT, 10-5M) and octopamine (Oct, 10-4M) induce rhythmic oscillations in membrane potential in synaptically isolated AB cells (Harris-Warrick and Flamm. J. Neurosci. 7: 2113, 1987). At 15°, 5HT and Octinduced oscillation depends upon Na⁺ entry (blocked by TTX) while DA-induced oscillation depends upon Ca²⁺ entry (not blocked by TTX but blocked by low Ca²⁺). At 22°, we found that all three amines can induce oscillatory behavior in the presence of TTX. DA-induced oscillators were strong and rhythmic, while 5HT- and Oct-induced oscillations were strong and rhythmic, while 5HT- and Oct-induced oscillations were often weak and irregular. At 22°, DA-induced oscillations were still blocked by reduced Ca²⁺ (25% of normal). In oscillations were still blocked by reduced Ca²⁺ (25% of normal). In contrast, 5HT-induced oscillations were not blocked by either low Na⁺ (50% of normal) or low Ca²⁺. Like 5HT, Oct-induced oscillations were not blocked by low Ca²⁺; however, they were sometimes blocked by low Na⁺. Low Ca²⁺ and low Na⁺ reduced the undershoot and broadened the slow wave of both 5HT- and Oct-induced oscillations. We suggest that elevated temperature shifts the ionic mechanisms of 5HT- and Oct-induced AB oscillations such that at 22° both Ca²⁺ and Na⁺ currents play important roles in burst production. (Supported by NIH grant #NS17323.)

DOPAMINERGIC NEURONS IN LOBSTER CENTRAL NERVOUS SYSTEM: COMPARATIVE IMMUNOCYTOCHEMICAL DISTRIBUTION OF TYROSINE HYDROXYLASE AND DOPAMINE. I. Cournil 1*, M.

SYSTEM: COMPARATIVE IMMUNOCYTOCHEMICAL DISTRIBUTION OF TYROSINE HYDROXYLASE AND DOPAMINE. I. Cournil¹*, M. Moulins¹ and M.P. Nusbaum², ¹Lab. Neurobiol. Physiol. Comp., Univ. Bordeaux/CNRS, Place Peyneau, 33120 Arcachon, France; ²Neurobiology Research Center/Dept. Physiol. & Biophysics, Univ. Alabama-Bham, Bham, Al. 35294.

Amines are believed to play crucial roles in controlling and regulating aspects of the behavioral repertoire of animals, and their hormonal action is directed both centrally and at the periphery. In this work, we have explored for dopaminergic neurons in the brain, the ventral nerve cord and the stomatogastric system of the lobster, Homarus gammarus. We apply immunocytochemical procedures with specific antibodies to detect, first, tyrosine hydroxylase (the dopamine synthetic enzyme) using immunofluorescence detection on whole mount preparations; second, dopamine transmitter using the peroxidase-antiperoxidase technique on paraffin serial sections. These two antibodies provide consistent mapping of dopaminergic neuronal cell bodies: about 100 neuronal somata are detected in all, of which 30 are found in the brain. A bilaterally symmetrical distribution is evident within each thoracic ganglion (4 somata) and abdominal ganglion (4-5 somata). No labelled somata were found in the stomatogastric and oesophageal ganglia. Stained fibre tracts have been followed through the whole nervous system and into some peripheral nerve roots. In these cases, it is possible to follow a labelled neuron from its central soma until its terminal projections, thus indicating, like other amines, a double action centrally and at the periphery.

IDENTIFICATION OF OCTOPAMINE-CONTAINING NEURONS IN THE LOBSTER NERVOUS SYSTEM. <u>D.E. Valentine</u>, <u>B.A. Trimmer</u>, and <u>E.A. Kravitz</u>, Dept.Neurobiology, Harvard Medical School, Boston, MA 02115.

Octopamine (OA) injection triggers a low-to-the-substrate posture in lobsters which resembles the stance assumed by subordinate animals, and which opposes the dominant-looking posture produced by serotonin. The which opposes the dominant-looking posture produced by serotonin. The subordinate-looking posture results from the readout from the ventral nerve cord of a motor program for extension. The action of OA on exoskeletal muscles is to prime them to respond more vigorously, and thus enhance the central effects of OA. We have begun the search for OA neurons involved in postural regulatory mechanisms in order to compare and contrast their actions with those of serotonergic neurons in lobsters.

Octopamine is found in low levels throughout the lobster nervous system and in much higher amounts in peripheral neurosecretory structures found along thoracic 2nd roots. Using antibodies to OA generated in our lab and by Geffard et al. we have constructed partial maps of OA-immunostaining

Geffard et al., we have constructed partial maps of OA-immunostaining neurons. Stained cells were seen on the dorsal midline of the subesophageal neurons. Stained cells were seen on the dorsal midline of the subesophageal ganglion (SEG), and in anterior and posterior pairs in each of the thoracic ganglia. Processes from the posterior pairs of cells could be traced to the 2nd root neurosecretory regions. Using a modification of the radioenzymatic assay developed by Molinoff et al. (1969), we have measured OA levels in single cells identified by location or by neutral red staining. The results show levels of OA in the range of 150 - 250 fmol (0.4 - 0.9 mM) in the anterior pairs of cells from thoracic ganglia and the dorsal midline cells of the SEG, while control neurons showed no measurable amine (limit of detection = 10 fmol). Nashville, TN.

Cardiac inhibition in <u>Limulus polyphemus</u> has been studied, electrophysiologically, during stimulation of the inhibitor nerve from the isolated cardiac ganglion. Computer assisted spike train analysis provided histograms of extra cellular recordings which indicated that burst rate, burst duration and burst content (spike per burst) decreased significantly. This decrease prove to be voltage and frequency dependent. Application of exogenous 5HT or GABA on the isolated ganglion mimic a similar response as stimulating the inhibitor nerve. While concentrations of GABA less than 5x10-6M showed no significant change in burst content, concentrations significant change in burst content, concentrations greater than $5 \times 10^{-6} M$ decrease both burst rate and spikecontent significantly. This decrease in burst rate and spike content was also evident with concentrations of SHT greater than 2x10-7M.

DEPLETION OF SEROTONIN IN THE CENTRAL NERVOUS SYSTEM OF LIMULUS POLYPHEMUS. B.S. McAdory* and R.F. Newkirk. Tennessee State University, Nashville, TN 37209 and B. Washington, Xavier University, New Orleans, LA 70125.

Washington, Xavier University, New Orleans, LA 70125.

It has long been established that serotonin (5-HT) is present in the central nervous system of Limulus polyphemus. Previous studies using techniques of immunocytochemistry demonstrated the presence of serotonin-like immunoreactivity. To further support the contention that these structures are serotonergic, 5,7-dihydroxytryptamine (5,7-DHT) was used to deplete cells and fibers. The chain of paraformaldehyde-fixed abdominal ganglia was pretreated with pargyline before incubating for 24 hours in 5,7-DHT in L-15 (Leibovitz) medium. The tissue was exposed to a rabbit anti-FHT antiserum followed by treatment with a goat anti-rabbit antiserum labeled with fluorescein isothiocyanate (FITC). The results of this study revealed that the neurotoxin depleted 5-HT from cells and fibers of the ventral nerve cord of Limulus, depletion being more complete in cells than in fibers and processes. These findings are supported by HPLC analysis which revealed that the levels of endogenous 5-HT were greatly reduced in experimental ganglia when compared to levels in control ganglia. These results support the contention that the ventral nerve cord of Limulus polyphemus contains 5-HT which serves as a central neurotransmitter.

A NEUROPEPTIDE RELATED TO CRUSTACEAN CARDIOACTIVE PEPTIDE IN MANDUCA SEXTA: CHARACTERIZATION AND DISTRIBUTION. J.G. Hildebrand, H.K. Lehman, T.A. Miller*, and N.T. Davis. ARL Div. of Neurobiology, Univ. of Arizona, Tucson, AZ 85721 Crustacean cardioactive peptide (CCAP) has been identified from the pericardial organs of a crustacean, Carcinus maenas, and from the nervous

Crustacean cardioactive peptide (CCAP) has been identified from the pericardial organs of a crustacean, Carcinus maenas, and from the nervous system of an insect, Locusta migratoria. Although the cardioactive properties of the peptide have been demonstrated in Carcinus, its role in insects remains unexplored. To study the physiological functions of CCAP-like neuropeptide(s) in the sphinx moth Manduca sexta, we have used ELISA techniques to monitor the chemical purification of CCAP-like immunoreactivity and determined its distribution in the nervous system, heart, and blood. We have also used bioassays to test the physiological activity of the synthetic and isolated peptides. A series of three gradient and isocratic HPLC steps were necessary to purify the CCAP-like material from extracts of M. sexta ventral nerve cords. In the

A series of three gradient and isocratic HPLC steps were necessary to purify the CCAP-like material from extracts of *M. sexta* ventral nerve cords. In the final purification step, the *M. sexta* peptide eluted with 19.0% acetonitrile as a single UV-absorbing peak, coincident with synthetic CCAP. Preliminary amino acid analysis has indicated, however, that the *M. sexta* peptide is not identical to CCAP. We are currently working to ascertain the primary structure of the *M. sexta* peptide by mass spectroscopy and amino acid sequence analysis.

to CCAP. We are currently working to ascertain the primary structure of the *M. sexta* peptide by mass spectroscopy and amino acid sequence analysis.

The distribution of the *M. sexta* CCAP-like peptide corresponds well with that of CCAP-like immunoreactivity visualized with immunocytochemical methods [see Davis et al. in these *Abstracts*]. The greatest concentrations were found in the ventral nerve cord and brain. Little activity was found in the heart, but CCAP-like activity was detected in the hemolymph. Moreover, the purified *M. sexta* peptide mimicked the effects of synthetic CCAP on the semi-isolated heart. Our findings suggest that CCAP-like peptide(s) may function as cardioregulatory agent(s) in insects. [Supported by a grant from Monsanto Co. to JGH.]

355.15

DISTRIBUTION OF PBAN-LIKE IMMUNOREACTIVITY IN THE CNS OF THE CORN EARWORM, Heliothis zea T.G. Kingan 1, A.K. Raina 1*, M. Blackbum 2*, M. Ma 2*. 1, Insect Chemical Ecology Laboratory, BARC-East, Bldg. 402, Beltsville, MD, 20705; 2, Dept. of Entomology, U. of MD, College Park, MD 20742

Production of female sex pheromones in several species of moths is under the control of a neuropeptide that is synthesized in the suboesophageal ganglion (SOG). The mechanism of action of this neuropeptide, termed pheromone biosynthesis activating neurohormone (PBAN), is of significant current interest. Early work indicated that PBAN-like bioactivity could be detected in the blood of scotophase females (Raina and Klun, Science 225, p. 531, 1984) while a more recent investigation suggested axonal transport to the terminal abdominal ganglion (TAG) and release of a second messenger from the TAG to induce pheromone biosynthesis. (Teal et al., PNAS 86, 2488, 1989). We have begun to address these possibilities with the production of antisera against PBAN and their use in immunochemical studies. In immunocytochemical studies, antisera reveal two sets of immunoreactive soma in the SOG. Processes from one set are apparently confined to the SOG and the adjacent tritocerebrum, while processes from the other set project to and apparently terminate in the corpora cardiaca, putative release sites for peptide neurohormones. Immunoreactive PBAN can be detected in the thoracic ganglia and the segmental ganglia of the abdomen; a single pair of immunoreactive fibers can be detected in the connectives of the ventral nerve cord in scotophase females. Using these antisera, we have developed a competitive ELISA for PBAN; we are now using this assay to quantify immunoreactive PBAN in hemolymph and in extracts of CNS ganglia of scotophase and photophase moths.

355.12

CRUSTACEAN CARDIOACTIVE PEPTIDE: IMMUNOREACTIVE NEURONS AND PHYSIOLOGICAL ACTIONS IN MANDUCA SEXTA. N.T. Davis, T.A. Miller*, H. Lehman, and J.G. Hildebrand. ARL Div. of Neurobiology, Univ. of Arizona, Tucson, AZ 85721.

We have studied physiological actions of Crustacean Cardioactive Peptide (CCAP) and the localization of CCAP-like immunoreactivity (CCAPLI) in the nervous system of the sphinx moth *Manduca sexta*.

A specific anti-CCAP antibody stains neurons containing CCAPLI in the brain, subesophageal ganglion, and abdominal ganglia of larvae and adults. In addition, the abdominal ganglia have CCAP-immunoreactive neurons that project into the transverse nerve (perivisceral organ), which is known to have a neuronemal function. The number of neuronemal CCAP-immunoreactive neurons increases during larval and pupal development, and in the transverse nerve, a peripheral neuron (L1) and its projections also exhibit CCAPLI.

nerve, a peripheral neuron (L1) and its projections also exhibit CCAPLI.

A comparable system of CCAP-immunoreactive neurons is found in representatives of 5 other orders of insects. Included in this group is *Periphaneta americana*, in which the Lateral White Cells in the abdominal ganglia are CCAP-immunoreactive.

Bioassays using the heart of *M. sexta* show that synthetic CCAP at physiological levels accelerates the heartbeat and stops the reversals of the heart. These results suggest that the heart of *M. sexta* is controlled, in part, by a CCAP-like neurohormone and that this peptidergic control system may occur widely in insects. [We thank Dr. Rainer Keller for generously providing the anti-CCAP antibody. This research was supported by a grant from the Monsanto Company to JGH.]

PEPTIDERGIC MODULATION DURING METAMORPHOSIS IN Manduca sexts: CAP, CONTROLS GUT EMPTYING IN WANDERING LARVAE. K. Edwards*, C.C. Cheung*, D.P. Kimble, A.W. Sylwester*, and N.J. Tublitz. Inst. of Neuroscience, U. Oregon, Eugene, OR 97403.

In preparation for metamorphosis Manduca larvae stop feeding, crawl off their

In preparation for metamorphosis <u>Manduca</u> larvae stop feeding, crawl off their food, and burrow underground in a complex behavior known as wandering. One component of this stereotypic behavior is 'gut emptying', a relatively rapid purging of gut contents. We report here on studies designed to test the hypothesis that the neuropeptide CAP₂ (Cardioacceleratory Peptide₂) modulates gut emptying in wandering cateroillers.

gut emptying in wandering caterpillers.

Biochemical studies using HPLC and immunoprecipitation experiments using an anti-CAP antibody independently confirmed the presence of CAP2 in the CNS of wandering larvae. Our first indication that CAP2, was involved during wandering came from measuring CAP2 levels in the larval CNS, the results of which showed that CAP2 declined precipitously at wandering. Although the notion that the larval heart was the primary target of CAP2 was empirically refuted, additional data did implicate the larval hindgut as a possible target tissue. CAP2 applied to isolated larval hindguts caused a dose-dependent increase in contraction frequency, amplitude and basal tension of the hindgut. Quantitative analyses indicated that hindgut sensitivity to CAP2 peaked on the day of wandering. In vivo measurements of hindgut activity in larvae revealed a dramatic increase in contraction frequency associated with gut emptying, which was partially blocked by the anti-CAP antibody. Immunocytochemical staining with the anti-CAP antibody uncovered several terminal ganglion cells projecting to the hindgut. This evidence taken together strongly suggests that CAP2 is involved in modulating gut activity during wandering behavior.

EFFECTS OF 5,7-DIHYDROXYTRYPTAMINE UPON THE IN VITRO UPTAKE, RELEASE AND SYNTHESIS OF SEROTONIN IN Rhodnius prolixus. H. Cook and I. Orchard. Dept. of Zoology, Univ. of Toronto, Toronto, Canada M5S 1A1

5,7-dihydroxytryptamine (5,7-DHT) is a neurotoxic analogue of serotonin which lesions serotonergic neurons. In Rhodnius prolixus, 5,7-DHT treatment (1 μ L of 10^3 M 24h injected previously) led to a severe depletion of serotonin immunoreactivity of the neurohaemal areas of the abdominal nerves. This toxin-induced depletion of serotonin was confirmed using HPLC. There was no significant change in the serotonin content of the brain, subesophageal ganglion, prothoracic ganglion or the mesothoracic ganglionic mass (MTGM).

In order to elucidate the mode of action of this neurotoxin in *Rhodnius*, we have examined the effects of 5,7-DHT upon the *in vitro* uptake, release and synthesis of serotonin by the neurohaemal areas of the abdominal nerves and the associated MTGM. We have found that 5,7-DHT elicits a significant release of previously accumulated ³H-serotonin in the presence or absence of calcium in the bathing medium. 5,7-DHT also reduces the specific uptake of ³H-serotonin but does not affect the uptake of ³H-tryptophan nor the subsequent synthesis of ³H-serotonin. The effects of this dosage 5,7-DHT appear to be transient as the neurohaemal areas appear to be fully recovered 4 weeks after injection, as witnessed by immunohistochemistry.

GABA RECEPTORS OF INSECTS SUSCEPTIBLE AND RESISTANT TO CYCLODIENES. N. M. Anthony, E. A. Benner*, C. D. Lamison*, J. G. Vassallo*, D. B. Sattelle and J. J. Rauh. Agricultural Products Dept., DuPont Experimental Station, Wilmington, DE 19880 and AFRC Lab of Molecular Signalling, University of

Cambridge, Cambridge CB2 3EJ U.K.

The interaction of insecticidal cyclodienes at the convulsant binding site of insect GABA receptors is believed to play a role in the toxic properties of these compounds. Previous studies suggested that cyclodiene resistance in roaches is due to insensitivity at the convulsant site. We examined GABA receptors from cyclodiene resistant (CYW) and susceptible receptors from cyclodiene resistant (CYW) and susceptible (CSMA) housefly strains to determine if alterations in the convulsant binding site exist. In toxicity tests, the CYW flies exhibited a high degree of resistance to the following compounds: ketoendrin, dieldrin, heptachlor epoxide and lindane. Using [35S]-TBPS as a probe for the convulsant site, we demonstrated specific binding to thorax/abdomen membranes prepared from resistant and wild type strains. Multiple membrane preparations from each strain failed to provide evidence for differences in either density or affinity of convulsant sites. Although cyclodienes appear to competitively displace TBPS, a mutation in the convulsant site might alter the binding of cyclodienes without altering TBPS binding. Therefore, we are currently assessing the relative efficacy of a variety of cyclodienes at displacing [35S]-TBPS from membranes of each housefly strain.

355.19

ACTIONS OF GILITAMATE, GABA AND OTHER PUTATIVE AMINOACID NEUROTRANSMITTERS ON THE NEUROPILE ARBORIZATIONS OF LOCUST MOTONEURONS. <u>F. Dubas</u>, Zoologisches Institut der

Universität, 4051 Basel, Switzerland. In locusts, there is evidence that certain amino-acids (aa) are centrally released neurotransmitters. To establish the pharmacological profile of aa receptors involved in synaptic transmission on locust flight motoneurons, the effect of pressure application of putative as neurotransmitters and certain of their agonists was recorded from neuropile impalement sites, in a preparation where neuropile recordings can be made during expression of the flight motor output.

The prevalent effect triggered by glutamate, GABA, aspartate and taurine was an inhibition of spontaneous or aspartate and taurine was an inimitation of spontaneous or evoked activity, accompanied by a chloride conductance increase. Responses to aspartate and glutamate had identical reversal potentials and cross-desensitized. Responses to GABA and taurine had more negative reversal potentials and neither cross-desensitized with those elicited by glutamate. Responses to GABA were blocked by

picrotoxin but those to glutamate were not.

NMDA and glycine were without effect while kainate and quisqualate caused large depolarizations and spiking even in cells inhibited by glutamate. Ibotenate triggered hyperpolarizations with reversal potentials similar to the responses to glutamate. Characterization of the receptors for GABA and glutamate is in progress.

MULTIPLE SEROTONIN-ACTIVATED CURRENTS IN ISOLATED, NEURONAL SOMATA FROM LOCUST THORACIC GANGLIA. I. Bermudez*†‡, D.J. Beadle*† and J.A. Benson[‡]. †School of Biological and Molecular Sciences, Oxford Polytechnic, Oxford OX3 0BP, England and ‡R & D Plant Protection, Agricultural Division, CIBA-GEIGY Ltd., CH-4002 Basel, Switzerland.

Serotonin (5-hydroxytryptamine, 5-HT) evokes changes in membrane potential and membrane conductance when applied to the somata of insect neurones in vitro (Usher wood, P.N.R. et al., In: Insect Neurobiology and Pesticide Action, pp. 115-128, 1980; Neumann, R. et al., In: Sites of Action for Neurotoxic Pesticides, pp. 25-43, 1987). To investigate the voltage-dependence, ionic basis and pharmacology of these serotonin sponses, we voltage-clamped mechanically isolated neurones from the thoracic ganglia of Locusta migratoria. These neurones remain viable in vitro for many hours and exhibit characteristic responses to GABA (Lees, G. et al., Brain Res. 401:267, 1987), nicotine and muscarine (Benson, J.A., Soc. Neurosci. Abs. 15:365, 1989). Pressure micro-application of serotonin (500 ms, 1 mM) evoked three different inward currents, not all of which were recorded in every neurone. I(SHT)Na was Na-dependent, increased with membrane hyperpolarisation and was insensitive to ketanserin, a vertebrate SHT2 membrane hyperpoarisation and was insentive to technicarin, a vertebrate 5/112 receptor antagonist. ICS 205 930, a 5HT3 antagonist, showed agonism at the receptor mediating the KSHTNA response, while MDL 72222, another 5HT3 antagonist, blocked this response. KSHTNK was K-dependent and maximally activated at a membrane potential of -60 to -70 mV. It was blocked by ketanserin, in a dose-dependent manner, and by 10 mM Cs and Rb but not by Mn. A third current, I(SHT)X, with faster kinetics than the other two, was evoked at membrane potentials more positive than -50 mV and increased with depolarisation. This current was blocked by 5 mM 4-aminopyridine. Numerous immunocytochemical studies have revealed serotonergic neurones in insects, receptor binding and re-uptake of radio-labelled serotonin by insect neurones has been demonstrated and serotonin is known to affect many physiological functions in insects as a neurohormone and possibly as a neurotransmitter. Here we identify individual serotonin-activated currents that are candidates for rôles in mediating neuronal responses to serotonin in insects.

EXCITATORY AMINO ACIDS: NMDA RECEPTOR ANTAGONISTS

356.1

ANTAGONISM OF EXCITATORY AMINO ACID NEURO-TRANSMISSION IN VIVO: COMPARISON OF SEVERAL ARTHROPOD TOXINS. M.G. Jones* and D.Lodge. The Royal Veterinary College, London, NWI OTU, U.K. Examining the specificity of arthropod toxins for the N-methyl-D-aspartate (NMDA), quisqualate (QUIS) and kainate (KAIN) subtypes of glutamate receptor, we have combined the techniques of microiontophoresis and extracellular recording to study the effects of several toxins, including philanthotoxin (PhTx), argiotoxin (ATX) and Nephila Spider toxin (NSTX) on responses of rat central neurones to excitatory responses of rat central neurones to excitatory

responses of rat central neurones to excitatory amino acids in vivo.

Under pentobarbitone anaesthesia a lumbar laminectomy was performed and 7-barreled glass microelectrodes inserted into the spinal cord. PhTx markedly reduced excitatory responses to QUIS and KAIN whilst those to NMDA showed a small overall increase. ATX was more potent but markedly least scales in a markedly least scales in a modernia was lambar and least scales in the second scales was more potent but

small overall increase. Alx was more potent but markedly less selective, reducing NMDA as well as Quis responses. Selectivity of NSTX resembled that of PhTx but recovery was more variable.
Whilst existing data from in vitro studies favour selectivity of such toxins for NMDA rather than non-NMDA mediated responses, factors perhaps operating only in vivo appear to reverse this selectivity. this selectivity.

INHIBITION OF ³H-PROLINE BINDING BY AP-7 INHIBITION OF ³H-PROLINE BINDING BY AP-7 Cordero, M.L.*, Negrón, A.*, Blanco, C.*, Santiago, G.*, Ortiz, J.G. Department of Pharmacology, School of Medicine, University of Puerto Rico, San Juan, Puerto Rico 00936 Proline has been described as a possible neuromodulator in mammalian CNS (Giacobini, 1983, Nadler et al., 1989). Several binding

sites for proline have been identified (Greene et al., 1986, Ortiz et al., 1989). Glutamate neurotransmission antagonists partially block proline actions in CNS (Ault et al., 1987). L-glutamate and AP-7 (10⁻⁹-10⁻⁶ M), an NMDA antagonist, inhibit proline binding by 60% in midbrain. In hippocampus, AP-7 inhibits proline binding by 80%. However, AP-7 does proline binding by 80%. However, AP-7 do not affect proline binding in cerebellum. These results are consistent with the possible neuromodulatory role of proline in the CNS, possibly through the NMDA receptor(s). Further studies with more specific agents, such as MK-801, could clarify the possible interaction(s) between proline and glutamate. (Supported by NIH/MBRS, and in part by RCMI)

THE DISCOVERY OF LY274614 AND LY233536 AND THEIR CHARACTERIZATION AS SELECTIVE AND COMPETITIVE NMDA ANTAGONISTS. Paul L. Ornstein, M. Brian Arnold*, Nancy K. Augenstein*, Darryle D. Schoepp, J. David Leander and David Lodge, Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, IN 46285 and Royal Veterinary College, London, NW10TU, UK.

We sought to develop an array of potent, selective competitive NMDA antagonists that have good systemic activity. Our efforts led to the

antagonists that have good systemic activity. Our efforts led to the discovery of LY274614 and LY233536. We will discuss the SAR for this novel series of amino acids. LY274614 and LY233536, the most potent compounds in this series, selectively displaced 3 H-CGS19755 binding (IC_{SO}s = 55 ± 14 and 627 ± 188 nM, respectively) and selectively inhibited NMDA-induced depolarizations in a cortical wedge preparation (IC $_{50}$'s = 0.15 ± 0.01 and 1.4 ± 0.3 μ M, respectively). These new antagonists also showed potent systemic activity in animals, e.g., against NMDA-induced lethality in mice; the MED's for LY274614 and LY233536 were 1.25 and 2.5 mg/kg (i.p.), respectively. In blocking NMDA-induced convulsions in neonatal rats, these amino acids were active following both parenteral and

neonatal rats, these amino acids were active following both parenteral and oral administration (MED's for LY274614 and LY233536 were 1 and 20 mg/kg (i.p.) and 100 and 200 mg/kg (p.o.)).

Thus, LY274614 and LY233536 are potent antagonists of neurotransmission at NMDA receptors in vitro and in vivo. These compounds may provide novel therapeutic intervention in a number of neurological disorders where excitotoxicity may have a role in neuronal damage, including cerebral ischemia and Alzheimer's disease.

356.5

CHARACTERIZATION OF MDL 100,453, A NEW COMPETITIVE ANTAGONIST OF GLUTAMATE AT THE NMDA RECEPTOR COMPLEX. J.P. Whitten¹, B.M. Baron¹, D.M.Muench¹, A.L. Slone¹, B.W. Siegel¹, C.J. Schmidt¹, H.S. White² and I.A. McDonald¹ Merrell Dow Research Institute, 2110 E. Galbraith Road, Cincinnati, OH 45215, ² Department of Pharmacology, University of Utah, Salt Lake City, UT 84112.

Pharmacology, University of Utah, Salt Lake City, UT 84112. MDL 100,453 ((R)-4-oxo-5-phosphononorvaline) binds to the glutamate recognition site on the NMDA receptor complex ($IC_{50} = 109 \text{ nM}$ vs. [3H]CPP) with IC_{50} values > 100 $_{\mu}M$ at other glutamate binding sites, such as those labeled by $[^3H$]kainate and $[^3H]$ AMPA and those mediating $[^3H]$ glutamate uptake into synaptosomes. This compound inhibits $[^3H]$ TCP binding in a manner reversible by NMDA but not by glycine. MDL 100,453 is a competitive inhibitor of several NMDA-mediated physiological

pyramidal and cerebellar granule cell neurons ($IC_{50} = 5 - 10 \mu M$).

In vivo, i.p administered MDL 100,453 antagonized the harmaline-induced elevation of cerebellar cGMP content of mice ($ED_{50} = 11.5 \text{ mg/kg}$) and displayed anticonvulsant activity vs. quinollinic acid-induced seizures in mice (ED $_{50}$ = 16.3 mg/kg), maximal electroshock seizures in rats (ED $_{50}$ = 2.3 mg/kg), and sound-induced convulsions in the audiogenic seizure-prone DBA/2J mouse (ED $_{50}$ = 3.5 mg/kg). Upon oral administration to rats, MDL 100,453 (50 mg/kg) markedly suppressed the expression of kindled seizures for > 24h.

356.7

EVIDENCE FOR NMDA ANTAGONIST PROPERTIES OF SIGMA AGENTS. S.Borosky, I. Ferkany, M. Pontecorvo and W. Karbon. Nova Pharmaceutical Corporation, Baltimore, MD 21224.

Ifenprodil is a potent sigma agent (Karbon et al., Eur. J. Pharmacol., 176:247, 1990) that also has cerebroprotective and NMDA antagonist properties (Carter et al., JPET., 247:1222, 1988; Reynolds and Miller, Mol. Pharmacol., 36:758, 1989), suggesting that other sigma agents might interact with the NMDA receptor/ionophore complex. In the present study sigma agents including caramiphen, haloperidol and BMY 14802, as well as ifenprodil, were tested for their ability to interact with [3H] TCP binding sites in well-washed rat cortical membranes in vitro, and to antagonize NMDA-induced seizures in mice. In the absence of glutamate, if enprodil inhibited [3H] TCP binding in a biphasic manner with IC_{50} 's of 5 nM and 14 μ M, whereas in the presence of glutamate (10 μ M) the IC_{50} 's S now and 14 μ m, whereas in the presence of glutamate (10 μ m) the 1C-50 were 16 nM and 19 μ M. Similarly, haloperidol inhibited glutamate-stimulated [3H] TCP binding in a biphasic manner exhibiting IC50's of 8 nM and 39 μ M, whereas caramiphen inhibition of [3H] TCP binding was monophasic in the absence and presence of glutamate, exhibiting IC50's of 14 μM and 22 μM, respectively. In contrast to the results obtained in well-washed cortical membranes, neither caramiphen nor haloperidol inhibited [3H] TCP binding to crude rat forebrain membranes. *In vivo*, ifenprodil (10 mg/kg, i.p.), haloperidol (0.75 mg/kg, i.p.) and BMY 14802 (30 mg/kg, i.p.) potentiated the ability of MK-801 to protect against NMDA (250 mg/kg, i.p.)-induced seizures at doses that provided little or no protection alone, whereas caramiphen itself was effective. These findings suggest a possible functional interaction between sigma binding sites and the NMDA receptor/ionophore complex.

356.4

THE BEHAVIORAL PHARMACOLOGY OF LY233536 AND LY274614: TWO NOVEL, SELECTIVE, COMPETITIVE NMDA ANTAGONISTS. J. David Leander and Paul L. Ornstein, Lilly Research Laboratories, Eli Lilly

David Leander and Paul L. Ornstein, Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, IN 46285.

LY233536 and LY274614 are two 6-substituted decahydroisoquinoline-3-carboxylic acid competitive NMDA antagonists (Ornstein, et al., this meeting). After i.p. administration (+30 min), the minimally effective doses (MED) of LY233536 and LY274614 to protect against maximal electroshock (MES) seizures were 10 and 5 mg/kg, respectively. At 5 min after i.v. administration, the ED₅₀'s were 6.6 and 2.9 mg/kg, respectively. LY233536 was most potent at the earliest time point of testing (5 min after i.v. administration), and the protection from LY233536 was gone by 40 min. In contrast, LY274614 was most potent (ED₅₀ = 1.25 mg/kg) at 60 min after i.v. administration and protection was sustained. The MED's (i.m.) for antagonizing the behavioral suppressant (ED_{S0} = 1.25 mg/kg) at 60 min after i.v. administration and protection was sustained. The MED's (i.m.) for antagonizing the behavioral suppressant effects of 10 mg/kg (i.m.) of NMDA on schedule-controlled responding in pigeons were 2.5 and 0.16 mg/kg for LY233536 and LY274614, respectively. The MED for producing the phencyclidine-like cataleptic response in pigeons was 5 mg/kg (i.m.) for LY274614, whereas LY233536 was ineffective (>160 mg/kg). The cataleptic effect of LY274614 had a delayed onset and long duration irrespective of the route of administration (i.v., i.m. or p.o.).

.Y274614 X = PO₃H₂ '233536 X = Tetrazole LY233536 (Racemic)

Thus, both compounds are competitive NMDA antagonists; they differ in that LY233536 has a fast onset and short duration of effect, whereas LY274614 has a slow onset and long duration of effect.

356.6

COMPARISON OF THE BEHAVIORAL EFFECTS OF COMPETITIVE AND NON-COMPETITIVE NMDA ANTAGONISTS IN MICE. D. Luttinger and D. Koonz*. Department of Neuroscience, Sterling
Research Group, Rensselaer, NY 12144.

Many of the effects of PCP and other similar

non-competitive NMDA antagonists are believed to be mediated by inhibition of NMDA coupled ion channels. present studies compared the behavioral effects of competitive and non-competitive NMDA antagonists.

The effects of NMDA antagonists were assessed in male, ${\tt Swiss-Webster\ mice\ following\ bilateral\ ICV}$ administration. The mice were observed once every ten minutes for ninety minutes post-drug administration by a "blind" observer using a modification of the rating scale of Sturgeon et al., <u>EJP.</u>, 59:169, 1979.
Non-competitive NMDA antagonists (e.g. PCP, MK-801,

(-)alpha- and beta-cyclazocine) increased locomotion stereotypic head-weaving and ataxia. In contrast, the competitive antagonists; CPP, AP-5, and AP-7 in doses sufficient to antagonize NMDA-induced lethality, did not increase locomotion or stereotypies but did increase ataxia.

The results indicate differences in the behavioral effects of non-competitive and competitive NMDA antagonists in mice. These differences might be due to differences in distribution, or to the involvement of non-NMDA coupled PCP sites underlying the mechanism for some of the behavioral effects in mice.

356.8

TETRAHYDROAMINOACRIDINE (THA) IS AN OPEN CHANNEL BLOCKER OF N-METHYL-D-ASPARTATE (NMDA)-GATED CATION CHANNELS. N. Hershkowitz and M. A. Rogawski. Medical Neurology Branch, NINDS, NIH, Bethesda, MD, 20892.

Among the proposed mechanisms of action of THA, an agent which may provide symptomatic benefit in Alzheimer's dementia, are inhibition of acetylcholinesterase and blockade of voltage-dependent K⁺ channels. Radioligand binding studies have indicated that THA may interact with the NMDA receptor-channel complex. In the present study, we examined the effects of THA on excitatory amino acid responses in cultured hippocampal neurons. In whole cell voltage-clamp recordings ($V_{\rm H}$, -60 mV), THA produced a dose-dependent block of NMDA-evoked inward current (IC_{50} , 190 μM), without effect on quisqualate or kainate re sponses. The block was nearly completely relieved at positive holding potentials, indicating that THA may act as a steric blocker of the channel pore. Single channel as a stelle blocker of the channel pote. Single channel recordings in excised outside-out membrane patches demonstrated that THA produces a decrease in the frequency of channel opening and in the mean channel open time without affecting amplitude, supporting the concept that THA is an open channel blocker.
(N.H. was a NIH Resident Research Associate of the

National Research Council.)

KINETIC ANALYSIS OF NMDA ANTAGONISM BY NOVEL ANTICONVULSANT PHENCYCLIDINE ANALOGS: COMPARISON TO PCP AND MK-801. Susan M. Jones and Michael A. Rogawski. Neuronal Excitability Section, Medical Neurology Branch, NINDS, NIH, Bethesda, MD 20892.

Non-competitive antagonists of the N-methyl-D-aspartate (NMDA) receptor channel complex including phencyclidine (PCP) and MK-801 are anticonvulsant in several animal seizure models, but cause motor toxicity at similar doses that protect against seizures. We have identified several PCP analogs that are comparable in potency to PCP in the maximal electroshock (MES) seizure test but produce less motor toxicity. In the present study, we examined the ability of one of these analogs phenylcyclohexlamine (PCA) to block NMDA mediated responses in cultured hippocampal neurons using whole-cell voltage-clamp recording techniques. The characteristics of the inhibition were compared to those of PCP and MK-801. The peak currents elicited by repetitive applications of NMDA or NMDA plus antagonist were plotted as a function of cumulative time of exposure to the antagonist. Kinetic parameters were estimated by fitting exponential curves to the successive peak current values. As reported by several groups, the inhibition of NMDA-induced current by PCP (3 µM) was usegroups, the inhibition of NMDA-induced current by PCP (3 μ M) was use-dependent (τ_{on} , 112 s; τ_{off} , 222 s at -60 mV) and also highly voltage-dependent. MK-801 (1 μ M) also showed use-dependency (τ_{on} , 52 s; however, the inhibition by MK-801 did not exhibit the marked voltage-dependence seen with PCP. Full recovery from MK-801 could only be obtained with agonist application at depolarized potentials. PCA produced a voltage-dependent blockade of NMDA responses (66% block by 5 μ M at -60 mV). However, in contrast to PCP and MK-801, the onset and recovery of block by PCA was rapid ($\tau_{on'}$ 4 s; τ_{off} , 1 s). The ability of PCA to block seizures without causing motor toxicity may relate to its rapid block of central NMDA mediated neurotransmission during the excessive stimulation that occurs at the onset of a seizure discharge

356.11

EXTRACELLULAR MAGNESIUM CONCENTRATION DETERMINES THE N-METHYL-D-ASPARTATE (NMDA) EVOKED FIRING PATTERN OF LATERAL HABENULA (LHB) NEURONS, IN VIVO. C. L. Meier* and P. L. Herrling, Sandoz Research Institute, P.O.Box, CH-3001 Berne, Switzerland.

Iontophoretic application of NMDA to LHb cells elicited a regular firing pattern in contrast to previous observations in other brain regions, e.g. caudate, where it caused bursty firing (Herrling et al., *J.Phys.*, 339:207, 1983). The present study was designed to determine if NMDA induced regular excitations in the LHb could be converted to bursts by increasing extracellular [Mg²⁺]. Extracellular single cell recordings were made from neurons in halothane anaesthetized cats.

extracellular [Mgs]. Extracellular single cell recordings were fliate from neurons in halothane anaesthetized cats.
Lontophoretically applied quisqualate (QUIS, N=77), α-amino-3-hydroxy-5-methyl-5-isoxazolepropionate (AMPA, N=4) and kainate (KA, N=12) elicited predominantly regular firing patterns in all cells tested.
Surprisingly, in 106 (88%) out of 121 neurons tested, NMDA application elicited regular firing up to inactivation. In 5 cells (4%), NMDA application elicited bursts, and a mixed firing pattern in 10 (8%) cells. NMDA, but not AMPA, QUIS or KA excitations were antagonized by AP7 or CPP. When Mg²+ (0.3-1M, MgCl₂ or MgSO₄, retaining current –5 to –50nA) was added to one barrel of the iontophoretic assemblies, NMDA now evoked irregular bursty firing in 9 (39%) out of 23 cells tested. In 4 (17%) additional cells, NMDA initially induced regular firing that could be changed to bursty firing by actively ejecting Mg²+. AMPA evoked regular firing could not be changed to bursts by Mg²+.
These results suggest that in the lateral habenula of the cat *in vivo* the Mg²+ concentration in the extracellular microenvironment determines the type of firing pattern evoked by activation of the NMDA receptor.

356.13

ANXIOLYTIC POTENTIAL OF DRUGS WORKING AT THE NMDA RECEPTOR COMPLEX. J.H. Kehne, T.C. McCloskey', B.M. Baron, B.L. Harrison', J.P. Whitten and M.G. Palfreyman. Merrell Dow Research Institute, 2110 E. Galbraith Rd., Cincinnati OH

Compounds with known or putative anxiolytic activity were evaluated for their potencies in suppressing "separation induced ultrasonic vocalizations" (SIV) in 10 day old rat pups isolated from the litter. Muscle relaxant/sedative potential was assessed using "time on an inclined plane" (TIP), the amount of time a pup was able to retain its position on a 70 degree incline. TIP was preferentially suppressed by mephenesin. The benzodiazepine agonist diazepam and the 5-HT_{1a} partial agonists buspirone or MDL 73,005EF all suppressed SIV, but the latter two compounds were inactive against TIP, reflecting their reported lack of muscle relaxant/sedative effects. The 5-HT₂ antagonist MDL 11,939 and the 5-HT₃ antagonist MDL 73,147EF were inactive against either SIV or TIP. The NMDA antagonists AP5 or MDL 100,453 and the ion channel blocker MK-801 decreased both SIV and TIP. In contrast, 5,7-dichlorokynurenic acid, an antagonist at the strychnine insensitive kynurenic acid, an antagonist at the strychnine insensitive glycine receptor, preferentially suppressed SIV, with little effect on TIP. Thus, antagonists acting at different sites of the NMDA/glycine complex all exhibited anxiolytic activity, but the glycine antagonist was unusual in its lack of prominent muscle relaxant/sedative side effects. These data generally support the utility of the SIV and TIP measures in separating anxiolytic activity from muscle relaxation/sedation.

INHIBITION OF [3H]TCP BINDING TO RAT BRAIN PCP RECEPTORS BY ALIPHATIC ALCOHOLS. F.R. DePietro and J.C. Byrd. Developmental Neurobiology Program, Center for Neuroscience, University of Pittsburgh, W.P.I.C., Rm. E-1226, Pittsburgh, PA 15213.

Ethanol is now known to inhibit the function of NMDA/PCP receptors at pharmacologically relevant concentrations. Since the binding site for PCP is thought to reside in the NMDA/PCP receptor-linked ion channel, it seemed probable that ethanol might also inhibit TCP binding to this site. Accordingly, we examined the effect of aliphatic alcohols on TCP binding to the PCP receptor in well-washed rat brain membranes. Ethanol did indeed inhibit TCP binding, but only at high concentrations (IC₅₀ = 1275 mM); the pseudo-Hill coefficient was -1.5. This inhibition was fully reversible after washing ethanol-treated membranes. At the IC₅₀ for ethanol, Scatchard analysis revealed an increase in the K_d of TCP for the PCP site from 9.5 nM to 25 nM. Methanol was a less potent inhibitor (IC₅₀ = 2200 mM), while propanol was more potent (IC₅₀ = 0.82 mM). This pattern of inhibition correlates with the membrane fluidizing potencies of these compounds. We have recently shown (J. Mol. Neurosci., in press) that membrane fluidizing agents are also capable of inhibiting TCP binding to the PCP site, suggesting that this parameter is important for NMDA/PCP receptor functioning. The high concentrations of ethanol required to inhibit TCP binding may indicate that the protein:lipid ratio is a critical factor in binding studies, as we have found in our previous work.

356.12

ANTAGONISTS AT NMDA AND GLYCINE RECEPTORS MIMIC ANXIOLYTICS IN REDUCING RAT PUP SEPARATION RESPONSES. J.T. Winslow, T.R. Insel, R. Trullas, P. Skolnick, Lab. Clin. Sci., NIMH, Poolesville, MD 20837 and Lab. of Neurosci., NIDDK, NIH, Bethesda, MD 20892

Several recent studies have suggested that drugs affecting the NMDA receptor-glycine receptor-cation channel complex might have anxiolytic properties as assessed glycine receptor-cation channel complex might have anxiolytic properties as assessed in rodent conflict models. To determine whether these agents might mimic anxiolytics in a non-conflict model, we studied rat pup ultrasonic vocalization (USV) emitted during social isolation. Previous studies have shown that this "distress call" is reduced by anxiolytics (benzodiazepines and 5-HT1a agonists) and increased by anxiogenics (pentylenetetrazol and 5-HT1b agonists). In the current studies, 10 day old pups were isolated for 2 min. as a pre-test, injected SC with drug or vehicle, returned to their litters for 30 min., then retested for 2 min. to assess change from baseline. The functional glycine antagonist 1-aminocyclopropanecarboxylic acid (ACPC) reduced the rate of USV in a dose-dependent fashion (12.5-200 mg/kg). Calling was reduced 40-90% at doses that did not affect locomotor or thermoregulatory measures and the effect on USV was still evident 4 hrs. after injection. Although glycine (50-200 mg/kg) did not show consistent intrinsic effects injection. Although glycine (50-200 mg/kg) did not show consistent intrinsic effects on USV, a glycine dose of 200 mg/kg doubled hippocampal glycine conc. and reversed the effects of 50 mg/kg ACPC. The glycine antagonist 7-chlorokynurenic acid (25 mg/kg) also decreased the rate of USV. In addition, rat pup separation behavior was sensitive to compounds binding to the NMDA receptor. NMDA increased the rates of USV as much as 50% at doses that were not convulsant (2.5-5 microscot fier arcs of USV as much as 30% at doses that were into convinsiant (2.5 mg/kg), the NMDA competitive antagonist AP-5 (30 mg/kg) decreased the rate of USV. Two non-competitive antagonists: MK-801 (0.05 mg/kg), which appears to bind to a site within the cation channel, and the polyamine site ligand ifenprodil (12.5 mg/kg) also decreased the rate of USV, but both compounds had a number of non-specific motor effects. Taken together, these results support previous behavioral studies with adult animals suggesting that agents which reduce activity at NMDA receptor-coupled cation channels may constitute a new class of anxiolytic agents.

356.14

EFFECTS OF N-METHYL-D-ASPARTATE (NMDA) AND NMDA RECEPTOR COMPLEX SITE-SELECTIVE AGENTS ON FIXED-RATIO RESPONDING IN SQUIRREL MONKEYS. J. Willetts and W.H. Morse*. NERPRC, Harvard Medical School, Southborough, MA 01772.

The effects of NMDA and its enantiomer NMLA, and of agents which antagonize NMDA-induced convulsions, including the competitive NMDA antagonists NPC 12626 and CGS 19755, the ion channel blocker phencyclidine (PCP), the glycine-site ligand HA-966, and dextromethorphan (DXM), were determined in squirrel monkeys trained under a fixed-ratio 20 schedule of food presentation. NMDA (3-17 mg/kg i.m.) dose-dependently reduced response rates. NMLA was less potent, having only limited rate-decreasing effects at 100 mg/kg. No effects on response rates were observed with NPC 12626 (1-10 mg/kg) or CGS 19755 (0.01-10 mg/kg) or CGS 19755 1 mg/kg) alone, but both antagonists shifted dose-effect curves for NMDA to the right. Effects of lower doses (3-10 mg/kg) but not of 17 mg/kg of NMDA were antagonized by PCP (0.01-0.1 mg/kg). PCP (0.1 and 0.3 mg/kg) alone decreased response rates and responding was abolished by 0.3 mg/kg PCP and 5.6 mg/kg NMDA. Neither HA-966 (0.1-3 mg/kg) nor DXM (0.01-1 mg/kg) antagonized NMDA; rather rate-decreasing effects of NMDA were enhanced by 3 mg/kg HA-966 and by 0.3-1 mg/kg DXM. Thus, PCP, HA 966 and DXM, unlike the competitive antagonists, NPC 12626 and CGS 19755, have limited ability to antagonize effects of subconvulsant doses of NMDA in squirrel monkeys.

BLOCKADE OF NMDA RECEPTORS POTENTIATES DOPAMINE MEDIATED TURNING BEHAVIOR IN THE 6-OHDA MODEL OF PARKINSON: DIFFERENT ROLE OF D1 AND D2 RECEPTORS M. Morelli, S. Fenu, A. Pireddu and G. Di Chiara Inst. Pharm. & Toxic. University Cagliari, Italy. Increase in neuronal activity of some basal

Increase in neuronal activity of some basal ganglia structures and motor thalamus has been described in Parkinson and after administration of MPTP, suggesting the presence of an unbalance between the glutamatergic and GABAergic systems after dopaminergic (DA) neuron lesion. In the 6-OHDA model of Parkinson, we studied the effect of the antagonist of the N-metyl-D-aspartate (NMDA) receptor (+)MK 801 on the contralateral turning induced in rats, by various DA agonists, after unilateral lesion. Administration of 0.1 mg/kg of (+)MK 801 which do not induce any change in the behavior per se, potentiated the turning induced (+)MK 801 which do not induce any change in the behavior per se, potentiated the turning induced by the D1/D2 agonist apomorphine and L-dopa. This potentiation seemed to be due to an action on D1 receptors since (+)MK 801 strongly potentiates the turning induced by SKF 38393 but not that induced by the D2 agonist LY 17555. In addition (+)MK 801 completely blocked the sensitization (priming) to the subsequent administration of DA agonists. Blockade of NMDA receptors therefore, acts synergistically with D1 agonists in inducing turning and prevents the development of adaptive mechanisms such as priming. mechanisms such as priming.

STRUCTURE AND BIOLOGICAL ACTIVITY RELATIONSHIPS OF RIGID FLUORENAMINE-BASED PHENCYCLIDINE ANALOGUES. Y.-P. Pang*, J. T. Wroblewski, and A. P. Kozikowski. Dept. of Chem., Univ. of Pittsburgh, Pittsburgh, PA 15260; Fidia-Georgetown Inst. for the Neurosciences, 3900 Reservoir Rd., N.W., Washington, DC 20007.

the Neurosciences, 3900 Reservoir Rd., N.W., Washington, DC 20007. We reported previously the design, synthesis, and testing (binding affinity) of a class of rigid fluorenamine-based phencyclidine analogues and deduced the structural determinants of high binding affinity (A. P. Kozikowski and Y.-P. Pang, Mol. Pharmacol., 37:352, 1990). Recently, we tested the ability of this class of analogues to inhibit NMDA-induced calcium influx using an established protocol (J. T. Wroblewski et al., Proc. Natl. Acad. Sci., USA, 84:5068, 1987). For all -NH2 bearing analogues, stereoselectivity of inhibition of Ca²⁺ influx was observed; the relative potency of inhibition of Ca²⁺ influx by these analogues was consistent with their binding affinities. Analogue 3 with the highest binding affinity (IC50=19 nM) showed the most potent inhibition (IC50=59 nM) while PCP with a binding affinity of 35 nM showed an inhibition of Ca²⁺ influx of IC50=100 nM. For all -NHEt bearing inhibition of Ca2+ influx of IC50=100 nM. For all -NHEt bearing analogues, no stereoselectivity of action was observed; all compounds showed weak inhibition of Ca^{2+} influx, and the relative potencies of such inhibition was inconsistent with binding affinities. Thus analogue 7 with a binding affinity of 68 nM had an IC_{50} for blockade of Ca^{2+} influx of 450 nM. These results indicate that: (a) analogue 3 is a potent NMDA receptor antagonist; (b) the presence of an ethyl group on the nitrogen atom reduces the ability to block Ca²⁺ influx, but only slightly reduces binding affinity. The anomalous effect of the ethyl group may provide some insight into the design of NMDA receptor ligands showing partial antagonism.

REGULATION OF AUTONOMIC FUNCTION: PERIPHERAL AUTONOMIC ORGANIZATION AND FUNCTIONS

357.1

COMPARISON OF THE DISTRIBUTION OF NEUROPEPTIDE Y (NPY) AND VASOACTIVE INTESTINAL PEPTIDE (VIP) IN RENAL POSTGANGLIONIC NEURONES OF THE RAT. <u>V. Chevendra and L.C. Weaver</u>. The John P. Robarts Research Institute and Dept. of Physiology, University of Western Ontario, London, Ontario, Canada. Noradrenergic nerves innervating the blood vessels and

Noradrenergic nerves innervating the blood vessels and calyx of the kidney in rats have been shown to have NPY-like immunoreactivity. Moreover, some noradrenergic nerves on renal vessels show VIP-like immunoreactivity. The extent of this peptidergic innervation cannot be readily quantified by identifying nerve terminals within the target organ. Therefore, the proportion of renal sympathetic cell bodies containing these peptides was determined. Renal postganglionic neurones were labelled in anaesthetised rats using retrograde transport of fluorescent dyes and serial sections of samplia were then processed immunocytochemically for the of ganglia were then processed immunocytochemically for the presence of NPY or VIP. The following table illustrates the distribution of peptides in 2144 renal neurons of five rats.

T12-T13 chain ganglia splanchnic ganglion 6-26% 19-35% NPY 0%

The majority of remaining neurones in the sympathetic ganglia examined showed NPY-like immunoreactivity, whereas, only few reacted positively for VIP. In conclusion, (a) VIP appears to make a minor contribution to the control of the kidney by postganglionic neurones, and; (b) the small proportion of NPY-immunoreactive cell bodies of renal neurones conflicts with the reported high density of NPY-immunoreactive sympathetic postganglionic terminals in the kidney. (Research support: Medical Research Council, Canada)

INCREASED CYTOCHROME OXIDASE ACTIVITY IN SUPERIOR CERVICAL GANGLION CELLS OF HYPERTENSIVE, BUT NOT HYPERACTIVE RATS. C.J. Forehand', H. Gutierrez' and E.D. Hendley'. Depts. of 'Anatomy and Neurobiology and 'Physiology and Biophysics, Univ. Vermont Coll. Med., Burlington, VT 05405.

A number of neural changes have been described in spontaneously hypertensive rats (SHR) as compared to their normotensive control, Wistar-Kyoto (WKY) rats. Since the SHR is both hypertensive and hyperactive, the extent to which these changes reflect hypertension-associated changes per se is unknown. To obviate this problem, two inbred strains of rats derived from the SHR have been developed; these are the WKHA, which is hyperactive, but not hypertensive, and the WKHT, which is hypertensive, but not hyperactive (Hendley et al., Hypertension, 5:211, 1983). We have used these strains to determine the level of metabolic activity in sympathetic ganglion cells as reflected by cytochrome oxidase levels.

Cryostat sections (20 µm) of superior cervical ganglia from WKY, SHR, WKHT and WKHA rats were processed for cytochrome oxidase histochemistry utilizing diaminobenzidine (DAB) as a chromogen. The relative level of cytochrome oxidase activity was determined by video densitometry of the DAB reaction product. Strain differences in the level of cytochrome oxidase in the ganglia were assessed by ANOVA. Significantly greater levels of cytochrome oxidase activity were present in the superior cervical ganglia of SHR and WKHT rats as compared with WKY and WKHA WKY and WKHA superior cervical ganglia exhibited similar levels of cytochrome oxidase activity. These results suggest that ganglion cells are more active in hypertensive animals than in either normal or hyperactive animals. Whether this increase in metabolic activity reflects electrophysiologically more active cells is currently under investigation.

MORPHOLOGICAL ORGANIZATION OF GANGLION CELLS AND SMALL INTENSELY FLUORESCENT (SIF) CELLS OF THE CANINE INTRACARDIAC GANGLIA. R.D. Wurster, X. Xi, M. Webber and W.C. Randall. Physiol. Dept., Loyola Univ. Med. Ctr. Maywood, IL 60153

Canine intracardiac atrial ganglia are innervated by vagal preganglionic and interganglionic nerves. Forty ganglion cells were intracellularly recorded (resting membrane potential > 45 mV) and labeled using horseradish peroxidase technique. In whole tissue mounts, cell morphology was traced using camera lucida technique. Somata were elongated (mean 40 x 63 µm) and had 2-12 primary dendrites (mean 5.5) which ranged in length from 16 and had 2-12 primary dendrites (mean 5.5) which ranged in length from 16 - 276 μ m (mean 80 μ m) with shorter secondary and tertiary branches and numerous spines. On 34 cells no dendrites were observed to extend beyond the ganglion. Axons could be distinguished by their length (110-2389 μ m), small diameter and sparcity of spines. All cells had one axon which arose from either the soma (n=28) or primary dendrite (n=6). Almost half of the axons (n=19) can be traced only within the ganglion, sometimes terminating on other neurons. These may be axons of interneurons. Another type of axon (n=21) coursed to the muscle or fat tissue or to interganglionic nerves. These axons were long (1043 vs 214 μ m, P<0.05), usually parallel to the long axis of the ganglion. These neurons could be parasympathetic postganglionic of the ganglion. These neurons could be parasympathetic postganglionic projection cells or interneurons that synapse on neurons in another ganglion. These two types of cells had similar somas and dendrites. Glyoxylic acid fluorescence staining for catecholamines in these ganglia revealed SIF cells which were near to other neuron soma but only 1/3 the diameter. Catecholamine containing nerve fibers ran along interganglionic nerves and around neurons, which were most likely sympathetic postganglionic axons. No large ganglion cell bodies were labeled. Conclusions: 1). Canine intracardiac ganglion is composed of vagal postganglionic projection neurons, interneurons and SIF cells. 2). Interganglionic nerves contained vagal pre and postganglionic axons, axons from interneurons, and sympathetic nostganglionic gang. (Supported by HI, 27595) sympathetic postganglionic axons. LIGHT AND ELECTRON MICROSCOPIC STUDY OF NEURONS IN CARDIAC GANGLIA OF THE RAT AND DOG. M.H. Mostafa, X. Xi, R.D. GANGLIA OF INE KAI AND BOO.

Murster, F. LaVelle, and E.J Neafsey. Neuroscience
Graduate Program and Departments of Physiology and
Anatomy, Loyola Univ. Sch. of Med., Maywood IL 60153.

Cardiac ganglia were processed for electron microscopy

where 70 profiles of cell bodies and their surrounding neuropil from each species were examined. In both rat and dog the somas were 25-30 um in diameter and were completely ensheathed by satellite cell processes, thus preventing synapses on them. On dendritic branches two types of synaptic boutons were found: boutons with homogeneous, round agranular vesicles (40 nm) and boutons with similar vesicles that also contained a few larger (70 nm) dense-cored vesicles. The predominant type of synaptic contact in the rat was asymmetric and in the dog synaptic contact in the rat was asymmetric and in the dog was symmetric. The large, wide based dendrites commonly seen in the dog were missing in 20 cell bodies of rat cardiac ganglia cut serially (2 um thick) and studied under light microscopy, leaving the rat with rather simple ovoid or round cell bodies. In agreement, neurons of rat cardiac ganglia injected intracellularly with horseradish peroxidase showed only few (1-3) long spiny dendrites compared to the many dendrites seen on dog ganglionic neurons. There are significant differences in the morphology of cardiac ganglia neurons in rats and dogs that may explain some of the differences in cardiac control between these species. (Support: NIH HL 27595)

VAGAL PROJECTIONS TO THE CELIAC PLEXUS OF THE RAT. T.L. Powley and H.-R. Berthoud. Lab. of Regulatory Psychobiology, Purdue University, West Lafayette, IN 47907.

Distal branches of the abdominal vagus are known to course into or through the region of the celiac plexus, but the exact trajectories and targets of these fibers have not been traced, in part due to difficulties both in discriminating vagal axons from the nonvagal elements with which they mix and in following them over long ances. In the present experiment, we used a protocol that combines anterograde Dil labeling, Fluoro-gold counterstaining, wholemount preparations of tissues, and confocal as well as conventional fluorescence microscopy to map these projections. Three weeks before sacrifice, male SD rats received multiple small Dil injections

(3 to 4 per side; 40 nL per injection; 5% solution) into the dorsal motor nucleus and adjacent vagal complex; three days before sacrifice, they also received an i.p. injection of 5 mg Fluoro-gold. Whole mounts of the celiac plexus region were prepared, processed in glycerin, and examined.

Dil-labeled vagal axons could be followed through connecting branches and nerves into both the celiac ganglia and the smaller associated ganglia in the plexus. Vagal fibers evidenced a selective projection pattern insofar as they distributed into--as well as terminated in--some ganglia but not others. Further, within those ganglia innervated, vagal terminals were observed on some cells and not others. Both large varicosities and finer terminal endings were observed. Additionally, a small population of neuronal somata in the celiac and accessory ganglia were retrogradely labeled with Dil. Apparently these cells (as well as similar neurons we have observed in the myenteric plexus of the proximal small intestine) must project centrally to the NTS or other regions within the dorsal vagal complex. NIH grants DK27627 and NS26632.

357.7

DII - TRACING OF DIRECT VAGAL INNERVATION OF RAT PANCREAS. H.-R. Berthoud and T.L. Powley, Laboratory of Regulatory Psychobiology, Purdue University, West Lafayette, IN 47907.

Activation of abdominal vagal motor fibers can powerfully stimulate pancreatic endocrine and exocrine secretions, and it is thought to play a major role in metabolic regulation during the cephalic phase of ingestion. Anatomically, the vagal fibers and terminals in the pancreas have not been well characterized, because silver staining for degenerating axons was the only method applied and yielded inconclusive results. Having recently identified the vagal innervation of the GI-tract with the carbocyanine dye DiI in combination with Fluorogold labeling of the enteric nervous system (Berthoud et.al., Neurosci. Abstr. 15: 264, 1989), we used the same strategy to visualize the vagal innervation of the pancreas.

Dil was injected bilaterally (3X40 nL per side, 5% in Eth) into the dmnX of male SD rats. After 3-6 weeks, animals were perfused with formalin, the pancreas was postfixed in 10% formalin, transferred to PBS, and systematically dissected into approx. 60 pieces, which were dehydrated in a series of glycerin, whole mounted, and examined by means of epifluorescence or laser scanning confocal microscopy. Fluorogold labeled pancreatic islets as well as ganglia and connecting nerve bundles in the interlobular septa could be clearly visualized using the appropriate filter cube, and then checked for vagal innervation by switching the filter.

Of the mean number of 232 ± 28 (n=5) pancreatic ganglia per rat, an average of 19 ± 5 (8%) of mainly the larger ones (10-30 neurons), located in the head of the pancreas, were vagally innervated. Highly varicose DiI labeled profiles, indicative of vagal motor terminals, characteristically encircled either only select, or most of the neurons of a given ganglion. No Dil labeled terminals could be found in islets and acinar tissue. These findings support the view that vagal preganglionics control the diverse pancreatic functions by affecting relatively few postganglionic neurons in the larger relay stations of the pancreas. (NIH grants DK27627 and NS26632)

DIFFERENTIAL 5-HT RECEPTOR-MEDIATED RESPONSES IN AORTIC RINGS FROM THYROPATHOLOGIC RATS. N.P. Edgington, J. Giordano and D.B. Stratton. Depts of Biology and Pharmacology, Drake University, Des Moines, IA 50311

The present study examined the effects of thyropathology upon 5-HT receptor-mediated contraction/dilation in 2mm ring sections excised from Sprague-Dawley rats (175-200g). Following 28 days of pathology induced by administration o propylthiouracil (PTU: hypothyroid), thyroxine (TRX:hyperthyroid) or saline (control), Rats were sacrificed and aortic sections were assayed for isometric contraction in response to increasing concentrations of 5-HT (0.1nM-10uM). 5-HT increased contraction in TRX rings, and reduced contraction in tissue from PTU-treated rats. Mechanical removal of the endothelium (denudation) reduced effects in PTU, but not TRX rings. The observed increased contraction in TRX rings was blocked by the 5-HT2-antagonist, ketanserin (KT). The blocked by the 5-HT2-antagonist, ketanserin (K.1). The contractile response elicited by high concentrations of 5-HT was also attenuated by the putative 5-HT3-antagonist ICS 205-930 (10uM). Distinct effects in PTU, TRX treated tissue following denudation suggests the possible involvement of 5-HT-induced endothelial relaxing/contractile factors. The efficacy of KT in antagonizing the differential contractile response in the property of the 5-HT2 receptor. thyropathologic rings implies that a role for the 5-HT2 receptor in these effects. The action of ICS 205-930, in light of the apparent lack of 5-HT3 sites in this tissue, suggests that the contractile response may be subserved, in part, by a 5-HT site with properties similar to the newly identified 5-HT4 receptor.

LOCATION, CHARACTERIZATION, AND PROJECTIONS OF MECHANOSENSITIVE ENTERIC NEURONS IDENTIFIED BY ACTIVITY INDUCED EXPRESSION OF C-FOS IMMUNOREACTIVITY. A. L. Kirchgessner and M. D. Gershon. Department of Anatomy and Cell Biology, Columbia Univ. P. & S, New York, NY.

The bowel is the only peripheral organ that is able to manifest reflex activity in the absence of input from the CNS. This activity depends on intrinsic primary afferent neurons, which have not previously been identified. Peristaltic reflexes are initiated by mechanical distension of the mucosal surface of the gut. We studied nuclear immunoreactivity (Ir) of the protein encoded by the proto-oncogene, c-fos, in order to visualize and characterize intrinsic mechanosensitive enteric neurons. Initial experiments utilized mucosal applications of cholera toxin (CTx), which activates enteric neurons, in order to determine whether c-fos is a marker for stimulation of these cells. No nuclear corder to determine whether c-los is a marker for stimulation of these cells. No nuclear c-fos-ir was found in the neurons of non-stimulated gut; however, following CTx, nuclear c-fos-ir appeared in neurons of each plexus. This effect of CTx was blocked by tetrodotoxin (TTx). In order to distend the mucosal surface of the bowel in vitro, segments of gut were opened and puffs of N₂ were delivered to the intestinal liming with a Picospritzer™. After 1 hr, c-los-ir was found in neuronal nuclei; this effect was blocked by TTx and 5-HT antagonists. A microinjection of the retrograde tracer, FluoroGold (FG), was placed in a single myenteric ganglion in order to tabel those submucosal neurons which project to the myenteric plexus. When this technique was combined with mucosal stimulation and demonstration of c-los-ir, a set of submucosal neurons was found that was doubly labeled by retroorage transport of FG and antibodies to c-loss. Some of these doubly labeled by retrograde transport of FG and antibodies to *c-fos*. Some of these neurons were found to contain calbindin-ir and/or substance P-ir. It is concluded that the gut contains submucosal mechanosensitive neurons that project to the myenteric piexus. 5-HT is involved in stimulating these cells, a proportion of which contain calbindin and/or substance P. ULTRASTRUCTURE OF HRP LABELED NEURONS IN THE GANGLIONATED PLEXUS OF THE GUINEA PIG GALLBLADDER. E.B. Combrooks, W.A. Pouliot * and G.M. Mawe, Department of Anatomy and Neurobiology, The University of Vermont, Burlington, VT 05405.

Little is known regarding the extent to which gallbladder function is regulated by neurons that are intrinsic to the organ. The wall of the gallbladder contains a prominent neural plexus comprised of small, irregularly shaped ganglia of 2-10 neurons. In this study, individual, physiologically identified neurons within these ganglia were injected intracellularly with horseradish peroxidase (HRP). The labeled cells were examined with light and electron microscopy to determine the morphology of galbladder neurons and their association with the surrounding ganglion.

microscopy to determine the morphology of gaibladder neurons and their association with the surrounding ganglion.

HRP labeled cells were large (avg. size 54 X 30 µm) with irregular contours. Most cells gave rise to a single unbranched axonal processes that exited the ganglion through a connective; some cells had a second process that passed directly across muscle fibers adjacent to the ganglion. Ultrastructurally, labeled cells revealed numerous short somal extensions that closely controlled the controlled to the controlled contro closely apposed adjacent neurons or enclosed terminals containing dense core and clear spherical vesicles or clear spherical vesicles only. Abundant glial processes surrounded most somal extensions within the ganglia and ensheathed individual axons in the ganglia and connectives. At the periphery of the ganglia, labeled cells had frequent direct contacts with the basal lamina.

Overall, ganglia were compact, lacked internal basal lamina and collagen, and were surrounded by a basal lamina and distinct connective tissue capsule.

These studies reveal that the intrinsic ganglia of the gallbladder more closely

resemble those of the enteric nervous system than traditional autonomic ganglia, and may similarly play an extensive role in the local regulation of the function of this organ. However, the simpler neuronal geometry, the greater extent of glial investment and a lower level of innervation indicate differences from enteric ganglia that may be functionally significant. RESTING SYMPATHETIC ACTIVITY IN DIABETIC NERVE. L.C. Russell. K. J. Burchiel and R.P. Lee*. Univ. of Washington, Dept. Neurological Surgery, SVAMC, Seattle, WA 98195, & Neurosurgery, Oregon Hith. Sci. Univ., Portland, OR.

Resting sympathetic activity(SA) was examined in saphenous nerve of 32 BB rats with diabetic durations of 3-15 mo., maintained on either a good (G) or poor (P) glycemic control regimen. Twenty two nondiabetic littermates and cousins served as controls (C). Unilateral whole nerve conduction velocities CV were obtained, then the nerve was cut near the knee and 30 microfilaments were dissected and examined for SA

Results: CV of 3-6 mo. G were not different than C, but 3-6 mo. P CV were significantly slower than C (pd.001) or G (pd.05). CV were also significantly slower than C in both 9-12 mo. G (pd.029) and P (p-0.04), but did not differ between treatment regimens. SA was found in significantly fewer microfilaments than controls in 3-6 mo. G (p@ 022) and P (p@ 001), but was not affected by treatment regimen. SA in 9-12 mo. diabetics did not differ from matched control level, nor did treatment groups differ. However, although CV did not differ among age groups, there was significantly less SA in the older C than in the younger(p-0.028). Conclusions: (1) CV was slower in diabetic BB rat nerve than in

controls. (2) Good glycemic control maintained normal CV in young adults, but the effect diminished with age. (3) SA levels in young adult BB rats were lower than in controls. (4) SA levels in old BB rats were low whether or not diabetes was present.

PEAK SYMPATHETIC NERVE ACTIVITY DURING FATIGUING ISOMETRIC EXERCISE IN HUMANS. D. R. Seals, M.J. Reiling*, and D. G. Johnson*. Depts. of Exercise and Sport Sciences, Physiology and Internal Medicine, Univ. of Arizona, Tucson, AZ

We tested the hypothesis that peak sympathetic activity is independent of the level of exercise during voluntary, constant-force muscle contractions sustained to the point of fatigue. In 6 healthy subjects, muscle sympathetic nerve activity (MSNA; peroneal microneurography), venous plasma norepinephrine levels (NE), arterial blood pressure (AP) and heart rate (HR) were determined before (control) and at the end (last and heart rate (HR) were determined before (control) and at the end (last 20% of contraction) of isometric handgrip exercise performed to fatigue at 20% (431±68 [SE] s), 40% (115±23 s) and 60% (64±9 s) of maximal voluntary force (random order). MSNA averaged 14 bursts/min and 175 units (total min activity) during the control periods and increased during all 3 levels of exercise (p<0.05). Peak MSNA was greater (p<0.05) during exercise at 40% (47±9 bursts/min, 710±257 units) and 60% (49±7 bursts/min, 720±186 units) of maximum than at 20% (31±3 bursts/min, 397±119 units). The increases in NE (136±11, 134±6, 135±12% of control at 20.40 & 60%) and mean AP (28±6, 33+6, 32±5). bursts/min, 397±119 units). The increases in NE (136±11, 134±6, 135±12% of control at 20, 40 & 60%) and mean AP (28±6, 33±6, 32±2 mmHg) were not different among the 3 exercise levels, but the increase in HR (bt/min) was greater (p<0.05) at 60% (39±6) than at 40% (29±7) and 20% (22±5) of maximum. We conclude that during fatiguing isometric exercise in humans, peak sympathetic nervous system activity to non-active skeletal muscle depends on the force of contraction. This influence is not reflected in plasma neurotransmitter levels, and there is no obvious effect on arterial blood pressure. (Supported by NIM HI no obvious effect on arterial blood pressure. (Supported by NIH HL 39966)

357.13

POSTNATAL DEVELOPMENT OF CARDIOVASCULAR AND SYMPATHETIC RESPONSES TO FICTIVE VALSALVA MANEUVERS. B.W. Hundley, P.M. Gootman, H.L. Cohen and G. Condemi*, Department of Gootman, H.L. Cohen and G. Condemi*, Department of Physiology, State University of New York, Science Health Center, Brooklyn, N.Y. 11203.

Studies of postnatal neural regulation of the circulation indicate variability of maturation of cardiovascular reflexes (Gootman, "Developmental cardiovascular reflexes (Gootman, "Developmental Neurobiology of the Autonomic Nervous System," Humana Press, 1986, pp. 279-325). We have now examined responses to more complex stimuli, the Valsalva Maneuver, using maintained lung inflations (MLI) as the test in Saffan-anesthetized, paralyzed piglets. Both efferent phrenic (PHR) and preganglionic sympathetic (SYMP) activity were recorded. Prior to 1 month of age, no overshoot of aortic pressure (AoP) or heart rate (HR) change could be elicited at the cessation of the MLI although PHR activity was inhibited. In 1 month old piglets, changes (@5%) in AoP and HR were obtained. It was not until 48 days of age that classical Valsalva Maneuver responses were obtained in the developing swine. In the >1 month old swine, SYMP responses included decreased activity followed by an increase and, upon removal of the MLI, inhibition followed by recovery. Thus, while the various component reflex pathways involved in complex cardiovascular response patterns are present in younger animals, the complete integration of responses to more complex stimuli was delayed until the piglets were at least 6 weeks of age. (Supported by NIH Grant HL-20864.)

357.15

ADRENOMEDULLARY CONTRIBUTION TO STRESS-INDUCED ADREMOMEDIATED BY B2 ADRENOCEPTORS IN RAT. R. Davisson, R. Kirby & A.K. Johnson. Dept. of Psychology

and Pharmacology, Univ. of Iowa, Iowa City, IA 52242.

We have previously found that blockade of \(\beta_2 \)
adrenoceptors increases the pressor response to acute stressors in rats. This response is most likely due to antagonism of epinephrine's action on β_2 adrenoceptors mediating vasodilation in skeletal muscle vasculature. The present study examined the relative contributions of the sympathetic nerves and the adrenal medulla to the pressor

response evoked by acute stress in Sprague Dawley rats.
The stressors, transfer to a novel chamber and footshock, led to immediate pressor responses in vehicle-treated animals. Blockade of sympathetic terminal release of norepinephrine with bretylium abolished this immediate pressor response to the stressors, with no effect on the delayed (7-9 sec) blood pressure response. The β₂ adrenoceptor antagonist ICI 118,551 led to an increased blood pressure response to transfer and a delayed pressor response to footshock as compared to vehicle-treated controls. Blockade of sympathetic terminal release with bretylium did not affect the increased pressor responses to the stressors produced by antagonism of 82 adrenoceptors. These results indicate that acute stressors adrenoceptors. These results indicate that acute stresson produce skeletal muscle vasodilation that is mediated by adrenomedullary epinephrine release on \$2 adrenoceptors.

ALTERED EXPRESSION OF PEPTIDYLGLYCINE α-AMIDATING MONO-OXYGENASE (PAM) IN HYPERTENSIVE AND HYPERACTIVE RATS.

K.M. Braas, E.D. Hendlev, and V. May. Departments of Anatomy & Neurobiology and Physiology & Biophysics, University of Vermont, Burlington, VT 05405

Many bioactive peptides influence cardiovascular function, and altered amidated peptide levels have been associated with hypertension. Peptidylglycine α-amidating monooxygenase (PAM) catalyzes the formation of bioactive α-amidated peptides from their inactive glycine-extended precursor molecules. Highest levels of PAM expression were found in the cardiovascular system. The expression of PAM in neuroendocrine tissues is coordinately regulated with amidated peptide biosynthesis. We have examined the tissue specific expression of soluble and membrane-associated PAM in tissues involved in cardiovascular regulation in the normotensive Wistar-Kyoto (WKY) and spontaneously hypertensive (SHR) rat strains. To determine whether altered PAM expression is associated with either the hypertensive or hyperactivity trait of the SHR, tissues from two inbred strains were also examined. The WK-HT is hypertensive but not hyperactive, while the WK-HA is hyperactive but normotensive (Hendley, et al., Hypertension § 2211, 1983). Tissue PAM activities in the SHR, WK-HT and WK-HA strains were compared to activities in the WKY strain. Membrane-associated PAM activity levels were elevated 1.5 - 2.0 fold in heart atrium and ventricle of the SHR and WK-HT strains, suggesting that peptidergic levels in these tissues are altered in the hypertensive animals. Ventricular soluble PAM activity was elevated over 4 fold in the WK-HT strain. Atrial PAM activity was lower in the WK-HA strain. The anterior pituliary gland, which is composed of many distinct endocrine cell types, expressed 2 - 3 fold increases in PAM activity in the SHR, WK-HA rats, subjectific association with hyperactivity. PAM activity in the neurointermediate pituitary lobe increased 2 - 4.5 fold only in the SHR and WK-HA rat

357.16

CALCIUM, BLOOD PRESSURE & SODIUM FLUX IN SHR & WKY RATS A. Derick Dalhouse , Dawn Erickson*, and Patrick Bellgowan* Dept. of Psy., Moorhead State University, Moorhead, MN. There is evidence that calcium (Ca) physiology is altered in essential hypertension. Intracellular Ca ions have direct effect on peripheral vascular tone, and hypertensives have increased intracellular free Ca that decreases to normal levels with anti hypertensive treatment. Serum Ca levels have been negatively associated with 24-hour urine sodium (Na) and positively associated with potassium (K) excretion. If abnormal cations transport is potassium (K) excretion. If abnormal cations transport is in fact a marker and precursor of hypertension it is important to identify potentially modifiable environmental or life style variables that might be useful for preventive purposes. In this experiement SHR and WKY rats were placed on normal, high, or low calcium diets for 7 weeks to investigate the effects of dietary calcium on blood pressure and red blood cell (RBC) Na flux. SHR pressures pressure and red blood cell (RBC) Na flux. SHR pressures were significantly higher than the WKY in all groups (p<.009), but not different from each other. The low calcium WKY rats showed a significant elevation in blood pressure (p<.003) compared to the normal and high calcium WKY rats. Thus high dietary calcium seems to have no effect on the blood pressure of genetically hypertensive or normotensive rats while low dietary calcium seems to have an elevating effect on that of normal rats. The Ca diets produced no significant differences in RBC Na flux, however the SHR rats showed higher Na flux than the WKY rats.

DIETARY CALCIUM ALTERS BP REACTIVITY TO NOREPINEPHRINE BUT NOT TO THE ALPHA-1 AGONIST METHOXAMINE D.C. Hatton, Deborah Levine*, D.A. McCarron*, Oregon Health Sciences University, Portland, OR 97201

Variations in dietary calcium cause blood pressure (BP) alterations in the spontaneously hypertensive rat (SHR). Animals fed supplemental dietary calcium have lower blood pressure than those fed restricted calcium diets. Along with the change in basal blood pressure, blood pressure reactivity to infusions of norepinephrine (NE) is altered with animals on low calcium diets having larger and more prolonged pressor respones to infused NE. To determine whether the alteration in blood pressure reactivity is due exclusively to activation of alpha-1 adrenergic receptors, the alpha-1 adrenergic agonist methoxamine (100, 200, 400 ug/kg) was given to 5-weekold SHRs maintained on either high (2.0%) or low (0.1%) calcium diets for two weeks. There was no difference in pressor response to methoxamine between dietary groups. However, as in previous studies, there was a significant difference in basal blood pressure between dietary groups (118 vs 105 mmHg, p<.01) as well as a significant difference (p<.001)between dietary groups in their response to doses of NE. The results suggest that diet-induced alterations in blood pressure reactivity to NE are not a consequence of changes in alpha-1 receptor activity.

AMPLIFICATION OF ANP-RELATED GENE FRAGMENTS FROM FISH

BRAIN cDNA BY PCR. D.A. Price and B.M. Byrne. Whitney Laboratory, 9505 Ocean Shore Bird., St. Augustine, FL 32086.

We previously isolated an ANP-related peptide from fish (<u>Fundulus heteroclitus</u>) brain by use of an antibody to rat ANP. The sequence of this

GWNRGCFGLKLDRIGSMSGLGC is similar to the known mammalian peptides within the disulfide ring but differs from them in its N-terminal sequence and most remarkably by ending with the second half-cystine of the disulfide-linked ring. The lack of a C-terminal tail is a unique feature among the known ANP-related peptides, so we wished to determine its biosynthetic basis, and first of all the structure of its precursor. A mixed oligonucleotide, encoding the N-terminal eight amino acids of the peptide, was synthesized. To reduce the degeneracy, inosine was used for all positions where any of the four bases might occur. The downstream primer consisted of an oligo(dT₁₀) extended at the 5' end by ten bases containing an EcoRI recognition site. Total RNA from fish brain was reverse transcribed using the downstream primer, and subsequently subjected to 30 cycles of amplification (48°C annealing temperature). The products were fractionated on a low melting int agarose (NuSieve) gel and selected regions of the expected size (250-400 bp, based on homology to mammalian sequences) were re-amplified for a further 25 cycles. The products of these second amplifications were made blunt-ended 25 cycles. The products of these second amplifications were made built-ended using T4 DNA polymerase and, after digestion with EcoRI, they were directionally cloned into Smal x EcoRI-digested pGEM-32. We have sequenced three recombinants; each contained both primers but the remaining sequence showed no similarity to ANP. Additional recombinants are currently being characterized by sequencing. (Supported by NIH grant HL28440).

DIFFERENTIAL DISTRIBUTION OF CATECHOLAMINES IN WHITE ADIPOSE TISSUE REVEALED BY VIDEO-ENHANCED AND CONFOCAL SCANNING LASER MICRSOSCOPY. M. Rebuffe-Scrive*, R. J. Wyman, and C. L. Keenan. Depts. of Psychology and Biology, Yale University, P.O. Box 11A, Yale Station, New Haven, CT 06520-7447.

Addominal distribution of fat is associated with increased risk factors for cardiovascular diseases and diabetes. It has been suggested that the elevated catecholamine (CAT) stimulated lipolysis found in abdominal, particularly intraabdominal fat depots might be a potential generator for the pathology of abdominal obesity. However, whether the sympathetic nervous system directly and differentially regulates the different depots of white adipose tissue (WAT) is not known. We used a modified de la Torre and Surgeon (1976) method for fluorescence histochemical detection of CATs in combination with video-enhanced and confocal scanning laser microscopy to localize CATs in four different WAT depots (mesenteric, retroperitoneal, epidydimal, and inguinal) of rats. We also studied the sensitivity of isolated adipocytes to norepinephrine (NE) stimulation. Three-dimensional and quantitative localization of the CATs in whole mounts of WAT depots allowed us to show that CATs are differentially distributed among WAT depots. Visceral depots contain the highest CAT innervation and non-neural CATs, particularly in the mesenteric region. Inguinal WAT had the lowest CAT content. CATs not specific to nerve terminals were distributed around the adipocytes primarily at the nexuses formed by the junctures of the adipocytes and the nerve terminals. Sensitivity of isolated adipocytes to bath applied NE (10-5M) also provided direct evidence that fat cell size is regulated by CATs. These preliminary results suggest that the higher content of CATs in intraabdominal fat tissues might explain the regional differences observed in lipolysis. Furthermore, it was shown that the methods utilized provide a direct in vitro means to study further the role and interactions of CATs with environmental and hormonal factors that might affect regional fat distribution .

MULTIPLE EFFECTS OF SPANTIDE IN THE ISOLATED PERFUSED GUINEA PIG HEART. D.B. Hoover. Dept. Pharmacol., Col. of Med., East Tennessee State Univ., Johnson City, TN 37614.

The present study was designed to determine the effect of spantide on perfusion pressure in isolated guinea pig heart and the ability of this drug to block vasodilator responses to substance P (SP). Hearts from male, Hartley guinea pigs were perfused at a constant flow rate with isotonic buffer containing 20 or 40 mM KCl. High KCl was used to increase perfusion pressure and eliminate cardiac contractions. Spantide (1 µM) increased the ED₅₀ for vasodilation by SP (1.3 vs 26 pmol; n=6 each; 40 mM KCl). Bolus injections of \leq 0.25 nmol spantide had no effect on perfusion pressure. However, 2.5 and 25 nmol spantide produced a biphasic perfusion pressure response. With t 25 nmol dose, an initial 12 ± 2% decrease in perfusion pressure was followed by a prolonged increase with a maximum 58 + 5% above baseline (20 mM KCl, n=5). Spantide also caused a brief resumption of cardiac contractions Histamine produced a similar response pattern to that of spantide, and a combination of $\rm H_1$ and $\rm H_2$ receptor blockers antagonized vascular and cardiac responses to spantide. Therefore, spantide is a weak antagonist at SP receptors in the guinea pig coronary vasculature and at high doses elicits vascular and myocardial responses mediated by histamine released from cardiac mast cells. Supported by NIH Grant HL38705 and a Grant-in-Aid from the American Heart Association, Tennessee Affiliate.

ALTERED NEUROPEPTIDE-Y IMMUNOREACTIVITY (NPY-IR) IN LEFT VENTRICULAR HYPERTROPY RESULTING FROM AORTIC STENOSIS. S. Love, C. Nyquist-Battie, and B.M. Chronwall, Schools of Pharmacy and Basic Life Sciences, University of Missouri, Kansas City, MO 64108.

Myocardial stores of norepinephrine(NE) are depleted in most models of hypertrophied and failing heart. The effect of cardiac hypertrophy on NPY, a cardiovascular regulatory peptide released from cardiac adrenergic nerve endings, is the focus of this study. Left ventricular hypertrophy was induced in female guinea pigs by subdiaphramatic aortic stenosis. Animals were sacrificed five weeks after surgery. The left ventricular/body weight ratio was elevated 49% by aortic stenosis. Cryostat sections of 4% paraformaldehyde fixed tissue were stained for NPY-IR using an indirect fluorescence method. A dense innervation by NPY-IR fibers was seen in the atria of control animals with less innervation present in the ventricles. NPY-IR fibers were present in all layers of the heart waill. Hearts from animals with aortic stenosis ventricies. NYTHE THEFTS were present in all layers of the heart wall. Hearts from animals with aortic stenosis showed a similar NPY-IR distribution in all chambers except the left ventricle which was nearly devoid of NPY-IR. These results indicate that NPY-IR is reduced in the pressure-overloaded ventricle in addition to NE depletion. Given the direct and indirect roles of NPY in cardiovascular functions, a reduction in NPY levels may contribute to the congestive heart failure seen in cardiac hypertrophy.

357.22

ACETYLCHOLINESTERASE (AChE) EXPRESSION IN CULTURED PERINATAL CARDIAC MYOCYTES. K. Hagler* and C. Nyquist-Battie. School of Basic Life Sciences, University of Missouri, Kansas City, MO 64108.

Globular(G) and asymmetric(A) molecular forms of AChE are present in the ventricles of rat heart. However, the relative contribution of A-forms is higher in the fetal period compared to the perinatal and adult periods. To determine if this change is the result of altered expression of AChE forms by cardiac muscle cells, ventricles from 17-19 day old embryos and 2-4 day old rats were dissociated by 0.1% collagenase. Dissociated cells were preplated in M199 and 0.5% fetal calf serum to remove non-muscle cells. Subsequently, myocytes were plated at 1.5 X 10° cells per 35mm dish, coated with fibronectin and laminin, in a defined medium. Myocytes were confluent and beating for at least 48-h before harvest. The specific activity of AChE in the cellular and secreted pools did not differ as a function of age of hearts from which myocytes were isolated. The tetrameric G, form was the predominate secreted form in both groups. G, (monomeric) and G, forms were the predominate forms in the myocyte-associated pool of both groups and exhibited a similar activities ratio. A-forms were barely detectable (< 5%) in the cell-associated and secreted pools in cultures from both pre- and post-natal hearts. In conclusion, there was no increased AChE synthesis or G, expression in cultured myocytes as a function of maturation. Secondly, A-form production is low in perinatal myocyte cultures compared to rates in yivo, suggesting that trophic factors are necessary in developing heart for A-AChE expression.

SINGLE JUNCTIONAL CHANNEL EVENTS IN HEART CELL PAIRS AND cAMP. W. C. De Mello. Department of Pharmacology,
School of Medicine, Univ. of Puerto Rico, PR 00936.
Evidence is available that cAMP increases the junctional conductance (gj) in isolated heart cell pairs. (De Mello, 1988). The mechanism by which cAMP increases gj might be related to: 1) increase in unitary channel conductance; 2) an increase in nº of channels or 3) a change in open-closed time kinetics. To investigate change in open-closed time kinetics. To investigate these possibilities heart cell pairs were isolated from adult rat ventricle. Only pairs with low gj (2-6 nS) were used. With a transjunctional voltage of -50 mV single junctional channel events were recognized. The unitary channel conductance was found to be 101 pS unitary channel conductance was found to be 101 pS ($^{\pm}$ 33). No change in single channel conductance was seen with isoproterenol (10 -6M) despite the increase in gj (75%). The open-time distribution was not changed by the drug. An increase in open probability is assumed to explain the increase in gj caused by cAMP. (Supported in part from grant #HL-34148 from NIH and M0786E87 from MBRS).

REGULATION OF AUTONOMIC FUNCTION: GASTROINTESTINAL CONTROL

358.1

PARTICIPATION OF THE PERIPHERAL AUTONOMIC NERVOUS SYSTEM IN EMESIS. M.T. Makale* and G.L. King, Dept. Physiology, AFRRI, Bethesda, MD 20814.

It is well established that the vagi play a key part in emesis. However, participation of the sympathetic n.s. is less well examined, and our study explored this topic. Ferrets were anesthetized with urethane i.p. and the right jugular were anesthetized with uretnane 1.p. and the right jugular and carotid cannulated. For bilateral vagotomy (vgx) or splanchnisectomy (spx), the animals were laparotomized and the nerves transected. The ferrets were then given 10 ml of CuSO₄ (5mg/ml) gastrically, or irradiated using a °Co source (γ) or reactor (γ/n=20:1) for 6 Gy at 1 Gy/min. Another group, anesthetized with isofluorane, cannulated, and allowed to recover, received cyclophosphamide (200 mg/kg). Ferrets not subjected to nerve transection received: atropine-CH₃Br (1 mg/kg), propanolol (3 mg/kg), α-blocker (DCMB 10 mg/kg), or 5HT₂ antagonists zacopride (0.3 mg/kg) and granisetron (0.5 mg/kg), i.v. before radiation, CuSO₄, or cyclophosphamide. All controls responded to radiation, and 0/2 to CuSO₄. With spx 2/8 ferrets responded to radiation, and 0/2 to CuSO₄. With spx 2/8 ferrets responded to radiation. After atropine, 3/4 animals responded to CuSO₄. With propanolol 12/15 responded to CuSO₄, and 3/3 to cyclophosphamide. After DCMB 4/6 animals responded to CuSO₄, and with granisetron 4/4. These early results suggest that both autonomic branches contribute to emesis, but afferent ACh and adrenergic contributions are minor. and carotid cannulated. For bilateral vagotomy (vgx) or and adrenergic contributions are minor.

TOPOGRAPHIC REPRESENTATION OF THE PROXIMAL AND DISTAL STOMACH IN THE DORSAL MOTOR NUCLEUS IN RAT. S.M. Altschuler. R.R. Miselis, T.H. Moran, P.R. McHugh, & G.J. Schwartz, Dept. Ped.,

Anim. Biol. & Inst. Neurol. Sci., Univ. of Penn., Phila., PA, 19104, & Dept. Psychiatry, Johns Hopkins Univ. Sch. Med., Balto., MD 21205. Small quantities (5-10 µl) of cholera-toxin conjugated to horseradish peroxidase (CT-HRP) were injected into the ventral pyloric/antral region (N=8) or the ventral forestomach (N=9) of rats to determine the topographic representation and dendritic projections of motoneurons within the dorsal motor nucleus (DMN). Although both injections labelled cells throughout the rostro-caudal extent of the DMN unilaterally, the majority of labelled cells in both cases were located along the rostral-caudal extent of the area postrema. Second, there was a prominent topographic representation of the two gastric regions injected. Motoneurons innervating the pylorus/antrum were found in the medial 1/3 -1/2 of the DMN. In contrast, motoneurons innervating the ventral forestomach were located in the lateral 1/3 of the DMN. Finally, dendritic projections from medially labelled DMN sites tended to extend into the lateral aspect of the subnucleus gelatinosus of the nucleus tractus solitarius, while those from lateral DMN sites tended to extend into more medial portions of the subnucleus gelatinosus. The results extend the notion of a topographic representation of visceral structures within the DMN GM27739, DK01747, & DK19302).

SOURCES OF GASTRIC VAGAL EFFERENT INNERVATION IN RATS. J.Y. Wei, Y. Taché and L. Kruger. CURE/VA Wadsworth Medical Center, Dept. of Medicine, Dept of Anatomy & Brain Research Institute, UCLA, CA 90073. Gastric vagal efferent sources were studied by recording ventral gastric vagal efferent discharges (VED) in urethane-chloralose anesthetized rats. After a single or multi-unit basal VED was recorded, the right and left cervical vagus and then the distal end and proximal end of the ventral gastric vagus were transected successively at about 30 min intervals, and comparisions of VED before and after each transection were made. Results: 1) the VED were increased in 15/21 cases by 4-53% (median 18%) and were reduced in 2 cases by 4 and 22% after the right cervical vagus was cut, suggesting that there is a numerous crossed inhibitory by 4-53% (median 18%) and were reduced in 2 cases by 4 and 22% after the right cervical vagus was cut, suggesting that there is a numerous crossed inhibitory afferent influence and few, if any, crossed gastric vagal efferents. 2) After both cervical vagi were cut, the VED were decreased by 10-99% (median 90%) in 14/17 of experiments. 3) A segment (4-5 mm) of the gastric vagus was isolated by additional cuts at the distal and proximal end of the nerve, abolition of VED were obtained in only 4/14 of successful cuts, 1 to 3 residual units of VED were recorded in 10 cases. Morphological evidence suggests that the presence of paraganglionic cells in the isolated specimen may account for the residual VED. These findings reveal that in rats, gastric vagal efferents do not all originate from the brain stem. Alternative descending sources may be located between the lower cervical to upper and/or lower abdominal esophageal levels. (Supported by NIH grants, DK33061, DK30110 and NS5685)

358.4

ABDOMINALLY PROJECTING NON-CHOLINERGIC NEURONES IN THE DORSAL MOTOR NUCLEUS OF THE VAGUS (DMN) IN THE RAT. <u>E.K. Tayo and C.J. Helke.</u> Dept. of Pharmacol., Uniformed Services Univ., Bethesda, MD 20814.

Efferent fibres arising from perikarya within the dorsal motor nucleus of the vagus (DMN), form a major autonomic, motor pathway involved in the regulation of abdominal visceral function. These neurones are classically regarded as being cholinergic and have been previously identified by a number of investigators using immunocytochemistry (icc) to choline acetyltransferase (ChAT) or acetylcholinesterase

to choline acetyltransferase (ChAT) or acetylcholinesterase (AChE) histochemistry.

The presence of AChE-negative abdominally projecting neurones has been previously reported (Hoover & Barron 1982, Tayo & Williams 1988), however, the fact that the same had not been shown using ChAT icc precluded the classification

of these cells as non-cholinergic.

The present study combines retrograde tracing with True
Blue, immunocytochemistry to ChAT, AChE histochemistry and Nissl staining techniques on individual 20 mm rat medullary

results show the distributions of ChAT-immunoreactive and AChE-containing cells to be identical throughout the rostrocaudal extent of the DMN. In addition, a comparison of the cholinergic cell localization with those cells identified subsequent to Nissl staining and/or retrograde transport of True Blue, reveals a population of cells which do not appear to contain AChE or ChAT.

DIRECT HUMORAL ACCESS TO DORSAL MOTOR NUCLEUS OF THE VAGUS PREGANGLIONIC NEURONS? F.B. Wang and T.L. Powley, Lab. of Regulatory Psychobiology, Purdue U., West Lafayette, IN 47907.

The autonomic outflow of the dorsal motor nucleus of the vagus (dmnX) is influenced by the concentrations of peptides and other active compounds in the ventricular and systemic circulations. These factors have traditionally been assumed to affect preganglionics indirectly by acting through afferents. In experiments on dmnX dendroarchitecture, we have observed some preganglionics which send dendrites to the ependymal wall as well as to blood vessels, raising the possibility of additional, direct humoral effects on dmnX motorneurons.

In male SD rats, the preganglionics of the dmnX were labeled by retrograde transport of Fast Blue. The brains were lightly fixed by perfusion, sections of the medulla oblongata were vibratomed, and the dendrites of individual neurons were stained by intracellular iontophoresis of lucifer yellow. Dendritic profiles were reconstructed with both laser scanning confocal and conventional microscopy

Although dendrites of dmnX preganglionics tended overall to remain within the nucleus and even within the longitudinal columnar subnucleus of origin (see Fox and Powley, Soc. for Neurosci. Abst. 15(1): 662, 1989), a number of medial gastric column neurons sent one or more dendritic process to the subependymal region of the fourth ventricle or central canal. Other preganglionics had one or more dendrite(s) within the dmnX running to and along blood vessels. Although EM analyses will be required to specify what if any contact occurs between dmnX neurons and these ventricular and vascular zones, the present observationsparticularly when taken in conjunction with previous observations suggesting a reduced blood-brain barrier in the region—raise the possibility that dmx neurons could be directly influenced by humoral factors. (DK27627 and NS26632)

358.7

EVIDENCE FOR GLUTAMATE AS A NEUROTRANSMITTER IN THE GASTRIC MECHANORECEPTOR AFFERENTS PROJECTING TO THE NUCLEUS OF THE SOLITARY TRACT (NTS). Richard Rogers, Monica McCann, and Robert Stephens.

The stephens of Physiology, Ohio State University, Columbus, OH 43210.

It is now well known that gastric distention can activate a subset of neurons in the medial NTS. These NTS neurons are probably involved in gastric vago-vagal reflexes and in the transmission of information regarding gastric fill to the central nervous system. Our electrophysiological studies demonstrate that the activation of NTS neurons by gastric inflation may depend upon the release of glutamate by the first order afferents. NTS neurons, identified by their increased firing rate upon inflation of the stomach, were excited by iontophoretically-applied glutamate and NMDA. As predicted, the glutamate and NMDA. As predicted, the glutamate antagonist, kynurenic acid, inhibited the excitation produced by glutamate. Furthermore, kynurenic acid blocked the increased firing rate of NTS neurons elicited by gastric inflation. These findings suggest that glutamate is released upon inflation from the gastric mechanoreceptor afferents projecting to the NTS. Supported by NIH grants NS24530 to RCR and NS08690 to MJM.

TRH-IMMUNOREACTIVE (IR) PATHWAYS PROJECTING TO THE DORSAL VAGAL COMPLEX (DVC) IN RATS. R.B. Lynn¹, M. Kreider², R.R. Miselis³. Depts. of Medicine¹, Psychiatry²,

Animal Biology³ and Institute of Neurological Sciences,
University of Pennsylvania, Philadelphia, PA 19104

TRH microinjections into the DVC stimulate marked gastric
motor and sensory responses. TRH receptors and TRH-IR nerve
terminals are present in the DVC and these terminals synapse
on gastric motor neurons (Rinaman & Miselis JCN '90).
However, the origins of these neurons are not mapped in Fluoro-gold and a Texas-red fluorescent secondary antibody were used in a double labeling protocol. RESULTS: Double labeled (DL) neurons were found exclusively in the medulla and were located in the nucleus raphe obscurus (nRO), nucleus raphe pallidus (nRP) and along the ventral edge of the medulla. A cluster of DL'd neurons was located medial and ventral to the lateral reticular nucleus. Representative medulla. A cluster of DL'd neurons was located medial and ventral to the lateral reticular nucleus. Representative quantitation of DL'd neurons from every fourth section of a rat brain that received multiple injections bilaterally at the level of the area postrema found: 31 in the nRO, 37 in the nRP and 38 in the ventral medulla. Many FG and TRH-IR neurons were in the paraventricular nucleus of the hypothalamus but these were separate populations of neurons with no double labeling. SUMMARY: We have identified specific sites in the ventrocaudal medulla that contain TRH-IR neurons that project to the DVC, and presumably are the neurons providing project to the DVC, and presumably are the neurons providing the endogenous TRH which stimulates gastric function. This work was supported by NIH Grant GM27739.

358.6

DIFFERENTIAL GASTRIC EFFECTS OF MICROINJECTION OF L-GLUTAMATE, TRH, AND A SEROTONIN1A RECEPTOR AGONIST INTO THE ROSTRAL AND CAUDAL DMV OF CATS. <u>C.D. Rossiter. R.A. Gillis*. and P.J. Hornby.</u> Dept. of Pharmacology, Georgetown University, Washington, D.C. 20007.

Recently we reported that increases and decreases in lower esophageal sphincter pressure occur after activation of neurons in the DMV rostral and caudal to the obex, respectively (Rossiter et al., Gastroenterology Abst., 1990). The purpose of the present study was first to determine the effects on intragastric pressure and gastric motility of activation of neurons in the DMV rostral to obex (0-3.0mm) or caudal to the obex (0 to -1.5mm) in chloralose anesthetized cats. A second purpose was to determine the gastric effects of TRH or a serotonin1A receptor agonist, [3H]8-hydroxy-N.N-dipropylarminotetraline (8-OH-DPAT), microinjected into the rostral and caudal DMV. <u>DMY rostral to obex</u>. Microinjection of L-glutamate (5-10nl of 500mM; N=6) resulted in significant increases in intragastric pressure (-6.9±2.5mmHg, p-0.05) and pyloric minute motility (MMI; +8.9±2.3MMI, p-0.05). Microinjection of TRH (25-200ng in 5-20nl) also significantly increased intragastric pressure (+6.9±2.5mmHg, N=6, p-0.05) and pyloric MMI (+6.7±2.2, N=6, p-0.05). However, no significant alteration in gastric function occurred after microinjection of 1-glutamate (-0.0 to-1.5mm) significantly decreased intragastric pressure (-7.5±2.2, p-0.05, N=4) without changing pyloric motility (-1.3±1.0, N=10). TRH microinjection of L-91 had no significant effect on either intragastric pressure or pyloric MMI. A decrease in intragastric pressure or caudal DMV. DMV stimulates gastric function whereas activation of neurons in the rostral DMV stimulates gastric function whereas activation of neurons caudal to the obex results in relaxation of the stornach. TRH appears to be excitatory to gastric function on whereas activation of neurons in the rostral DMV candal to the obex. Supported by NIH grant AM29

ATRIAL NATRIURETIC FACTOR (ANF) INJECTIONS INTO THE DORSAL MOTOR NUCLEUS (DMN) INCREASE GASTRIC MOTILITY AND ACTIVATE DMN NEURONS. Monica J. McCann and Richard C. Roqers. Dept. of Physiology, Ohio State University, Columbus, OH 43210

McCann and Richard C. Rogers. Dept. of Physiology, Ohio State University, Columbus, OH 43210.

ANF has been associated with the central and peripheral regulation of cardiovascular (CV) homeostasis. In the brain, ANF-containing terminals and ANF receptors are located in sites known to influence CV function such as the DMN, which contains the vagal preganglionic neurons. However, ANF applied to the DMN has no effect on CV parameters. Given the role of DMN in the regulation of the digestive tract, we hypothesized that ANF may be a regulator of vagal outflow to the stomach. By applying picomolar amounts of ANF to the DMN, we established that this peptide significantly reduced gastric motility and tone; vagotomy eliminated this reduction. In electrophysiological studies, we observed that femtomolar quantities of ANF excited antidromically-identified DMN neurons. We conclude that ANF reduces gastric motility by activating inhibitory vagal projections to gastric smooth muscle. Supported by NIH grants NS24530 to RCR and NS08690 to MJM.

COMPARISON OF MICROINJECTION OF TRH ANALOGUE RX 77368 AND ELECTRICAL STIMULATION OF THE NUCLEUS AMBIGUUS (NA) ON GASTRIC MOTOR AND SECRETORY RESPONSES IN CATS. H-S. Feng*, J. Han* and F.P. Brooks. Depts. of Medicine and Physiology. Sch. Med., Univ. of PA, Philadelphia, PA 19104.

We wished to compare the force of gastric contraction and gastric acid output during electrical stimulation with the response to microinjections of TRH analogue into the NA of anesthetized cats. Cats were equipped with force transducers on the antrum and a gastric cannula. A semi micro-electrode (16 cats) or a micropipette (22 cats) was inserted into the NA on the left and right side under stereotaxic guidance. Current was held constant at 100µ Amp and frequency and pulse duration varied independently. Microinjections of TRH analogue varied from 50-1000 ng in 100 nl. The force of gastric contractions was determined over 15 min. periods. Acid output was determined by measuring volume and acid conc titrimetrically. Force of antral contractions reached 26.2± 1.34g with 2 msec pulse durations. Peak force of 28.7± 2.1g was obtained with 50 Hz. There was no increase in acid output. The peak force of contractions occurred after microinjection of 500 ng of TRH analogue (33.2±1.7g). Acid output also peaked at 0.33±0.04 mM/15 min with 500 ng of TRH analogue. Taché and her colleagues reported an increase in force of contraction and acid output in different rats microinjected with TRH analogue. The force of antral contractions in our experiments continued to increase after acid output had returned to baseline. We think TRH analogue acts on two different pathways in the NA to excite force of contraction and acid output. Electrical stimulation excites only the motor response.

BOMBESIN MICROINJECTED INTO THE NUCLEUS AMBIGUUS

BOMBESIN MICROINJECTED INTO THE NUCLEUS AMBIGUUS (NA) INHIBITS GASTRIC ACID SECRETION THROUGH PARASYMPATHETIC PATHWAY. H. Yang, T. Ishikawa* and Y. Taché. CURE, V A Wadsworth Medical Center, Dept of Medicine and Brain Research Institute, UCLA, Los Angeles, CA 90073.

Microinjection of bombesin (0.6-6.2 pmol/100 nl)into the NA and the surrounding areas including C1 in the rat brain stem inhibited pentagastrin stimulated gastric acid secretion (FASEB J. 2:A498,1988). This work was designed to identify whether 1) the NA itself is an effective site for bombesin to inhibit gastric acid secretion and 2) the effect of bombesin in the NA is mediated through the parasympathetic pathway. Male SD rats (250-300g, n=5-7/group) fasted for 24 h were anesthetized with urethane. A PE-90 cannula was inserted into the cervical artery to measure blood pressure and heart rate. Gastric acid secretion was measured by titration of the flushed perfusate. The basal parameters were monitored after the obex region of the dorsal medulla was exposed, then a glass micropipette was positioned into the NA or the dorsal motor nucleus (DMN) according to the atlas of Paxinos and was exposed, then a glass micropipette was positioned into the NA or the dorsal motor nucleus (DMN) according to the atlas of Paxinos and Watson. The location of microinjection sites was identified after experiment. Bombesin (6.2 pmol, 5 - 50 nl) microinjected into the NA inhibited the gastric acid secretion induced by: 1) pentagastrin (16 µg/kg/h iv) by 41% (5 nl); 2) RX77368 into the DMN (30 ng) by 63.3% or into the NA (3 ng, together with bombesin) by 55.4% (50 nl) and inhibited heart rate (5 nl). The inhibitory effect of bombesin on pentagastrin-stimulated gastric acid secretion and on heart rate was compeletly abolished by vagotomy. The antisecretory effect of bombesin co-injected into the NA with RX77368 was still observed after spinal cord tracescion. Conclusions: 1) The NA is a site of action after spinal cord transection. Conclusions: 1) The NA is a site of action for bombesin to inhibit gastric acid secretion; 2) the inhibitory effect is mediated at least in part through parasympathetic pathway

CCK ACTIVATES C-FOS IN PARAVENTRICULAR NEURONS PROJECTING TO

THE DORSAL VAGAL COMPLEX B.R. Olson, J.G. Verbalis, A.F. Sved, E.M. Stricker and G.E. Hoffman. Departments of Medicine and Behavioral Neuroscience, University of Pittsburgh, Pittsburgh, PA 15261.

Our previous results suggest that systemic administration of cholecystokinin-8 (CCK) decreases food intake and gastric motility through oxytocinergic (OT) projections from the paraventricular nucleus (PVN) of the hypothalamus. To To study the functional anatomy of this phenomenon, we measured CCK-stimulated c-fos expression in PVN cells of male rats (n=2) 2 weeks after injecting 4% fluorogold (100 nl) into the dorsal vagal complex (DVC). One hour after CCK administration (100 μ g/kg ip), rats were perfused for immunohistochemical staining with antiserum directed against the N-terminus of c-fos antigen (Cambridge Research Blochemicals) as described previously (Hoffman et al., <u>Endocrinol</u>, 1990). Previous studies with this antiserum have demonstrated absent expression of c-fos in the PVN under basal conditions, but marked stimulation of OT and CRF neurons in response to CCK. Brains were cut into 25 μ m sections, and retrogradely-labelled cells in every twelfth section were counted. In the PVN sections counted, a mean total of 563 cells were retrogradely labelled; of these, 310 (54%) also expressed c-fos. These double-labelled cells distributed predominantly in the medial parvocellular subdivision, with fewer occurring in periventricular, anterior and dorsal parvocellular PVN. We also observed many cells in the PVN expressing c-fos that were not retrogradely labelled, as well as numerous c-fos negative neurons parvocellular PVN. We also observed many cells in the PVN expressing c-tos that were not retrogradely labelled, as well as numerous c-fos negative neurons labelled intensely with fluorogold in the perifornical area, lateral to PVN, and in the dorsal hypothalamus, caudal to PVN. The overall distribution of c-fos activation closely resembled that found previously in CCK treated animals. These results suggest that CCK activates parvocellular neurons in several subdivisions of the PVN that project to the DVC of the brainstem, and support the hypothesis that the PVN modulates autonomic activity in response to systemically-administered CCK.

EFFECT OF HYPOTHALAMIC STIMULATION ON ILEAL WATER ABSORPTION IN RATS. X. Zhang*, T. Kong*, W.E. Renehan, R. Fogel. Depts of Medicine and Anatomical Sciences and Neurobiology, University of Louisville, Louisville, KY

Although a cephalic phase of intestinal water and ion absorption has been proposed, specific central nervous system regions that serve this function are not clear. this study was to determine the effects of lateral (LH) and paraventricular (PVH) hypothalamic stimulation on intestinal water nypothalamic stimulation on intestinal water absorption, and to examine possible pathways for these effects. Intestinal water absorption was measured by the single pass perfusion technique with ¹⁴C-PEG, M.W. 4,000, as the nonabsorbable marker. Electrical stimulation of the LH (4Hz, 4V, 0.2 msec) increased basal water absorption. This effect was prevented by systemic reserpine, yohimbine or prazosin but not by propranolol. In contrast, electrical stimulation of PVH and intracerebroventricular injection of vasopressin or oxytocin did not alter water absorption. These results suggest that the LH increases water absorption by a pathway involving alpha adrenergic receptors. The specific location of these receptors is not yet known.

Parvocellular neurons in the PVN projecting to the dorsal

Parvocellular neurons in the PVN projecting to the dorsal motor nucleus of the vagus may participate in the inhibition of gastric motility seen after administration of CCK (1.0 ug/kg, ip) or LiCl (1.5 mEq/kg, ip) in rats. To test this hypothesis, rats were given bilateral lesions of the PVN made by rotating a triangular knife positioned in the third ventricle 2 mm behind bregma. When rats were allowed to recover from this procedure for 2-3 weeks, systemic CCK and LiCl each produced inhibitory effects on gastric motility similar to that seen in inhibitory effects on gastric motility similar to that seen in intact or sham lesioned rats (n=6 per group). In addition, the inhibitory effect of these treatments on deprivation-induced food inhibitory effect of these treatments on deprivation-induced food intake was not discernibly different 2-3 weeks after knifecut lesion of the PVN. In contrast, rats studied 12 h after PVN lesions showed almost no inhibition of gastric motility in response to either CCK or LiCl (n=3), and analogous results were found 20 min after injection of lidocaine bilaterally into the PVN (n=3). These data therefore suggest that the PVN normally modulates gastric motility inhibitory responses to CCK and LiCl. The return of normal responses 2-3 weeks after PVN lesions, however, suggests functional recovery of inhibitory vagal efferent activity by this time. efferent activity by this time.

VAGAL STIMULATION INDUCED GASTRIC DAMAGE IS DEPENDENT UPON AN NTACT PVN. L.E. Hierlihy and A.V. Ferguson. Dept. of Physiology, Queen's University, Kingston, ONT K7L 3N6.

Recent work from our laboratory has implicated the paraventricular nucleus (PVN) and the vagus nerve in the development of gastric mucosal erosions. The present studies were therefore undertaken to investigate the influential role of the PVN in vagal stimulation induced gastric damage

Sprague Dawley rats were anesthetised with sodium pentobarbital and placed in a stereotaxic frame. A monopolar electrode was advanced toward the region of the PVN and lesions were made by passing direct current (0.5mA, 30s). One week later following 24 hours of fasting, rats were anesthetised with urethane. Cervical vagus nerves were isolated and laid over hook electrodes which were used to deliver supramaximal stimulation (5Hz) for 1 hour. stimulation, the stomach was removed, examined macroscopically and assigned a damage score ranging from 0-3 based on an arbitrary scale in which 0 indicates no damage and 3 indicates extensive gastric damage. The brain was perfused, removed and prepared for histological determination of lesion sites.

Electrical stimulation of intact vagus nerves following bilateral lesion of PVN resulted in significantly reduced gastric damage scores (0.42±0.20, mean±SEM) as compared to damage elicited in rats with an intact PVN (2.00±0.33). Similar vagal stimulation was found to produce significant gastric damage (1.50±0.22) in animals lesioned in non-PVN regions. No visible gastric damage was observed in lesioned animals in which no vagal stimulation was applied. In conclusion, these experiments demonstrate the dependence of vagal stimulation induced gastric damage upon an intact PVN and further emphasize a role for vagal afferents as well as efferents in the development of gastric mucosal erosions.

PHARMACOLOGIC INVESTIGATION OF THE DIGESTIVE TRACT RESPONSES TO MOTION SICKNESS IN THE CAT. I. M. Lang and M. Steensrud*. Depts of Surgery & Physiology, Med. Coll. Wisc. & Zablocki VAMC, Milwaukee, WI 53295.

We found previously that motion sickness is associated with three distinct gastrointestinal (GI) events: 1) decreased motor activity, 2) bradygastria, and 3) the retrograde giant contraction. The aim of this study was to determine the role of dopaminergic, serotonergic, opioid, and adrenergic receptors in mediating these responses. Five cats, preselected for their susceptibility to motion sickness, were chronically instrumented with strain gauge transducers and bipolar chronically instrumented with strain gauge transducers and bipolar electrodes on their GI tract. Motion sickness was induced by vertical oscillation (VO) at 0.5 HZ. The effects of the following pharmacologic agents, given 5 min before VO, were tested: haloperidol, Sch 23390, domperidone, 1-1-naphthyl piperazine (1-NP), fentanyl, guanethidine, and phentolamine. We found that all three responses were blocked by haloperidol or Sch 23390 but not domperidone, 1-NP, or fentanyl. The decrease in motor activity was inhibited by guanethidine or phentolamine. These results was inhibited by guanethidine or phentolamine. These results suggest that 1) motion sickness may be mediated by 5HT-1 or D-1 but not 5HT-2 or D-2 receptors, 2) the decrease in motor activity may be mediated by the sympathetic nervous system through alpha receptors, and 3) cats respond to antiemetic agents differently than dogs.

5-HYDROXYTYPTAMINE, $_{\rm IA}$ (5-HT), RECEPTORS LOCALIZED TO NON-CHOLINERGIC MOTORNEURONS IN GUINEA-PIG ILEUM

(GPI). J. Galligan* and R. Rech. Dept. Pharmacol., Michigan State Univ. E. Lansing, MI 48824

Previous studies have shown that 5-HT_{1A} agonists inhibit synaptic transmission but not cholinergic neuromuscular transmission in the GPI. In the present study, the actions of 5-HT and the 5-HT_{lx} agonist, 5-carboxamidotryptamine (5-CT) on noncholinergic (1 µM scopolamine present) longitudinal muscle contractions of the GPI were studied in vitro. Contractions were evoked by trains of VILTO. Contractions were evoked by trains of transmural electrical stimuli (10 Hz for 1 s); 5-HT (EC₅₀, 0.1 μ M) and 5-CT (EC₅₀, 6 nM) inhibited these contractions. The actions of 5-CT were blocked by spiperone (pA₂, 7.25, K₀, 56 nM), a 5-HTin antagonist. The contractions were reduced by 80% by the substance P (SP) antagonist D-arg', D-phe', D-trp 7 , leu" SP (1 μ M), indicating that SP is a mediator of non-cholinergic contractions. 5is a mediator of non-cholinergic contractions. 5-CT (0.1 µM) did not affect contractile responses to exogenous SP (1-30 nM) suggesting that the actions of 5-CT on nerve-mediated contractions are prejunctional. Conclusions: 5-HT_{la} receptors are localized to motor nerve terminals releasing SP. As 5-HT_{la} receptors are not localized to cholinergic motor nerves, it is likely that SP and acetylcholine are released from different motor neurons in GPI. (Supported by PMAF and DK40210) neurons in GPI. (Supported by PMAF and DK40210)

NEURORNDOCRINE REGULATION: OTHER II

359.1

ANGIOTENSIN II (AII) ENHANCED ACTIVITY OF SUPRAOPTIC VASOPRESSIN (VP) NEURONS IS POTENTIATED IN RATS WITH IBOTENATE LESIONS OF EITHER DIAGONAL BAND OF BROCA (DBB) OR THE PERINUCLEAR ZONE (PNZ). L.P. Renaud, R. Nissen and J.T. Cunningham. Neuroscience Unit, Ottawa Civic Hospital, Ottawa, Ontario, K1Y 4E9.

Circulating All increases the activity of supraoptic VP neurons. Due to the potent pressor actions of All, this facilitation is often masked by simultaneous baroreceptor activation. The latter transiently suppresses the spontaneous activity of VP-neurons, presumably through involvement of relay neurons in the DBB and inhibitory through involvement of relay neurons in the DBB and inhibitory neurons in PNZ. In order to separate these opposing mechanisms, the excitotoxin ibotenic acid (1.25 ug/250 nl) was injected into the vertical limb of the DBB or into the PNZ surrounding the supraoptic nucleus (SON) in pentobarbital anesthetized male Long-Evans rats. After a minimum recovery period of 3 days, rats were reanesthetized with pentobarbital and prepared for extracelluar recording of identified SON neurons using a transpharyngeal approach. In control rats (N=5), intracarotid infusions of All (500 pmol/kg) increased the activity of VP neurons by 33.2 ± 11.7%. By contrast, DBB lesioned rats (N=5) displayed a 101.8 ± 21.1% increase in activity following identical All infusions, significantly elevated from the control group (F(1,8)= 8.06, p<0.05). Similarly, in PNZ lesioned rats (N=4), VP-neurons displayed a 131.8 ± 34.6% increase in their activity in response to All (F(1,7)= 8.85, p<0.05). The blood pressure elevations coincident with All administration tended to be higher in both lesioned groups but were not significantly different from the control group. Therefore, lesions of forebrain pathways for baroreceptor mediated inhibition of VP neurons potentiate the facilitatory actions of blood borne All. (Supported by FRSQ, NRSA MH0977 and MRC).

REGIONAL BRAIN AND PITUITARY ENKEPHALINS CHANGES WITH AGE AND METAMORPHOSIS Ambystoma tigrinum. A. Cano-Martínez*,
A. Vargas-González*, G. Matamoros-Trejo*, F. Antón-Tay (1)
and M. Asai*. Neurosci. Div. Instituto Mexicano de Psiquiatria. Calz. Méx-Xochimilco 101, San Lorenzo Huipulco, Tlalpan, México 14370, D.F. (1) UAM Iztapalapa, México.
The concentrations of Metionine and Leucine-Enkephalin in

the telencephalon, diencephalon-mesencephalon, romben cephalon and hypophysis of juvenile and neotenic adults \underline{A} . tigrinum individuals were determined before and after metamorphosis. A radioimmunoassay method was used. exception of unchanged Leu-enkephalin concentration in the diencephalon-mesencephalon, all other levels of enkephalins were found to be 2 to 10 fold higher in neotenic adults compared to juvenils. The concentration of both enkephalins increased between 35 to 70% in the diencephalonmesencephalon and the rombencephalon of juvenile and adults after metamorphosis. In metamorphosed organisms the Metionine-Enkephalin levels showed a 30% increase in the telencephalon of the juveniles. In contrast a 30% decrease was found in the hypophysis of adults. These results suggest that either the enkephalins play a role in the maturation, neotenia and metamorphosis of A. tigrinum, or the changes are derived from aging of the individuals.

IBOTENATE LESIONS IN THE PERINUCLEAR REGION OF THE SUPRAOPTIC NUCLEUS (SON) ATTENUATES BARORECEPTOR BUT NOT MEDIAN PREOPTIC NUCLEUS - INDUCED INHIBITION OF VASOPRESSIN (VP) NEURONS IN RAT. R. Nissen, J.T. Cunningham and L.P. Renaud. Neuroscience Unit, Ottawa Civic Hospital, Ottawa, Ontario, K1Y 4E9.

Ontario, K1Y 4E9.

Brief elevations in arterial pressure, sufficient to activate peripheral baroreceptors, transiently suppress spontaneously active VP-synthesizing neurons in rat SON. Recent evidence suggests that this inhibition is GABA mediated, presumably through inhibitory interneurons located in the perinuclear zone (PNZ) adjacent to the SON. Therefore, in pentobarbital anesthetized male Long-Evans rats, neurons in PNZ were lesioned by stereotaxic injections of the excitotoxin ibotenic acid (1.25ug/250ni). After a minimum of 3 days recovery, extracellular recordings were obtained from identified SON neurons using a transpharyngeal approach in rats reanesthetized with pentobarbital. In vehicle injected control rats (N=2), 18/23 phasic VP-synthesizing neurons were inhibited by pressor responses of at least 50mmHg produced by administration of metaraminol (10ug/10ul iv). The number of phasically active neurons that were inhibited by similar metaraminol induced pressor responses (16/31) was significantly decreased in PNZ lesioned rats (N=6, X¹(df=1)=4.02, p < 0.05). In contrast, electrical activation of an alternate (presumably direct) inhibitory pathway to SON from the median preoptic nucleus remains unaffected. Thus, destruction of cell bodies in the PNZ selectively attenuates baroreceptor mediated inhibition of VP-synthesizing neurons and supports the hypothesis that neurons in PNZ mediate this response. (Supported by FRSQ, NRSA MH0977 and MRC). Brief elevations in arterial pressure, sufficient to activate peripheral

EFFECTS OF SYMPATHECTOMY AND CAPSAICIN DENERVATION ON SKELETAL AND CALCITONIN CHANGES IN RESPONSE TO TAIL-SUSPENSION. E.L. Hill's.C. M. Cone*1. B.B. Matril's 2.B. Arnaud*1_P. Fung*1_and E_Morey-Hollon*1_1 NASA-Ames Research Center, Moffett Field CA 94035 and ²Orthopaedic Research Laboratory, U.C. Davis, Davis, CA 95616.

Sympathetic and partial sensory (capsaicin) denervation were both previously shown to affect bone resorption (Hill et al, 1990 submitted). To evaluate the effect of such denervations on bone formation, tail-suspension (SUSP) which results in reduced bone toerievations or toerie formation, and maturation in the unloaded hindlimbs of growing rats was used. The skeletal and hormonal response in 49-day old male rats which had either neonatal guanethidine-induced sympathectomy (GUAN) or neonatal capsaicin-induced denervation (CAP) was investigated in both SUSP and weight-bearing (WTB) controls. At the end of a 7 day experimental period, chemical (bone Ca, 45ca and 34-proline uptake), histological (cortical bone formation rates and area), calcitonin (CT), and mechanical (three-point breaking strength) parameters were

Vehicle-treated (VEH) SUSP animals had decreased 45Ca and 3H-proline uptake in the femur, decreased bone formation and apposition rates at the tiblo-fibular junction (TFJ), decreased plasma CT levels and reduced mechanical strength in the femoral shaft as compared to VEH WTB, while mechanical and chemical parameters were largely unaffected in the humerus which was weight-bearing. CAP rats responded to SUSP in the same manner as VEH. GUAN SUSP rats showed similar chemical changes in the femur and histological changes at the TFJ as other SUSP animals, but did not have lower CT levels than GUAN WTB. Mechanical and chemical parameters were altered in the humerus of GUAN SUSP rats as compared to GUAN

The results of these studies indicate that the skeletal and CT responses to tail-suspension are not altered by the selective destruction of unmyelinated and fine myelinated sensory nerves by capsaicin. However, sympathetic innervation may be important in a systemic and/or hormonal response to unloading.

Angiotensin II applied to the subfornical organ increases glucose utilization in the hypothalamo-neurohypophysial system. M.L. Terrell, M.Kadekaro and S. Freeman. Division of Neurosurgery, University of Texas Medical Branch, Galveston, Texas 77550. Using quantitative [14C]deoxyglucose (DG) autoradio-

graphy, we studied the neural pathways activated by topical stimulation of the subfornical organ with angiotensin II (AII). Under Equithesin anesthesia a 23 ga. stainless steel guide cannula was stereotaxically implanted 1 mm above the subfornical organ in male, adult Sprague-Dawley rats. Seven to ten days later, an internal cannula connected to a Hamilton microsyringe containing AII or normal saline was inserted into the guide cannula to deliver 2 pulses of 10^{-10} moles of AII in 0.5 ul of saline (n=8) or same volume of saline in control animals (n=7). increased arterial blood pressure and stimulated water intake (4.9±0.5ml) with a short-latency (58.5±13.6s); means±SEM. Glucose utilization increased (p<0.05) in the subfornical organ (+27%), paraventricular (+24%) and supraoptic nuclei (+24%) and pituitary neural lobe (+73%). Glucose utilization tended to increase in the nucleus medianus (p=0.065) and in the organum vasculosum laminae terminalis (p=0.08). These results indicate that specific chemical stimulation of the subfornical organ increases functional activity of the hypothalamo-neurohypophysial system and demonstrate that the DG method is useful for quantifying transient metabolic responses in the neuroendocrine circuit.

GROWTH HORMONE SECRETION DURING THE PERIPUBERTAL PERIOD IN MALE AND FEMALE RATS. S.M. Gabriel. Department of Psychiatry, Mount Sinai School of Medicine, New York, NY 10029.

A sex-specific pattern of growth hormone (GH) secretion is recognized in adult rats. Males exhibit high amplitude GH pulses at 3-4 hour intervals, while females have lower amplitude GH pulses at 1-2 hour intervals. This sexually dimorphic pattern is thought to contribute to the differential growth rates observed in rats. Episodic GH release has not been studied in the young rat, however. In the present study, 25-50 d.o. rats received jugular catheters and were housed in chambers designed for stress-free blood sampling. Four to 7 days after surgery, 300 µ blood was collected every 10 minutes between 1600h and 2000h. Red cells were returned in artificial plasma. Rats were grouped by age and endocrine state as: immature (<30 d.o., immature testes; anestrus); early puberty (30-37 d.o., increased testes weight, first proestrus); and late puberty (>37 d.o., mature testes, estrous cycles). GH secretion was similar in immature male and female rats, being characterized by baseline GH secretion with few GH pulses. During early puberty, male rats weighed more than female rats. However, both male and female rats showed low amplitude, high frequency GH pulses. In late puberty, the sex difference in body weight increased and a sexual dimorphism in GH secretion became apparent. Male rats had increased GH pulse amplitudes and decreased pulse frequency, while females continued to have low amplitude, high frequency GH pulses. These studies suggest that the sexually dimorphic pattern of GH release emerges during puberty in the rat. Because a sex difference in body weight develops before this pattern is established, other factors may contribute to the sex difference in growth rates.

SOMNOGENIC DOSES OF GHRH AND IL1 INDUCE GH BUT NOT PRL RELEASE IN RATS. L.C. Payne*, F. Obal Jr.*, L. Kapas*, and J.M. Krueger. Dept. of Physiology Univ. of TN. Memphis TN. 38163.

TN. Memphis TN. 38163.

Growth hormone-releasing hormone (GHRH) promotes non-rapid eye movement sleep (NREMS) and rapid-eye movement sleep (REMS) (1). Interleukin-1 (IL1) elicits growth hormone (GH) secretion via a hypothalamic mechanism (2), probably GHRH, and it strongly enhances NREMS (3). IL1 stimulates PRL release via the hypothalamus in vivo (2) but inhibits PRL secretion from the pituitary in vitro (4). The effects of hypnogenic doses of GHRH (0.16 ug) and IL1 (2.5 ng) plasma concentrations of GH and PRL in free moving rats provided with intracerebroventricular cannulae were determined. GH and PRL were determined by RIA in plasma plasma concentrations of GH and PRL in free moving rats provided with intracerebroventricular cannulae were determined. GH and PRL were determined by RIA in plasma samples taken every 20 min. GHRH and IL1 caused a significant increase in GH secretion 20 and 40 min postinjection. PRL levels were not affected by any of the treatments. These data provide evidence for the hypothesis that the NREMS promoting effect of IL1 may be mediated via GHRH, and provide an additional link between NREMS and GH.

LESIONS OF THE CIRCUMVENTRICULAR ORGANS DISRUPT THE PRESSOR RESPONSE TO RELAXIN IN ANAESTHETISED RATS. L.J.Parry & A.J.S. Summerlee. Biomedical Sciences, Veterinary College, Guelph, Ontario, N1G 2W1, Canada.

The role of the subfornical organ (SFO) and the antero-ventral region of the third ventricle (AV3V) in mediating the pressor effects of iv relaxin (RXN) was tested in urethane-anaesthetised female rats. Blood pressure was recorded directly from a cannulated common carotid artery. The animals were placed in a stereotaxic frame, and radiofrequency lesions were created in either the SFO or the AV3V region. In each case, the pressor response to iv porcine RXN (5µg in 0.1ml saline) was determined, and compared with the response in animals with control lesions in the wall of the left lateral ventricle. In SFO lesioned animals, the pressor response to RXN (n=9) was significantly (P<0.05: ANOVA) attenuated, compared with control lesioned RXN-treated animals (n=12), but was still present. Blood pressure started to rise 1-3 minutes after RXN treatment in the control lesioned animals, with increases of 10.0 \pm 1.84 systolic and 14.0 ± 2.07 diastolic (mean ± s.e.m. percentage increases over baseline values), compared with 4.4 \pm 0.59 systolic and 7.0 ± 0.99 diastolic in SFO lesioned animals. Lesion of the AV3V (n=14) further reduced this pressor response significantly (P<0.05), 3 and 6 minutes after RXN injection. These data imply that both the AV3V and SFO have a role in mediating the pressor response to RXN. Supported by NSERC Canada.

LOCALIZATION AND REGULATION OF PREPROGRF mRNA IN ARCUATE NUCLEUS AND IN NEURONS IN PERIVENTROMEDIAL HYPOTHALAMUS, J.D. White, J. Bruno*, D. Olchovsky*, M. Kershaw* and M. Berelowitz, Div. Endocrinology, SUNY, Stony Brook, NY 11794

Growth hormone releasing factor (GRF) is the principal stimulatory hypothalamic neuropeptide controlling growth hormone (GH) secretion from pituitary somatotrophs. Recently, we demonstrated that hypothalamic preproGRF pittulary somatotropus. Recently, we demonstrated that upportunation preprovided in RNA levels are decreased approximately 5-fold in animals subjected to 72 hr food deprivation and in streptozotocin diabetic rats. In this study we examined the hypothalamic and extra-hypothalamic sites of preproGRF mRNA expression using in situ hybridization and determined which brain loci modulate preproGRF mRNA levels in response to food deprivation or experimental diabetes mellitus. Control and experimental male Sprague-Dawley rats were anesthetized with ketamine / xylazine and perfused with 4% paraformaldehyde. The brains were removed, post-fixed in paraformaldehyde and free-floating 30 µm coronal sections were processed for preproGRF mRNA localization using a *S-cRNA probe. The distribution of hybridization was analysed using both film and emulsion autoradiographs. These injointation was analysed assignment in an authority and adopting in the hypothalamic arcuate nucleus with an additional population of neurons lying in the periventromedial region of the hypothalamus. In agreement with data from nuclease protection studies, preproGRF mRNA levels in both of these populations of protection studies, preproduct minima levels in oour of these populations of hypothalamic neurons declined following food deprivation or streptozotocin-induced diabetes mellitus. Hybridization signal was also detected in paraventricular nucleus of the hypothalamus, in hippocampus and in piriform cortex, however, hybridization signal in these regions was not markedly affected by either experimental protocol. These data implicate two neuronal populations in modulating GH secretion and suggest specific modulation of hypothalamic preproGRF mRNA levels by food deprivation and diabetes. NIMH 42074, 00801 (JDW); NIH AM 36831 (MB)

359.10

ACUTE EFFECTS OF STRESS ON SOMATOSTATIN (SS)-CONTAINING CELL BODIES AND FIBERS IN THE PREOPTIC-ANTERIOR HYPOTHALAMUS (PO-AH) AND MEDIAN EMINENCE (ME) OF FEMALE RATS. M. Bhatnagar, G. Nilaver and V. Critchlow. Oregon Regional Primate Research Center, Beaverton, OR 97006.

Stress in rats causes acute hypothalamic release of SS that induces a marked, prolonged suppression of growth hormone (GH) secretion. The objective of this study was to determine whether stress causes acute changes in neuronal content of SS that can be detected with immunocytochemistry (ICC). Groups (N=5) of adult female rats were decapitated under nonstress conditions or 30, 60, 120 or 180 min after 15-min leg restraint stress. Treatments were assigned and performed with a randomized block design. Brains were rapidly removed, blocked and fixed by immersion for ICC: $50 \mu m$ serial sections were cut on a vibratome and stained with an Avidin biotin-peroxidase complex method. The rabbit antiSS used detects SS-14 and -28. SScontaining cell bodies were most numerous, largest and filled with SS granules in brains from nonstressed rats. Most cell bodies were in the periventricular (PeV) zone of the PO-AH; some were found in sites not heretofore described. SS was largely in the internal zone of the ME in nonstress brains. At 30, 60 and 120 min after initiation of 15 min stress, there was a marked decrease in the number and size of SS cell bodies, a reduction in cytoplasmic SS granules and a striking increase in SS in the external zone of the ME. The most conspicuous and reproducible changes in cell bodies involved subsets of PeV neurons; some clusters of SS neurons were not visibly affected by stress. The stress-induced changes were largely reversed by 180 min. These results demonstrate that stress causes acute changes in the PO-AH SS system as assessed by ICC. It appears that stress acutely affects both synthesis and secretion of SS. Supported by NIH grants DK32442 and RR00163.

COLOCALIZATION OF THE ANDROGEN RECEPTOR AND SOMATOSTATIN MESSENGER RNA IN NEURONS IN THE PERIVENTRICULAR NUCLEUS. K.A. Burton*, R.A. Steiner, D.K.

Clifton. Departments of Physiology and Biophysics and Obstetrics and Gynecology, University of Washington, Seattle, WA 98195.

Growth hormone secretory patterns in the adult male rat are influenced by sex steroids. Somatostatin (SS) is involved in the regulation of growth hormone secretion, and we have previously demonstrated that SS gene expression in neurons of the periventricular nucleus (PeN) is dependent expression in neurons of the periventricular nucleus (PeN) is dependent upon the activation of androgen receptors. It is uncertain, however, whether androgens act directly on SS neurons or, atternatively, act through an intermediate neuronal pathway to effect their action. We tested the hypothesis that androgen receptors are localized in neurons in the PeN expressing the SS gene. Coronal sections were taken through the arterior hypothalamus of the adult male rat brain and double-labeled by immunocytochemistry with an antibody against the rat androgen receptor (kindly provided by Dr. S. Liao) and *in situ* hybridization with an ³⁵⁵-labeled RNA probe complimentary to pre-pro SS mRNA. Androgen receptor immunostaining was found in approximately 50% of the SS mRNA-containing neurons in the PeN. Fewer than 30% of the SS mRNA-containing neurons in the amygdala and less than 5% of SS neurons in the cortex were immunopositive for the androgen receptor.

Conclusion: Androgens, such as testosterone, are capable of acting

Conclusion: Androgens, such as testosterone, are capable of acting directly on a subpopulation of SS neurons in the PeN to regulate SS gene expression. Moreover, this effect may subserve sexually dimorphic GH secretory patterns and underlie the developmental changes in GH secretion

DOES FREQUENCY ENCODING OF [Ca2+] OSCILLATIONS REGULATE GROWTH HORMONE RELEASE IN SOMATOTROPHS? S.R. Glaum*, R.J. Miller*, B.J. Collins®

HORMONE RELEASE IN SOMATOTROPHS? S.R. Glaum*, R.J. Miller*, B.J. Collins* and L. Cuttler.* *Dept. Pharm/Phys; *Dept. Pediatrics, University of Chicago, Chicago, IL 60637. †Dept. Pediatrics, Case Western Res. Cleveland, OH 44122.
Although spontaneous [Ca2+] ioscillations have been described in somatotrophs, their role in mediating somatotroph function is unknown. We studied the effects of known regulators of growth hormone (GH) release on [Ca2+] in individual cultured adult male rat anterior pituitary cells using fura-2 based digital video microscopy. [Ca2+]i oscillations were characterized with the pulse analysis program ULTRA (Van Cauter, Am. J. Physiol. 254, E786-94). Somatotrophs were identified by their response to the specific and Ca2+dependent secretagogue GH-releasing factor (GRF; see adjoining abstract). Individual CfRF responses were defined as mean [Ca2+]i >mean_225D prestimulus [Ca2+]i. Cumulative GRF dose-response data gave a sigmoidal curve with an EC50=0.67nM. However, individual cells exhibited primarily all-or-none responses over a dose range of 10pM-100nM. No evidence of desensitization was observed at the near EC90 dose of 10pM-100nM. No evidence of desensitization was observed at the near EC90 dose of 10pM-100nM. No evidence of desensitization was observed at the near EC90 dose of 10pM-100nM in similar effects. Somatostatin (1nM), the major physiological inhibitor of GH release, blocked the GRF-response frequency. The calmodulus antagonist calmidizolium (40µM) produced similar effects. Following chronic phorbol ester treatment (100nM PMA, 20-120 min), both basal and GRF-response frequency were increased, but the increase in [Ca2+]i and pulse amplitude produced by GRF was attenuated. Nimodipine (1µM) reversibly inhibited all three components of both basal and GRF-response frequency. increased, but the increase in [Ca2+]1 and pulse amplitude produced by GRF was attenuated. Mimodipine (IHM) reversibly inhibited all three components of both basal and GRF-response [Ca2+]i signalling. These data suggest that, in cultured rat somatotrophs: 1) GRF produces parallel increases in mean GH release and [Ca2+]i that are dependent on Ca2+ influx. These responses may be mediated via recruitment of cells rather than by augmented responses in individual cells; 2) Major regulators of GH release alter [Ca2+]1 and pulse amplitude in a parallel manner; 3) Oscillation frequency does not appear to be coupled to the other components of [Ca2+]i signalling. Therefore, frequency encoding may not regulate GH release in somatotrophs.

DISTRIBUTION OF MELATONIN RECEPTORS IN NEUROENDOCRINE TISSUES OF THE EWE. <u>Eric L. Bittman¹ and David R. Weaver²</u>

¹Dept. of Zoology and Program in Neuroscience, University of Massachusetts, Amherst, MA 01003, and ²Laboratory of Developmental Chronobiology, Children's Service, Massachusetts General Hospital, Boston MA 02114, U.S.A.

Photoperiod controls reproduction in ewes by regulating the duration of nightly melatonin secretion by the pineal gland. Melatonin acts on brain targets which have not been identified in this species. We examined specific high affinity binding of 2-1¹²⁵11-melatonin in 20 micron sections prepared from intact Suffolk ewes killed during late anestrus or the breeding season. The pars tuberalis contained by far the highest concentration of receptors of all areas studied. Within the telencephalon, intense labeling was found in the mediciateral septum, the ventrolateral septal and septohypothalamic nuclei, entorhinal cortex, subiculum, and the inner and outer molecular layers of CA1 adjacent to the dentate gyrus. Melatonin binding in the bed nucleus of the stria terminalis, medial preoptic nucleus, and medial preoptic area was less striking but still distinct. Among diencephalic regions, melatonin receptors exist in low concentrations in anterior hypothalamus, ventral tuberal region, paraventricular thalamic and supramammillary nuclei. Little binding was evident in the suprachiasmatic or ventromedial nuclei of the hypothalamus. In the midbrain, significant binding was restricted to the ventral raphe complex and the interior colliculus. Little specific binding was found in the pituitary or pineal glands. Several sites of intense IMEL binding are areas in which immunocytochemical studies indicate high concentrations of estrogen receptors. These data suggest sites at which melatonin might act to regulate reproduction and other photoperiod-dependent functions. Supported by NSF BNS86-16935, NIH MH44132, and NIH NRSA HD-06976.

DIHYDROPYRIDINE-SENSITIVE CALCIUM CHANNEL ACTIVITY IN PERINATAL SOMATOTROPHS. L. Cuttler, B. J. Collins, S.R. Glaum, and M. Szabo*. Dept. Pediatrics, Case Western Reserve Univ., Cleveland, OH, A4106; Depts. Pediatrics/Pharmacology, Univ. of Chicago, Chicago IL, 60637; Dept. Medicine, Michael Reese Hosp, Univ. of Illinois, Chicago IL, 60616. The factors that regulate somatotroph function in immature animals are not

well understood. We have previously found that, compared with mature animals, well understood. We have previously found that, compared with mature animals, perinatal somatotrophs are highly sensitive to the GH-secretory effects of GH-releasing factor (GRF), phorbol myristate acetate (PMA), and forskolin (FSK). To assess the role of dihydropyridine-sensitive $Ca^{2^{1}}$ channels in mediating these actions, we tested the effects of the antagonist, nisoldipine (NIS; $1 \mu M$) and the agonist, BAY K8644 (BAY; $1 \mu M$) on GRF-, PMA-, and FSK-induced GH release from cultured pituitary cells of 2-day-old and adult male rats (n=3-5 experiments/group; also see adjacent abstract). GRF stimulated GH release in an age-dependent manner; in response to 1 nM GRF, GH release was 509 ±5 and 279 ± 32% of controls from pituitaries of 2-day and adult rats, respectively an age-dependent manner; in response to 1 nM GRF, GH release was $505 \pm 3.2\%$ of controls from pituitaries of 2-day and adult rats, respectively (P < 0.01). Similar results were obtained with 0.15 μ M PMA and 1 μ M FSK. NIS markedly reduced 1 nM GRF-induced GH release in both age groups (P<0.02); GH release was only 168±17 and 114±23% of controls in 2-day-olds and adults, respectively. NIS also reduced PMA-and FSK-induced GH release in and adults, respectively. Nis also reduced PMA-and PSK-induced GH release in both age groups. BAY augmented GRF-, TPA-, and FSK-induced GH release from pituitaries of both neonatal and adult rats. The degree of enhancement by BAY was age-dependent. For example, BAY increased GRF-induced GH release 1.8 fold from pituitary cells of 2-day-olds but only 1.3 fold from adults (P<0.01); the effects of BAY on PMA- and FSK-induced GH release were similar to those on GRF. <u>Conclusion</u>: Immature rat somatotrophs possess functional dihydropyridine-sensitive Ca²⁺ channels, which may mediate GH release in response to regulatory agents during the perinatal period.

CHARACTERIZATION OF A NA++, CL-, AND CA++ -INDEPENDENT [3H] GLUTAMATE BINDING SITE IN RAT PINEAL. L. Kus, R.J. Handa, I.A. McNulty, Department of Cell Biology, Neurobiology, and Anatomy Loyola University, Maywood, IL 60153

Neuronal control of melatonin production in the pineal gland appears to be primarily mediated by alpha and beta adrenoceptors. The pineal, however, possesses a number of other receptor types whose functions are at present unknown. Using quantitative receptor autoradiography, we have detected a Na⁺⁺,Cl⁻ and Ca⁺⁺ independent binding site for [³H]glutamate in the rat pineal. The binding site is saturable, stereospecific, temperature dependent, and displays an apparent dissociation equalibrium constant (Kd) of 556 + .136 X X10⁻⁶M. Competition studies showed that radioinert L-glutamate was the most potent displacer of [3H] glutamate binding with a Ki value of .536 + .037 X X10-6M. Quisqualate displayed moderate affinity with a Ki value of 34 + .06 X10-6M. All other compounds tested were ineffective competitors. Peripheral dennervation of the pineal gland by removal of the superior cervical ganglion increased the number of of Highitamate binding sites by approximately 50% suggesting the possibility of receptor upregulation. A day/night difference in the number of pineal [3H]glutamate binding sites was not observed. The presence of a binding site for [3H]glutamate in this gland suggests an important role for glutamate as a modulator of pineal function. ELECTROPHYSIOLOGICAL INTERACTION BETWEEN MELATONIN AND MONO AMINES IN THE ANTERIOR HYPOTHALAMUS. Prieto-Gómez, B., García, J.A. and C. Reyes-Vázquez. Deptos. de Fisiología y Farmacología, Facultad de Medicina, UNAM México 04510, D.F.

Local application of MELATONIN (MEL) on the anterior hy pothalamus (AH) induces antigonadotropic effects as a result of an interaction with monoaminergic neurons. When MEL is microiontophoresed, a decrease on the spontaneous and evoked activity is observed. If such electrophysiological effect of MEL provokes the antigonodotropic action, then effect of MEL provokes the antigonodotropic action, then this would be related also to monoaminergic neurons. This study analyses the electrophysiological effect of MEL and 5-Metoxytriptophol (5-MTP), applied by micropressure, on neurons from AH of rats pretreated with reserpine (RES), 6-hydroxidopamine (6-OHDA) or 5-7,dihydroxytryptamine (5,7-DHTP). Both, 6-OHDA (200 µg) and 5,7-DHTP (200 µg) were applied intracerebroventricularly and RES (1 mg/kg) IP. In the recording sesion, a four micropipette multibarrel containing: MEL (0.1 M), 5-MTP (0.1 M), glutamate (0.05 M), and NaCl 3M with fast green, was lowered in AH. In control rats, MEL and 5-MTP elicited a consistent decrease in the spontaneous and glutamate-provoked activity on AH units. However, in RES, 6-OHDA and 5,7 DHTP pretreated rats, both, the intensity and number of affected units, were significant reduced as compared to untreated rats. These results indicate an interaction between these metoxyindols and mono amines in the AH.

ONTOGENY OF TYROSINE HYDROXYLASE (TH) mRNA LEVELS AND CATALYTIC ACTIVITY IN THE RAT HYPOTHALAMUS. L. A. Arbogast and J. L. Voogt. Physiology Dept., Univ. Kansas Med. Ctr., Kansas City, KS 66103.

J.L. Yoogt, Physiology Dept., Univ. Kansas Med. Cir., Kansas City, KS 66103. Tuberoinfundibular dopaminergic (TIDA) neurons with cell bodies in the acruate nucleus (AN) and nerve terminals in the stalk-median eminence (SME) release dopamine, a PRL inhibiting hormone. The objectives of this study were: 1) to determine the catalytic activity of TH in the SME during neonatal, peripubertal and adult life, 2) to examine the TH mRNA signal levels in the AN, and 3) to relate changes in TIDA neuronal function to circulating PRL levels. Male and female rate were used at 5 day intervals between days 5 and 40 of age and diestrous females and intact males were used as adults (60-80 days). In vitro TH activity was assessed by insubating hypothelium and the probability in the broad-barrier and activity was assessed by insubating hypothelium explants with hercesting a deactory such as in his intervals. incubating hypothalamic explants with brocresine, a decarboxylase inhibitor. Dihydroxyphenylalamine (DOPA) accumulation in the SME was measured by HPLC. TH activity (ng DOPA/mg protein/30 min) rose between days 10 and 15 from 4.04 ± 0.8 to 13.23 ± 1.86 and from 5.09 ± 1.14 to 9.95 ± 1.75 in females and males, respectively, and remained unchanged in both sexes between days 15 and 35. TH activity increased in females, but not males, between days 35 and adulthood 33. 14 activity increased in temales, but not males, between days 35 and adultinood and was 2.5-fold higher in diestrous females than in males. In a second group, frozen brain sections (15 μM) through the AN were hybridized at 45 C with a ³⁵S-labeled riboprobe for TH. After RNAase treatment and stringent post-hybridization washes, slides were dipped in emulsion and exposed for 4 weeks. The RNA signal levels in the AN were low on days 5 and 10 of age and increased by day 20 in both sexes and between days 30 and 40 in females, but not males. The TH mRNA levels in the AN were higher in diestrous females than males during adulthood. Serum PRL levels were low (2-3 ng/ml) until day 15, rose 4-6 fold by day 20 and an additional 2-4 fold by day 40 in both sexes. Conclusions; 1) The early (days 10-15) increase in TH mRNA levels and activity in the TIDA neurons occurs before the rise in circulating PRL and may be controlled by a mechanism common to both sexes.

2) The later (day 40) increase in TH is sex-specific and may be related to the hormonal events surrounding puberty in females. Supported by HD 24190.

HYPOTHALAMIC PARAVENTRICULAR NUCLEUS ALPHA, ADRENERGIC RECEPTORS, BUT NOT ALPHA, OR BETA RECEPTORS, MAY BE INVOLVED IN THE REGULATION OF RAT BLOOD CORTICOSTERONE LEVELS. M.W. Gunion, M.J. Rosenthal*, S. Miller*, and B. Zib*. GRECC, Sepulveda VAMC, Sepulveda, CA 91343.

Neurons in the paraventricular nucleus of the rat hypothalamus synthesize and release corticotropin releasing factor to regulate blood corticosterone levels, and have also been implicated in metabolic fuel regulation. This nucleus receives ascending adrenergic and noradrenergic projections from lower brainstem sites which may be involved in corticosterone and metabolic fuel regulation. Unilateral microinfusions of the agonists methoxamine (α_1) , clonidine (α_2) , and isoproterenol (β) (0,10,30,100 nmol/500 nl 0.9% NaCl+0.1% BSA) were made into the hypothalamic paraventricular nucleus or caudate nucleus of adult male albino rats through chronic guide cannulae. Blood samples (120 ul) taken from the tail tip 0, 15, 30, 60, 90, and 120 min postinfusion were assayed for serum corticosterone, glucose, and free fatty acids. Although both the α and the β agonists cause dose-related increases in serum glucose and free fatty acid levels, there was no detectable difference between paraventricular nucleus and caudate nucleus infusions, suggesting that the effects seen on these measures were due to leakage of agonists into the periphery Corticosterone was strongly affected by paraventricular nucleus infusions of α_2 agonist and only weakly changed by caudate infusions, but was affected equally by β agonist infusions into the paraventricular and caudate nuclei. The α_1 agonist had no effect on any measure at any site. These data suggest a possible role for α_2 receptors in the regulation of corticosterone by paraventricular nucleus neurons. THE STIMULATORY AND INHIBITORY MODULATION OF AMPHETAMINE (AMPH) STIMULATED DOPAMINE (DA) RELEASE FROM THE CORPUS STRIATUM (CS) OF FEMALE RATS BY PROGESTERONE (P) IS STEREOSPECIFIC. D. Dluzen and V. Ramirez. Department of Physiology and Biophysics, University of Illinois, Urbana Illinois 61801.
Progesterone

linked to bovine serum albumin position 3 of the steroid ring (P-3-BSA) increased AMPH stimulated DA release in vitro from superfused corpus striatal (CS) tissue fragments of ovariectomized-estrogen striatal (CS) tissue fragments of ovariectomized-estrogen treated female rats when administered in a pulsatile mode directly into the superfusion chambers, but inhibited AMPH stimulated DA release when administered in a continuous mode (Dluzen and Ramirez, Brain Res. 476:388, 1989). To examine the structure-activity of these effects we used P linked with BSA at the 11 position (P-11-BSA) and deoxycorticosterone-21-hemisuccinate (DOC-BSA). The areas under the AMPH stimulated DA release curves (x±SEMpg/50 min) in response to DOC-BSA (5ng/ml) were not significantly altered by either pulsatile $(613\pm72, N=4)$ or continuous $(565\pm137, N=4)$ infusion modes compared to control superfusions $(473\pm93, N=4)$. In contrast, both the pulsatile (937 \pm 182, N=4) and continuous (1025 \pm 111, N=4) infusion of P-11-BSA (5 ng/ml) significantly increased AMPH stimulated DA release over control levels. The results demonstrate that P-11-BSA was capable of exerting a stimulatory but no inhibitory effect upon AMPH stimulated DA release while DOC-BSA was without effect.

A NEURAL NETWORK MODEL OF SOUND LOCALIZATION BASED ON SPECTRAL CUES Chalapathy Neti and Eric Young. Dept. of Biomedical Engineering and Ctr. for Hearing Sciences, The Johns Hopkins Univ. School of Medicine, Baltimore, MD 21205.

Psychophysical evidence suggests that localization of sound depends upon directional filtering of the pinna in mammals in addition to interaural disparity cues. We are interested in studying the kinds of response properties of neurons that are studying the kinds of response properties of neurons that are useful in extracting sound location information from spectral cues provided by the pinna. Using a systematic map of pinna transfer functions of a cat for different points in space (Rice et. al. JASA 85: S67) We have constructed a layered neural network that transforms pinna filtered stimuli to a two dimensional representation of spatial location (modelled according to the spatial code in superior colliculus). The resulting network solutions are characterized by generating response maps of network units to tones. Network inputs to tones are rate-profiles of auditory nerve (AN) fibers for single tones. Rate-profiles at different stimulus levels are generated by a computational model different stimulus levels are generated by a computational model. different stimulus levels are generated by a computational model of AN fiber rate level functions (Sachs. et. al Hear.Res. 41) and AN of Alvinder fate lever infections (Sacris, et. at new Ness, 71) and Alvinder tuning curves (from B.Delgutte). We will describe computational properties of the network solutions and response properties of network units. Particularly interesting are first, the existence of level invariant network solutions; Second, response existence of revel invariant network solutions; Second, response properties of network units resemble cochlear nucleus types III and IV units (Young and Brownell) and their composites (including non-monotonic rate responses); and third, particular frequency regions of the spectra are relatively more important for the computation. Supported by NIH grant DC00115.

APPLICATION OF NEW ELECTROTONIC MODELING METHODS: RESULTS FROM TYPE I CELLS IN GUINEA PIG VENTRAL COCHLEAR NUCLEUS. J.A. White*. E.D. Young, and P.B. Manis. Center for Hearing Sciences, Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205.

Stellate cells of the mammalian ventral cochlear nucleus (VCN) modify the neural signal conveyed to them by the auditory nerve (AN) into spike trains that are more regular than those of AN fibers and less strongly phase-locked. We have proposed that an important mechanism underlying these transformations is low-pass filtering by the passive electrotonic structure of the dendritic tree. In this study we quantitatively assess this hypothesis by determining the parameters of the somatic shunt model [Durand, D., Biophys. J., 46:645-53, 1984) which best describe Type I (stellate) cells in the guinea pig VCN.

We use Monte Carlo analysis to show that the parameter identification problem for the somatic shunt model is unstable, in that low-level electrophysiological noise can lead to grossly inaccurate parameter estimates and predicted synaptic responses. However, morphologic information can be used to add stability to the problem. Intracellular electrophysiological data required for these analytical techniques were collected from Type I cells in a guinea pig VCN brain slice preparation. Data include I-V curves for cell response type characterization, responses to AN electrical stimulation, and averaged responses to injected steps of hyperpolarizing current. Some neurons were stained with Lucifer Yellow to gather morphologic data. For Type I cells we obtain a mean estimated electrotonic length of 1.6 length constants, a dendritic membrane time constant of 6.6 ms, and a dendritic dominance factor of 1.8 (5.9 in shunt-corrected cells). These values support the hypothesis that the passive electrotonic architecture of stellate cells contributes strongly to their response properties. Supported by NIH grants DCOO115 (EDY) and DCOO425 (PBM).

RESOLUTION OF USEC TIMING IN A NEURAL COMPARTMENTAL MODEL. W.E. Sullivan, Dept. of Biology, Princeton Univ., Princeton, N.J. 08544.

Behavioral discrimination of µsec. time differences has been described in owls, bats and weakly electric fish. The neural basis of this acuity has thus been subject to bats and weakly electric fish. The neural basis of this acuity has thus been subject to speculation since physiological events are thought to operate in msec. rather than µsec. ranges. Either these groups have membrane and synaptic processes which are many times faster than normal or µsec. resolution is in fact possible with conventional cells. Simulations using a neural model with both passive and active compartments (i.e. the Hodgkin-Huxley model) show that µsec. accuracy can be achieved without rapid membrane conductance in one of the passive compartments. Synaptic then falling membrane conductance in one of the passive compartments, Synaptic duration was 1.0 msec. To measure time resolution, twin inputs of 52.5, 55, 60, 75 and 90 % of single pulse threshold were presented at varying time intervals. The largest interval evoking a spike was then found for each input level.

In single active compartment models, time resolution was minimized by increasing active-to-passive conductance, raising voltage sensitive K+ channel density or by adding steady inhibition. These produce onset responses to sustained excitation, in these models, time resolutions of only about 100 µsec could be achieved before the size difference between subthreshold and suprathreshold responses became so gradual as to be arbitrary. Improvements in resolution were accompanied by higher threshold so that the "best" models appeared to be attenuating input pairs with large delays rather than selecting for short delays. By adding active compartments, both temporal tuning and the all-or-none nature of the response were improved. In these models, time resolutions of <10 usec for inputs each 75% of single pulse threshold were achieved, but only in the most distal compartment. If spikes in proximal segments fire too slowly, they become asynchronous and attenuate each other. A key segments into do stowly, they become asymmotious and attendate each other. A key feature of models with fine time resolution is the rate of voltage change rather than peak voltage. Slight differences in the rising phase of spikes in proximal segments are magnified by intracellular temporal filtering so that only the most rapidly activated spikes are propagated. Distal compartments fired larger spikes because they were isolated from the passive compartments and were subject to less loading.

PARAMETERS AFFECTING GAP DETECTION IN THE RAT. D. S. Leitner, G. Hammond*, C. Springer*, K. Ingham*, A. Mekilo*, P. Bodison*, M. Aranda* and M. Shawaryn*. Dept. of Psychology, St. Joseph's University, Philadelphia, PA 19131.

An important aspect of the functioning of the auditory system is temporal acuity, the ability to track rapidly changing acoustic transients. It is particularly important in human speech comprehension; if the auditory system continues to respond as if a recently terminated stimulus is still present, then it will interfere with the perception of a new stimulus, blurring the transition. In theory, a failure by the nervous system to resolve temporal detail will occur to the extent that the activity engendered by an auditory stimulus outlasts the actual physical event.

The present research used a startle amplitude reduction paradigm to investigate the ability of brief gaps in otherwise continuous acoustic stimulation to reduce the amplitude of a subsequently elicited acoustic startle reflex was examined. In the first experiment, 12 rats were exposed to a gap, embedded in otherwise continuous 60 dB (SPL: A-weighted) white noise, whose duration varied among 5, 10, 15, 20, 25, 30, 40, and 50 msec. Also included was a "0" gap condition, consisting only of the 1 msec rise-fall time used in the other gap conditions, and a control condition in which the 50 msec, 125 dB (SPL: A-weighted) white noise startle-elicting stimulus (SES) was presented without a gap preceding it. These 10 conditions were presented to each rat in a block-random fashion, with a total of 30 blocks being presented. The gaps were presented either 30, 50, 100, 200, 300, or 500 msec before the SES. A second experiment used gaps with durations varied among 0, 1, 2, 3, 4, 5, 6, 8, and 10 msec, and the interstimulus intervals were varied among 0, 1, 2, 3, 4, 5, 6, 8, and 10 msec, and the interstimulus intervals of 50 msec, and with rise/fall times varied among 0, 1, 2, and 4 msec.

The results of these experiments indicated that the mo

MODELING AMPLITUDE-MODULATED (AM) TONE ENCODING BEHAVIOR OF COCHLEAR NUCLEUS NEURONS. S. Ghoshal, D.O. Kim and R.B. Northrop, Div. Otolaryn., Surg. Res. Ctr, Ctr. Neurol. Sci., Biol. Engin. Prog., Univ. Connecticut Health Ctr., Farmington, CT 06032

Ctr., Farmington, CT 06032

A study of AM tone envelope encoding behaviors of dorsal and posteroventral cochlear nucleus (DCN & PVCN) neurons by Kim et al. (Hearing Res., 1990) reported that DCN pause build-type-III neurons and chop-S neurons exhibited band-pass modulation transfer functions (MTFs) and intrinsic oscillations (IOs) whereas chop-T neurons exhibited low-pass MTFs and no IOs. The goal of this study is to develop models for band- and low-pass MTFs of these neurons. We used the models of stellate and fusiform cells developed by Arle and Kim (Assoc. Res. Otolar., 1990) based on a modified MacGregortype neuron model. We represented a high carrier-frequency AM tone by applying at the soma of a model neuron a current consisting of DC, AC and zero-mean Gaussian noise. We found that, when a relatively strong noise was present, the stellate-cell model exhibited a low-pass MTF and no IO, thus reproducing a chop-T neuron's behavior. We also found that, with proper DC, AC and noise amplitudes, both the fusiform-cell model and the stellate-cell model exhibited band-pass MTFs and prominent IOs, thus reproducing the exhibited band-pass MTFs and prominent IOs, thus reproducing the behaviors of a pause-build neuron and a chop-S neuron. The fusiform-cell model exhibited a more robust band-pass MTF and IO than the stellate-cell model in the sense that a strong noise tended to abolish the IO and band-pass MTF more readily in the latter model. These results support a hypothesis that intrinsic cellular mechanisms of fusiform and stellate cells similar to those postulated in the present models may underlie the observed MTFs and IOs of CN

SOUND LOCALIZATION IN THE BARN OWL: A QUANTITATIVE MODEL OF BINAURAL INTERACTION IN THE NUCLEUS LAMINARIS. S. Grūn 1 A. Aertsen H. Wagner C. Carr 1 Max-Planck-Inst. für biol. Kybernetik. Spemannstr. 38, 7400 Tübingen. FRG; Dept. of Neurobiol. and Anatomy, Univ. of Rochester, NY 14642, USA.

The barn owl is a nocturnal hunter that uses interaural time difference (ITD) to determine the azimuth of a sound source. The first two stages in the neural pathway dealing with ITD are the nucleus magnocellularis (NM) and the nucleus laminaris (NL). Neurons in these two nuclei exhibit phase-locking, as demonstrated in the period histogram (PH). Magnocellular neurons are spontaneously active, respond only to ipsilateral stimulation, and project bilaterally to NL. Laminaris neurons are binaural: their response varies in a cyclic manner with ITD. The response to monaural stimulation is generally between the minimum and the maximum of the ITD-curve.

We found that the underlying neural computations can be described by a simple two-stage model: linear summation followed by an algebraic nonlinearity. The model is formulated in terms of firing probabilities, as measured by the PHs. Phase-locking of the NM-neurons is described by modulation of firing rate around the spontaneous level. In the NL, inputs from both sides, together with an unspecific, hyperpolarizing inhibition, are linearly summated. The result is subsequently transformed by a sigmoid-shaped nonlinearity, modeling the probability of spike generation in the NL-neuron. The inhibition effectively serves as a control parameter, shifting the operating point on the nonlinearity in NL. For physiologically realistic values of these various parameters, this simple, general model correctly describes the monaural and binaural response properties of laminaris neurons, without having to invoke any problem-specific mechanisms. The model predicts that weakening of the inhibition would reduce the sensitivity for ITD.

SENSORY SYSTEMS-AUDITORY SYSTEM: HAIR CELLS AND COCHLEA I

361.1

TWO-TONE DISTORTION PRODUCTS IN THE BASILAR MEMBRANE OF THE CHINCHILLA COCHLEA. <u>L. Robles*#, M. A. Ruggero and N. C. Rich*</u> Dept. of Otolaryngology, Univ. of Minnesota, Minneapolis, MN 55414.

Motion of the basilar membrane (BM) in response to two-tone stimuli was measured in the chinchilla cochlea using a new application of laser velo-cimetry. BM velocity was determined from the Doppler frequency shift of laser light reflected from glass microbeads (10-30 um) placed on the BM in the basal turn of the cochlea. Two locked primary tones (f_1 and f_2 , 10-ms duration) were digitally generated and delivered to the ear canal via two acoustically-coupled earphones. BM responses were averaged over 1024 stimulus repetitions and Fourier transformed to obtain frequency spectra. Distortion products (DPs; i.e., spectral components with frequencies such as 2f₁-f₂, 2f₂-f₁, 3f₁-2f₂, 3f₂-2f₁, etc.) were observed in responses of 6 cochleae to primary tones with intensities as low as 30 dB SPL. Some pairs of primaries evoked multiple DPs at frequencies both lower and higher than those of the primaries. Under optimal conditions, the effective SPLs of the $2\mathbf{f}_1\mathbf{f}_2$ and $2\mathbf{f}_2\mathbf{f}_1$ DPs were only 11 dB and 22 dB, respectively, below the levels of the primaries. [Effective SPL is the SPL of a single tone at the DP frequency required to elicit the same response magnitude as that evoked at the DP frequency by the two-tone stimulus.] Such prominent DPs undoubtedity originated in the cochlea, since controls showed that artifactual DPs in the acoustical and measuring systems were at least 50 dB below the primary levels. These results are the first to demonstrate that mechanical DPs are present in the BM at low and moderate stimulus levels and that they

travel along the cochlea in both directions.

DEVELOPMENT OF THE ORGAN OF CORTI IN THE RAT: A SCANNING ELECTRON MICROSCOPIC STUDY. L.P. Rybak, C. Whitworth,*
A. Weberg*and V. Scott* Dept. of Surgery, SIU School of Medicine, Springfield, IL 62794-9230.

The rat is an altricial animal which has proven to be a useful model for the study of auditory development. The purpose of the present study was to study the surface development of the organ of Corti using scanning electron development of the organ of Corti using scanning electron microscopy (SEM). Rat pups from 1-30 postnatal days of age were anesthetized with pentobarbital and the cochleas were removed and processed for SEM using a modification of the TOTO procedure (Davis and Forge, J Microsc 1987; 147: 89-101). The specimens were viewed with a Hitachi 5500 Scanning Electron Microscope. The stereocilia of the apical region were very immature but underwent sequential maturation. By contrast the outer hair cells of middle maturation. By contrast, the outer hair cells of middle and basal turns were more mature in appearance. Kinocilia were present on both inner and outer hair cells in very young pups, but disappeared by 10 days of age. The inner hair cell stereocilia of the middle and lower turns of the cochlea had a V-shaped configuration similar to that of the outer hair cells of early postnatal ages, but became arranged into a linear row with maturation. The effects of maturational changes in stereocilia may have important effects on cochlear micromechanics in development. (Supported by NIH - NIDCD #5R01DC00321-05)

THE MAGNITUDE OF THE NEGATIVE SUMMATING POTENTIAL VARIES DIRECTLY WITH PERILYMPH CALCIUM LEVELS. R.P. BOBBIN and M. FALLON*. Kresge Hearing Research Lab., LSU Medical Center, New Orleans, LA 70112.

Previous results (Soc. Neurosci. Abstr., 15: 210, 1989) demonstrated that nimodipine, an L-type of $\mathrm{Ca^{2^+}}$ channel antagonist, abolished the negative summating potential (-SP), suggesting that $\mathrm{Ca^{2^+}}$ is involved in generation of the -SP. This study examined the effect of $\mathrm{Ca^{2^+}}$ on cochlear potentials. Perilymph spaces of guinea pig cochleae were perfused with Ringer solutions containing zero $\mathrm{Ca^{2^+}}$, zero $\mathrm{Ca^{2^+}}$ with 2 mM EGTA, and increasing levels of $\mathrm{Ca^{2^+}}$ (2, 4, 8, 16 mM) at a rate of 2.5 μ l/min for 10 min. Immediately after each period of perfusion the compound action potential of the auditory nerve (CAP), cochlear microphonics (CM) and the -SP evoked by 10 kHz tone bursts of varying intensities were recorded from a wire inserted in the basal turn scala vestibuli. Decreasing the level of $\mathrm{Ca^{2^+}}$ decreased the magnitude of the -SP whereas increasing the levels of $\mathrm{Ca^{2^+}}$ progressively increased the magnitude of the -SP. The results are in harmony with the hypothesis that the -SP is $\mathrm{Ca^{2^+}}$ dependent. We speculate that the -SP represents a $\mathrm{Ca^{2^+}}$ current and/or a $\mathrm{Ca^{2^+}}$ dependent change in the length of the outer hair cells. ADENYLATE CYCLASE SYSTEM AS A RESERVE BATTERY IN THE GUINEA PIG COCHLEA. K. Doi*, N. Mori*, K. Wada and R. J. Wenthold. Dept. of Otolaryngology, Osaka Univ. Med. Sch., Osaka 553, Japan and Lab. of Molecular Otology, NIDCD, Bethesda, Maryland 20892.

We reported (Doi et al., <u>Hear. Res.</u>, 45: 157, 1990) that the perilymphatic perfusion with forskolin, known as an adenylate cyclase (AC) stimulant, produced a reversible 10-20 mV elevation of the endocochlear potential (EP). To examine whether or not this EP elevation is mediated by the activation of the AC-dependent protein kinase (A-kinase), we studied the effect of H-8, an A-kinase inhibitor, on the EP and the EP elevation produced by forskolin. During the recording of the EP, the scala vestibuli was perfused from the basal turn to the apex at a rate of 8μl/min with forskolin (10⁻⁴M, 2x10⁻⁴M), H-8 (10⁻⁴M) or the mixture of forskolin and H-8. We found that 10⁻⁴M H-8 eliminated the effect of 10⁻⁴M forskolin (n=5) but did not significantly affect that of 2x10⁻⁴M forskolin (n=5). We also found that 10⁻⁴M H-8 did not significantly affect the EP itself (n=3). The results suggest that the cochlear AC system may be inactive in

The results suggest that the cochlear AC system may be inactive in the normal state and that it may be activated and play a role as a reserve battery in some pathological conditions.

TEMPORAL REGULARITY MEASURES OF THE FIRING PATTERNS OF AUDITORY NERVE FIBERS TO COMPLEX SOUNDS. D. Lim and R.R. Capranica. School of Electrical Engineering and Section of Neurobiology and Behavior, Cornell University, Ithaca, NY 14853.

Spike trains in response to 300-msec duration simple and complex tones and to natural and synthetic calls were studied in detail for over 50 single auditory fibers in the eighth nerve of the green treefrog (Hyla cinerea). The acoustic stimuli were generated on-line by means of a Macintosh-based auditory workstation in our laboratory (J. Vrieslander and R. Capranica, J. Acoust. Soc .Am. Suppl.1,87: S25,1990). Each stimulus was presented once every 1.5 seconds for five repetitions at each of several different sound intensities, and resultant spike times were determined with an accuracy of 1.0 usec. For each stimulus and each intensity, cross-correlation functions were computed within the set of spike trains for the same fiber (iso-fiber correlation functions) and also between spike trains from different fibers (cross-fiber correlation functions). For each correlation function, it s peak value was divided by its area to yield a normalized temporal regularity index between 0 and 1. This index provides a more meaningful measure of the ability of an auditory neuron to encode dynamic temporal patterns, compared to other techniques such as coefficient of synchronization or PST histograms which are based on averaged activity. Our results indicate that there is a variety of spike train regularities within the population of fibers in the peripheral auditory system. [Supported by NINCDS.]

EFFECT OF INTERMITTENT NOISE ON COCHLEAR POTENT-IALS IN THE CHINCHILLA. F.A. Boettcher and R.J. Salvi. Hearing Research Lab, State University of New York at Buffalo, Buffalo, NY 14214.

New York at Buffalo, Buffalo, NY 14214.

The effect of intermittent noise exposure on sensitivity of the whole-nerve action potential (AP) and amplitude of the AP and cochlear microphonic (CM) were examined in the chinchilla. The subjects were exposed to an octave band of noise (95 dB SPL, 0.5 kHz center frequency) for 3 hours twice daily. The threshold of the AP was elevated by approximately 46 dB on the third day of exposure, then the shift decreased to approximately 10 dB by the 10th day of exposure. The amplitude of the AP decreased across intensity on the first day of exposure and gradually recovered across the duration of the exposure. The slope of the AP input-output functions showed little change. The amplitude of the CM response decreased on the first day of exposure and remained depressed until the termination of the exposure. The mechanism of recovery of sensitivity during exposure will be discussed in terms of outer hair cell function and data will be compared to other investigations of modification of susceptibility to noise-induced hearing loss by previous acoustic stimulation. SUSCEPTIBILITY TO TONAL OVER-EXPOSURE IN AWAKE AND ANESTHETIZED RABBITS. M.C. Patterson. 1 B.D. Mensh. 2.3 M.L. Whitehead. 1 B.L. Lonsbury-Martin 1.2 and G.K. Martin 1. 1 Dept. of Otolaryngol. Commun. Sci., 2Div. of Neurosci., 3 Med. Sci. Tr. Prog., Baylor Col. of Med., Houston, TX 77030.

Exposure to moderate pure tones causes cochlear damage, as measured by a reduction in the amplitude of 211-f2 distortion-product otoacoustic emissions (DPOAEs). Previous work in our laboratory has shown that the susceptibility to damage is greater in anesthetized rabbits during a second exposure, 40 min after the first. The present study examined the role of the acoustic reflex in the increased susceptibility and extended the results to awake animals. The paradigm consisted of: 1) establishing baseline DPOAEs to 50-dB SPL primaries at 2.3 kHz (geometric-mean), 2) exposing the ear to multiple 10-s, 100-dB SPL stimuli at 1.768 kHz, and 3) monitoring the reduction in DPOAEs during a first and second exposure separated by 40 min. The contralateral acoustic reflex was monitored throughout the protocol. Each animal was exposed to the paradigm three times at 2-3 day intervals while awake, and three times while anesthetized.

The increase in susceptibility to overstimulation 40 min after the initial exposure in anesthetized rabbits was not accompanied by a diminished acoustic reflex, implying a cochlear origin of the altered susceptibility. However, anesthetized rabbits were found to be more susceptible to overstimulation than awake rabbits. Because the acoustic reflex was considerably smaller in anesthetized animals, it may be a significant contributor to the difference in susceptibility to overstimulation between the awake and anesthetized states. [DC00313, ES003500].

HISTOPATHOLOGICAL CHANGES FOLLOWING IMPLANTATION OF INTRACOCHLEAR ELECTRODES VARY WITH THE LENGTH OF DEAFNESS PRECEDING THE PLACEMENT OF THE ELECTRODE. S.A.Larsen, Ph.D., and T.M. Kirchhoff, M.D., Depts. of Anat. Sci. & Neurobiol. and Surgery, Div. of Otolaryngol., Univ. of Louisville, Ky. 40292.

Previous studies have shown that insertion, presence and stimulation of cochlear prostheses result in damage to the auditory system; such changes are of concern for long-term use of these devices. We report results from two studies following implantation of intracochlear electrodes. We used Macaca Nemestrina that had been deaf five months prior to the insertion of the

Previous studies have shown that insertion, presence and stimulation of cochlear prostheses result in damage to the auditory system; such changes are of concern for long-term use of these devices. We report results from two studies following implantation of intracochlear electrodes. We used Macaca Nemestrina that had been deaf five months prior to the insertion of the electrodes in one study while in the second investigation, normal-hearing and white-deaf cats that had been deaf for as long as five years were implanted. Cochleas and auditory nerves of implanted and control animals were studied with electron microscopy. Differences were not observed when comparing cochleas or auditory nerves of implanted or control animals in either study, however, degeneration found in the normal-hearing animals could be distinguished from that found in deaf animals. In addition, auditory nerves of the primates appeared to have a normal density of fibers compared to that found in the deaf cats with the remaining auditory fibers falling to show the degree of degeneration observed in deafened primates. Nerves of normal-hearing animals showed patches of fibers that appeared normal intermingled with patches of degenerating fibers that were similar in appearance to the degenerating fibers observed in the deaf primates. We conclude that degeneration seen in both deafened primates and white-deaf cats is due to the deafness itself not to the insertion or the presence of the electrodes while degeneration of cochleas and auditory nerves seen in normal-hearing animals is due to the insertion or presence of the electrodes. In our opinion, the period of the deafness prior to electrode insertion is an important factor determining the degree of degeneration. [125] Sar¹, Ile8-Angiotensin II Receptor Binding in the Cochlea of SHR, WKY and SD Rat Pups.

J.K.M. Coleman, V.I. Cook, K.L. Grove*, H.A. Dengerink, J.W. Wright and R.C. Speth. Departments of Psychology and VCAPP, Washington State University, Pullman, WA 99164.

Our laboratory has been investigating the effects of arginine vasopressin (AVP), angiotensin II (AII), and substance P on cochlear blood

flow (CBF) because these vasoactive hormones may be implicated in otopathologies such as Meniere's disease, noise induced hearing loss tinnitus and sudden deafness syndrome. present investigation utilized the radioligand [125]Sar',Ile⁸-AII to determine the distribution of AII receptor populations in the cochlea of 3 day old spontaneously hypertensive rats, and Sprague-Dawley and Wistar-Kyoto normotensive controls. The results indicate substantial levels of AII binding in the cochlear vasculatures of each strain and represent the first autoradiographic analyses of the cochlea for AII binding. Our previous research has shown dose-re-lated decreases in CBF with the infusion of AII into the supplying vessels of the cochlear vasculature. Taken together these results support an important role for AII in the control of CBF.

ARGIOTOXIN-636 BLOCKS EFFECTS OF N-METHYL-D-ASPARTATE ON LATERAL LINE OF XENOPUS LAEVIS AT CONCENTRATIONS WHICH DO NOT ALTER SPONTANEOUS OR EVOKED NEURAL ACTIVITY. S.L. Guth. D.A. Scapini, M.J. Drescher and D.G. Drescher, Laboratory of Bio-otology, Wayne State University School of Medicine, Detroit Michigan 48201

Detroit, Michigan, 48201 Excitatory amino acids (EAA), their analogs and antagonists can modulate the activity of afferent neurons in acousticolateralis organs, and EAAs are nne activity of alterent neurons in acousticolateralis organs, and EAAs are among the better candidates for afferent transmitter between hair cells and afferent neurons. Argiotoxin-636 (ATX) is a spider venom toxin that is a selective antagonist of the N-methyl-D-aspartate (NMDA) subtype of excitatory amino acid receptors in vertebrates (Priestley et al., Brit. J. Pharmacol. 97: 1315-1323, 1989). We compared the effects of NMDA alone and in combination with ATX on resting firing rate (spontaneous activity) and mechanically stimulated activity of lateral line afferent neurons of early post-metamorphic Xenopus laevis. Perfusion of NMDA (100 or 200 μM) typically produced a biphasic effect on spontaneous activity, which consisted of a transient increase followed by a decrease in firing rate. After spontaneous activity had stabilized in the presence of NMDA, mechanical stimulation evoked an increase in firing rate which was not significantly different from the increase in firing rate evoked by mechanical stimulation in the absence of NMDA. The biphasic effect of NMDA on spontaneous activity was blocked in a reversible manner by concentrations of ATX (1-2 μM) which, when applied alone, did not alter either spontaneous or mechanically evoked activity. While these results suggest that NMDA receptors are present in the lateral line, it appears that the generation of action potentials by the afferent transmitter in this organ is not dependent on activation of postsynaptic NMDA receptor-ion channels. among the better candidates for afferent transmitter between hair cells and

PHOSPHOINOSITIDE METABOLISM IN THE GUINEA PIG COCHLEA: DIFFERENCES BETWEEN BASE AND APEX. A. Niedzielski and J. Schacht. Kresge Hearing Research Institute, University of Michigan, Ann Arbor, MI, 48109-0506.

Functional differences between the base and apex of the cochlea are believed to have an important role in auditory processing. It has been suggested that these differences are the result of longitudinal gradients in cochlear anatomy, biochemistry, and physiology. Gradients in efferent innervation and in Na+K+ ATPase are two examples with tinctional significance. Previously, we have reported that in whole tissue preparations in vitro, ³²P-labelling of phosphoinositides is significantly higher in the apex of the guinea pig cochlea. The phosphoinositide second messenger system has been hypothesized to phosphoinositide second messenger system has been hypothesized to mediate cell signalling in the cochlea, including outer hair cell contractility. We have now determined that the differential distribution of phosphoinositide labelling is not due to differences in ATP pools or in substrate availability between the base and apex of the cochlea. In contrast, direct assay of diacylglycerol kinase revealed 1.6-fold higher activity in the apical cochlea. Similar differences may exist in other enzymes of phosphoinositide metabolism. The differential distribution of the phosphoinositide second messenger system may have important implications for cochlear function.

REGULARITY ANALYSIS OF UNITS IN THE ANESTHETIZED GERBIL DORSAL COCHLEAR NUCLEUS (DCN). I.C. Maghirang*, R. Wallace*, S. Xue*, T.E. Benson Engineering, Boston University, Boston, MA 02215.

Responses of units in the DCN of barbiturate-anesthetized gerbils to 50-ms tone-bursts were recorded in

order to establish a normative data-base for peri-stimulustime (PST) histograms and regularity analysis in this species. Responses to 100 stimulus presentations were recorded at best frequency (BF) and up to 30 adjacent frequencies (0.2 octave steps) for several sound pressure frequencies (0.2 octave steps) for several sound pressure levels (10 dB steps). This report is based on the analysis of BF responses at 20 dB re threshold in 61 units. A decision tree (after Blackburn and Sachs, J. Neurophysiol., 62:1303, 1989 and Young et. al., J. Neurophysiol., 60: 1, 1988) was developed for unit classification based on PST-type, spikes/peak test, regularity analysis (mean interval and standard deviation (SD) vs. time following stimulus onset), coefficient of variation (CV = SD/mean interval). Of 61 units classified, 7 are Primary or Pri/Notch; 24 are Chopper-S; 5 are Chopper-T, 1 is a Chopper-I; 11 are Pausers; 5 are Buildups; 7 are Onset or Onset-sustained, and 1 is an Off-responder. To our knowledge, this is the first use of regularity analysis applied to unit classification in gerbil cochlear nucleus. [Work supported by NIH]

RESPONSE MAP MEASUREMENTS OF UNITS IN ANESTHETIZED GERBIL DORSAL COCHLEAR NUCLEUS (DCN). G.T. Glowski*, K. Kreitner*, T.E. Benson, H.F. Voigt.
Dept. of Biomedical Engineering, Boston University, Boston, MA 02215.

Responses of units in the DCN of barbiturate-anesthetized gerbils to 32-, 50-, and 200-ms tone- and 200-ms noise-bursts were recorded in order to establish normative response-map (RM) data in this species. Threedimensional RMs (rate vs sound level vs frequency) and twodimensional RMs were generated from responses to single presentations of the 32-ms tones and compared to those based on responses to 100 50-ms tones. Units were typed according to the presence and location of excitatory and inhibitory RM regions, rates of spontaneous activity (SPAC), and relative noise index [p= (maximum noise response -SPAC)/(maximum best frequency (BF) tone response -SPAC)]. Of 126 units classified, 20 are type I (no inhibition, SPAC \(\)2.5 Spk/s); l8 are type II (no inhibition, SPAC \(\)2.5 Spk/s, p\(\)2.31; 56 are type I/III (no inhibition detected, SPAC \(\)2.5 Spk/s, p>0.3); 30 are type III (side-band inhibition, SPAC >2.5 Spk/s); and 2 are type IV (inhibition above excitation at BF; SPAC >2.5 Spk/s). These are consistent with data from the DCN of other anesthetized species. [Work supported by

EVALUATION OF NEURONAL ACTIVITY IN THE MEDIAL GENICULATE BODY OF THE RAT IN RESPONSE TO NOVEL STIMULI. D. S. Weiss and S. Reinis.

Department of Psychology, University of Waterloo, Waterloo, ONT,

Extra-cellular activity was recorded using tungsten microelectrodes. Subjects were Long-Evans hooded rats anaesthetized with Rompun and Ketaset. Data were digitized at 10 kHz. Spikes in the multi-unit record were separated and discriminated according to voltage into leading cell and mass activity categories. Frequency histograms of interspike intervals (auto-correlograms) were calculated in order to determine significant interactions between neurons. Stimulus conditions were No Stimulus (NS); Tone Continuous (TC); Tone Burst (TB), 100 msec at 500 msec intervals; and novel stimulus (CL). Tone stimuli were presented at characteristic frequencies. The novel stimulus was a sharp clanging sound produced by a mechanical device at a rate of 2 Hz.

Neuronal systems recorded under the NS and TC conditions reacted in a similar manner. Both mass and leading cell correlograms were characterized by either predominantly short-term interspike intervals of less than 100 msec or evenly distributed patterns of short, medium, and long-term intervals over the full 1000 msec correlogram. A completely different configuration was evident in the TB and CL conditions where both leading cell and mass activity correlograms were characterized by a W-like shape with peaks congregated at interspike intervals of 5-100, 450-550, and 900-1000 msec.

RECOVERY OF AUDITORY NEURONS FROM PRIOR STIMULATION VARIES WITH SPONTANEOUS ACTIVITY. E.M. Relkin and J.R. Doucet*. Institute for Sensory Research and Dept. of Bioengineering, Syracuse Univ., Syracuse, NY 13244

Studies of forward masking in primary auditory neurons have revealed that probe-tone thresholds recover more slowly from the effects of a 100 ms masker for low and medium spontaneous-rate (SR) neurons compared to high SR neurons. Complete recovery takes $2.0\ \bar{s}$ for the former groups and 200 ms for the latter. These results suggest the hypothesis that recovery from adaptation is slower for low and medium SR fibers. PST histograms were recorded for the responses to 100 ms toneburts at a neurons's characteristic frequency with interstimulus intervals (ISI) of 100 ms, 300 ms, and 2.0 s. For all SR groups, both onset and average responses are reduced for the 100 ms ISI compared to the 2.0 s ISI. However, only for low and medium SR neurons are these measures also reduced for the 300 ms ISI. These results are consistent with the hypothesis, and explain why onset responses are often small or absent when low and medium SR neurons are studied with typical ISI's that are chosen to avoid the effects of adaptation in high SR neurons.

STEREODYNAMIC STUDIES OF AUDITORY POTENTIAL (AER) OF THE LIMBIC AND NON-AUDITORY NEOCORTEX. C.C. Turbes and G.T. Schneider*. Creighton University, School of Medicine, Omaha, NE 68178.

These studies use 24 cats under non-anesthetic states. Electrodes are implanted, under appropriate anesthetic and stereotoxic procedures in non-auditory neocortical

areas, nucleus accumbens, and certain nuclei of the amygdala complex.

Auditory stimulation was done using the free field method with periodic tones at 2.0 KHz to 3.0 KHz at

30db. The auditory stimulation and recording was performed with hard wire and telemetry methods.

The analog data is collected on FM tape and processed with minicomputer. Digital filtering, cross, coherence, phase, spectral and cycle time analyses are used on the analog data

The (AER) potentials and spontaneous electro potentials in these brain areas are investigated noting simularities and differences relating to physiological interactions.

362.4

LESION OF THE ACOUSTIC NERVES OR VENTRAL COCHLEAR NUCLEI ABOLISH MOTOR BUT NOT CARDIOVASCULAR RESPONSES TO AIRPUFF STARTLE STIMULI. B.K. Taylor, R. Casto and M.P. Printz. Pharmacology M-036, Univ. of California, San Diego, La Jolla, CA 92093.

Air-puff stimuli (12.5 psi, 100-ms duration) elicit behavioral (motor)

startle reactions accompanied by a complex cardiovascular (CV) constellation which includes pressor, bradycardic and tachycardic components. We previously found an acoustic component of the airpuff. After tympanic membrane rupture (TMR) the motor response to air-puff (and acoustic) stimuli was abolished but not the CV responses. The present study extends this observation by transecting the VIII cranial nerve (acoustic) and lesioning the ventral cochlear nucleus (VCN).

Under halothane anesthesia, the acoustic nerve of Sprague-Dawley rats was severed bilaterally by aspiration and animals tested after 7-10 days of recovery. Successful transection (TRANS) was verified. Shams had surgery without transection. For trial 1, motor responses to air-puff simuli were abolished by acoustic nerve transection (SHAM: 50.3±12.5, TRANS: 4.2±2.1) but CV responses were intact (pressor SHAM: 31.3±2.5, TRANS: 31.8±4.9 mmHg; bradycardia SHAM: -21.2±7.8, TRANS: -26.1±4.9 bpm; tachycardia trial 15: SHAM: 20.4±6.4, TRANS: 24.9±3.8 bpm).

Under anesthesia, the VCN was bilaterally RF-lesioned. Shams received no current. Testing was 9-12 days after surgery. Again, after VCN destruction motor but not CV responses to air-puff stimuli were abolished. Results were similar between the VCN lesioned, VIII-transected, and TMR groups providing further evidence that the acoustic component of the airpuff stimulus is essential to the behavioral motor response.

VOICE ONSET TIME ENCODING FOR SYLLABLES IN PRIMATE

VOICE ONSET TIME ENCODING FOR SYLLABLES IN PRIMATE AUDITORY CORTEX. M. Steinschneider, J. Arezzo, C. Schroeder and H.G. Vaughan, Jr., Albert Einstein College of Medicine, Bronx, NY 10461. Voice onset time (VOT) is a speech parameter which denotes the interval between stimulus onset and the onset of periodic portions of speech sounds. The differential perception of consonants such as /d/ and /l/ is partially determined by the VOT. We investigated the cortical encoding of VOT by examining laminar profiles of auditory evoked potentials, current source density and multiple unit activity (MUA) elicited by the syllables /da/ (VOT=0 msec) and /da/ (VOT=80 msec) in auditory cortex of an awake macaque. Stimuli were delivered to the contralateral ear at 85 dB SPL.

ar at 80 up 57 L.

In thalamocortical (TC) fibers, responses to /da/ predominantly reflect
the 0 msec VOT by phase-locked activity to the syllable periodicity that
begins at stimulus onset and persists throughout its duration. In contrast, begins at stimulus onset and persists throughout its duration. In contrast, the response to /ta/ consists of an initial burst time-locked to stimulus onset followed by phase-locked responses delayed by the increased 80 msec VOT. Two cortical patterns reflecting VOT are observed. In the first pattern, the temporal sequence of current sinks mirrors that seen in TC fibers, with prominent phase-locked responses extending throughout the duration of /ta/ and delayed by the increased VOT for /ta/. In the second pattern, the onsets of the periodic and aperiodic segments of the syllables are accentuated in the initial laminae 4 and lower 3 current sinks and MUA while the phase-locked responses are diminished in amplitude. The presence of MUA inhibition suggests that inhibitory processes help shape this response transformation. this response transformation.

We conclude that auditory cortex encodes VOT by: 1) the faithful transmission of TC fiber input patterns, and 2) a transformation of thalamic input that accentuates important acoustic transients used in the VOT distinction. (supported by MH06723)

SPATIAL EXTENT OF COHERENT SENSORY-EVOKED CORTICAL ACTIVITY Z. L0* and S.J. Williamson, Neuromagnetism Lab., Dept. of Physics and Center for Neural Science, N.Y.U., New York, NY 10003.

To estimate the extent of cortical involvement that could account for observed human sensory-evoked magnetic fields or electric potentials, we have analyzed data on current source-density analyses in the somatosensory cortex of macaque monkey (Cauller, L.J., Kulics, A.T., submitted) and visual cortex of cat (Mitzdorf, U., J. Neurosci. 33: 33, 1987). By integrating through cortex the deduced *intracellular* current density flowing perpendicular to the cortical laminae, we deduced the net current dipole moment per unit area of cortical surface for several evoked components of long latency. Similar values were obtained across species and modalities, suggesting that suprathreshold response levels for natural stimuli are similar when characterized this way. The overall average current-dipole moment density is about 50 $\mu\text{A/m}$ (S.D. = 30 $\mu\text{A/m}$). We suggest because of the similarities of mammalian cortical structure that this may also be taken as a reasonable estimate for human cortex as well. Since the total current dipole moments obtained from neuromagnetic studies on human subjects fall in the range 2-20 nA·m, the corresponding coherent neuronal activity extends over a cortical area that is typically 40-400 mm². At least for the auditory system, this is incompatible with a columnar organization where the response is limited to an area corresponding to linear dimensions that determine the just-noticeable differences for pitch (about 10 μm) and loudness (about 100 μm). One implication of this comparison is that neuronal activity in human auditory cortex evoked by the onset of a tone burst is sufficiently extensive to be largely overlapping for the close-lying but distinguishable attributes of pitch and loudness.

RESPONSES OF INFERIOR COLLICULUS NEURONS IN YOUNG ADULT C57BL/6J MICE AS A FUNCTION OF STIMULUS AZIMUTH. McFadden* and J.F. Willott. Psychology Dept., Northern Illinois University, DeKalb, IL 60115.

To examine neuronal responses as a function of sound source location in the horizontal azimuthal plane, recordings were made from inferior colliculus neurons in recordings were made from interior contains an esthetized 2-month-old C57BL/63 mice. Pure tone stimuli were presented at 7 angles in the free field. Many neurons (approximately half of the sample) behaved as though they were binaurally excited, with discharge rates varying little as a function of stimulus azimuth. Other units had discharge rates that varied markedly with speaker location. Maximal excitation nearly always occurred when the speaker was positioned in the hemifield contralateral to the recording site. Some units responded as though they were monaurally excited; in these cases, response variations could be attributed to the head shadow effect (attenuation of the signal at the distal ear by the presence of the animal's head in the sound field). In other cases, response variations were greater than could be accounted for by the head shadow effect alone, suggesting binaural interactions. Similar types of units (e.g., omnidirectional, hemifield) appear although proportions may differ between species.

PHASE-SENSITIVE BINAURAL INHIBITION IN LATERAL SUPERIOR

PHASE-SENSITIVE BINAURAL INHIBITION IN LATERAL SUPERIOR OLIVARY NEURONS. P.G. Finlayson and D.M. Caspary, Dept. of Pharmacology, Southern Illinois Univ. School of Medicine, Springfield, IL 62794-9230. The lateral superior olive (LSO) is involved in the localization of sound. LSO neurons in the lateral limb receive low frequency (<1.2 KHz) inputs. Tone-evoked responses from 96 chinchilla LSO neurons and 10 rat LSO neurons with CFs less than 1.2 KHz were characterized, and most displayed phase-locked tone-evoked temporal discharge patterns to ipsilateral CF stimuli. Low-CF LSO neurons comprised between 5% and 10% of all LSO neurons encountered. Discharge rate of low-CF LSO neurons increased as ipsilateral intensity increased and decreased as contralateral intensity increased. In over 60% of neurons, Discharge rate of low-Cr LSO neurons increased as ipsulateral intensity increased and decreased as contralateral intensity increased. In over 60% of neurons, binaural inhibition, inhibition of ipsilaterally-evoked activity by contralateral stimuli, was dependent on interaural phase differences (IPD). Maximal binaural inhibition does not appear to occur more frequently with in-phase or out-of-phase stimuli for neurons tested with like binaural stimuli. Maximal binaural inhibition was observed at intermediate IPDs (i.e. between 0 and 180°) in cells tested with smaller phase increments. Interaural phase differences had profound effects on binaural inhibition in many low-CF LSO neurons. Responses of phase-sensitive neurons to binaural stimuli often varied with 90° or 180° changes in IPD from total inhibition to a facilitated response (compared to responses to control ipsilateral stimuli alone). The present study finds that most or all low-CF LSO neurons do receive a functional inhibitory contralateral input and that these neurons are sensitive to interaural phase differences as well as interaural intensity differences. The role of these low-CF LSO neurons in shaping the activity of inferior colliculus neurons should be considered and contrasted with low-CF lasts are the residual to the residu

inputs originating from the medial superior olive.

DIRECTIONAL SENSITIVITY OF AUDITORY NEURONS IN THE OWL. T.T. Takahashi and H. Wagner. Institute of Neuroscience, University of Oregon, Eugene, OR 97403; Max-Planck Institut fur Biologische Kybernetik, D-7400 Tubingen, FRG.

The barn owl captures moving prey using only its sense of hearing. To study the neural basis of sensitivity to moving sound sources, we recorded the responses of 68 neurons in the owl's superior and inferior colliculi to the motion of a target simulated by sequentially activating 7 speakers placed at 30° intervals in the horizonal plane. Stimuli were typically 100-msec bursts of broadband noise, presented every 95 msec, simulating a speed of 102°/sec. The response of the neurons were plotted as post-stimulus time histograms to determine whether spike discharge was greater in one direction than in the other. As a control, we disconnected all speakers except the most effective speaker and repeated our stimulus presentation. The single speaker condition, which contains no motion cues, represents a reference with which to judge the directional preference of a neuron statistically (chi-squared). Of the total, 37% displayed a significant directional preference. Inhibition in the null direction (89% of cells) facilitation in the preferred direction (11%), and both (11%) accounted for directional sensitivity.

RESPONSE PROPERTIES OF NEURONS IN THE COCHLEAR NUCLEUS OF BEHAVING CATS. B. May * M.B. Sachs and C. M. Aleszczyk*. Ctr. for Hearing Sciences and Depts. of Biomedical Engineering and Otolaryngology-Head and Neck Surgery, The Johns Hopkins Univ. School of Medicine, Baltimore, MD 21205.

We have recorded single unit responses from over 100 neurons in the cochlear nucleus (CN) of awake and behaving cats. Microelectrodes are directed to the CN by a chronically implanted recording chamber. When an auditory neuron is encountered, the unit's best frequency (BF) and threshold are determined. Each unit is classified by the shape and regularity of peristimulus time (PST) histograms describing responses to 50-ms tone bursts. Dynamic range properties of the neuron are measured in behavioral tests. Our subjects must press a lever as 200-ms BF tone bursts covering a 100-dB range are presented. When the testing sequence is interrupted at random by an increase in the rate of stimulus presentation (i.e., an abrupt decrease in stimulus duration and interstimulus interval), subjects momentarily release the lever to obtain a food reward. A function relating the unit's discharge rate to stimulus level is computed for the 200-ms tones in the testing sequence. Rate-level functions are also obtained using noise bursts as stimuli and BF tone bursts in continuous background noise. A computational model (Sachs et al., Hearing Res., 41:61-70, 1989) is applied to these data to quantify the effects of noise on dynamic range. This report will compare sensitivity, PST types and dynamic range properties of units obtained in behaving cats to responses observed in anesthetized and other nonbehaving preparations, and to psychophysical measures of performance.

DYNAMIC EFFICACY OF THE TYPE II/TYPE IV SYNAPSE IN THE CAT DORSAL COCHLEAR NUCLEUS. M.R. Sydorenko and E.D. Young. Department of Biomedical Engineering & Hearing Science Center, Johns Hopkins University, Baltimore, MD 21205.

The dynamic efficacy of the synapse between type II and type IV cells in the cat dorsal cochlear nucleus (DCN) was investigated in vivo. Type II cells provide a mono-synaptic inhibitory input to type IV cells. Data for estimating the synaptic impulse response were collected by simultaneously recording the relative occurrence times of action potentials (APs) from a type II and a type IV neuron with similar best frequencies. Synaptic efficacy is expressed as the expected number of post-synaptic (type IV) APs eliminated per pre-synaptic (type II) AP. The efficacy of the synapse was estimated over a series of brief time windows spanning the stimulus duration. Also, various other parameters such as pre- and post-synaptic rate were computed for each window. Results reveal a consistent inverse relationship between average pre-synaptic rate and synaptic efficacy. No consistent relationship between synaptic efficacy and post-synaptic rate or poststimulus onset time was observed. An analysis of synaptic efficacy conditional on instantaneous pre-synaptic interspike interval (ISI) indicated that the efficacy of the synapse is not dependent on the previous ISI. Rather, this study suggests that type II/type IV synaptic efficacy is a long memory, pre-synaptic history predictable process; and, that type II/type IV synaptic efficacy is inversely and roughly linearly related to type II average rate. AUDITORY-NERVE RATE REPRESENTATION OF SOUND LO-CALIZATION INFORMATION PRESENT IN SPECTRA GENER-ATED BY DIRECTION-DEPENDENT PINNA FILTERING E.D. Young, J.J. Rice*, and G.A. Spirou*. Dept. of Biomedical Engineering & Hearing Science Center, Johns Hopkins Univ., Baltimore, MD 21205

The cat pinna modifies the spectra of stimuli in a fashion that depends

on the direction of sound origin; a prominent component of the resulting spectra are notches with center frequencies above 8 kHz which move in an orderly fashion as sound source direction changes. Because these features occur at frequencies above the cutoff for phase-locking, they must be represented at the level of the auditory nerve (AN) by profiles of discharge rate versus best frequency (BF). In this paper we report on AN rate profiles in decerebrate cats for responses to stimuli generated by filtering broadband noise with pinna transfer functions. Rate profiles reveal a rather poor representation of the spectra of pinna-filtered stimuli when plotted as rate, as driven rate, or as normalized rate versus BF. However, when plotted as the difference in response rate between two stimuli, a clear representation of the ratio of the two magnitude spectra is seen. This result suggests that precise information about stimulus spectra is present in discharge rate, and that the poor quality of rate profiles is due to scatter that is not controlled by normalization. If stimuli are presented simultaneously to the left and right ears with spectra appropriate to the same position in the free field, a weak inhibitory effect of the contralateral stimulus is seen. The inhibition may be due to activation of the olivocochlear bundle. Sharp spectral features of the contralateral stimulus is seen. lus such as notches are not observed in a frequency-specific fashion in the contralateral inhibition. Supported by NIH grant 5 R01 DC00119.

ATTENUATION OF SALICYLATE-INDUCED TINNITUS BY EXOGENOUS CALCIUM IN RATS. J.F. Brennan¹ and P.J. Jastreboff². ¹Dept Psychology, Univ of Massachusetts/Boston, MA 02125 and ²Dept Surgery, Yale Sch Med., New Haven, CT 06510.

The influence of 0.05 M calcium chloride solution substituted for tap water on salicylate-induced tinnitus was evaluated in 72 pigmented rats through a procedure described earlier for our

The influence of 0.05 M calcium chloride solution substituted for tap water on salicylate-induced tinnitus was evaluated in 72 pigmented rats through a procedure described earlier for our animal model of tinnitus (Beh.Neurosc., 1989, 188, 811-822). Combinations of 2 doses of salicylate (200- and 300-mg/kg) and 2 levels of continuous background noise (42- and 62-dBC) were used with groups of 18 water deprived rats trained to lick for the calcium solution and then given an acclimation session of exposure to the to-beconditioned stimulus (CS), consisting of 5 offsets of the background for 1 min durations. 2 training sessions involved the 5 CSs' terminating with a 0.5 s, 1 mA footshock, and 7 extinction sessions followed. 6 subjects began daily salicylate injections before the 1st training session, 6 rats after training and before the 1st extinction test, and the remaining 6 rats served as saline injected controls. Under calcium supplement, the salicylate effects were attenuated compared to water alone, consistent with reversal of other salicylate effects by exogenous calcium. (NIH DC00299).

EVALUATION OF BRAINSTEM EVOKED RESPONSE AIMED AT DETECTION OF TINNITUS IN HUMANS. P.J. Jastreboff, C.L. Ikner, and A. Hassen. Dept Surgery, Yale Univ Sch of Med, New Haven, CT 06510, Dept Clinical Sci and Physiol, W.V. Sch of Osteopathic Med., Lewisburg, WV, 24901.

This study attempted to create an objective method for tinnitus detection in humans based on mathematical analysis of brainstem evoked response (BSER). In a blind study, (PJJ) was provided with BSERs from 3 groups of 7 patients with normal hearing. Extending a previously developed method (Biol.Cybernetics 33:113-120, 1979), an approach was made to detect tinnitus related changes in BSERs, employing both frequency and time domains. The method enabled the correct identification of each group of patients (1 normal and 2 tinnitus groups). Highly significant differences (p<0.001) were obtained between the normal group and either of the two tinnitus groups. There were no differences between tinnitus groups, which were statistically indistinguishable. The time domain analysis indicated differences occurring for the potentials of latencies 4-7 msec. The frequency analysis showed differences for 600 Hz and below. At present, work is in progress in an effort to expand this method for evaluation of a single individual with tinnitus. Support: NIH DC00299.

EFFECTS OF TEMPORAL LOBE LESIONS ON THE PRECEDENCE EFFECT IN SOUND LOCALIZATION. J. L. Cranford, E.T. Goldstein, S. Preskorn, C. Moore*. Dept. Communicative Disorders, Wichita State Univ., & Psychiatric Res. Unit, St. Francis Regional Med. Center, Wichita, KS 67208.

The precedence effect involves presentation of pairs of

The precedence effect involves presentation of pairs of clicks from spatially separated speakers in the sound field, with one speaker leading the other in time (.2 to 8 msec.). Normal subjects perceive a fused auditory image which appears to originate from the side of the leading speaker. Cats with unilateral auditory cortex lesions (Cranford, J.L., Oberholtzer, M., Brain Res., 111:225, 1976) correctly identify the leading source only when it is located opposite the intact hemisphere; when the leading speaker is located opposite the lesion side, cats approach the side of the trailing source. Eight humans with unilateral neocortical lesions were tested with this procedure. An effect similar to that seen with cats was found in 4 subjects in which the lesions involved areas 41 and 42 of the temporal lobe. Lesions located in non-auditory areas had no effects. The severity of the deficit appeared to be related to both the size of the lesion as well as the length of time since the occurrence of the lesion. Additional tentative evidence suggests the deficits may be more severe with left hemisphere lesions than with right lesions.

AGE-RELATED TEMPORARY THRESHOLD SHIFTS AND COCHLEAR MICROPHONIC ALTERATIONS AFTER CALCITONIN INFUSION IN A MACAQUE MONKEY MODEL. A.M. SHAPIRO*, R.N. STROMINGER*, H. ARBABZADEH*, A.T. CACACE*, S.M. PARNES* and N.L. STROMINGER. Departments of Surgery (Otolaryngology) and Anatomy, Albany Medical College, Albany, N.Y. 12208

Recent studies have demonstrated a relationship

Recent studies have demonstrated a relationship between hypocalcemia and temporary auditory threshold shifts (TTS) using surface recorded brainstem auditory evoked potentials (BAEPs); promontory recorded cochlear microphonics (CMs) also are affected. These phenomena have been shown in rabbits and monkeys after calcitonin infusion, and in rabbits after thyroparathyroidectomy. There is evidence suggesting that calcium is involved with age-related alterations in active neural processing. Thus, we studied the response of calcitonin infusion and consequent transient hypocalcemia on BAEPs and CMs in four young (2-4 years) and four aged (>22 years) macaque monkeys. Hypocalcemia was correlated with increased auditory thresholds and CM alterations in all animals. The older monkeys displayed larger and longer lasting TTS and CM changes than younger animals. These findings support the premise that age-related calcium regulation plays a role in sensorineural auditory functions.

VISUAL INFORMATION FROM ARTICULATION MODIFIES ACTIVITY OF THE HUMAN AUDITORY CORTEX. Mikko Sams, *Reijo Aulanko, Matti Hämäläinen, Riitta Hari, Olli V. Lounasmaa, Sing-Teh Lu, and Juha Simola. Low Temperature Laboratory, Helsinki University of Technology, 02150 Espoo, Finland, and *Department of Phonetics, University of Helsinki, 00170 Helsinki, Finland.

Neuromagnetic measurements were used to find out in which cortical area the heard and seen speech are integrated. The auditory stimuli were Finnish consonant-vowel syllables /pa/ presented together with a videotaped face articulating either the concordant syllable /pa/ (84% of the stimuli, V=A) or the discordant syllable /ka/ (16% of the stimuli, V=A). Magnetic field was recorded over the left hemisphere with a 24-channel SQUID-magnetometer.

The subjects heard the V≠A stimulus as /ta/ or /ka/ or their mixture. The magnetic responses to these stimuli had similar initial deflections as those to the V=A stimuli. However, at the latency of about 150 ms the responses started to differ. This long-lasting difference peaked at 200 - 500 ms depending on the subject, and could be explained by activity at the supratemporal auditory cortex. This indicates that seeing the articulatory movements of the face has an effect on signal processing occurring at the auditory cortex.

The present results show that visual information from the articulatory movements has an entry into the auditory cortex. Interestingly, the neural activity observed correlates with auditory, especially phonetic, perception rather than with the acoustical energy of the stimuli.

THE ROLE OF MYELINATION IN THE DEVELOPMENT OF NUCLEUS LAMINARIS IN THE BARN OWL. C. E. Carr and G. A. Higgins. Dept. of Zoology, University of Maryland, College Park, MD 20742 and Gerontology Res. Ctr., NIA/NIH, Baltimore MD 21224.

The barn owl uses interaural time differences to localize sound in azimuth. Sensitivity to these interaural time differences arises in the brainstem nucleus laminaris (NL). Maps of interaural phase difference are formed in the dorsoventral dimension of NL by interdigitating axons from the ipsi- and contralateral magnocellular cochlear nuclei (NM). The amount of delay mapped in NL depends on the length and conduction velocity of the axons. Since myelination is important in determining conduction velocity, we have used immunohistochemical and in situ hybridization techniques to describe development of myelination in the month posthatch.

describe development of myelination in the month posthatch.

At hatching, the auditory nerve fibers are myelinated, and the NM axons that project to NL are myelinated up to the border of NL. In the first week post-hatch, oligodendrocytes line the borders of NL, and a wave of myelination of the NM axons in NL begins towards the end of the first week posthatch. Myelination proceeds slowly and is complete at 1 month posthatch. At this time the circuit in NL is almost adult in appearance.

Thus the delay lines acquire a functional appearance towards the end of the first month of life. The maturation of this circuit coincides with the time that the head stops growing, and the bird is no longer subject to changing interaural time differences. (Supported by R29 NS25507 to C.E.C.)

CYCLIC GMP RELEASE AND CAROTID CHEMORECEPTOR INHIBITION PRODUCED BY ATRIAL NATRIURETIC PEPTIDE. L, Hex J. Chen, W.-J. Wang, B. Dinger and S. Fidone. Dept. of Physiol., Univ. of Utah Sch. of Med., Salt Lake City, UT 84108.

Recent studies in our laboratory demonstrated the existence of ANP in preneural type I cells in the carotid body and showed that brief exposures to nanomolar concentrations of the ANP fragment atriopeptin III (APIII) induced large increases in the content of cyclic GMP (cGMP) in these cells. Furthermore, 100 nM APIII was shown to inhibit by more than 80% the carotid sinus nerve (CSN) activity evoked by a moderate hypoxic stimulus in vitro (media equilibrated with 20% O₂); but APIII did not significantly alter the stimulus evoked release of catecholamine from the tissue. We have now examined the hypothesis that the CSN inhibition produced by APIII is mediated by cGMP.

Rabbit carotid bodies were superfused in vitro in studies of cGMP release evoked by APIII. RIA measurements of superfusion media collected during sequential 10 min control, stimulus and poststimulus periods showed that basal levels of cGMP released from the tissue $(7.62 \pm 0.60 \text{ fmol/mg} \text{ tissue}; \tilde{X} \pm \text{SEM})$ were elevated by 64.9-fold ± 21.9 in the presence of 100 nM APIII. Also, CSN activity was recorded in vitro to examine the effects of cGMP and the cell-permeant analogue dibutyryl-cGMP (db-cGMP). In six experiments the CSN response evoked by 20% O₂-media was inhibited by 66% ± 6% in the presence of db-cGMP (2 mM). In contrast, cGMP did not alter the response evoked by hypoxia, even when the phosphodiesterase inhibitor isobutylmethyl-xanthine was present in the incubation media. Although APIII evokes a large increase in the generation and release of cGMP, the results suggest an intracellular site of action for the inhibition produced by this cyclic nucleotide second messenger Supported by USPHS Grants NS12636 and NS07938.

AN IMMUNOCYTOCHEMICAL STUDY OF BIOGENIC AMINES AND NEUROPEPTIDES IN THE HYPOXIC CAT CAROTID BODY. Wang, B. Dinger, S.J. Fidone and L.J. Stensaas. Dept. of Physiology, Univ. of

Utah Sch. of Med., Salt Lake City, Utah 84108

Long-term hypoxia induced by high altitude has been shown to elicit a number of structural and functional changes in chemosensory elements of the Current concepts of chemoreception implicate multiple neuroactive agents in chemotransmission. The present immunocytochemical study investigated the effects of chronic hypoxia on biogenic amines and neuropeptides in intact, sinus nerve denervated, and sympathectomized cat carotid bodies. Adult cats were exposed to a hypoxic gas mixture (10% O₂ and 90% N₂) for 2 weeks, and fixed by perfusion. Semithin sections (1 μ m thick) of carotid body embedded in Epon were immunostained with antisera to tyrosine hydroxylase (TH), substance P (SP), met-enkephalin (M-ENK) and serotonin (5-HT) using the avidin-biotin-peroxidase method. M-ENK and 5-HT immunoreactivity in type I cells was unchanged following chronic hypoxia, while the high SP level found in 70% of type I cells of normoxic cats was reduced with hypoxia to less than 10%. A similar effect of hypoxia was also consistently seen in chronically CSN-denervated and sympathectomized carotid bodies. Chronic hypoxia significantly increased both the number and intensity of TH immunostained type I cells, an effect slightly attenuated by sympathectomy. However, sympathectomy increased the number of SP and TH positive nerve profiles nearby to type I cells in the hypoxic carotid body. CSN denervation eliminated these profiles. In conclusion, chronic hypoxia had profound effects on catecholamine and neuropeptide stores in the carotid body, findings which suggest their involvement in chemoreceptor adjustments to long-term hypoxia. Supported by USPHS Grants NS12636 and NS07938.

IMPLANTS OF RAT PERIPHERAL GANGLIA AND CAROTID BODY ONTO THE CHICK EMBRYO CHORIOALLANTOIS. A. Gual, J. Eugenin, J. Alcayaga, V. Gotzems*, L.J. Stensaas and C. Eyzaguirre. Dept. of Physiol, Univ. of Utah Sch. of Med., Salt Lake City, UT 84108.

To study reciprocal influences between arterial chemoreceptors and sensory or sympathetic neurons, we implanted rat carotid bodies, nodose- and superior cervical ganglia, either alone or together, on the chicken chorioallantoic membrane (CHAM). Grafts obtained from 100 g anesthetized rats were placed over the CHAM of 6-12 days chick embryos. After 5-6 days, successful grafts (50-90%) were surrounded by the CHAM and were well vascularized. Light microscopy revealed survival of glomus cells and neurons, hyperplasia of glial cells and proliferation of capillaries. Electron microscopy showed that regenerating axons from nodose ganglia penetrated the carotid body stroma, entered the lobules, and contacted the surface of glomus cells. Immature junctional complexes (membrane densities and synaptic vesicles) between domus cells and the regenerated unmyelinated axons were identified. Intracellular recordings of nodose ganglion neurons are in progress. Preliminary observations show properties similar to those of normal ganglia. Thus, chorioallantoic grafting may permit the study of interrelations between chemoreceptors and neurons. Supported by granst NS 05666 and NS 07938. J.E. is a Fogarty International Fellow; J.A. is an O.A.S. Fellow.

363.2

EFFECT OF BRIEF HYPOXIC EXPOSURE ON CYCLIC AMP LEVELS IN THE RABBIT SUPERIOR CERVICAL GANGLION IN VITRO. J. Chen, W.-J. Wang, B. Dinger and S. Fidone. Dept. of Physiol., Univ. Utah Sch. of Med., Salt Lake City, UT 84108

Earlier studies by Libet and Owman (J. Physiol. 237: 635, 1974) established that preganglionic nerve stimulation evokes the release of dopamine (DA) from small intensely fluorescent (SIF) cells of the rabbit superior cervical ganglion (SCG). In addition, DA release from these cells is believed to activate adenylate cyclase via D-1 dopaminergic receptors on post-ganglionic neurons. Previous studies in our laboratory (Soc. Neurosci. Abstr. 13: 1674, 1987) demonstrated that incubation of SCG in low-O₂ media increases the content of DA and its metabolite, dihydroxyphenyacetic acid (DOPAC); findings which are consistent with the hypothesis that hypoxia, like preganglionic stimulation, evokes DA release from SIF cells. To further test this hypothesis, we have examined the possibility that hypoxia elevates the content of cAMP in the SCG.

Desheathed SCG were preincubated for 30 to 40 min in modified Tyrode's media equilibrated with 100% O_2 and then exposed for 10 min to 100% O_2 -, 10% O_2 - or 5% O_2 -media. The tissues were then processed by RIA for determination of cAMP. In 100% O₂- media, the cAMP content of SCG was 2.80 \pm 0.18 pmole/mg tissue ($\dot{X}\pm$ SEM). Incubation in 10% O₂- and 5% O₂- media elevated the cAMP content to 4.00 \pm 0.38 (p<0.01) and 4.74 \pm 0.19 pmole/mg tissue (p<0.0005), respectively. Because the cAMP generated by the action of DA has been demonstrated to modulate slow synaptic potentials in rabbit post-ganglionic neurons, our data suggest that local tissue PO_2 can influence impulse traffic through sympathetic ganglia. Supported by USPHS Grants NS12636 and NS07938,

363.4

EFFECTS OF HYPOXIA ON TYROSINE HYDROXYLASE AND CYCLIC GMP IMMUNOREACTIVITY IN SIF CELLS OF THE RAT SUPERIOR CERVICAL GANGLION. L.J. Stensaas, Z.-Z. Wang, B. Dinger and S.J.

Fidone. Dept. Physiology, Univ. Utah Sch. of Med., Salt Lake City, UT 84108
Previous neurochemical studies in our laboratory demonstrated that hypoxic stimulation of superior cervical ganglia (SCG) in vivo or in vitro reduced the content of substance P, increased the release of catecholamines, and triggered the induction of tyrosine hydroxylase (TH) activity. Parallel studies with the arterial chemosensitive tissue of the carotid body (CB) revealed similar changes which suggested that the SCG may, therefore, contain intrinsic chemosensory mechanisms. The present immunocytochemical study attempted to localize hypoxia-induced changes to specific cellular elements of the rat SCG.

SCGs and CBs were removed from rats either immediately, or 48 hr following a 3 hr exposure to a hypoxic gas mixture (10% O_2 and 90% N_2). TH immunoreactivity in frozen sections stained with the avidin-biotin peroxidase method was found in ganglion cells and in small intensely fluorescent (SIF) cells. Forty-eight hours after hypoxia, the number and intensity of stained SCG SIF cells and chemosensitive CB glomus cells was increased. A less remarkable effect was apparent immediately following hypoxia. For in vitro studies of cGMP, rat SCG and CB were incubated in Locke's solution equilibrated with either 100% O2 or 10% O2 for 10 min and then fixed. cGMP immunoreactivity was found in SIF cells and glomus cells exposed to 100% O2 media, but was visibly reduced following hypoxic exposure; postganglionic sympathetic neuron TH and cGMP levels were not altered by hypoxia. The findings that a similar TH and cGMP response to hypoxia occurred both in SIF cells and in glomus cells suggest the possible involvement of SIF cells as chemosensory elements in

Supported by USPHS Grants NS12636 and NS07938.

GHEMOSENSORY RESPONSES OF NODOSE GANGLION NEURONS CO-CULTURED WITH CAROTID BODY CELLS. J. Alcayaga and C. Eyzaguirre. Dept. Physiol., Univ. Utah., Sch. Med., Salt Lake City, UT 84108. Nodose ganglion (NG) neurons and carotid body (CB) cells, enzymatically dissociated and plated on Plys- or FN-coated dishes, were cultured with Ham's F-12 supplemented with 10% FBS, 10% HS, 20mM HEPES and NGF (15 ng/ml). NG neurons, cultured either alone or with CB cells for up to 78 days were recorded intracellularly during superfusion with Earle's solution equilibrated with 95% O₂ and 5% CO₂ (pH 7.35-7.47). Acid solutions, added to the bath or pressure-ejected near the neurons, were used as "natural" chemoreceptor stimuli. NG neurons had similar passive and active properties in both cultures, but co-cultured neurons had smaller and shorter after-hyperpolarizations. Neuronal spontaneous activity was higher in co-cultures (16%) than in pure nodose cultures (73%). Acid applied to pure nodose cultures produced small changes in membrane potential and blocked the spikes evoked by supra-threshold pulses; increased pulse strength restored the response. Similar results were found in 80% of co-cultured neurons, but the rest showed clear acid-related responses. Acid added to the bath induced slow depolarizations up to 45 mV, that returned to the baseline within 3 min with no associated action potentials. Pressure-ejected acid elicited rapid depolarizations, up to 25 mV, increased discharge frequency with either small changes in membrane potential, or a combined response. Depolarizations resembled synaptic potentials, suggesting synapses (morphologically confirmed) near the recordings. Thus, nodose neurons acquire or resume chemosensory properties in the presence of glomus cells probably mediated by synaptic interactions. Supported by grants NS 05666 and NS 07938.

OF SENSORY NEURONS BY HISTAMINE ACTIVATION SEROTONIN AND ATP INCREASES INTRACELLULAR CALCIUM CONCENTRATION. J.F. Fiekers, S.B. Bevan, J.C. Yeats and H.P. Rang. Dept. of Anat. and Neurobiol., Univ. of Vermont Coll. Med., Burlington, VT and The Sandoz Inst. Med. Res., 5 Gower Place, London, England.

The mechanisms of nociceptor activation and sensitization are believed to originate from receptor activation by endogenous mediators. Calcium ions and intracellular mediators have been implicated in this response. The present study examined the action of histamine (H) serotonin (S) and ATP on fura-2-loaded adult DRG neurons. Calcium measurements were obtained by analyzing the ratio of the fura-2 fluorescence. H (10uM), S (1-10 uM) and ATP (1uM) each caused a marked rise in calcium levels which reached a peak and decayed exponentially to the resting level. When examined in the same neuron responses were obtained to both H and S. Increases in calcium were also obtained in the absence of external calcium. When tested, neurons responding to H and S were responsive to capsaicin. These results demonstrate that increases in intracellular calcium may be involved in the activation and/or sensitization of sensory neurons. Supported by IBRO/UNESCO and NIH (NS27319) grants to JFF.

PRESENCE OF D-1 RECEPTORS IN THE RABBIT CAROTID BODY. C. Gonzalez, M.T. Pérez-Garcia* and L. Almaraz*. Dept.Fisiol.Fac.Med.Valladolid,(Spain). and L.

The carotid body (CB) contains dopamine (DA) that is released in a Ca⁺⁺-dependent manner during natural stimulation. Exogenously applied DA behaves as an inhibitory, an excitatory or a neutral agent depending on the experimental conditions. These observations may reflect a preferential action of DA on different sets of conditions. These observations may reflect a preferential action of DA on different sets of receptors. Only D-2 receptors, located in the sensory nerve endings and in the chemoreceptor cells, have been recognized in the C.B.

cells, have been recognized in the C.B.

Working with an in vitro preparation of rabbit CB we found that: 1) DA (10 to 10 M) increases C.B. cAMP levels in a dose-dependent manner; 2) + -sulpiride and haloperidol (10 M) reduced to 50% the cAMP accumulation induced by 10 MD; 3) the specific D-1 blocker SCH-23390 (10 M), inhibited completely the effect of DA, 4) SKF-38393, a D-1 agonists, increases also cAMP and its effect is fully blocked by SCH-23390, and; 5) SCH-23390 does not modify the ongoing release of DA. These findings suggest that, in addition to the well recognized D-2 receptors, the CB contains D-1 receptors that do not appear to be contains D-1 receptors that do not appear to be located in chemoreceptor cells. PHYSIOLOGICAL STUDIES ON CULTURED RAT SENSORY NEURONS FROM THE PETROSAL AND JUGULAR GANGLIA. A. Stea and C.A. Nurse. Department of Biology, McMaster University, Hamilton, Ontario L8S 4K1.

As part of our investigations on chemosensory mechanisms in the rat carotid body we are interested in the physiological properties of the chemoreceptor neurons in the petrosal ganglion which supplies the afferent innervation to the carotid body. Whole-cell recordings from dissociated cell cultures of the petrosal and (juxtaposed) jugular ganglia from 6-9 day old pups revealed distinct populations of neurons. depolarizing voltage steps all neurons produced a transient inward current followed by a prolonged outward current that often contained an inactivating (presumably $I_{A)}$ component. At least 3 types of inward currents, Na) Component. At least 3 types of limited cutrents, present in variable proportions, were recorded from 30 cells: a TTX-sensitive Na⁺ current; a TTX-insensitive Na⁺ current; and a Co²⁺-sensitive Ca²⁺ current. The mean input resistance was 492 ± 243 Mohms (n = 30). Under current clamp, a few neurons showed multiple spiking whereas the majority responded with only a single or at most a few spikes with depolarizing currents. The fact that several of these neurons survive in long-term co-culture (>40 days) with chemosensory glomus cells of the carotid body provides the opportunity for studying chemosensory mechanisms in vitro. Supported by NIH #1 R01 HL 43412-01.

CHARACTERIZATION OF A Ca PUMP FROM PARAMECIUM: PUTATIVE COMPONENT OF CHEMOSENSORY TRANSDUCTION. J.L. Van Houten,

M. V. Wright*, and N. Elvess*, Dept. of Zoology, University of Versont, Burlington, VT, USA 05405

Previously, we presented evidence that implicated a calcium ATPase pump in the hyperpolarizing 0.2 nA current that is an integral part of Paramecium chemoresponse (Wright et al., Chem. Senses 14 762-3, 1989). Here we report a surface associated Ca^{2*}-ATPase activity and a report a surface associated Ca^{2+} -ATPase activity and a corresponding phosphoprotein intermediate characteristic of a pump. The activity requires 3 mM Mg for optimal Ca^{2+} stimulation ($K_{Ca}=$ 90 nM) and is specific for ATP as substrate ($K_{m}=75$ uM). Vanadate and calmidazolium inhibit Ca^{2+} stimulated activity with EC50s of "2 uM and 0.5 uM respectively. 10 uM trifluoperazine or 2 uM selittin inhibit "80% of activity, but bovine calmodulin fails to stimulate. The Ca^{2+} -ATPase is not inhibited by Na Azide (10 mM), oligomycin (10 ug/m1) or ouabain (0.2 mM). [δ -32]-ATP specifically labels a 133 kDa protein from the surface membranes in a Ca^{2+} dependent, hydroxylamine sensitive manner, and the level of phosphorylation is increased by 100 uM La^{3+} . Similar phosphorylation of an endoplasmic reticulum enriched fraction results in labeling increased by 100 un La². Similar phosphorylation of an endoplasmic reticulum enriched fraction results in labeling a protein of lower molecular mass, unaffectd by La³⁺. Ca²⁺ uptake by the alveolar sacs, integral components of the surface membrane complex, is poorly coupled to Ca²⁺ stimulated ATP hydrolysis and is much less sensitive to vanadate inhibition (EC₅₀ ~20 uM) compared to the total Ca²⁺-ATPase activity. Supported by NSF, Whitehall, VRCC.

CHRMICAL SRNSRS: PRRIPHRRAL MRCHANISMS III

DETERMINATION OF CELL TYPE IN ACUTELY ISOLATED TASTE CELLS USING QUINACRINE FLUORESCENCE. R.J. Delay. C.J. Ruiz. S.C. Kinnamon. & S.D. Roper, Dept. of Anatomy and Neurobiology, Colorado State University, Ft. Collins, CO 80523 and Rocky Mountain Taste & Smell Center, Denver, CO 80262.

Studies indicate that Necturus taste buds contain four different cell types:basal (stem), dark, light and Merkel-like cells. Using the patch-clamp recording technique, we have shown that cells isolated from Necturus have a variety of voltage-dependent currents and show differential responses to chemical stimuli. In order to correlate physiology with taste cell type, we have developed a fluorescent technique to distinguish taste cell type in the light microscope prior to recording. Stripped lingual epithelium was soaked in 5 X 10-6 M quinacrine for 15 min and washed for 20 min prior to our standard cell dissociation procedure (Chem. Senses 13: 355-66, 1988). Isolated cells were plated onto Cell Tak-coated plastic petri dishes and observed for fluorescence. Two types of staining were observed. Most elongated receptor cells and a subpopulation of small round basal cells showed bright, punctate fluorescence in the cytoplasm. In contrast, a small number of receptor cells and basal cells showed little or no cytoplasmic fluorescence. Following fixation and examination in the electron microscope, we have correlated the presence of punctate fluorescence with membrane-bound granules characteristic of dark cells and membrane-bound vesicles of Merkel-like cells. Elongated receptor cells lacking fluorescence were found to be light cells, and the non-fluorescent small round cells were found to be an undifferentiated cell type, presumably the basal (stem) cell. Preliminary whole-cell patch-clamp recordings show no deleterious effects of the quinacrine fluorescence with short exposures to fluorescence illumination. This technique should prove useful for correlation of structure and function in isolated taste cells. (Supported by N.I.H. grants DC00378, DC00244, & AG06557).

CHEMICAL SENSITIVITY IN TASTE CELLS OF NECTURUS MACULOSUS IS VOLTAGE-GATED. A. B. Bigiani* and S. D. Roper. Dept. of Anatomy and Neurobiology, Colorado State University, Ft. Collins, CO 80523 and Rocky Mountain Taste & Smell Center, Denver, CO 80262.

Studies have shown that Necturus respond to a wide variety of chemical stimuli other than sweet compounds as glucose (Chem. Senses 10: 341, 1985). To investigate transduction mechanisms, we impaled taste cells in thin slices (200 μ) of lingual epithelium and recorded responses elicited by brief pulses of focally applied solutions of KCI (100 mM), citric acid (400 mM), CaCl₂ (200 mM) and glucose (400 mM). These chemicals were delivered to the pore of the taste bud from multi-barrelled micropipettes (overall tip dia., 15-20 µ). Only taste cells with stable resting potentials (-40 to -70 mV) and that responded with action potentials to brief depolarizing current pulses (Science 220: 1311, 1983) were studied. At resting membrane potentials, KCI, CaCI2, and citric acid elicited depolarizing responses that could trigger action potentials in taste cells. These responses did not desensitize with repeated application of the stimulus if a sufficient interval elapsed between chemostimuli. The amplitude of these responses proved to be highly voltage-dependent. The more negative was the membrane potential, the <u>smaller</u> were the receptor potentials. Hyper-polarization below -100 mV abolished receptor potentials. In contrast, glucose did not evoke responses at any membrane potential. A single taste cell typically responded to all chemostimuli (other than glucose). These data indicate that the first step of the chemosensory transduction pathway for KCI, CaCI2 and citric acid perception is a depolarizing response in taste cells. The marked voltagesensitivity of chemoresponses is consistent with the interpretation that voltage-gated ion channels, especially voltage-gated K channels, play an integral role in taste transduction. (Supported by N.I.H. grants DC00374, PO NS20486 & AG06557).

LOCALIZATION OF RECEPTORS FOR EPIDERMAL GROWTH FACTOR (EGF) IN TASTE BUDS OF NEONATAL RATS: EFFECTS OF SODIUM RESTRICTION DURING DEVELOPMENT. R.E. Stewart and D.L. Hill. Departments of Psychology and Neuroscience, Univ. of VA, Charlottesville, VA 22903.

Epidermal growth factor is an important regulator of growth and differentiation in most epithelia. In several tissues, initial biological activity of EGF is noted post-partum, initial receptor expression and ligand availability. Because the majority of taste bud and taste response development occurs postnatally in rats, we sought to establish taste cells as a target for EGF. In addition, we hypothesized that alterations in the expression EGF receptors in Na *-restricted rats might be correlated with altered peripheral taste function. Frozen sections of tongue from control and Na *-restricted rats were incubated with EGF-biotin and then with either streptavidin-Texas Red or extravidin-peroxidase for visualization. Analysis of labeled sections revealed the presence of apparently specific EGF binding sites in lingual epithelium and in taste buds. In 2 day old rats of either group, binding of EGF-biotin was rarely detected in taste buds. In contrast, the percentage of taste buds showing EGF-biotin binding was markedly increased in both groups at 6 days of age. Ten day old rats showed profiles of EGF-biotin binding similar to those observed in tongue from 45 day old rats. This time course parallels the appearance of amiloride-sensitive taste responses in rat. At no age examined were any group differences in the percentage of taste buds showing EGF-biotin binding noted. We conclude that EGF could be involved in postnatal taste development, and that differences in the time of EGF receptor expression cannot account for altered deripheral sodium taste function in Na *-restricted rats. We are currently assessing receptor kinetics and tissue responsiveness to EGF in normal and Na *-restricted rats. Supported by NIH grants DC00025, DC00407 and HD07323.

ODOR AND VOLTAGE-DEPENDENT CURRENTS IN CULTURED LOBSTER OLFACTORY NEURONS. D.A. Fadool W.C. Michel and B.W. Ache. Whitney Laboratory and Depts. of Zoology and Neuroscience, University of Florida, St. Augustine, FL 32086.

Previously, both excitatory and inhibitory conductances have been identified in the olfactory receptor cells of the Caribbean spiny lobster, Panulinus argus. To facilitate voltage clamping and to provide access to the long and thin dendritic processes for single channel recordings of odor activated currents, the olfactory organ cells were placed in sustained primary culture. Following L-cysteine-activated papain treatment (0.25 mg/ml; 50 min) and mechanical disruption, individual cells were plated on poly-D-lysine coated coverslips in L15 media supplemented with salts, serum, and nutrient factors. Neurons rapidly expressed processes and were viable for 3-4 weeks. Four neuronal cell types, with an average soma diameter of 7 to 12 microns, were defined by their number of processes: (1) no visible processes, (2) unipolar with thin process over 30 μ in length, (3) bipolar, and (4) multipolar. The current-voltage relationships of cell types 1-3 were identical to those of cells recorded in situ. Both the average maximum outward and inward current of multiprocess cells were only ca. 1/3 the amplitude of the other cell types. In whole cell voltage clamp experiments (day 3 - day 10), application of various odors resulted in the generation of rapid (latency < 20msec) inward or outward current with a percentage of all neuronal cell types responding to the applied odorant: TetraMarin fish food extract (100% responded, avg pA; 38.7 inward/22.0 outward), and proline (88% responded, avg pA; 35.2 inward/ 16.2 outward). These results indicate that cultured lobster olfactory receptor neurons retain their voltage dependent conductances and express odor-activated conductances identical to those seen in situ. Supported by ONR N00014-90-J-1566 and NSF 88-10261.

THE ELECTROTONIC STRUCTURE OF LOBSTER OLFACTORY RECEPTOR CELLS: A COMPARTMENTAL MODEL. F.Pongrace. T.S. McClintock. B.W. Ache and G.M. Shepherd. Sec. Neuroanatomy and Sec. Molecular Neurobiology, Yale Univ. Sch. Med., New Haven, CT 06510 and Whitney Lab., Univ. Florida, St. Augustine, FL 32086.

The electrotonic structure of lobster olfactory (antennular) receptor cells was evaluated in a compartmental model derived from EM reconstruction (Cell Tiss Res, 251.95, 1968) using SABER simulation software. Values for R_N (1.6 $G\Omega$) and

Res. 25:193, 1999, Using 3-12ER similariant soluware. Vain T_m (100 msec), but not T₁ (11 msec), determined from whole-cell recordings, could be represented in models with a uniform R_m only by assuming C_m ≥ 1.5 μF/cm². Selectively increasing R_m in the outer dendritic (ods) compartments, however, had little influence on R_N while markedly decreasing the electrotonic length (L). In vivo determinations were best represented with R_m in the ods compartments between 120-150K ohm.cm² and R_m in the inner dendritic (ids), soma and axon compartments between 40-50K ohm.cm², holding C_m = 1μF/cm². The total value for L was 1.5. Calculations of current spread in the model cell indicate that 1.6 nS total input (e.g., 160-10 pS channels) applied equally to all ods compartments depolarizes the soma compartment 32 mV, a value consistent with whole-cell odor evoked depolarizations (J. Neurophysiol, 61:994, 1989). The model suggests that receptor potentials arising in the ods could passively invade a solike generator in the initial segment, in spite of the

Neurophysiol, 61:394, 1989). The model suggests that receptor potentials arising in the ods could passively invade a spike generator in the initial segment, in spite of the extreme ods-soma distance (1 mm) of these cells. Supported by awards from the ONR (to BWA and GMS) and the NIH (to TSM).

364.4

TASTE AVERSION TO INTENSE NATURAL SWEETENERS BY THE GERBIL. W. Jakinovich Jr. and E. Vasquez*, Dept. of Biological Sciences, Herbert H. Lehman College and the Graduate School, City University of New York, Bronx, NY 10468; N.P.D. Nanayakkara*, R.A. Hussain*, and A. Douglas Kinghorn*, Program for Collaborative Research in the Pharmaceutical Sciences, College of Pharmacy, University of Illinois at Chicago, Chicago, IL 60612.

Last year (Neurosci Abs #302.9, 1989), we reported

Last year (Neurosci Abs #302.9, 1989), we reported that the INTENSE NATURAL SWEETENERS stimulated the gerbil's chorda tympani nerve. Since that time, we have conducted conditioned taste aversion studies to determine how the gerbil responds behaviorally to these compounds, such as hernandulcin (Hern), mogroside V (Mogro), periandrin III (Peri), rebaudioside A (Reb-A), and stevioside (Stev). It was observed that gerbils trained to avoid these compounds generalized an avoidance to sucrose but not to HCl. Also, animals trained to avoid Hern, Mogro, Peri, and Reb-A generalized an avoidance to quinine HCl. In addition, animals trained to avoid Hern, Peri, and Reb-A generalized an avoidance to the salty and bitter tastes, these results indicate that the INTENSE NATURAL SWEETENERS taste like sucrose to the gerbil as they do in the human. (Supported by grants RO3-DE-07560-01 of NIDRS,NIH, RO1-NS2538-01 of NINCDS,NIH and SO6 RRO8225 of MBRS/NIH).

OLFACTORY RECEPTOR CELL OUTPUT IS SHAPED BY SUMMATION OF OPPOSING, ODOR-ACTIVATED CONDUCTANCES. W.C. Michel and B.W. Ache. Whitney Lab. & Depts. Zool. & Neurosci., Univ. Florida, St. Augustine, FL 32086.

Whole cell current clamp recording from lobster olfactory receptor cells shows that odors activate excitatory sodium, calcium or non-selective cation conductances, as well as an inhibitory potassium conductance. Excitatory and inhibitory conductances occur on the same receptor cell. To determine if opposing conductances shape the output of the cell, we examined the effect of increasing concentrations of inhibitory odorants on the magnitude, rate, and duration of excitation. Inhibitory odorants attenuated the magnitude of odor-evoked depolarizations in a dose dependent manner with a threshold below 1 µM. Inhibitory odorants slowed the rate of depolarization, which delayed the peak of the response as long as 1000 ms (average ca. 100 ms). Inhibitory odorants truncated odor-evoked depolarization; cells with opposing conductances depolarized in a characteristic phasic/tonic manner, which changed to a strictly tonic response in the absence of inhibitory odorants. Corresponding effects were observed in extracellular recordings. Olfactory receptor cells in the lobster, at least, are not just selectivity filters but must be viewed as the first level of olfactory integration. This research was supported by awards from the ONR and the NSF.

SPATIAL INFORMATION CONTAINED IN THE THREE-DIMENSIONAL FINE STRUCTURE OF AN AQUATIC ODOR PLUME. Paul A. Moore, Nat Scholz Jelle Atema, and Greg A. Gerbardt (B.U.M.P., Marine Biological Laboratory, Woods Hole, MA 02543 Departments of Psychiatry and Pharmacology, University of Colorado Health Science Center, Denver CO 80262)

Odor plumes serve as sources of information for many animals during chemically mediated orientation. However, the information contained within the odor plume is poorly understood due to inadequate stimulus detection techniques. Using high speed electrochemical recording techniques, we have quantified the three dimensional structure of an aquatic odor plume within a laboratory flume. The plume was created in a uni-directional seawater flume (90 x 250 x 20 cm). Odor profiles were recorded for three minutes at 10 Hz from 63 different sample sites. Analysis showed that spatial gradients of odor pulse parameters point to the source. Specifically, the pulse height and slope values increase towards the source. We conclude that the type of information available to the orienting animal depends upon the chemoreceptor filter properties.

MEMBRANE PROPERTIES OF FROG OLFACTORY RECEPTOR NEURONS S. Kleene⁴, R. Pun, & R. Gesteland, Anatomy & Cell Biology, Univ. of Cincinnati Medical Center, OH 45267.

S. Kleene*, R. Pun, & R. Gesteland, Anatomy & Cell Biology, Univ. of Cincinnati Medical Center, OH 45267.

In isolated frog olfactory receptor neurons it is difficult to elicit an action potential except after hyperpolarizing the cell. We are studying the cellular mechanisms underlying this lack of excitability. With whole-cell recording under voltage clamp, the threshold for eliciting a fast inward current is about -40 mV. The current peaks near -20 mV. The voltage for half-inactivation is -81.8 ± 3.4 mV (range -72 to -98 mV; n = 8). This is about 30 mV more negative than the resting membrane potential. The voltage dependence of decay for the fast inward current was studied using Cs* and TEA* in the recording pipette to block outward currents. Under these conditions, a slower inward current occasionally follows the fast inward current. The threshold for the slow current is about -20 mV; it peaks near 0 mV. This current runs down, disappearing about 10 min after establishing whole-cell recording. The fast inward current is unaffected by rundown. The decay of the fast inward current has a time constant of 1.63 ± 0.19 mscc at -20 mV and 1.10 ± 0.14 mscc at 0 mV (n =5). The fast inward current is mediated by voltage-dependent Na* channels.

Currents of single cilia in isolated neurons are measured by drawing one of the cilia into a pipette and forming a seal near the base of the cilium. All experiments are done under voltage clamp. At rest, few cells produce spontaneous action potentials, but injecting current through the cilium often elicits spikes. About 15% of the cells respond to an odorant mixture. The pipette containing the cilium can be excised from the cell and immersed in a pseudointracellular solution. Addition of 10 μM cAMP to the bath causes a large increase in the ciliary membrane conductance, indicating that the cytoplasmic face of the membrane is exposed to the bath. This conductance increase is reversible. Adding Ca** to the bath increases the ciliary conductance and inhibits the response to AMP.

364.11

PERIPHERAL OLFACTORY GLIA IN DISSOCIATED CELL CULTURE ARE IMMUNOPOSITIVE FOR S100, GFA, 217C AND NSE. S.K. Pixley. Dept. Anat. & Cell Biol., Univ. of Cincinnati
Coll. Med., Cincinnati, OH 45267.

Peripheral olfactory glial cells ensheath olfactory receptor neuron (ORN) axons between the olfactory epithelium and the olfactory bulb, and they may participate in regeneration of ORN axons. We confirm glial immunostaining for S100, a Schwann cell-specific protein, and glial fibrillary acidic protein (GFA) in adult Spraque-Dawley rat masal tissue sections. We further report that, in dissociated cell cultures of newborn rat nasal tissues, glial cells were immuno-positive for S100 or GFA. They were also immunostained by the monoclonal antibody 217C, which binds to NGF receptors (Kumar and de Vellis, <u>Neurochem. Abs.</u>, p.158, 1990). Glial cells in serum-free medium, compared to those in serum-containing medium, were more frequently bipolar, had longer and thinner processes and more often had beaded processes. Immunostaining with an antiserum specific for neuron-specific-enolase (NSE) showed some staining of cultured olfactory Schwann cells although cultured ORNs were more densely stained. Cultures of olfactory glia will be useful in studying ORN and glial cell physiology. This study also illustrates some problems in ORN identification in culture. {Supported by Amer. Paralysis Assoc. Grant PB1-8803-1}.

364.13

ISOLATION AND MOLECULAR CLONING OF A TISSUE SPECIFIC MEMBRANE PROTEIN WHICH IS A MAJOR COMPONENT OF OLFACTORY DENDRITES AND WHICH POSSESSES ODORANT BINDING PROPERTIES.

R.G. Vogt and M.R. Lerner*. Molecular Neurobiology, Yale Univ. Sch. of
Med., P.O. Box 3333, 333 Cedar Street, New Haven, CT 06512.

Odorant detection is thought to be mediated through receptor proteins associating with the membrane of olfactory cilia/dendrites, though the isolation of such proteins has been elusive. A 69 kDa protein of the silk moth *Antheraea polyphemus* was previously implicated as an olfactory receptor protein: it was a component of the olfactory dendrite membrane; it could be labeled with a photoaffinity analog of a sex-pheromone odorant, and labeling could be blocked by sex-pheromone; it was specific to offactory tissue (Vogt, R.G. et. al., <u>J. Biol. Chem.</u>, 263:3952, 1988). *In vivo* labeling with ³⁵S-methionine has subsequently shown that a 69 kDa protein is a major component of olfactory dendrite membranes in two moth species, that it is absent from other neuronal tissue, and that it is developmentally expressed at a time coincident with other olfactory proteins. We isolated olfactory dendrite membranes from 800 male A. polyphemus antennae, and electrophoreticly purified the 69 kDa protein in sufficient quantity to obtain a partial N-terminal amino acid sequence. We designed PCR primers to the N-terminus, and synthesized, purified, cloned and sequenced a 90 base PCR product corresponding to this region. We then synthesized a 65 base oligonucleotide which was used as a probe for Northern blot analysis of mRNA. Specificity to olfactory tissue was confirmed by both PCR and Northern blot analysis. We then successfully used this probe to screen oligo-dT and random primed cDNA libraries generated against antennal mRNA. The properties of the 69 kDa protein will be presented, with respect to tissue distribution and deduced amino acid sequence.

ANTIBODY IDENTIFICATION OF CELL TYPES IN THE AMPHIBIAN OLFACTORY EPITHELIUM: DIFFERENCES ACROSS SPECIES. M.J. Crowe and S.K. Pixley. Dept. of Anatomy & Cell Biology Univ. of Cincinnati, Cincinnati, OH 45267.

To facilitate studies of the amphibian olfactory epithelium (CE), in particular the electrophysiological proper-

ties of olfactory receptor neurons (ORNs). it would be useful to have cell-type-specific antibody markers. However, immunostaining specificity differs drastically across amphibian species. We report here on immunostaining with a monoclonal antibody (Mab) directed against carnosine synthetase (CS) (from Dr. F. Margolis) and a novel Mab (1D9) developed by M. Crowe. Staining was done on cryostat sections of paraformaldehyde-fixed OE from bullfrog (Rana catesbiana), grass frog (Rana pipiens) and salamander (Ambystoma tigrinum). Anti-CS labelled ORNs in bullfrog and grass frog OE, but showed no specific staining in salamander OE. This distribution of synthetic enzyme follows the biochemical localization of carnosine in OE from these species as determined by Dr. F. Margolis. Mab lD9, in frog tissues, appears to label all cells in the OE, nerve bundles and Bowman's glands, but did not stain other lamina propria cells. In contrast, in the salamander, Mab 1D9 identified a subset of basally located epithelial cells resembling ORNs. These data show the usefulness of these antibodies and support a concept of biochemical differences between species

2-MERCAPTOETHANOL PROMOTES THE SURVIVAL OF RETROGRADELY LABELLED OLFACTORY RECEPTOR NEURONS IN VITRO. R. Grill and S. K. Pixley. Dept. of Anat. and Cell Biol., Univ. of Cincinnati, Cincinnati, OH 45267.

A primary culture system of olfactory receptor neurons (ORNs) has been developed in which ORNs were characterized by immunocytochemistry and the whole cell 'tight-seal' recording technique (Pixley, S.K. and Pun, R., <u>Dev. Brain Res</u>., 53:125, 1990). Cultured ORNs responded to odors. Here we describe further identification of ORNs and a culture medium which enhances survival of ORNs. Rhodamine-labelled lates microspheres were injected into newborn Sprague Dawley rat olfactory bulbs. Two days were allowed for retrograde transport of microspheres to the ORNs, which the nasal tissues were taken for culture. ORNs containing microspheres were seen in culture and were electrically active. The culture medium which supported survival of these ORNs varied from other neuronal growth media in that it contained 2-mercaptoethanol (2ME). We have determined that 2ME is a significant survival enhancing factor for cultured ORNs. These ORN cultures should prove useful for studies of neuronal regeneration and the mechanisms of olfactory transduction. (Supported by American Paralysis Association Grant # PBI-8803-1).

364.14

IRREVERSIBLE RADIOLABELING OF SCHIFF BASE-FORMING MEMBRANE PROTEINS IN THE OLFACTORY EPITHELIUM OF TIGER SALAMANDERS(Ambystoma tigrinum). L.E. Grishow.* M.G. Kelcher.* and T. H. Morton. University of California, Riverside, CA 92521.

Specific odor blindness results from irreversible covalent modification of the olfactory epithelium. Replication of this procedure in vivo with tritiated ligand shows significant incorporation of nondialyzable radiolabel. Lavage of salamander olfactory sacs with [1,2-³H]-ethyl acetoacetate followed by NaBH₃CN yields greater (p<0.0002) incorporation of radioactivity versus a control without NaBH $_3$ CN. In vitro labeling of isolated membrane fractions and in vivo labeling of intact tissue are both specific for olfactory epithelium, as compared to buccal epithelium, brain, and tongue membranes, which show no significant radioactivity in the experimental (w/NaBH₃CN) versus control (w/oNaBH₃CN) fractions (p>0.15). Partial purification of detergent-solubilized membrane protein yields a fraction that can still be irreversibly labeled.

Monitoring of an authentic sample of the modified lysine unit (CEIP-Lys) by NMR shows that hydrolysis of the ethyl ester is pHdependent and can be fit to the rate expression k=kok1[OH-]/ $(k_0+k_1[OH^-])$, where $k_0=.005min^{-1}$ and $k_1=10^3M^{-1}$ min⁻¹. Modified protein appears to lose radiolabel by hydrolysis when denatured, but has greater stability when undenatured

AUTOLOGOUS OLFACTORY EPITHELIAL TRANSPLANTS IN MICE: A SYSTEM FOR EXAMINING EFFECTS OF LOCAL FACTORS ON THE PROCESS OF NEURON RENEWAL. M.A. Schwartz, C.B. Heilman and J.S. Kauer. Neurosci. Program, Tufts/NEMC, Boston, MA 02111.

Little is known about the regulation of olfactory neuron renewal which occurs by differentiation of the epithelial basal cells. To determine whether local, diffusible factors are involved, autologous olfactory epithelial transplants were made into contralateral mucosae of C57BL/6J mice. Transplants consisted of epithelium taken 4 days after unilateral bulbectomy (4-Bx), unoperated control epithelium (0-Bx), and frontalis muscle (M). Transplants were placed between the cartilaginous septum and lamina propria on the undisturbed side and examined at 4 and 11 days. BrDU labelling (BrDU-I), using injections 1 hour prior to sacrifice, was used to examine cell proliferation. In the 4-Bx condition, there was no change in BrDU-1 in the recipient epithelium, but the transplant showed the normal heavy BrDU-1 of bulbectomized tissue, suggesting continued ability to proliferate. condition, there was increased BrDU-l in the recipient epithelium and normal BrDU-1 was seen in the transplant. These data suggest that the 0-Bx transplant may have proliferative signals not present in the 4-Bx condition. Sham operations and M transplants indicated these effects were not due to surgical trauma. Examination for the expression of cytokeratin (CK) showed both 4-Bx and 0-Bx transplants and recipient epithelia were CK+, indicating the persistence of horizontal basal cell populations. In the 4-Bx transplant, GAP43+ fibers were seen penetrating into the recipient epithelium, with no change in GAP43 staining in the 0-Bx condition. recipient epithetium, with no change in GAP43 stating in the 0-50 condition. Taken together, these findings suggest that different local signals may expressed during the degeneration-regeneration process observed in the olfactory system.

SOMATIC AND VISCERAL AFFERENTS III

365.1

DISTRIBUTION AND ULTRASTRUCTURE OF SPLANCHNIC VISCERAL AFFERENTS AND EFFERENTS IN THE RAT THORACIC SPINAL CORD S. E. Kapadia . C. M. Kocol. and C. C. LaMotte. Section of Neurol. Surgery, Yale Univ. Sch. of Med., New Haven, CT. 06510. The greater splanchnic nerve of rats anesthetized with 40mg/kg

pentobarbitol was injected with a combination of 0.5 mg of WGA-HRP and .05 mg bCT-HRP. Spinal sections from T4-T11 were cut on a vibratome and reacted using a TMB method for LM and an AHM (ammonium heptamolybdate) method for EM; EM sections were also stabilized with DAB. Visceral afferents (VA's) were found in a distinct bundle in Lissauer's tract, and terminals were located in lamina I, where they occupied distinct, superficial outcroppings of the medial and lateral margin of the dorsal horn. VA's also terminated in lamina X dorsal to the central canal or adjacent to the ependyma, and ocassionally in the contralateral lamina X or intermediate grey. Terminals in lamina I were of several types: intermediate grey. I erminals in lamina I were of several types:

1) dark, sinuous glomerular terminals, with both large dense core
vesicles and large clear vesicles, which contacted many dendrites; 2) simple terminals with clear and dense core vesicles; and 3) simple terminals with mainly clear round vesicles. The last two types were also found in lamina X. Labelled preganglionic splanchnic motoneurons were seen in the intermediolateral (IML) and intercalatus (IC) nuclei. Often their dendrites extended to lamina X; these dendrites received few synapses before reaching lamina X, where they became finely branched and were contacted by many terminals. (NIH grant NS13335)

365.3

EFFECTS OF URINARY BLADDER DISTENSION (UBD) AND SOMATIC INPUT ON VENTROPOSTEROLATERAL (VPL) THA-LAMIC CELLS IN PRIMATES. M.J. Chandler, S.F. Hobbs, Q.-G. Fu*, D.R. Kenshalo, Jr., R.W. Blair, R.D. Foreman. Univ. of Okla. Hlth. Sci. Ctr., Okla. City, OK 73190. NIH-NIDR, Bethesda, MD 20892.

Urinary bladder distension (UBD) increases activity of some lumbosacral spinothalamic tract (STT) neurons antidromically activated from the VPL nucleus of the thalamus (Milne et al., 1981). These same cells receive convergent excitatory somatic input from lower-body regions. The purpose of this study was to determine effects of visceral input from UBD on activity of neurons located in VPL thalamus. We hypothesized that UBD would excite VPL neurons that were excited by stimulation of skin and muscle of the lower body. Extracellular action potentials of 27 cells were recorded from the right VPL thalamus in 11 monkeys (Macaca fascicularis) anesthetized with alpha-chloralose. UBD excited 9 VPL cells, inhibited 4 cells and did not affect activity of 14 cells. Eight of 9 VPL cells excited by UBD also were excited by stimulation of lower-body somatic fields. Five VPL neurons were activated antidromically from the SI cortex. Activity of 3 of these cells was affected by visceral input from UBD. These results showed that (1) stimulation of visceral afferent input by UBD affected activity of neurons located in VPL thalamus, (2) VPL cells affected by UBD also were excited by input from skin and muscle, and (3) visceral input stimulated by UBD reached the SI cortex. (Supported by NIH grant HI 22732)

INNERVATION OF THE PYLORIC REGION OF THE STOMACH IN THE BRAZILIAN OPOSSUM. J. K. Elmquist, C. A. Fox, and C. D. Jacobson. Dept. of Vet. Anatomy, Iowa State Univ., Arnes, Iowa 50011.

Vagal afferents from the pyloric region of the stomach (PRST) are thought to be involved in the regulation of food intake. In this study, we have used Dil to trace the innervation of the PRST in the Brazilian opossum, Monodelphis domestica. Dil was injected intramurally into the PRST. After 24 hours, animals were killed and perfused with 4% paraformaldahyde. Sections of the brain, stomach and nodose ganglion (NDC) were viewed with a fluorescence microscope. Dil labeled cell bodies were found in the NDC, and the motor nucleus of vagus. Other neuronal elements (fibers, and terminals) containing Dil were found in the nucleus of the solitary tract (Sol) and lateral reticular nucleus (LRt). In addition to labeling in the brainstem, Dil containing structures were located in the paraventricular (Pa) brainstem, Dil containing structures were located in the paraventricular (Pa) and ventromedial (VMH) nuclei of the hypothalamus. In order to verify specific Dil labeling in the vagal afferents to the stomach a group of animals were exposed to Dil as above. However, prior to injection of the animals were exposed to Dil as above. However, prior to injection of the dye the gastric branches of the vagus nerve were severed as they ran along the terminal part of the esophagus. Fluorescence microscopy of tissue obtained from these animals did not yield any labeled structures in the regions stated above. Consequently, these results indicate that vagal afferents from the stomach communicate with neurons in the Sol, LRt, Pa and VMH. Two possible mechanisms can explain the hypothalamic staining patterns observed: 1- There are direct neuronal projections from the stomach to the Pa and VMH of the hypothalamus. 2- The Dil can label neurons trancellularly. Further studies are underway to explain these findings. These results support the use of this animal model in studies findings. These results support the use of this animal model in studies aimed at describing the ontogeny of the neuronal circuitry involved in control of food intake. Supported by Iowa State University, NSF grant BNS 8909751 and USDA Formula Funds Section 1433.

IMMUNOCYTOCHEMICAL CHARACTERIZATION OF NEUROPEPTIDES WITHIN THE AFFERENT RENAL NERVE OF THE RAT. M. Burg*, D.S. Zahm, M.M. Knuepfer, Dept. of Pharmacol., Anat. & Neurobiol. St. Louis Univ., St. Louis, MO 63104.

We have shown that afferent renal nerves (ARN) in the rat contain only unmyelinated and small myelinated axons. Although the function of different types of ARN fibers is not clear, small calibe fibers in other nerves often mediate nociception. Nerve fibers within the renal pelvis contain substance P and calcitonin-gene-related peptide (CGRP) and are suggested to be sensory. This study was designed to determine directly whether substance P, CGRP and/or vasoactive intestinal polypeptide (VIP) exist within ARN. Fluoro-Gold was placed on the central cut end of the renal nerve 3-4 days before intrathecal application of colchicine (25 μ g at T10). 24 hours later, rats were perfused for immunocytochemical localization of substance P, CGRP and VIP in dorsal root ganglionic soma (T9-L1). Fluoro-Gold labelling was observed only in soma of the ipsilateral ganglia. Neurons were located primarily at T12 and T13, were generally small in diameter (20-40 μ m) and were not numerous (less than 10% of all neurons). Substance P, VIP or CGRP immunofluorescence was observed in a number of Fluoro-Gold labelled neurons. These results indicate ARN fibers project predominatly to ipsilateral dorsal roots at spinal levels of T12 and T13 and that specific neuropeptides are present in many of these fibers. The presence of substance P in small diameter fibers suggests the possibility that these axons mediate nociception. (Supported by HL38299 and NS23805).

NON-PAINFUL SENSATIONS EVOKED BY THERMAL STIMULATION OF TEETH IN MAN. B.Matthews, W.Kollmann*, J.E.Crapper* and A.S.Walters*. Dept. of Physiology, University of Bristol, England BS8 1TD.

Much of the available evidence indicates that pain is the only sensation which is produced in man by natural stimuli which excite nerves in teeth, although electrical stimulation close to threshold is known to produce non-painful sensations. The present experiments were carried out to investigate the sensations evoked by

thermal stimuli close to sensory threshold.

Stimuli in the range 5 to 60°C and 10s in duration were applied by switching the flow of saline from thermostatically-controlled reservoirs through a small chamber (o.d. 6mm, i.d. 4mm) which was cemented to the enamel over the centre of the labial surface of the crown of a maxillary central incisor. Saline at 30°C was used as control. The temperature in the chamber and that of the adjacent gingival margin were recorded with thermocouples. Six different stimuli were each applied twice in random order. The subjects were told that stimuli might be a change in temperature, pressure or chemical composition of the solution in the chamber. Apart from effects due to changes in tooth temperature, they had no cue as to when stimuli were applied. The subject indicated the onset and time-course of any sensation perceived with a push-button and visual-analogue scale. After each stimulus, the subjects identified the sensations from a list of descriptors.

In 10 subjects, stimuli of 5-10°C or 50-60°C evoked responses in up to 100% of applications, but no more than 50% were described as uncomfortable or painful. The other sensations were difficult to describe and most frequently attributed to cold stimuli, even when they were hot. Stimuli of 20 and 40°C were detected in up to 40% of applications and were rarely uncomfortable. Such stimuli are within the range likely to occur during eating and drinking and indicate that intradental nerves are often activated under physiological conditions. The results demonstrate that sensations other than pain may be produced by thermal stimulation of teeth.

CENTRAL REPRESENTATION OF PERIPHERAL INNERVATION TO THE IOWER EXTREMITY: TRANSGANGLIONIC HRP STUDY IN DORSAL COLUMN AND ADJACENT PRECEREBELIAR NUCLEI OF CAT AND RAT. T. Ueyama, T. Houtani*, M. Ikeda* and T. Sugimoto, Dept. of Anatomy Kansai Medical Univ., Osaka 570 Japan. Primary afferents from the skin of lower extremity were traced in the dorsal column.nuclei and in a novel precerebellar cell group of the cat and rat. HRP was applied to the central cut end of the lateral femoral cutaneous, posterior femoral cutaneous, saphenous, genitofemoral superficial peroneal, plantar, sural and pudendal nerves. In the cat, afferent fibers containing large—sized terminal knobs were densely distributed to the cell nest region of the ipsilateral gracile nucleus. Each nerve terminal was arranged in this sequence with a lateromedial direction. In the gracile reticular region such a topographic distribution could not be detected. In contrast, the middle region of rat gracile nucleus showed an overlapping, lateromedially—directed arrangement of plantar, superficial peroneal, saphenous and pudendal nerve terminals. In the cat we identified a novel cell group with HRP—labelled afferents from the lower extremity. This compact neuronal collection was located medial to the external cuneate nucleus and lateral to the descending vestibular nucleus, and was here shown to project to the cerebellar cortex. In the rat a homologous cell group, though organized by a fewer neurons, was also identified at the medial border of the external cuneate nucleus. The results suggest different primary afferent organization in feline and rodent gracile nuclei, and emphasize the presence of a medullary station to convey inputs from the lower extremity to the cerebellum.

A LIGHT MICROSCOPIC STUDY OF INNERVATION OF THE LUMBAR A LIGHT MICROSCOPIC STUDY OF INNERVATION OF THE LUMBAR FACET JOINT CAPSULE. AC Ozaktay*, T Yamashita*, JM Gavanaugh, AI King*, #loengineering Center, Wayne State University, Detroit, MI 48202.

The innervation of the facet joint capsule of the

human lumbar spine was investigated using high-power light microscopy. The description and localization of nerve fibers are presented. MATERIALS and METHODS: Four lumbar facet joint capsules were obtained from three fresh adult cadavers. Two capsules were from 1.4/1.5, one from 1.3/1.4, and one from 1.5/51. The specimens were treated by using a silver impregnation method for whole mount (Winkelman, <u>Staff Meet.</u>, <u>Mayo Clin.</u>, 32; 217-222, 1957) and 70 µm thick frozen sections were made and mounted on slides. They were examined at magnifications of 40 to 1000. RESULTS: Many nerve fibers with small diameters were found in the facet joint capsules. 76.9 % of the nerve fibers had diameters of 0.5-2 µm, 17.6 % had diameters of 2-5 μm , and 5.5 % had diameters of 5-10 µm. A majority of the fibers were found in the lateroinferior area of the capsule close to the inferior articular recess. 68.5 % of the nerve fibers were in the deeper capsular layers which consist mainly of elastic connective tissue. Also, free nerve endings and encapsulated nerve endings were seen, primarily in the elastic fiber layers of the capsules.

SEGMENTAL DISTRIBUTION AND CENTRAL PROJECTIONS OF CLITORAL AFFERENT PATHAYS OF THE CAT. M. Kawatani and W.C. de Groat. Depts. Pharmacol. and Behavioral Neuroscience,

Univ. of Pittsburgh, Pgh., PA 15261
Axonal tracing techniques were used to label the afferent pathways to the clitoris of the cat. Under halothane anesthesia 5 µl of 1%, WGA-HRP was injected into the clitoris. After 5 days for transport of tracer anesthetized animals were perfused with fixative and tissues were removed and processed for HRP using the TMB method. An average of 650 neurons were identified in the lumbosacral dorsal root ganglia (DRG) with the majority of cells in the S1-S2 DRG. The average cell size was 2280 µm2. In the spinal cord HRP reaction product was present in fibers passing through lamina I on the medial edge of the dorsal horn into the dorsal gray commissure (DGC). Very little HRP reaction product was present in Lissauer's tract or on the lateral edge of the dorsal horn. Labeled axons in medial lamina I and the DGC occurred in bundles, averaging 70 µm in width and occurring at approximately 200 µm intervals in the rostrocaudal axis. No labeled neurons were identified in the spinal cord. In conclusion, the clitoris is innervated by a large number of afferent neurons which project to a discrete region of the medial spinal cord. This central projection contrasts with that from the uterine cervix which terminates in the lateral dorsal horn.

EXPRESSION OF "CLASSICAL NEUROTRANSMITTERS" BY PRIMARY SENSORY NEURONS OF THE CHICK DORSAL ROOT GANGLIA. E. PHILIPPE. C. ZHOU*, M. GEFFARD and M. DESCHENES. Neurobiology Res. Center and Laval University, 1401, 18e Rue, Quebec - CANADA and IBCN-CNRS -Bordeaux - FRANCE.

Neurons of the dorsal root ganglia (DRG) subserve a great variety of sensory modalities and subpopulations of these cells appear to contain different neurotransmitters including neuropeptides, amino acids and catecholamines.

acids and catecholamines.

Among the amino acids which could be considered as putative neurotransmitters, gamma aminobutyric acid (GABA) was immunocytochemically detected in ganglion cell bodies belonging to 2 subclasses of sensory neurons. These 2 subclasses were related, at least in part, to the peripheral sensory innervation of the skin and the striated skeletal muscle. Moreover, by using polyclonal antibodies raised against dopamine, a small percentage of sensory neurons expressed a light immunoreactivity. These immunostained cell bodies were mainly related to a subclasse of large A sensory neurons. In contrast, after immunostaining performed with antibodies raised to serotonin, the few immunostained sensory neurons were mainly related to a subcopulation of small B neurons.

serotonin, the few immunostained sensory neurons were mainly related to a subpopulation of small B neurons.

Thus, the characterization of "classical neurotransmitters" in the sensory neurons and their related peripheral target tissues allowed a better understanding of the various sensory modalities. The fact that these classical neurotransmitters constitute only a small proportion of neuronal cell bodies suggest that there may be considerable heterogeneity among the sensory neurons with regard to both neurotransmitters and peptide content. (Supported by grants of C.R.M. and F.R.S.Q.).

INNERVATION PATTERNS OF COLLATERAL KNEE LIGAMENTS AS REVEALED BY SILVER STAINING AND IMMUNOHISTOCHEMISTRY. K.A. Sharkey and R.C. Bray. Departments of Medical Physiology and Surgery, University of Calgary, Calgary, Alberta, Canada.

Articular ligaments are known to contain neural elements responsible for proprioception and nociception. However, little is known about the pattern and distribution of nerve terminals in discrete ligaments. Collateral ligament from adult rats, rabbits and human cadavers were fixed and frozen sections were stained with a modified Bielshowsky-Gros technique or for substance Pand CGRP-immunoreactivity (IR). In all species nerve bundles entered the ligaments obliquely and became longitudinally oriented in the deep tissue. The commonest nerve termini identified by silver staining were free endings arising from myelinated and unmyelinated intraligamentous nerves. Encapsulated endings (e.g. Golgiform, and Ruffiniform) were less frequently observed, but when present were usually found superficially, near ligament attachments to bone. Nerve bundles entered the tissue with blood vessels and often form multiple "tangles" of unmyelinated fibres which become intimately associated with branching vessels deep in the ligament. Substance P- and CGRP-IR together mirrored the pattern of unmyelinated fibres identified by silver staining and were predominately found associated with blood vessels. The structures described above could provide proprioceptive and nociceptive input from ligament. The predominant association between nerves and blood vessels suggests important vasomotor functions previously unrecognized in this tissue.

INTRACELLULAR NEUROBIOTIN INJECTION: A NEW METHOD FOR RAPID STAINING OF THE LONG-RANGE PROJECTIONS OF FUNCTIONALLY DIVERSE TRIGEMINAL GANGLION CELLS. J.W. Hu*, B.J. Sessle, & M.F. Jacquin. Fac. of Dentistry, Univ. of Toronto, Toronto, Ontairo M5G1G6 & Dept. of Anat. & Neurobiol., St. Louis Univ. Sch. of Med., St. Louis, MO 63104.

Currently available methods for study of the morphology of physiologically characterized primary afferents are limited by 2 factors: it is very difficult to impale and stain thin fibers, and staining is restricted to, at best, 0.5 cm from the region of the injection site. Sugiura et al., (Science 234:358, '86) have shown that intracellular PHA-L injections are effective in long-range staining of the projections of unmyelinated spinal primary afferents; however, long survival times are required. We have encountered an alternative method that overcomes the above limitations. Intracellular injection of Neurobiotin (Vector Labs) into rat trigeminal ganglion cells provided long-range staining with 10-55 min. of depolarizing injection currents of 6-10 nAmp (2 Hz, 250ms pulses) through Microstar capillaries beveled to 50-80 mOhms. Pipettes contained 2% Neurobiotin in 1.0M KCl. Rats were perfused with 4% paraformaldehyde within 4.5-10 hr. of tracer injection and brainstems were processed by avidin-biotin immunohistochemistry. Reliable axonal labeling in the medulla occurred in 5 cases attempted to date. Three were skin-or-hair-responsive A-delta fibers with relatively thin axons, and 2 were whisker-sensitive A-beta fibers. In all cases the parent axon was stained in the V spinal tract to the level of the obex. Collaterals were visible at the level of nucleus principalis and each of the spinal V subnuclei. THE VGF8a PPOTEIN IS EXPRESSED BY PRIMARY SENSORY AND OTHER PEPIPHERAL NEURONS AND BY CERTAIN ENDOCRINE CELLS.

G.-L. Ferri*, P. Possenti, L. Abelli*, A. Levi, W. Neuhuher*. Dept. Cytomorphology, Univ. Cagliari, 09100 Cagliari; CNR Inst. Neurobiology, Rome; Pent. Pharmacology, Menarini Ricerche Sud, Pomezia, Italy. Dept. Anatomy, University Zürich, Switzerland

The 712 aminoacid protein VGFRa was recognized in PC12 cells on the basis of its rapid induction by NGF. A variety of mammalian peripheral tissues were studied by immunocytochemistry, using two antisera raised against beta-galactosidase fusion proteins, corresponding to non-overlapping regions of the VGFBa sequence. Controls included cross-absorption of antisera with both fusion proteins. Striking immunoreactive fibres were seen in the dorsal spinal cord, which were almost absert in rats treated neonatally with capsaicin, and greatly decreased after dorsal zhizotomy. Neuronal perikarya were stained in spinal ganglia, and intrinsic gut neurons were seen after colchicine. Nerve fibres were detected in para- and pre-vertebral ganglia, which decreased after capsaicin. Endocrine cells in adenohypophysis and adrenal medulla showed immunoreactivity, and Western blot of bovine adrenal extracts revealed high MW material reactive for both antisera, comigrating with PC12 cells-VCFBa protein.

In conclusion, the VGF8a protein was demonstrated in a variety of peripheral sites, including primary sensory and visceral neurons and certain endocrine populations.

TEMPERATURE SENSITIVITY OF EFFECTS OF STATIC MAGNETIC FIELDS ON ACTION POTENTIALS OF SENSORY NEURONS IN CELL CULTURE. R.R. Holcomb, A.W. Wamil*, J.D. Pickett* and M.J. McLean. Depts. of Neurology and Neurosurgery, Vanderbilt Univ. Med.Ctr., Nashville, TN 37212.

M.J. McLean. Depts. of Newborg and American Vanderbilt Univ. Med.Ctr., Nashville, TN 37212.

We investigated effects of static magnetic fields on adult mouse dorsal root ganglion neurons in dissociated cell culture using conventional intracellular electrophysiological recording techniques. In some neurons, 0.5 msec current pulses elicited action potentials (APs) of 0.5-0.5 msec duration and 500 msec pulses elicited one or a few APs. Other neurons fired 2-4 msec APs in response to brief stimuli and fired throughout 500 msec depolarizations. Placing quadripolar arrays of permanent magnets beneath the recording chamber reversibly abolished APs elicited by brief pulses and limited firing during long pulses at 37°C. Reduction of the temperature to 33°C led to recovery of APs in the continuing presence of magnets. Rewarming to 37°C once again limited firing and removal of the magnets led to recovery of APs. Magnets had no significant effect on chronaxie or input resistance of the neurons. These findings suggest that specific configurations of static magnetic fields limit firing by a temperature—sensitive effect on AP generating mechanisms. These effects may be important in controlling different components of pain.

HERPES SIMPLEX VIRUS (HSV) INFECTION OF MOUSE DORSAL ROOT GANGLIA (DRG): EFFECTS OF INOCULATION ROUTE AND VIRUS STRAIN. <u>D.B. Henken & I.R. Martin</u>, Laboratory of Experimental Neuropathology, NIH, NINDS, Bethesda, MD 20892

DRG neurons can be divided into two populations based on morphology, connections and peptide content: smaller diameter neurons contain peptides (e.g., calcitonin-gene related peptide (CGRP)) and larger diameter neurons do not. We examined whether HSV-2 strains differing in virulence preferentially infect one or the other of these populations following unilateral peripheral (footpad) or intraneural (sciatic nerve) inoculation. Anaesthetized female BALB/c mice were infected with one of three HSV-2 strains: 186, MS or HG52 (descending order of virulence); five days later they were perfusion-fixed. Vertebral columns, with associated spinal cords and DRG, were decalcified and paraffin sections immunoreacted to detect HSV-2 antigen. Adjacent sections were processed for CGRP-immunocytochemistry. Somal areas for all HSV- and CGRP-labelled and unlabelled neurons in the infected DRG were compared with the somal areas of the contralateral uninfected DRG. With footpad inoculation, 9.5% of DRG neurons were HSV-antigen positive with 186, 7.7% were positive with MS strain and thus far labelling has not been detected with HG52. Labelled HSV-positive cells were in the category of smaller DRG neurons. With the sciatic nerve inoculation model, 80% of DRG neurons were antigen-positive with MS. Labelled HSV-positive cells were not confined to the small cell range. In all cases, equal numbers of CGRP-positive neurons were seen in infected and uninfected ganglia. These results suggest that the footpad inoculation model targets the small population of DRG neurons. With sciatic nerve inoculation, more neurons, with a broader range of cell sizes are infected. The proportion of neurons infected appears to be strain related. Modification of host peptide production is not detectable five days following infection.

365.14

ELECTRICAL CHARACTERISTICS OF ACUTELY ISOLATED NEURONS FROM RABBIT NODOSE GANGLIA.

J.H. Leal-Cardoso*, G. Koschorke*, G. Talyor* and D. Weinreich.
University of Maryland, Sch. of Med., Baltimore, MD 21201.

Passive and active membrane properties were examined to determine whether isolated neurons possessed membrane properties similar to those found in intact ganglia. Neurons were dissociated by the method of Wonderlin & Weinreich (J. Neurosci. Methods, 22:53, 1987) and allowed to settle onto round glass coverslips for 2-3 hr before recording in a HEPES-containing Locke solution at 22°C. Fifty-two neurons were studied. The following values were obtained (mean \pm sem): cell dia., 59.3 \pm 2.2 μ m; E_m, -50.1 \pm 1.5 mV; tau, 6.2 \pm 0.9 msec; R₁, 86.8 \pm 9.9 M Ω ; C_m, 0.78 \pm 0.11 μ F/cm². Action potential amplitude, overshoot, dV/dt and duration were 84.0 \pm 2.4 mV, 19.7 \pm 1.4 mV, 198.1 \pm 12.6 V/sec and 8.9 \pm 0.4 msec, respectively. Spike threshold was -40.0 ± 2.0 mV. All cells revealed a fast spike after-hyperpolarization immediately following the spike (11.5 \pm 0.7 mV, 60.8 \pm 8.8 msec). Nine neurons manifested an additional spike after-hyperpolarization that was long-lasting (15.0 \pm 2.1 sec) and 14.3 \pm 2.0 mV in amplitude. These values are comparable to those obtained with similar recording micropipettes in neurons from intact ganglia. conclude that isolated nodose neurons retain the properties of intact neurons. Supported by NIH grant NS22069.

INCREASED RECIPROCAL I-A INHIBITION FOLLOWING SPINAL CORD INJURY IN HUMANS. G.Boorman*, R.G. Lee, W.J. Becker, and R. Tanaka*. Dept. of Clinical Neurosciences, University of Calgary, Calgary, Alberta, Canada T2N 4N1.

Damage to descending motor pathways due to spinal cord injury (SCI) might interfere with mechanisms which normally produce reciprocal I-a inhibition between agonistantagnoist muscle groups. We have used the method of Mizuno et al (1971) to investigate this question.

H-reflexes were recorded from the soleus muscle while

subjects maintained a relaxed sitting position. Tibial nerve stimuli to elicit the H-reflex were preceded by stimulation of the peroneal nerve at varying intervals. The effect of the conditioning peroneal nerve stimulus on the soleus H-reflex was analyzed.

When the peroneal nerve stimulus preceded the tibial nerve stimulus by 1-2 ms an inhibition of the H-reflex was seen. In normal subjects this early inhibition reduced the H-reflex by about 10%. A later inhibition was also detected when the interval between stimuli was 15-20 ms. The extent of the later inhibition was more variable and reduced the soleus H-reflex in normal subjects by 10-20%. In SCI patients a significant increase in the early in-

hibition was seen, with the H-reflex being reduced by 50%. The later inhibition was variable and did not differ significantly from the later inhibition seen in normals. We are now investigating the effect that voluntary activity of ankle muscles has on the above results.

366.3

VOLTAGE THRESHOLDS OF HUMAN MOTONEURONES.

K.S. Türker and T.S. Miles. Department of Physiology, The University of Adelaide, Adelaide, S.A. 5000, Australia. In reduced animal preparations, the amplitude of the initial-segment voltage threshold of motoneurones of different functional types is said to be similar. However, it is not clear whether this is also true in the absence of anaesthesia, when the motoneurones are subject to a constant barrage of inhibitory and excitatory inputs. Here we describe a novel technique for indirect estimation of voltage threshold of motoneurones in conscious humans. The essence of the technique is to establish the minimal stimulus required to activate a resting soleus motor unit via the Ia reflex pathway, and subsequently to determine the size of the EPSP evoked in the motoneurone by this stimulus: this then equals the voltage threshold of the resting motoneurone. The method used to measure the amplitude of the EPSP has been described in detail elsewhere (Miles, T.S., Türker, K.S. & Le, T.H. *Exp. Brain Res.* 77, 628-636, 1989). Based on an AHP of 10 mV, the voltage thresholds of 4 soleus motoneurones ranged from 4.1 to 5.9 mV. Further experiments are in progress to determine the relationship between the motor unit type and its voltage

THE GAIN OF THE HUMAN STRETCH REFLEX.M. Gorassini*, O. Mao*, and A. Prochazka. Division of Neuroscience, Univ. of Alberta, Edmonton, Alberta, T6G 2S2, CANADA.

The gain of the human stretch reflex is difficult to measure since, anatomically, it is impossible to open this negative feedback pathway. We have, however, developed a two part strategy, the result of which was equivalent to opening the stretch reflex loop. First, sinusoidal movements of varying frequencies were imposed on a subject's arm. Rectified EMG from the triceps muscle was recorded and averaged, along with the displacement produced by the perturbation. In the second part of the experiment, the subject was instructed to produce a volitional, unloaded, sinusoidal movement, whose EMG matched in amplitude and frequency that of the EMG produced in the imposed trial. The ratio of the displacement produced in the volitional trial to that of the imposed trial gave us a measure of the open loop gain of the stretch reflex. Net phase around the loop was obtained by summing the phase advance of EMG on movement in imposed trials and the phase lag of movement on EMG in volitional trials. Similar to the stretch reflex in decerebrate cats (Rosenthal et al., J. of Neurophys.33:713, 1970), the gain decreased with increasing frequency of modulation, with a concomitant increase in phase lag. Gains of 3 or more were inferred at frequencies of 1 Hz, dropping below 1 at 4 Hz and beyond. The phase lag exceeded 180° at 4.5 Hz. From these results, a more accurate and quantitative prediction can be made as to the contribution of the stretch reflex in reducing the effects of an external perturbation. For example, a gain of 2 @ 3 Hz will reduce an external perturbation by a factor of 1/3rd (1/1+GAIN). Supported by Medical Research Council of Canada.

366.2

DISSOCIATION OF SOLEUS SINGLE MOTOR UNIT RESPONSES WITH PERONEAL NERVE STIMULATION. J.S. Halle* and C.G. Kukulka. Physical Therapy Laboratories, University of Iowa Medical College, Iowa City, IA 52242.

Consistency of human soleus motor unit (MU) response

to peroneal nerve stimulation was investigated in adults to peroneal nerve stimulation was investigated in adults with no known pathology. Single 0.5 msec electrical pulses were delivered 3/sec at fixed intensities of 0.9 or 1.25 motor threshold. In 11 cases, two MU's (a MU pair) were detected and isolated for the same supraspinal set (voluntary activation) and reflex input (peroneal stimulation). Peristimulus time histogram analysis demonstrated qualitative dissociation of the MU's response in 8 of the 11 pairs (73%). Five of the 8 MU's demonstrated a robust dissociation, with one MU exhibiting a strong, short latency (mean 37.5 msec), short duration, enhanced firing probability, that was not short duration, enhanced firing probability, that was not observed in the second MU. Longer latency responses were usually qualitatively similar in the MU pair. These results indicate that soleus MU's recruited at low force levels do not always respond homogeneously to external stimuli. The dissociation of reflex effects may represent a means of selective activation of low threshold soleus motoneurons, and may provide a mechanism for reflex reversal of these motoneurons. Supported by Grant #5-R29-NS24991, National Institute of Neurology and Communicative Disorders and Stroke, Department of Health and Human Services.

366.4

SPATIAL SUMMATION OF MECHANICALLY EVOKED PERIORAL REFLEXES IN HUMAN. S.M. Barlow. Orofacial Physiology Lab., Indiana University, Bloomington, IN 47405.

An issue of special importance to studies of facial motor control concerns how systematic variations in the spatial properties of external mechanical inputs influence the excitability of trigemino-facial reflexes during voluntary motor activity. In the present report, the skin contactor was systematically varied in size to quantify the effects of spatial summation on the amplitude and time course of the early component (R₁) of the human perioral reflex sampled bilaterally from tonically active muscles of the lower face.

Results indicate that the amplitude of R₁ responses from orbicularis oris and mentalis muscle recording sites are local in sign and positively related to the size of the contactor array using constant amplitude mechanical inputs delivered to the lip vermilion. Varying skin contactor size from 2 to 16 points was also effective in shortening the latency of R₁ by 3 to 5 milliseconds. It appears that spatial summation is effective in modulating the excitability of trigemino-facial pathways in humans. Supported by NIH grant DC 00365-04.

366.6

REFLEX CHANGES ACCOMPANYING ISOMETRIC STRENGTH TRAINING OF THE CONTRALATERAL LIMB A.J. Butler, W.G. Darling. Exercise Science, University of Iowa, Iowa City, IA 52242. Department of

It has been shown by numerous investigators that exercising one limb is usually associated with an increase in strength in the homonymous muscles of the contralateral limb. The mechanisms of this cross-education of strength have not been completely investigated. It has been suggested, however, that the improvement in strength in the contralateral untrained limb may be attributed to neural adaptations at various levels of the nervous system (i.e. increased facilitation or disinhibition of motor neurons). The purpose of this project was to determine whether training of the left triceps surae muscle would produce changes in the excitability of spinal motor neurons and interneurons controlling the right, untrained triceps surae.
The following measurements were made prior to and immediately following

unilateral, isometric strength training three times a week, for 4 weeks: (1) Electromyography's (EMG) of triceps surae, H-reflexes and conditioned H-reflexes, and plantarflexion torque during maximal plantarflexion contraction, (2) maximal twitch and M-responses of triceps surae. The subjects ankle and knee joint angles along with EMG and stimulating electrode positions were held the same for pre and post testing sessions. After training, increases in plantarflexion torques of the trained and untrained leg, triceps surae EMG's, and reflexes were observed. Although inter-subject variability was high, these observations support the theory that cross-education effects result from neural adaptations.

A PILOT STUDY INVESTIGATING A REFLEX EXCITABILITY MEASUREMENT TECHNIQUE TO ASSESS CEREBRAL SPASTICITY IN MEASUREMENT TECHNIQUE TO ASSESS CEREBRAL SPASTICITY IN HUMANS. K. HARBURN, A. VANDERYOORT, A. HELEWA, C. GOLDSHITH, A. KERTESZ, R. TEASELL, (K. HILL*). Departments of Occupational and Physical Therapy, The University of Western Ontario, London, Ontario, N6G 5C1. The purpose of this study was to evaluate the feasibility of a reflex excitability measurement technique (RENT) to assess spasticity related to cerebral stroke. The H-reflex was evoked at 4 degrees of plantarflexion during a stationary condition and during slow passive

during a stationary condition and during slow passive movement of the ankle. Pilot testing demonstrated less inhibition of the H-reflex during passive movement of the affected ankle in stroke subjects (n=12) than matched control subjects (n=12) (p<.05). This finding was felt to be related to faulty presynaptic inhibition. A positive, but weak correlation was found between the REMT positive, but weak correlation was found between the kind index and a clinical measure of spasticity in stroke subjects (Spearman R=.49). Stroke subjects demonstrated greater average stiffness (Nm deg/deg) of the affected ankle than control subjects (p<.05). Size of cerebral lesion was not significantly related to any of the variables examined. Further testing of the reliability and validity of the REMT index is required to establish its usefulness as an outcome measure in a clinical trial of therapy.

ELICITATION OF A LARYNGEAL EXTEROCEPTIVE REFLEX FOLLOWING SUPERIOR LARYNGEAL NERVE STIMULATION IN HUMANS. C. L. Ludlow, S. G. Yin*, J. Kohda* and M. Hallett, Speech and Voice Unit, NIDCD and Human Motor Control Section, NINDS, Bldg. 10/5N226. Bethesda, MD 20892.

Bidg. 10/5N226. Bethesda, MD 20892. Previously a long latency response between 55 and 80 ms was elicited bilaterally in the thyroarytenoid (TA) and sometimes in the ipsilateral cricothyroid (CT) muscle following electrical stimulation of the recurrent laryngeal nerve on one side containing glottic afferents and motor fibers for several laryngeal muscles including the TA (Ludow C.L.. Yin S.G. and Hallett, M., Neurosci Abstracts, 1989). The purpose of this study was to determine if a similar response could be elicited from the TA and CT muscles bilaterally by stimulating the The purpose of this study was to determine if a similar response could be elicited from the TA and CT muscles bilaterally by stimulating the superior laryngeal nerve containing supraglottic afferents and motor fibers for the CT. During nerve stimulation, simultaneous bilateral hooked wire recordings were made from the TA and CT muscles with unilateral surface recordings from the posterior cricoarytenoid and obicularis oculi. The stimulation levels were varied between threshold and supramaximal for direct ipsilateral CT muscle responses. The ipsilateral direct CT response occurred at 3 ms, and the adductor response occurred at low levels of stimulation in the ipsilateral CT and TA, and the contralateral TA at 13, 15 and 22 ms respectively. The long latency response occurred at low levels of stimulation starting at 50 ms and lasting to 80 ms in the laryngeal muscles, but not the obicularis oculi. This was more consistent and appeared at lower stimulation levels in the TA than in the CT muscles. This later response was more consistant, higher in amplitude and longer than the adductor response. The results demonstate that an exteroceptive response appears following stimulation of either glottic or supraglottic afferents.

DIFFERENTIAL EFFECTS OF A CONDITIONING STIMULUS UPON THE CONTRALATERAL ALPHA MOTONEURON POOL. <u>D.M. Koceja & G. Kamen</u>, Motor Control Lab, Indiana University & Neuromuscular Research Center, Boston University.

In this study, the tibial nerve H-reflex (50% In this study, the tibidi herve hereiter (so max.) was conditioned by either a contralateral tibial nerve H-reflex or a tap to the contra-lateral Achilles tendon in a group of normal college-age subjects (n=12). Conditioning lateral Achilles tendon in a group of normal college-age subjects (n=12). Conditioning intervals of 10, 25, 40, 55, 70, 85, 100, 115, 130 and 145 ms were used. The results indicated that the conditioning H-reflex stimulus produced a facilitation while the conditioning tendon-tap stimulus produced an inhibition to the contralateral alpha motoneuron pool, as shown
below for peak force and peak to peak EMG:

EFFECT OF STIMULANT MEDICATION ON MOTONEURONAL EXCITABILITY IN ADDH CHILDREN. R.T. PIVIK AND F.W. BYLSMA* DEPTS. PSYCHIATRY, PHYSIOLOGY AND SCHOOL OF PSYCHOLOGY, UNIV. OF OTTAWA, ONT.

UNIV. OF OTTAWA, ONT.

Previous reports have indicated unmedicated ADDH children may exhibit disparate levels of spinal motoncuronal excitability as indexed by H-reflex recovery function profiles. The present study provides a comparison of these profiles in ADDH children both while receiving stimulant medication and while unmedicated.

Fifty-two children (26 ADDH: 18 males, 8 females; X ages = 9.58 ± 1.58 years; 26 controls: 22 males, 4 females; X ages = 10.12 ± 1.66 years) participated in the investigation. Clinical diagnoses were based on psychological evaluations, DSM-III criteria and scores of ≥ 15 on the hyperactivity scale of Connors' Parent and Teacher Behavioral rating scales. Muscle action potentials were recorded from gastrocnemius-soleus muscles. Above threshold equal intensity stimuli were delivered in pairs at intra-pair intervals ranging from 50-2000 msec. Ratios of test (H₂) to conditioning (H₁) reflexes were averaged (5/interval) and analyzed using repeated measures analysis of variance. Group comparisons of indexes of secondary facilitation (the average of reflex ratios at 100, 200 and 300 msec intervals) revealed that, relative to controls, reflex amplitude was significantly secondary facilitation (the average of reflex ratios at 100, 200 and 300 msec intervals) revealed that, relative to controls, reflex amplitude was significantly depressed in ADDH children when nonmediated (p = .013) and that medication was associated with a reduced difference between control-ADDH data (p = .094). Approximately 1/3 of the ADDH subjects actually showed reflex facilitation when unmedicated. In conjunction with medication administration, these subjects showed a 10% decrease in excitability, whereas the remaining subjects showed a 34% increase in excitability. These data, obtained under resting conditions, reinforce the notion that motor-related symptomatology generally noted in this disorder is fundamental and does not require activation of complex behavioral patterns to become evident. Furthermore, the data suggest that stimulant medication has the effect of modifying levels of motoneuronal excitability in the direction of normality, regardless of initial levels of excitability. -- Research assisted by Ontario Mental Health and Hospital for Sick Children's Foundations.

EFFECTS OF GRADED JENDRASSIK FACILITATION ON TYPE IA AND II MEDIATED REFLEXES IN ABLE-BODIED AND IA AND II MEDIATED REFLEXES IN ABLE-BODIED AND SPINAL CORD INJURED HUMANS.

Leckey*. Dept. of Medicine, U. Manitoba, Winnipeg, Man. and Dalhousie U., Halifax, N.S., CANADA The soleus deep tendon reflex (DTR) is a type Ia mediated spinal relex which can be facilitated by a Jendrassik Maneuver (JM) or inhibited by vibration (v). Since v activates dynamic muscle spindle receptors, only the static stretch receptors, mediated by Type II fibers, respond to a tendon tap during v. Type Ia and Type II mediated reflexes were tested in able-bodied (n=10) and spinal cord injured (SCI) (n=10) men before and during a graded JM:a 3 s Maximum Hand Grip (MHG), 50%MHG and 25%MHG. Both Ia and II reflex facilitation was greatest during 50%MHG. Type Ia and II reflex amplitudes of motor spared SCI subjects were greater (p<0.001) than motor complete SCI subjects and able-bodied subjects. Reflexes of the motor complete SCI subjects failed to facilitate and controlled of the NM. subjects and able-bulled subjects. Relief to facilithe motor complete SCI subjects failed to facilitate at any grade of the JM. Able-bodied subjects (3/10) showed reflex inhibition during MHG which (3710) Showed reflex inhibition during MHG which none of the SCI subjects showed. Thus, reflex facilitation by the JM is mediated via a descending motor pathway and requires the normal compliment of innervation for inhibitory gating. Potentiation and diminution of a Pavlovian UR (rabbit eyeblink) as a function of the CS - US interval in training and testing. T. Canli. W.M. Detmer*, N.H. Donegan. Dept. of Psych., Yale Univ., New Haven, CT 06520.

Defensive motor reflexes elicited by a US can be 1) potentiated when the target US is preceded by a CS associated with an aversive US (fear potentiated startle; Davis et al., 1979, Psychopharm, 65, 111); or 2) diminished when the target US is preceded by a CS with which it has been paired (the conditioned diminution of the UR; Donegan, a CS with which it has been paired (the conditioned diminution of the UR; Donegan, 1981, JEP:ABP, 7, 295). We propose that these different outcomes result from two separate associative processes that develop when a CS is associated with an aversive US: 1) conditioning of a fear response that is present during much of the CS; 2) conditioning of a brief, discrete motor CR (e.g., eyeblink) timed to occur near the US onset. This is assumed to produce a short lasting inhibition of the US sensory pathway, and thus a diminished UR (Donegan et al., Psy. of L & M, 1989, 23, 109). Consequently, a CS paired with an aversive US should diminish the UR when the same US occurs at the training interstimulus interval (ISI), but should potentiate the UR when the same US occurs during the CS, but outside the training ISI.

OR when the same US occurs during the CS, but outside the training 1S1. Seven rabbits received discrimination training in which a 1040 msec CS was paired with a 40 msec periorbital shock US (5 msec pulses, 100 Hz, 4.0 mA) on half of the trials (CS+), thus defining a training ISI of 1.0 sec. On the other half of the trials, a different CS was presented alone for 1040 msec (CS-). Subsequently, probe test-trials in which the US was presented alone, preceded by a 1 sec CS+ or CS-, and a 10 sec CS+ or CS-, were introduced in the course of discrimination training sessions. The CS+ or CS-, were introduced in the course of discrimination training sessions. The findings were consistent with the above hypotheses. When the US was presented 1.0 sec after CS onset (the training ISI), the eyeblink UR amplitudes were diminished on CS+US trials, compared to CS-US and US alone test trials. Importantly, UR amplitudes were diminished on CS+ trials in which there was an eyeblink CR, but not on CS+ trials in which a CR was absent. However, when the US occurred at the end of a 10 sec CS, the UR amplitude was potentiated by CS+ compared to CS- or US alone test trials. The potentiation produced by CS+ was greater on trials on which an eyeblink CR occurred compared to trials on which a CR did not occur.

In Search for a Primary Startle Pathway in the Rat. Karin Rüttgers, Karl Kandler*, and Horst Herbert; Univ. of Tübingen, Dept. Animal Physiol., Morgenstelle 28, 7400 Tübingen, FRG.

The acoustic startle response is a short latency reflex. Head muscles are the first to react with minimal latencies of 5.5 ms (Caeser et al., 1989, Behav. Neurosci. 103: 1075-1081). Therefore we assume a startle pathway with only one synapse between the sensory input (cochlear nucleus, CN) and the motor output (motor nuclei of the trigeminal and facial nerve, Mo5 and Mo7). In the rat brain a structure receiving input from the CN and in turn projecting to Mo5 and Mo7 is not known. In search for such a sensorimotor interface we injected Mo5 and Mo7 with the retrograde tracer Fluoro-Gold and mapped the distribution of labeled neurons. In a second set of experiments we injected Phaseolus vulgaris leuccoagglutinin into CN and looked for labeling in areas that were previously shown to contain premotor neurons.

We found four sites where premotor neurons and auditory terminal fibers coincide: the lateral paragigantocellular nucleus (LPGi), an area including the ventral part of the caudal pontine reticular nucleus (PnC) and the adjoining ventral part of the caudal pointine reticular nucleus (FIC) and the adjoining dorsal periolivary nucleus, the pontine nuclei (Pn), and the ventrolateral tegmental nucleus (VLTg). Retrograde double-labeling experiments revealed that some neurons in these areas project to both, Mo5 and Mo7. This is in accordance with Caeser et al., who demonstrated that different groups of head muscles show a common fluctuation in response latency and amplitude

Our data implicate, that the above mentioned nuclei are potential sensori-motor interfaces responsible for mediating the acoustic startle response. Currently retrograde/anterograde double tracing experiments are done to clarify whether the auditory efferent fibers from CN synapse on the premotor neurons (Supported by Deutsche Forschungsgemeinschaft SFB 307)

MOTOR UNIT- MUSCLE SPINDLE INTERACTIONS DURING FATIGUE. R.M. Enoka^{1,2}, M.A. Nordstrom¹, R.M. Reinking ^{*1} and D.G. Stuart¹. Depts of Physiology¹ and Exercise & Sport Sciences², Univ. of Arizona, Tucson AZ

The effect of motor unit (MU) activation on spindle afferent discharge was studied during a 6-min fatigue test (cf. Burke et al., J. Physiol., 234:723, 1973) in the tibialis posterior muscle of anesthetized cats. Single MUs were activated repetitively by stimulating ventral root filaments, while afferent activity was recorded from dorsal root filaments. The interaction between a MU and a muscle spindle was quantified using a coupling index (CI; Munson et al., <u>J. Neurophysiol.</u>, 51:1288, 1984), where CI = (1 - a/p) x 100; "a" is the number of action potentials from the afferent during the last 250 ms of each 330 ms epoch of MU activation (at 1/s), and "p" is the afferent action potential count from a 250 ms epoch during the quiescent period following each tetanus. The CI was plotted against the corresponding MU peak force for the 360 activations of the fatigue test. They usually changed in parallel, provided the MU and spindle were mechanically coupled. However, for selected fatigable units it was possible to compare spindle responses to the same MU peak force after different periods of activity, because an initial force potentiation was followed by fatigue. The ability of a MU to influence spindle discharge was time-dependent; a given peak force was more effective in Linloading the muscle spindle during the period of fatigue when force was declining, compared to the same force during the period of potentiation. This finding is consistent with the earlier suggestion using a different paradigm (Christakos & Windhorst, <u>Brain Res</u>, 365:388, 1986), that the gain of the system linking MU force and spindle discharge increases during fatigue. DIRECT STIMULATION OF MUSCLE IS SUFFICIENT TO PRODUCE PERSISTENT HINDLIMB FLEXION IN RAT. M.F. Anderson and B.J. Winterson. Depart. of Physiology, Univer. of New England College of Osteopathic Medicine, Biddeford, ME 04005.

Electrical current (2mA, 7ms, 100Hz for 1 hr) delivered through wound clips attached to the medial and lateral

thigh skin induces a persistent flexion. Since current also passes through the underlying muscle, we assessed the relative contribution of muscle and skin in this paradigm. Long-Evans rats (200-275g) were anesthetized and assigned to three groups: MUSCLE & SKIN; MUSCLE; SKIN. In the MUSCLE & SKIN group, wound clips were attached to the thigh skin. & SKIN group, wound clips were attached to the thigh skin. In the MUSCLE group, skin was removed from the thorax to the hindlimb footpads and exposed muscle was wrapped in sterile gauze soaked in normal saline. Wound clips were applied through the gauze and into the underlying muscle. Body temperature was maintained by wrapping a thermostatically controlled heating pad around the thorax and upper thighs. In the SKIN group, wound clips were applied to the thigh skin and lcc of Vaseline was injected subcutaneously at each site. Capacitative current was monitorcutaneously at each site. Capacitative current was monitored continuously at the muscle via insulated 27g needles and did not exceed 0.3mA. Following stimulation, mean flexion was 9.5g for the MUSCLE & SKIN group, 8.9g for the MUSCLE group and 4.0g for the SKIN group. These results suggest that muscle afferents are more influential than skin afferents in the induction of a persistent hindlimb flexion.

367.4

THE EFFECT OF LOW TEMPERATURES ON POST-TETANIC POTENTIATION IN THE FROG SPINAL CORD. M.-S. Rioult-Pedotti and H.P. Clamann, Dept. of Physiology, University of Bern, CH-3012 Bern,

Switzerland.

Temperature is known to affect neuron excitability, the size of post-synpatic potentials, and the size of reflex responses. Action potential (AP) duration increases with decreasing temperature, increasing the reliability of AP propagation across axonal branch points. It has been suggested that post-letanic potentiation (PTP) increases the reliability of AP propagation in a similar manner. Thus low temperature should increase the size of a reflex response while reducing the effect of PTP.

Frogs were cooled in ice, decapitated and the spinal cord removed. The spinal cord was hemisected, placed in a plexiglass chamber and superfused with cooled Ringer's solution. Lumbar dorsal (DR) and ventral roots (VR) were drawn into suction electrodes for stimulation and recording of reflex responses. The hemicord was kept at a constant temperature between 5-22°C. Stimuli of 0.1 ms duration were applied to the DR singly or at 1/s before and after 500/s tetanic trains and the reflex response recorded from the VR.

the VR. A single supramaximal DR stimulus elicited a reflex response with a large polysynaptic component which was greater the lower the temperature. At 22°C a reflex response was often virtually absent. Monosynaptic or short-atency polysynaptic components were most prominent at 5-15°C. A tetanus always augmented the shorter-latency response at the expense of longer-latency responses. PTP was most effective at the highest and weakest at the lowest temperatures tested. In some cases a hemicord at > 20°C showed no reflex response until after PTP. No PTP could be evoked at 6°C in some experiments, while the same hemicord showed marked potentiation at higher temperatures. These results are consistent with the hypothesis of Lüscher et al. (J. Neurophysiol. 50:1045, 1983) that branch-point failure of presynaptic axonal arborizations and its relief by PTP can modulate spinal reflexes. (Supported by the Sandoz-Stiftung.)

DESCENDING INPUTS AFFECT CROSSED EXTENSION MORE THAN STRETCH REFLEX RECORDED FROM QUADRICEPS FEMORIS IN DECER-STRETCH REFLEX RECORDED FROM QUADRICEPS FEMORIS IN DECE EBRATE CATS. J.A. McMillan, M.J. Serwacki* and W.A. Yuhas*. Dept. of Biol. and WAMI Program, Montana State University, Bozeman, MT 59717 We examined effects of changing body position, known

to affect excitability of the crossed extension reflex (McMillan, J.A. and Koebbe, M.J., Exp'l Neurol. 73:233, 1981), on both crossed extension (CER) and stretch reflex (SR) recorded from right quadriceps femoris in midcolliques decomposite cate. licular decerebrate cats. Reflexes were recorded with the cat on the right and left body sides respectively. Magnitude of response was determined by measuring the area under the force X time curve.

The CER was stronger when the cat was on the right as compared to left side (mean R/L= $3.15^{+}0.96$, P=0.03) whereas the SR was not changed (R/L= $1.00^{+}0.13$, P=0.45). Since SR is a monosynaptic reflex, these results suggest that incluences of descending inputs, as proposed by Bruggencate and Lundberg for the lateral vestibulospinal tract (Exp. Brain Res. 19:248, 1974), are exerted predominantly on interneurons in the CER pathway rather than directly on motor neurons. (Supported by NSF BNS 86-19148 and NIH RR08218-06. RECURRENT COLLATERALS OF FLEXOR HALLUCIS LONGUS AND FLEXOR DIGITORUM LONGUS MOTONEURONS OF THE CAT. T.M. Hamm and M.L. McCurdy. Div. Neurobiology, Barrow Neurological Inst., Phoenix, AZ 85013.

Recent studies have demonstrated differences in recurrent inhibition to and from flexor hallucis longus (FHL) and flexor digitorum longus (FDL) motoneurons (Hamm, <u>J. Neurophysiol</u>, 63:395, 1990), including an absence of recurrent inhibition from FDL motoneurons in several species of motoneurons (Fleshman et al., Exp. Brain Res. 54:133, 1984; Hamm, 1990). In the present study, the recurrent collaterals of FHL and FDL motoneurons have been examined for a potential morphological basis of differences in patterns of recurrent inhibition. Experiments were performed using cats which had been ischemically decapitated under isoflurane anesthesia. Individual motoneurons were injected intracellularly with horseradish peroxidase. To date, 4 FHL and 1 FDL motoneurons with distinct, well-stained axonal systems have been examined. Three of the FHL motoneurons had one first order collateral; the fourth cell had two. Each collateral tree had no more than 5 swellings and 6 blunt endings located in the ventral part of lamina VII. The one FDL motoneuron studied to date had no recurrent collaterals. This preliminary data indicates that these motoneurons have very simple axon collateral systems in relation to most other species of hindlimb motoneurons, consistent with the small recurrent IPSPs, and the absence of recurrent IPSPs, produced by FHL and FDL motoneurons, respectively (Hamm, 1990). Considering the absence of recurrent collaterals in motoneurons that innervate the short plantar muscles (Cullheim and Kellerth, J. Physiol. Lond. 281:285, 1978), these data provide evidence for a morphological basis for a proximal-distal gradient in the strength of recurrent inhibition in motor nuclei that innervate the cat's hindlimb.

HETEROGENIC REFLEX ORGANIZATION WHICH MIRRORS SPECIALIZED ACTIVATION PATTERNS OF FLEXOR DIGITORUM LONGUS AND FLEXOR HALLUCIS LONGUS MUSCLES IN THE CAT. T. R. Nichols and T. R. Nichols and J. Bonasera*. Department of Physiology, Emory University Atlanta, GA 30322.

The different activity patterns of flexor hallucis longus and flexor digitorum longus muscles (FHL and FDL) during locomotion and the facultative activation of FDL are discordant with the strong Ia synergism between these two muscles (O'Donovan et al., J. Neurophysiol., 47:1126, 1982). In an attempt to obtain a more global view of the reflex organization of these muscles, we evaluated stretch-evoked reflexes among FHL, FDL and other hindlimb muscles in decerebrate cats. FHL and FDL were indeed linked by powerful excitatory pathways, but the interactions between either FHL and FDL and quadriceps, gastrocnemius, plantaris soleus and pretibial flexors were largely, although not exclusively, inhibitory. Reflex interactions for FDL were weaker and more variable than those of FHL, suggesting a greater flexibility of control for FDL. Additionally, the distribution and strength of inhibitory interactions for FHL and FDL were similar to the pattern of recurrent inhibition for these muscles (Hamm, T. M., J. Neurophysiol. 63: 395, 1990). The strong Ia synergism between FDL and discordant with the strong Ia synergism between these two 63: 395, 1990). The strong Ia synergism between FDL and FHL may serve to reinforce the response of these muscles to external, mechanical disturbances rather than mediate patterns of activity during locomotion.

COMPUTER SIMULATION OF THE STEADY-STATE BEHAVIOR OF THE MOTONEURON POOL: COMPARISONS WITH EXPERIMENTAL DATA ON FREQUENCY MODULATION. CJ. Heckman, J.J. Gemperline and M.D. Binder.

PREQUENCY MODULATION. CJ. Heckman JJ. Gemperline and M.D. Binder. Dept. of Physiology, Northwestern University, Chicago, IL, 60611.

A realistic computer simulation of the medial gastrocnemius motoneuron pool and muscle was used to investigate the nature of the synaptic input required to generate normal steady-state frequency modulation of single motor units. We recently hypothesized that synaptic inputs which generate larger effective synaptic currents (In) in type S than F motoneurons (e.g., the spindle la input) are used to produce low forces, while production of higher forces requires the addition of inputs with the opposite distribution of In (Heckman and Binder, NP 60:1946, 1988).

Here we consider the hypothesis that such a "crossover" between very different input systems is also sufficient to account for frequency limiting of low threshold units as recruited. Simulation outputs were compared to plots of single unit discharge rates versus background force in human subjects (Monster and Chan, NP 40:1432, 1977). Various versions of a "crossover" input scheme were found to simulate frequency limiting. However, accurate simulation of the experimental data required that the synaptic input meet 3 specific criteria: 1) the low level input had to generate much less In in S than FF units; and 3) the crossover point had to occur at a low In amplitude, at less than 5% of maximum terest and the four the property of the constituent of the tense intense of the property of the constituent of the tense intense of the property of the constituent of the tense intense of the property of the constituent of the tense of the property of the constituent of the tense of the property of the constituent of the tense of the property of the constituent of the tense of the property of the constituent of the tense of the property of the constituent of the tense of the property of the constituent of the tense of the property of the constituent of the tense of the property of the constituent of the constituent of the constituent of the crossover point had to occur at a low In amplitude, at less than 5% of maximum force and well before the recruitment of any FF units.

These results appear to be consistent with some of the known characteristics of the monosynaptic la input (a putative "low level" input favoring S units) and the polysynaptic rubrospinal/sural inputs (putative "high level" inputs favoring F units). Further, the simulations predict that a good indicator of the distribution synaptic input should be the slope of the relationship between the rates of two different motor units as force is increased. Experiments are underway to obtain detailed measurements of rates of pairs of motor units to evaluate this approach.

PARTICIPATION OF FLEXOR HALLUCIS LONGUS MOTONEURONS IN THE PLANTAR CUSHION REFLEX AND ITS RELATIONSHIP TO DENDRITIC ORIENTATION IN THE CAT. M.L. McCurdy and T.M. Hamm. Div. of Neurobiology, Barrow Neurological Inst., Phoenix, AZ 85015

Motoneurons innervating short plantar muscles of the foot respond with short latency EPSPs to natural stimulation of the plantar footpad (Egger et al., J These motoneurons have a bundle of Physiol. 306:349-363, 1980). dorsomedially oriented dendrites which project into Rexed's laminae VI of the dorsal horn. Flexor hallucis longus (FHL) and/or flexor digitorum longus (FDL) and plantaris (Pl) motoneurons also respond to plantar cushion stimulation (Engberg, I., <u>Acta Physiolog. Scand. 52: Suppl.</u> 235:1, 1964). We tested the responses of FHL, FDL and Pl motoneurons to electrical stimulation of the plantar cushion (1.5-2T) in ischemically decapitated low-spinal cats and subsequently injected some cells with horseradish peroxidase to investigate dendritic specialization in the dorsal horn.

Our preliminary findings indicate that short latency (< 3 msec) EPSPs vary from < 1 to 3 mV in FHL and PI motoneurons and the cells with the strongest responses have a substantial dendritic projection in the dorsal horn. These dendrites do not extend as far medially and do not form a discrete bundle as in motoneurons of short plantar muscles but rather fan across the lateral half of laminae VI. Some FHL motoneurons lack prominent dorsomedial dendrites. In FDL cells studied to date, only weak EPSPs from plantar cushion stimulation have been observed. The morphology of one FDL cell has been examined and dorsomedially directed dendrites were confined to the lateral edge of lamina VI. Our results to date are consistent with a correspondence between the dendritic morphology of FHL and PI motoneurons and their participation in the plantar cushion reflex

COMPUTER SIMULATIONS OF SOLEUS MOTONEURON POOL DYNAMIC RESPONSES TO RAMP STRETCHES STARTING FROM DIFFERENT OPERATING POINTS. Di. T. Boškov and W. Z. Rymer. Dept. of Physiology, Northwestern University, Chicago, IL. 60611.
Previously we have shown that, during ramp and hold stretches of the soleus
muscle in decerebrate cats, the reflex components of EMG and force show a variety
of behaviors for nearly stereotyped spindle afferent input. In order to simulate the reflex output under these conditions, we developed a model of neural network of the
soleus motoneuron pool using the neuron model by MacGregor and Oliver (Kybernetikl 6:53, 1974). The neural network consisted of 50 simulated soleus motoneurons
innervated by two groups of 50 input fibers, one corresponding to spindle afferent input and another representing the central input. The thresholds of motoneuronal firing
were determined from the previously reported rheobase currents and synaptic currents across the pool and the other model parameters were based on experimental data on single neurons. Different initial forces were simulated by changing the background activity of the central input.

ta on single neurons. Different initial forces were simulated by changing the background activity of the central input.

We first tested the hypothesis that simple changes in central tonic activity, coupled with stereotyped spindle afferent activity, are sufficient to explain changes in recruitment patterns during stretch. As the simulated tonic activity increased, the number of newly recruited units during stretch decreased and most of these new units were recruited shortly after the simulated onset of stretch. These results were entirely in accord with experimental data, suggesting that intrinsic properties of motoneurons are sufficient to account for the observed recruitment patterns under a wide range of background activities.

are sufficient to account for the observed recruitment patterns under a wide range of background activities

We have previously shown that the sensitivity of force responses to reflexive recruitment pattern decreases with background force. We performed a sensitivity analysis of simulated recruitment patterns to the step increase and slope of spindle rate during stretch. The results indicated that, as the background activity increased, the normalized sensitivity decreased from 2-5 to x1 shortly after stretch onset, whereas the slope effect was insignificant. These results suggest that the sensitivities of recruitment patterns to variations in step phase of afferent input are well suited to muscle properties.

COMPUTER SIMULATION OF THE STEADY-STATE BEHAVIOR OF THE MOTONEURON POOL: COMPARISONS WITH EXPERIMENTAL DATA ON RECRUITMENT ORDER. M.D. Binder and C.J. Heckman. Dept. of Physiol. and Biophysics, University of Washington, Seattle, WA 98195.
We have developed a computer simulation of the steady-state behavior of the cat

medial gastrocnemius (MG) motoneuron pool and muscle. A neural network was constructed consisting of 100 motor units with neural and mechanical properties that very closely matched the available experimental data. The use of realistic single elements permits quantitative comparisons between simulation outputs and normal motor outputs and creates new approaches for testing hypotheses about the single unit basis of motor behavior.

basis of motor behavior. We investigated the hypothesis that the intrinsic properties of motor units are sufficient to account for the phenomenon of orderly recruitment. All units received precisely equal shares of the effective synaptic current, so that recruitment thresholds were solely determined by current thresholds for rhythmic firing (*Ithres*). We began with a relationship between *Ithres* and maximal unit force output (*Fmax*) that was monotonic, giving perfect recruitment order. We then used Monte Carlo techniques to add varying amounts of random variance to the *Ithres-Fmax* relationship. Pairwise comparisons of recruitment order were performed to relate *Ithres-Fmax* cor-

relation coefficients to the orderliness of recruitment.

Our results showed that reducing the *lithres-Fmax* covariance to that reported in the experimental data (Fleshman et al., J. Neurophysiol. 46: 1981) generated recruitment orders that were much more variable (28% reversals on average) than those reported orders that were much more variable (25% reversals on average) man hose reported for hindlimb muscles of decerebrate cats (0-8%: Zajac and Faden, J. Neurophysiol. 49: 1985; Botterman and Tansey, Soc. Neurosci. Abstr. 15: 1989). Application of steady-state homonymous la effective synaptic current to the pool, which is about wice as large in low threshold as in high threshold units, substantially improved the orderliness of recruitment (18% reversals). These results suggest that intrinsic motoneuron properties alone are not sufficient to account for rank-ordered recruitment by motor-with force and that superficie input most along an entire to select scale. by motor unit force and that synaptic input must play an important role.

RELATIVE ENDURANCE AND RECRUITMENT ORDER AMONG PAIRS OF FAST-TWITCH MOTOR UNITS IN THE CAT MEDIAL GASTROCNEMIUS MUSCLE. A.K. Yee, K.E. Tansey and B.R. Botterman. Depts. of Cell Biology & Neuroscience and Physiology, UT Southwestern Medical Center, Dallas, TX 75235.

A muscle's ability to maintain a specified force output is largely determined by the relative forcefulness and fatigability of motor units recruited during a contraction. Generally the earliest recruited and most frequently used units of a muscle produce the smallest tensions and have highest resistance to fatigue Indeed, a number of laboratories, including our own, have shown that a unit's tetanic tension (P_a) is an excellent predictor of its order within a motor pool. It is less clear whether a similarly strong correlation between recruitment order and fatigability exists among fast-twitch units of medial gastrocnemius (MG). Based on the strong correlation (r=-85) between P_o and endurance time (E_i) in MG units (*J. Neurophysiol. 60:1215,1988*), such a relationship might be expected. The present experiments were undertaken to test directly this possibility.

In decerebrate, unanesthetized animals spinalized at C1, pairs of motor axons were isolated from the MG nerve and their recruitment order determined during monosynaptic reflexes elicited by stimulation of the L₇+S, dorsal roots. If one or both units of a pair were recruited during the reflex, then their P_e's and E's were determined. E, was the length of time that a unit could maintain 25% of its P. Unit tension was clamped at this output level by altering the stimulation rate of a unit's axon through computer feedback control. For 6/7 pairs of units studied in 3 experiments, the lower threshold unit had the smaller Po and the larger E_{r.} In the remaining pair, the lower threshold unit had a P_o and E_r of 28.7g and 156.5s, compared to 20.6g and 236.4s for the higher threshold unit.

The present study provides additional evidence that motor units of a pool are

generally recruited in order of increasing fatigability. Among fast-twitch units of MG, the correlation between recruitment order and E, would seem to be as strong as that observed previously between recruitment order and P_e. (NIH NS17863)

STRETCH EVOKED MONOSYNAPTIC EPSP AMPLITUDES IN ANKLE EXTENSOR MOTORNEURONS ARE INCREASED IN THE CHRONIC SPINAL CAT A. Jones, S. Hochman, and D. McCrea. Dept of Physiology, University of Manitoba, Winnipeg, Manitoba Canada, R3E 0W3.

Earlier work in this lab showed that the amplitudes of electrically-evoked

homonymous EPSPs in 6 week chronic spinal cats were increased in lateral gastrocnemius but not medial gastrocnemius motoneurons. The present study used muscle stretch to evoke combined homonymous and heteronymous EPSPs in triceps surae and plantaris motoneurons in unlesioned and chronic spinal (L1-Lt2) barbiturate-anaesthetized cats. Brief (< 2 ms) small (5 to 100 μ m)stretches of the Achilles tendon were used to evoke EPSPs in ankle extensors with initial muscle tensions of 100-500 g. Motor units were also mechanically typed as FF, Fint, FR, or S. Amplitudes of EPSPs evoked by 20 µm (200g initial tension) stretches were increased by more than 70% in ankle extensors including MG in the chronic spinal preparation. In Fast-Fatiguable motor units of chronic spinal cats EPSPs increased by 83%. As stretch amplitude increased, however, the difference between the unlesioned and chronic spinal preparations diminished. Thus stretches that produced sub-maximal EPSPs in the unlesioned state produced considerably larger EPSPs in the chronic spinal preparation. The use of stretch to evoked combined homonymous and heteronymous EPSPs is more likely to mimic clinical assessment of monosynaptic reflexes. We conclude that increased Ia EPSPs would contribute to increased reflex recruitment of all ankle extensor motoneurons in the chronic spinal state. THE EFFECT OF FATIGUE-INDUCED FEEDBACK ON MOTONEURON LATE RATE ADAPTATION IN THE DECEREBRATE CAT. L. Hayward, U. Wesselmann and W.Z. Rymer, Dept. of Physiology, Northwestern University and The Rehabilitation Institute of Chicago, Chicago, IL 60611.

A fatigue-induced inhibitory motor reflex (Woods J., et al., J. Neurophysiol.

58:125, 1987) has been identified as one possible mechanism underlying the decline in mean motor unit firing rate observed during fatiguing contractions in humans. Previously, we demonstrated that small diameter muscle afferents are stimulated during fatigue and may mediate this inhibitory reflex. In the present study the effect of this fatigue-induced inhibitory reflex on motoneuron rate adaptation was examined in the decerebrate cat.

MN discharge rate was recorded from medial gastrocnemius (MG) motor axons isolated from a small filament cut from the intact MG muscle nerve. Muscle force, Isolated from a simal finament cut from the inact five function (such as the first property), the first property of the first proper Tate rate adaptation, supporting the role of reflex modulation of MN rate during fatiguing contractions. Before fatigue there was a significant correlation between the initial discharge rate of a MN (measured at 1.5 seconds) and the drop in rate over 5 seconds. During fatigue alone moderate changes in the drop in rate over 5 seconds. seconds. During largue atotic molectaic charges in the drop in rate was measured in only 4 of 17 MNs recorded (one-way ANOVA, p<0.05). During fatigue combined with ischemia the drop in rate over 5 seconds increased in all the MNs recorded. This fatigue/ischemia-induced change was significant in 7 out of 14 MNs tested. Procaine block (0.01%) of the MG muscle nerve produced a reversal of the fatigue/ischemia-induced changes in 6 of 8 motoneurons.

MEMBRANE ELECTRICAL PROPERTIES OF EXTERNAL URETHRAL SPHINCTER AND EXTERNAL ANAL SPHINCTER MOTONEURONS IN THE DECEREBRATE CAT. S. Hochman, B. Fedirchuk, and S.J. Shefchyk. Depts. Med. and Physiol., Univ. of Manitoba, Winnipeg, Canada R3E 0W3.

Intracellular measurements were made of passive and threshold membrane properties of antidromically identified pudendal motoneurons innervating either the external urethral spincter (EUS) or the external anal sphincter (EAS). Mean values for EUS and EAS motoneurons were similar and are combined in the Table below. A strong correlation between motoneuron input resistance and membrane time constant suggests that the variations in input resistance between motoneurons depend primarily on membrane resistivity rather than cell size and geometry. The mean electrotonic length of 1.4 is identical to that of hindlimb motoneurons. Compared to hindlimb motoneurons, however, these cells have higher input resistance, lower rheobase and conduction velocity and a longer afterhyperpolarization duration. Although the electrical properties most closely resemble those of hindlimb motoneurons innervating slow twich muscle, EAS is a predominantly fast muscle in the cat (Krier et al., Am. J. Physiol., 255). Subthreshold rectification processes (i.e. anomalous rectification and SAG) were found in several motoneurons. A preliminary examination of motoneuron firing properties suggest that these motoneurons can be made to fire rhythmically with the interval between first and second spikes reaching a minimum of 3.6 - 7.0 ms near 4 times rheobase current.

afterhyperpolarization duration (ms)	98	rheobase (nA)	3.4
conduction velocity (m/s)	48	threshold voltage (mV)	8.1

MOTOR UNIT PROPERTIES AND REFLEX RECRUITMENT IN THE MEDIAL GASTROCNEMIUS OF THE DECEREBRATE CAT. B.D. Clark and T.C. Cope. Dept Physiol & Biophys, Hahnemann Univ, Philadelphia, PA 19102.

It has been reported that in decerebrate cats the motor unit of a pair with the lower axonal conduction velocity (CV) was almost always recruited first in muscle stretch reflexes (Bawa et al., J. Neurophysiol., 1984). We measured multiple motor unit properties under these same conditions to determine their relationships with recruitment sequence and to assess the possible dependence of recruitment on the source of synaptic drive. Axons of medial gastrocnemius (MG) motoneurons were penetrated 2 at a time with microelectrodes in ventral rootlets of decerebrate cats. The rank order within unit pairs by CV (42/55), maximum isometric force (40/53) and potentiated twitch contraction time (32/37) were significantly associated (G test; p<0.005) with recruitment order elicited by MG stretch. These findings differ from those of Zajac and Faden (J. Neurophysiol., 1985), who found recruitment by high frequency stimulation to be perfectly ordered by tension. Reversal of the recruitment order obtained with MG stretch was observed in 5/19 pairs during electrical stimulation of the sural nerve; reversal also occurred in 2 trials involving combined stretch of MG and synergistic muscles. We conclude that recruitment does not proceed in strict accord with any measured physiological property, and that it may indeed depend on the source of synaptic drive. (Supported by NIH NS21023)

OPERANT CONDITIONING OF TRICEPS SURAE H-REFLEX: THE FIRST DAYS. <u>J.R. Wolpaw.</u> Wadsworth Labs, NY St Dept Health & SUNY, Albany, NY 12201. Earlier studies have shown that monkeys (Macaca

nemestrina) can gradually increase or decrease the size of the spinal stretch reflex (SSR) or of its electrical analog the H-reflex (HR), and that such conditioning changes the spinal cord itself (Wolpaw & Carp, <u>TINS</u> 13:137-142, 1990). SSR conditioning occurs in two phases: a rapid phase I change of about 8% occurs within 6 hours and a very gradual phase II change of 1-2%/day occurs over at least 40 days. Previous data suggested similar phases in HR conditioning. The present study, comprising data from 33 HR animals (20 HRup & 13 HRdown), further evaluates change in the first days.

The HRup data showed a marked phase I increase. Initial analysis indicated that it was about twice as large as the phase I increase with SSR conditioning. In contrast, the HRdown data, while showing amplitude decline in the first days, did not appear to show an abrupt phase I decrease.

These results could indicate a fundamental difference

These results could indicate a fundamental difference between HRup and HRdown conditioning. However, it seems more likely that they reflect the presense of a nonspecific factor, associated with the onsets of both HRup and HRdown conditioning, that acutely increases HR size, thereby exaggerating HRup phase I change and cancelling out HRdown phase I change.

DO MUSCLE AND MOTONEURON CHANGES ACCOUNT FOR LOCOMOTOR DEFICITS AFTER SENSORIMOTOR CORTEX LESIONS IN RATS? D.M. Basso, A.M. Gentile and D.G. Stein. Brain Research Laboratory, Rutgers-The State University, Newark, NJ 07102

This study evaluated the effects of sensorimotor (SM) cortex lesions on locomotor behavior, muscle and motoneuron (MN) morphology and metabolism. Sprague Dawley adult rats (n=24) were pre- and postoperatively trained to locomote on a narrow elevated runway. Twelve rats had bilateral SM aspirations (SM) and 12 were sham operated. After 15 days, animals were sacrificed and sections of brain, cord L_{3.5}, Soleus and Extensor Digitorum Longus were taken. Using mean run time (RT) and cinematographic measures of the hindlimb swing movement, locomotion of SM rats was found to be significantly impaired postoperatively. Although SM rats achieved preoperative RT by the 7th session, the hindlimb movement deficit persisted. There was no apparent muscle atrophy or change in metabolic activity following SM damage. Hence, the aberrant movement patterns that persist following SM removal appear unrelated to changes at the muscle level.

GOING FOR A WALK INDUCES WIDESPREAD EXPRESSION OF THE FOS PROTEIN PRODUCT OF THE C-FOS PROTO-ONCOGENE IN CENTRAL MOTOR SYSTEMS. K.R. Gogas. S.C. Ahlgren, J.D. Levine and A.I. Basbaum Depts. of Anatomy, Physiology and Medicine, UCSF, CA 94143.

Most studies that monitor the expression of c-fos to define populations of active

neurons use an exogenous stimulus and/or drug. This study evaluated the pattern of Fos expression that results from a maintained behavior, namely walking on a rotarod

Fos expression that results from a maintained behavior, namely walking on a rotarod treadmill. The rotarod was set at a slow turning speed (2rpm) so that the rats could walk uninterrupted for one hour. The rats were then anesthetized, perfused and sections of brain and spinal cord were processed for Fos-like immunoreactive (FLI) neurons. Some rats underwent unilateral dorsal rhizotomies (C5-T1) prior to testing. The pattern of FLI in both the lumbar and cervical enlargements was comparable. Numerous cells were found in the nucleus proprius, in the medial parts of laminae V,VI and the inner substantia gelatinosa. Finally, cells were found in the ventral hom, including several densely labelled motorneurons. Labelled cells were also found in the dorsal column nuclei (DCN) and in the lateral cuncate nucleus. The cerebellum contained were extremised bebling in the flocoulus and pareforchus and in the in the dorsal column nuclei (DCN) and in the lateral cuneate nucleus. The cerebellum contained very extensive labelling, in the flocculus and paraflocculus and in the cerebellar hemispheres. The labeling was concentrated in dense patches of granule cells. Some folia contained labelled cells in the molecular layer. Purkinje cells were never labelled. Because of the relatively high basal level of Fos expression in the cerebral cortex, this region was not further analyzed. With the exception of the flocculus, deafferentation significantly reduced the numbers of FLI neurons in the spinal cord, medulla and cerebellum ipsilateral to the rhizotomy.

We conclude that walking results in widestread expression of the cafes prote-

spinal cord, medulla and cerebellum ipsilateral to the rhizotomy.

We conclude that walking results in widespread expression of the c-fos protooncogene; the effect of rhizotomy indicates that this is, in part, generated via input
over large diameter afferents from muscle and joints. The appearance of labelled
motorneurons (previously unreported even after peripheral nerve stimulation or
section) and labelling in the DCN (not seen after non-noxious peripheral stimulation)
indicates that the pattern of inputs may be critical to the induction of this early
response gene. Supported by NS 14627, 21445, 07265 and AM32634

MEDIOVENTRAL MEDULLA-LOCOMOTOR REGION SPINAL PROJECTIONS IN RAT. Y Ishikawa*, R.D.Skinner and E.Garcia-Rill
Department of Anatomy. University of Arkansas for Medical Sciences, Little Rock, AR.

Previously we described a region in the rat medioventral medulla (MED) which, 1) can be electrically and chemically activated to produce locomotion, and 2) receives input from the mesencephalic locomotor region. The MED includes most of the NR gigantocellularis pars alpha (GiA), the rostral half of pars ventralis (GiV) and the ventralmost region of NR gigantocellularis (Gi) dorsal to GiA and GiV. True Blue (TB) was injected (0.2 µl x 6) into the cervical enlargement and 6-7 days later Nuclear Yellow (NY) was injected (0.1 μ I x 6) into the lumbar enlargement. After 1-2 days, the rats were anesthetized and perfused with 4% paraformaldehyde in phosphate buffer. Labeled cells were plotted on outlines of sagittal sections using a fluorescence image-analysis system (Biographics). Single TB and NY-labeled neurons were found throughout the medial medulla and caudal pons in Gi, GiA and GiV, and NR magnocellularis (MC) and pontis caudalis (PC). Single TB-labeled neurons were more numerous and their distribution extended more into MC and PC. TB-NY double-labeled neurons tended to cluster in the MED region with 58% of them being found within this small region. They represent 15% of all labeled MED cells (TB 36%, NY 49%). These results suggest that the MED-locomotor region has descending output to each of the enlargements with some projections to both. Supported by USPHS Grant NS 21981.

EFFECTS OF MOVEMENT HISTORY AND REFLEX ACTION ON MUSCLE STIFFNESS PROPERTIES OF THE DECEREBRATE CAT. R.F. Kirsch, D. Boskoy, and W.Z. Rymer, Northwestern Univ. Med. School, Chicago, IL 60611.

The intrinsic stiffness properties of triceps surae muscles of the decerebrate cat, and the impact of reflex action on these properties, were examined in 10 preparations for two conditions: during the transition from the isometric state to motion produced by 'step" stretches of several amplitudes and during the continuous movement imposed during various stochastic perturbations. Mean force was established by the crossed extension reflex or electrical stimulation of the muscle nerve. In 4 experiments, muscle responses were examined before and after deafferentation by dorsal rhizotomy.

Areflexive muscle responded in qualitatively different ways to the step and stochastic perturbations. Previously stationary muscle "yielded" abruptly if the muscle was stretched more than a fraction of a millimeter, with force declining while length was still increasing. After an initial transient phase, however, stochastically-perturbed muscle reached an equilibrium condition where force variations were linearly related to the length changes and no further amplitude-dependent nonlinearities were observed, even though movements larger and more rapid than those which caused yielding during "step" trials were common.

Reflex action was found to offset these intrinsic muscle properties, significantly enhancing muscle stiffness during step stretches, but having a more modest effect during stochastic perturbations. In both cases, however, the effect of reflex action appeared to be predictive in nature. The reflexively-mediated increase in stiffness during stochastic trials was not shifted in time by known loop delays, but simply scaled the instantaneous stiffness magnitude. Reflex responses during step stretches also preceded those expected of a negative feedback response to yielding.

It is hypothesized that reflex action in this preparation is organized in a loose, predominantly predictive manner to prevent catastrophic muscle nonlinearities rather to rigidly regulate any particular property such as muscle length or stiffness.

LOCALIZATION OF SPINAL NEURONS ACTIVATED DURING TREADMILL

LOCALIZATION OF SPINAL NEURONS ACTIVATED DURING TREADMILL LOCOMOTION USING THE C-FOS IMMUNOHISTOCHEMICAL METHOD. X.Dai*, J.R.Douglas*, J.I.Nagy, B.R.Noga, and L.M.Jordan. Dept. of Physiology, University of Manitoba, Winnipeg, M.B. R3E 0W3
Immunohistochemical detection of the proto-oncogene c-fos expression has been used successfully to detect spinal cord neurons activated by sensory stimulation (Hunt et al., Nature, 328:632, 1987). We have adopted this method to determine the location of spinal cord neurons which show c-fos induction during treadmill

the location of spinal cord neurons which show c-fos induction during treadmill locomotion induced by stimulation of the mesencephalic locomotor region (MLR). Cats were anaesthetized with halothane, intubated and then decerebrated at the precollicular-postmammillary level. Following a recovery period (1 hour), the MLR was electrically stimulated (50-150 µA, 0.5 mscc duration pulses, 20 Hz) to induce bouts of treadmill locomotion over a 9 hour period. Control animals were subject to the same procedure but were not electrically stimulated. The animals were perfused with a mixture of 4% paraformaldehyde and 0.2% picric acid in the phosphate buffer solution ten hours after decerebration, and the spinal cord (L3-S1) was recessed for c.fos impunopractivity.

phosphate buffer solution ten hours after decerebration, and the spinal cord (L3-S1) was processed for c-fos immunoreactivity.

In cats subject to the locomotor task, most labelled cells were found in Rexed's laminae III, IV, VI, and VII. A bimodal distribution of labelled cells was found among Rexed's laminae, such that labelled cells in the dorsal horn were concentrated mostly in laminae III and IV. A more ventrally located group of labelled cells was concentrated in lamina VII, with some extending into lamina VI. Very few labelled cells were observed in control cats. It is suggested that cells primarily located in laminae VI and VII are involved in the production of MLR-evoked locomotion. The dorsal group of labelled cells may have been activated primarily located in laminae VI and VII are involved in the production of Mrk.-evoked locomotion. The dorsal group of labelled cells may have been activated largely due to afferent feedback from the moving limb. The results are consistent with those obtained previously (Fortier et al., Soc. Nsci. Abstr., 1988) and show that M.R. stimulation activates interneurons mostly in laminae VI and VII of the lower lumber segments. Supported by the Medical Research Council of Canada.

ENTRAINMENT OF THE LOCOMOTOR RHYTHM IN SPINAL CATS BY STRETCH OF ANKLE EXTENSOR MUSCLES.

ENTRAINMENT OF THE LOCOMOTOR RHYTHM IN SPINAL CATS BY STRETCH OF ANKLE EXTENSOR MUSCLES.

K.G.Pearson and J.M.Ramirez. Department of Physiology, University of Alberta, Edmonton, Canada.

In walking cats the transition from stance to swing in each leg is regulated by afferent input. The identity of the proprioceptors involved in this regulation has not been firmly established, although receptors associated with the hip and with the ankle extensor muscles have been implicated. To further investigate the role of proprioceptive input from ankle extensor muscles we have examined the influence of rhythmically stretching the ankle extensor muscles on the locomotor pattern generated in chronic spinal cats (3 to 10 days after spinalization). Both hindlegs in adult cats were extensively denervated leaving intact the innervation to ankle extensor and knee flexor muscles. Following decerebration and recovery from anesthetic Clonidine (50 to 100µg/Kg) was administered i.v. thus enabling sustained sequences of locomotor activity to be elicited in response to stimulation of the skin of the perineum. When the ankle extensor muscles of both legs were rhythmically stretched in antiphase the locomotor rhythm was entrained over a wide range of frequencies (0.4 to 1 Hz). At all frequencies the bursts of activity of knee flexor activity commenced immediately following the onset of the shortening phase of the stretch and following a marked decline in the force in the ipsilateral ankle extensor muscle. Currently we are attempting to establish whether the decrease in muscle learnth or the decline in a tempting to establish whether the decrease in muscle a marked decline in the force in the ipsilateral ankle extensor muscle. Currently we are attempting to establish whether the decrease in muscle length or the decline in extensor muscle force is responsible for initiating flexor burst generation. One indication for the latter is that the locomotor rhythm can be entrained by rhythmically stimulating the distal cut stump of one L7 ventral root at strengths that are below those necessary to activate \(\gamma \)—motoneurons. Thus our findings are consistent with the notion that a necessary condition for the initiation of the swing phase is a decline in the force in extensor muscles.

RESPONSES TO HIND PAW STIMULATION DURING BACKWARD AND FORWARD WALKING IN CATS. J. A. Buford and J. L. Smith. Neuromotor Control Laboratory, Dept. Kinesiology, UCLA, Los Angeles, CA 90024-1568. We have previously described kinematics (Buford et al. 1988) and EMG (Buford and

We have previously described kinematics (Buford et al. 1988) and EMG (Buford and Smith 1989) for backward (BWD) and forward (FWD) treadmill walking in normal cats. Although details of the EMG distinguished motor patterns for BWD and FWD walking, flexors were active in swing and extensors were active in stance for both directions.

Our present studies explore cutaneous reflexes referred to as "stumbling corrective" reactions by Forssberg (1979). An object striking the paw anteriorly would be an obstacle during FWD swing, but not during BWD swing. How will the neuromuscular responses to paw stimulation differ for BWD and FWD walking? To investigate, we implanted EMG electrodes in selected hindlimb muscles of cats trained to walk BWD and FWD on a motorized treadmill (0.4-0.6 m/s). Stimuli were applied at various stages of the step cycle through subcutaneous electrodes at the anterior aspect of the naw and EMG and cine data were recorded.

paw, and EMG and cine data were recorded.

Our prior studies demonstrated that semitendinousus (ST) was active throughout swing for BWD walking, compared to the two-burst pattern with activity at paw off and at paw contact for FWD walking. EMG data indicate that despite different patterns for BWD and FWD walking, reflex responses for ST were similar. For both directions, ST was activated at short (10-20 ms) and medium (40-55 ms) latencies for stimuli delivered in swing, and ST did not respond to stimuli in stance. The anteriorly applied stimuli tended to cause posterior motion of the paw, retarding forward limb motion during FWD swing and accelerating backward motion during BWD swing. For both directions, anterior biceps femoris (ABF), a hip extensor active in stance, was inhibited at medium (20-25 ms) latency by stimuli delivered in stance, but showed no response to stimuli delivered in swing. Kinematic responses in stance were slight.

at medium (20-25 ms) latency by stimuli delivered in stance, but showed no response to stimuli delivered in stance, but showed no response to stimuli delivered in swing. Kinematic responses in stance were slight.

Thus, for ST and ABF, EMG responses to dorsal paw stimuli were similar for BWD and FWD walking, suggesting similar control for both directions. Other muscles under study may show different, context-dependent responses for BWD and FWD walking. The present data support a multi-use CPG model. Supported by NIH NS19864.

POTENTIAL SOURCES FOR DIFFERENTIAL CONTROL OF TWO SHORT-LATENCY CUTANEOUS PATHWAYS TO CAT FDL MOTONEURONS. R.E.Burke, G.N.Sholomenko and A.K.Moschovakis Lab. of Neural Control, NINDS, NIH, Bethesda, MD 20892

Previous work from this laboratory has shown that low threshold cutaneous afferents in the superficial peroneal (SP) and medial plantar (PLNT) nerves produce minimally-disynaptic excitatory postsynaptic potentials (EPSPs) in flexor digitorum longus (FDL) α-motoneurons. SP and PLNT EPSPs are differentially modulated in various step cycle phases during fictive locomotion in the decerebrate cat (Schmidt et al., *Exp. Brain Res.* 71:568, 1988; Sholomenko et al., *Soc. Neurosci. Abstr.* 15:394, 1989). This indicates that the SP→FDL and PLNT→FDL pathways are entirely separate interneuronal systems that are subject to differential control by the central pattern generator (CPG) for locomotion. We have now begun studies to determine whether there are other definable input sources that can exert differential control of the two pathways. To date we have studied the effects from two supraspinal sources, the red nucleus (RN) and Deiters' nucleus (LVN) on transmission in the SP→FDL and PLNT→FDL pathways in adult cats anesthetized with chloralose or in unanesthetized, decerebrate cats. Short trains of pulses (4 pulses, 200 Hz, 50-100µA, monopolar tungsten electrodes) delivered to RN facilitated both SP (n-25) and PLNT (n=27) short-latency EPSPs. Stimulation of LVN produced less consistent results but there was also no evidence of differential effect on SP and PLNT EPSPs in individual neurons. These descending systems thus cannot account for the differential modulation of the two pathways during fictive stepping. Testing of other input sources for differential effects is underway.

MEDIAL GASTROCNEMIUS TENDON FORCES AND MUSCLE ACTIVITY DURING CAT SCRATCHING. P. Carlson Kuha and J.L. Smith. Neuromotor Control Lab., Dept. Kinesiology, UCLA, Los Angeles, CA 90024-1568.

Comparison of hindlimb muscle activities between no-contact 'air scratching' in

Comparison of hindlimb muscle activities between no-contact 'air scratching' in decerebrate cats and contact scratching in normally-behaving cats suggest that force feedback or other motion-related feedback may be important in prolonging the extensor burst and delaying the onset of flexor activity during paw contact (Carlson Kuhta & Smith 1989). To test this hypothesis, fine-wire electrodes were surgically implanted in tibialis anterior (TA) and medial gastrocnemius (MG) and MG-tendon forces were measured by a buckle force transducer. Scratches were elicited by ear stimulation; in some trials EMG and force measurements were synchronized with 100 ff(scine film

measured by a docket force transducer. Scratches were elected by ear summanon; in some trials, EMG and force measurements were synchronized with 100 ft/s ciné film. During each scratch cycle, the paw normally contacted the head at the base of the pinna, and during contact, peak MG tendon forces varied between 3-6 N, about 60% of the peak developed during walking (Walmsely et al. J. Neurophysiol. 1978). Force increases usually coincided with the onset of contact, and MG tendon forces gradually increased to a peak value during contact. The termination of contact usually coincided with peak force. MG-EMG activity preceded paw contact by 15-20 ms, and MG burst durations ranged from 48-84 ms in cycles with low forces vs. high-force cycles, respectively; similarly, cycle periods varied between 138-181 ms. In contrast, TA burst durations remained relatively constant, ≈ 45 ms, in all cycles, with the onset of TA-EMG coinciding with peak tendon force.

TA-EMG coinciding with peak tendon force. Our results suggest that ankle extensor activity varies with cycle period and peak force, suggesting that the timing and amplitude of MG-EMG is influenced by motion-related feedback, either proprioceptive or tactile or both. Possibly, extensor activity is first facilitated by contact or development of contractile force, but as tension increases, feedback may inhibit extensor and facilitate flexor activity, thereby preventing the development of large contact forces at the head. In contrast, extensor bursts are very brief (= 30 ms) in decerebrate air-scratching (Deliagina et al., Brain Res. 1975), a behavior in which no paw contact occurs, thereby limiting modulation by feedback on spinal centers that program scratching. Funded by NIH NS 19864.

GAIT-RELATED SEMITENDINOSUS EMG PATTERNS AND KINEMATICS FOR TREADMILL LOCOMOTION IN CATS. S.H. Chung, J.A. Buford, and J.L. Smith. Neuromotor Control Lab, Dept. Kinesiology, UCLA, Los Angeles, CA 90024-1586

In a recent paper from our lab (Wisleder et al. Exp. Brain Res. 1990), we described gait-related changes in hip and knee joint dynamics during locomotion at a slow walk to a moderately-fast gallop. From our dynamical data, we hypothesized that biarticular posterior thigh muscles, such as the semitendinosus (ST, hip extensor and knee flexor), function differently for walking and trotting than for galloping. Here, we relate changes in ST-EMG patterns to gait-related changes in hindlimb kinematics. We recorded EMG from electrodes surgically implanted in hindlimb muscles including the proximal ST and assessed kinematics from high-speed, cine film.

During walking and trotting, there were two ST-EMG bursts for each step, one

During walking and trotting, there were two ST-EMG bursts for each step, one associated with paw off (STpo) and one with paw contact (STpc). STpo onset preceded the knee E3-F reversal (ext.-flex.), occurring before paw off for walking but at paw off for trotting. Cycle period decreased markedly with increased speed, but STpo burst durations did not change. In contrast, an increase in integrated STpo burst amplitude reflected an increased range of knee flexion during swing. STpc onset preceded paw contact and coincided with the E1-E2 reversal (ext.-flex.), occurring at contact for walking but before contact for trotting. STpc burst duration and amplitude increased with speed and reflected a greater need to decelerate the hindlimb's forward motion (hip flexion and knee extension) at the end of swing. Taken together, our data suggest that the two bursts which characterized the walk and trot—STpo and STpc—are under different sensorimotor control by spinal or supraspinal circuits.

different sensorimotor control by spinal or supraspinal circuits.

During the gallop, ST activity was markedly different. There was only one major ST burst during swing which occurred appreciably after the knee F-E1 reversal and preceded the onset of knee flexion just before contact. This burst was largely coactive with extensors at the ankle, knee and hip and may increase hindlimb stiffness for an effective stretch-shorten cycle in stance. Research supported by NIH NS 19864.

PHASIC MODULATION OF EPSPs IN EXTENSOR MOTONEURONES EVOKED BY Ib INPUT DURING FICTIVE LOCOMOTION IN THE SPINAL CAT. J.-P. Gossard, H. Hultborn*, I. Barajon*, O. Kiehn* and B. Corway*. Dept. Neurophysiology, Univ. Copenhagen, DK-2200 Copenhagen, Denmark. Proprioceptive input from knee and ankle extensors are able to reset the fictive but the incident with selections and the control of the contr

Proprioceptive input from knee and ankle extensors are able to reset the fictive rhythm in spinal cats injected with nialamide and L-DOPA by aprutly terminating the flexor activity and initiating an extensor burst (Conway et al. Exp. Brain Res. 68: 643-656, 1987). This study investigates the changes in transmission in the lb excitatory pathway to extensors that occur during fictive locomotion.

Cats underwent anaemic decerebration and spinalization (T12) under steroid anesthesia. Muscle nerves from both hindlimbs were dissected and mounted to be recorded or stimulated. Laminectorny was performed and motoneurones were recorded with K+-acetate micropipettes. Slow infusion of nialamide and L-DOPA first uncovered long-lasting FRA responses and later induced sustained fictive locomotion.

locomotion.

Responses to the stimulation of different nerves were recorded in ankle extensor motoneurones during the long-lasting FRA responses and later in different parts of the fictive locomotor cycle (LC). Before the L-DOPA infusion, the stimulation of plantaris (or medial gastrocnemius (G), lateral G-soleus, quadriceps; 1.6 to 2.0xT) elicited IPSPs in the impaled cells. Slow infusion of L-DOPA decreased progressively the amplitude of the IPSPs and revealed EPSPs (Ib EPSPs) of increasing amplitude (>10mV). Injection of depolarizing currents in the motoneuronal soma through the micropipette increased the amplitude of the Ib EPSPs while hyperpolarizing currents decreased it. During fictive locomotion, the amplitude of the EPSPs was profoundly modulated through the LC: minimum during the extensor phase and maximum during the flexor phase. The maximum locomotor drive potential in the recorded cells were always out-of-phase with the maximal Ib EPSP.

One possible explanation is that transmission of the Ib EPSP is occluded during

One possible explanation is that transmission of the Ib EPSP is occluded during the extensor phase when the "extensor center" mediating the Ib EPSP is already active.

RESPONSES TO MICROSTIMULATION OF THE MEDIAL RETICULAR FORMATION DURING FICTIVE LOCOMOTION IN THE DECERBRATE CAT. M-C. Perreault, T. Drew and S. Rossignol, Centre de Recherche en Sciences Neurologiques, Univ. de Montréal, Montréal, Québec, Canada.

Short (30ms) trains of stimuli delivered to the medial medullary reticular formation (mMRF) in the decerebrate walking cat evoke short latency phase-dependent responses in both extensor and flexor limb muscles; such trains have only weak effects on the duration and the timing of the step cycle (Drew and Rossignol, <u>J. Neurophysiol.</u>, 55 375-410, 1984). In the present study we have examined the effects of similar mMRF stimulation during fictive walking. Trains of stimuli (30ms train of 0.2ms pulses at 330Hz, 20-40uA) were delivered

Trains of stimuli (30ms train of 0.2ms pulses at 330Hz, 20-40uA) were delivered to the mMRF through glass-coated tungsten microelectrodes in three decerebrate and curarized cats. Along each electrode trajectory, the stimuli, applied at 3-5 depths, were delivered at different phases of the fictive locomotor cycle. The electroneurographic activity was monitored with monopolar cuff electrodes placed around the proximal part of sectioned motor nerves of each of the four limbs.

The stimulation evoked short latency excitatory responses (6-13ms), in both flexor and extensor motor nerves, which were often followed by a period of inhibition (lat = 25-45ms). Although less common, other excitatory responses were also seen at longer latencies (25-30ms). The amplitude of these excitatory responses was modulated in relation to the phase of the cycle in which the stimulus was applied. Unlike the situation in the decerebrate walking cat, these stimuli were also capable of arresting and resetting the rhythm.

Thus, as in the decerebrate cat walking on a treadmill, stimulation of the mMRF may cause transient changes in muscle activity which are modulated as a function of the step cycle. However, the fact that these short trains may also reset the locomotor rhythm, suggests that the effect of this descending pathway on the timing of the locomotor cycle is larger in the absence of peripheral afferent feedback from the moving limbs. SARCOMERES WORK IN THE 'ASCENDING LIMB' IN CAT MEDIAL GASTROCNEMIUS MUSCLE DURING WALKING. A.A. Caputi, J.A. Hoffer & I.E. Pose*. Dept. Clin. Neurosci., U.Calgary, Calgary, Alta. T2N 4N1 Canada. During walking, length changes of cat medial gastrocnemius (MG) muscle fibers depend on their location in the muscle. In particular, proximal fibers move over a wider range (100-150% of "resting" length) than distal fibers (90-110%; SN Abstr 15:521, 1989). We have now investigated fiber movement at the sarcomere level. End-to-end fiber length was recorded at up to four different mid-sagittal MG locations during walking, using ultrasound transit-time. Post-mortem, in the formalin-fixed muscles of four cats, fiber fascicles were teased from locations where piezoelectric crystals had been sutured, sarcomere spacings were measured optically, average sarcomere lengths were calculated and total numbers of sarcomeres per fiber were estimated. Sarcomere lengths used by each cat during walking were then estimated from the in-vivo fiber length recordings.

The total number of sarcomeres per fiber increased linearly from 6000 ± 500 (SD) in proximal fibers (at 20% of the MG belly length) to 11500 ± 1000 in distal fibers (at 100%). During level walking at ~5 m/s, the amplitude of sarcomere movement decreased linearly from .70 ± .08 µm for proximal fibers to .44 ± .08 µm for distal fibers. In spite of these systematic, site-specific differences, at mid-stance phase the average sarcomere length was 1.81 ± .10 µm in all measured MG muscle locations.

Thus, although the length changes of muscle fibers depend systematically on fiber location, all sarcomeres work at the same length during the phase of walking when the MG muscle is both active and loaded. Since sarcomere lengths of 1.7-1.9 µm fall in the 'ascending limb' of the sarcomere length uring the phase of walking when the MG muscle is both active and loaded. Since sarcomere lengths of 1.7-1.9 µm fall in the 'ascending limb' of the sarcomere length uring the phase of walking when th

ALPHA-MOTONEURON ACTIVITY, AFFERENT ACTIVITY AND MUSCLE FIBER MOVEMENT SIMULTANEOUSLY RECORDED FROM CAT MEDIAL GASTROCNEMIUS MUSCLE DURING POSTURE AND LOCOMOTION. J.A. Hoffer and J.L.F. Weytjens. Dept. Clinical Neurosciences, Fac. Medicine, Univ. Calgary, Calgary, Alberta T2N 4N1, Canada.

During cat locomotion, the range and time course of movement of muscle fibers depend systematically on fiber location within the medial gastrocnemius (MG) muscle(^{1,2)}. To interpret the origin of the discharge of muscle afferents as well as to estimate the force-generating reporties of more units, it is thus precessed to below.

muscle(1.2). To interpret the origin of the discharge of muscle afferents as well as to estimate the force-generating properties of motor units, it is thus necessary to take into account local muscle fiber movement, rather than muscle length. We developed a preparation to record simultaneously the activity of individual muscle afferent and efferent neurons and length and pinnation angles changes of relevant muscle fibers. In cats trained to perform a variety of postural and locomotory tasks, the lengths and pinnation angles(2) of MG muscle fibers are obtained from the transit-time of pulsed ultrasound between pairs of implanted piezoelectric crystals. Extracellular action potentials from single motor or sensory axons are recorded by floating microelectrodes chronically implanted in the MG nerve, inserted through a window cut in the wall of a silicone nerve cuff implanted around the whole sciatic nerve. Two tripolar sets of circumferential electrodes inside the cuff serve to identify the direction and velocity of axonal conduction using spike-triegered averagine(3) Two tripolar sets of circumferential electrodes inside the cuff serve to identify the direction and velocity of axonal conduction using spike-triggered averaging⁽³⁾. Artifacts in microelectrode records caused by high-voltage excitation of the crystals are avoided by careful routing and shielding of lead wires. Stable recordings are obtained from individual axons, usually lasting one or several days.

This preparation is currently being used to study relationships between afferent and efferent firing, and between afferent firing, efferent firing and muscle fiber movement, in normal cats and in cats rendered spastic by thoracic hemicordotomy.

CONTROL OF POSTURE AND MOVEMENT: LEARNING AND DEVELOPMENT

369.1

SEARCHING FOR SOLUTIONS: THE ACQUISITION OF COORDINATED MOVEMENT. P. V. McDonald*, R. E. A. van Emmerik*, P. N.

Kugler* and K. M. Newell. Dept. of Kinesiology, University
of Illinois, Urbana, IL 61801

The process of acquiring a skill may be characterized
as an exploratory search for a solution in a region defined

by the confluence of constraints arising from features of the task, the learner, and the environment. The experiments reported examine the exploratory behavior individuals used in mastering redundant degrees of freedom during the acquisition of coordinated movement. Of particular interest were the search strategies used to explore the perceptual-motor workspace and the relation of these strategies to features of the workspace. Subjects were asked to minimize as quickly as possible continuous, real time error information via motion of their two elbows. The error information (z) was generated by some function, z = f(x,y), where x and y were the current joint angles of the two elbows. The data reported address the significance of the gain between elbow motion and error magnitude; the effects of number of local minima; and the symmetry of the function, with respect to a performance criterion, and more importantly the form of the search trajectory through the workspace. By adopting this approach we hope to understand the construction of a perception-action loop established during learning. It is the mapping of the kinematic and kinetic field properties that constrains and organizes the perception-action cycle (Kugler & Turvey, 1987).

369.3

ADAPTABILITY OF MULTI-JOINT ARM MOVEMENTS TO ALTERATIONS IN SEGMENTAL INERTIA. G.K. Kerr and R.N. Marshall*. Univ. Lab. Physiology, Parks Road, Oxford OX1 3PT, and Dept. Human Movement, The Univ. Western Australia, Nedlands, 6009, Western Australia.

Unrestrained uniplanar vertical arm movements made to a target without vision of the limb were examined using a three-dimensional motion analysis system (Vicon). The self paced movements were performed under four load conditions; unweighted, hand weighted, forearm weighted, and upper-arm weighted. Under all experimental conditions hand paths were curved and the tangential velocity profiles were unimodal. Addition of the weight resulted in hand paths that differed from unweighted limb hand paths. These differences were dependent upon the limb segment to which the weight was added. However, subjects adapted to alterations in segmental inertia towards trajectories that were typical of an unweighted limb. This adaptation was extremely rapid and occurred within one to three trials. Our data suggests that the motor control system attempts to maintain a given hand path and tangential velocity profile for a particular movement, irrespective of external load conditions.

369.2

LOAD COMPENSATION IN HUMAN AIMED ARM MOVEMENTS. O.Bock* (SPON: European Neuroscience Association). Human Performance Lab, Inst.f.Space&Terrestrial Science, York University, Toronto, Ont., Canada.
We analysed the execution of pointing movements in

humans while different loads were applied to the pointing hand. Visual feedback on arm and hand was excluded.

Hand movement paths, final positions, and normalized velocity profiles were load-independent except for the very first movement after a load change.

When weight loads (0.45-2.00 kg) were applied, movement velocity decreased and duration increased by the same factor, i.e. the velocity profiles were re-scaled in magnitude and time; rescaling depended consistently on weight size. When spring loads (35 N/m) were applied, scaling of the velocity profiles was not different from no-load trials.

To understand these findings, we propose the following hypothesis of load compensation. The controlled variable of pointing movements is a fictional external force acting on the hand; inertia-, and gravity-related components of that force are controlled separately; changes of inertia are compensated by time-scaling of the inertia-related component, while changes of gravitational (and elastic) load are compensated by magnitude-scaling of the gravity-related component. This hypothesis predicts qualitatively and quan-

titatively well our experimental data.

THREE PHASES OF HUMAN MOTOR LEARNING. H.-G. Ross.

Physiologisches Institut, Universität Düsseldorf, F. R. G.
Tap dancing requires intricate sequences of leg & foot movements with appropriate postural adjustments. Sithese patterns interfere with established postural & loco-

motor routines, tap dancing is hard to learn & thus an excellent paradigm to study the acquisition of motor skills.

The training of 10 adult beginners was observed until they reached an advanced, though not perfect, stage (1 hr/week for 3 yrs). This PHASE 0 (learning the technique) week for 3 yrs). This PHASE 0 (learning the technique), which is not amenable to quantitative assessment, may be the adult analogy of a child's learning to walk.

Thereafter, 3 subjects from this group & a professional (15 yrs of experience) were asked to practice a written

choreography previously unknown to them. Taps were recorded by microphones under the soles of the shoes & evaluated in terms of inter-tap interval histograms. During practice, another two learning phases could be discerned: PHASE I (professional: ca. 400; advanced: ca. 800 taps) characterized by the absence of a detectable pattern, using the wrong foot (or wrong parts of the feet), and periods of hesitation & deliberation. After having understood WHAT t hesitation & deliberation. After naving understood whal to do in PHASE I, subjects switched over to PHASE II, during which the required pattern was correctly produced and facility (accuracy and speed) gradually increased.

Summary: Characteristics of PHASES I & II suggest that

humans apply learning strategies like those seen in monkeys (Brooks, V.B. et al., <u>Physiol. Behav.</u>, 31:561, 1983).

A NEW STUDY OF HUMAN MOTOR LEARNING: STRATEGY AND TACTICS FOR MOVING OBJECTS IN SIMULATED REDUCED GRAVITY

V.B. Brooks², F. Hilperath*, U. Longerich*, H.-G. Ross¹, and H.-J. Freund.

V.B. Brooks², F. Hilperath*, U. Longerich*, H.-G. Ross¹, and H.-J. Freund. Depts. of Neurology, and Physiology II¹, Univ. of Düsseldorf, F.R.G.; and Dept. of Physiology², Univ. of Western Ontario, London, Canada. We show that human subjects need to adopt a behaviorally appropriate task strategy (WHAT to do) in a new manual task before they can use well-programmed movements in task context (skill tactics, HOW to do it). The two kinds of learning always follow one another in two recognizable phases. Subjects moved a stylus on a digitizing tablet to move a cursor accurately and rapidly on a display screen from a start box to a target box. This 'step-tracking' had to be completed in 2 s and the cursor held in target for a further 1 s. Screen vision and auditory cues signalled accuracy and task completion. The learning of a new strategy needed for a simple task, usually obscured by its rapidity in human learning, was studied by inserting a new, non-linear relation between stylus and cursor movements. The cursor was made to move with simulated increased inertia, like an object in space that requires a push to with simulated increased inertia, like an object in space that requires a push to start it and another, opposite one to stop it; implemented through modulating cursor positions on the screen by velocity changes of the hand-held stylus.

Normal, naive subjects at first made unsuccessful task attempts with dysmet-

ric movements, programmed and nonprogrammed. After 60-80 such trials, in a series of 250, each learned to adopt the correct strategy of making two suca series of 250, each learned to adopt the correct strategy of making two successive, oppositely directed hand movements to start and then stop the simulation-induced single glide of the cursor (learning WHAT, phase 1). From then on, most hand start-movements became well-programmed (learning HOW, phase 2) with brief, clustered reaction times. Initially tremulous hand stop-movements became smoother in 100-200 trials. The two learning phases resemble those in normal animal motor learning of ordinary step-tracking tasks. (Brooks VB, Kennedy PR, Ross H-G. Physiol. Behav., 31: 561-563, 1983; Brooks VB, Watts SL. J. Motor Behav., 20: 117-132, 1988).

369.7

INTERSEGMENTAL DYNAMICS OF TREADMILL STEPPING IN INFANTS AND ADULTS J. L. Jensen*, B. D. Ulrich*, E. Thelen, K. Schneider* & R. F. Zernicke.

Department of Psychology, Indiana University, Bloomington, IN 47405 and Department of Kinesiology, UCLA, Los Angeles, CA 90024-1568.

During their first year, infants who cannot stand or step alone will take well-coordinated, alternating steps when supported on a motorized treadmill. Here we compare the qualitative dynamics and underlying apportionment of torques during treadmill steps of 7-month-old infants and adults. Phase plane dynamics showed that infants were unstable at all three leg joints during the stance phase. In the swing, similar pendular actions were observed in the knee in both infants and adults. Qualitative differences in the hip between infants and adults pointed to differences in the underlying control strategy. Intersegmental dynamics revealed that infants maintained a strong flexor muscle torque during the entire swing phase. Adults, in contrast, exploited the inertia of the swing leg and used a flexor muscle torque only to initiate the swing. These results are consistent with a general developmental tendency for increasing exploitation of passive dynamics in the service of intentional movement.

369.9

EFFECT OF AGE AND MOVEMENT SPEED ON COORDINATION OF RISING FROM A CHAIR. M.G. Hoy. Rehabilitation Research and Development Center, VA Medical Center, Palo Alto, CA 94304-1200.

Coordination of rising from a chair depends on movement speed in young adults (Pai, Y.C. et al., <u>Proc. Am. Soc. Biomech.</u>, 1988). Since movement speed tends to decrease with age, the purpose of this study was to determine if the elderly coordinate the task in the same way as young adults.

Seventeen active elderly (71±6 yrs) and six young (24±2 yrs) women were asked to rise from a chair at slow, normal, and fast speeds. Joint motions were quantified with a video-based motion analysis system. Reaction forces were neasured using force plates mounted in the ground and the chair seat Muscle activity data were collected for seven lower-extremity muscles

Although some elderly women moved at the same "normal" speed as young women, they were not able to increase their movement speed as much as the young women in the "fast" trials (elderly 24%; young 36%). The vertical ground reaction force (GRF) maximum when chair contact was lost increased with speed (normal 1.2 bw (body weights); fast 1.3 bw), and the GRF minimum associated with trunk deceleration at the end of the movement decreased with speed (normal 0.8 bw; fast 0.6 bw) for both groups. The peak magnitude of muscle activity relative to the magnitude during standard voluntary contractions tended to be greater for the elderly than for the young women, especially for tibialis anterior (elderly 1.4; young 0.9) and vastus medialis (elderly 1.2; young 0.9).

Differences between young and elderly women during rising may be due to differences in movement speed and muscle strength rather than by a fundamental difference in the ability of the elderly to coordinate the

CHANGES IN SPATIAL PATTERNS OF MUSCLE ACTIVATION FOLLOWING PARALYSIS OF A SYNERGIST MUSCLE. M. Moniz*, J.P.A. Dewald, T.S. Buchanan, R. Beer, J. Erikson, and W.Z. Rymer. Sensory Motor Performance Program, Rehabilitation Institute of Chicago, and Departments of Rehabilitation Medicine & Biomedical Engineering, Northwestern University,

Performance Program, Rehabilitation Institute of Chicago, and Departments of Rehabilitation Medicine & Biomedical Engineering, Northwestern University, Chicago, IL 60611.

In previous studies we have examined muscle activation levels associated with changes in load direction during isometric contractions and have observed orderly spatial patterns of EMG activity, traversing angular ranges up to 180 degrees, with EMG peaks located at or near the angle of optimum muscle mechanical effect [1]. In this study we have investigated the plasticity of these patterns at the wrist and elbow by paralyzing a single muscle and examining the changes in the spatial relations of EMG activity from the remaining muscles acting at the joint.

At the elbow, EMG activities in up to ten muscles were recorded with surface and intramuscular electrodes during controlled static postures. Forces were applied at the wrist and were measured in three dimensions (flexion/extension, varus/valgus, and supination/pronation) while the arm position was fixed at 90° elbow flexion, neutral pro-supination position, and 65° shoulder abduction. At the wrist, EMGs were collected from the five muscles primarily responsible for flexion/extension and radial/ulnar deviation while florces were applied at the hand. At the elbow, the biceps brachii was paralyzed by injecting carbocaine at multiple motor points. For the wrist, the ulnar nerve was blocked at the elbow, which paralyzes the flexor carpi ulnaris.

We observed that, for some muscles with moment arms similar to those of the paralyzed muscle, the peak direction of the EMG activation curves shifted orientations.

We observed that, for some muscles with moment arms similar to those of the paralyzed muscle, the peak direction of the EMG activation curves shifted orientation after neural blockade; however, the polar plots of EMG activity as a function of direction did not broaden following the block. Other muscles with moment arms further away from the blocked muscles (i.e. less spregic muscles) showed little or no change in their spatial patterns of activation. These results suggest that muscles with similar actions are able to compensate for each other within the limits dictated by the orientation of their moment arms, and that patterns of muscle co-activation can be modified quickly (within less than one hour).

LOAD SENSITIVE REGULATION OF PRECISION GRIP: DIFFERENCES IN YOUNG AND OLD SUBJECTS. B.A. Hart and J.H. Abbs. Dept. Human Kinetics, University of Wisconsin-Milwaukee, WI 53201 and Speech & Motor Control Labs, Waisman Center, University of Wisconsin-Madison, WI 53706. Adults in their 6th and 7th decades frequently experience difficulty in manual skills requiring fine grip control. Cutaneous mechanoreceptors of glabrous skin

skills requiring fine grip control. Cutaneous mechanoreceptors of glabrous skin of the hand, which mediate precise force control (Westling & Johansson, 1984, 1987), are known to undergo age related reduction in density and changes in morphology. Although decrements in somatosensory thresholds have been reported for the aged, the functional consequences of such changes, and other nervous system changes, remain to be elucidated. In this experiment we compared young (n=10, avg age=22) and old (n=10, avg age=71) subjects' kinematic and kinetic features of precision grip and lift of a small instrumented object which was randomly varied at .5,1,2,3, or 4 Ns in vertical load. Frictional characteristics of the skin of the finger and thumb pads were assessed by determining the grip force below which the object slipped from grasp (slip force). Although slip force levels tended to be higher for the older subjects, group differences were not significant. Grip force safety margins (i.e., grip force enerated for static hold in excess of slip force) were significantly greater in group differences were not significant. Grip force safety margins (i.e., grip force generated for static hold in excess of slip force) were significantly greater in older subjects (m=2.5N, range=2.3 to 2.7N) than the young (m=1.45N, range=30 to 2.4N). Further, the safety margins were uniform across loads in the old but proportional to load in the young subjects. Group differences were found for the dynamic phase of the task as well. Duration of grip force onset to initial object displacement was 30% longer for the old, who concomitantly reached a significantly higher grip force prior to displacing the object. In spite of non-significant group differences in two-point discrimination and slip force levels, the older subjects demonstrated a grip and lift pattern which was slower, overly forceful, and not well scaled to the object load. Such performance characteristics may reflect subtle changes in hand sensibility, or alternatively, age related changes in integration of sensory and motor processes.

WITHDRAWN

INFORMATION FEEDBACK PRODUCES INTERFERENCE IN REPRODUCING MOVEMENTS. D.E. Nicholson and R.A. Schmidt*. Motor Control Laboratory, University of California, Los

Knowledge of results (KR), a type of information feedback, when presented frequently, degrades long-term retention of motor skills. One explanation for this finding is that frequent KR increases performance variability, and KR-induced variability is detrimental to long-term retention. UCLA undergraduates (N=80) attempted to depress a lever for 1600 msec. Subjects practiced 68 trials, with KR presented after 50% of the trials. On 16% of the 68 trials, instead of attempting to achieve the 1600-msec goal, subjects were instructed to repeat their previous movement; KR, when presented, preceded repeat instructions. After repeat instructions, performance was more consistent than when attempting a 1600-msec goal (pc.01). After KR, changes in performance were large, relative to when KR was withheld. Even when instructed to repeat, KR produced systematic changes in performance, relative to no-KR conditions (p<.01). This interference, produced during attempts to repeat movements after KR, suggests that KR causes subjects to "update" previous movement representations, leading to increased variability on subsequent trials.

DEVELOPMENTAL ASPECTS OF INTERSENSORIMOTOR INTE-GRATION.A. J. Chicoine², L. Proteau¹ and M. Lassonde^{2*}. ¹U.Q.T.R., Trois-Rivières, Canada, G9A 5H7, ²Lab. de Neuropsychologie Expérimentale, Université de Montréal, Canada, H3C 3J7. The ontogenesis of the ability to integrate different sources of afferent The ontogenesis of the ability to integrate different sources of afferent information in order to perform accurate aiming movement was studied in 3 groups of subjects (5-6, 11-12 and 20-30 years of age). In each group, half the subjects performed 144 acquisition trials under a condition where only the target to be reached was visually available (target only condition, TO) while the other half were allowed to see both the target and their aiming movement (full vision condition, FV). Knowledge of results (KR) was provided after each trial. Following the acquisition period, all subjects were submitted to the same transfer task performed under the TO condition, with no-KR. The root mean square error of aiming accuracy obtained under the acquisition and transfer conditions was used to compute an index of aiming deterioration. The results showed that the subjects who practiced under the FV condition suffered a large increase in error when submitted to the transfer task and this effect was more pronounced in the older groups (3.34, 2.68 and 1.50, respectively). The fact that the younger subjects showed less decrease in accuracy than older subjects when submitted to the transfer task support the notion that the improvement of aiming accuracy occurring during childhood is linked to the ability to integrate numerous occurring during childhood is linked to the ability to linegrate numerous sources of sensory information. These results further lead to the conclusion that the underlying principle for skilled movement acquisition is intersensorimotor integration, where the available sources of sensory feedback are integrated and used in conjunction with central planning and execution processes to form the basis of movement representation.

A LONGITUDINAL STUDY ON THE TRANSITION TO INDEPENDENT

A LONGITUDINAL STODY ON THE TRANSITION TO INDEPENDENT STANCE IN CHILDREN H. Syesistrup* M. Woollacott, A. Shumway-Cook an G. McCollum. Univ. of Oregon, Eugene, OR 97403.

This set of experiments is part of a larger study which takes a system approach to the study of the emergence of independent stance, determining the contributions of and interactions among sensory, motor, and musculo-skeletal feeters. The dayaloment of holoace control has practicable bean studied secret contributions of and interactions among sensory, motor, and musculo-skeletal factors. The development of balance control has previously been studied cross-sectionally in children but cross-sectional studies mask some of the important factors in temporal sequencing and the individuality of developmental paths. Mature postural responses to anterior platform translations consist of activation of the stretched ankle muscle (tibialis anterior (TA) at 80-100 ms), then the thigh (quadriceps (Q)) and trunk (abdominal (A)) muscles at 20-40 ms lags.

In this study longitudinal data from 4 children aged 7-14 mos were grouped into 3 developmental stages: dependent stance 1 (pulls to stand using arms), dependent stance 2 (pulls to stand using half-kneet), and independent stance. Surface EMG measured the responses from the left TA, Q, A, gastroc. (G), hamstrings (H), and trunk extensor (TE) muscles to anterior or posterior supports surface perturbations. Muscle strength was also monitored across stages.

(G), hamstrings (H), and trunk extensor (TE) muscles to anterior or posterior support surface perturbations. Muscle strength was also monitored across stages, by determining the % of the child's total weight that she could support. All children were able to support their total body weight well before the emergence of independent stance. However, no organized responses were present in children for either direction of platform perturbation at the beginning of the phase 1 of dependent stance. Preliminary results showed differences in the development of 'extensor' synergies (G-H-TE) vs. "flexor' synergies (TA-Q-A). The TA-Q-A synergy emerged first, with the G-H-TE synergy emerging approximately 4 weeks later. The frequency with which responses could be elicited increased gradually across phases. This was accompanied by a decrease in the absolute latency and the variability of response onset. As independent stance emerged, there was a temporary increase in response variability, and disruption in response organization followed by further refinement of response characteristics. MOTOR LEARNING OF SINGLE-JOINT (ELBOW) MOVEMENTS WITH ASYMMETRIC VELOCITY PROFILES. J.L. McFarland, S.M. Botros*, and C.G. Atkeson. Department of Brain and Cognitive Sciences, Massachusetts Institute of Technology, Cambridge, MA 02139

We set out to test the hypothesis that the human neuromuscular system is specialized to produce limb movements with symmetric tangential velocity profiles by asking subjects to make single-joint (elbow) arm movements with specific tangential velocity profiles. We studied the motor learning of movements with asymmetric and symmetric velocity profiles. If there were no differences in the learning or performance of these two classes of movements then we would have evidence for rejection of this hypothesis. Subjects performed horizontal elbow movements with specific amplitudes, durations, and velocity profiles. Immediately after each trial the subject was shown a display of their actual movement (both position and velocity over time) superimposed on a template of the desired movement. Subjects typically performed more that 50 trials for each test template.

When subjects were asked to make movements with symmetric velocity profiles they learned relatively quickly. They were able to match the

profiles they learned relatively quickly. They were able to match the amplitude, duration, and peak velocity of the movements and make movements with unimodal, symmetric velocity profiles. When the same subjects were asked to make movements (of the same amplitude and duration) whose velocity profiles were asymmetric they learned more slowly. Although subjects had little trouble matching the amplitude and duration of the desired movements, they had difficulty producing the desired asymmetric velocity profiles. Furthermore, even after 50 trials subjects would intermittently make movements whose velocity profiles were distinctly

MOTOR SYSTEMS AND SENSORIMOTOR INTEGRATION: CEREBELLUM II

SIMPLE SPIKE REPRESENTATION OF THE BODY SURFACE WITHIN CLIMBING FIBER RECEPTIVE FIELDS OF PURKINJE CELLS IN CAT CEREBELLUM. J.F. Brons, L.T. Robertson, G. Tong., Dept. Anatomy, SD. Oregon Health Sciences Univ., Portland, OR 97201-3097

The body surface is mapped onto the cerebellar cortex by both the climbing fiber (CF) and the mossy fiber/granule cell system. The degree of congruence of body representation by both systems was studied by mapping the simple spike (SS) responses associated with receptive fields based on CF responses. Single Purkinje cells were recorded extracellularly in the intermediate zone of lobule V in decerebrate cats. CF and SS responses were elicited by mechanical stimulation of the skin of the distal extremities and the face. In almost all cases, stimulation of the receptive field representing the CF response also elicited SS responses. However, 67% of the time, excitatory or inhibitory components of the SS responses were elicited by only a part of the CF receptive field such as either the proximal or distal region. SS responses probably reflect a mapping of the body surface that only partially overlaps the somatosensory projections of the CF system. (Supported by NIH grant NS18242)

NEURONS IN POSTERIOR CEREBELLUM OF RAT RESPOND TO SOMATOSENSORY AND AUDITORY

STIMULI. P.W. Archer, M.A. Meredith and B.E. Stein. Depts. of Physiology and Anatomy, Med. Coll. Va., Va. Commonwealth Univ., Richmond, VA, 23298.

The convergence patterns of various sensory modalities onto

The convergence patterns of various sensory modalities onto individual neurons in the posterior cerebellum were studied in Long-Evans rats anesthetized with urethane and stabilized with a skull-mounted head-holding device. The most effective natural sensory stimulus for these cerebellar neurons proved to be tactile: gentle tapping, or brushing across the hair and skin activated 75/135 neurons. The receptive fields of these tactile neurons were most frequently found on the face (41%) and were overwhelmingly ipsilateral (99%). Surprisingly, approximately one third (n=24/75) of them proved to be multisensory (bimodal). They were activated by both tactile and auditory stimuli. Since the range of stimuli delivered (e.g. only white noise; only low intensity visual stimuli) was limited, this undoubtedly represents an underestimate of the incidence of multisensory convergence here. In 42% of the bimodal neurons studied the laterality of the receptive fields matched: both were ipsilateral. In 50% of them here. In 42% of the bimodal neurons studied the laterality of the receptive fields matched: both were ipsilateral. In 50% of them the auditory receptive field encompassed ipsilateral and contralateral space and in 8 % the receptive fields were clearly discordant (tactile = ipsilateral, auditory = contralateral). In several cases combined tactile-auditory stimulation produced response interactions, as has been noted elsewhere in the nervous system (e.g. see Meredith & Stein, J. Neurophysiol. 56:640-662, 1986). Supported by NIH grants NS 22543 and NSO8638

LESIONS OF THE CEREBELLAR NUCLEI, BUT NOT OF MESENCEPHALIC STRUCTURES ALTERS THE SPATIAL PATTERN OF COMPLEX SPIKE SYNCHRONICITY AS DEMONSTRATED BY MULTIPLE ELECTRODE RECORDINGS. E. J. Lang, I. Sugihara, R. Llinás Dept of Physiology & Biophysics, New York University Medical Center, 550 First Avenue, New York, NY 10016

Multiple electrode recordings of the complex spike activity (CS) of Crus IIa Purkinje cells (PCs) were used to investigate the influence of inferior olive (IO) afferents from the cerebellar nuclei (dentate) and red nucleus in controlling the synchronicity and rhythmicity of olivary cells in female albino rats. The cerebellar nuclear projection to the IO has been shown to account for the vast majority of the GABAergic terminals found within the olivary glomeruli. If these terminals are responsible for controlling the degree of IO electrotonic coupling, then lesions of the cerebellar nuclei should cause an increase of CS synchronicity. While simultaneously recording the CS of up to 44 PCs we pressure injected a mixture of kainic acid and NMDA directly into the dentate nucleus. The injection resulted in a significant (p<<.0005) increase in the simultaneous (within 1 msec) firing of PCs throughout Crus IIa (the average zero-time cross-correlation between PCs increased up to 11-fold from the control value). Lesions of the mesencephalon in the region of the red nucleus were made by pressure injecting kainic acid or lidocaine. These lesions altered the frequency of the CSs, but they did not produce a change in the pattern of synchronicity, nor did they prevent

increases in CS synchronicity following IP injections of picrotoxin.

The results of these experiments provides strong support for the hypothesis that the electrotonic coupling of IO neurons is modulated by GABA release within the glomeruli from afferents arising in the cerebellar nuclei and that this modulation is the basis by which the pattern of synchronicity of CS is determined. Supported by grant 13742 from NINDS.

THE ACTIVITY OF BLINK-RELATED PURKINJE CELLS DOES NOT AFFECT THE BLINK REFLEX J. J. Pellegrini and C. Evinger, Dept.

Neurobiology & Behavior, SUNY Stony Brook, Stony Brook, NY 11794 Recordings from crus II Purkinje cells of rats reveal that corneal stimulation evokes a time locked complex spike (latency ~20ms), a pause in activity, and a subsequent burst of simple spikes, all of which correlate with the concomitant blink. The decrease in blink magnitude produced by preceding a corneal stimulus with an identical conditioning stimulus correlated with a reduction in the Purkinje cell response. In order to assess the contribution of Purkinje cell activity to the execution of reflex blinks, we recorded orbicularis oculi EMG (OOemg) responses to electrical stimulation of the cornea before, during and after inferior olive inactivation in rats anaesthetized with urethane.

Microinjections of lidocaine into the contralateral inferior olive radically altered the response of blink-related Purkinje cells to corneal stimulation. Not only was the complex spike and the pause in simple spikes which follow it absent, but the subsequent burst of activity was smaller or nonexistant. During inferior olive inactivation however, the OOemg exhibited no consistent change. Similarly, while both microinjections of lidocaine into the inferior olive and intraperitoneal injections of 3-acetylpyridine dramatically changed the Purkinje cell responses, neither altered the difference between control and conditioned OOemg responses. Also, in normal rats, complex spikes consistently occurred at lower stimulus intensities than did OOemg responses and appeared time locked to the stimulus but not the movement. These results reveal that Purkinje cell activity reflects sensory elements associated with corneal stimuli and blinking rather than modulating the real time motor commands for each blink. SYNAPTICALLY INDUCED DENDRITIC CALCIUM TRANSIENTS IN GUINEA PIG CEREBELLAR PURKINJE CELLS IN VITRO.

V. Lev-Ram, H. Mivakawa, N. Lasser-Ross and W.N. Ross. Dept. of Physiology, N.Y. Medical College, Valhalla, NY 10595.

We measured the spatial and temporal characteristics of synaptically activated Ca transients using high speed imaging of changes in arsenazo III absorbance and fura-2 fluorescence while recording the intrasomatic membrane potential. All or none CF responses were elicited by bipolar stimulation of the white matter. PF potentials were evoked by stimulation near the pial surface and generated graded electrical responses blocked by CNQX. CF inputs produced no detectable ligand-gated calcium entry since the Ca changes had a latency from the onset of the synaptic potential at all dendritic locations. The CF response had two components which could have different spatial distributions. One was driven by the synaptic potential and the second by the Ca spike evoked by the synaptic potential. Both components showed rapid recovery. At high rates the spike component failed at some locations but not others, suggesting localized dendritic spiking. PF synaptic potentials produced small, localized Ca transients. When the electrical response was large enough to show signs of regenerative activity larger Ca changes over a wider area were detected with the same time course as somatically evoked calcium spike transients.

ARE THERE SUBCLASSES OF GRANULE CELLS AND PURKINJE CELLS? C.F.Hsiao, R.Huang*, H.Mu* and C.Huang. Div. Structural & Systems Biol., Sch. Basic Life Sci., Univ. Missouri-Kansas City, Kansas City, MO 64110.

To correlate the electrophysiological and morphological properties of granule cells and Purkinje cells, we have used HRP-filled glass microelectrodes to record and stain 30 granule cells and 25 Purkinje cells from the cerebellum of the cat. Granule cells showed extracellular action potentials with broader half-widths (0.78±0.14 ms) than those of Purkinje cells (0.22±0.06 ms). Resting membrane potentials for granule cells and Purkinje cells were 40 and 65 mV respectively. The inter-spike interval of granule cells (333.3±195.4 ms) was longer than that of Purkinje cells (47.3±31.8 ms). Granule cells had small soma (5-8 μ m) with 3-5 short dendrites (<30 μ m). Purkinje cells had larger soma (25-40 μ m) and a characteristic, two-dimensional dendritic tree structure. A tentative subclassification of granule cells into two types was attempted on the basis of the complexity of their dendritic arborization. A similar classification for Purkinje cells was made on the width of its dendritic tree structure. (Supported by PHS grant AA07643.)

FURA-2 IMAGING OF INTRACELLULAR CALCIUM TRANSIENTS IN URKINJE CELLS FOLLOWING GLUTAMATE IONTOPHORESIS. M. Sugimori and R. Llinás,

Dept. of Physiology and Biophysics, N.Y.U. Medical Center, 550 First Ave, N.Y., N.Y. 10016.

It has been amply confirmed that Purkinje cells generate Ca-dependent action potentials in their dendrites (Llinás and Sugimori, J. Physiol. 305:197, 1980). Arsenazo-3 (Ross and Werman, J. Physiol. 389:319, 1987) and Fura-2 (Tank et al.; Science, 242:773, 1988) studies indicate that such spikes invade most of the Purkinje cell dendritic tree. Using a fast Fura-2 recording system (Sugimori & Llinas, Soc. Neurosci. Abst., 15:179, 1989) we determined that dendritic spike initiation starts with the generation of a plateau potential at the spiny branchlets where voltage-dependent Ca conductances reached threshold before Ca action potentials are generated in the main dendrite. In the present study, glutamic acid was iontophoresed at different sites in the dendritic tree of Fura-2 loaded Purkinje cells. The Fura signal and intrasomatic voltage were monitored simultaneously allowing a detailed analysis of the site of plateau potential activation and its relation to Ca spike generation. We found that short iontophoretic pulses of glutamate produced graded postsynaptic responses that were not accompanied by intracellular Ca²⁺ transients (ICTs). However, if the glutamic acid depolarizations reached threshold for plateau potential activa-tion, the spiny branchlets alone demonstrate ICTs. When the threshold for dendritic activation was attained the main dendritic tree displayed ICTs follow ing a well-defined wave which moved downwards toward the Purkinje cell soma and antidromically into the other dendrites up to the level of the spiny branchlets. These results support the view that parallel fiber activation normally regulates Purkinje cell firing via the activation of plateau potentials in the spiny branchlets. Supported by NINDS 13742.

INCREASED GLUTAMIC ACID DECARBOXYLASE (GAD) mRNA IN CEREBELLAR PURKINJE CELLS FOLLOWING CLIMBING FIBER LESION-INDUCED INCREASES IN CELL FIRING.

FIBER LESION-INDUCED INCREASES IN CELL FIRING. Litwak*, M.Mercugliano, M.-F. Chesselet and G.A. Ottmans. Dept. of Pharm. and Mol. Biol., Chicago Med. Sch., N.Chicago, IL 60064 and Dept. of Pharm., Univ. of Pennsylvania, Philadelphia, PA 19104. The neurotoxin 3-acetylpyridine (3-AP) selectively destroys the inferior olive-climbing fiber input to the cerebellar cortex, resulting in (1) increased Purkinje cell firing, and (2) increased GAD activity in Purkinje cell terminals. Cell firing rates are initially doubled following the lesion, but return to baseline at about 30 days post-lesion. In contrast GAD activity increases gradually and remains elevated up to 45 lesion. In contrast, GAD activity increases gradually and remains elevated up to 45 days post-lesion. The increase in GAD activity may be due to an induction of enzyme synthesis in response to the increase in cell firing. If so, increases in GAD mRNA might underlie the increase in GAD activity. In the current study, in situ hybridization was used at various post-lesion intervals to determine if Purkinje cell GAD mRNA levels increase following climbing fiber lesions, and to assess factors which might explain the discrepencies between changes in Purkinje cell firing rate and GAD activity.

Adult male rats were injected with either 3-AP or saline. At 7 days post-lesion the animals were killed and the brains rapidly frozen. Tissue sections for determining GAD mRNA and GAD activity were taken throughout the extent of the deep cerebellar nuclei (DCN). At 7 days post-lesion, GAD activity at Purkinje cell projection sites in the DCN was significantly increased (+58%) above control levels. GAD mRNA levels in Purkinje cell bodies from the same animals were also GAD mRNA levers in Purkinje cell bodies from the same animals were also significantly elevated (442%) above control. Because the lesions increase Purkinje cell firing rates, these results suggest increased firing induces transcription of GAD mRNA, which in turn increases GAD availability in Purkinje cell terminals. Other post-lesion periods are currently being studied to determine if this relationship exists beyond the initial lesion period. (Supported in part by the Dystonia Medical Research Foundation)

CLIMBING FIBER-INDUCED DECREASES IN 'SIMPLE SPIKE' DISCHARGES OF CEREBELLAR PURKINJE CELLS IN THE UVULA-NODULUS OF THE RABBIT. H. Shojaku¹ and N.H. Barmack², ¹ Dept. of Otolaryngol, Toyama Med.& Pharm. Univ., Toyama, Japan and ²RS Dow Neurological Sciences Inst., Good Samaritan Hosp.& Med. Ctr., Portland, OR 97209.

The cerebellar uvula-nodulus receives vestibular and visual signals conveyed by both mossy fibers and climbing fibers. Interactions between these two afferent systems may be important for determining the functional output signal mediated by Purkinje cells. In this report we describe the vestibularly- and visually-evoked climbing fiber responses (CFRs) recorded from Purkinje cells and we examine how such CFRs influence Purkinje cell simple spike responses (SSs). We have recorded from single Purkinje cells in lobules 9c, 9d, and 10 of anesthetized rabbits during vestibular and optokinetic stimulation. Most vestibularly- and visually-evoked CFRs were synergistic. For example, CFRs recorded in the left nodulus, and evoked by vestibular stimulation in the plane of the left posterior-right anterior semicircular canals were also driven by downward optokinetic stimulation of the posterior field of the left eye. CFRs evoked by vestibular sinusoidal roll stimulation discharged in phase with stimulus angular velocity or stimulus position. Without exception, if both CFRs and SSs were modulated during sinusoidal vestibular roll stimulation in a single Purkinje cell, the modulation was antiphasic. Following the occurrence of a vestibularly-evoked CFR, there was a decrease in SSs. The duration of this CF-evoked decrease was inversely proportional to the initial frequency of SSs prior to the occurrence of the CFR. Our data suggest that vestibularly-evoked CFRs play an important role in the control of SSs and that this CFR-SS interaction may determine the specificity and amplitude of postural responses.

MODULATION OF PURKINJE CELLS BY ENKEPHALIN AND CORTICOTROPIN RELEASING FACTOR IN THE OPOSSUM'S CEREBELLUM. G.A. Bishop and J.S. King. Dept. of Anatomy and Neuroscience Program. The Ohio State University. Columbus. OH 43210

University, Columbus, OH 43210
In addition to the amino acids glutamate and aspartate, several peptides have been identified within cerebellar afferent systems. Two of these peptides, enkephalin (ENK) and corticotropin releasing factor (CRF) have been colocalized within climbing and mossy fibers (Cummings and King, '90; Synapse 5:167). The iontophoretic application of these peptides reveals that they alter the firing rate of Purkinje cells. ENK suppresses spontaneous, as well as glutamate and aspartate-induced firing of isolated neurons. Preliminary studies indicate that the effect is not blocked by the opiate antagonist Naloxone (Nal). Nal applied by itself at low currents also blocks neuronal activity; moreover, when Nal and ENK are applied simultaneously the suppressive effects are greater as compared to application of either chemical alone. Iontophoresis of CRF potentiates spontaneous activity, as well as the effects of glutamate and sapartate and partially blocks the suppressive effects elicited by the iontophoretic application of ENK. The present findings are somewhat paradoxical as they indicate that ENK and CRF, which are present in afferent systems known to be excitatory, have opposite effects in regulating Purkinje cell activity. On the basis of the Nal response, the data suggest that the suppressive effects of ENK are mediated at receptive sites that are not specific for opioids. In contrast, CRF likely elicits its effects through CRF receptors which have recently been identified in the opossum's cerebellum (Cummings et al., '89; JCN 280:501). Future studies will be designed to determine the circuitry involved as well as the mechanism(s) of action of these peptides in the cerebellar cortex (Supported by NS 08798).

PROJECTIONS FROM RAT TRIGEMINAL NUCLEUS ORALIS TO THE CERE-BELLUM. L. A. Smith and W. M. Falls, Dept. of Anatomy, Michigan State University, East Lansing, MI 48824.

Michigan State University, East Lansing, MI 48824.
Unilateral deposits of PHA-L were made into each subdivision of rat trigeminal nucleus oralis (Vo). Axons of trigeminocerebellar projection neurons traversed the ipsilateral inferior cerebellar peduncle and formed terminal arborizations of two types bilaterally in Crura I and II, and lobules 7, 8 and 9 as well as ipsilaterally in the paramedian lobule (PML). The first type, arising from eurons in dorsomedial (DM) and dorsal one-half of the border zone (BZ) subdivisions terminated in superficial and deep portions of the granule cell layer in complex mossy Those located superficially had beaded branches extending into the Purkinje cell layer which approximated Purkinje cell somata. The second type of DM-BZ efferent terminated between the outer portion of the granule cell layer and the Purkinje cell layer and formed a claw-shaped terminal arbor with boutons surrounding a Purkinje cell soma. Injections made in the ventrolateral (VL) subdivision labeled axons similar to the first type of DM-BZ efferents. They terminated superficially in the granule cell layer, but were principally located in PML.

These findings suggest that many endings of Vo efferents in Crura I and II, lobules 7, 8 and 9 and PML are positioned to provide not only a direct synaptic influence on granule cell dendrites, but also on the output cell of the cereellum, i.e., Purkinje cell, through synapses on its soma (Supported by Grant DE06725)

370.10

RENAL REPRESENTATION BY THE CLIMBING FIBER SYSTEM IN THE VERMAL CORTEX OF THE CAT CEREBELLUM. G. Tong, J.F. Brons, L.T. Robertson. Dept. Anatomy, SD. Oregon Health Sciences Univ., Portland, OR 97201

The projections of renal afferent fibers by the climbing fiber system to the vermal cortex were determined for a population of the Purkinje cells in the cat cerebellum. Under alpha chloralose anesthesia, the responsiveness of the Purkinje cells by the climbing fiber system were determined by the repeated presence of the complex spikes elicited by electrical stimulation of the central cut end of the renal nerves and by mechanical stimulation of the body surface. Of 255 isolated Purkinje cells, 15% responded to electrical stimulation of the renal nerves. Almost all of these Purkinje cells also received somatosensory input, mainly from forelimb and face. The renal climbing fiber responses (CFRs) were found in lobules V, VI, and VII. The highest percentages of responses were found in sublobules Vf (62.6%) and VIIB (31.6%). The latencies of the renal CFRs were from 23 to 106 ms. The average latency of the renal CFRs in sublobule VIIB (76 ms) was significantly longer than that in lobules V (46 ms) and VI (39 ms) (p<0.002). The findings indicate that the renal input projects to the vermal cortex via the climbing fiber system. (Supported by NIH grant NS18242)

TEMPORAL RELATIONSHIP OF INTERACTIONS OF VISUAL AND AUDITORY STIMULI IN RAT PARAFLOCCULAR NEURONS. <u>Brian N. Maddux, S.A. Azizi, and D.J. Woodward.</u> Dept of Cell Biology and Neuroscience, UT Southwestern Medical Center, Dallas, Texas 75235.

Ongoing studies in this laboratory, have been aimed at clarifying the functional role of cortical input to the cerebellum. This study posed the question: what are the temporal interactions of visual and auditory cortical signals projecting to the parafloccular lobule? Our previous reports have demonstrated visual and auditory cortical input to the rat paraflocculus via the dorsolateral basilar pons, and interactions between concurrent stimuli have been recorded. However, it was unknown whether the interaction was confined to the time of the concurrent stimulation or whether longer lasting interactions could be observed. In this study, unit recordings from parafloccular neurons were obtained with glass micropipettes in immobilized, sedated, locally anesthetized Long-Evans rats during visual and auditory stimulation. Images (dot patterns or bars) were projected onto a screen in front of the rat, and 10 kHz sinusoidal tones were issued from a frontally placed speaker. Delivery of individual or combined stimuli was precisely controlled by a computer. The tone was sounded either coincidentally with appearance of the image or 0, 200, or 500 ms following initiation of image movement (500 ms after appearance). Concurrent visual and tone stimuli were often observed to facilitate responses over either alone. In many cases, one or both of the stimuli were below threshold to cause an observable change in firing when presented in isolation. In a subset of the units, combinations of tone and image movement resulted in augmentation of the response to subsequent image movement in the same field after delays of up to 2 seconds in studies to date. These findings argue for the existence of a process (i.e., short-term storage) which sustains an interaction between visual and auditory modalities in a time frame longer than the known synaptic processes within the cerebellar cortex. Supported by the Biological Humanics Foundation.

Complex oscillations in patients with cerebellar lesions. A. Beuter, C. Labrie*, J. Milton*. Univ. of Quebec at Montreal, C.P. 8888, Succ. A, H3C 3P8 and Univ. of Chicago. Patients with lesions in the cerebellum (CL) have deficits in preprogramming and executing voluntary movements. We compared the effect of delayed visual feedback on a simple motor task in 8 patients with uni- or pan- cerebellar lesions and 8 normal subjects, matched for age, sex and laterality. This task required the subjects to maintain a constant finger position relative to a stationary baseline displayed on an oscilloscope. The signal controlled by the finger was delayed (0-1400 ms), recorded for 80 s using a LVDT, and digitized at 102 Hz. In the absence of a delay, time series for normal subjects displayed regular low amplitude, high frequency oscillations around the baseline. Traces for patients with unilateral CL indicated a tendency for smaller tremor amplitude, on the lesioned side. We also observed sudden destabilizations of the finger producing large amplitude, simple or double oscillations lasting between 0.5 and 1.0 s. With the addition of a 1400 ms delay, time series for normal subjects displayed complex, high amplitude, low frequency oscillations around the baseline with a period between 2 and 4 times the delay. Traces for patients with CL indicated qualitatively different dynamics on the lesioned side. These results suggest that the cerebellum plays a more significant role in this task than the basal ganglia (Beuter, A. et al., Neurosci., 15:692, 1989).

POSSIBLE MECHANISMS UNDERLYING REORGANIZATION IN FRACTURED TACTILE CEREBELLAR MAPS: CORRELATIONS WITH S-1 CORTICAL PLASTICITY. C.A. Shumway, L.G. Posakony, J. Morissette, and J.M. Bower. Div. of Biology 216-76, CalTech, Pasadena, CA. 91125.

Posakony et al., this volume, demonstrated that fractured tactile cerebellar maps in rats reorganize following infraorbital nerve lesion. In this study, we explored possible rats reorganize rottowing intraorottal nerve testion. In this study, we explored possible mechanisms underlying crus IIa reorganization. First, we physiologically characterized the crus IIa map in adult rats immediately before and after deafferentation. On average, only 13% of the penetrations in the denervated area displayed new representations, suggesting that immediate unmasking of existing connections does not play a significant role in cerebellar reorganization. Second, we characterized maps in animals deafferented at various developmental stages, and found that the denervated region filled in predominantly with the upper incisor representation, which expanded to 5 times its normal area. This small patch was the most variable in location in normal animals, at times not even adjacent to the area innervated by the infraorbital nerve. If reorganization were occurring in the fractured cerebellar map itself, we would expect the deafferented patches to be invaded by afferents from neighboring adjacent patches. Third, we explored whether the observed upper incisor expansion in the fractured map might instead be correlated with changes in the topographic cortico-cerebellar pathway. We found that the upper incisor representation in S-1 cortex in deafferented animals was indeed much larger than that of the normal animal, increasing 10-fold. These results suggest that reorganization does not take place in the cerebellum but rather in the sensory afferents projecting to the cerebellum. Using electrical stimulation, lidocaine injections, and cortical ablations we then demonstrated that the S-1 cortex is the primary contributor to the long-latency evoked cerebellar response to tactile stimulation which is particularly resilient to peripheral lesions. Supported by NIH# 22205, BRSG# RR07003, L.P. Markey Trust, and NIMH and NIH NRSA awards to CAS and LG P.

COMPENSATORY RESPONSES TO WEIGHT AND TEXTURE CHANGES IN A PREHENSION TASK FOR CEREBELLAR PATIENTS. C. Dugas, A.M. Smith, D. Bourbonnais, L.F. Charron* and M.I. Botez*. Centre de Recherche en Sciences Neurologiques, Université de Montréal et Service de Neurologie, Hôtel-Dieu de Montréal, Québec, Canada. Subjects were asked to grasp, lift and hold within a narrow position window

subjects were asked to grasp, lift and note within a narrow position window an object of varying weight and texture. Three weights (200, 600 and 800 g) and two textures (polished metal and coarse grain sandpaper) were used. Three patients with an olivo-ponto-cerebellar (OPC) syndrome and two patients with advanced Friedreich's ataxia (FA) (ages 28 & 29) were compared to agematched control subjects. The OPC patients had similar large oscillations in both the dynamic and static components of the movement which were caused by a breakdown of the normal synergy between the grip and load forces in this task. Despite this deficit the patients were able to scale the grip force appropriately according to the three loads used in this study. Moreover, these forces were always greater than for the control group. The grip forces applied to the smooth and rough surfaces for the three different weights were of similar magnitude suggesting a deficit in adapting to the surface friction. The OPC patients suggesting a deficit in adapting to the surface friction. The OPC patients demonstrated a strategy that was somewhat similar to patients with sensory deficits by adopting a large security margin with greater energy expenditure. For the FA patients there were no systematic oscillations in the force traces as observed for the OPC patients. The grip and load force profiles were smooth but with a much slower ramp-like increase in the dynamic phase of the task. The force amplitude of both the static and dynamic components were always smaller than for either the control or the OPC patients. The FA patients had a much smaller security margin and a clear effect of the texture was noted in their results. These advanced FA patients did not show a clear ataxic syndrome when compared to the OPC. These results suggest that advanced FA is characterized less by asynergia than a simple loss of muscle force. Supported by MRC of Canada.

MOTOR SYSTEMS AND SENSORIMOTOR INTEGRATION: CEREBELLUM III

FRACTURED TACTILE MAPS RETAIN FRACTURED SOMATOTOPY FOLLO-WING DEAFFERENTATION AT DIFFERENT STAGES OF DEVELOPMENT. J. Morissette, L.G. Posakony, C.A. Shumway, M.G. Paulin, J.M. Bower. Division of Biology, 216-76, California Institute of Technology, Pasadena, CA, 91125.

Tactile projections to the rat cerebellar hemispheres are characterized by a series of patches representing different regions of the body surface (Shambes et al., Brain Behav. Evol. 15: 94-140, 1978). In the current experiments, we deprived the large central upper lip and upper-lip related patches found in crus IIa of their normal source of peripheral innervation by cauterizing the infraorbital branch of the trigeminal nerve. Twelve rats were deafferented between postnatal days 2 and 30, and the resulting reorganization of tactile inputs to the granule cell layer was determined using high-density physiological mapping procedures 2 to 3 months later.

Our results indicate that these cerebellar maps reorganize regardless of the postnatal day of the lesion. In each case, the map maintained an overall patchy organization, with the upper incisor representation consistently invading most of the denervated region. This result was surprising since the upper incisor crus IIa patches in normal animals are both the smallest and most variable in location. Although reorganization occurred at all developmental stages, we did find a developmental effect with respect to the different components of the evoked granule cell response to tactile stimulation. In normal animals, tactile evoked responses always consist of short- (5-10ms) and long- (20-50ms) latency components. In deafferented animals, some recording sites showed only the long-latency component. The number of these recording sites increased as lesions were made later in development (3% at PND2 versus 22% at PND30), suggesting developmental differences in the capacity of cerebellar projecting circuits to reorganize. In Shumway et al. this volume, the long latency response is shown to be associated with the somatosensory cortico-cerebellar pathway.

371.3

DIFFERENCES IN ULTRAMORPHOLOGY AND DENDRITIC TERMINATION SITES OF SYNAPSES ASSOCIATED WITH THE ASCENDING AND PARALLEL FIBER SEGMENTS OF GRANULE CELL AXONS IN THE CEREBELLAR CORTEX OF THE ALBINO RAT. <u>G. Gundappa-Sulur and J.M. Bower</u>, Div. of Biology 216-76, Caltech, Pasadena, CA, 91125.

Previous electrophysiological investigations have demonstrated that focal granule cell layer activation generates an equally focal activation of the overlying Purkinje cell layer (Bower and Woolston, J. Neurophys. 49: 745-766, 1983). It was proposed that synapses associated with the ascending branch of the granule cell axon are responsible for this vertical organization of excitatory effects and that synapses of the parallel fiber segment might be responsible for more subtly modulating this ascending influence. The idea that these two segments subserve different physiological functions was supported by subsequent intracellular brain slice experiments demonstrating that the ascending branch segment generates a long duration (200-300 ms) plateau potential in Purkinje cell dendrites (Rao et al., Soc. Neurosci. Abst. 13, 602, 1987).

To further contrast the properties of the two segments of the granule cell axon, we

have contrasted serial EM reconstructions of synapses associated with both. Complete reconstructions of 36 synapses demonstrate no statistically significant differences in presynaptic and postsynaptic volumes or the area of the postsynaptic density. However ascending branch synapses do contain, on average 1/3 more presynaptic vesicles than parallel fiber synapses (p<.016). Perhaps more interestingly, spines associated with the ascending branch have been found to arise exclusively from the smallest terminal dendrites of the Purkinje cell (average diameter .5 µm) while spines contacted by parallel fibers are exclusively associated with dendrites considerably larger in diameter (1.4-2.0 µm). This juxtaposition of parallel fiber effects between ascending branch synapses and the main dendrites of the Purkinje cell is compatible with the previously proposed modulatory role of the parallel fiber segment

THE VENTRAL LATERAL NUCLEUS (VL) OF THE RHESUS MONKEY MOTOR THALAMUS: LIGHT AND ELECTRON MICROSCOPIC ANALYSIS. K. Kultas-Ilinsky and I. Ilinsky. Department of Anatomy, University of Iowa College of Medicine, Iowa City, Iowa 52242

The VL, or projection zone of cerebellar afferents to the thalamus as defined earlier by Ilinsky and Kultas-Ilinsky (1987), was analyzed with respect to its neuronal composition and synaptic organization using various neuroanatomical techniques: retrograde and anterograde labeling from the cortex, anterograde labeling from the cerebellum, immunocytochemistry and quantitative morphometric analysis. types of neurons: thalamocortical projection neurons (PN) and GAD-positive local circuit neurons (LCN) differed in size and number. LCN:PN ratio was 1:3. Proximal parts of somadendritic membrane of PN (soma, primary and secondary dendrites) were contacted by large number of cerebellar boutons (LR type). Second major synaptic input to these sites was provided by LCN dendrites that formed symmetric synapses and frequently, but not always, were a part of a triad arrangement with cerebellar boutons. Finally, a small number of axon terminals of unknown origin were also found forming symmetric contacts at proximal locations on PN. Moreover, the relationships observed suggest a possibility of synaptic contacts on PN initial axonal segments and axon hillocks although no clear examples have been encountered as yet. The major input to distal dendritic branches of PN was from SR-type boutons that were confirmed to be of cortical origin. Synaptic input to somata of LCN was extremely sparse and was provided by small to medium size GAD-positive boutons of unidentified origin forming symmetric contacts. Glomeruli were formed at the branching sites of primary or secondary dendrites. They were encountered infrequently hence did not represent the major feature of the neuropil. Our findings provide evidence that the ultrastructure of the VL is different in principle from that of nigrothalamic afferent territory as well as of somatosensory thalamus and do not support the concept of a common blueprint of neuronal circuitry in all thalamic nuclei. Supported by NS R0124188.

POSITRON EMISSION TOMOGRAPHY IN SPINOCEREBELLAR DEGENERATION. A. Russo-Neustadt. S. Lottenberg*, A. Starr, L. Sporty* and M. Buchsbaum*. Brain Imaging Center, Departments of Psychiatry and Human Behavior and Neurology, University of California, Irvine, CA 92717.

We present two cases of spinocerebellar degeneration occurring in a family. The patients examined are brothers, ages 48 and 52, who presented with progressive muscular incoordination, decreased strength, impaired concentration, and altered social judgment. Anatomical changes, revealed by magnetic resonance imaging (MRI) are examined in conjunction with metabolic patterns evident on positron emission tomography (PET). MRI revealed degeneration of the cerebellar vermis, with normal anatomy maintained in the rest of the brain. PET showed depressed metabolic rates throughout the cerebellum, as well as the inferior frontal cortex, the posterior temporal cortex, and regions of the corpus callosum and cingulate gyrus. Neuropsychological evaluation of these patients, along with their history, revealed progressive motor deficits as well as emotional and personality changes which correspond with the metabolic deficits examined with PET. This study indicates that degenerative disorders of the cerebellum can involve subtle changes in distant areas of the brain which are involved in the efferent and afferent connections of the cerebellum and not evident grossly as structural changes.

PRETECTO-PONTINE AND INCERTO-PONTINE PROJECTIONS AND SYNAPTIC BOUTONS IN THE RAT. G.A. Mihailoff and K.W. Bourell*, Cell Biology and Neuroscience, Southwestern Medical School, Dallas, TX 75235

Previous retrograde transport studies in the rat have established that the anterior pretectal nucleus (APT) and zona incerta (ZI) contain neuronal somata that project to the basilar pontine nuclei (BPN). Further, it has been shown that each of these pontine afferents is comprised in part of GABA fibers, while the incerto-pontine system is also known to contain glutamate-positive components. The objective of the present series of experiments was to visualize the pattern of axon terminal fields formed by these two afferent systems within the BPN and, with electron microscopy, identify the synaptic boutons that arise from each axonal system. Injections of WGA-HRP were placed within the APT or the ZI and after survival periods of 24-48 hours and routine fixation and histochemical processing of the tissue, axon terminal fields were observed in the BPN ipsilateral to each injection. Only the incerto-pontine system exhibited a small contingent of labeled terminals in the contralateral ventromedial pontine region. Both the incerto- and pretecto-pontine systems established terminal fields of varying density and size in lateral, ventral and medial BPN zones. Although such projection fields occupied similar territories within the BPN, there appeared to be only minimal overlap in some areas and each system seemed to establish exclusive terminal regions, at least with respect to one another. With electron microscopy, both systems gave rise to similar types of boutons that were small to medium in size, and often formed synaptic arrangements in which a single labeled bouton contacted multiple postsynaptic profiles that included dendritic spines and shafts. These observations confirm the existence of yet additional BPN afferents, and suggest an emerging ultrastructural theme that places afferent boutons as the central profile in a glomerular-like synaptic arrangement. Supported by USPHS grant NS12644.

CEREBELLOTHALAMIC PROJECTIONS IN THE MOUSE. A. J. Haroian

and L. M. Eisenman. Hahnemann University, Philadelphia, PA
19102 and Jefferson Medical College, Philadelphia, PA
19107.

The purpose of this study was to identify the cerebellothalamic (CBT) projection from each of the cerebellar nuclei (CN) in the normal mouse. These data will be used as the basis for future comparative studies of this projection in mutant mice with severe defects in cerebellar development. Unilateral iontophoretic injections of WGA-HRP were made into the CN and anterograde transport was detected with TMB. Cerebellar terminations were observed in the intralaminar and the ventral tier (VTN) nuclei of the thalamus. The dentate (DN) and interpositus (IN) nuclei projected to the paracentral nucleus (PC). The fastigial nucleus (FN) had a more caudal input to the central lateral and parafascicular nuclei. Each of the CN projected to the VTN. Caudally, labeling from the IN and DN was observed along VIN. Caudally, labeling from the IN and DN was observed along the border between the ventral medial and ventral lateral (VL) nuclei. Rostrally, labeling also extended more laterally along the dorsal border of the VL adjacent to the internal medullary lamina. Terminations from the IN and parvocellular DN occupied a central zone within the rostral pole of the VL; those from the magnocellular DN were observed most laterally. Projections from the FN were modest and terminated most medially within the rostral VL. An obvious recrossing component to the ipsilateral thalamus was observed from the IN and DN. These data suggest that there is evidence of a topographic organization in CBT terminations despite an extensive overlap of terminal fields within the VTN. Grant NS16531 is gratefully acknowledged.

EVIDENCE THAT CERTAIN GABAERGIC NEURONS IN THE CEREBELLAR NUCLEI LIE OUTSIDE CLIMBING FIBER TERMNAL FIELDS. K. A. Starr and H. H. Molinari. Dept. of Anatomy, Albany Medical College, Albany, NY, 12208. Inputs to the cerebellar nuclei (CN) include climbing fiber (CF)

collaterals from the inferior olive (IO). We investigated whether GABAergic neurons in the CN may be influenced by input from these collaterals. Cells in the IO of rats were selectively destroyed using the neurotoxic drug, 3-acetylpyridine, according to the protocol of Llinas et al. (Science 190:1230, 1975). After 3, 4 or 5 days survival, rats were perfused transcardially and 30 μ m-thick, transverse serial sections of the cerebelli were obtained. Every other section was processed for immunocytochemistry using a GABA antibody (Inestar Corp). These sections were used to plot the location of GABAergic cells in the CN. In adjacent sections, stained with a Fink-Heimer procedure, we determined whether these GABAergic cells were located in terminal fields of CF collaterals.

Results of this study indicate that almost half of the GABAergic

cells lie outside of CF terminal fields and that many of these cells are located ventrally in the CN. It has been shown by others that neurons of the cerebello-olivary projection, particularly the GABAergic portion, are concentrated in the more ventral areas of the CN. Thus, it may be that the ventrally located GABAergic neurons that we identified as lying outside CF terminal fields may be involved in this pathway. This suggests that, at least in part, the cerebello-olivary projection may not be directly influenced by input from the IO (Supported by NSF Grant BNS-8809840).

IMMUNOCYTOCHEMICAL IDENTIFICATION OF CEREBELLAR NEURONS IN SITU AND FOLLOWING TISSUE DISSOCIATION.
L. Yousif. L. Rucker* and P.E. Hockberger. Dept. of Physiology,

Northwestern University Medical School, Chicago, IL 60611.

Cell-specific immunostaining was used to identify neurons and glia in adult and developing rat cerebellum. Staining was also used to identify isolated cells following tissue dissociation (P. Hockberger et al. J. Neurosci. 9: 2258, 1989.). For the *in situ* determinations, animals were perfused with 4% paraformaldehyde, and free-floating frozen sections (adults 30μm, juvenile 60μm) were stained using either the peroxidase-antiperoxidase or the avidin-biotin technique. Isolated cells were plated onto coverslips, fixed, and stained similarly. Purkinje cells were stained using polyclonal antibodies against calbindin (1:40,000 dilution; antibody provided by Dr. Sylvia Christakos, NJ Medical School) and Peptide-19 (1:1000; Dr. James Morgan, Roche Institute), while Golgi and deep nuclei cells were stained using monoclonal antibodies against Rat-303 (1:10; Dr. Susan Hockfield, Yale). In addition Rat-302 antibodies were used identify a popul cell three that is found cells in the vermis and to identify a novel cell type that is found only in the vermis and flocculus (1:10; S. Hockfield, <u>Science</u> 237: 67, 1987). Bergmann glial cells were stained using GFAP antibodies (1:8,000; DAKO Corp). Purkinje cells also stained with anti-GFAP serum in twoweek old animals, but not in adult, suggesting that this antigen may be expressed in these neurons during development. This research was supported by NIH grants NS-26915 and NS-17489.

371.8

CEREBELLAR CHANGES FOLLOWING UNILATERAL LESION OF THE INFERIOR OLIVE IN THE ADULT RAT W.S.T.Griffin., K. Ito*, Y. Ishikawa*, M. Morrison-Bogorad+ and

R.D. Skinner Depts. Anatomy and Pediatrics, UAMS, Little Rock, AR 72205; +Dept. Neurology, UTSWMC, Dallas, TX 75235

The inferior olivary nucleus (ION) is the only source of climbing fibers in the rat. The majority of these fibers innervate Purkinje cells in the contralateral cerebellum and form the largest portion of the inferior cerebellar peduncle. We hypothesized that the loss of climbing fiber innervation would result in alterations in Purkinje cell genetic expression as well as astrogliosis (numerous reactive astrocytes) in contralateral brainstem and cerebellum. Serial sections of Bouin's-fixed, paraffin-embedded cerebellum taken at different days following electrolytic lesion of the right ION were examined. Immunohistochemistry was used to determine the levels of glutamic acid decarboxylase (GAD) in Purkinje cells and to identify reactive astrocytes. At 10 days postlesion, astrocytes in the brainstem and cerebellum contralateral to the lesion contained more GFAP and S-100 immunoreactive product in enlarged cell bodies and prominent processes, i.e., astrogliosis was found. In addition, orthograde transneuronal atrophy of Purkinje cells and decreased levels of GAD were apparent contralateral to the lesion. We conclude that atrophy and astrogliosis occur in the cerebellum by day 10 following lesion of the contralateral ION.

THREE-DIMENSIONAL RECONSTRUCTION OF SPINES IN THE INFERIOR OLIVE THAT RECEIVE SOMATOSENSORY INPUT. H.H. Molinari. Department of Anatomy, Albany Medical College, Albany, NY 12208.

Spines in the inferior olive have received considerable attention because of their proposed role in electrotonic coupling. Yet their potentially large synaptic surface area suggests that they may also serve as important sites for integration of information. In the caudal half of the cat medial accessory olive (cMAO), spines constitute one of the major targets of afferents from the gracile nucleus and lumbosacral spinal cord. Both of these afferents were labeled in the present study, one by anterograde transport of wheat germ agglutinin-horseradish peroxidase and the other by degeneration. Three dimensional reconstructions of spines contacted by labeled terminals were generated from serial section electron micrographs

Three types of spines received somatosensory input: simple stalks, club-shaped spines, and spine-crowned appendages. Virtually all of the spines received multiple inputs; most of these convergent inputs displayed the morphological characteristics classically associated with excitatory synapses. Furthermore, spines constituted the major site of convergence of afferents from the gracile nucleus and lumbosacral spinal cord. Considerably less common were gap junctions and inputs to the spines from pleomorphic-vesicle containing terminals (although two thirds of the spines participated in attachment plaques). Thus, spines in cMAO appear to be sites for integration of excitatory inputs, often from multiple somatosensory structures. Supported by NSF grant BNS-8809840.

EFFECTS OF HARMALINE ON THE ACTIVITY OF CELLS IN THE DEEP CEREBELLAR NUCLEI OF NORMAL AND GENETICALLY DYSTONIC RATS. J. F. Lorden and J. Ervin.* Dept. Psychology, Univ. Alabama at Birmingham, Birmingham, AL 35294.

The genetically dystonic (dt) rat does not display harmaline tremor, an effect produced by rhythmic activation of the olivocerebellar system. Because this system appears to be intact morphologically in the mutants, functional differences have been sought between dt and normal rats. Although the spontaneous firing rate of cells in the caudal inferior olive is significantly slower than normal, cells in the dt olive respond to harmaline with rhythmic increases in firing rate indistinguishable from normal. Few vermal Purkinje cells in the dt rat, however, are activated normally after harmaline. We have now used harmaline as a probe to investigate the output of the cerebellar cortex by recording from cells in the medial and interpositus nuclei. In urethaneanesthetized rats, the spontaneous firing rate of cells was 60% higher in the dt rats than in controls. Following harmaline. however, 78% of the cells from normal rats increased their firing rate in comparison with only 20% in the mutants. Cells in normal rats showed bursts of activity following the drug that were not evident in the dt rats. The activity of cells in the cerebellar nuclei of the dt rat does not appear to be modulated normally by the cerebellar cortex. (Supported by the Dystonia Med. Res. Fdn.)

CROSSCORRELATION ANALYSIS OF NEURONAL ELE-MENTS OF THE CEREBELLAR CORTEX. Iwona Zurawska and Remigiusz Tarnecki*. Dept. of Neurophysiology, Nencki Institute of Experimental Biology, 02-093 Warsaw, Poland.

Crosscorrelation is an analysis used to study the relationships between temporally disparate events. It has been previously used in studies of temporal interactions in computer simulated neuronal nets (Gerstein, G.L., 1970). In order to demonstrate the validity of crosscorrelation in real neuronal networks, we applied it to the study of the cerebellar cortex in the cat. The circuitry of this structure has been well described with microstimulation, as well as anatomical and immunocytochemical approaches. These techniques reveal both excitatory and inhibitory interactions between the neurons. We examined spontaneous activity of single cerebellar neurons, as well as the single unit potentials produced by electrical stimulation of a front limb. With crosscorrelation analysis we were able to reveal all of the previously described neuronal interactions and classify them as: direct excitatory, direct inhibitory, and those with common input from a shared source. Moreover we were able to differentiate the activity of Golgi cells from other inhibitory interneurons. Our results demonstrate the power of crosscorrelational analysis in the study of neuronal interactions.

QUIPAZINE HAS DIFFERENT ELECTROPHYSIOLOGICAL AND BEHAVIORAL EFFECTS IN DEVELOPING NORMAL AND DYSTONIC RATS. V. L. Michela and J. F. Lorden. Dept. Psych., Univ. Alabama at Birmingham, Birmingham, AL 35294.

Systemic administration of the serotonin (5HT) agonist guipazine produces a high frequency tremor in the forepaws of newborn rats. In normal rats, this response declines and is no longer evident by postnatal day 16. In the dystonic rat (dt), a genetic mutant with a movement disorder that appears around postnatal days 9-10, a tremor can be elicited with quipazine throughout the postnatal The dose-dependent effects are blocked by prior administration of the $\mathsf{5HT}_2$ antagonist, ketanserin. Because other studies have implicated the olivo-cerebellar system in the motor syndrome of the mutants, we compared the effects of systemic quipazine on the complex spike activity of cerebellar Purkinje cells in urethane-anesthetized normal and dt rats at 18-25 days of age. In normal rats, the frequency of complex spikes was significantly reduced from predrug rates. In the mutant rats, predrug firing rates of Purkinje cells were significantly slower than those of normal rats; however, quipazine increased the complex spike rate in the mutants. Although it is not known whether cerebellar mechanisms underly the quipazine-induced forepaw tremor, these behavioral and physiological data suggest an abnormality in 5HT systems of the dt rat. (Supported by the Dystonia Med. Res. Fdn.)

EFFECTS OF HEMICEREBELLECTOMY ON CAT INFERIOR OLIVARY NEURONS. T.J.H.Ruigrok*, M.P.A.Schalekamp*, C.I.de and J. Voogd* (SPON: Europ. Neurosci. Assoc.) Dept. Anat., Erasmus Univ. Rotterdam, 3000DR, the Netherlands.

After hemicerebellectomy, neurons in the cat contralateral (affected) inferior olive (IO) may either

contralateral (affected) interior of live (10) may either degenerate, appear unchanged or become hypertrophic.

Injections with the anterograde tracer Phaseolus vulgaris leucoagglutinin in the affected medial accessory olive (after 3 and 12 months) indicated that the axons remain within the restiform body, where they end as terminal clubs or as glomeruloid structures. Many terminal clubs expressed immunoreactivity for growth associated protein 43 (GAP-43: Benowitz and Routtenberg, TINS,10:527, 1987). Neurons in the affected IO were studied after stimulation of the mesodiencephalo-olivary pathway (MOP) and intracellularly injected with horseradish peroxidase. Injected neurons usually resemble normal olivary cells, whereas the somata of hypertrophic neurons were enlarged and studded with spiny processes. MOP stimulation resulted in monosynaptic activation followed by rebound spiking, or in long latency (120-300msec) reponses only. Dendritic Ca2+ spiking was seldomly observed in hypertrophic cells.

It is argued that cat IO neurons may survive axotomy due to a strong and continuous electrotonic coupling,

caused by the destruction of the cerebellar GABAergic input. The expression of GAP-43 in terminal clubs appears not to be related to axonal outgrowth.

MOTOR SYSTEMS AND SENSORIMOTOR INTEGRATION: OCULOMOTOR SYSTEM I

DIRECT COMPARISON OF REFLEX AND REMEMBERED SACCADES TO FLASHED TARGETS IN PARKINSON'S DISEASE. C.J. Lueck. T.J. Crawford, L. Henderson, C. Kennard. The London Hospital, Whitechapel, London El, U.K.

It has previously been shown that remembered saccades are impaired in patients with Parkinson's disease (PD). One hypothesis is that the impairment is generated by the act of suppression of a reflex saccade during fixation before remembered saccade execution.

In order to test this hypothesis, ten patients with idiopathic PD were compared with ten age-matched controls in a task requiring the execution of four saccades to a 200 ms flashed visual target. The first (reflex) saccade was made directly to the target. Subjects then had to look back to the central fixation light which was still illuminated. Shortly thereafter, the central light was extinguished and subjects were required to make a third (remembered) saccade to the remembered location of the original flash before finally returning to centre.

centre.

Reflex and remembered saccades were compared. Latencies of reflex saccades were prolonged to over 400 ms in both groups, possibly related to the multiple-task nature of the paradigm. PD reflex saccades were significantly hypometric compared to those of controls (gain 0.82 compared to 0.97). This result differs from previous reports of reflex saccades in PD in which gains are normal, and presumably relates to the flashed nature of the target. Remembered saccades were even more significantly affected (gain 0.57 vs. 1.03). For both reflex and remembered saccades there was no significant difference in peak velocity between PD and controls.

The hypothesis is therefore disproved. The findings are discussed in relation to the theoretical requirement that a visual stimulus be present for Parkinsonian saccades to be executed normally.

372.2

CORTICOTECTAL NEURONS IN THE FRONTAL EYE FIELDS OF THE AWAKE CORTICOTECTAL NEURONS IN THE FRONTAL ETE FIELDS OF THE AWAKE CAT. T. Weyand, J. Malpeli, and R. LaClair*, Dept. Psych., University of Illinois, Champaign, IL 61820

We have recorded from 22 antidromically-identified corticotectal cells in the frontal eye field region of cats

trained in visuomotor tasks. Head position was fixed, and trained in visuomotor tasks. Head position was fixed, and gaze monitored using the scleral search coil technique. The activity of 4 cells could not be reliably influenced by any of the visual or auditory stimuli we presented, or related to task demands or eye movements. Twelve cells could be reliably driven by visual stimuli, with all but 3 possessing huge receptive fields that included most of the contralateral hemifield and the area centralis.

The most common pattern of activity was suppression whenever fixation was demanded (n=10). This included suppression of both spontaneous and visually evoked activity, beginning whenever the fixation target appeared. Spontaneous saccades not related to the task did not result in sup-

saccades not related to the task did not result in sup-pression. Among the other cells, three appeared to be excited by fixation and one other possessed a punctate excited by fixation and one other possessed a punctate receptive field with a large and potent suppressive surround. Activity tightly linked to oculomotor behavior was not common, but was observed among non-corticotectal cells in this region. The suppression of activity associated with task demands is consistent with the notion that the frontal eye fields are involved in target acquisition and maintenance of fixation. (Supported by NIH Grants EY06818 and EY02695)

QUANTITATIVE ANALYSIS OF THE TRAJECTORY OF ELECTRICALLY ELICITED SACCADIC EYE MOVEMENTS IN THE FRONTAL EYE FIELD AND SUPPLEMENTARY EYE FIELD OF THE MONKEY. G. S. Russo and C. J. Bruce.

Section of Neuroanatomy, Yale Univ. Sch. of Med., New Haven, CT 06510.

Saccades elicited by electrical stimulation have often been classified either as being constant-vector (with roughly the same amplitude and direction regardless of the

constant-vector (with roughly the same amplitude and direction regardless of the direction of gaze when stimulated) or as goal-directed (appearing to direct gaze to a specific orbital goal). We analyzed the effect of eye position on saccades electrically elicited from 30 sites in the frontal eye field (FEP) and 8 sites in the supplementary eye field (SEP). All sites had either low thresholds (<50µA) for eliciting saccades or escacade related neuronal activity, with 27 FEP and 7 SEP sites fulfilling both criteria. Saccades were elicited while the monkey fixated a target at one of a matrix of nine locations separated by 15°. Approximately 10 saccades were elicited from each fixation target in a pseudorandom order. Electrical stimulation was through glass-coated elgipoy electrodes with exposed tips of 20-40 µm using 70 ms trains of 350 Hz biphasic pulses. At each site, the vertical and horizontal components of the elicited saccades were separately fit to the linear model: Elicited saccade = Kg * gaze position + elicited saccade from the primary position. The coefficient Kg indexes the orbital dependence of the electrically elicited saccades: Kg of -1 indicates perfectly constant-vector saccades whereas Kg of -1 indicates perfectly goal-directed saccades.

the electrically elected saccades: Kg of 0 undicates perfectly constant-vector saccauses whereas Kg of -1 indicates perfectly goal-directed saccades.

For saccades electrically elicited from FEF, Kg ranged from -0.41 to +0.01 (mean -0.17) for the horizonal component and -0.58 to +0.03 (mean -0.10) for the vertical component. For saccades electrically elicited from SEF, Kg ranged from -0.50 to 0.00 (mean -0.13) for the horizonal component and from -0.47 to 0.00 (mean = -0.15) for the perfect of the proposation of the perfect o

These results seem to be at odds with previous studies associating FEF with constantvector saccades and SEF with goal-directed saccades. Instead, the orbital dependence coefficients of FEF and SEF spanned a similar range of values (approximately -0.5 to 0) and their means did not significantly differ. We suggest that this regression analysis may be useful as an objective method for quantifying the effect of orbital position on electrically elicited saccades. Supported by PHS grant EY04740.

372.5

NEURAL ACTIVITY IN MONKEY SUPERIOR COLLICULUS DURING EVOKED SACCADES MODIFIED BY INTRASACCADIC ELECTRICAL STIMULATION OF SUPERIOR COLLICULUS OR FRONTAL
EYE FIELDS. E. L. Keller, E. J. FitzGibbon, and M. E. Goldberg. Laboratory of
Sensorimotor Research, National Eye Institute, Bethesda, MD 20892, and Smith-Kettlewell Eye Research Institute, San Francisco, CA 94115.

The amplitude and direction of a saccade evoked by electrical stimulation of the monkey frontal eye field (FEF) or superficial layers of the superior colliculus (SSC) can be modified when the stimulation is applied during an ongoing visually voked saccade. The modified saccade has dimensions suitable for the acquisition of the target that would have been acquired by the original fixed vector electrical saccade had the intervening saccade not taken place (J. Schlag et al. Exp. Br. Res, 1989). Movement related neurons in the intermediate layers of the monkey SC (ISCN) discharge before saccades of a particular direction and amplitude, and their discharge may be related to dynamic motor error. We studied the activity of ISCN during saccades evoked by electrical stimulation of SSC and FEF to see if neural activity, like saccade trajectory, were modified when stimulation was applied at the beginning of a voluntary saccade. We found that ISCN activity initiated before the voluntary saccade continues through the saccade evoked by electrical stimulation of the SSC, even though the resultant eye movement was not in the movement field of the neuron. Neurons that ordinarily discharge before voluntary saccades equal to the modified electrically evoked saccade do not discharge when that saccade occurs because of prior-saccade modification. Conversely ISCN activity initiated before the voluntary saccade is terminated at the onset of the saccade evoked by electrical stimulation of the FEF. These data suggest the existence of two mechanisms for the modulation of saccade trajectory by an antecedent saccade, one above the level of the superior colliculus, a second below the colliculus.

372.7

RELATIONSHIP OF MONKEY FRONTAL EYE FIELD ACTIVITY TO SACCADE DYNAMICS. M. A. Segraves, K. L. Park*, and M. E. Goldberg, Dept. of Neurobiology and Physiology, Northwestern Univ., Evanston, IL 60208, and Lab. Sensorimotor Res., National Eye Inst., Bethesda, MD 20892.

The frontal eye field (FEF) and the superior colliculus (SC) control saccadic eye movements in primates. Movement neurons in intermediate SC have discharge patterns related to the metrics of the saccade, both to velocity (Berthoz et al., 1986) and dynamic motor error (Waitzman et al., 1988). The latter have proposed that the SC lies within the feedback loop generating the saccade velocity pulse. We have now asked if activity of anatomically identified FEF neurons could also be related to the metrics of the saccade and lie within the loop

FEF presaccadic neurons were recorded in three behaving Rhesus monkeys. We identified neurons' projections with antidromic collision: of the neurons chosen for this study, 40% projected to SC, 30% to the pons, and 30% had unidentified projections. Unit activity sampled at 1Khz was transformed to a continuous spike density function by convolving with a Gaussian function ($\sigma = 8 ms$). Each neuron's spike density began to rise above baseline 100-300 ms before the start of the saccade. For 80% of the neurons examined, spike density peaked during the saccade, then began to decrease, but did not reach baseline levels until 100-200 ms after the end of the saccade. Some corticotectal neurons had their peak of spike density about 100 ms before the start of the saccade and then dropped to baseline before the end of the eye movement, but the spike density profiles did not match saccade trajectories or velocities. There was no consistent relationship between spike density and motor error. FEF neurons do not have the tight relationship to saccade metrics that certain SC neurons do. FEF activity may enable a brainstem saccade generation mechanism to proceed, and may signal target location, but does not directly influence saccadic velocity and time cours

OCULAR TRACKING IN PATIENTS WITH UNILATERAL FRONTAL LOBE Mark J. Morrow and James A. Sharpe. LESIONS. Neurology and Playfair Neuroscience Unit, The Toronto Hospital, University of Toronto, Toronto, Ontario M5T 2S8

We studied horizontal ocular tracking in 7 patients with unilateral frontal lobe tumor or infarction, using a magnetic search coil technique. We measured steady-state smooth pursuit gain to sinusoidal targets, and initial saccade and pursuit responses to unpredictable step-ramps. Four of 7 patients had asymmetrical steady-state pursuit, with lower smooth eye velocities toward the side of the lesion; lesions in these patients involved precentral cortex and underlying white matter. Three of the 4 patients with asymmetrical pursuit gain also made inaccurate saccades to step-ramp targets moving away from the lesion; these saccades underestimated target motion. O Only l patient had asymmetrical initial pursuit responses to

Steady-state pursuit asymmetry is common in patients with unilateral frontal lobe lesions, but initial pursuit is usually symmetrical, implying that the frontal lobes participate in the maintenance, but not the initiation, of the pursuit response. Contralateral saccade hypometria to step-ramps signifies a deficit in directing saccades to moving targets, which may result from damage to the human frontal eye fields.

SACCADIC EYE MOVEMENTS IN HUMAN POSTERIOR PARIETAL CORTEX LESIONS. J.-R. Duhamel, E. J. FitzGibbon, A. Sirigu, J. Grafman.
Lab. Sensorimotor Research, N.E.I. and Cognitive Neuroscience Section, N.I.N.D.S., Bethesda, MD 20892.

We studied saccadic eye movements in a patient with right posterior parietal lobe damage, incomplete left homonymous hemianopia and mild neglect, using infrared and magnetic search coil techniques. We measured the latency, amplitude and velocity of saccades to stimuli appearing unpredictably at different locations within the intact portion of the patient's visual field, from different initial orbital eye positions and in "gap" and "no-gap" conditions. Saccades to contralesional visual field targets were smaller and slower than saccades to ipsilesional visual field targets. Initial orbital eye position affected saccades to contralesional targets only: a target presented at the same retinal location elicited saccades of decrea amplitude and velocity as the initial position of the eye in the orbit shifted from the ipsilesional side to the contralesional side. In the no-gap condition (0 msec between fixation off and target on), mean saccade latency was longer for contralesional than ipsilesional targets. In the gap condition (200 msec interval between fixation off and target on), mean latencies were shorter in both directions and did not differ from one another. This was not due to a shift of the distribution toward shorter latencies but to the appearance of a second, smaller peak of express saccades (Fisher and Boch, 1983). The fact that saccadic reaction times to a contralesional stimulus can be reduced without explicitly cueing its spatial location is in accord with the notion that unilateral visual neglect results from the impaired ability of sensory input to the damaged hemisphere to release attention from its current locus (Posner et al., 1984). Posterior parietal cortex function is not, however, limited to stimulus selection, since deficits in saccade execution occur as well. The participation of posterior parietal cortex in both attentional and motor processing is consistent with current neurophysiological evidence in monkeys.

BIDIRECTIONAL CONTROL OF SACCADIC EYE MOVEMENTS IN THE BISECTED BRAIN. P.A. Reuter-Lorenz, H.C. Hughes, R. Fendrich M. S. Gazzaniga. Program in Cognitive Neuroscience, Dartmouth College & Medical School, Hanover, NH.

Stimulation and recording studies reveal that cortical (FEF and parietal) and collicular mechanisms direct saccades contralaterally. In contrast, studies of hemispherectomy and callosotomy patients suggest that a single hemisphere can generate both ipsiversive and contraversive saccades. However, saccades directed into generate boil injuries reality contraversive sactaces. However, sactaces directed into the blind field in hemispherectomy patients could be mediated by the superior colliculus (SC), as has been argued in cases of "blind-sight". In addition, previous demonstrations of ipsiversive control in callosotomy patients were taken to reflect a weak representation of the ipsilateral visual field in each hemisphere rather than bidirectional saccadic control. In this report we show that callosotomy patient JW demonstrates bidirectional control of saccades in response to a lateralized visual stimulus in the absence of interhemispheric transfer of the visual information.

Two tasks utilized the same stimulus conditions, but varied the response requirements. One task involved verbal reports of color names; in the other, JW was instructed to saccade either towards or away from the light source, or to make no response, depending on cue color. The cues were red, green or yellow LEDs unilaterally presented for 150 ms at an eccentricity of 7.0°. In the naming task, we expected that, in the absence of visual interhemispheric transfer, accuracy for LVF trials would approach chance, since IW's right hemisphere cannot control speech. J.W.'s naming accuracy for RVF cues was 100%, whereas LVF accuracy was at chance indicating that JW could not transfer the color information from the RH to the LH. In contrast, JW reliably produced both ipsiversive and contraversive saccades with normal latencies for both RVF and LVF cues (71% and 76%, respectively). Given the absence of visual transfer, these findings indicate that a single hemisphere can generate saccades in either direction, a result not readily explained by current models of oculomotor control.(supported by NIH grant PO1 NS 17778-08)

BIDIRECTIONAL PURSUIT OF LATERALIZED TARGETS IN A CALLOSOTOMY PATIENT R Fendrich P Reuter-Lorenz* H Hughes. MS Gazzaniga Dartmouth Medical School & College, Hanover NH.

While each cerebral hemisphere receives its input from the contralateral visual field, past investigations have suggested that each is dominant for ipsiversive pursuit eye motions. It follows that the leftward pursuit of targets in the left visual field, or rightward pursuit of targets in the right visual field, should require an interaction between the hemispheres. In the monkey, an anatomical pathway suited to mediate this interaction passes through the splenium of the corpus callosum. Severing this pathway in the monkey car

sprentian of the corpus canosium. Severing this pathway in the monkey can generate a deficit in the pursuit of lateralized targets which are moving outward from the fovea (Keating, 1988).

We investigated lateralized pursuit in a human callosotomy patient. Adapting Keating's procedure, we presented the subject with "step-ramp" targets. Since the latency for pursuit is typically shorter than the latency for saccades, such stimuli can elicit a brief interval of pursuit prior to refoveation of the stimulus. Steps were 2.50 into the left or right visual field, and ramp motion was 3.30/sec. towards or away from the fovea. In addition, we presented lateralized targets that were retinally stabilized. Such stimuli can elicit chasing smooth pursuit eye motions in normal observers.

With step-ramp stimuli, the subject's pursuit gain in the 60 ms interval just prior to his saccade to the target did not differ significantly for targets moving towards and away from the fovea (.33 vs. 29). Stabilized lateralized stimuli elicited pursuit similar to that found in normal subjects. These results suggest each hemisphere in a callosotomy patient is equally able to initiate insiversive and contraversive pursuit, or that pursuit can be mediated subcortically.

EYELID MOVEMENT IN PROGRESSIVE SUPRANUCLEAR PALSY (PSP). T. C. Hain and T. T. Tsai. Depts of Neurology and Otolaryngology. Johns Hopkins University, Baltimore, MD 21205. PSP is a disease of humans characterized by

slowing or inability to initiate vertical saccades. We measured the velocity of blinks with the magnetic search coil in 5 subjects with PSP

the magnetic search coil in 5 subjects with PSP and in 5 normal subjects.

In subjects with PSP, mean peak opening velocity was 196 ± 142 deg/sec and closing velocity was 777 ± 522 deg/sec. In normal subjects, opening velocity was 326 ± 87 deg/sec and closing velocity was 818 ± 405 deg/sec. These means are not significantly different ('t'est). The average ratio between peak opening of the state of the sta test). The average $\underline{\text{ratio}}$ between peak opening and closing velocity, was $0.25 \pm .07$ in subjects with PSP vs $0.46 \pm .15$ in normal subjects. These means are significantly different (p < 0.05). Voluntary eyelid closing and opening showed a similar trend but no significant differences. We conclude that the velocity of the opening

we conclude that the velocity of the opening phase of blinks is decreased in PSP, relative to the closing phase. This is consistent with the either inability to release orbicularis oculi tension, or inability to resume levator palpebrae tension.

372.13

DIRECTION SPECIFIC PURKINJE-CELL ACTIVITY IN THE OCULO-MOTOR VERMIS DURING TARGETING SACCADES. K. Ohtsuka, H. Noda. H. Sato. Y. Nagasaka* and R. Noda*. Sch. of Optometry, Indiana Univ. Bloomington, IN 47405.

Discharges of Purkinje cells (P cells) were recorded from lobule Vic and VII, when a macaque monkey made saccades from the central LED to one of 8 peripheral LEDs, or vice versa. The majority of P cells bursted during visually guided saccades in any direction. There were P cells pausing with all or some saccades in a particular direction. Even in these omnipause P cells, the degree of depression was different depending on the direction of saccade. There were also P cells bursting with saccades in one direction and pausing in the opposite direction. Saccade-related discharges were thus directionally specific in all P cells.

Typical saccadic response of the P cells consisted of a burst starting slightly after the onset of saccade during contralateral saccades. The latency of burst onset from saccade onset was shorter for smaller saccades. During ipsilateral saccades, the same P cells showed a prelude starting 40-50 msec prior to the onset, developing gradually and peaking at midsaccade. The latency of burst offset from saccade onset was also shorter in smaller saccades. Usefulness of these directionally specific Pcell activity during targeting saccades in modifying fastigial neurons will be discussed (Supported by NIH grant EY 04063).

Electrical stimulation of the dorsomedial frontal cortex (DMFC) of the rhesus monkey. E. J. Tehovnik and K-M. Lee. Department of Brain & Cognitive Sciences, M.I.T., Cambridge MA 02139
Schlag and Schlag-Rey (1987) used electrical stimulation to show

that the DMFC of monkeys is involved in the mediation of saccadic eye movements. From their study there is no suggestion of an organized motor map. We have preliminary evidence for the existence of such an organization. Electrical stimulation was used to elicit saccades from the DMFC after a monkey fixated different points in craniotopic space. Of the DMFC sites studied we found that the saccades evoked were always contraversive and that larger saccades were evoked when the eyes fixated a target in ipsiversive space and smaller saccades or no saccades were evoked when the eyes fixated a target in contraversive space. This depended on where along the rostral-caudal axis of the DMFC (about 8 mm in length) the simulation was applied: if applied rostrally, eye movements were evoked following fixation in both contralateral and ipsilateral space with the largest eye movements occurring for contralateral space. On the other hand, if stimulation was applied caudally, saccades were evoked only for gaze toward ipsilateral space, but with much shorter amplitudes than those occurring when the rostral DMFC was stimulated. Lastly, for rostral DMFC sites, when the eyes were positioned in extreme contralateral space, stimulation caused the eyes to remain fixated for the duration of stimulation; while for caudal DMFC sites, stimulation caused the eyes to remain fixated in central and contralateral space, again for the duration of stimulation. The foregoing suggests that the DMFC is intimately involved not only in saccadic generation but also in maintenance of gaze.

TOPOGRAPHICAL SEGREGATION OF VESTIBULAR AND SACCADIC NEURONS IN THE POSTERIOR CEREBELLAR VERMIS OF MACA QUES. H. Sato, H. Noda, K. Ohtsuka, Y. Nagasaka* and R. Noda*.

Sch. of Optometry, Indiana Univ., Bloomington, IN 47405. Purkinje cells (P cells) bursting and pausing with saccades are confined to the oculomotor vermis (lobules VIc and VII). These cells do not modulate with head movements. recording activity from posterior vermis, P cells responding to head rotation are often encountered above and below the folia of saccadic P cells, suggesting that vestibular and saccadic areas are juxtaposed.

Locations of P cells modulating sinusoidally during rotation of monkeys around their vertical axes were determined in reference to the recording sites of saccadic P cells. Confirming the previous results, the location of saccadic P cells was confined to vermal lobule VII and a part of folia VIc. Vestibular P cells were found in lobules VIa, b, and VIII, namely in the folia adjacent to the oculomotor vermis. P cells in the transition from saccadic to vestibular zones in lobule VI showed some changes in activity during head rotation but they were far from sinusoidal. These findings suggest that the areas of vestibular and saccadic functions occupy segregated folia in the posterior vermis. The intermediate zone may contain the P cells which receive converging eye- and head-velocity signals. (Supported by NIH grant EY 04063)

VISUAL MOTION SIGNALS FOR PURSUIT EYE MOVEMENTS
IDENTIFIED ON FLOCCULAR PURKINJE CELLS IN MONKEY.

R.J. Krauzlis and S.G. Lisberger. Dept. of Physiology, Neuroscience
Graduate Program, University of California, San Francisco, CA 94143
Smooth pursuit eye movements are driven by visual motion signals related to image velocity and acceleration. Since the cerebellar flocculus receives visual projections and is critical for generating pursuit, we sought to

ceives visual projections and is critical for generating pursuit, we sought to determine if its visual responses were appropriate for driving pursuit. We recorded the activity of single floccular Purkinje cells (P-cells) in alert monkeys as they pursued a set of target motions designed to test the range of visual motion signals used by the pursuit system. The stimulus set consisted of constant velocities (5 - 30 o/s) and constant accelerations (45 - 180 o/s²) of a 0.5 degree spot. We analyzed the responses of each P-cell under the assumption that the firing rate could be modelled as the sum of four signals: eye velocity, image velocity, image acceleration, and a motion onset impulse. The eye velocity contribution to firing rate was determined from measurements of steady-state firing rate during tracking at different eye velocities. Using an iterative optimization procedure, we determined the contribution of the three visual signals required to match the actual firing rate observed during tracking of each target motion.

The population of P-cells displayed a variety of firing rate profiles during the initiation of pursuit with differences that can be attributed to variations in their sensitivities to visual motion signals and eye velocity. Most P-cells

the initiation of pursuit with differences that can be attributed to variations in their sensitivities to visual motion signals and eye velocity. Most P-cells displayed responses which were combinations of all three visual signals and eye velocity. Several P-cells showed more specific responses, such as tuning for image velocity or a response dominated by a sensitivity to motion onset. Our analysis indicates that floccular P-cells receive visual motion signals appropriate to drive pursuit eye movements and that they vary in the strength of their visual and eye velocity inputs. SACCADES CONTRIBUTE TO VERGENCE IN RHESUS MONKEYS. J. S. Maxwell* and W. M. King. University of Rochester Medical School, Rochester, NY 14642.

In humans, disjunctive saccades contribute to the amplitude (up to 85%, Erkelens, et al., 1989) and speed of vergence eye movements. We show that in monkeys, saccades also interact with vergence eye movements. Rhesus monkeys were equipped with scleral search coils in both eyes and were monkeys were equipped with scleral search coils in both eyes and were trained to fixate near or far visual targets. Near targets required a vergence angle of 5-20 deg and far targets required no vergence. The near and the far targets were placed in the monkey's sagittal plane, aligned with one or the other eye, or offset horizontally (± 30 deg) and in depth to elicit both a saccade and a vergence movement. High velocity vergence (200-300 deg/sec) was always associated with a saccade and peak vergence velocity was correlated with saccadic velocity. During midline vergence trials monkeys often made a saccade away from and then back to the target so that no net version occurred. Midline vergence trials with saccades were faster than those without saccades (250 vs. 100 deg/sec). Midline divergence movements contained a saccade more often than convergence movements movements contained a saccade more often than convergence movements (81% vs 14% of the trials). In general, divergence movements reached higher average velocities (70-100deg/sec) than convergence movements (50-80 deg/sec) and were more stereotyped. These results show that the monkey is a suitable model for studying the neurophysiology of rapid vergence eye movements. Supported by PHS grants RR05403, EY01319, and EY06632.

CHASING ILLUSIONS: SMOOTH PURSUIT OF IMAGINARY ARGETS DEFINED BY EXTRAFOVEAL CUES. J. Pola, H.J.

Wyatt & B. Fortune.* SUNY College of Optometry, New York, NY.

Moving objects are often large and lack central detail, yet
most studies of pursuit have used small foveal targets. A few studies have examined pursuit of extrafoveal targets, but the dependency of pursuit initiation and maintenance on target configuration is unknown.

We asked subjects to track an imaginary target (ImT), located (i) midway between two cues (small spots) 30 deg apart, or (ii) 15 deg offset from a single cue. The cues moved in a horizontal step-ramp. Responses were analyzed for latency,

With an ImT between two cues, pursuit was good (slightly better for vertical and diagonal than horizontal pairs). With one cue, pursuit was degraded (most for a diagonal offset; less for horizontal; least degraded for a vertical offset). Varying cue eccentricity from 5 to 20 deg markedly degraded pursuit with one cue, but had little effect on pursuit with two cues.

We used two more cue configurations: (iii) a horizontal pair 30 deg apart, with the ImT 15 deg above the midpoint, gave good pursuit; (iv) a vertical pair, 30 deg apart, with the ImT 15 deg left or right of the midpoint, gave rather poor pursuit.

Conclusions: (i) and (ii) indicate that spatio-temporal stimulus attributes, perhaps related to perceived structure, can strongly influence pursuit guided by extrafoveal cues. (iii) and (iv) suggest that what gives such cues potency may be less a matter of wide separation than of foveal "enclosure."

THE AMPLITUDE OF VISUALLY GUIDED SACCADES IS SPECIFIED

THE AMPLITUDE OF VISUALLY GUIDED SACCADES IS SPECIFIEI GRADUALLY IN HUMANS. T.R. Stanford, L.H. Carney, and D.L. Sparks. Dept. of Psychology, Univ. of Pennsylvania, Philadelphia, PA 19104.

The generation of an accurate visually guided saccade requires that, prior to execution, saccade metrics must be programmed to compensate for the distance and direction of the image from the fovea. Recent studies of arm movements suggest that response specification is a gradual process, dissociable from that of initiation (Hening, Vicario, and Ghez, Exp. Brain Res. 71:103, 1988). That the metrics of saccadic eye movements are also specified gradually might 67 1070 and from the doubletter expression of Palescond Vicario Res. 10:1071 (1070) and the process of th

metrics of saccadic eye movements are also specified gradually might be inferred from the double-step studies of Becker and Jurgens (Vision Res. 19:967, 1979) and others, which demonstrated a gradual modification in the amplitude of an already programmed saccade by changing the target location slightly before movement onset. We sought to determine if this were true for saccades made to a single visual goal, and if so, to determine the time course of response specification.

Using a paradigm similar to that of Hening et al., human subjects synchronized saccade onset with the fourth of a series of equally spaced tone bursts. By presenting the target for varying amounts of time before the auditory cue, we varied the amount of time available to process information about its location from 0 - 325 ms. A rightward target LED was presented at one of three possible amplitudes with respect to a central fixation LED. Although subjects were familiar with the range of possible amplitudes, target position was randomized from trial to trial, as was the amount of time allowed for processing. Saccades begun within about 50 ms of target presentation had similar amplitudes randomized from trial to trial, as was the amount of time allowed for processing. Saccades begun within about 50 ms of target presentation had similar amplitudes regardless of which target was presented. This default amplitude was influenced by the range of potential targets. As the amount of time available to process visual information increased from 50 to 150 ms, saccade amplitude deviated from the default value and gradually approached that of the target.

These findings complement and extend those of double-step studies by demonstrating that the amplitude of a saccade to a single visual goal is specified

gradually, and proceeds from a default value that reflects the range of potential targets. (Supported by NIH EY01189).

SACCADIC EYE MOVEMENTS IN MEDICATED AND UNMEDICATED SCHIZOPHRENIC PATIENTS. T.J. Crawford, B. Haeger, L. Henderson, M. Revelev & C. Kennard. The London Hospital, Whitechapel, London El, U.K.

Recent studies of the pathophysiology of schizophrenia have suggested abnormal functioning in the frontal lobes and basal ganglia. There have been few studies of saccadic eye movements in schizophrenia, although specific patterns of abnormalities have been found in certain neurological disorders. In this study we have used various behavioural paradigms to clicit saccades in schizophrenic patients to determine if there is a similar abnormal pattern.

The subjects studied consisted of schizophrenic patients currently taking medication (MS, n=33), schizophrenics off medication for >1 year (UMS, n=13), manic-depressive patients (MD, n=17) and normal controls (NC, n=30). The paradigms used were the reflex task (RS), the antisaccade task (AS) and the remembered target task (REM), In RS the subject made a saccade to the onset of a peripheral visual target (±7.5, ±15 deg), whereas in AS the subject was instructed to make a saccade to a location equally eccentric but in an opposite direction to the peripheral target. In REM the target was presented for 200 msec and the subject was instructed to make a saccade only when the central fixation was extinguished 500 msec later.

In RS there were no differences in saccadic latencies or amplitude between the four groups. In AS the patient groups showed significantly more saccadic errors (an initial saccade toward the target) than NC (MS, 63%: UMS, 47%: MD 45%). The mean saccadic amplitude remained the same for both 7.5 and 15 deg targets in the patient groups was slightly reduced in the REM condition. There were no left/right asymmetries in latency or amplitude for any condition. There were no left/right asymmetries in latency or amplitude for any condition.

INTERACTION BETWEEN EYE AND LID MOVEMENT: BLINKS ENCODED WITH VOLUNTARY GAZE SHIFTS. K.A. Manning, C. Evinger, P.A. Sibony, Depts. Neurobiology & Behavior, and Ophthalmology, SUNY Stony Brook, Stony Brook, NY 11794

A variety of observations suggest a link between blinking and eye movements in humans. First, cocontraction of the extraocular muscles accompanies voluntary blinks. Second, a blink commonly accompanies large vertical saccadic eye movements. Finally, in patients with slow saccades, a voluntary blink concomitant with a saccade increases saccade velocity to a normal value. The present study

reveals that a blink also accompanies the generation of large horizontal gaze shifts.

We measured the lid closing orbicularis oculi EMG activity (OOemg) of the upper eyelid and eye and head position of both experienced and naive human subjects during voluntary saccadic eye movements or combined eye and head movements. EOGs measured eye position and a magnetic coil system showed head position. A pair of small silver plates (<2 mm diam) on the upper eyelid monitored OOemg without contamination from other muscles. At the sound of a tone, subjects made horizontal gaze shifts from the midline to targets 17 to 44° eccentric and back to the midline.

A burst of OOemg activity occurred during saccadic eye movements alone and an even more robust burst of OOemg activity accompanied combined eye and head movements. This activity in the orbicularis oculi muscle began 20 ms before movement of the eye. Since both extraocular and lid closing muscle activation must have been nearly simultaneous, the blink cannot be a response to corneal stimulation introduced by the eye movement. OOemg activation became apparent when maximum saccadic velocity exceeded 250-400 °/sec, increased with higher maximum saccadic velocities, but could be suppressed under certain experimental conditions. Thus, the data demonstrate that the neural program generating saccadic gaze shifts includes a blink. Supported by EY07391.

EFFECTS OF SACCADIC VARIABILITY ON SACCADIC PREDICTION BY NEURAL NETWORK AND CURVE FIT PREDICTORS. L A Abel and S Kolli. Ocular Motility Lab., Dept. of Biomed.
Engr., Univ. of Akron, Akron, OH 44325.
Study of saccadic variability may be important

when predicting saccadic endpoint from partial information. This is useful in flight simulators when, to save computation, high display resolution is used only in the vicinity of predicted eye position. We trained a small backpropagation network on 4 samples of the initial 8msec segment of 20 saccades, in the range of 1 to 30°, collected from 4 normals. Regression coefficients for actual vs predicted saccadic amplitudes were .95, .93, .88 and .81. The network training time was 5 min; for less variable subjects prediction accuracy was comparable with conventional curve fitting techniques and required much less of the saccade's duration. Next, 15 saccades of the worst and the best cases were fitted with a cumulative normal distribution function. Both the initial 8msec and entire first halves of saccades were fitted, with regression coefficients of .74 & .84 and .87 & .80, respectively. The percentage coefficient of variance was approximately the same for both peak velocity and the amplitudes of the four initial samples, for all sizes of saccades. Though this variability is within normal limits it had significant impact on both curve fitting and neural network prediction.

ADAPTIVE CHANGES IN THE AMPLITUDE OF SMALL SAC-CADES. Joanne E. Albano, Center for Visual Science, University of Rochester, NY 14627.

The amplitude of saccades to target displacements can be modified in response to artificially created visuo-motor errors. For large saccades (>10°), induced errors of 30% would create significant postsaccadic retinal errors, whereas, for small saccades (<3°), postsaccadic retinal errors would fall within the noise of the system. Though within the normal range of saccadic errors, it is still possible that small induced postsaccadic retinal errors are available to the mechanism controlling recalibration.

To examine this question small saccades were adapted by displacing the target by amounts equal to 30 or 40% of the size of the ongoing eye movement (Albano & King, 1989). Each experiment consisted of a set of preadaptation, adaptation, and postadaptation trials. Significant changes in the gain of saccade amplitudes were seen during the course of 100 trials. The amplitudes could be increased or decreased with positive or negative feedback. The velocity profiles of small adapted saccades were unimodal and the peak velocities were increased or decreased in the direction appropriate for the change in amplitude.

The recalibration of small saccades suggests that the mechanism responsible for the gain changes is sensitive to small dysmetrias. Somehow these unexpected induced errors are distinguished from those resulting from the normal noise of the system or alternatively an averaged error is computed and used to continuously adjust the gain. Supported by EY07344 and EY01319.

MOTOR SYSTEMS AND SENSORIMOTOR INTEGRATION: OCULOMOTOR SYSTEM II

373.1

RELATION OF THE DORSOLATERAL PONTINE NUCLEUS OF THE MONKEY TO OCULAR FOLLOWING RESPONSES.

K.Kawano, M.Shidara*, and S.Yamana*. Neuroscience Sect., Electrotechnical Lab., Tsukubashi, Ibaraki 305, JAPAN

Recent studies suggest a major role of the dorso-lateral pontine nucleus (DLPN) in the mediation of smooth pursuit eye movements and initial optokinetic responses (OKR). Although a close correlation between the initial OKR and ocular following responses was suggested, the role of the DLPN in the mediation of the latter was left unknown. The present experiments were concerned with the relation of the DLPN to the ocular following responses. A monkey faced a screen onto which a large field visual stimulus was projected, and its eye move-ments were recorded with the magnetic search coil tech-Single unit activity was recorded in the DLPN. Most of the neurons, which were activated by the movements of the visual scene, showed similar dependence on the visual properties of the stimulus to that of ocular following, e.g. preference to high speed, latency delay following, e.g. preference to high speed, latency delay due to blurring and oscillation at the high temporal frequency (40Hz). Their latencies were very short. 40% of the neurons started their increase of firing rate more than 10ms before the eye movement. After the lidocaine injection in the DLPN, the gain of the ocular following reduced. On the other hand, the gain increased after the bicuculline injection. These results suggest an important role of the DLPN in the control of ocular following.

CHARACTERISTICS OF MIDBRAIN NEAR RESPONSE CELLS PROJECTING TO MEDIAL RECTUS MOTONEURONS Yihong Zhang, Paul Gamlin, and Lawrence Mays, Department of Physiological Optics, School of Optometry, University of Alabama at Birmingham, Birmingham, AL. 35294.

Midbrain near response cells, which are located just dorsal and lateral to the oculomotor nucleus, increase their firing rate when a nearby visual target is fixated. We have shown by antidromic activation and collision testing that a subgroup of these near response cells projects directly to target is inxated. We have snown by antidromic activation and collision testing that a subgroup of these near response cells projects directly to the medial rectus subdivision of the oculomotor nucleus (MRS) (Zhang et al., 1989, Invest. Ophthal. & Vis. Sci. (Suppl.) 182). However, the vergence and accommodation systems are cross-coupled. Also, midbrain near response cells are reported to form a heterogeneous group, with some related to the angle of vergence, others related to lens accommodation, and still others related to both vergence and accommodation (Judge and Cumming, 1986, J. Neurophysiol. 55:915). Therefore, the present study investigated the relationship to vergence and accommodation of midbrain near response cells in general and, in particular, those cells that project directly to the MRS. Recordings from 58 near response cells in two monkeys revealed a continuous distribution of cell properties, ranging from those cells that were related predominantly to vergence to those that were related predominantly to accommodation. Seventeen of these cells could be antidromically activated from the ipsilateral MRS and, in contrast to the entire population, these cells carried a signal related mainly to vergence. We propose a model that explains the behavior of both the general population of midbrain near response cells and the subgroup of near cells projecting to the MRS. This model is based on differential strengths of accommodation and vergence input to individual neurons. (Supported by EY03463 & CORE grant P30 EY03039).

EVE MOVEMENT DURING MOTION AFTEREFFECT (MAE). S.H.Seidman*. C.W.Thomas*, W.P.Huebner, C.Billian*, and R.J.Leigh. VA Med. Center, University Hospitals and Dept. Biomed. Eng. Case Western Reserve Univ., Cleveland, OH 44106.

We measured torsional eye movements in three male Ss (ages 24-43) while viewing a circular target of 4-16 alternating light and dark sectors, subtending -30°. The target rotated around the line of sight with angular velocities ranging from 60-180°/s for 20s, then stopped, remaining in view. Ss reported perception of motion with a potentiometer. During target rotation, Ss developed torsional nystagmus with slow phases in the direction of the stimulus (typical gain=.05). Following cessation of target rotation, Ss experienced a perceptual MAE in the direction opposite to prior target motion, with a duration of >15s. During MAE, slow phase eye movements (SEMs) were in the same direction as the perception, but did not persist as long as the MAE. Therefore, the direction of MAE was opposite to that of retinal slip. In another experiment, horizontal eye movements were recorded while Ss viewed 16 alternating vertical light and dark bars, with a stationary central fixation spot, also subtending -30°. Targets moved horizontally at -5 or 7.5°/s, stopping after 20s. SEMs in the direction of the stimulus occurred during target motion (typical gain=.1), despite attempts to fixate. Following cessation of motion, eye movements were suppressed but MAE in the direction opposite to prior stimulation persisted for typically 7s. In conclusion, although MAE may be accompanied by eye movements or their visual consequences. (Supp. by VAMC and NIH EY06717)

PRENATAL DEVELOPMENT OF MONKEY EXTRAOCULAR MUSCLE. John D. Porter and Robert S. Baker. Depts. of Anatomy and Neurobiology and Ophthalmology, Univ. of Kentucky Medical Center, Lexington, KY 40536-0084. In order to better understand the basis for the unique structural-functional

Ophthalmology, Univ. of Kentucky Medical Center, Lexington, KY 40536-0084. In order to better understand the basis for the unique structural-functional diversity of extraocular muscle, ontogeny of lateral rectus muscles was studied in Macaca nemestrina fetuses of 62-156 days gestation, using light and electron microscopy. At F62, intramuscular unmyelinated axons, enclosed in clusters (not individually) by Schwann cells, and infrequent, very primitive neuromuscular contacts were seen. Myofilaments already were organized into sarcomeres, while fiber mitochondria and internal membrane systems were nascent. By F92, presumptive singly (SIF) and multiply (MIF) innervated fiber types could be distinguished on the basis of myofibril delineation. Association of primitive with more developed myofibers was a prominent feature. Maturation of internal membrane systems was well underway; although presence of active golgi-like organelles suggested continuing elaboration of these elements. Intramuscular axons were myelinated only near point of entry into the muscle; terminal axons exhibited lengthy muscle contacts. The mnjs were primitive, with wide synaptic clefts, high vesicle content and junctional accumulations of myonuclei. No elaboration of postjunctional folds was evident. Multiple innervation of putative SIFs was apparent. By F135, axon myelination increased and synaptic cleft width was reduced, although many nmjs continued to occupy long segments of sarcolemma. Discrete clusters of vesicles appeared to mark sites that would later form definitive mnjs. Muscle oxidative capacity, evidenced by fiber mitochondrial content and microvascular network development, was clearly increased by F156, and served to define SIF subtypes. At this stage, mnjs more closely resembled those of the adult, but still lacked postjunctional folds. In all, global MIFs preceded and orbital SIFs followed all other types in attaining mature fiber characteristics.

Taken together, these observations suggest that some unique features of extraocular m

OPTOKINETIC NYSTAGMUS IN TURTLES: EVIDENCE OF A BEAT-TO-BEAT CYCLE GENERATOR FOR SLOW PHASE DURATIONS. C.D. Balaban and M. Ariel. Depts. of Otolaryngology & Behavioral Neuroscience, Eye & Ear Institute, University of Pittsburgh, Pittsburgh, PA 15213.

An analysis of optokinetic responses suggests that there is a basic cycle generator that sets the timing of nystagmus fast phases. Red-eared turtles (Pseudemys scripta elegans) were fitted with a search-coil contact lens for recording optokinetic nystagmus elicited by a monocular random pattern drifting at constant velocities of 0.25-42°/s. The times and eye positions at the onset and end of each fast phase were used for analysis positions at the observation of the properties of slow phase durations (SPDs). The behavior of SPDs is consistent with a model incorporating a basic cycle generator (BCG), with each SPD equal to $(1 + \varepsilon)$ times the duration of the previous SPD ($\epsilon \sim N(0, 0.1 - 0.2)$). The parameter λ , defined as the current SPD divided by the previous SPD, was used to analyze beat-to-beat operations of the BCG. The basic cycle length was defined as median SPD; its log was proportional to log (slow phase eye velocity). When initial eye position deviated in the slow phase (SP) direction, the SPDs reflect one cycle of the BCG. However, the SPDs 'skipped-a-beat' with probability 0.3 when initial eye position deviated in the fast phase direction; the BCG appeared to cycle a second time before producing a fast phase. The estimates of the variance of ϵ and p from the data sast pulses. The estimates of the variance of ε and p from the data were sufficient to reproduce the observed distributions of λ and SPDs across stimulus conditions. Thus, this novel model using both timing and position information can reproduce the alternation between mystagmus slow and fast phases. ULTRASTRUCTURE AND CONNECTIONS OF IRIS AND CILIARY MOTO-NEURONS IN THE PRIMATE CILIARY GANGLION. Paul J. May. Depts. of Anatomy and Ophthalmology, U. of Mississippi Med. Ctr., Jackson, MS 39216.

The ciliary ganglion receives input from the Edinger-Westphal (EW) nucleus and contains the postganglionic motoneurons that supply the iris constrictor pupillae muscle and the ciliary muscle of the lens. There is limited data on ciliary ganglion ultrastructure in primates, despite the well developed near response present in foveate monkeys. Electron microscopic investigation of ganglia from Macaca fascicularis revealed that the motoneurons have large ovoid somata (45-70 um long) with pale nuclei and numerous stacks of rER and Golgi apparati. In stark contrast to the axosomatic calyces found in birds, the somata in macaque ciliary ganglia are nearly devoid of synaptic contacts and are instead ensheathed by glia with dark cytoplasm. Most of the synaptic contacts are found in the perisomatic neuropil, where the dominant presynaptic (presumably preganglionic) profile varies from 0.5 to 3.0 um in diameter, is filled with large (0.04 um diameter) spherical vesicles and often has scattered large (0.08 um diameter) dense-cored vesicles. Generally, the postsynaptic rofiles are dendrites up to 5.0 um in diameter and their appendages (0.4 -0.8 um). Glomerular arrangements with a central axonal element contacting several small dendritic appendages were also frequently observed. A second, very rare, profile containing only large dense-cored vesicles was also found, indicating a catecholaminergic input. To differentiate the pupillary from the lens-related motoneurons WGA-HRP was injected into the anterior chamber. The labeled pupillary ganglion cells (20%) showed no consistent ultrastructural differences from the unlabelled lens cells. In contrast to the discrete ganglionic labelling, trans-synaptic labelling was observed in most EW moto-neurons, suggesting that the "lens" related EW cells may actually subserve both intrinsic components of the near response. DEFICITS IN SMOOTH-PURSUIT EYE MOVEMENTS FOLLOWING LIDOCAINE INJECTION IN MONKEY NUCLEUS RETICULARIS TEGMENTI PONTIS (NRTP). D.A. Suzuki, R.D. Yee, & K. Betelak PONTIS (NRTP). D.A. SUZUKI, A.P. 1887, a.R. 1888, a.R.

A behavioral test of NRTP involvement in smooth-pursuit eye movement (SPEM) control was undertaken in light of observed inputs from the frontal eye field and the SPEM deficits resulting from frontal eye field lesions. NRTP activity was recorded in alert monkeys trained to fixate a moving 0.5 deg spot. Eye position was monitored with the scleral search coil technique. After recording pursuit-related unit activity, a 28 ga. needle replaced the µelectrode and 5-10 µl of lidocaine were injected. SPEM gain was calculated as the ratio of eye and target velocities. Pre-injection control values were measured before and after placement of the injection needle. Following injection of lidocaine, SPEM gain decreased by 20-35%. The SPEM deficits were direction selective. Although saccadic eye movements appeared normal, the

Although saccadic eye movements appeared normal, the monkeys experienced difficulty in foveating a moving target. The effects of the lidocaine were diminished 20-30 minutes following injection and SPEM gains were normal at 60 minutes

These results implicate NRTP involvement with SPEM control. Frontal eye field to NRTP projections could constitute a route that parallels the cortical visual motion (MT/MST) to dorsolateral pontine nucleus pathway. Such a parallel SPEM circuit could account for the recovery of SPEM ability following placement of lesions in the dorsolateral pontine nucleus

Gaze Pursuit of Predictable and Unpredictable Moving Visual Targets Compared to Smooth Pursuit and Vestibulo-ocular Reflex Cancellation. K. E. Cullen and R. A. McCrea Comm. on Neurobiology, Univ.

The ability of squirrel monkeys to track both predictable and unpredictable moving targets by generating combined eye-head movements, gaze pursuit (GP), was compared to both 1) their ability to track the same target in a head fixed paradigm by generating smooth pursuit (SP) eye movements, and 2) their ability to cancel their vestibulo-ocular reflex (VORc) by fixating a target during comparable vestibular stimulation.

vestibular stimulation.

The accuracy (gaze velocity gain) of GP and SP was similar when the monkeys tracked predictable sinusoidally moving targets (0.25-3.5Hz, 20% peak velocity); while the gain of VORc was slightly higher than that of GP and SP at low frequencies of stimulation (< 1.0 Hz). The phase lag of gaze velocity during VORc with respect to stimulus velocity, was less than that of GP and SP at higher frequencies (> 1.0 Hz).

Linurgiciable results reador motions at least the strength of the stren

frequencies (> 1.0 Hz).

Unpredictable pseudo-random stimulation consisted of the sum of five nonharmonically related sinusoids in which the highest frequency was 1.9 Hz. The velocity of each component wave was either 5°/s or 10°/s. The gaze velocity gain during GP of unpredictable moving targets was greater than the gain of SP for all frequencies of the pseudo-random stimulus, although gaze velocity gain was greater during VORc than during either GP or SP. The phase lag of gaze velocity during VORc was less than that during GP, which in turn was usually less than that of SP. The increase in gaze velocity gain during GP compared to SP was positively correlated with the proportion of gaze velocity generated by head movement.

These results suggest that in generating combined eye-head movements during GP, monkeys make use of non-visual afferent information in addition to the visual feedback of target motion. The differential effect of this input is obscured when predictable stimuli are used, indicating that head and eye movement generation mechanisms receive input from a common predictive element.

mechanisms receive input from a common predictive element.

IMMUNOHISTOCHEMICAL LOCALIZATION OF GLYCINE IN THE OCULOMOTOR NUCLEI OF THE GROUND SQUIRREL (Citellus

IMMUNOHISTOCHEMICAL LOCALIZATION OF GLYCINE IN THE OCULOMOTOR NUCLEI OF THE GROUND SQUIRREL (Citellus tridecemlineatus).

M.A. BASSO*, S. AGRWALA*, J.K. MOORE & J.C. MAY. Depts. of Psychology and Anatomical Sciences, SUNY at Stony Brook, NY 11794.

The oculomotor nucleus (OMN) in the ground squirrel is notable in that the extraocular motorneuron pools appear to be spatially segregated to a greater degree than that seen in other mammalian species. This observation has prompted us to compare the immunohistochemical labeling patterns of selected neurotransmitters across these different motorneuron pools and across the other extraocular motor nuclei. Physiological, autoradiographic and immunohistochemical evidence from the primate and cat has implicated both GABA and glycine as the transmitters involved in the inhibitory limb of the vestibulo-ocular circuit. Recent uptake and pharmacological studies suggest that GABA may be the principal inhibitory neurotransmitter in the adducens nucleus (Spencer, et al. 1987, 1990). In support of this view the prisent study revealed heavy glycinergic reactivity throughout the abducens nucleus. Glycinergic label was also found in the oculomotor and trochlear nuclei but was meager in comparison with that seen in abducens. Though relatively sparce, this labeling was interesting in that it was seen only within restricted cellular groups along the midline and ventrolateral portions of the OMN. Supported by Sigma Xi G.I.A. (SA), NSF BNS-8896117 (JGM), NIH NS-26516 (JKM) and NIH EY-07113 (Heywood Petry).

The vestibulo-ocular (V-O) pathway in the chick embryo. J.Stomm-Mathisen, J.K.S.Jansen, J.C.Glover and B Fischer. Depts. of Anatomy and Physiology. Oslo Oslo, Norway.

To generate appropriate eye movements during head rotation the V-O pathways must excite contralateral and inhibit ipsilateral eye motoneurons. We have preliminary information in E day 11 chick embryos on putative transmitters of certain vestibular subgroups involved in vertical V-O reflexes.

A ventral subdivision of the superior (SV) nucleus related subdivision of the superior (SV) nucleus projects ispilaterally to superior oblique (SO) and rectus inferior (RI) motor nuclei. This group was retrogradely labeled from the ascending MLF. Immunhistochemically, many labeled neurons reacted with a GABA specific antiserum. Additionally, neurons of the same group were labeled autoradic graphically after $^3\mathrm{H}$ Nipecotic acid (a GABA analogue) injected into the oculomotor nucleus.

The dorsal subdivision of the SV projects to the contralateral IO and RS motoneurons. This group is labeled autoradicgraphically after injection of ³H Asp in the oculomotor nucleus. Such injections also label a more caudal group of ${\bf vestibular}$ neurons which project to contralateral SO and RI motoneurons.

The results are consistent with observations in mammals showing that second order (V-O) neurons directly excite contralateral and inhibit ipsilateral eye motoneurone pools.

Cytoarchitectonic Parcelation of the Perihypoglossal Complex in theRat R.S. Revay and G. Aston-Jones. Dept. Mental Health Sci., Hahnemann University, Philadelphia, PA, 19102.

The perihypoglossal complex, composed of Roller's nucleus, and the nuclei intercalatus, prepositus hypoglossi (PrH), and supragenualis, is situated in the dorsomedial medulla. A subset of PrH neurons form a major afferent to the nucleus locus coeruleus (LC) as demonstrated by tract tracing studies. We examined the cytoarchitechtonics of this region to define the relation of these LC afferents to other parts of the perihypoglossal complex. Fortymicron-thick sections were cut in the three principle planes from snap-frozen, fresh brains of male Sprague-Dawley rats and Nissl stained. This method provided material with minimal tissue shrinkage. A series of transversely cut fixed brains were stained by a modified Weil method to demonstrate myelinated fibers. Tenmicron-thick sections cut from methyl/butyl methacrylateembedded tissue provided Nissl stained sections with superior morphological detail. Careful inspection of the above material made possible a detailed description of the perihypoglossal complex. It was found that the PrH is composed of several cytoarchitonically distinct subdivisions. One of these subdivisions, located in medial suprafasicular PrH and along the dorso-lateral border of the medial longitudinal fasiculus, corresponds to the region that contains LC-projecting neurons. Thus, it appears that a cytoarchitectonically distinct region of the PrH is afferent to the locus coeruleus. Supported by USPHS grants NS24698 and DA06214.

TRANSIENT RESPONSES OF PRIMATE PONTINE NEURONS FOR VISUALLY TARGETED EYE AND HEAD MOVEMENTS. L. Ling*, J.O. Phillips, and A.F. Fuchs. Regional Primate Research Center and Depts. of Psychology and Physiology and Biophysics, University of Washington, Seattle, WA, 98195.

Monkeys naturally perform gaze shifts through a combination of eye and head movements. We have developed a preparation that allows us to record extracellular single unit activity in a rhesus monkey who is free to turn his head in the horizontal plane to look at eccentric targets. Animals were trained to follow a spot of light using combined eye and head movements (with the head free to move about a vertical axis through the atlanto-axial joint) or employing eye movements alone

(with the head held stationary).

We have used this preparation to record from the pontine brain stem in the region containing cells that are part of the legendary saccadic burst generator. A preliminary analysis from 13 burst neurons shows that some exhibit a sudden high frequency burst that precedes gaze movements regularly by about 70-80 msec and gives way to a gradual decrease in activity that seems to be related to parameters of the head movement. For these neurons, greater head movements are accompanied by more spikes. A similar analysis of 4 omnipause neurons shows that these cells are related to eye movement alone.

DESCENDING CONNECTIONS OF THE MACAQUE NUCLEUS OF THE OPTIC TRACT. M.I. Mustari, A.F. Fuchs and C.R.S. Kaneko. Dept. of Physiology & Reg. Primate Res. Center, Univ. Washington, Seattle WA 98195. Lesion studies have shown that the nucleus of the optic tract (NOT) is essential for horizontal optokinetic nystagmus. However, the neural pathways used by the NOT to support this important function have not been elucidated. We localized the NOT by single unit recording and placed small (5nl-15nl) injections of 2% WGA-HRP into the NOT of three monkeys (2 Macaca mulatta and 1 M. fascicularis). After 24-h survival, animals were sacrificed and prepared for TMB histology. The injection sites involved all of the NOT, the dorsal terminal nucleus, and other caudal pretectal nuclei, and spread in varying degrees to the rostral superficial layers of the ipsilateral superior colliculus. The principal projection of the NOT was to the <u>ipsilateral</u> dorsal cap of the inferior olive (dC). The NOT also had substantial reciprocal connections with the <u>contralateral</u> NOT and <u>both</u> lateral terminal nuclei of the accessory optic system. Connections with other vestibulo/oculomotor areas were disappointingly much lighter in density. At the level of the medulla, they included <u>ipsilateral</u> efferent connections to the nucleus prepositus hypoglossi (NPH), medial vestibular (MVN), and abducens (AB) nuclei; the inhibitory burst neuron area also received a light projection. A few retrogradely labeled neurons were present in the contralateral NPH and MVN nuclei. At the level of the pons, the NOT projected lightly to the <u>ipsilateral</u> nucleus reticularis tegmenti pontis (NRTP) and dorsolateral pontine nuclei (DLPN). These results show that the NOT appears to have efferent connections with structures known to be involved in oculomotor control. These include possible output pathways through the cerebellar flocculus via the dC, NRTP and the DLPN and more direct pathways through the MVN, NPH and AB. CAT LATERAL RECTUS (LR) MOTOR UNITS: RECRUITMENT, K VALUES, AND HYSTERESIS. M.A. Snyder and S.J.Goldberg. Dept. Anatomy, Medical College of Virginia - VcU, Richmond, VA 23298.

60 antidromically identified abducens nucleus motoneurons (MNs) in 12 anesthetized cats were tested for morosynaptic recruitment by stimulation of the contralateral medial rectus subdivision of the oculomotor nucleus. These same MNs were then directly stimulated and the mechanical responses of their muscle units were recorded with the LR muscle at maximal isometric tension.

MNs, within and among cats, were not recruited based on axonal conduction velocity, contraction speed or force, fatigue index, or K value.

K values (slope of MN stimulation frequency needed to increase tetanic tension by 1 mg.) were higher for weak motor units and lower for powerful ones, (range=0.20 - 6.42; r=0.97). The highest K values were associated with fatigue resistant units and the lowest with fatigable units.

A 200 msec. continuous stimulation train of 350 pps for 10 msec., 200 pps for 15 msec., and 100 pps for 175 msec. produced a force record to be compared to that of a monotonic train of 100 pps for 200 msec. A force level hysteresis, at 100 pps, was seen in most motor units.

RESPONSE PROPERTIES OF MONKEY NOT NEURONS. U.J. Ilg & K.-P. Hoffmann Allgemeine Zoologie und Neurobiologie, Ruhr-Universität, Postfach 10 21 48, D-4630 Bochum, F.R.G.

Results will be presented obtained from single unit recordings in the nucleus of the optic tract (NOT) of trained monkeys working on the following paradigms

- Fixation of a spot while the background (random dot pattern) is moving. Pursuit of a spot across a stationary random dot or uniform background.
- Optokinetic nystagmus (OKN) and optokinetic after nystagmus (OKAN). Additionally we performed experiments on anaesthetized and paralysed rhesu monkeys especially to study the response properties of antidromically identified neurons projecting from cortex to NOT.

The results can be summarized as follows: 1. NOT neurons code for direction and speed of retinal image motion (slip detectors). 2. During OKAN there is no relationship between slow phase eye velocity and NOT activity. Thus the eye velocity storage mechanism does not include the NOT, whereas NOT provides the visual input for the storage mechanism. 3. The transfer function between retinal slip and slow-phase eye velocity also describes the relationship between retinal slip and discharge rate of single NOT neurons. 4. During smooth pursuit across uniform background NOT neurons code target slip while during pursuit across a random dot pattern they code background slip suggesting that the pursuit system is not relying on NOT signals. 5. The modulation of NOT neuron activity decreases if the stimulus consists only of colour-contrast, i.e. is isoluminant. 6. The activity of NOT neurons is influenced by saccades via a visual (reafference) and a non-visual (efference copy) signal. 7. There is physiological evidence that NOT in monkey receives input from area FST of the superior temporal sulcus

CYTOARCHITECTURE OF THE PRIMATE ZONA INCERTA. T. P. Ma, Y. Anavi*, X. J. Hu*, and J. A. Rafols. Laboratory of Sensorimotor Research, National Eye Institute, NIH, Bethesda, MD 20892 and Department of Anatomy and

Cell Biology, Wayne State University School of Medicine, Detroit, MI 48201.

The neurons in the zona incerta (ZI) of the monkey (Macaca mulatta) were examined in Nissl, fiber-stained, cytochrome oxidase, and Golgi preparations sectioned in the frontal, horizontal, and sagittal planes. In the frontal plane, the ZI was oriented in the dorsolateral to ventromedial axis and could be separated into dorsal and ventral sublaminae on the basis of staining and morphological features in the Nissl, cytochrome oxidase, and Golgi preparations. In particular, the ventral sublamina was intensely stained for cytochrome oxidase. The dendrites of most neurons in both sublaminae were oriented preferentially along the long axis of the nucleus. Three neuronal types (I-III) were distinguished on the basis of features of the somata, dendrites, and axons in Golgi preparations. Type I cells had fusiform or polygonal cell bodies (long axis from 21 to 40 μ m) and dendrites that radiated for up to 725 μ m within the sublamina and along the axis of the nucleus. Neurons with similar dimensions were observed to be darkly stained in cytochrome oxidase preparations. Type II cells had polygonal cell bodies (18-20 μm) and thin, varicose dendrites that extended up to 300 µm. These cells were rare in our preparations. Type III cells were local interneurons that had small (12-16 µm), round cell bodies with wavy dendrites (up to 400 µm). Numerous multilobed appendages (1-3 µm) and axon-like processes originated from these dendrites and made apparent contacts with other Type III dendrites or with dendrites of Type I cells. The ZI is reported to receive projections from many centers of the brain, and has reciprocal projections with many of these centers, to the cerebral cortex, and other brainstem nuclei. Our results support the notion that complex intrinsic circuits formed by morphologically heterogeneous neuronal types exist in the primate zona incerta to integrate these inputs.

LOCOMOTOR ACTIVITY AND ACTIVE AVOIDANCE IN RATS: EFFECTS OF INTRAHIPPOCAMPAL INJECTIONS OF NEUROTRANSMITTER ANTAGONISTS. L.S.O.Brito* and and N.O.Brito. Setor de Neurociencias, UFF. Brasil.

Brasil.

Previously, we showed that lesions in the septo-hippocampal system increase general activity, but do not alter the performance of a one-way active avoidance task. Seventy five male Wistar rats underwent surgery for implantation of bilateral 22 ga. cannulae aimed at the dorsal hippocampus. Rats were tested for general activity and one-way active avoidance after 1ul injections of one of the following drugs: Krebs (N=8); scopolamine (9 ug/ul, N=8; 18 ug/ul, N=8); sulpiride (5 ug/ul, N=9; 10 ug/ul, N=9); propranolol (5 ug/ul, N=9; 10 ug/ul, N=8); cimetidine (0.75 ug/ul, N=8; 1.5 ug/ul, N=8). The results showed that only intrahippocampal injections of scopolamine increase activity, and that there were no drug effects on total number of avoidances in the one-way active avoidance task. We conclude that one-way active avoidance task. We conclude that disruption of cholinergic mechanisms in the hippocampus mimic some of the behavioral effects of lesions in the septo-hippocampal system.

DOSE-DEPENDENT EFFECTS OF PILOCARPINE ON ACQUISITION AND RECALL OF STEP-THROUGH PASSIVE AVOIDANCE IN THE RAT. W. Jeffrey Wilson! & Jennifer A. Cook?, 'Dept. of Psychological Sciences, Indiana-Purdue University, Fort Wayne, IN 46805; 'Zbept. of Psychology, Ernory University, Atlanta, GA 30322.

Wayne, IN 4580s; 2Dept. of Psychology, Emory University, Atlanta, GA 30322. Sprague—Dawley rats received one of four doses of pilocarpine (0, .33, 1.00, & 3.00 mg/kg, n=6/group) prior to both the training and test session of a step—through passive avoidance procedure. In training, the 1.0 mA shock was escapable, and the session continued until the rat remained on the safe side for 60 s. Test session continued until the rat stepped through or for 600 s. Pilocarpine produced a dose—dependent increase in the number of trials required to reach criterion, and a dose—dependent decrease in the number of rats in each group that performed perfectly in the test. Dose—dependent increases in latency to cross, and to escape shock, occurred in training. These motor and memory effects interacted to produce a biphasic effect of drug dose on latency to cross in the test.

We have previously shown that a high dose of pilocarpine impairs both learning and performance of this task, as does scopolamine. The present results demonstrate that low doses of a muscarnic against do not produce effects apposite to those produced by scopolamine, and suggest that both increases and decreases in central cholinergic activity can disrupt memory.

374.5

SCOPOLAMINE SUPPRESSES BOTH LOCOMOTION AND OBJECT CONTACT IN A FREE EXPLORATION SITUATION.

M. J. Renner, D. L. Dodson, & P. A. LeDuc. Department of Psychology, Memphis State University, Memphis, TN 38152

The anticholinergic drug scopolamine is widely reported to have amnestic prop-

erties. Buhot, et al. (Psychobiology, 1989, 17, 409-417), recently reported that presession cholinergic disruption with scopolamine decreases time spent in proximity to novel objects while increasing locomotor behavior. In the experiment reported here, male Long-Evans hooded rats (Rattus norvegicus, 80 days old) were given access to an arena containing objects on three consecutive nights. On Day 1 subjects were familiarized with the apparatus and procedure: Each was injected with saline (SAL), and 12 minutes later given access to the arena under low light. Subjects were randomly divided into four groups, with half given SAL and half given scopolamine (SCO, 1 mg/kg) on Day 2 and Day 3, resulting in SAL-SAL, SAL-SCO, SCO-SAL, and SCO-SCO groups. Videotapes of these sessions were scored according to a standardized protocol (Renner, J. Comparative Psychology, 1987, 100, 94-100), which allows separate quantification of locomotor, general, and object interaction behaviors. Scopolamine suppressed object investigation (both gross contact measures and indices of interaction character) whenever present: Day 2 drug experience had significant effects on Day 3 behavior in the arena, but this appeared to be mediated through suppression of Day 2 investigatory behavior. Scopolamine's arousal-modulating effects must also be considered: In contrast to Buhot, et al. (who used a forced-exploration situation) in this free-exploration context SCO suppressed locomotor behavior. This study replicates and extends Buhot, et al.'s conclusion that anticholinergies impair information gathering rather than affecting memory directly, which calls into question memory-related explanations of cholinergic treatments unless controls for behavior during the purported "learning" event are included.

PROTECTIVE EFFECT OF A CHOLINOMIMETIC DRUG, $\alpha\text{-}GLYCERYLPHOSPHORYLCHOLINE}$ ($\alpha\text{-}GFC$) ON SCOPOL-AMINE-RELATED DEFICIT OF MEMORY AND BRAIN ACETYLCHOLINE (ACH) LEVELS IN THE RAT. C. Lopez*, A. Gagnoni*, F. Battaini±, S. Govoni*A, and M. Trabucchit. Inst. Pharmacol. Sci., Univ. Milan, + Dept. Exp. Med. Biochem. Sci., Univ. Rome, ^ Dept. Pharmacobiol., Univ. Bari, Italy.

The cholinergic system has been implicated since many years in the

process of learning and memory in animals and man. The cholinolytic process of learning and memory in animals and man. The cholinolytic drug, scopolamine (a well known amnestic drug) produces impairment in the acquisition of the passive avoidance task. The studies reported here investigated the effects of α -GFC on the performance of passive avoidance (step-down). Male Wistar rats (150-200 g) were given α -GFC (0.1, 0.3, 0.6, 1.0 g/kg; 1, 5, 20, 48 hours before the training session). Scopolamine was injected 30 minutes before the training session (0.75 mg/kg s.c.). The levels of ACH were determined using HPLC with electrochemical detection (Damsma, G. et al., J. Neurochem., 45:5, 1985). The results indicate that rats receiving 0.3 and 0.6 g/kg i.g. α -GFC, 5 hours before training, perform significantly better in comparison with those treated with scopolamine (mean latency and 0.6 g/kg i.g. α -Gr-C, γ nours before training, perform significantly better in comparison with those treated with scopolarmine (mean latency times: 155°, 293°, 25 sec. respectively. $^{\sim}$ p<0.01). The peak effect was obtained with 0.6 g/kg i.g. α -GFC, while rats receiving 0.1 and 1 g/kg did not differ from the scopolarmine treated group. α -GFC prevented partially the decrease of ACH levels induced by scopolarmine in cortex but not in striatum. However, the time course of the behavioral response and that of ACH levels were not superimposable. These results suggest that changes in ACH levels mediate the antiamnestic effect of α -GFC, though this neurotransmitter may not be the only correlate of the behavioral response.

DIFFERENTIAL IMPAIRMENT OF DISCRIMINATION LEARNING IN RATS DUE TO NUCLEUS BASALIS MAGNOCELLULARIS LESIONS OR SCOPOLAMINE TREATMENT. A. E. Butt, J. E. Dencoff, B. G. Cooper*, K. Nopp-Dvorak*, and G. K. Hodge. Department of Psychology, University of New Mexico, Albuquerque, NM 87131.

Changes in learning and memory were related to disruptions of cholinergic function in a neurotoxic and pharmacologic animal model of Alzheimer's disease.

The effects of bilateral ibotenic acid (IBO) lesions of the nucleus basalis magnocellularis (nbm) and the subsequent response to scopolamine administration were evaluated in multiple tests of discrimination learning in rats. IBO (10 $\mu g/\mu l$) infused bilaterally into nbm impaired performance as determined by the failure of IBO-treated rats to decrease nonrewarded (SD-) responding relative to rewarded (SD+) responding. The IBO group also had more difficulty than controls in adjusting to subsequent transitions in reinforcement contingency parameters. Lesion-induced deficits diminished within 6 weeks post-surgery. Scopolamine (0.06 mg/kg, i.p.) was then administered on alternate test days, which retarded response rate and decreased total responding for both groups; although performance was slower, accuracy relative to animals' spontaneous performance was unimpaired. Results suggest that the nbm is involved in the acquisition of adaptive behaviors relying on accurate responding to environmental cues, but that scopolamine-induced deficits may partly reflect other components in addition to any disruption of memory. The qualitative differences shown in response to nbm lesions and scopolamine treatment suggest that injury of basal forebrain systems may model Alzheimer's disease better than the global cholinergic inhibition caused

THE DURATION OF A SHORT-TERM MEMORY IMPAIRMENT FOLLOWING CHRONIC SCOPOLAMINE EXPOSURE DEPENDS ON THE AGE WHEN THE TREATMENT IS ADMINISTERED. R. Paylor, Psychology Dept., University of Colorado, Boulder, CO 80309

Long-term scopolamine treatment is known to result in a transient (less than 10 days) increase in the number of hippocampal muscarinic receptors in both neonatal and adult rats (J. Ben-Barak & Y. Dudai, Brain Res., 193, 309-313, 1980). Previously, we demonstrated that rats exposed to a long-term scopolamine treatment during the early postnatal (PN) period (PN day 1 to 19) produced a selective impairment in the short-term memory processes underlying performance on a conditional spatial discrimination task (CSD task). The memory imairment, however, lasted at least 41 days which is much longer than receptor numbers are known to be above normal following chronic scopolamine treatment

scopolamine treatment.

The present experiments were designed to determine if the enduring memory impairment following scopolamine treatment is restricted to subjects treated when the CNS is immature. Rats were, therefore, administered the 19 day scopolamine treatment when they were 70 days old. Two, 11 or 41 days following the last injection subjects were tested on the CSD task. Results showed that subjects given either a 2 or 11 day recovery period were capable of learning the CSD task, but were impaired when their short-term memory

of learning the CSD task, but were impaired when their short-term memory based performance was further challenged. Subjects given a 41 day recovery period, however, appeared to be unimpaired.

The present results, together with the results from subjects treated during the early postnatal period demonstrates that (a) chronic exposure to scopolamine produces a specific behavioral impairment which can not be easily explained by a receptor number hypothesis and (b) the duration of the impairment depends upon the maturation of the CNS at the time of treatment.

AGE-DEPENDENT EFFECTS OF HIPPOCAMPAL MUSCARINIC RECEPTOR BLOCKADE ON MEMORY-BASED LEARNING IN THE RAT E.C. Pollock, M.W. Lilliquist, N.J. Lobaugh & A. Amsel. Dept. of Psychology & Inst. for Neuroscience, University of Texas at Austin, 78712

Inst. for Neuroscience, University of Texas at Austin, 78712
Hippocampal cholinergic blockade has been shown to produce a deficit in response suppression in passive avoidance learning (Blozovski & Hennocq, Psychopharm., 76:351, 1982), in which external cues, rather than memory of the previous trial, guide behavior. The present study examined the effects of intrahippocampal atropine (ATR) on a discrimination task, patterned alternation (PA), that requires intact short-term memory of the previous trial. In 16-17-day-old pups, ATR treatment disrupted acquisition by interfering with approach to the goal, but did not eliminate PA at 8-s intertrial interval (ITI) if acquired under saline. We also tested rats at two stages of hippocampal development (16-17 and 28-32 days of age), using a modified training procedure, to examine the effects of ATR on suppression in PA learning at 15-s ITI. Relative to controls, no deficit was observed in the younger age group; however, the older atropine subjects demonstrated a suppression deficit on nonrewarded trials. In contrast, the suppression deficits seen by Blozovski et al. were observable in pups as young as 13 days of age, perhaps because of the aversive rather than appetitive nature of passive avoidance. This evidence suggests that there is increased involvement of the hippocampus in the acquisition of this memory-based learning task as the rat pup matures. BEHAVIORAL CONDITIONING INCREASES MUSCARINIC2 RECEPTOR BIND-ING IN LIMBIC THALAMUS AND CORTEX.B.A. Vogt,M. Gabriel,L.J. Vogt*,A. Cox,E.J. Jensen*,Y. Kubota and E. Kang. Dept. of Pharmacology, Boston Univ. Sch. of Med., Boston, MA & Dept. of Psycology, Beckman Inst., Univ. of Illinois, Urbana, IL

Little is known of the molecular mechanisms which subserve learning and memory in the mammalian brain. This study analyzes N₂ receptor regulation which occurs in tandem with training-induced neuronal plasticities during discriminative avoidance learning. Rabbits were trained to one of 5 stages of performance wherein hopping in a wheel to a CS* prevents negative reinforcement. Upon reaching a particular stage the brains were sectioned, incubated in 3H-oxotremorine-M and autoradiographed. In the parvocellular part of the anteroventral thalamic nucleus there was a progressive increase in OXO-M binding which peaked when rabbits met the criterion stage of learning. Binding in the magnocellular part increased only during the criterion stage. Increases in binding also occurred in mid levels of cingulate cortex and were more pronounced at the stage when the rabbits first performed a significant discrimination. Binding in AVp and cortex were highly correlated.

The parallel increases in $\rm M_2$ receptor binding and discriminative neuronal activity throughout training provides a new approach for analyzing the mechanisms of behaviorally-relevant neuronal plasticities. Furthermore, neuronal plasticities in some limbic structures may depend on up-regulation of muscarinic receptors. (Air Force Office of Scientific Res.)

A COMPARISON OF THE EFFECTS OF CHOLINESTERASE INHIBITORS AND MUSCARINIC AGONISTS ON ACQUISITION OF A SPATIAL WATER-MAZE TASK BY C57BL/10j MICE. W. Lipinski, C.J. Moore, C. Bay, M. Smith, J. Kinsora, M. Dickerson and R.E. Davis. Parke-Davis Div. of Warner-Lambert Co., Ann Arbor, MI 48105.

NATION MI 48105.

C57BL/10J mice have difficulty acquiring a spatial water-maze task. This deficit can be ameliorated by administration of cholinesterase inhibitors. It is thought that cholinesterase inhibitors improve performance through their ability to elevate central cholinergic function. Muscarinic agonists also enhance central cholinergic function but through a different mechanism than cholinesterase inhibitors. An investigation was conducted to compare the relative ability of these two classes of cholinomimetics to improve acquisition of a spatial water-maze task in B10 mice.

Acetylcholinesterase inhibitors (tacrice UDCCC)

mice.

Acetylcholinesterase inhibitors (tacrine, HPO29, physostigmine, RA 10) showed greater efficacy than the muscarinic agonists (CI-969, CI-979, arecoline, oxotremorine, RS 86) in reducing the behavioral impairment of the B10 mice. This difference was most noticeable on the first day of testing. These results suggest that cholinesterase inhibitors are more effective than muscarinic agonists in improving performance deficits of B10 in the water maze. This may reflect differences in the mechanism by which these classes of cholinomimetics enhance central cholinergic activity. Alternatively, cholinesterase inhibitors may affect noncholinergic systems and changes in these systems may mediate their effect on mouse water-maze performance.

THE EFFECIS OF RO 23-4749, A FURO[2,3-C]PYRIDINE DERIVATIVE, ON LEARNING AND MEMORY IN MICE. G.P. Vincent, E. Chiang, G. Olson and J. Sepinwall. Neurobiology and Obesity Research and Medicinal Chemistry II, Hoffmann-Ia Roche Inc., Nutley, NJ 07110. Ro 23-4749, a furo[2,3-c]pyridine derivative, was evaluated in mice in various tests to assess its

Ro 23-4749, a furo[2,3-c]pyridine derivative, was evaluated in mice in various tests to assess its activity as a potential cognition enhancing agent. In CF1 mice, Ro 23-4749 protected over a wide range of doses (1 to 300 mg/kg, RO) against electrobrain shock (ERS) disruption in retrieval of an active avoidance response. A peak recovery of function of 68 percent was obtained at a dose of 300 mg/kg. In a time course evaluation using this peak active dose, the compound was active only after a 60 minute pretreatment. When administered to "poor learning" mice (doses of 100 and 300 mg/kg, RO) immediately after training, Ro 23-4749 responses made in the subsequent testing session 24 hours later. In C578L/10 mice, Ro 23-4749 significantly decreased the latency to find the hidden platform in the Morris water maze test. Active doses were 1 to 300 mg/kg, PO, with the exception of 3 mg/kg. These results demonstrate that Ro 23-4749 enhances several stages of memory processing, including acquisition, storage and retrieval.

PHYSOSTIGMINE DECREASES A NEOPHOBIC RESPONSE WITHOUT AFFECTING SELECTIVE ATTENTION. M.A. Pelleymounter and M.J. Cullen.* Dept. of Neuroscience, Oberlin College, Oberlin, Ohio 44074. It has been suggested that the amnestic effects of scopolamine are the result of a deficit in maintenance of attention, rather than the result of a deficit in storage, or

It has been suggested that the amnestic effects of scopolamine are the result of a deficit in maintenance of attention, rather than the result of a deficit in storage, or "memory". The present study was designed to further test this idea by observing the effects of physostigmine, a cholinesterase inhibitor which has been widely used to reverse memory deficits, on two forms of attention; neophobia and selective attention. Selective attention was tested using the latent inhibition paradigm. Long-Evans male rats were either pre-exposed or not pre-exposed to three 72 dB, 30 sec tones presented in Coulbourn test cages (Day 1). Licks per sec were measured throughout all training and test sessions. On Day 2, all rats were exposed to the 30 sec tones followed by a 0.4 mA, 1 sec footshock. On the test day, rats were presented with the 30 sec tones and lick suppression ratios were calculated. Physostigmine (0.06mg/kg) or saline was injected either 30 min prior to the pre-exposure session (Day 1) or 30 min prior to the tone-shock pairing session (Day 2). Pre-exposed rats that received saline on both Day 1 and Day 2 showed significantly less suppression than their counterparts that were not pre-exposed, indicating that these rats had attended to the tone presentation on Day 1 and had failed to associate it with shock. Physostigmine treatment on either day did not alter this pre-exposure effect, indicating that it did not affect selective attention. These rats were then tested in a neophobia paradigm, where they were given either dilute grape juice or water to drink for 15 min sessions, followed by a 15 min presentation of water. Rats were injected with physostigmine or saline 30 min prior to the presentation of grape juice or water to drink for 15 min sessions, followed by a 15 min presentation of water. Rats were injected with physostigmine or saline 30 min prior to the presentation of prape juice or water. All rats showed significant suppression to the novel flavor on the second day of exposure to grape juice than did sa

MUSCARINIC SUBTYPE INVOLVEMENT IN HABITUATION OF LOCOMOTOR ACTIVITY. M. J. Buckley and M. W. Decker, Neuroscience Research, Abbott Labs, Abbott Park, IL 60064.

The muscarinic cholinergic receptor, particularly the M1 receptor subtype, has been targeted in the development of cognition enhancers for the treatment of Alzheimer's disease. Toward further characterizing the behaviors mediated by M1 and M2 cholinergic receptor subtypes, we compared the effects of scopolamine (SCOP) and methylscopolamine (MSCOP), two non-selective muscarinic antagonists, with those of pirenzepine (PZ), an M1-selective antagonist, on mouse locomotor activity.

On each of 2 consecutive days, activity was measured for 1 min time bins over the course of 3 min. in male, CD1 mice. Systemically-administered SCOP (1.0 mg/kg) effected an increase in locomotor activity on day 1 and a failure to habituate (defined as a time-dependent decrease in activity) both within the day 1 session and between the 2 sessions. Systemically-administered MSCOP, which does not readily cross the blood-brain barrier, had no such effect. Centrally-administered PZ (1.0 ug, i.c.v.) had an effect similar to that of systemically-administered SCOP, although the between trial habituation effect did not quite reach statistical significance (p<.07). Much higher doses of PZ (100 ug, i.c.v.) were required to attenuate the hypothermic effects of the muscarinic agonist oxortemorine (0.5 mg/kg, i.p.). In contrast, central administration of MSCOP at doses that significantly attenuated oxotremorine-induced hypothermia (0.3, 1.0 & 3.0 ug) produced less marked increases in locomotor activity and only a borderline trend toward reduced habituation of activity on day 1 (dose by time interaction, p<.06).

Results suggest a dissociation between M1-mediated cholinergic effects on locomotion and habituation and M2-mediated cholinergic effects on temperature regulation.
