To quantify the diffusion, different volumes of 14 C-lidocaine were infused over a 2 To quantify the diffusion, different volumes of ¹⁴C-lidocaine were infused over a 2 min period into the dorsal (0.5, 0.75, or 1.0µl) or pentral (0.5 or 1.0µl) hippocampus (dH or vH), or into the inferior colliculus (IC, 0.5µl). The brains were removed and frozen within 6-10min post-infusion. Frozen 300µm sections through the area of infusion were obtained and a template was used to obtain 9-35 frozen tissue infusion were obtained and a template was used to obtain 9-35 frozen tissue punches/section. Radioactive counts were obtained for each punch and plotted on drawings of the sections as a function of the percent of radioactivity present at the infusion site. For all areas infused, and for all volumes, diffusion remained confined to the injected structure. Within the IC, diffusion of 0.5µl lidocaine was largely restricted to +/-900µm A-P, +/-Imm M-L and +/-Imm D-V. Peculiarities in diffusion patterns were noted in the dH and vH, where diffusion appeared to follow laminar contours, and these will be illustrated.

contours, and these will be illustrated.

To determine the duration and extent of inactivation following lidocaine infusion, current source density (CSD) analysis was applied to field potential profiles obtained in the dH by electrical stimulation of the perforant path pre- and post-lidocaine. The CSD analysis revealed a complete absence of both sinks and sources 3-8 min post-lidocaine which gradually recovered over the next 30-120 min to baseline levels. The extent and pattern of tissue inactivated was closely associated with that seen in the diffusion experiments.

ARACHIDONIC AND OTHER UNSATURATED FATTY ACIDS BLOCK ACh-ACTIVATED C1 CURRENT AND OTHER 'FAST' TRANSMITTER RESPONSES

IN APLYSIA NEURONS. V. Březina. Howard Hughes Med. Inst., Columbia University, 722 W. 168 St., New York, NY 10032.

Aplysia neurons exhibit three main types of response to transmitters: 'fast' Na and Cl currents, and a 'slow' K current. K-current responses have been suggested, because they are mimicked by arachidonic acid (AA) metabolites and blocked by inhibitors of their production, to be mediated by AA metabolites acting as second messengers. Unexpectedby A metabolites acting as second messengers. Onexpected-ly, I have found that certain 'fast' responses, whose speed and activation in cell-free patches make second-messenger mediation unlikely, are equally or more sensitive to the inhibitors and fatty acids. Thus, the Cl-current response to ACh was blocked by the phospholipase- A_2 blocker BPAB (50% at <5 μ M), by the lipoxygenase blocker NDCA (2 μ M), by (30% at $<3 \mu n$), by the Hipoxygenase blocker block (2 μn), by the cycloxygenase blocker indomethacin (10 μ M), and by the lipo- and cycloxygenase blocker BW755C ($<50 \mu$ M). Superfusion of 10-60 μ M AA (20:4) or any of the unsaturated fatty acids 22:6, 22:4, 20:3, 20:2, 18:3 and 18:2 blocked >50% acids 22:6, 22:4, 20:3, 20:2, 18:3 and 18:2 blocked >50% (often >90%) of the current. At least NDGA and indomethacin also blocked the 'fast' GABA-activated Cl and histamine-activated Na currents (but not the 'fast' Na-current response to FMRFamide). Leaving aside the possibility of action at sites unrelated to AA metabolism, these results are most consistent with the hypothesis that the inhibitors block steady fatty acid release and metabolism, leading to accumulation of free fatty acids that then directly block certain 'fast' transmitter-activated Cl and Na channels.

ISOLATION AND CHARACTERIZATION OF ENDOGENOUS PROTEIN PHOSPHATASE INHIBITORS FROM APLYSIA. S. Endo, S. Shenolikar ¹*, A. Eskin ², and J.H. Byrne. Depts. of Neurobiology and Anatomy, and Pharmacology ¹, Univ. of Texas Medical School, Houston, TX 77225, Dept. of Biochem. and Biophys. Sci. ², Univ. of Houston, Houston, TX 77224. The phosphorylation state of a given protein reflects the activities of both protein kinases and protein phosphatases (PrPs). Although the role of cAMP-dependent protein kinase is well-recognized in the induction and the maintenance of sensitization, the role of PrPs in these processes remains unknown. Recent biochemical studies indicate that PrPs in Aplysia are similar to those of mammals, including their substrate specificity and sensitivity to the mammalian inhibitor 1-2 and okadaic acid (OA), a specific inhibitor of PrP-1 and PrP-2A. Moreover, OA alters cAMP-dependent membrane currents in voltage clamped pleural sensory neurons (Endo et al., 1989; Ichinose et al., this volume). To further examine the regulation of PrPs in Aplysia, we have isolated and characterized endogenous inhibitor(s) of PrP in Aplysia tissues. An inhibitor fraction was obtained from a trichroloacetic acid precipitate of a 100,000xg supernatant of whole central nervous system or buccal

An inhibitor fraction was obtained from a trichroloacetic acid precipitate of a 100,000x supernatant of whole central nervous system or buccal muscle. Inhibitory activity was analyzed using PrP-1 and PrP-2A purified from rabbit skeletal muscle and ³⁴P-phosphorylase a as a substrate. The heat-stable inhibitor fraction strongly inhibited PrP-1 (50 % inhibition was obtained in approximately 0.1 mg/ml) but did not inhibit PrP-2A. The activity of this trypsin-labile inhibitor(s) was reduced by incubation with alkaline phosphatase. These data suggest the presence of an Aphysia PrP inhibitor(s) which is subject to regulation by reversible protein phosphorylation, in a manner similar to mammalian inhibitor-1. Regulation of the inhibitor by phosphorylation could have profound effects on the second messenger cascade that contributes to behavioral sensitization in Aphysia.

COMPUTER SIMULATION OF IAHP KINETICS. P. Pennefather 1, F. Sala 2 and A. Hernandez-Cruz 3. Howard Hughes Med. Inst., Stony Brook, NY;1, Fac. Pharmacy, Univ. of Toronto, ON;2, Dept. Neuroquimica, Univ. Alicante, Spain;3, Roche Inst. Mol. Biol, Nutley, N.J.

The relation between the time course of the Ca-activated K-current, IAHP, and calcium loads induced by action potentials (APs) in bullfrog ganglion neurons has been characterized empirically by Goh and Pennefather¹. We have now used that data to place constraints on gangion heimons has been characterized empirically by Gon and Pennefather¹. We have now used that data to place constraints on simulations of the fate of calcium after it enters the neuron during trains of AP's. We used the calcium diffusion model of Sala and Hernandez-Cruz² which considers the effects of buffers of defined capacity, mobility and kinetics on the diffusion of calcium. Two principal types of buffers are considered: fast buffers (B_f) and slow buffers (B_s). We have simulated IAHP by considering a third type of buffer, BAHP, restricted to the outermost shell. We estimate that each AP produces 6 nA.ms of ICa. We first set out to generate an IAHP that had an amplitude close to maximal and decayed roughly exponentially. The amplitude close to maximal and decayed roughly exponentially. The assumption that activation of BAHP was cooperative proved essential. We assumed that activation resulted from occupancy of three equivalent binding sites for Ca with KD=0.1 μ M and k_{OD} =108/M/s. Acceptable results were obtained with a relatively immobile Bf with [Bf]=40 μ M, KD=5 μ M, k_{OD} =108/M/s. Higher values of [Bf] reduced the amplitude of IAHP and gave rise to a slow tail. With [Bf] at least 20 μ M and setting other parameters of the model similar to those used previously², setting other parameters of the model similar to those used previously², we reproduced the relation between IAHP decay half-time and AP train length (log-log slope = .55) observed by Goh and Pennefather¹. As also was observed¹, the model predicted that a 3-fold reduction of the calcium influx per AP causes a 3-fold shift to the right in that relation. 1, Neurosci. Abst. 14, 1089, 1988;2, Biophys. J., 57, 313, 1990

MULTIPLE PATHWAYS MODULATE CAN CURRENT IN SNAIL NEURONS. <u>Don Partridge</u>, <u>Dieter Swandulla*</u>, and <u>Thomas Müller*</u> Dept. of Physiol., Univ. of N.M., Albuquerque, N.M. 87131; Neurophysiology Dept., Max-Planck Institute, Planegg-Martinsried, F.R.G.

Calcium activated non-specific (CAN) current provides an important depolarizing drive in many bursting and secretory cells. In the bursting neurons of snail ganglia, CAN channels open in response to intracellular calcium and the resultant current provides the maintained depolarization for bursts.

We have studied the CAN current in the fast burster neuron of Helix aspersa and Helix pomatia following fast quantitative pressure injections of Ca⁺⁺ into the cell. We have previously shown that CAN current amplitude is depressed by a cAMP-dependent phosphorylation process (J. Physiol. in press). Bath application of 5-HT causes a reversible reduction in CAN current that can be blocked by pre-injection of the cells with protein kinase A inhibitor. Injection of GTP₇S leads to an increase in CAN current. Cholera toxin application, however, causes a reduction in CAN current similar to that observed with 5-HT. This latter effect implicates an involvement of an α_s subunit of a G protein

The most parsimonious explanation of these results is that the 5-HT receptor is linked via an $\alpha_{\rm S}$ to adenylate cyclase but that a second G protein-dependent avenue for modulation of CAN current exists. This might be an effect through an α_i on the adenylate cyclase or an effect at another point in the phosphorylation process.

ROLE OF PROTEIN PHOSPHATASES IN FMRFamide-, SEROTONIN-, AND CAMP-DEPENDENT MODULATION OF MEMBRANE CURRENTS IN SENSORY NEURONS OF APLYSIA. M. Ichinose, S. Endo and J.H. Byrne. Dept. of Neurobiology & Anatomy, Univ. of Texas Medical School, Houston, TX 77225.

Recent biochemical studies indicate that protein phosphatases (PrPs) in Aplysia are similar to those of vertebrates including their inhibition by okadaic acid (OA) (Endo et al., 1989; this volume). To examine the contribution of PrPs acd (OA) (Endo et al., 1969, this volume). To examine the contribution of PP's to the modulation of membrane currents (I_m), we measured the responses to brief applications of 5-HT, 8-bromo-cAMP and FMRFa in pleural sensory neurons (SNs) voltage clamped at approx. -30 mV. Intracellularly applied OA by itself mimicked the effects of 5-HT and cAMP and produced an inward shift by itself mimicked the effects of 5-HT and cAMP and produced an inward shift in I_m associated with a decrease in input conductance (G_{in}). OA apparently occluded the responses to either 5-HT or cAMP. For example, as the OA-induced shift in holding I_m occurred, the amplitudes of the responses became smaller. Moreover, the durations of the responses were greatly increased (from initial values of 1 min to new values of up to 20 min). The FMRFa-induced outward I_m was reduced in the presence of OA. This suggests that FMRFa acts, at least in part, via activation of phosphatases. Injections of PrP-1 and PrP-2A, leated from rehibit settled manufactors. isolated from rabbit skeletal muscle, into SNs mimicked the effects of FMRFa, producing an outward I_m associated with an increase in G_m . Moreover, in the presence of the PrPs 5-HT-induced inward I_m were potentiated. The effects were greater in the presence of PrP-2A than PrP-1. These data suggest that: 1) there are relatively high basal activities of PrPs in the SNs; 2) PrPs contribute significantly to the recovery time course of 5-HT and cAMP responses; 3) the PrPs responsible for the dephosphorylation are OA-sensitive PrP-1 and/or PrP-2A; and 4) the response to FMRFa depends at least in part on the activation of

MICROCYSTIN-LR IS A POTENT PROTEIN PHOSPHATASE INHIBITOR AND PROLONGS THE SEROTONIN- AND cAMP-INDUCED CURRENT IN SENSORY NEURONS OF APLYSIA.

J.H. Byrne, M. Ichinose, S. Endo, S.D. Critz and S. Shenolikar I. Depts. of Neurobiology and Anatomy, and Pharmacology I, Univ. of Texas Medical School, Houston, TX 77225.

Recent biochemical studies indicate that protein phosphatases (PrPs) in Aplysia are similar to those of mammals including their substrate specificity and sensitivity to I-2 and okadaic acid (OA), a specific inhibitor of PrP-1 and -2A (Endo et al., 1989, 1990). In addition, OA prolonged the duration of both cAMP- and serotonin(5-HT)-induced membrane currents in voltage clamped pleural sensory neurons (SNs) (Ichinose et al., 1990).

Microcystin-LR (MCYST-LP) is a hepatotoxic cyclic heptapeptide purified from Microcystis aeruginosa. We examined whether it possessed PrP inhibitory activity against vertebrate PrPs using ³²P-phosphorylase a as a substrate. MCYST-LR strongly inhibited both PrP-1 and PrP-2A purified from rabbit skeletal muscle (ICso of both PrP-1 and -2A was approximately 10⁻¹⁰ M). Moreover, both crude extracts and salt-extracted PrP from particulate fractions of abdominal ganglia of Aplysia were completely inhibited by MCYST-LR acts as an inhibitor of PrPs in Aplysia, it would be expected to enhance cAMP-dependent processes. Consequently, we examined its effect on responses to application of either 5-HT or cAMP in SNs voltage clamped at ~ ~30 mV. By itself, intracellular application of MCYST-LR induced an inward shift of holding current and decreased input conductance, effects similar to those of 5-HT and cAMP. In addition, in the presence of MCYST-LR, the recovery of both 5-HT and cAMP-induced inward currents was markedly slowed (from the control of about 1 min to more than 15 min). This prolongation of recovery from the response peak is similar to the effect of intracellularly applied OA, and may be induced by the persistence of cAMP-dependent protein phosphorylation. These data suggest

EXTRACELLULAR TUMOR NECROSIS FACTOR INDUCES A DECREASED CONDUCTANCE IN IDENTIFIED NEURONS OF APLYSIA KURODAI. M. Sawada, N. Hara* and T. Maeno*. Dept. Physiol. and Cent. Res. Lab., Shimane Medical Univ., Izumo 693, JAPAN.

The ionic mechanism of the extracellularly ejected recombinant human tumor necrosis factor-alpha (rhTNF) on the membrane of identified neurons R9 and R10 of Aplysia kurodai was investigated with conventional voltage-clamp, micropressure ejection, and ion substitution techniques.
Micropressure - ejected rhTNF caused a marked hyperpolarization in the unclamped neuron. Clamping the same neuron at its resting potential (-60 mV) and reejecting rhTNF with the same dose resulted in the development of a slow outward current (I (TNF)) associated development of a slow outward current (I (TNF)) associated with a decrease in input membrane conductance. I (TNF) was decreased by depolarization and increased by hyperpolarization. The extrapolated reversal potential of I (TNF) was approximately +10 mV. I (TNF) was, sensitive to changes in [Na] but not to changes in [Ca] [K] and [Cl] and was resistant to ouabain (10 M), tetraethylammonium (5 mM) and 4-aminopyridine (5 mM). Ion substitution and barmonicated experiments superst that substitution and pharmacological experiments suggest that I (TNF) in identified neurons R9 and R10 of Aplysia is due to a decreased Na conductance but not due to an activation of the Na -K pump and that immunomodulator such as TNF is capable of influencing directly the nervous system function as well as the immune system.

PHORBOL ESTERS MODULATE I IN SENSORY NEURONS OF APLYSIA. S.D. Critz and J.H. Byrne. Dept. of Neurobiology & Anatomy, University of Texas Medical School, Houston, TX 77225.

Although much is known about the modulation of membrane currents by cAMP-dependent kinase in sensory neurons of *Aphysia*, less is known about their modulation by protein kinase C (PKC). A two-electrode voltage-clamp was used to measure current responses to 200 ms pulses from -50 mV to membrane potentials of -20, -10, 0, +10, and +20 mV in isolated clusters of pleural sensory potentials of 20, 1-10, 0, +10, and +20 mV in isolated clusters of pleufal scisory neurons. Responses were first measured in ASW (+150 μ M TTX) and again after application of phorbol 12,13-dibutyrate (PDBu) or phorbol 12-myristate, 13-acetate (PMA) (max. DMSO=.05%). Phorbol esters had little effect on membrane current at pulses from -20 mV to 0 mV. Above 0 mV there was complex modulation of membrane current, the most prominent effect of which was an increase in outward current at the end of the pulse. PDBu was more potent than PMA and its effects were dose-dependent (threshold \$\infty 50 nM, saturation \$\infty 1.5 μ M). Neither inactive 4α-phorbol ester nor DMSO alone had any effect on membrane current. In 2.0 mM TEA, which blocks a calcium-activated K⁺ (I_{K,Ca}) current in these neurons (Baxter & Byrne, 1989), the ability of PDBu to modulate

current in these neurons (Barker & Byrne, 1989), the ability of PDBu to modulate membrane current was reduced suggesting that PKC increased I_{K.Ca}.

To examine whether PKC acted directly on I_{K.Ca} or indirectly via modulation of Ca²⁺ currents (Braha et al., 1988), sensory neurons were voltage-clamped at a fixed potential (-35 mV) and Ca²⁺ (500 mM) was injected directly into the cells (10 ms pulses of 100-900 nA at 50 Hz for 1-2 s) about every 60 s from a separate electrode. After three stable outward currents were elicited, PDBu (500 nM) was applied. PDBu led to a 5-fold increase in response to Ca²⁺ injection, consistent with an enhancement of $I_{K,Ca}$. This effect of PDBu persisted when experiments were repeated in ASW that contained reduced Ca^{2+} (0.5 mM) and 10 mM $CoCl_2$ where the action in ASW that contained a contained contained a co

DOWN REGULATION OF VOLTAGE DEPENDENT SODIUM HANNELS INITIATED BY SODIUM INFLUX IN DEVELOPING NEURONS. B.Dargent, P. Cau and F. Couraud. Biochimie, CNRS UA 1179 Fac. de Médecine Nord, Bd P. Dramard, 13326 Marseille Cedex 15-France

In order to address the issue of whether regulatory feedback exists between the electrical activity of a neuron and ion channel density, we investigated the effect of Na+ channel activators (α-scorpion toxin, batrachotoxin and veratridine) on the density of Na+ channels in fetal rat brain neurons in vitro. A partial but rapid (t1/2 = 15mn) disappearance of surface Na+ channels was observed as measured by a decrease in the specific binding of ³H-saxitoxin and ¹²⁵I-β scorpion toxin and a decrease in specific ²²Na+ uptake. Moreover, the increase in the number of Na+ channels which normally occurs during neuronal maturation in vitro, was inhibited by chronic channel activator treatment. The induced disappearance of Na+ channels was abolished by tetrodotoxin, was found to be dependent on the external Na+ concentration and was prevented when either choline, a non permeant ion, or Li+, a permeant ion was substituted for Na+. Amphotericin B, a Na+ ionophore and monensin were able to mimick the effect of Na⁺ channel activators while a KCl depolarisation failed to do this. This feedback regulation seems to be a neuronal property since Na⁺ channel density in cultured astrocytes was not affected by channel activator treatment nor by amphotericin B. The present evidence suggests that an increase in intracellular Na+ concentration, whether elicited by Na+ channel activators or mediated by a Na+ ionophore, can induce a decrease in surface Na+ channels and therefore is involved in down regulation of Na+ channel density in fetal rat brain neurons in vitro

PEPTIDES: PHYSIOLOGICAL EFFECTS I

87.1

VASODILATOR PROSTAGLANDINS MAY SERVE A PROTECTIVE ROLE DURING THE DEVELOPMENT OF HYPERTENSION IN THE SHR. D.R.

VASODILATOR PROSTAGLANDINS MAY SERVE A PROTECTIVE ROLE DURING THE DEVELOPMENT OF HYPERTENSION IN THE SHR. D.R. Luthin , W.H. Cline. Dept. of Pharmacology, Southern Illinois Univ. Sch. of Med., Springfield, IL 62794-9230.

Prostaglandins (PGs), specifically PGL2 and PGE2, have been shown to decrease norepinephrine(NE) release from presynaptic nerve terminals and to act as vasodilators postjunctionally. It has been proposed that the modulation of noradrenergic neurotransmission by endogenous PGs is diminished in the aging adult spontaneously hypertensive rat(SHR). To determine the role of PGs in modulating responses to either periatrical nerve stimulation (PNS) or angiotensin II (ANG II) perfusion during the development of hypertension in the SHR, the cyclooxygenase inhibitor, indomethacin (INDO) at a concentration of 3 µ M was perfused continuously throughout the experiments in the presence or absence of ANG II (10 nM) in the isolated perfused mesenteric vasculature of 4-6 weeks old SHR and age-matched Wistar-Kyoto (WKY) rats. INDO alone enhanced perfusion pressure responses (PPR) to PNS at 8-14 Hz in the SHR and at 12-14 Hz in WKY preparations. PPR to exogenous NE (1.5-44 mmol) were not altered in either SHR or WKY. PNS-induced NE release was enhanced only at 14 Hz in the SHR and not in WKY preparations. ANG II alone enhanced PPR to PNS at 10-14 Hz in the WKY, but had no effect on SHR preparations. PPR to exogenous NE were enhanced at 6-44 mnol in SHR, but were not altered in WKY preparations. NE release was enhanced only at 4 Hz in the SHR and was unaltered in WKY preparations. Simultaneous perfusion of INDO and ANG II significantly potentiated PPR to PNS at 6-14 Hz in SHR, and at 3-14 Hz in WKY preparations. These data indicate that vasodilator PGs are released in response to PNS and ANG II perfusion, and act primarily postjunctionally, with the effect being greater in SHR preparations. These data also suggest that these vasodilator PGs may serve a protective role during the development of hypertension in the

EFFECTS OF THYROID DENERVATION ON THYROID BLOOD

EFFECTS OF THYROID DENERVATION ON THYROID BLOOD FLOW AND VIP CONTENT. M. Michalkiewicz*, L.J. Huffman* and G.A. Hedge. Physiology, West Virginia University, Morgantown, WV 26506.

The presence of VIP in thyroid nerve fibers and its stimulatory effect on thyroid blood flow (TBF) have prompted us to study the effects of denervation on TBF and thyroid VIP content. Male Sprague-Dawley rats (220-250 g) were anesthetized prior to either sham surgery or one of the following bilateral denervations: superior cervical gandlionectomy (SCGX): superior larvncervical ganglionectomy (SCGX); superior laryngeal neurectomy (SLNX); inferior laryngeal neurectomy (ILNX). Two weeks after surgery, the rectomy (ILMX). Two weeks after surgery, the following measurements were made: thyroid VIP concentrations (by RIA); TBF (using ¹⁴ Ce-labeled microspheres); plasma levels of TSH, T₃, and T₄ (by RIA); and thyroid weight (TW). SLNX, but not SCGX or ILNX, caused a significant 62% decrease in thyroid VIP concentrations (when compared with shams). TBF, TW, and plasma levels of TSH, T₃, and T were not affected by any of the denergy. and T, were not affected by any of the denerva-tions. Conclusion: The majority of thyroidal VIP is derived from the SLN (parasympathetic nerve supply). The lack of change in TBF or hormone secretion two weeks after thyroid denervation may be due to a functional reorganization of the autonomic pathways to the thyroid. (NIH DK35037; NSF DCB-8904470).

RELEASE OF SUBSTANCE P, SUBSTANCE K AND CALCITONIN GENERALATED PEPTIDE FROM THE RAT TRACHEA X.-Y. HUA & T.L. YAKSH Dept. of Aneasthesiology, Univ. of California, San Diego, CA92093

Substance P(SP), Substance K(SK) and Calcitonin gene-related peptide (CGRP) exist in primary sensory afferents which innervate the airway, including the trachea. The present study is to investigate if activation of the peripheral primary sensory terminals in the trachea could evoke the release of these neuropeptides. The trachea (below larynx to bifucation) was dissected and perfused intraluminally with Krebs solution(37°C: 0.2ml/min). After lyophilization, the perfusates were subjected to RIA for determining the peptides. K⁺(70mM-120mM) and capsaicin(10⁻⁸M-10⁻⁴M) caused a concentration-dependent increase in the level of CGRP,SP and SK in the perfusates. The effect was attenuated in the absence of calcium. Two exposure to K^+ did not diminish peptides release in the second exposure, but capsaicin desensitized the tissue to subsequent capsaicin exposure. The result suggests that the peripheral terminals of primary afferents in the trachea possess releasable stores of these 3 peptides. Such release may create the changes in airway reactivity which are observed in the presence of irritant stimuli.

PLASMA EXUDATION INDUCED BY HUMAN ALPHA-CGRP AND ITS SEQUENCES IN RAT SKIN. K. Tuominen, A. Koskinen* and H. Uusitalo. Dept. of Anatomy, Eye Res. Lab. Univ. of Helsinki, Finland, 'Dept. of Chemistry, Univ. of Surrey, Guilford, UK.

CGRP is a potent vasodilator and may have a role in neurogenic inflammation. The activity of alphahcGRP and its fragments to induce plasma extravasation in the rat skin was studied by using intravenous Evans Blue and '15' human serum albumin. CGRP and CGRP fragments in concentrations of 2x10' ill - 2x10' mol/20 µl were intradermally injected in dorsal skin. Plasma exudation 30 min after the injections was expressed as blood plasma leakage in a skin sample. A significant increase in Evans blue area and plasma exudation were induced by at doses 2x10'-10 - 2x10' mol. CGRP₈₋₃₇ induced both plasma exudation and extravasation equipotently to whole CGRP. The effects of CGRP₁₅₋₂₄ and CGRP₁₅₋₃₇ were smaller and CGRP₈₋₃₇, has only a minor effect. Based on the present findings it is evi-dent that CGRP can induce changes in rat skin in concentration of 2x10' mol resembling those induced by neuro-genic inflammation. It is further suggested that sequence 15-24 is important in this respect. Based on the previous data it seems evident that CGRP has two active epitopes: one in the amino-terminal end (cysteine loop) and the other in CGRP, 5-24.

87.7

CALCITONIN GENE-RELATED PEPTIDE (CGRP) MEDIATES NERVE STIMULATION-INDUCED VASODILATION IN RAT MESENTERY S.P., Han, X. Chen, L. Naes and T.C. Westfall Dept. of Pharmacol., St. Louis Univ. School of Medicine, St. Louis, MO 63104

The mediator of nonadrenergic-noncholinergic (NANC) vasodilation was studied in the isolated perfused rat mesenteric vascular bed precontracted with methoxamine. Norepinephrine release was abolished by guanethidine. Periarterial nerve stimulation elicited a frequency-dependent vasodilation which was resistant to atropine and propranolol but sensitive to tetrodotoxin and was resistant to atropine and proprantion but sensitive to terrodotoxin and capsaicin indicating its neurogenic nature. The NANC vasodilation was significantly attenuated by CGRP receptor desensitization, infusion of CGRP antiserum or hCGRP (8-37), a CGRP receptor antagonist. Vasodilation induced by exogenous CGRP was similarly attenuated by these procedures. Infusion of CGRP antiserum or hCGRP (8-37) also elevated the basal perfusion pressure in the mesentery suggesting that the vascular tone is tonically regulated by endogenous CGRP. The NANC vasodilation was smaller in amplitude and shorter lasting in the mesentery from SHR than that from normotensive rat. These data suggest that primary sensory nerve-derived CGRP 1) mediates NANC vasodilation, 2) tonically regulates vascular resistance and 3) its deficiency may play a role in pathogenesis of hypertension (Supported by HL 26319 and HL 35202).

THE RESPONSE OF NEURAL ELEMENTS OF RAT DURA MATER IN AN EXPERIMENTAL MODEL OF SAH. B.G. MULLEN*, M.J. FRITTS* AND J.T. KELLER. Depts. of Neurosurg. U. of Cincinnati, The Christ Hosp., J.N.G. Inst. of Med. Res. Cinti, OH 45219 While the effect of subarachnoid hemorrhage (SAH) upon

neurotransmitter/neuropeptide content has been examined in perivascular nerves, its effect on dural nerves and mast cells is unknown. The density of calcitonin gene related peptide (CGRP) and neuropeptide Y (NPY) in perivascular nerve fibers and serotonin(5-HT) in mast cells was exam ined immunocytochemically following the production of SAH. Cisternal subarachnoid injections of either 0.3ml autologous blood (experimental) or 0.3ml buffered lactated ringer's solution (sham-operated controls) were performed in Sprague-Dawley rats which were subsequently sacrificed/examined at 6,24, or 48 hours or 6 days. The pattern and intensity of labeling of CGRP fibers was similar in all animals and in each time period following SAH. The intensity of NPY labeling of perivascular nerves and 5-HT labeling of the mast cell population was diminished in both 6 and 24 hour animals (experimental and sham-operated controls) and returned to normal (non-operated controls) at 48 hours and 6 days. The changes in 5-HT and NPY content in dural mast cells and nerve fibers, respectively, may reflect a general response to the increase in intra-cranial pressure following SAH. These substances are also of interest with regard to their potential role in vascular headache and neurogenic inflammation.

87.6

NEUROPEPTIDE Y AND OPIOIDS MODULATE RESPONSES TO NERVE ACTIVATION OF THE PERFUSED RAT MESENTERY. Y.J. Li* and S.P. Duckles. Dept of Pharmacol, Coll of Med, Univ of Calif, Irvine, CA 92717.

Le and S.P. Duckles. Dept of Pharmacol, Coll of Med, Univ of Calif, Irvine. CA 92717.

In perfused rat mesentery the contractile response to transmural nerve stimulation (TNS) was the net result of both constrictor and dilator nerve activation. In control tissues TNS produced a frequency-dependent increase in perfusion pressure, which was potentiated by pretreatment with capsalcin (3x10-7 M, 20 min) to deplete sensory transmitters. When adrenergic nerves were blocked with guanethidine (5x10-6 M) and methoxamine (3x10-6 M) was added to increase smooth muscle tone, TNS caused a dilator response which was abolished by capsaicin, but not by propranolol or atropine. Treatment with indomethacin (10-6 M) resulted in a significant increase in the vasodilator response to TNS, but no change in dilation to exogenous calcitonin gene related peptide. NPY (10-8 M) significantly potentiated vasoconstrictor responses to TNS, but suppressed the capsaicin sensitive vasodilation. Mu, delta or kappa opioid receptor agonists, DAMGO, ([D-Ala²,NMe-Phe⁴,Gly-Ol]-enkephalln; 5x10-8 M). PDPDE ([D-Pen²-5]-enkephalln; 10-7 M) and EKC (ethylketocyclazocine: 5x10-8 M), had no effect on the vasoconstrictor response to TNS. In contrast, DAMGO and DPDPE significantly inhibited vasodilator responses to TNS, but EKC was without effect. After treatment with indomethacin, DAMGO still inhibited the vasodilator responses but DPDPE was no longer effective. Our results show that both adrenergic vasoconstrictor and capsaicin-sensitive sensory vasodilator nerves can contribute to the control of vascular tone in the rat mesentery. Prejunctional control of transmitter release by NPY or opioid receptors is dependent on the specific nerve type as well as, in some cases, the participation of endogenous prostaglandins. NIH #DK36289.

NEUROPEPTIDE Y AND GALANIN: OPPOSING CENTRAL AND PERIPHERAL ACTIONS ON GASTRIC ACID SECRETION. J.G. Geoghegan,* D.C. Lawson* Schiffman, T.N. Pappas*. Duke University Medical Center, Durham, NC 27710.

Several brain-gut peptides have opposite central and peripheral effects on gastric function. This study compares the central and peripheral actions of Neuropeptide Y (NPY) and peripheral actions of Neuropeptide Y (NPY) and Galanin (GAL) on meal-stimulated gastric acid secretion. Six gastric fistula dogs with cerebroventricular guides were given peptide (NPY or GAL) or carrier (control) by bolus intraventricular injection or IV infusion.

Results: Central NPY increased gastric acid (control: 13.6±2.3 mmol/hr; NPY 500 pmol/kg:

30.6±6 mmol/hr*), and peripheral infusion inhibited gastric acid (Control: 22.9±2.7 mmol/hr; NPY 500 pmol/kg/hr: 15.5±2.6 mmol/hr*). Central GAL augmented gastric acid (Control: 11.5±2.1 mmol/hr; GAL 62.5 pmol/kg: 21.8±1.9 mmol/hr*). This is the opposite of the properties of the control of the properties of the control its reported peripheral inhibitory effect on stimulated gastric acid. (*p<0.05) Conclusions: NPY and GAL both have opposing

central and peripheral effects on gastric acid secretion.

SINGLE FIBER VAGAL AFFERENT RESPONSES TO INTRAGASTRIC SALINE INFUSIONS AND CELIAC ARTERY CHOLECYSTOKININ INFUSIONS IN RATS. G.J. Schwartz, P.R. McHugh & T.H. Moran, Johns Hopkins Univ. Sch. Med., Dept. Psychiatry, Balto., MD. 21205.

A role for the vagus has been proposed in the inhibition of food intake elicited by gastric distension and cholecystokinin (CCK). We examined the electrophysiological responses of single vagal afferent examined the electrophysiological responses of single vagal afferent nerve fibers to intragastric (i.g.) saline influsions and celiac artery (c.a.) CCK influsions. Two response patterns were identified. One pattern (N=12) demonstrated increased vagal firing both in response to 2 ml i.g. saline influsions and to 0.1 ml c.a. influsions of CCK, while the other (N=4) showed increased firing during i.g. infusions but not following CCK infusions. Fibers demonstrating the first pattern were further investigated to determine the relationships between 1) i.g. infusion parameters and firing rate and 2) c.a. CCK dose and firing rate. When the i.g. infusion volume was held constant at 2 ml, firing rate did not change with increasing i.g. infusion rate over a 0.1-2.5 ml/min range. However, if the i.g. infusion rate was held constant at 0.1 ml/min, the firing rate increased with increasing i.g. infusion volume over a 0.5-2.0 ml range. In response to CCK infusions, both firing rate and response duration increased over a 10-1000 pmol dose range, while response latency decreased. Finally, CCK pretreatment enhanced the response to a subsequent 2 cc i.g. saline load. The results demonstrate that some, but not all, vagal fibers responding to intragastric infusions respond to CCK, and suggest that the effects of these stimuli interact at a peripheral level. (Supported by NIH grant DK19302).

CCK FACILITATES GANGLIONIC TRANSMISSION IN THE CCK FACILITATES GANGLIONIC TRANSMISSION IN THE GUINEA PIG GALLBLADDER VIA A PRESYNAPTIC CCK-A RECEPTOR. G.M. Mawe. Department of Anatomy and Neurobiology, The University of Vermont, Burlington, VT 05405 Cholecystokinin (CCK) is named for its ability to cause contractions

of smooth muscle fibers, resulting in an emptying of the gallbladder. There has been some dispute as to whether, in addition to its direct effect on smooth muscle, CCK acts through the ganglionated plexus of nerves in the wall of the gallbladder. In this study, intracellular recording techniques were used to test for direct and presynaptic effects of CCK on gallbladder neurons.

Direct application of CCK had no direct effect on the membrane

potential or input resistance of gallbladder neurons. However, CCK had a presynaptic facilatory effect on nicotinic transmission in gallbladder ganglia. CCK (0.1 µM) increased the amplitude of fast EPSPs in gallbladder ganglia, but it did not affect the amplitude or duration of responses to exogenously applied acetylcholine. CCK caused a 3-fold increase in the quantal content, measured from fast EPSPs recorded in low Ca²/high Mg² solution. The selective CCK-A receptor antagonist L-364,718 (1 nM) blocked the presynaptic facilatory effect of CCK, but the selective CCK-B antagonist L-365,260 (10 nM) did not.

Results from this study indicate that CCK does not affect gallbladder ganglion cells directly. However, CCK does have a facilatory effect on nicotinic transmission that is mediated by CCK-A receptors in gallbladder ganglia. Supported by NS26995.

SPINAL AND PERIPHERAL NEUROPEPTIDE Y (NPY) DIFFERENTIALLY ALTER DUODENAL AND COLONIC INTRALUMINAL PRESSURE. S.Wager-Srdar, B.Ghazali* & J. Davison*, Dept. of Medical Physiology, Univ.of Calgary, Calgary, Alberta, Canada

S.Wager-Srdar, B.Ghazali* & J. Davison*, Dept. of Medical Physiology, Univ. of Calgary, Calgary, Alberta, Canada
NPY is widely distributed in the central nervous system, spinal cord and gastrointestinal (GI) tract of several species, including rats. Hellstrom, et al. reported that intravenous (IV) administration of NPY to rats inhibited the propagation of the migrating myoelectric complex (MMC) and the GI transit of STC. Nitecki, et al. demonstrated that NPY had opposing effects on the fasting MMC following central or peripheral injections in dogs. We compared the effects of NPY administered intrathecally (INTH) at the level of T4 (n=11) and (IV) via the femoral vein (n=6) on the intraluminal pressure in the duodenum and colon of urethane anesthesized rats. The duodenum and colon were perfused with saline via indwelling catheters and pressures were recorded simultaneously during a baseline (BL) period, saline (Sul), or following NPY (200 pmole in 5 ul of saline). In contrast to BL (4.17 ± 0.4 cm H₂0), NPY (IV) decreased colonic pressure (1.37 ± 0.33 cm H₂0), p<0.003. Colonic pressure was unchanged following NPY (INTH) compared to BL. The responsiveness of the colon to NPY following INTH or IV injection was found to be statistically different, F(1,15)=8.07, p<0.01. Following saline (INTH), BL duodenal pressure was (2.55 ± 0.32 cm H₂0). However, following NPY (INTH), duodenal pressure exhibited a biphasic response with inhibition (1.63 ± 0.35cm H₂0), p<0.05, followed shortly by excitation (3.97 ± 0.39 cm H₂0), p<0.001, compared to BL. In contrast to BL (1.53 ± 0.21 cm H₂0), p<0.05; however, this observation was variable. These observations indicate that NPY may be having an effect on GI muscle tone which altered intraluminal pressure. However, the effect of NPY on intraluminal pressure in the colon appeared to be mediated through independent neural pathways or receptor populations following spinal or peripheral administration. This work was supported by Medical Research Council of Canada. S.W-S. is a post-doctoral fellow and B.G. is a Saudia Arabia government post-doctoral fellow.

EFFECTS OF GALANIN ON THE FUNCTION OF PANCREATIC SECRETION AND ELECTRICAL ACTIVITY OF B

X. W. Fu*. and X. Y. Shen. Dept. of
logy, Shanghai Med. Univ., Shanghai, CELL. Physiology, 200032, China.

The present study was designed to investigate the effects of galanin on the insulin and glucagon secretions of isolated rat islets and electrical activity of mice B cell by glucagon secretions of isolated rat islets and electrical activity of mice B cell by incubation, radioimmunoassay and intracellular microelectrode techniques. Galanin 0.3 µmol/L had a more pronounced inhibitory effect on insulin secretion in culture medium with a glucose concentration of 5.5 mmol/L than in medium with 2.7 or 20 mmol/L of glucose. Galanin did not affect glucagon release. Addition of galanin (0.15 and 0.3 µmol/L) to the perfusion medium inhibited spontaneous electrical activity with decreases in frequency and amplitude of the spike of B cell. Verapamil (0.03 - 0.09 mmol/L) blocked dose-dependently the depolarization induced by high K+ (50 mmol/L). Galanin also attenuated the depolarization induced by high K+, which showed the same tion induced by high K+, which showed the same results as the effect of verapamil. The results suggest that galanin inhibits insulin release and electrical activity of B cell by blocking of voltage-dependent Ca2+ channels.

EXCITOTOXICITY I

ELEVATION AND OSCILLATION OF [Ca2+]; AND INTERCEL-LULAR COMMUNICATION IN GLIAL CELLS IN RESPONSE TO TRAUMA AND GLUTAMATE. A. Charles, J. Merrill*, E. Dirksen and M. Sanderson. Depts. of Neurology and Anatomy and Cell Biol., UCLA School of Med., Los Angeles, CA 90024.

Mechanical trauma to a single cell in a mixed glial cell culture induced an increase in intracellular Ca²⁺ concentration ([Ca²⁺]_i) in the traumatized cell. This Ca²⁺ response was communicated cell-by-cell to surrounding cells. [Ca²⁺]_i, measured by digital fluorescence imaging and fura-2, increased from about 75 nM to 500-700 nM. As $[Ca^{2+}]_{i}$ recovered to resting levels, cells displayed asynchronous $[Ca^{2+}]_{i}$ oscillations with a periodicity of 5-20 sec. In the absence of extracellular calcium, trauma induced a similar response except that $[Ca^{2+}]_i$ decreased in the traumatized cell and the $[Ca^{2+}]_i$ oscillations in the surrounding cells were decreased in amplitude and duration. Glutamate ($100 \,\mu\text{M}$) induced a simultaneous [Ca^{2+}]_i increase in most cells, followed by asynchronous oscillations of [Ca^{2+}]_i having greater periodicity than the oscillations induced by trauma. Based on similarities of the Ca²⁺ response of glial cells to trauma and excitotoxic concentrations of glutamate, we propose that communicated changes in $[Ca^{2+}]_i$ initiate the response of glial cells to injury. CALCIUM LOCALIZATION IN RETINA IN GLUTAMATE TOXICITY AND ISCHEMIA IN VITRO. M.S. Burns and C.M. Panattoni*. Ophthalmology

Research Laboratories, UCDavis, Davis, CA 95616.

Increased intracellular calcium (Ca_i²⁺) is thought to be a mechanism of toxic cell death in both neural and non-neural cells. Increases in Ca_i²⁺ can arise from redistribution of intracellular Ca and/or influx from extracellular calcium. To test if extracellular Ca influx occurs in retinal cell toxicity, and to localize exogenous Ca influx, we incubated retinas in the stable isotope, ⁴²Ca, and imaged total Ca content in retinal cell layers using Secondary Ion Mass Spectrometry (SIMS).

Rat retinas were incubated in modified Ames' medium for up to 6 hours under

normal conditions or 5 mM glutamate or ischemia (100% N₂) and then prepared for SIMS analysis by low temperature freeze drying. Electrolyte localizations were compared to non-incubated control retinas.

Approximately 35% of the total retinal Ca was exchanged for ⁴²Ca in 6 hours of normal incubation conditions. The tracer was equally distributed in all retinal layers. With glutamate incubation, 50% of the endogenous total Ca content was layers. With glutamate incubation, 50% of the endogenous total Ca content was lost from the inner plexiform layer (IPL), but little loss was seen in other retinal layers. Exogenous ⁴²Ca uptake occurred in all layers, but was greater in the inner nuclear (INL) and IPL. In ischemia, total retinal Ca loss was seen in all areas, but uptake occurred predominantly in the INL and IPL. Cell death in the INL was greatest in the glutamate treated retinas. Cell death under ischemic conditions was similar to normal incubation.

These results indicate that there is influx of exogenous Ca into retinas made toxic by either glutamate or ischemia, and there is preferential localization in the layer comprised by amacrine and bipolar cell synaptic processes and glial (Müller) cell

ENERGY METABOLISM, CALCIUM HOMEOSTASIS AND EXCITOTOXICITY IN VITRO. A. Schurr, P. Lipton', C.A. West* and B.M. Rigor. Dept. of Anesthesiology, Univ. of Louisville Sch. of Med., Louisville, KY 40292, and 'Dept. of Physiology, Univ. of Wisconsin Med. Sch., Madison, WI 53706.

The excitotoxic hypothesis postulates glutamate (Glu) and the property of t

The excitotoxic hypothesis postulates glutamate (Glu) and aspartate (Asp) to have a major role in the neuronal damage inflicted by various brain disorders. Disturbed energy metabolism and ion homeostasis have been implicated as contributing factors in excitotoxicity. The rat hippocampal slice preparation and electrophysiology were used to study the relationships between oxygen, glucose, Ca²⁺, Mg²⁺, Glu, Asp, N-methyl-D-aspartate (NMDA) and neuronal damage. Under standard conditions (95% O₂, 10 mM glucose) Glu and Asp were innocuous. However, the rate of recovery of neuronal function (evoked population spike) after hypoxia and reoxygenation decreased with elevated [Glu], [Asp] or [NMDA] in the artificial cerebrospinal fluid (ACSF). Omitting Ca²⁺ from, or elevating Mg²⁺ in, the ACSF during hypoxia, abolished excitotoxicity. NMDA enhanced hypoglycemic neuronal damage, effect that was intensified by low-Mg²⁺ ACSF and antagonized by Ca²⁺-free ACSF. Lactate protected against, while the glycolytic inhibitor 2-deoxyglucose sensitized slices to, NMDA-enhanced, hypoglycemic neuronal damage. These results indicate that the excitotoxins have only a secondary role in hypoxic and hypoglycemic neuronal damage and are innocuous when energy metabolism is adequate and calcium homeostasis is maintained.

CALCIUM CHANNEL ANTAGONISTS AT NANOMOLAR CONCENTRATIONS ATTENUATE NMDA RECEPTOR-MEDIATED NEUROTOXICITY OF RETINAL GANGLION CELLS IN CULTURE. Jeffrey T. Offermann, Nikolaus J. Sucher, and Stuart A. Lipton. Dept. of Neurology, Children's Hospital & Progr. in Neurosci., Harvard Med. Sch., Boston, MA. Dihydropyridine calcium channel antagonists block a

Dihydropyridine calcium channel antagonists block a prolonged or 'L-type' component of voltage-gated Ca²+ current in patch-clamp recordings of postnatal rat retinal ganglion cells (Karschin and Lipton, *J. Physiol.* 1989;418:379). In the present study on these neurons, 500 -1000 nM nifedipine or nimodipine completely blocked the toxic effects of either 200 μM *N*-methylD-aspartate (NMDA) or an endogenous glutamate-related compound present in the retinal cultures. Previous data have shown that the neurotoxicity engendered by these agents can also be completely prevented by selective NMDA antagonists (200 μM APV or 20 μM MK-801; Hahn et al., *PNAS* 1988;85:6556). Under our culture conditions, ≥96% of each dihydropyridine is bound to rat serum, yielding an effective free concentration of approximately 20 nM. It is interesting to compare these results with those of murine cortical cultures in which 30-100 μM nifedipine is necessary to attenuate toxicity due to even weak NMDA agonists (Weiss et al., *Science* 1990;247:1474). The present findings suggest, at least in our preparation, that NMDA receptor-mediated toxicity is dependent on both receptor-activated and voltage-gated Ca²+ channels.

CALCIUM-INDEPENDENT ARACHIDONIC ACID-INDUCED CELL DEATH IN HIPPOCAMPAL PYRAMIDAL CELLS IS A RESULT OF FREE RADICAL GENERATION. <u>B.E. Alger and D.O. Keyser</u>. Dept. of Physiology, Sch. of Med., Univ. of MD, Baltimore, MD 21201.

Arachidonic acid (AA) release is associated with cytotoxicity but the mechanism of action has not been studied in single neurons. We have used whole-cell voltage-clamp to investigate neuronal death observed following application of AA (50 µM) to acutely isolated hippocampal neurons (n=55). Five to seven min following application of AA an increase in background current noise at the holding potential of -50 mV occurred that was followed by a gradual inward shift in holding current and, after 15 min, cell death. This sequence was not altered by inhibitors of AA metabolism or by buffering of extracellular and intracellular calcium to \sim 10 nM. The free radical generating system, xanthine (XA) and xanthine oxidase (XO) applied extracellularly resulted in cell death. Superoxide dismutase (SOD; 90 U/ml) or a cocktail of free radical scavengers, blocked AA-induced and XA+XO-induced cell death for up to 30 min suggesting the effect was due to superoxide radical formation. To determine if the change in holding current was due to movements of particular ions, we altered the concentrations of Ca2+, Ba2+, Na+, K+ and Cl intra- and extracellularly. Neither these changes nor substitution of Tris CH3SO3 for permeant ions altered the onset of AA-induced cell death. Our results indicate that AA can cause cell death via generation of oxygen free radicals and this effect is independent of Ca2+ and other physiological ions tested.

EXCITATORY AMINO ACID EVOKED CALCIUM INFLUX AND CALCIUM-DEPENDENT NEUROTOXICITY IN RAT CORTICAL CULTURES. W. C. Zinkand, C. Thompson, A. I. Salama, and J. Patel. ICI Pharmaceuticals Group, ICI Americas Inc., Wilmington, DE 19807.

Several groups have shown that removal of extracellular calcium both during and after an EAA insult will provide neuroprotection. In primary cultures of rat cerebral cortex, we have observed that EAA-induced neurotoxicity is dependent on extracellular calcium both during and after exposure to EAA's. Incubation of cells with glutamate (Glu) or N-Methyl-D-Aspartate (NMDA) for 5 min causes an influx of calcium as monitored by ⁴⁸Ca⁴⁺ and Fluo-3. Eighty to ninety-nine percent of the cells treated as such are destined to die within 24 hours as measured by release of lactate dehydrogenase to the cell culture media. Neuroprotection, as well as abolition of the primary Ca⁺⁺ influx, can be obtained by co-incubating EAA's with the NMDA-associated channel blocker MK-801 or the strychnine-insensitive glycine antagonist 7-chlorokynurenic acid (7-CK). In addition, a secondary influx of calcium following washout of the EAA was observed. This secondary influx is not blocked by the presence of MK-801, 7-CK, the NMDA receptor antagonist CPP, or the inorganic calcium channel blocker lanthanum. Cytotoxicity, however, can be blocked by removing extracellular calcium concomitantly with the secondary calcium influx suggesting a role in EAA neurotoxicity.

88.6

DELAYED CALCIUM INCREASES IN RAT HIPPOCAMPAL NEURONS FOLLOWING GLUTAMATE EXPOSURE. R.D. Randall and S.A. Thayer Dept. of Pharmacology, Univ. of Minnesota, Minneapolis, MN 55455.

The intracellular free calcium concentration, [Ca2+]i, was measured in single rat hippocampal neurons grown in primary culture using indo-1 based microfluorimetry. Neurons exposed to glutamate (100 µM) for 5 min, in the presence of Mg²⁺, responded with large increases in $[Ca^{2+}]_i$ (4.5±0.8 μ M; n=17). Each cell was observed for a total of 3 hours. Following removal of glutamate, [Ca²⁺]; returned to basal levels (16 of 17) indicating that at this time the ability of the cell to buffer the Ca2+ load had not been compromised. The cells subsequently displayed a period of [Ca2+]i spike activity of variable duration (108±15 min). [Ca²⁺]; spikes were also observed in control cells and could be blocked with 1 μM tetrodotoxin. Finally the [Ca2+]; gradually increased to uM levels for the remainder of the recording period (14 of 17). Control cells (6 of 14) also displayed a slight increase in [Ca²⁺]; toward the end of the recording period. Glutamate treated cells displayed profound morphological changes including, axonal swelling, distortion of the soma, and in some cases death (n=5). These data suggest that three Ca2+ mediated events may contribute to excitatory amino acidinduced neurotoxicity including an initial exposure or triggering event, a period of synaptically driven Ca2+ spiking, and a large sustained elevation in [Ca2+]i.

THE EXCITOTOXIN β-N-OXALYL-L-α, β-DIAMINO-PROPIONATE (β-L-ODAP) IS A POTENT ASTROGLIAL TOXIN. C.G. Hatalski, H.S. Roberts* and R.J. Bridges, Departments of Psychobiology and Neurology, University of California-Irvine, Irvine, CA 92717.

Astrocytes play a key role in excitatory amino acid (EAA)

Astrocytes play a key role in excitatory amino acid (EAA) neurotransmission by transporting and metabolizing L-glutamate. Damage to these cells would be expected to reduce the efficiency of these processes and, thus, increase the probability of excitotoxic neuronal damage. We found that the EAA agonist that is the causative agent in human neurolathyrism, β-L-ODAP, is a potent gliotoxin. Primary cultures of cortical astrocytes were prepared and purified from Sprauge-Dawley rat pups (McCarthy and deVellis, J. Cell Bio. §5, 890, 1980). β-L-ODAP was dissolved in media and added to confluent secondary cultures of type I astrocytes. The cells were observed for 48 hours and cell survival was determined by quantifying lactate dehydrogenase activity in both the culture medium and the remaining cells (Koh and Choi, J. Neurosci. Meth. 20, 1987). At low concentrations of β-L-ODAP (500μM), treated astrocytes show dramatic morphological changes (e.g., increased cell swelling and vacuoles). Increasing the concentration of β-L-ODAP, resulted in lysis of the cells. The potency of this effect (LD50 approximately 2mM) is similar to that observed with the well known gliotoxin, L-α-aminoadipate. In contrast to β-L-ODAP, the α-L- and β-D- isomers, as well as L- and D-γ-N-oxalyl-α-γ-diaminobutyric acid, were not toxic. The results of these studies suggest that the CNS damage induced by β-L-ODAP may include a pathological effect on astrocytes, as well as neurons.

BMAA ACTIVATES AN IONIC CURRENT WHICH IS BLOCKED BY EXTRA-CLLULLAR CALCIUM. C.N. ALLEN, D.O. Carpenter and P.S.

Spencer, Cntr. Res. Occ. & Envir. Tox., Or. Hlth Sci. Univ
Portland, Oregon 97201 and Wadsworth Cntr for Labs &
Res., Albany, New York 12201.

BMAA is a neurotoxic amino acid present in seeds of the false sago palm, Cycas circinalis, a plant which is etio-logically linked to Western Pacific Amyotrophic Lateral Sclerosis Parkinsonism-Dementia (ALS/P-D). Ionic currents were recorded from cultured hippocampal neurons using the whole-cell voltage clamp technique. BMAA (0.5 mM) in the absence of bicarbonate activated inward currents at membrane holding potentials more negative than 0 mV. Increasing the BMAA concentration to 2 mM caused an apparent current desensitization. The BMAA currents were not blocked by 1 mM Mg, but increasing the extracellular Ca concentration from $0.1\,$ mM to 3 mM reduced the current amplitude 90%. The IC_{50} of the Ca block was estimated to be 0.65 mM. Sodium bicarbonate (20 mM) potentiated BMAA currents in solutions containing 3 mM Ca while currents recorded in 0.1 mM Ca were not potentiated. dition of sodium bicarbonate to solutions containing calcium results in the formation of calcium-bicarbonate complexes which reduce the free calcium concentration These data suggest that bicarbonate may potentiate BMAAactivated currents in part by reducing extracellular calcium. (Supported by NIH-NINCDS grant NS-23807).

88.11

A ROLE FOR GLUTAMATE UPTAKE IN MODULATING GLUTAMATE NEUROTOXICITY IN CULTURES OF RAT CEREBRAL CORTEX. K.M. Harris, D. Rulf, and P. A. Rosenberg. Dept. of Neurol-

ogy, Children's Hospital and Program in Neuroscience,
Harvard Medical School, Boston, MA 02115.

Previous results [Neuroscience Lett., 103, 162, 1989]
have shown that cortical neurons in astrocyte-poor cultures are killed by glutamate via an NMDA receptor de-pendent mechanism, but are one hundred times more sensi-tive to the toxicity of glutamate than neurons in astro-cyte-rich cultures. This suggests that the vulnerability of neurons to glutamate toxicity may be dependent upon normal astrocyte function.

In the present study, the neurotoxicity of glutamate was compared with that of NMDA, a poorly transported glutamate agonist. Cortical cultures were exposed to selected concentrations of NMDA for 20-24 hours. Unlike glutamate, NMTA had similar potencies as a neurotoxin in astrocyte-rich and in astrocyte-poor cultures. One ex-planation for the different pharmacology of glutamate and NMDA is the presence of an active uptake system for glutamate in astrocyte-rich cultures. We found that by substituting choline for sodium, the potency of gluta-mate as a neurotoxin in astrocyte-rich cultures was greatly increased. These data are consistent with gluta-mate uptake playing an important role in determining the vulnerability of cortical neurons to glutamate toxicity.

88.13

ELECTROPHYSIOLOGY OF GLUTAMATE EXCITOTOXICITY IN CULTURED HIPPOCAMPAL NEURONS: MEMBRANE POTENTIAL AND CULTURED HIPPOCAMPAL NEURONS: MEMBRANE POTENTIAL AND NMDA CHANNEL ACTIVITY. S. Sombati, W.W. Anderson, R.B. Lee* and R.J. DeLorenzo. Dept. of Neurology, Med. Col. of Virginia, Richmond, VA 23398.

Electrophysiological changes due to short and long-term glutamate (GLU) application were studied in cultured rat hippocampal pyramidal neurons.

Membrane potential (MP) recordings were performed using whole-cell current patch-clamp. Long (10 min) application of 500 uM GLU caused rapid, sustained depolarization from -60 mV resting potential (RP) to 0 mV. After GLU application, 60% of the neurons remained depolarized (-35 to 0 mV) throughout the recording session (20-90 min) (n=15). The remaining neuron MPs recovered, although the membrane conductance at RP was twice that of pre-GLU. After brief (10-30 s) application of 500 uM GLU, all cells returned to RP within 5 s.

Because NMDA receptors are crucial for GLU excitotoxicity, we also studied

application of 500 uM GLU, all cells returned to RP within 5 s.

Because NMDA receptors are crucial for GLU excitotoxicity, we also studied NMDA channel activity during GLU application using cell-attached patch-clamp. When the cell was bathed in saline + TTX, and the pipette contained 10-500 uM NMDA (plus saline; 0-Mg, TTX, 10 uM glycine), 45-50 pS channels occurred with a reversal potential about 60 mV above RP. With no NMDA in the pipette, channels of this type were not observed. At >= 50 uM NMDA, the channels underwent slow desensitization. With 200-500 uM NMDA in the pipette, application of 500 uM GLU to the bath caused NMDA channel amplitude to decrease to 0, indicating membrane depolarization. The patch membrane was then hyperpolarized by 50-60 mV to a potential where the amplitude of NMDA channels was about -3 pA. During GLU application the channel activity first decreased and then increased above pre-GLU controls. Burst lengths were 1-9 s vs 100-500 ms pre-GLU. Channel activity then disappeared 30-60 min after GLU application.

The MP and non-invasive NMDA channel recordings show that 10 min GLU application produces long-lasting membrane depolarization. This post-GLU depolarization could enhance excitotoxic effects by removing the Mg block of the NMDA channel. The transient increase in NMDA channel activity could contribute to, or be the result of, excitotoxic damage.

to, or be the result of, excitotoxic damage.

BASIC FIBROBLAST GROWTH FACTOR ATTENUATES NMDA RECEPTOR MEDIATED NEUROTOXICITY IN STRIATAL NEURONS

A. Freese, S. Finklestein, and M. DiFiglia. Department of Neurology, Mass. General Hospital & Harvard Medical School, Boston, MA 02114.

We have recently characterized the neurotoxicity of glutamate (glu) in primary striatal cultures (Freese, et. al., *Brain Res.*, 1990, in press). As shown by Mattson, et. al. (*J. Neurosci.* 9:3728, 1989), Fibroblast Growth Factor (FGF) reduces the neurotoxicity of glu in hippocampal cultures. In the current study, the neuroprotective effect of basic (b)FGF was further evaluated in striatal cultures.

In separate experiments, striatal cultures were incubated with or without bFGF (6 pM) from the day of plating for 12-18 days in culture. These cultures were then exposed to 3 mM glu, 1 mM Quinolinate (QA), or 1 mM Kainate (KA) for 3 h., and survival of neurons was quantitated. Neurons exposed to bFGF and glu had a survival of 86+/-2% (n=21 dishes, 7 experiments), whereas those exposed to glu only had a survival of 54+/-3% (n=19, 7 exps). Striatal neurons exposed to QA (an agonist of the NMDA receptor) had a survival of 96+/-2% (n=12, 4 exps) with bFGF and 74 +/-4% survival (n=12, 4 exps) without bFGF. Surprisingly, when exposed to KA, survival of neurons was not affected by preincubation with bFGF (survival of 64+/-6% with and 64+/-10% without bFGF; n=5, 2 exps). Quisqualate is not toxic in these cultures. Control cultures, not exposed to glu, QA, or KA, had a survival of 99+/-1% with and 98+/-1% without bFGF. The protective effect of bFGF on glu neurotoxicity was observed in cultures treated as little as 2 h. before glu exposure.

These results suggest that bFGF markedly protects striatal neurons

from glu excitotoxicity by attenuating NMDA receptor function. Whether such an effect is mediated by the receptor or post-receptor events remains to be determined. Supported by NIH grant NS 16367 to MD.

88.12

SYNTHESIS OF GLUTAMATE FROM GLUTAMINE CONTRIBUTES TO EXTRACELLULAR GLUTAMATE ACCUMULATION ACCOMPANYING GLUTA-MATE NEUROTOXICITY IN CORTICAL CULTURES. P. A. Rosenberg. Dept. of Neurology, Children's Hospital and Program in Neuroscience, Harvard Medical School, Boston,

The neuronal mechanism(s) contributing to extracellular glutamate accumulation accompanying neuronal injury and death have not been well characterized. In order to isolate the neuronal contribution to extracellular glutamate accumulation, cultures of embryonic cerebral cor-tex were used in which astrocyte proliferation was tex were used in which astrocyte proliferation was stringently suppressed by early exposure to the mitotic inhibitor cytosine arabinoside (at 4 days <u>in vitro</u>). Killing of neurons in these cultures by exposure to 10 µM glutamate in the absence of glutamine resulted in no detectable increase in the extracellular glutamate con-centration following a 20-24 hour incubation, using HPIC with ninhydrin detection. In contrast, when neurons were killed by exposure to glutamate plus glutamine (2 mM), substantial amounts of glutamate could be demonstrated in the extracellular medium. Using ¹⁴C-glutamine, it was possible to show that the extracellular glutamate derived from glutamine. These results suggest that extracellular glutamate accumulation accompanying glutamate mediated neurotoxicity at least in part depends upon the synthesis of glutamate from glutamine, and is not simply due to release of pre-existing stores.

WITHDRAWN

NEUROPROTECTIVE EFFECTS OF IFENPRODIL AGAINST GLUTAMATE TOXICITY IN HIPPOCAMPAL CELL CULTURES. I.A. Shalaby, M. Prochniak*, and "B. Chenard*. Prizer Central Research, Groton, CT 06340

We have examined the neuroprotective efficacy and potency of the novel NMDA antagonists ifenprodil and SL-82,0715 against glutamate induced neurotoxicity in hippocampal cell cultures. 2 to 3 week hippocampal cultures from fetal rats were exposed to glutamate or NMDA with or cultures from fetal rats were exposed to glutamate or MMA with or without antagonist for 15 minutes. The drugs were washed out and cells allowed to remain in the media for 24 hours following the glutamate exposure. Glutamate and MMA induced dose - dependent increases in LDH reaching 3 fold above control levels. Morphological examination confirmed the neuronal specificity of the degeneration. The putative antiischemic compounds ifenprodil and SL-82,0715 blocked the glutamate (1 mM) toxicity with logs of 200 mm and 1 uM, respectively. The protective fiftens of increased in the state section of the state of the tective effects of ifenprodil were not due to its potent alpha-1 tective effects of ifenproal) were not due to its potent alpha-i adrenergic receptor antagonism as prazosin had no neuroprotective activity up to 10 µM. Similarly, the neuroprotective effects of ifen-prodil were not due to its sigma receptor activity (Karbon et. al., Eur. J. Pharmacol. 176, 247-, 1990), as sigma ligands such as DTG, haloperidol, and 3-PPP were not neuroprotective up to 1 µM. Ifenprodil does not act through the modulatory strychnine insensitive glycine binding site, as exogenous glycine failed to reverse its neuroprotective effect. We conclude that the antiischemic agents ifenprodil and SL-82,0715 are potent neuroprotective compounds in vitro, and attenuate glutamate - induced neurotoxicity by mechanisms related to their NMDA antagonist properties.

DIFFERENTIAL EXPRESSION OF C-FOS mRNA FOLLOWING KAINIC ACID ADMINISTRATION. G. Tocco, S. S. Schreiber, P. C. May. R. F. Thompson, M. Baudry. Program in Neuroscience, University of Southern California, Los Angeles, CA 90089-2520. Systemic or intracerebral injection of the neurotoxin, kainic acid (KA), in rats induces limbic seizures and extensive neuronal damage throughout the limbic system. Since the proto-oncogene c-fos increases in rodent brains after seizure activity, we were interested in determining the regional expression of c-fos at different times following KA administration.

Rats received KA (8-10 mg / kg i. p.) and were killed at various time intervals following seizure induction. The levels of expression of the c-fos mRNA were quantified by in situ hybridization. One hour after the induction of seizures, coronal sections at the level of dorsal hippocampus exhibited a generalized increase in the expression of c-fos message. However, 12 hours and up to three days after the onset of seizures, the increase in c-fos expression was mostly confined to CA3 pyramidal cells. These results suggest that prolonged c-fos expression may be a characteristic of cells that are selectively vulnerable to KA.

selectively vulnerable to KA.

IS THERE A LINK BETWEEN N-METHYL-D-ASPARTATE RECEPTORS AND SIGMA RECEPTORS IN METHAMPHETAMINE-INDUCED NEUROTOXICITY IN MICE? P.K. Sonsalla, D.E. Vitagliano and I.A. Terleckyl. Dept. Neurology, UMDNJ-Robt. Wood Johnson Med. Sch., Piscataway, NJ 08854.

The N-methyl-D-aspartate (NMDA) receptor is comprised of the NMDA recognition site, the co-agonist glycine site, and seyeral modulatory sites (including phencyclidine, Mg., Zh. and possibly polyamine sites). Excitotoxicity mediated by NMDA receptors can be altered by compounds which act at these various sites. We have found that competitive and noncompetitive NMDA antagonists which interact with several of the sites mentioned above protect against the neostriatal dopaminergic damage induced by methamphetamine (METH); these findings indicate that the excitatory amino acids play an important role in this neurotoxicity. Recently, it has been suggested that there may be a link between the putative haloperidol-sensitive sigma site and NMDA receptors. If so, we hypothesized that compounds with high affinity for this site should modify the neurotoxic effects of METH. Of the compounds tested, only BMY 14802 provided protection against the METH-induced decrements in neostriatal TH activity and DA content. None of the other compounds at the doses tested (rimcazole, DTG, (+)3-PPP, dextromethorphan, 1-butaclamol, or clorgyline) altered these METH-induced changes. These findings indicate 1) that the activation or inhibition of these putative sigma receptors is unlikely to be an important aspect of METH-induced neurotoxicity, 2) that the sigma receptor does not appear to be linked to NMDA receptors and 3) that the neuroprotection afforded by BMY 14802 against damage induced by METH may be due to some property other than its ability to bind to the sigma site.

EXCITOTOXICITY II

PHYSIOLOGIC and ANTICONVULSANT EFFECTS OF AN INHIBITOR OF GABA-T: IN VIVO CEREBRAL MICRODIALYSIS STUDY. R.S.K. Young, M.J. During, W.J. Aquila*; Yale Medical School; New Haven, CT.

To investigate the potential anticonvulsant effects of increased extracellular fluid levels of GABA, Aminooxyacetic acid (AOAA), an inhibitor of GABA-aminotransferase (GABA-T), was administered parenterally to rabbits. AOAA (400 mg/kg) produced high voltage slowing of the EEG, followed by marked attenuation. In vivo microdialysis of cerebral cortex showed a bimodal response to AOAA with either significant increase in glutamate, aspartate, and GABA, or, little change in these amino acids (Table). Administration of either flurothyl or bicuculline (2 mg/kg) produced seizure in the low GABA, but not the high GABA group. Animals in whom levels of extracellular fluid GABA are raised by AOAA have marked protection from seizure.

value by Analysis of variance)

EFFECTS OF INTRAOCULAR ADMINISTRATION OF N-methyl-D-aspartate (NMDA) ON THE RETINA OF THE ADULT RAT. R. Siliprandi, R. Canella*, R. Zanoni*, G. Carmignoto and N. Schiavo*. Fidia Research Laboratories, Abano Terme (PD), Italy.

We investigated the effect of a single intravitreal injection of NMDA (from 2 nmoles to 200 nmoles) on the adult rat retina. One week after injection, morphological analysis of Nissl-stained, transverse sections of retinae showed a dose-dependent loss of cells in the ganglion cell (GC) layer. Quantitative analysis of Nissl-stained, whole-mounted retinae showed that the administration of 20 nmoles NMDA resulted in a 60% loss of cells with somal diameter exceding 8 µm. Choline acetyl-transferase (ChAT) activity also decreased in NMDA treated retinae in a dose-dependent manner (ED50 ~ lonmoles). The results indicate that GCs and cholinergic retinal neurons (presumably cholinergic amacrine cells) of the adult rat retina are highly vulnerable to NMDA and represent a useful and reproducible model system for in vivo studies of pharmacological agents able to limit neuronal damage produced by the excitotoxic action of NMDA.

MECHANISMS UNDERLYING EXCITOTOXICITY ASSOCIATED WITH METABOLIC INHIBITION. W.J. Nicklas and G.D. Zeevalk. Dept. of Neurology, UMDNJ-Robert Wood Johnson Med. Sch., Piscataway NJ 08854.

Numerous studies have suggested that CNS ischemic damage is mediated by excitatory amino acid (EAA) associated excitotoxicity. We have made use of an ex vivo preparation of E13 chick neural retina to evaluate effects of chemically-induced hypoglycemia (iodoacetate, 10A) or hypoxia (KCN) and their relationship to acute excitotoxicity. Histology and amino acid release were used as indices of acute excitotoxicity. The mild excitotoxic lesion produced by either drug alone was completely inhibited by NMDA, but not non-NMDA, antagonists. A more robust lesion produced by combination of IOA and KCN was only partially prevented by NMDA antagonists showed little protection but a combination of both types of EAA antagonists afforded considerable protection. Aspartate or glutamate efflux was not increased in mild lesions but medium levels of these EAAs were elevated with more severe metabolic inhibition. Increasing [K], also produced excitotoxic-like lesions; the histological damage at 55 mM [K'] was almost completely prevented by MK-801. Tetrodotoxin (TTX) only minimally protected against elevated K', NMDA, IOA or IOA-KCN mediated toxicity. The data are consistent with energy depletion initially causing NMDA receptor activation via membrane depolarization, i.e., mild lesions are prevented by NMDA antagonists. As the damage becomes more robust, non-NMDA mediated toxicity is apparent. This may have relevance to the disparate literature findings concerning the efficacy of NMDA antagonists as anti-ischemic agents.

89.5

DIFFERENTIAL LOSS OF [3H]MK801, [3H]SCH23390 BINDING SITES AND CAT ACTIVITY FOLLOWING QUINOLINIC ACID-INDUCED LESIONS OF RAT STRIATUM. A.B. Norman. M. Kolmonpunporn, L.M. Ford and P.R. Sanberg. Div. of Neuroscience, University of Cincinnati College of Medicine, Cincinnati, OH 45267.

The excitotoxin quinolinic acid (QA) is thought to exert its neurotoxic actions by activation of the NMDA glutamate receptor. The

neurotoxic actions by activation of the NMDA glutamate receptor. The measurement of excitotoxin-induced damage in rat striatum generally employs the neurochemical assay of choline acetyltransferase (CAT) or glutamate decarboxylase (GAD). Theoretically, neurons which express NMDA glutamate receptors should be primarily lost following QA lesions. Furthermore, D₁ dopamine receptors should also provide a good index of neurotoxicity as these receptors are located entirely on intrinsic striatal neurons. Male Sprague-Dawley rats received bilateral intrastriatal injections of QA (75,100,150 nmol) or vehicle (n=6 per group). After 21 days striata were dissected and stored at -70°C.

Control 75 nmol 100 nmol 150 nmol

	Control	/3 nmoi	100 nmoi	130 nmoi

alues in parentheses represent % control.

CAT containing neurons in rat striatum are relatively resistant to QA-induced toxicity and therefore may not represent an appropriate neurochemical assay. D₁ dopamine receptors are very sensitive to QA-induced toxicity and may represent a very good neurochemical assay. Interestingly, the loss of only 47% of [³H]MK801 binding sites indicates that a population of [³H]MK801 binding sites may not be associated with QA-sensitive NMDA receptors. Supported by NINDS.

SUBSTANCE P[5-11] INHIBITS NMDA-INDUCED NEURO-TOXICITY BOTH IN VITRO AND IN VIVO. J.B. O'Neill, H. Jaffe*, J.M. Hill, G.M. Barbour*, L.D. Kwart*, D.I. Lambie*, W.D. Bowen1, M.R. Ruff*, and C.B. Pert*. Peptide Design L.P., Germantown, MD 20874, ¹Brown University, Providence, RI 02912.

Recently we isolated a peptide from rat brain with phencyclidene-like properties and identified it as substance P (1). We now report that a heptapeptide fragment of substance P, SP[5-11], which we have termed alpha-neuroprotectin (aNP), potently inhibits binding of the NMDA receptor antagonists, [3H]-TCP and [3H]-CGS 19755, to rat brain membranes, without affecting binding of [3H]-DTG to the sigma receptor (guinea pig membranes). NMDA-induced toxicity of mouse hippocampal neurons was potently and completely prevented by αNP (EC₅₀, 1pM) and substance P. αNP was not itself neurotoxic at concentrations up to 10-5 M under these conditions.

concentrations up to 10-3 M under these conditions. Additionally, *in vivo* administration of α NP protected against NMDA lethality in newborn Sprague Dawley rat pups in a dose-dependent fashion. Further studies showed that an NMDA-induced behavioral deficit in young rats, as measured by observing the air righting reflex, was also prevented by α NP. Structure-activity and receptor binding studies indicate that the neuroprotection isn't mediated through the classical substance P receptor. Therefore, αNP antagonizes the neurotoxic effects of NMDA in vitro and in vivo by a mechanism probably related to the interaction of this peptide with the

NMDA receptor complex.

SUBSTITUTED GUANIDINES: CORRELATION BETWEEN PCP RECEPTOR BINDING AND IN VITRO NEUROPROTECTION. C.J.KIRK*, REDDY*, J.B.FISCHER, R.N.MCBURNEY*, A.C. SERVER, E.WEBER¹*, J.F.W. KEANA²*. Cambridge NeuroScience Research, Inc. Cambridge, MA 02139, ¹Dept. Pharmacol., U.C. Irvine, Irvine, CA 92717, ²Dept. Chemistry, U. Oregon, Eugene, OR 97403

Much interest has been generated concerning the potential neuroprotective qualities of compounds such as MK-801 which have a high affinity for the PCP receptor. We report here on the correlation between PCP binding affinities and <u>in vitro</u> neuroprotection exhibited by a series of substituted guanidine compounds. Displacement of ³H-MK-801 from rat brain membranes was used to determine PCP binding affinities and selected drug candidates were subsequently tested in an <u>in vitro</u> excitotoxicity assay. The toxicity assay was based on the measurement of lactate dehydrogenase (LDH) released into the medium by dead and dying neurons following a brief exposure to glutamate in the presence or absence of a putative neuroprotective compound. Drugs with nanomolar affinities gave neuroprotection in the micromolar range. The binding affinity (IC_{50}) was plotted against the ED_{50} for neuroprotection for each drug tested. The resultant graph indicated a very strong correlation between PCP affinity and neuroprotection, and suggests that binding studies may be reliable predictors of neuroprotective activity.

A PARALYTIC DOSE OF DYNORPHIN 1-13 IN THE RAT SPINAL CORD FAILS TO ENHANCE THE RELEASE OF EXCITATORY AMINO ACIDS BUT DECREASES THE EXTRACELLULAR CONCENTRATION OF GLUTAMINE. D. H. Smullin, S. R. Skilling* and A. A. Larson. Department of Veterinary Biology, University of Minnesota, St. Paul, MN 55108.

Excitatory amino acid (EAA) antagonists have been shown to protect against

Excitatory amino acto (EAA) antagonists have been shown to protect against dynorphin (DYN)-induced neurotoxicity in the spinal cord (Brain Res 507 1-5 1990). We tested the hypothesis that the neurological damage produced by intrathecal DYN, therefore, involves facilitated release of neurotoxic concentrations of the EAA neurotransmitters aspartate (Asp) and glutamate (Glu) into the spinal cord ECF. Using microdialysis, Asp and Glu release in the lumbar spinal cord of conscious rats was monitored before and after intrathecal injection of 20 nmoles of conscious rats was monitored before and after intrathecal injection of 20 nmoles of DYN 1-13. While 100% of the animals became paralyzed within 10 min of the DYN injection, we did not observe a significant increase in the average release of either Asp or Glu during the 60 min collection period following injection. A portion of the animals did show release of Asp and Glu, however, there was no correlation between release and the degree of neuronal damage visualized histologically. These results argue against EAA release as a mechanism for DYN-induced paralysis or neurotoxicity. We did observe, however, a significant decrease (40%) in the ECF concentration of glutamine (Gln) following DYN in all of the animals tested. Previous research has shown that, in the absence of Gln, Glu is not resurretive (I) Neurochem 51 f604 1690 and the EAA anteroprise can inhibit Gln. neurotoxic (J. Neurochem 52 1694-1699) and that EAA antagonists can inhibit Glnneurotoxic (I. Neurochem 52 1694-1699) and that EAA antagonists can inhibit GIniduced changes in Glu release (Abstr. Soc Neurosci. 15 480, 1989). The present results, therefore, support the hypothesis that DYN-induced neurotoxicity involves an enhanced uptake of Gln and its subsequent conversion into ammonia and glutamate within the neuron. Alternatively, the decrease in extracellular Gln could result in a decrease in its conversion to GABA. Loss of this inhibitory transmitter could also play a role in the neurotoxic effects of DYN. NEUROPROTECTIVE PHARMACOLOGY OF AMPA AND QUISQUALATE INDUCED BRAIN INJURY. M.V. Johnston, J.W. McDonald and W.H. Trescher,

The Johns Hopkins University and Kennedy Institute, Baltimore, MD 21205.

The neuroprotective characteristics of antagonists of quisqualate (QUIS) and MMDA receptors, and anticonvulsant drugs were evaluated against AMPA and quisqualate induced brain injury in perinatal rats. PND 7 rats received unilateral NMDA receptors, and anticonvulsant drugs were evaluated against AMPA and quisqualate induced brain injury in perinatal rats. PND 7 rats received unilateral intrastriatal stereotaxic injections of either 10 nmol AMPA or 100 nmol QUIS and either a potential neuroprotective compound or an equivalent volume of saline (n = 5-10 per group). MK-801 and anticonvulsant drugs were administered i.p. 15 minutes after intrastriatal excitotoxin injection and CNQX was co-injected with excitotoxins intrastriatally. The severity of brain injury was quantitated 5 days later by comparison of the weights of injected (i) and contralateral (C) cerebral hemispheres; %damage=100(C-I)/C. Data are presented as %protection (mean±SEM), a term that reflects the degree of damage in neuroprotective groups vs saline treated groups. Coinjection of CNQX, a competitive ionotropic quisqualate receptor antagonist, markedly reduced both AMPA and QUIS neurotoxicity (AMPA, 10 nmol CNQX = 37±2%, protection, p<0.05, 20 nmol CNQX = 68±7% protection, p<0.001; QUIS, 10 nmol CNQX = 43±15% protection, p<0.001. Treatment with the non-competitive NMDA receptor antagonist MK-801 (1 mg/kg, i.p.) significantly reduced both AMPA (32±8%, protection, p<0.01). Treatment with the non-competitive NMDA receptor antagonist MK-801 (1 mg/kg, i.p.) significantly reduced both AMPA (32±8% protection, p<0.001) and QUIS (21±4% protection, p<0.05) (1 mg/kg) produced near complete neuroprotection (AMPA, 92±5% protection, p<0.001; QUIS, 79±13% protection, p<0.001). The anticonvulsant drugs diazepam (1-10 mg/kg) and phenytoin (40-80 mg/kg) effectively limited QUIS toxicity but not AMPA induced brain injury. The maximal protection against QUIS toxicity was 69±17% tor diazepam (10 mg/kg, p<0.01) and md et-22% (or phenytoin (80 mg/kg). The data provide an initial characterization of the in vivo pharmacology of non-NMDA receptor mediated excitotoxic brain injury. pharmacology of non-NMDA receptor mediated excitotoxic brain injury.

MK801 TRANSIENTLY DECREASES CEREBRAL TEMPERATURE IN PERINATAL RATS. C.-K.Chen, J.W.McDonald, W.H.Trescher and M.V. Johnston, Kennedy Research Institute and The Johns Hopkins University School of Medicine. Baltimore. MD 21205

Johnson, Kennedy Research institute and the Johns Hopkins University School of Medicine, Baltimore, MD 21205

MK801, a noncompetitive NMDA receptor antagonist, has neuroprotective activities on focal ischemic-hypoxic and NMDA-induced brain injury in perinatal rats (McDonald et al., 1987). Recently it has been suggested that hypothermia induced by MK801 may account for its neuroprotection. In this study, we investigated the effect of temperature on NMDA-induced brain injury and the effect of MK801 on temperature; in perinatal rats

investigated the effect of temperature on NMDA-induced brain injury and the effect of MK801 on temperature in perinatal rats.

In 7-day-old rats, under ether anesthesia, NMDA (25 nmol) was injected into the right striatum and the rats were then put in an incubator at various temperatures(40°, 36°, 33°, 31°, 28° and 25°C) for 2 hr. The degree of unilateral brain injury was assessed by disparities in cerebral hemisphere weights 5 days later. Lower ambient temperature decreased the degree of brain injury and there was a linear correlation between the ambient temperature and injury(R²=0.991). To study the relationship between the body and ambient temperatures, a filament-thin temperature probe was inserted into the right striatum of an additional group of 7-day-old rats. Rat pups were then put in an incubator at 36°, 33° and 30°C. There was a linear correlation between cerebral, skin and ambient temperatures (R²≥0.88). To assess the effect of MK801 on body temperature, MK801(1mg/kg) was injected ip into rat pups. The cerebral temperature decreased slightly (0.98t-0.08°C, n=4) immediately after the injection and then increased gradually and coincided with the controls 40 min later. From the correlation between temperature and brain injury(2.48% change damage/°cerebral temp.), we estimated that the temperature difference induced by MK801 could decrease NMDA-induced brain injury by 2.4%.

In this model, there is an excellent correlation between ambient, skin and

In this model, there is an excellent correlation between ambient, skin and cerebral temperatures. Although MK801 transiently decreased cerebral temperature, our data indicate that this change accounted for less than 3% of the drug's neuroprotective effect.

THE DEVELOPMENTAL TIME COURSE AND IONIC DEPENDENCE OF KAINATE MEDIATED TOXICITY IN CEREBELLAR GRANULE CELLS. P.S. Puttfarcken, K. Kato, W.E. Lyons, and J.T. Coyle, Dept. of Psychiatry. Johns Hopkins Sch. of Med., Baltimore, MD 21205.

In the presence of physiological concentrations of Mg²⁺ and in the absence of glycine, the mechanisms associated with kainate (KA) induced toxicity were examined in cerebellar granule cell cultures. Pharmacological characterization indicated toxicity was mediated exclusively through the KA receptor in these cells. Two separate components of toxicity were observed and differentiated according to time of onset, morphological change, and ionic dependence. Acute toxicity, as determined by the release of lactate dehydrogenase (LDH) after 30 min of 1 mM KA exposure, was apparent betweeen 8-11 days in culture (DIC) and was dependent on both Na⁻ and Cl⁻. Removal of Ca²⁺ intensified acute toxicity. Vulnerability to acute toxicity did not correlate with KA receptor expression (5 DIC) nor receptor mediated Cl⁻ influx (8 DIC). Delayed neurotoxicity, as determined by LDH release 24 hrs after KA exposure, was apparent after 8 DIC and dependent on Cl⁻. Removal of Ca²⁺, during the 30 min drug exposure, did not alter delayed toxicity. Under conditions in which acute toxicity was not detected (-Na⁻), KA mediated cell death was still apparent. These observations, together with the difference in onset and ionic dependence, suggest that the mechanisms involved for each component are different.

EXTRACELLULAR GLYCINE, BUT NOT GLUTAMATE, REMAINS ELEVATED AFTER TRANSIENT GLOBAL CEREBRAL ISCHEMIA IN THE RABBIT. A. J. Baker.* M. H. Zornow, M. S. Scheller.* T. L. Yaksh, S. R. Skilling.* D. H. Smullin, A. A. Larson and R. Kuczenski Neuroanesthesia Research Lab., Univ. of California, San Diego, La Jolla, CA 92093 & Univ. of Minnesota, St. Paul, MN 55108

The neuronal injury that results from transient global cerebral ischemia continues to evolve in the post-ischemic period. Significant elevations in extracellular concentrations of nutative mediators of ischemic neuronal

The neuronal injury that results from transient global cerebral ischemia continues to evolve in the post-ischemic period. Significant elevations in extracellular concentrations of putative mediators of ischemic neuronal injury (eg glutamate or dopamine) however, return to baseline immediately upon reperfusion. This raises questions about the mechanisms of post-ischemic injury. Using a model of transient global cerebral ischemia in the rabbit, extracellular hippocampal glutamate, aspartate and glycine, and striatal dopamine and serotonin were measured using microdialysis with high temporal resolution during and after ischemia. The concentrations of glutamate and aspartate increased to peak levels that were dependent on ischemic duration but returned briskly to baseline levels with reperfusion. There was a massive elevation of extracellular dopamine, which also returned to baseline after reperfusion. Glycine concentrations increased during ischemia but in contrast to the previous neurotransmitters, remained elevated throughout the 80 min reperfusion period. Glycine has recently been shown to facilitate the activity of glutamate at the NMDA receptor. The sustained elevation of glycine concentrations after ischemia therefore, may explain the apparent ongoing toxicity of glutamate in the reperfusion. These results may also have implications for new avenues of therapeutic intervention.

Effects of L-NG-monomethylarginine and Sodium Nitroprusside on Kainate Mediated Toxicity in Rat Cerebellar Granule Cell Cultures. W.E. Lyons, P.S. Puttfarcken, and J.T. Coyle. Dept. of Psychiatry. Johns Hopkins Sch. of Med., Baltimore, MD 21205. The characterization of kainate (KA) induced toxicity in rat cerebellar granule cell cultures, has demonstrated a lack of correlation between

The characterization of kainate (KA) induced toxicity in rate cerebrain granule cell cultures, has demonstrated a lack of correlation between osmotic imbalance, receptor expression, and KA mediated cell death (Kato, K., et al. submitted). This discrepancy suggests that other events may be critical for the induction of a KA mediated toxicity, the involvement of receptor linked transmembrane processes was examined in cerebellar granule cell cultures. Previous studies have demonstrated that KA receptor activation ultimately leads to the synthesis of nitric oxide (NO) from arginine in slices of rat cerebellum (Garthwaite et al., 1989). In the current study, the role NO may play in the toxic response elicited by KA was evaluated. Dose response curves performed in the presence of varying concentrations (100 nM to 1 mM) of L-NG-monomethylarginine (MA), a competitive inhibitor of the NO generating enzyme, indicated that MA produced a dose-related depression of maximally stimulated KA (500 μ M) toxicity. At a concentration of 300 μ M, MA produced a maximum inhibition of approximately 50-60%. Furthermore, the addition of a subtoxic dose (300 μ M) sodium nitroprusside (NP), a compound which spontaneously generates NO, greatly potentiated KA induced toxicity. KA was more potent in eliciting a toxic response in presence of 300 μ M NP, as indicated by the leftward shift in the KA dose response curve. These data suggest that NO may be involved in mediating the toxic effects of KA in cerebellar granule cell cultures.

PROLINE: A POTENTIAL EXCITOTOXIN IN THE MAMMALIAN CENTRAL NERVOUS SYSTEM. S.W. Helm*, D.B. Reichling and A.B. MacDermott. Dept. of Physiology and Center for Neurobiology and Behavior, Columbia University, New York City, NY 10032.

The amino acid proline (Pro) has been implicated as an endogenous excitatory agonist, with partial activity at the NMDA receptor (Nadler, et al, 1989). We have attempted to further define the receptor subtypes involved in Pro's excitatory activity. Multiple concentrations of Pro were screened for excitatory activity using whole cell recording. Solutions were applied to voltage-clamped embryonic rat spinal cord neurons in culture, and the responses compared to those obtained with glutamate (Glu). Application of 3.0 mM Pro or 1.0 uM Glu resulted in currents of nearly equal amplitude APV (50 uM) suppressed the response to Pro by 25-50% in all cells tested, and giveine (5.0 uM) potentiated the response to Pro. consistent with an effect on the NMDA receptor. An additional 25-50% of the Pro response was inhibited by CNQX (30 uM). In about 50% of the cells screened, part of the current activated by Pro was resistant to APV and CNQX. Thus Pro activates both NMDA and non-NMDA subtypes of Glu receptor and, in addition, can induce an APV/CNQX-insensitive response. When applied to addition, call induce all APV/CNOAA issistive response. When applied to cells loaded with the calcium indicator indo-1, 3.0 mM Pro resulted in a significant increase in [Ca²⁺]. This effect was virtually eliminated by the addition of 10 uM Mg²⁺, suggesting the NMDA receptor as the primary route of calcium entry following Pro activation. The significance of Pro's excitatory action is two-fold. First, the APV/CNQX-insensitive component of the Pro response suggests a possible unique role for Pro in excitatory transmission. Second, the Pro-induced elevation in [Ca2+]; implicates Pro as a potential neurotoxin in the mammalian CNS.

89.14

CHANGES IN BINDING TO THE N-METHYL-D-ASPARTATE (NMDA) RECEPTOR COMPLEX IN RAT HIPPOCAMPAL SUBREGIONS AT VARIOUS TIMES FOLLOWING RECOVERY FROM INSULIN-INDUCED HYPOGLYCEMIA. L.P.Miller. D. Panchison*. and R.N.Auer. Lab Neurosci Vet Adm Med Ctr, Dept Pharm, Georgetown Univ Sch Med, Wash D.C.20007 & Dept Path, Hith Sci Ctr, Univ Calgary Alberta, Canada T2N 4N1

Insulin-induced hypoglycemia with attending isoelectric(ISO)EEG leads to neuronal damage in the neostriatum, hippocampal dentate gyrus (DG), subiculum, CA1 and outer cortical regions (Auer et al 1984). Cumulative evidence now supports excitotoxic mechanisms (Wieloch 1985) as an underlying cause of striatal cell damage. The present investigation explored the etiology of cell death in the hippocampus by examining the effect of 30 min hypoglycemia-induced ISO on binding to NMDA receptor complex within this region. We examined 4 sets of experimental animals: controls, 30 min ISO + no recovery,30 min ISO + 1 day recovery and 28 day recovery. Using 12 micron coronal sections components of the NMDA receptor complex were characterized in various subregions of the dorsal hippocampus as: A) 3H-glycine binding to the modulator site, B) 3H-TCP binding to the ion channnel portion of the complex and C) 3H-glutamate binding to the recognition site. Quantitative autoradiography was performed using a LOATS RAS 1000 image analysis. Our results showed differential changes:

RAT STRAIN DIFFERENCES IN KAINIC ACID (KA) NEUROTOXICITY III: INFLUENCE OF AGE. G.T. Golden, G.G. Smith*, J.H. Kulp*, P.F. Reyes and T.N. Ferraro. VA Med. Ctr., Coatesville, PA 19320 and Thomas Jefferson Univ., Philadelphia, PA 19107.

Adult Wistar-Furth (WF) and F344 rats are exceptionally sensitive to the neurotoxic effect of KA, reliably demonstrating EEG and behavioral status epilepticus in response to a 10 mg/kg, sc dose. Responses of SD and LEH rats are much more variable. We now report dose-response data for juvenile (35-40 days old) and adult (70-90 days old) WF, F344, SD and LEH rats. Juvenile male WF (n=51), F344 (n=55), SD (n=60), LEH (n=50) and adult male WF (n=64), F344 (n=52), SD (n=52), LEH (n=53) rats were given KA 6, 8, 10, 12 or 14 mg/kg, sc. In adults, WF and F344 strains demonstrated the greatest sensitivity and most reliable convulsant responses to KA; SD and LEH strains were less sensitive and and showed more variable convulsant responses. Regardless of strain, all juvenile rats exhibited greater sensitivity and less variable convulsant responses to KA compared to adults. This was most evident in juvenile SD and LEH rats, however the rank order of sensitivity and seizure proneness observed among juveniles was the same as adults (WF = F344 > SD > LEH). Mortality rates were equivalent for adults and juveniles when collapsed across all doses. Compared to adults, however, juvenile mortality rates were higher at the lower KA doses (6, 8 and 10 mg/kg) and lower at the higher doses (12 and 14 mg/kg). Results suggest that while seizure sensitivity to KA decreases with age, genetic factors may regulate the expression of this resistance. (Supported in part by VA funds.)

SPINAL CORD ISCHEMIA-INDUCED ELEVATION OF EXTRACELLULAR AMINO ACIDS AS MEASURED BY MICRODIALYSIS. R.K.Simpson. C.S.Robertson, and J.C.Goodman, Dept.Neurosurg., Baylor Col. of Med., Houston, TX, 77081

A simple yet reliable model of spinal cord ischemia has been developed by inserting a catheter into the abdominal aorta of rabbits and inflating the balloon just inferior to the renal arteries. Recent investigations have shown that paraplegia is consistently reproduced if the balloon is inflated for 20 minutes after loss of the N3 component of the somatosensory evoked potential (SEP). Because of its high reliability, this model has been successfully used to study several biochemical events that occur as a consequence of ischemia-induced spinal cord damage. Our study focused on the role of excitatory amino acids in acute, severe spinal cord injury by measuring changes in the extracellular concentrations of amino acid neurotransmitters using microdialysis techniques. Dialysis tubing, 0.2 mm in diameter, with a molecular weight cut-off of 6000 was inserted through the spinal cord via a laminotomy and perfused with artificial cerebrospinal fluid at 5 µl/min. Samples were collected prior to, and during the ischemic period immediately following loss of the N3 SEP componentproduced by sciatic nerve stimulation. Samples were also collected immediately upon reperfusion, and 20 min, 40 min, and 60 min after reperfusion. Glutamate, asparate, glutamine, asparagine, glycine, taurine, valine, and leucine were measured in the microdialysis perfusate by high pressure liquid chromatography. The concentrations of glutamate, glycine, and taurine were significantly higher during ischemia and reperfusion than controls. Delayed elevations in the concentrations of asparagine and valine were also detected. The elevation of glutamate is consistent with the hypothesis that excitotoxins may mediate neuronal damage in the ischemic spinal cord. Increased extracellular concentrations of asparagine and valine may reflect preferential use of amino acids for energy metabolism under ischemic conditions. The significance of increased levels of inhibitory amino acid neurotransmitters is unclear and is the subject of a future study.

VISUALIZATION OF GUANYLATE CYCLASE IN CULTURED CNS NEURONS. Jonathan Chen. Bing Chang*, Michael Heller*, and Ferid Murad*. Abbott Laboratories, Pharmaceutical Product Division, Abbott Park, IL 60.064

The relevance between glutamate neurotoxicity and cGMP accumulation is fundamental to the understanding of many neurological disorders. Glutamate induced neuron death may be attributed to cGMP increases intracellularly. Therefore, guanylate cyclase (GC), the enzyme that catalyzes cGMP formation through EDRF/NO may be essential for the process of neuronal degeneration.

In order to test this hypothesis, rat embryonic CNS neurons were cultured. Fluorescent immunocytochemical studies showed that soluble GC specific monoclonal antibodies react quantitatively with cell bodies and dendritic - axonal processes. Results also showed sodium nitroprusside stimulated cGMP accumulation, indicating that the cultured CNS neurons express functional soluble GC activity *in vitro*.

In summary, we have found cultured CNS neurons a plausible model for cyclic GMP and guanylate cyclase studies. Whether EDRF/NO affects the process of neuronal degeneration is the central interest for our future studies.

OUABAIN INCREASES EXTRACELLULAR GLUTAMATE AND ASPARTATE IN HIPPOCAMPAL SLICES. J. E. Madl. Dept. of Anatomy and Neurobiology, Colorado State University, Ft. Collins, CO 80523

Ouabain and other cardiac glycosides can produce signs of CNS toxicity when given in high doses. Ouabain is an inhibitor of the Na/K ATPase and has been reported to release several types of neurotransmitters, including GABA. Extracellular accumulations of glutamate (Glu) and aspartate (Asp) have been implicated in many types of CNS disease and dysfunction. The possibility that ouabain might cause extracellular accumulations of Glu and Asp was therefore examined in hippocampal slices.

Transverse, 400µm sections of hippocampus were obtained from adult rats and washed 3 times, 15 min per wash, in Hank's balanced salt solution with an additional 10mM glucose and 10 mM HEPES (HBSS, pH 7.3) to remove amino acids released by cutting the slice. Slices were incubated for various periods of time in 4 ml of the same HBSS in a humidified incubator under 5% CO₂. The concentrations of Glu and Asp in the supernatants of slices incubated with 100 µM ouabain were increased more than 10-fold over the supernatant of control slices. In contrast, supernatant concentrations of the asparagine increased only 2-3 fold.

These results suggest that ouabain may cause a selective extracellular rise of Glu and Asp. This extracellular rise may be due in part to decreased Na-dependent uptake of Glu and Asp by glia from decreases in the Na-gradient of the plasma membrane. The extracellular rise of Glu and Asp may contribute to the CNS signs of toxicity seen with cardiac glycosides.

89.18

SELECTIVE NEURON DAMAGE IN THE RAT SPINAL CORD INDUCED BY ACROMELIC ACID. S. Kwak¹, H. Aizawa¹, M. Ishida² and H. Shinozaki².

National Institute of Neuroscience, Tokyo 187, ²The Tokyo Metropolitan Institute of Medical Science, Tokyo 113, Japan. A single systemic injection of acromelic acid, a novel kainate

A single systemic injection of acromelic acid, a novel kainate analogue, caused long-lasting spastic paraparesis in the rat. Two rats developed paraparesis were neuropathologically examined one week and three months after the injection, respectively. Numerous chromatolytic neurons with marked reactive gliosis were scattered in the gray matter of the spinal cord of the rat paralytic for one week. Degenerated neurons were most abundant at lumbar and sacral segments but scanty in laminae I, II and IX of Rexed. The cytometry on the 1st sacral segment disclosed that the number of small size neurons was significantly decreased in both rats. The rest of the central nervous system was intact except for the slight increase of gliosis in CAA of the hippocampus. Above findings indicate that acromelate selectively destroyed interneurons in the caudal spinal cord presumably through excitotoxic mechanism, which induced spastic paraparesis in the rat. These behavioral and neuropathological changes in the rat induced by acromelic acid are quite different from those by kainic acid and suggest that acromelic acid may act on a different glutamate receptor subtype from the kainate receptor in the rat central nervous system when injected systemically.

AN IN VIVO MODEL OF NMDA EXCITOTOXICITY IN RATS: SUPRASPINAL VERSUS SPINAL SITES OF ACTION. L. Robles, E. Echevarria, J. E. Moreton, J. B. Long and F. C. Tortella, Neuropharmacology Br., Div. of Neuropsychiatry, Walter Reed Army Institute of Research, Washington, DC 20307-5100.

We recently described an in vivo EEG and behavioral model of NMDA excitotoxicity in rats (Robles et al., FASEB J. 4: 1990)

NMDA excitotoxicity in rats (Robles et al., FASEB J. 4: 1990) where i.v. NMDA (100 mg/kg) produced a continuum of responses marked by 1) initial non-convulsive (NC) spike-wave EEG complexes followed by 2) episodes of vigorous behavioral "running fits" (RFs) immediately preceding 3) full clonic "popcorn" (PC) convulsions and 4) culminating in tonic forelimb extension and death. However, it was observed that the EEG associated with the PC convulsions was not always reflective of ictal activity prompting appropriate propagation of postion prompting speculation that supraspinal and spinal sites of action may be involved. This issue was studied by treating rats, under identical experimental conditions, with i.c.v. (12.5 nmol; n=5) or i.t. (25 nmol; n=9) administered NMDA. The immediate response to i.c.v. NMDA was PC convulsions associated with highamplitude EEG slow-waves and intermittent spikes followed by multiple episodes of NC EEG seizures. At higher doses rostrallydirected scratching and brief RFs emerged several minutes postinjection. In contrast, the excitotoxic profile for i.t. NMDA was temporally reversed: i.e. immediate (albiet moderate) RF was temporally reversed; i.e. immediate (albiet moderate) Rf activity with ataxia followed by jacknife posturing of the body, caudally directed preening, and vocalization. Although EEG spike-wave NC seizures occurred several minutes postinjection, PC convulsions were not observed after i.t. NMDA.

KAINATE NEUROTOXICITY IN AGED RATS: A MODEL FOR TUDYING DOMOATE DEMENTIA IN AGED HUMANS. D.F. Wozniak, G.R. Stewart, B. Fry*, L. Kettinger* and J.W. Olney, Washington University, St. Louis, MO 63110.

Domoate (Dom) is a kainic acid (KA) analog recently implicated in a

human seafood poisoning incident in Canada which resulted in convulsions and death or longterm neuropsychological deficits (profound memory loss) in some victims, with elderly individuals being the most severely affected (I. Teitlebaum, in I. Hynie & E. Todd, Eds, Proc. Symp. on Domoate toxicity, in press, 1990). Dom expresses neurotoxic (excitotoxic) activity in vitro by an action at the KA subtype of glutamate receptor and, when administered to adult rats, Dom mimics KA in causing status epilepticus and a severe seizure-related brain damage causing status epilepticus and a severe seizure-related brain damage syndrome (See Stewart et al., Soc. Neurosci, Abst., 1990). Because Dom is prohibitively expensive, we explored the feasibility of using KA to study the age dependency of Dom neurotoxicity. Young (6 mos), middle age (12 mos) and old (24 mos) rats (n = 30, 23, 24 respectively) were compared for sensitivity to the KA neurotoxic syndrome. Doses of KA (mg/kg sc) that induced the syndrome in 50% of young, middle age and old rats (ED₅₀ and 95% confidence levels) were 9.04 (7.61-10.99), 3.87 (2.36-5.56), 2.06 (1.02-3.31) respectively. Thus, sensitivity increased markedly in the 6 to 12 mos interval and continued to increase, but at a slower pace, between 12 and 24 mos. Whether the age-related sensitivity to KA neurotoxicity is mediated by a CNS or peripheral but a slower pace, overwell 12 and 24 lines. Which the age-leated sensitivity to KA neurotoxicity is mediated by a CNS or peripheral mechanism warrants further study. Resolving this question in KA-treated rats may help clarify the extreme sensitivity of aged humans to Dom neurotoxicity. Supported by MH14677 (DFW), AG05681 & MH38894 (JWO).

SYNERGISM BETWEEN EXCITATORY AMINOACIDS IN CANADIAN TOXIC SYNERGISM BETWEEN EXCITATIONY AMINOACIDS IN CANADIAN TOAIC MUSSELS. A. Novelli, J. Kispert*, S. Gascón*, M. Baraldi and V. Zitko*. Dept. Biochem., Sch. of Med. 33006 Oviedo, Spain; Lab. of Bioph., I.S.A.S., 34014 Trieste, Italy; Lab. Mol. Biol., NINDS, Bethesda, MD 20892, USA; Lab. of Pharmac., Sch. of Pharm., 41100 Modena, Italy; Marine Chem. Div., Biol. Station, St. Andrews, N.B. E0G2X0, Canada.

During the period November-December 1987, more than 100 Canadians suffered intoxication after eating cultured mussels. For many of them, symptoms included disorientation, confusion and memory loss, long-lasting at times. The mussels were found to contain high amounts of domoic acid (DA), a rare excitatory amino acid, agonist at the NON-NMDA type of excitatory aminoacid receptors. We used rat cerebellar neurons in primary culture (10-30 days in vitro) as an experimental system where to characterize the neurotoxicological properties of a "toxic mussels" extract (TE). Neurotoxic effects of TE, DA on cerebellar neurons in primary culture (very compared following 24 hrs exposure in the growth medium. Purified DA was less neurotoxic (Tox₅₀~7,4µM) than comparable concentrations of DA within the TE (Tox₅₀~1μM DA). Quisqualic acid (QA=100μM) selectively antagonized DA neurotoxicity. However, full protection from TE neurotoxicity was achieved only by simultaneous addition of QA + APV(ImM) or QA + Mk-801(IµM), indicating the presence of NMDA receptor agonists. A "normal mussels" extract (NE) was than tested for neurotoxic effects. NE induced a dilution-dependent neurotoxicity which was fully antagonized by APV or MK-801. Similarly, glutamic acid (GA) neurotoxicity (Tox₅₀~13µM) was antagonized by APV or by MK-801. Both TE and NE resulted to contain similar amounts (in μ mol/gr fw) of aspartic acid (AA) and GA . Neurotoxicity by NE occurred at higher concentrations (Tox50~20 μ M AA+GA) than neurotoxicity by TE (Tox50~8µM AA+GA). On the other hand, 50% neurotoxicity was produced by TE with an internal concentration of DA~1μM, lower than the concentration required The with an internal concentration of DA-1μM, lower than the concentration required by purified DA (~7.4 μM). A synergism factor (SF) between excitatory aminoacids equal to ~3.3 was calculated. We suggest that SF may have been responsible for the neurological problems reported in humans who ingested "toxic mussels".

AGE- AND DOSE-RELATED EFFECTS OF INTRAHIPPOCAMPAI IBOTENIC ACID ON NEURAL DEGENERATION AND MEMORY-BASED LEARNING IN THE INFANT RAT. N.J. Lobaugh, D.S. Norton*, & Amsel. Dept. of Psychology and Inst. for Neuroscience, University of Texas at Austin, 78712.

Ibotenic acid (IBO) is an effective neurotoxin in the dorsal hippocampus in 5 and 7-day-old (DO) rat pups (Cook & Crutcher, hippocampus in 5 and 7-day-old (DO) rat pups (Cook & Crutcher, Neurosci. 18:79, 1986; Steiner, et al., <u>Brain Research</u>, 307:117, 1984). In the present study, four unilateral injections of IBO were made through the extent of the hippocampus in either 11 or 15 DO rat pups, using 1 or 5 µg/µl (in 1 or .5 µl) with 3 or 7 days survival. The hippocampus was more susceptible to IBO at 11 than at 15 days: 1µg resulted in an absence of pyramidal— and granule—cell layers, while 5µg produced complete destruction of the hippocampus at the injection sites. At 15 days, $1\mu g$ produced minimal damage that was restricted to injection sites, and $5\mu g$ produced damage similar to that seen in the 11-DO hippocampus after 1µg. Fink-Heimer degeneration was not seen in 11-DO pups, or in 15-DO pups that received 1µg injections. In 15-DO pups that received 5µg/µi injections, 62% showed degeneration in the medial corticohabenular tract, with no apparent cell loss in the habenula or in septum.

We assessed the behavioral effects of this lesion following bilateral injections of IBO using a discrimination task that requires intact short-term memory of the previous trial, and found only small effects of the lesion at the $1\mu g$ dose: Pups injected at 15 days and allowed to survive 7 days showed a reduction in the magnitude of the discrimination compared to saline controls. This grant was supported by NSF Grant BNS 8609877.

COMPETITIVE AND NON-COMPETITIVE ANTAGONISTS ON DOMOIC ACID TOXICITY IN MICE. Strain and R.A.R. Tasker. Dept. of Physiology, Atlantic Veterinary College, Dept. of Anatomy P.E.I., Charlottetown, P.E.I., Canada, C1A 4P3

In December of 1987, a number of individuals suffered seizures and memory loss following the consumption of contaminated mussels. The toxin responsible was identified as domoic acid (DOM), an excitatory amino acid (EAA) similar to kainic acid. The present study was designed to investigate the effects of both competitive and non-competitive EAA antagonists on i.p. DOM with an ED50 (100 ug) of DOM and were scored for toxicity behaviors for 60 minutes. Antagonists (or saline) were injected 15 minutes before DOM. Antagonists tested were DNQX (50 & 100 mg/kg), MK801 (0.1 & 0.3 mg/kg), kynurenic acid (200 & 400 mg/kg), GDEE (50 & 75 mg/kg), and dextrorphan (20 & 40 mg/kg). DNOX, MK801, kynurenic acid and GDEE produced no significant change in behavioral toxicity scores when compared to either vehicle control or antagonist control values. Dextrorphan (20 mg/kg), however, produced a 50% reduction in the time spent in seizure activity and significantly decreased the overall toxicity score (p<0.01). We are currently investigating the pharmacological and histopathological effects of dextrorphan on DOM toxicity in greater detail.

90.6

BEHAVIORAL INDEX OF A "WINDOW OF VULNERABILITY" TO PERINATAL MONOSODIUM GLUTAMATE. K. Fisher*, R. Turner*, J. Kleim*, G. Pineault*, and M. J. Saari, Neuroscience Research Unit, Nipissing University College, North Bay, Ontario. PlB 817.

Perinatal monosodium glutamate (MSG) administration to rats causes significant organ system dysfunction, developmental anomalies and behavioral deficits. Injections administered after day 10 post partum do not appear to lead to similar damage. In this experiment we demonstrate that rat pups are maximally influenced by MSG when the amino acid is administered before 6 days of age. Male and female Wistar rat pups were cross fostered and injected with MSG (4g/kg; 20% aqueous solution; s.c.) or saline vehicle on days 2, 3, 5, 7 and 9 post partum. The surface righting reflex was tested twice daily from day 3 to day 9. The results support the interpretation that rat pups are particularly sensitive to MSG during the first 5 days post partum and that this sensitivity is reduced by day 7 to control levels. It is likely that the long lasting neurotoxic effects of MSG administration in rats is due to a specific vulnerability present in the early post natal period.

EXTREME SENSITIVITY OF INFANT ANIMALS TO GLUTAMATE TOXICITY: ROLE OF NMDA RECEPTORS. G.J. Wang, J. Labruyere*, M.T. Price, J.W. Olney. Washington University, St. Louis, MO 63110.

Infant animals are much more sensitive than adults to hypothalamic damage following oral or subcutaneous administration of glutamate (Glu). That this can be attributed to "weakness" of blood brain barriers during infancy is a common misconception; the arcuate hypothalamic (AH) nucleus, like other circumventricular organs, has <u>no</u> blood brain barrier protection either in adulthood or infancy. In theory, Glu excitotoxicity can be expressed through either N-methyl-D-aspartate (NMDA), kainic acid (KA) or quisqualic acid (Quis) receptors. However, in view of evidence that NMDA receptors are hypersensitive and non-NMDA receptors hyposensitive to excitotoxic stimulation during development, Glu neurotoxicity in the immature CNS may be expressed predominantly through NMDA receptors. Supporting this view is evidence that, in the infant rat, NMDA antagonists provide excellent protection against hypoxic/ischemic brain damage (thought to be mediated by endogenous Glu). Here we show that NMDA receptor antagonists, when co-administered systemically with Glu to immature rats, are highly effective in preventing Glu from destroying AH neurons. This suggests that Glu neurotoxicity in the immature AH is mediated primarily by NMDA receptors; thus, the tendency of immature NMDA receptors to be hypersensitive to excitotoxic stimulation may help explain the extreme sensitivity of immature AH neurons to Glu-induced damage. Supported by HD24237, DA05072 & RSA MH38894 (JWO).

FOCAL INJECTIONS OF EXCITOTOXINS I LEVATE METENKEPHALIN LEVELS IN THE RAT STRIATUM AND GLOBUS PALLIDUS. B.B. Ruzicka and K. Jhamandas. Department of Pharmacology and Toxicology, Queen's University, Kingston, Ontario, Canada, K7L 3N6. To develop a model of the striatopallidal enkephalin efficit associated with Huntington's disease, we examined the sensitivity of the enkephalinergic neurons to four excitatory amino acids (EAA's) - N-methyl-D-aspartate (NMDA, 50-150 nmol), quisqualate (QUIS, 26-106 nmol), kainate (KA, 0.5-7 nmol) and quinolinate (QUIN, 18-288 nmol) - following single injections into the right striatum of the rat. Levels of met-enkephalin-like immunoreactivity (ME-i.r.) in the striatum and globus pallidus were estimated by RIA seven days post injection. Each of the four EAA's produced doserelated and bilateral elevations in ME-i.r. in both the striatum and globus pallidus. The rank order of apparent efficacy of the EAA's, based on the pallidus. The rank order of apparent efficacy of the EAA's, based on the magnitude of the maximal effect, was QUIN = KA > NMDA = QUIS. magnitude of the maximal effect, was QUIN = KA > NMDA = QUIS. The rank order of apparent potency, based on the doses producing a maximal effect, was KA > QUIS > QUIN > NMDA. QUIN (72 nmol)-induced increases in pallidal ME-i.r. were attenuated by the EAA receptor antagonists, kynurenate (KYN, 36 nmol) and CPP (1.8 nmol). KYN (52 nmol), but not CNOX (1.4-5.3 nmol), also reduced the QUIS (53 nmol)-induced elevations in pallidal ME-i.r. Injections of CPP (1.8-3.6 nmol) into the striatum contralateral to the QUIN (72 nmol) infusion did not block the QUIN-induced response in the contralateral hemisphere, but it did decrease this response in the insulateral collidary suggesting that contralateral challed in the contralateral collidary suggesting that contralateral challed in the contralateral ch the ipsilateral pallidum, suggesting that contralateral changes in ME-i.r. did not involve the mobilization of an endogenous EAA. These results show that activation of EAA receptors increases ME-i.r. in the striatum and globus pallidus at seven days following exposure to EAA's, a finding possibly unique to enkephalinergic neurons. 90.11

NMDA EVOKES THE RELEASE OF SOMATOSTATIN FROM STRIATAL NEURONS IN PRIMARY CULTURE. J.S. Williams, I. Berbekar* and S. Weiss. Neuroscience Research Group, University of Calgary, Calgary, AB, Canada T2N 4N1.

It has been suggested that the resistance of specific neuronal phenotypes, e.g. striatal somatostatinergic neurons, to NMDAinduced neurotoxicity may be due to a paucity of this subtype of excitatory amino acid (EAA) receptor on these neurons. A highly sensitive radioimmunoassay was used to examine the actions of EAAs on the release of endogenous somatostatin-like immunoreactivity (SLI) from mouse striatal neurons in primary culture. Indirect immunocytochemistry of these neuronal cultures suggested that 2-4% of the neurons contained SLI. During a 15 min incubation period, 47±10 fmoles of SLI were released from 14 days in vitro striatal neurons, cultured in 35mm dishes. In the presence of 100μM NMDA, an additional 112±21 fmoles of SLI were released (+238%); the NMDA-evoked release was dose-dependent (EC_{so}, 20µM), attenuated in the absence of added Ca²⁺, potentiated in the absence of added Mg* and unaffected by the presence of $1\mu M$ TTX. The selective antagonists APV (100 μM) and MK-801 (1μM) blocked the NMDA-evoked release of SLI. Kainate was equieffective yet 5-fold less potent (EC_{so}, 100µM) than NMDA in evoking SLI release; quisqualate was marginally effective. The results of this study suggest that NMDA and KA receptors are present on striatal somatostatinergic neurons in primary culture.

ONTOGENETIC DEPLETION OF SOMATOSTATIN AND NEUROPEPTIDE Y IN THE RAT STRIATUM. M.A. Musgrave*, R.J. Boegman, J.V. Milligan. Dept. of Pharmacology and Toxicology, Queen's University, Kingston, Ontario, Canada, K7L 3N6.

Somatostatin (SS) and neuropeptide Y (NPY) are two neuropeptides implicated in several neurodegenerative disorders including Alzheimer's and Huntington's diseases. The actual role played by these peptides in disease states is as yet undetermined. The consequences of neuropeptide depletion in terms of neuromodulatory and behavioral effects are not well investigated. With this in mind, the focus of the present study was to excitotoxically deplete SS and NPY in a discrete brain area to develop a possible working model for further investigations of neuropeptide influence. The area chosen for nvestigation was the striatum due to the colocalization of both peptides with investigation was the striatum due to the concanzation of both peptides with the enzyme NADPH-diaphorase. Rat pups were lesioned with N-methyl-D aspartate (NMDA) at either of two points in post natal development (PND 23 or PND 30). Lesions were accomplished using volumetric doses $(0, 0.5, 1, 2, \text{ or } 3 \mu\text{I})$ of NMDA at one of two concentrations $(50 \text{ nm}/\mu\text{I})$ or $25 \text{ nm}/\mu\text{I})$. At both PND ages, a double histochemical staining technique for NADPH-diaphorase and Acetylcholinesterase (AChE)-positive neurons revealed an approximate 75% depletion of NADPH-diaphorase positive staining, compared to the contralateral side, with either 2 or 3 μ l of NMDA (25 nm/ μ l). At both volumes AChE-positive staining was found to be unchanged compared to the contralateral side. The neuromodulatory and behavioral consequences of such depletions are currently being investigated. (Supported by the Medical Research Council of Canada)

QUINOLINIC ACID-INDUCED BRAIN DAMAGE PREVENTED BY N-METHYL-D-ASPARTATE ANTAGONISTS. C.M. WRAY* AND R.J. BOEGMAN. DEPT. PHARMACOLOGY AND TOXICOLOGY, QUEEN'S UNIVERSITY, KINGSTON, ONTARIO, CANADA, K7L 3N6.

The ability of two selective N-methyl-D-aspartate (NMDA) receptor antagonists The ability of two selective N-methyl-D-aspartate (NMDA) receptor antagonists to protect against the neurotoxicity induced by the endogenous tryptophan metabolite quinolinic acid (Quin) was evaluated in the rat striatum. MK-801 {(+)-S-methyl-10.11-dihydro-5H-dibenzo(a,d)cycloheptene-5,10,-imine maleate} partially antagonized the toxic effects of QUIN on striatal acetylcholinesterase (AChE) and NADPH-diaphorase neurons, increasing cell survival to 66% and 47% respectively when administered 1 hour after an infusion of Quin. In contrast, a intransport does of CPB (4/2 absorbhoracent) 2 integration activation of the production of the prod 47% respectively when administered 1 nour after an intusion of Quin. In contrast, an intravenous dose of CPP {4-(3-phosphonopropyl)-2-piperazine-carboxylic acid} partially protected only AChE-containing neurons against a lower dose of QUIN. However, when co-injected with Quin, CPP fully protected NADPH-d neurons. Our results indicate that striatal neurons containing NADPH-d or AChE show a differential response to Quin-induced neurotoxicity and that some can be rescued from neurotoxin-induced cell death even after pre-exposure to the neurotoxin alone for up to four hours. Supported by the Medical Research Council of Canada and the Huntington's Society of Canada.

HALOPERIDOL ATTENUATES QUINOLINATE TOXICTY IN THE STRIATUM M.F. Mazurek and S. Garside. McMaster University Medical Centre, Hamilton, ONT, L8N 3Z5 Canada.
Excitotoxicty mediated by the NMDA receptor has been

implicated in neuronal damage associated with such disorders as stroke, epilepsy and Huntington's disease. We have investigated the ability of the dopamine D-2 receptor antagonist haloperidol to modify NMDA-mediated toxicity in the striatum. The specific NMDA agonist QUIN was injected into the right striatum of rats pretreated with one of: (1) saline (controls); (2) haloperidol 0.2 mg/kg (LOW HAL); (3) haloperidol 2.0 mg/kg (HIGH HAL); (4) 6-OH DA lesion of the nigrostriatal tract. Animals were sacrificed by decapitation 7 days later. Brains were sliced in the coronal plane and photographed. Lesion size was estimated using two measures: ranking of lesion size from photographs by blinded observers; and quantitation of lesion size using the Bioquant II programme. of the lesion was significantly attenuated by both measures in the HIGH HAL and the 6-OH DA groups. LOW HAL animals had lesions comparable to those of controls.

These results suggest that dopamine D-2 receptor activation is important for the expression of excitotoxicity in the striatum. Haloperidol might help prevent neuronal damage in stroke and Huntington's disease.

KAINIC ACID TOXICITY IN STRIATUM IS PARTIALLY BLOCKED BY ANTICONVULSANT MEDICATION. S.Garside and M.F. Mazurek McMaster University Medical Centre, Hamilton, ONT, L8N 3Z5, Canada.

Intrastriatal injections of Kainic acid (KA) produce lesions not only of the striatum but also of many extrastriatal brain regions. It is believed that these 'distant' lesions represent epileptic-induced brain damage rather than direct KA-receptor-mediated toxicity. We investigated the possibility that a portion of the striatal damage from intrastriatal KA injections might also result from epileptic activity. KA 10 nmols was injected into the right striatum of rats pretreated with one of: (1) saline (controls); (2) dilantin 50 mg/kg (DIL) (3) phenobarbital 5 mg/kg (PB). Animal were sacrificed 7 days later. Brains were sliced in the coronal plane and the magnitude of the lesion was assessed by morphological and biochemical criteria. The size of the lesion (as assessed by the Bioquant II programme) was significantly attenuated by 35% in DIL animals and by 28% in the PB group. Somatostatin immunoreactivity was reduced by only 17% in DIL and 8% in PB striatum vs. 60% depletion in controls. Substance P immunoreactivity was reduced by 60% in DIL and 53% in PB vs. 83% in controls.

At least part of the striatal damage produced by intrastriatal injection of KA may be due to indirect or 'distant' effects similar to those operative at extrastriatal sites.

DISAPPEARANCE OF BEHAVIOURAL HYPERACTIVITY IN RATS WITH KAINIC ACID-INDUCED STRIATAL LESIONS. J.C.S. Furtado and M.F. Mazurek, McMaster University Medical Centre, Hamilton, ON, L8N 325, CANADA.

Rats with kainic acid (KA) lesions of the striatum are known to demonstrate nocturnal hyperactivity. We have used Digiscan Animal Activity Monitors to study the time course of behavioural changes in rats with KA- or quinolinic acid-(QUIN) induced striatal lesions. Rats received 1) saline (CONT), 2) 10 nmol KA or 3)240 nmol QUIN injected stereotaxically into the right striatum. For a period of 10 weeks post-surgery, KA-lesioned animals demonstrated a profile of nocturnal hyperactivity, when compared to the CONT group, on most behavioural parameters, including total distance travelled, rest time, number of movements and movement time. By contrast, the QUIN-lesioned animals were not hyperactive in relation to controls. By 16 weeks post-surgery, and thereafter, neither the KA- nor the QUIN-lesioned animals were

distinguishable from controls.

These results suggest that the hyperactivity induced by KA striatal lesions may disappear over time. attenuation of hyperactivity may have important consequences for the interpretation of behavioural changes in animal models of Huntington's Disease.

ACRTYLCHOLINE I

CHOLINERGIC PROPERTIES OF A MURINE SEPTAL CELL LINE, SN56.B5.G4. J.K. Blusztain and A. Venturini*. Dept. of Pathology, Boston Univ. Sch. of Med., Boston, MA 02118.

We investigated the processes of acetylcholine (ACh) synthesis and release in the SN56.B5.G4 cell line derived from the fusion of neurons of

the mouse postnatal day 21 septum and the murine neuroblastoma cells, N18TG2 (Hammond D.N., et al., Science, 234: 1237, 1986). The cells expressed choline acetyltransferase activity and, when incubated with [14C]choline, accumulated [14C]ACh. This [14C]ACh was synthesized from choline taken up by a high-affinity transport (apparent K_m =4.6±0.7 μM) which required Na+. (Substitution of Li+ for Na+ in the medium inhibited the [14C]ACh accumulation by 70%.) The spontaneous and evoked release of [14C]ACh from the cells (measured at 5 mM and 40 mM extracellular K⁺, respectively) was small and variable. In order to investigate whether ACh release could be enhanced by cellular differentiation, the cells were incubated for two days with 1 mM dibutyryl cAMP. This treatment resulted in neurite extension but had no effect on [14C]ACh accumulation. However, the dibutyryl cAMP-treated cells were capable of both spontaneous and evoked ACh release (7% and 17% were capable of both spontaneous and evoked ACI release (7% and 17% of their content, respectively, over a 30 min period). These data demonstrate that the SN56.B5.G4 cells exhibit a number of features of the cholinergic phenotype and may be useful as models of septal cholinergic neurons in long term culture.

MOLECULAR ANALYSIS OF THE CHOLINE ACETYLTRANSFERASE STRUCTURAL GENE FROM THE NEMATODE C. ELEGANS. A. Alfonso-Pizarro*, K. Grundahl* and J. B. Rand. Program in Molecular and Cell Biology, Oklahoma Medical Research Foundation, Oklahoma City, OK 73104.

We have cloned and begun to analyze the cha-1 gene complex from the soil nematode Caenorhabditis elegans. cha-1 is the structural gene for choline acetyltransferase (ChAT), the enzyme which synthesizes acetylcholine, and we wish to investigate its spatial and temporal control during neural development. In addition, genetic evidence suggests that the ChAT protein in <u>C. elegans</u> may consist of multiple structural and functional domains, and we are The used the transposable element Tcl to "tag" and clone part of the https://doi.org/10.108/j.com/clones spanning most of the region. The genomic clones were used to isolate cDNAs and to analyze <a href="https://doi.org/10.108/j.com/cnas/ pig and Drosophila ChAT amino acid sequences. Using the cDNAs as probes on Northern blots, we have identified a low-abundance mRNA of approximately 2 kb. In addition, we have identified and mapped insertions and deletions associated with 10 independent mutations in the cha-1 complex.

CIS-REGULATORY ELEMENTS OF THE DROSOPHILA CHOLINE ACETYLTRANSFERASE GENE. T. Kitamoto*, K. Ikeda and P.M. Salvaterra. Beckman Research Institute of the City of Hope, Duarte, CA 91010

Biochemical and immunocytochemical studies have shown that the expression of Drosophila choline acetyltransferase (ChAT) is subject to exquisite temporal and spatial regulation. Although our previous studies have indicated the importance of translational regulation of ChAT mRNA, the main regulation of ChAT expression is expected to be accomplished at the transcriptional level. As a first step toward understanding the molecular mechanism of transcriptional control of ChAT expression, we have analyzed the cis-regulatory elements of the ChAT gene by P-element mediated germ line transformation.

Fusion of a 7.4kb 5'-flanking sequence to E.coli lacZ gene directed expression of B-galactosidase in the optic lobe and the antenna of transformed flies with a pattern which corresponded closely to the distribution of endogenous ChAT protein. Furthermore, the fusion of this 7.4kb sequence to ChAT cDNA resulted in the rescue of the lethality of Cha^{tt-1}, a temperature sensitive ChAT allele. 5'-deletions of the 7.4kb fragment to 3.3kb or 1.2kb in the lacZ fusion genes led to a more restricted pattern of B-galactosidase expression in specific regions of the optic lobe. These results indicate that different subsets of cholinergic neurons may show different transcriptional regulation of the ChAT gene. (supported by NIH-NINCDS)

CHARACTERIZATION OF RAT FIBROBLASTS GENETICALLY MODIFIED TO EXPRESS DROSOPHILA CHOLINE ACETYLTRANSFERASE (dChAT). M. SCHINSTINE¹, C. WARD³, M.B. ${\color{red}{ROSENBERG}}^2$, T. ${\color{red}{FRIEDMANN}}^{2*}$, R.L. ${\color{red}{WHITING}}^3$, AND F.H. ${\color{red}{GAGE}}^1$. DEPT. OF NEUROSCIENCES1 AND PEDIATRICS2, UNIV. OF CALIF.-SAN DIEGO, LA JOLLA, CA 92093 and SYNTEX RESEARCH3, PALO ALTO, CA 94304.

Choline acetyltransferase catalyses the formation of acetylcholine (Ach) from choline and acetyl-CoA. In the present experiments, the genes encoding for Drosophila choline acetyltransferase (generously donated by Dr. P.M. Salvaterra) and neomycin resistance were introduced into fibroblasts using retroviral vectors derived from Moloney murine leukemia virus. This study reports on the characterization of dChAT expressed by G418-resistant rat fibroblasts. Most studies were conducted on the fibroblast cell line Rat1.

The success of dChAT infection was confirmed immunocytochemically, biochemically, and by Northern blot analysis. The level of dChAT enzyme expressed both including and yloridate not aniasys. The level of clint a legisle expression by infected Rat1 fibroblasts (Rat1/ChAT) was measured using a modification of the Fonnum assay. This procedure revealed an enzyme activity of ~300 nmoles Ach/hr/mg protein. No activity was detectable in uninfected cells. The presence of dChAT within Rat1/ChAT cells was accompanied by a constitutive secretion of Ach. The level of extracellular Ach, measured by HPLC with electrochemical detection, was The level of extracellular Ach, measured by HPLC with electrochemical detection, was ~30 uM/20 hr/25 cm² flask. Comparatively, intracellular levels of Ach were 0.99 uM. There were no detectable levels of Ach, either secreted or intracellularly, in cultures of uninfected fibroblasts. Secretion of Ach in Ratl/ChAT cells was modulated by extracellular choline in a dose-responsive manner. Levels of secreted Ach were ~128% greater, as compared to controls, when 0.5 mM choline (the highest concentration used) was added to the culture medium. Choline had no effect on uninfected Ratl cells. Additional studies using other compounds to control Ach secretion are currently in progress. Moreover, we will report on the transplantation of primary fibroblasts, genetically modified to secrete Ach, into the brain.

TWO SPECIES OF HUMAN CHOLINE ACETYLTRANSFERASE mRNA WITH DIFFERENT PROTEIN CODING DOMAINS. W.L. Strauss, R. Zhang and M.V. Lorenzi. Dept. of Pharmacology, Univ. of Miami Sch. of Med., Miami, FL 33101

The existence of multiple forms of the enzyme choline acetyltransferase (ChAT) has been reported by a number of laboratories. In order to determine whether ChAT protein isoforms might be translated from different mRNAs, restriction fragments isolated from a clone of the human ChAT gene were hybridized to Northern blots of RNA isolated from CHP134 human neuroblastoma cells and adult human nucleus basalis. One of these probes, pChAT1.2, contains an exon with 86% and 73% identity to the regions of porcine and rat ChAT mRNA which code for the amino termini of the corresponding proteins. pChAT1.2 detects two transcripts in RNA isolated from CHP134 cells and human nucleus basalis. Both the 6000 and 2300 nt mRNAs detected with pChAT1.2 are large enough to code for a protein with the reported size of human ChAT. A second restriction fragment, pChAT5, contains an exon with 96% identity to porcine ChAT mRNA and 94% identity to rat ChAT mRNA. The region of identity between these sequences corresponds to amino acids 203-263 of the predicted rat and porcine ChAT proteins. In contrast actus 203-203 of the predicted rat and porcine ChAT proteins. In contrast to pChAT1.2, a probe prepared from pChAT5 detects the 2300 nt form of ChAT mRNA, but not the 6000 nt form, in both CHP134 cells and human nucleus basalis. The ability to distinguish between the two species of human ChAT mRNA using a probe that contains a protein-coding exon suggests that each mRNA encodes an isoform of ChAT with a unique amino acid sequence. It is not clear how the corresponding translation products are related to previously identified ChAT isoforms.

SPECIFIC IMMUNOPRECIPITATION OF CHOLINE O-ACETYLTRANSFERASE FROM RAT HIPPOCAMPAL NERVE TERMINALS REVEALS AN ENDOGENOUS

FORM OF PHOSPHORYLATED ENZYME. B.M. Schmidt and R.J.Rylett.
Dept. Physiology, Univ.Western Ontario, London. N6A 5C1
The enzyme choline O-acetyltransferase [ChAT; EC 2.3.1.6]
catalyses the formation of acetylcholine in cholinergic nerve terminals. Little is known about the regulation of nerve terminals. Little is known about the regulation of this enzyme although interest has recently increased due to its apparent association with neuropathological conditions such as Alzheimer's disease. Subcellular fractionation of synaptosomes prepared from hippocampus of rat brain was used to isolate cytosolic (cChAT) and membrane-associated (mChAT) pools of the enzyme. Selective activation of mChAT followed depolarization of the nerve terminals by both 40mM potassium (124+3% control) and 50uM veratridine (124+5% control), similar to findings by Carroll (1986). In order to test the hypothesis that this enhanced activity involves phosphorylation of the protein, a common regulatory process phosphorylation of the protein, a common regulatory process in the central nervous system, we have developed a method to isolate each enzyme pool from a crude synaptosomal to isolate each enzyme pool from a crude synaptosomal preparation using immunoprecipitation. Rat hippocampal synaptosomes were incubated with [\$^32\$]-inorganic phosphate to label ATP pools and achieve protein phosphorylation, then ChAT was isolated by immunoprecipitation. SDS-PAGE and-autoradiography reveals an endogenous pool of ChAT which exists in the phosphorylated state. This is in agreement with the findings of Hersh et al. (1989) for whole rat brain. (Supported by a grant from MRC Canada).

CHARACTERISTICS OF SOLUBILIZED [3H]HEMICHOLINIUM-3 BINDING SITES PROM RAT STRIATAL TISSUE. T.K. Chatterjee and R.K. Bhatnagar,
Dept. of Pharmacology, University of Iowa, Iowa City, IA 52242
We have reported that [3H]hemicholinium-3 ([3H]HC-3) binds to

choline uptake sites and that these binding sites show ATP-dependent affinity conversion (J. Neurochem. 54: 1500, 1990). Here we show that [3H]HC-3 binding sites could be solubilized using 0.2% deoxycholate in 50 mM glycylglycine buffer pH 7.4 using 0.2% deoxycholate in 50 mM glycylglycine buffer pH 7.4 containing 200 mM NaCl and assayed in 50 mM glycylglycine buffer containing 200 mM NaCl, 0.2% BSA, 50 mM cacl2, 1 mM MgCl₂ with final detergent concentration of 0.05%. The solubilized preparation bound ['H]HC-3 with a $\rm K_D$ of 8.9 nM and a $\rm B_{max}$ of 574 fmol/mg protein. Similar to the membrane bound form, the solubilized sites showed ATP-dependent conversion to a low affinity state with a $\rm K_D$ of 23.4 nM and B_{max} of 587 fmol/mg protein. Unlike the membrane bound form, the solubilized ['H]HC-3 binding sites showed sensitivity to certain trypsin inhibitors. Parasites showed sensitivity to certain trypsin inhibitors, Para-aminobenzamidine, benzamidine and aprotonin inhibited [3H]HC-3 binding with IC-50s respectively of 200 µM, 410 µM and 0.51 trypsin inhibitor units/ml. Other trypsin inhibitors, PMSF (1 mM) and α_1 antitrypsin (lmg/ml) did not affect the binding. Taken together, these results suggest that choline transport process might involve ATP-dependent phosphorylation of choline transporter sites. The significance of sensitivity to certain trypsin inhibitors remains uncertain. Nevertheless, certain endogenous proteins having such an inhibitor domain (e.g., A4 amyloid) might well play a modulator role in choline binding and transport. Supported by DAMD contract #17-87-C-8113.

ANALYSIS OF EPITOPES ON CHOLINE ACETYLTRANSFERASE (ChAT) USING MONOCLONAL ANTIBODIES (Mabs). C. Cozzari*, I. Howard*, and B. Hartman. Istituto Biologia Cellulare CNR, Roma (Italy), and Dept. Psychiatry, Univ. of Minnesota, Minneapolis (MN).

Twelve different monoclonal antibodies against rat brain Chat (affinity constants from 107 - 10¹¹) were prepared. The immunohistochemical localization in rat brain did not differ between MAbs, but the intensity and detail was enhanced with the high affinity MAbs. The antigenic and detail was enhanced with the high affinity MAbs. The antigenic domains of ChAT and their evolutionary modifications, as indicated by cross-reactivity, were studied. The relative location of the epitopes were determined by assessing how binding of MAbs against a given epitope affected binding of MAbs against all other epitopes. The 12 MAbs were separately conjugated to Sepharose and allowed to bind ChAT. The Sepharose linked MAb-ChAT complexes were then separately incubated the complexes were the separately incubated the complexes were then separately incubated the complexes were the separately incubated the complexes were the separately incubated the complexes were the complexes were the separately incubated the complexes were the complexes were the complexes were the complexes which in the complexes were the complexes which in the complexes were the complexes which in the complexes were the complexes wh with each 125 I-labeled MAb. Comparison of results obtained with all pairs showed the existence of at least three distinct immunogenic domains. The main domain contained the epitopes that produced the three highest affinity MAbs plus several others. With two exceptions these epitopes were present on all non-primate mammals (rat, mouse, pig,beef) but not primates (monkey and human) nor non-mammals (bird, pig, oeer) out no primates (monkey and numan) nor non-mammais (pird turtle, fish). The first exception was an epitope highly conserved in all species. The second exception was an epitope on the "edge" of the main domain which was conserved in all mammals (including primates) but not non-mammals. This epitope overlapped with an epitope in the second domain with a similar cross-reactivity profile (conserved in all mammals but not in the other classes). The third domain (widely separated from the other two) contained an epitope which was conserved in all species with the interesting exception of the primates.

STRUCTURE-FUNCTION RELATIONSHIPS OF HUMAN BUTYRYLCHOLINE-STERASE (CHE) BY THE IN OVO PRODUCTION OF RECOMBINANT CHE

L.F. Neville*, A. Gnatt*, Y. Lowenstein*, R. Padan*, S. Seidman*, and H. Soreq. Dept. of Biological Chemistry, The Life Sciences Institute, Hebrew University of Jerusalem, Jerusalem 91904, Israel.

To characterize the effects of point mutations on \mathtt{CHE} function, synthetic RNAs derived from abnormal human chromosome 3 (Gnatt et. al., Cancer Res. 50:1983, 1990) and other various libraries were injected into Xenopus occytes and their CHE activities assessed. Asp70 to Gly substitution markedly reduced succinylcholine (SuCh) interaction as well as exhibiting decreased binding to CHE inhibitors. An additional Ser425 to Pro mutation rendered CHE "atypical" since SuCh and dibucaine binding was abolished. Additional CHE muteins containing single Pro425, Hisl14, or Tyr569 mutations failed to modify CHE ligand binding.

These data demonstrate that Asp70 functions in anionic site binding of CHE inhibitors but only some choline substrates since CHE muteins bound other choline substrates normally. The synergistic effect of Pro425 with Gly70 suggests that the 2 conserved domains harboring ser425 and asp70 in all cholinesterases lie adjacent with each other.

STEREO-SELECTIVITY OF THE SODIUM-DEPENDENT HIGH-AFFINITY CHOLINE UPTAKE SYSTEM. S. Ferguson, M. Diksic, and B. Collier. Dept. Pharmacology and Therapeutics, Mc Gill University, Montreal, Canada H3G 1Y6.
Choline and its analogues are limited in their use for in vivo visualization of the central cholinergic system as they act as substrate for choline phosphotransferase (CPK), the first step for phospholinid synthesis and exemptable accurate in the observations.

substrate for choline phosphotransferase (CPK), the first step for phospholipid synthesis, and eventually accumulate in the phospholipids of all cells. To attempt to circumvent this difficulty we have studied the isomeric forms of α - and β -methylcholine (MeCh), as well as a non-hydroxyl choline analogue. In rat cortical synaptosomes choline uptake (1 μ M) was selectively inhibited by the stereoisomeric analogues. (R)- α -MeCh and (S)- β -MeCh (IC₅₀ = 10 μ M and 55 μ M) were better able to block uptake than their stereoisomers (IC₅₀ 40 μ M and 180 μ M, respectively). ³H-labelled (R)- α -MeCh and (S)- β -MeCh as well as the non-hydroxyl analogue could be transported by rat synaptosomes (K, 9 μ M, 6.8 μ M, 50 μ M, respectively), while their stereoisomers could not. In addition, the stereo-analogues served as poor substrates for CPK (in vitro), only (S)- α -MeCh was well phosphorylated with respect to choline. The non-hydroxyl analogue was not phosphorylated. These results suggest that (R)- α -MeCh and the non-hydroxyl choline analogue may be useful for in vivo visualization of cholinergic neurons as they are unlikely to accumulate zation of cholinergic neurons as they are unlikely to accumulate in the phospholipids of non-cholinergic cells. Supported by AHAF (Alzheimer's program)

STIMULATION OF [3H]-HEMICHOLINIUM-3 BINDING IN CORTICAL OR HIPPOCAMPAL TISSUES AFTER TREATMENT WITH \$\text{\text{\$F\$-CARBOLINES}}\$
OR MDL 26,479.
J.A. Miller and P.A. Chmielevski*. Merrell Dow Research Institute, Cincinnati, 0H 45215.

Merrell Dow Research Institute, Cincinnati, OH 45215.

[3H]-Hemicholinium-3 ([3H]HC-3) binds to the high affinity choline uptake (HACU) site. Increased turnover of acetylcholine in cholinergic nerve terminals results in increased HACU and increased [3H]HC-3 binding. Several cognition enhancing drugs have been shown to increase HACU in cortical or hippocampal tissue and may enhance memory, in part, by this mechanism. In this study, β-carboline inverse-agonists (.1-10 mg/kg) and the triazole, MDL 26,479 (1-5 mg/kg), were administered to rats i.p., the hippocampi and cerebral cortices were removed and homogenized.

[3H]HC-3 binding was measured in membranes prepared from these tissues.

Following treatment with the β-carbolines, methyl 6,7-dimethoxy-4-ethyl- β-carboline-3-carboxylate (DMCM),

dimethoxy-4-ethyl β -carboline-3-carboxylate (DMCM), ethyl β -carboline- 3-carboxylate (β -CCE) and methyl β -carboline- 3-carboxylate (β -CCM), resulted in increased β-carboline- 3-carboxylate (β-CCM), resulted in increased [3H]HC-3 binding ex vivo in rat cortical and hippocampal membranes. Additionally, treatment with the triazole MDL 26,479 resulted in increased [3H]HC-3 binding in cortical but not hippocampal membranes. Unlike the β-carbolines, MDL 26,479 is not convulsant even at high doses. This may indicate that MDL 26,479 may prove effective in enhancing memory as has been reported for β-carbolines, but with the terrories to a supersultant series. but without serious toxicity such as seizures.

HEMICHOLINIUM MUSTARD INHIBITION OF HIGH AFFINITY CHOLINE TRANSPORT: Na⁺ DEPENDENCE AND EFFECTS ON [3H]-HEMICHOLINIUM-3 BINDING. K.H. Gylys, H.M. Vargas and D.J. Jenden. Dept. of Pharmacology and BRI, UCLA School of Medicine, Los Angeles, CA 90024.

Hemicholinium mustard (HCM), a nitrogen mustard analog of hemicholinium-3 (HC3), has been shown to be a potent irreversible inhibitor of high affinity choline transport (HAChT; Smart, 1981; Gylys et al., 1989). The present work expands our pharmacological characterization of this compound by examination of the sodium dependence of HCM effects. Rat brain synaptosomes were incubated with HCM for 10 min. in sodium-free medium. This preincubation was followed by 3 washes in fresh buffer; HAChT was then measured in a subsequent 4 min. incubation. In the absence of sodium, HCM inhibition of HAChT was reduced by 85%. This result demonstrates that HCM inhibition is sodium dependent, an important criterion for HAChT specificity. [3H]-HC3 binding techniques were then used to examine in more detail the irreversible effects of HCM. Preincubation of rat brain membranes with $1\mu M$ HCM for 10 min., followed by washing, resulted in a 70% decrease in binding capacity (B_{max}) of [3 H]-HC3. These results indicate the suitability of HCM as an affinity ligand for future studies of HAChT. (Supported by MH17691).

ACETYLCHOLINE-RECEPTORS: MUSCARINIC I

THE IDENTIFICATION OF MUSCARINIC RECEPTOR SUBTYPES IN PC12 CELLS. A. Takashima* and J. G. Kenimer, Lab. Cell Physiology, CBER, FDA, Bethesda, MD 20892

We have previously presented pharmacological and biochemical evidence that muscarinic stimulated phosphatidyl inositol(PI) hydrolysis and norepinephrine (NE) release in PC12 cells are independent events controlled by separate muscarinic receptor subtypes (Takashima and Kenimer J. Biol. Chem. 264, 10654-10659, 1989). Moreover, these distinct muscarinic stimulated events are differentially expressed during the cell cycle and during cell growth. Muscarinic-stimulated NE release is maximal in the Gl cell cycle phase whereas muscarinic-stimulated PI hydrolysis is at a minimum. In order to identify these muscarinic receptors, we utilized a method based on the polymerase chain reaction (PCR). Poly (A^+) mRNA was isolated from PC12 cells synchronized at G1 phase and was reverse transcribed with an oligo(dT) phase and was reverse transcribed with an origidaly primer. The synthesized cDNAs were amplified by PCR using a set of degenerate primers corresponding to sequences within the 3rd and 6th transmembrane region of five reported rat muscarinic receptor subtypes (ml-m5). After 35 amplification cycles, agarose gel electrophoresis revealed two distinct PCR products, one approximately 800 bp in size and the other approximately 900 bp. These cDNA fragments were ligated into the pGEM3zf(-) vector and subcloned. The partial sequence analysis of these cDNA fragments reveals high homology with the rat m1 muscarinic receptor subtype

DIFFERENTIAL EFFECTS OF SODIUM FLUORIDE OR ORTHOVANADATE TREATMENTS ON MUSCARINIC RECEPTOR-MEDIATED INOSITOL PHOSPHATE METABOLISM IN TE671/RD, SH-SY5Y AND PC12 CELLS.

M. Bencherif and R.J. Lukas. Division of Neurobiology, M. Bencherif and R.J. <u>Lukas</u>. Division of Neur Barrow Neurological Institute, Phoenix, AZ 85013.

Cells of the TE671/RD human clonal line express a pharmacologically-identified M3 muscarinic acetylcholine receptor (mAChR) subtype coupled to inositol phosphate (InsP) metabolism through a G-protein sensitive to cholera confirmed the presence of similar mAChR subtypes, but with distinctive toxin sensitivities, on cells of the SH-SY5Y human neuroblastoma (Lei et al., 1988) or the PC12 rat pheochromocytoma (Horwitz, 1989). Studies on functional coupling of mAChR demonstrate that NaF treatment enhances mAChR-mediated Ins monophosphate accumulation in PC12 cells, but not in TE671/RD or SH-SY5Y cells. The NaF effect has complex kinetic and dose-dependent character, but is not due to AlF₄ contamination. By contrast, sodium vanadate treatment induces increases in the resting and vanadate treatment induces increases in the resting and stimulated levels of Ins mono-, bis- and tris-phosphate in all three cell lines. Other studies suggest that the vanadate effect most likely involves inhibition of Ins phosphatases, whereas the mechanism(s) and potential species-specificity of the NaF effect needs to be elucidated. The results indicate that functional M3-type mAChR activity is differentially sensitive to agents acting at G-proteins or other, down-stream sites.

THE MUSCABINIC AGONIST OXOTREMOBINE-M ACTIVATES CATECHOLAMINE SECRETION AND 45Ca++ UPTAKE IN BOVINE CHROMAFFIN CELLS: EVIDENCE FOR A NOVEL TYPE OF CHOLINERGIC RECEPTOR. E. Heldman . M. H. Shirvan and H.B. Pollard. Lab. Cell Biol. and Genetics, NIH, Bethesda, MD 20892

Bovine chromaffin cells secrete catecholamines (CA) in response to nicotinic but not muscarinic agonists. Chromaffin cells from most other species, however, secrete in response to muscarinic agonists, and it puzzled us that while bovine cells possessed functional muscarinic receptors they were nonetheless not coupled directly to secretion. To examine this in more detail we tested the effect of a series of muscarinic agonists on secretion and 45Ca++ uptake in bovine chromaffin cells. We found that the full muscarinic agonist oxotremorine-M (Oxo-M) induced a robust CA secretion. Oxotremorine evoked only a moderate secretion at the highest concentration ested (1mM). By contrast, muscarine, pilocarpine, bethanechol, and McN-A-343 did not elicit any secretory response. Secretion by both Oxo-M and nicotine was inhibited by hexamethonium and high concentrations of atropine (100 µM). Secretion induced by nicotine and Oxo-M, but not by high K+ was blocked by the selective ganglionic M-1 agonist, McN-A-343, indicating a direct action of McN-A-343 on the receptor rather than indirect effect on the secretory mechanism. Secretion induced by Oxo-M and nicotine was also relatively insensitive to both kappa bungarotoxin, an effective ganglionic nicotinic blocker, and to alpha bungarotoxin, a specific blocker of muscle nicotinic receptors. Pretreatment with either nicotine or Oxo-M led to desensitization to a repeated dose of either agonist. However, homologous desensitization was more profound. Oxo-M also induced 45Ca++ uptake by chromaffin cells. These data suggest that the "nicotinic" receptor in bovine chromaffin cells may have some muscarinic character, and is distinct from those nicotinic receptors heretofore described in ganglia, brain or muscle. We have tentatively named this unusual receptor the "muscatinic receptor."

VOLTAGE-DEPENDENCE OF NICOTINIC BUT NOT MUSCARINIC RECEPTOR-MEDIATED SECRETION IN PORCINE ADRENAL CHROMAFFIN CELLS. Y. XU and E.J. Forsberg. Dept. of Physiology, Univ. of Wisconsin, Madison, WI 53706.

Catecholamines and ATP are co-localized in granules of adrenal medullary chromaffin cells, and are co-released upon stimulation by cholinergic agonists. In bovine chromaffin cells, nicotinic, but not muscarinic, acetylcholine receptors have been shown to mediate cholinergic agonist-evoked catecholamine and ATP release. In contrast, we have found that both nicotinic and muscarinic receptor selective agonists could evoke ATP release in porcine chromaffin cells. The release of ATP was monitored on-line using a photoluminescence, luciferin/luciferase, assay. Methacholine (a selective muscarinic receptor agonist) stimulated ATP release in a dose-dependent fashion with an EC50 of about 200 µM. The methacholine response was totally blocked by 1 µM atropine. Methacholine also caused an increase in cytosolic Ca monitored by the Ca sensitive dye fura-2. Predepolarization of the cells with high extracellular K (40-100 mM) did not block methacholine-evoked ATP release and the increase in cytosolic Ca⁴⁷, but did block responses mediated by nicotinic agonists. Extracellular application of EGTA (30 s before adding agonist) reduced muscarinic receptor-mediated ATP release by about 70% both in normal and predepolarized cells, but totally blocked nicotinic receptor-mediated secretion. These experiments suggest that in porcine chromaffin cells nicotinic responses are mediated by activation of voltage-dependent Ca influx, while muscarinic responses are mediated by both voltage-independent Ca influx and by intracellular Ca mobilization.

EFFECT OF ANTAGONISTS TO SUBTYPES OF MUSCARINIC RECEPTORS ON MOTONEURONS OF THE LOBSTER CARDIAC GANGLION. <u>J. Freschi</u>. Neurology Dept., Emory Univ., Atlanta, GA 30322.

Muscarinic agonists evoke a voltage-dependent slow inward current in motoneurons of the lobster cardiac ganglion (Freschi & Livengood, J. Neurophysiol. 62:984, 1989). To determine the subtype of muscarinic receptor that mediates the cholinergic current, various antagonists, having specificity for subtypes of mammalian muscarinic receptors, were applied to neurons under voltage clamp. The muscarinic agonist methacholine was used in all of these experiments ($K_D = 0.45$ mM; nH = 1.08). The M1 agonist McN-A-343 had no effect. From the competition curves of antagonists vs. 1 mM methacholine, slope factors and antagonist K_1 values were calculated. Slope factors were all close to 1. The results (-log K_1) in order of potency were: atropine (7.69) > pirenzepine (6.37) \geq 4-DAMP (6.09) > methoctramine (5.37) \geq HBSiD (5.08) = (R)-HHD > (S)-HHD (4.0). Neither AF-DX 116 nor gallamine had an effect at 10^{-4} M.

This profile of antagonist potencies is unlike that for any of the mammalian muscarinic receptor subtypes. Although the terms "MI-like" and "MZ-like" have been used in studies of various invertebrate muscarinic receptors, invertebrate nervous systems appear to have their own unique profiles and will require their own nomenclature.

ANTICHOLINESTERASES REVEAL A MUSCARINIC INHIBITION OF NICOTINIC TRANSHISSION IN THE CAT SUPERIOR CERVICAL GANGLION. M. Bachoo* and C. Polosa. Physiology Dept., McGill Univ., Montreal, Canada H3G 1Y6.

In anesthetized cats, under partial nicotinic block (hexamethonium infusion) and pretreated with pirenzepine (50 µg/kg), methacholine (25-100 µg) injected into the arterial supply of the superior cervical ganglion depressed dose-dependently the postganglionic compound action potential (CAP) evoked by preganglionic stimulation. The depression was blocked by the M2-muscarinic antagonists AFDX (125-300 µg/kg) or pancuronium (200-400 µg/kg). These antagonists did not enhance the amplitude of the CAP evoked by repetitive preganglionic stimulation. Eserine (0.1-0.5 mg/kg) depressed the amplitude of the CAP in a dose-dependent manner at all frequencies above 0.5 Hz. This depressant effect was blocked by AFDX or pancuronium at doses which block the methacholine-evoked depression. A similar depression, also sensitive to AFDX and pancuronium, was produced by the anticholinesterases neostigmine and edrophonium. Thus, nicotinic ganglionic transmission is depressed by an M2-mediated mechanism. This mechanism is activated by exogenous agonists but not by ACh released by the nerve terminals, unless an anticholinesterase is present. The data suggests that the M2 receptor of the sympathetic ganglion synapses has properties (e.g. location, number, affinity for the transmitter) resulting in resistance to synaptic activation. Funded by MRC and QHF.

EVIDENCE POR INHIBITORY MICOTINIC AND FACILITATORY MUSCASINIC RECEPTORS ON CHOLINERGIC MERVE TERMINALS OF THE RAT URINARY BLADDER. G.T. Somogyi and W.C. de Groat, Departments of Pharmacology and Behavioral Neuroscience, University of Pittsburgh, Pittsburgh, PA 15261.

Cholinergic modulation of 3H-acetylcholine (ACh) release was studied in the body of the urinary bladder (UB) of the rat which was prelabelled with 3H-choline. 3H-

Cholinergic modulation of ³H-acetylcholine (ACh) release was studied in the body of the urinary bladder (UB) of the rat which was prelabelled with ³H-choline. ³H-choline uptake was very prominent in the UB body where there is a dense cholinergic innervation. Electrical field stimulation in the presence of 1 µM hemicholinium-3 markedly increased ³H-ACh outflow from the superfused tissue. Eserine (ES) in 1, 5, 25 µM increased the evoked release of ACh in a dose dependent manner by 64%, 220% and 306%, respectively. Atropine (1 µM) alone increased the release of ACh by 44% but atropine decreased by 48% the amount of ACh release in the presence of 5 µM ES. McN-A 343 (50 µM) an Ml muscarinic receptor agonist increased the ES-induced increased release by 63%. The nicotinic antagonist D-tubocurarine (50 µM) (DTC) significantly increased the ES-induced increased release by 63%. The nicotinic antagonist D-tubocurarine (50 µM) (DTC) significantly increased the ES-induced release of ACh. We conclude that in ES treated UB, Ml receptors are activated leading to an increased ACh release. This increased release was depressed by the specific Ml blocker pirenzepine. However, ES also unmasked an inhibitory nicotinic mechanism. Block of this mechanism with DTC further increased ACh release in the presence of ES. Supported by USPHS Grant MH 30915, NSF BN-82-08348, NIH AM 316 888.

Stimulation of Smooth Muscle Contraction by Anatoxin-a by Its Interaction with Nicotinic Receptors. Peter K. Chiang, D. L. Butler, N. D. Brown, A. D. Wolfe, and Peter Kostka, Dept. of Applied Biochemistry, Walter Reed Army Institute of Research, Washington D. C. 20307-5100

Anatoxin-a is an exotoxin that has been isolated from the blue green algae Anabaena flos, and is known to cause death among waterfowl, livestock and fish that inhabit or frequent water areas with high algae bloom. Synthetic anatoxin-a was tested for its effect on guinea pig ileum contraction. It was found that anatoxin-a stimulated ileum contraction with a potency similar to acetylcholine (ACh). Even though the stimulation could be blocked by both atropine or hexamethonium, no specific inhibition of the binding of [3H]N-methylscopolamine to ileum plasma membranes was observed in the presence of anatoxin-a. In comparison, the stimulation of ileum contraction by ACh was not blocked by hexamethonium or tubocurarine, thus indicating that the action of anatoxin-a might possibly be at the presynaptic nicotinic receptor sites. Furthermore, anatoxin-a failed to modulate the secretion of alpha amylase from pancreatic acinar cells, a process that is controlled by muscarinic receptors. Anatoxin-a also failed to inhibit acetylcholinesterase or butyrylcholinesterase. inferred that anatoxin-a binds to presynaptic nicotinic receptors, thus releasing endogenous ACh, which in turn causes ileum contraction by interacting with the postsynaptic muscarinic receptors.

ACTIVITY OF MUSCARINIC AGONISTS AND ANTAGONISTS AT CLONED M1 MUSCARINIC RECEPTORS AND RAT SUPERIOR CERVICAL GANGLION. H.W.G.M. Boddeke*, G. Gmelin Sandoz Pharma, Sandoz Preclinical Research, CH 4002 Basle, Switzerland.

In this study the effects of muscarinic agonists and antagonists in A9-L cells transfected with ml muscarinic receptors were compared with the responses of the same compounds measured in rat superior cervical ganglia, an in vitro model for ml receptors.

A9-L cells were cultured in Dulbeccos Modified Eagle medium supplemented with 10% fetal calf serum. Increases in intracellular calcium were measured using the calcium indicator fura-2. In rat superior cervical ganglia muscarinic agonistinduced slow depolarizations were recorded extracellularly.

In contrast to muscarinic antagonists a tenfold lower potency of agonists at cloned receptors compared to ml receptors in rat superior cervical ganglion was observed. Good correlations for both agonist pD2 values (r=0.80) and antagonsit pA2 values (r=0.94) at cloned ml receptors and rat ganglion were found.

These results indicate that the effects of

These results indicate that the effects of muscarinic agonists and antagonists at cloned ml receptors can be used to predict effects of muscarinic compounds in functional in vitro models.

CEREBROVASCULAR MUSCARINIC CONSTRICTION IS MEDIATED BY M₁ RECEPTORS COUPLED TO PHOSPHO-INOSITIDE (PI) TURNOVER. F. Dauphin* and E. Hamel. Cerebrovasc. Lab., Montreal Neurological Institute, Montréal, Québec, Canada.

The muscarinic receptor subtype involved in the acetylcholine (ACh)mediated constriction of the cat middle cerebral artery was pharmacologically characterized in endothelium-denuded vascular segments. Cholinergic agonists (ACh, carbachol, methacholine and oxotremorine) elicited contractile responses which corresponded to 50-70% of the maximal constriction induced by 127 mM K+ with similar affinities (pD2 values ranging from 4.65 to 4.85) except for oxotremorine (pD $_2$ of 5.85). Non-selective (atropine) or selective M $_1$ (pirenzepine, UH-AH 371), M $_2$ (AF-DX 116, methoctramine and AQ-RA 741) and M₃ (4-DAMP and HHSiD) muscarinic antagonists potently inhibited the ACh-induced constriction. Their order of potency (pA $_2$ values from 10.48 to 6.23) was: UH-AH 371 > atropine ≥ 4 -DAMP > HHSiD \ge pirenzepine \ge AQ-RA 741 \ge AF-DX 116 > methoctramine. The carbachol-induced stimulation of PI turnover was investigated in [3H]-myo-inositol prelabeled cat cerebral arteries and characterized using selective muscarinic antagonists. Carbachol induced a dose-dependent increase in PI-hydrolysis which was blocked by 4-DAMP, pirenzepine and UH-AH 371 with high potency (-logIC₅₀ values of 8.92, 7.87 and 7.84, respectively) while AF-DX 116 was less potent (-logIC₅₀ of 7.07). These results indicate that a M₁ muscarinic receptor coupled to PI turnover mediates this ACh-induced constriction. Supported by the MRC of Canada and Dr. Karl Thomae GmbH.

m2 AND m4 MUSCARINIC RECEPTOR SUBTYPES INHIBIT CALCIUM m2 AND m4 MUSCARINIC RECEPTOR SUBTYPES INHIBIT CALCIUM CURRENTS IN DNA-TRANSFECTED NG108-15 NEUROBLASTOMA HYBRID CELLS. H. Higashida¹, *M.Hashii¹, *K.Fukuda², *S. Numa² & D.A.Brown³. ¹Dept.Biophysics, Univ. Kanazawa Med.Sch., Kanazawa 920, Japan, ²Dept.Med.Chem. & Mol.Genet., Kyoto Univ.Fac.Med., Kyoto 606, Japan and ³Dept.Pharmacol.,

Univ.Fac.Med., Kyoto 606, Japan and 'Dept.Pharmacol., Univ. Coll., London WC1E6BT, U.K. Stimulation of muscarinic acetylcholine receptors (mAChR) inhibits Ca currents (I_{Ca}) in nerve cells. To determine which molecular subtype of mAChR is responsible, inhibition of I_{Ca} in clones of NG108-15 cells transfected with DNA for mAChRI-IV (K.Fukuda et al., 1988:Nature, 335, 355) was measured. I_{Ca} was recorded at 33-350C with "whole-cell" patch clamp electrodes using 50 mM Ba as charge carrier and 1 s commands to +20 mV from $_{Ca}$ R1 mV charge carrier and 1 s commands to +20 mV from -80 mV Maximum inhibition at 1 mM ACh in non-transfected cells was 12.8+1.8% (mean \pm s.e.m., n=36). All clones of mAChRII-and mAChRIV-transformed cells showed a significant increase in inhibition to between 18.1 and 23.1%. In contrast no increase in inhibition was detected in vector-transfected cells, or in pooled clones of cells transfected with DNA cells, or in pooled clones of cells transfected with DNA for mAChRI or mAChRIII. Inhibition did not correlate with total mAChR number measured by 3H -QNB binding. Hence, ICa in these neuronal cells is preferentially inhibited by molecularly defined mAChRII and mAChRIV. Supported by JPMESC, JSPS and UKMRC.

PHYSIOLOGICAL ACTIONS OF AN M1 MUSCARINIC AGONIST, AF102B. A. Fisher, D. Gurwitz*, R. Haring*, Z. Pittel*, E. Heldman* and M. Segal*#, Israel Inst. Biolog. Res., Ness-Ziona and #The Weizmann Inst., Rehovot, Israel.

acetylcholine (ACh) and of the M1 The effects of muscarinic agonist AF102B were compared in CA1 neurons of muscarinic agonist Ariozb were compared in CAI neurons of rat hippocampal slices. ACh produces a slow depolarization associated with decreased persistent K^+ current (I_K), a blockade of a Ca²⁺-dependent I_K underlying the slow AHP, a blockade of the m-current and a reduction in EPSP's evoked blockade of the m-current and a reduction in EPSP's evoked in these cells by stimulating stratum radiatum. These effects are known to be mediated by M1, M2, M3 muscarinic receptors. AF102B (microperfusion: 10mM, 1-2nl microdrop) blocked AHP and caused an associated increase in the number of action potentials evoked in response to a long depolarizing current pulse. This effect of the drug was blocked by low concentration of the M1 antagonist, pirenzepine (100 uM, 10nl microdrop). AF102B (10-50mM, 10nl) caused a slow depolarization and an associated increase in input resistance, but did not affect EPSP's at any concentrations used. In line with these discriminative any concentrations used. In line with these discriminative effects, AF102B did not potentiate phosphoinositides (PI) turnover but rather attenuated carbachol (CCh)-induced PI turnover in rat cortex (m1, m2, m3, m4) and SK-N-SH cells (mostly m3) and an associated CCh-induced mitogenesis in these cells. Cu²⁺-pretreatment of cortical homogenetes uncovered the agonistic binding parameters of AF102B. In summary, AF102B as a selective M1 agonist displays a unique profile in central neurons. Supported by Snow Brand, Japan.

CHARACTERIZATION OF MONOCLONAL ANTIBODIES AGAINST AN m1 MUSCARINIC RECEPTOR PEPTIDE. C.P. Bolden, D.J. McCormick*, C. Krco* and E. Richelson. Mayo Foundation, Jacksonville, FL 32224 and Rochester, MN 55905

Three monoclonal antibodies (mab's) were raised against a synthetic peptide corresponding to a unique portion of the amino terminal extracellular domain of the human m1 (Hm1) and rat m1 (Rm1) muscarinic receptor (MR). Comparison of the amino acid sequences of the different subtypes of the MR indicates that there is little conservation in the amino terminal domain. This observation permits the production of mab's to MR subtypes that will likely be subtype selective/specific. The three mab's produced to date (oligopeptide VSPNITVLAPGKGPW) recognize a single protein (-80 kD) by Western blot analysis in membranes prepared from rat cortex. The m1 oligopeptide inhibits mab binding in this preparation in a dose-dependent manner. ELISA indicates the mab's demonstrate little or no cross reactivity with synthetic peptides corresponding to a portion of the amino terminal domain of the Rm3, Rm4, porcine m2 (Pm2) or Hm4 receptors. In addition, these antibodies have no apparent effect on specific muscarinic antagonist binding or muscarinic receptor-mediated responsiveness. (Supported by MH27692 from the USPHS)

SIGNALING THROUGH THE MUSCARINIC RECEPTOR-ADENYLATE CYCLASE SYSTEM OF THE HEART IS BUFFERED AGAINST GTP OVER A RANGE OF CONCENTRATIONS. F. J. Ehlert and B. E. Rathbun*. Dept. of Pharmacology, Col. of Med., Univ. of Calif., Irvine, California 92717

The influence of GTP on muscarinic receptor occupancy and inhibition of adenylate cyclase activity was investigated in well washed homogenates of the rat myocardium. In these homogenates, the highly efficacious muscarinic agonist oxotremorine-M was without effect on adenylate cyclase activity in the absence of exogenous GTP but caused a maximal 38% inhibition of the enzyme in the presence of 0.1 μ M GTP. Increasing the concentration of GTP to 0.1 mM caused small to moderate increases in the maximal inhibition of adenylate cyclase elicited by oxotremorine-M and in the concentration of this agonist required for half-maximal inhibition of the enzyme. In contrast, the same change in the concentration of GTP (0.1 μ M - 0.1 mM) caused a relatively large increase (46-fold) in the concentration of oxotremorine-M necessary for half-maximal receptor occupancy. Similar observations were made for the highly efficacious muscarinic agonist carbachol. Our results show that GTP increases receptor coupling efficiency and decreases agonist affinity and that these two effects oppose one another so that the level of muscarinic agonist-mediated inhibition of adenylate cyclase activity remains relatively constant over a range of concentrations of GTP. We have also used a model to predict the influence of GTP on receptor binding properties and agonist-mediated inhibition of adenylate cyclase activity and have calculated theoretical results generally consistent with the experimental observations. Supported by N.I.H. Grant NS 26511.

OLIGONUCLEOTIDE PROBE FOR THE RAT MUSCARINIC ACETYLCHOLINE RECEPTOR M3 MRNA HYBRIDIZES WITH A MURINE MRNA UNDER HIGH STRINGENCY CONDITIONS IN THE CNS OF TWO STRAINS OF MICE. I. Tsiokas, S.C. Zhang*, J.J. McArdle and M. Watson. U. of Med. & Dent. of N.J.- N.J. Med. Sch., Newark, N.J. 07103. <u>In situ</u> hybridization (ISHH) studies were done in male

Sprague-Dawley rats and two strains of mice with synthetic oligonucleotide probe complementary to 4-48 or 4-51 base sequence of m1-m5 (NEN, Boston) muscarinic acetylcholine receptors (mAChR). Quantitative ligand autoradiography usreceptors (mAChR). Quantitative ligand autoradiography using mAChR selective ligands was also done on adjacent CNS slices. Probe was 3'-end labeled by terminal deoxynucleotidyl transferase and ³⁵S-dATP, (>1,000 Ci/mmol, NEN), 3'-end tails had 10 bases (specific activity>2.4x10'dpm/ug). Probe was purified by NENSORB 20 cartridges and recoveries were -65%. Sections (10um) of 84d old long and short-sleep (IS/SS) mouse brain were incubated in hybridization buffer with 1x10⁶dpm probe (25°C; 24h) in a humid chamber. Washes were done in moderately high stringency zation buffer with 1x10°dpm probe (25°C; 24h) in a humid chamber. Washes were done in moderately high stringency conditions (T_m=55°C; 2xSSC). After post-hybridization procedures slices were air-dried and apposed to Hyperfilm-Bmax (Amersham). ³⁵S brain paste standard was used to quantitate autoradiograms (4wk; 0-4°C) via a DUMAS image analysis system. Except for dentate gyrus which was densely labeled in LS mice, rat m3 probe showed a distribution consistent with rat m3 mAChR density in hippocampus, striatum and cortex, but with significantly less expression in SS mice. These data suggest the rat m3 probe can be used to clone the murine m3 mAChR. Support from MH-43024. to clone the murine m3 mAChR. Support from MH-43024.

92.16

PROBING THE STRUCTURE-FUNCTION RELATIONSHIP OF THE M1 AND M2 MUSCARINIC CHOLINERGIC RECEPTORS. J. Lai, J.W. Bloom*, W.R. Roeske and H.I. Yamamura. Depts. Pharmacology and Internal Medicine, Univesity of

The structurally defined rat m₁ and m₂ muscarinic receptor gene products expressed in vitro (murine fibroblast B82) are distinguished by both their ligand binding characteristics and their functional coupling via distinct G-proteins. The runctional coupling via distinct G-proteins. The two gene products resemble pharmacologically the brain M_1 and cardiac M_2 type muscarinic receptors, respectively. Pirenzepine is selective for the m_1 receptor (K_1 = 13 nM) and himbacine, methoctramine and AF-DX 116 are selective for the m_2 receptor (K_1 = 10.2 nM, 44 nM and 92 nM, respectively). The $(R_1-10.2)$ mM, 44 m and 92 mM, respectively). The m_1 receptor is coupled to the hydrolysis of inositol lipids (EC₅₀= 15.8 μ M) whereas the m_2 receptor is inversely coupled to adenylate cyclase (EC₅₀= 1.6 μ M), the latter mediated by a G-protein 1000x more sensitive to pertussis toxin (1 ng/ml) than more sensitive to pertussis toxin (1 ng/ml) than that mediating the former. These well defined characteristics of the m_1 and m_2 receptors are essential to the analysis of a series of m_1/m_2 chimeric receptors to delineate structural components pertaining to the distinct nature of the two receptors. Supported in part by AHA, USPHS and ADCRC.

AMPLIFICATION OF GENES ENCODING THE RAT MUSCARINIC RECEPTOR SUBTYPES BY POLYMERASE CHAIN REACTION (PCR). E.V.Varga, K.Kashihara, J.Bloom, J.Lai, W.R. Roeske and H.I.Yamamura. Dept. of Pharmacol. and Internal Med., Univ. of Arizona,

Tucson, AZ 85724.

PCR is an efficient method for amplification of genes from the genomic DNA for the purpose of in vitro expression. This technique has previously been employed to amplify and express previously been employed to amplify and express the rat m_2 muscarinic receptor gene. The error rate of the PCR was 1 nucleotide substitution in 841 base pairs. The rat m_3 gene was amplified by PCR in a similar manner and showed 1 nucleotide difference compared with the published sequence. The deduced amino acid sequence demonstrated one mismatch at residue 349 (Val>Ala). Because we have found the same sequence in three of four different PCR products, we do not attribute the difference to the PCR. The coding region of the m₅ gene was also amplified, but for this amplification we found 3 nucleotide substitutions in 1536 base pairs. We conclude that DNA sequence analysis is a requisite for the use of PCR products.

EXPRESSION AND PHARMACOLOGICAL STUDIES OF A HUMAN M1 MUSCARINIC RECEPTOR CARRYING A MYC EPITOPE AT N- OR C-TERMINAL T.V. Dam. P. Bouchard*, P. Payette*, M. Dennis* and F. Gossard*. National Research Council of Canada, Biotechnology Research Institute, Montréal, Québec, CANADA.

Montréal, Québec, CANADA.

In an attempt to study the human muscarinic receptor 1 subtypes (Hm1) with immunochemical methods, a synthetic oligo cDNA coding for 10 amino acids of the C-myc protein was inserted by mutagenesis in the Hm1 gene. The synthetic sequence was inserted in frame at the N- or C-terminal ends of the protein. The mutated gene was then inserted in the expression vector pSVP4 under the SV40 early promoter and introduced in Neuro-2A neuroblastoma cells (N2A) (ATCC # CCL131). To determine the binding properties of the myc-tagged receptors, membranes prepared from N2A cells, stably transfected with the constructs, were labeled with [3H]-N-methyl-scopolamine (NMS) in a Tris-HCl buffer, pH 7.4 at 4°C containing 2 mM MgCl₂. The results showed that the myc-tag at the C-terminal did not affect the expression of Hm1 receptor both in the affinity (Kd) and the maximum number of sites (Bmax). Experiments are in progress to determine if the Hm1 muscarinic receptors tagged with a myc epitope retain fully their biological activity. (Supported by FRSQ, NRC, MRC).

EXPRESSION OF 5 HUMAN MUSCARINIC RECEPTOR SUBTYPES IN HeLa CELLS. S. Pepitoni*, J. Borkowski*, R. Mallon* and R.D. McQuade, Schering-Plough Research, Bloomfield, New Jersey, 07003.

Researchers have previously cloned at least 5 subtypes of human muscarinic receptors (Bonner et al., Science, 1987). We have obtained these clones from Dr. Bonner and have successfully inserted them into a eukaryotic expression vector under the control of the SRα-promoter. Subsequently, the muscarinic receptor subtypes were transiently expressed in HeLa cells. The receptor gene products from these cells were then analyzed for their binding profiles and for their abilities to stimulate phospholipase C.
Receptor binding experiments were performed with the non-selective

radioligand, ³H-quinuclidinyl benzilate (QNB). These studies demonstrated that all 5 of the receptor subtypes were expressed. Subsequent studies were undertaken to examine the abilities of these receptors to bind to the m-1 selective radioligand, 3H-pirenzepine. The m-1 receptor exhibited the highest degree of binding to ³H-pirenzepine, however the m-3 and m-5 subtypes were also labeled to a lesser degree. The m-2 receptor did not demonstrate any labeling with the 3H-pirenzepine.

Studies were then initiated to examine the abilities of these expressed receptor subtypes to mediate stimulation of phospholipase C. Phospholipase C is the enzyme responsible for the metabolism of phosphotidyl inositol (PI)) and for the generation of the second messenger IP3. Stimulation of the m-1 receptor by 1 mM oxotremorine-M resulted in an approximately 7-fold increase in PI turnover and this stimulation was virtually eliminated by preincubation with 10 µM atropine. The m-3 and m-5 receptors also stimulated PI turnover, albeit to a lesser degree, while stimulation of m-2 sites did not. These data suggest that the m-1 receptor is linked to stimulation of phospholipase C and that m-2 receptors must be associated with some other second messenger system.

ACETYLCHOLINE-RECEPTORS: NICOTINIC I

93.1

EFFECT OF PHOSPHORYLATION ON LIGAND BINDING TO THE MICOTINIC ACETYLCHOLINE RECEPTOR. J.M. Herz, W. Xian*, P. Berryhill* and B. Schmid *. Inst. for Neuroscience and Cell Research Inst., Univ. of Texas, Austin, TX. 78713

The nicotinic acetylcholine receptor (nAChR) can be phosphorylated by a protein tyrosine kinase both in vivo and in vitro. Since it has previously been demonstrated that the nAChR isolated from Torpedo californica electroplax is phosphorylated on tyrosine residues, it is of interest to determine the functional significance of this finding. To examine whether ligand binding properties of interest to determine the functional significance of this finding. To examine whether ligand binding properties are modified by phosphorylation, receptors in <u>Iorpedo</u> membranes were phosphorylated by activation of an endogenous tyrosine kinase using [V-32P]ATP in the presence of PKI and in the absence of detergent. Samples were analyzed by SDS-PAGE and autoradiography. Incorporation of ³²P into nAChR subunits was quantitatively determined by gel excision and liquid scintillation counting. High stoichiometric incorporation was achieved after incubation for 60 min with 200 M ATP. Monoclonal anti-phosphotyrosine antibodies recognized recentor subunits in Western blots. antibodies recognized receptor subunits in Western blots. antibodies recognized receptor subunits in Mestern blots. Phosphorylated membranes were washed and resuspended in an appropriate buffer for ligand binding. Fluorescent ligands specific for the agonist/antagonist sites and the noncompetitive inhibitor site have been used to determine binding affinities and maximal number of sites. This has allowed us to correlate changes in binding parameters with phosphorylation. Supported by AHA Texas Affiliate 89G-401.

93.2

THE EFFECTS OF CHRONIC CORTICOSTERONE ADMINISTRATION ON THE EFFECTS OF CHRONIC CONTICUSTERONE ADMINISTRATION ON SENSITIVITY TO NICOTINE AND NICOTINIC CHOLINERGIC RECEPTOR BINDING ARE REVERSIBLE. J.R. Pauly. E.U. Grum and A.C. Collins. Institute for Behavioral Genetics, University of Colorado, Boulder, CO 80309.

Studies from our lab have demonstrated corticosterone (CCS) modulation of sensitivity to nicotine in mice. Chronic CCS administration reduces sensitivity to nicotine and also the number of CNS receptors labeled by alphabungarotoxin (BTX) by 40-70%. This study examined the time course for normalization of nicotine sensitivity and BTX binding following CCS pellet removal. C3H animals were adrenalectomized (ADX) and implanted with hormone pellets (60% CCS) which were removed after 1 week. Animals were tested for nicotine sensitivity, plasma CCS and BTX binding 0, 1, 3, 5, 7 and 9 days following pellet removal. Plasma CCS levels returned to ADX levels 9 days after pellet removal. Nicotine sensitivity was normalized 7 or 9 days after pellet removal, depending on test measurement. CCS-induced reductions in BTX binding were also reversed following pellet removal; the time course depended on brain region. In cerebellum, binding returned to ADX control levels by day 5. Binding in midbrain, cortex and the colliculi increased to control values by day 9. In other regions (striatum, hippocampus and hypothalamus), binding remained 40-50% below control binding at the 9 day time point. Supported by DA-05131 and a grant from R.J. Reynolds Tobacco Co.

ACUTE EXPOSURE TO NICOTINIC AGONISTS DOWN REGULATES CELL SURFACE NICOTINIC ACCTYLCHOLINE RECEPTOR ON THE TE671/RD CLONAL CELL LINE. A.M. Joy and R.J. Lukas. Division of Neurobiol., Barrow Neurol. Institute, Phoenix, AZ 85013. Cells of the TE671/RD line express a muscle-type nicotinic acetylcholine receptor (nAChR). The regulation of cell surface nAChR was studied using a radiolabeled alpha-bungarotoxin (1-Bgt) binding assay peformed on adherent cells in culture. Exposure to 1 mM nicotine resulted in an apparently maximal 50% down regulation of cell surface I-Bgt binding sites within 10 minutes of drug treatment. These sites were not recovered up to four nours after removal of nicotine. Scatchard analysis revealed no change in $K_{\rm D}$, but a decrease in $B_{\rm max}$ for remaining specific I-Bgt binding sites at saturation. Down regulation of nAChR also occurred during acute treatment with nicotinic antagonists pancuronium (1 mM, less than 50% down regulation) or d-tubocurarine (0.1 mM, more than 50% down regulation) or d-tubocurarine (0.1 mM, more than 50% down regulation) seen with antagonist treatment alone. Treatment of cells with nicotine and antagonist produced a level of down regulation seen with antagonist treatment alone. Treatment of cells with agents presumed to block clathrin coated pit-mediated endocytosis, such as 2-10 mg/ml bacitracin, or in hypotonic medium (0.2 M sucrose) failed to block nicotinic ligand-induced nAChR down regulation precedes a more slowly evolving up regulation of surface nAChR induced by nicotinic agonist treatment.

93.5

EFFECTS OF OXIDIZING AGONISTS ON NICOTINIC RECEPTORS. R.H. Loring, Y. Xie and G.S. Jones, Jr. Dept. of Pharmaceutical Sciences, Northeastern University, Boston, MA 02115

One feature of all known nicotinic receptor subtypes is that reduction of an invariant disulfide by dithiothreitol (DTT) substantially decreases the responsiveness of the receptor to agonists. Therefore, we have synthesized nicotinic agonists with the ability to reoxidize disulfides for use as potential probes at the nicotinic agonist binding site. Dithio-bisacetylcholine (DT-ACh) and dithio-bis(1,1 dimethyl, 4-acetylpiperazinium) (DT-DMAP) were tested as nicotinic agonists in the chick retina preparation (Loring, Br. J. Pharm. 99:207, 1990). The EC50 for nicotinic stimulation by DT-ACh was 10 $^{-M}$ M while that of DT-DMAP was > 1 mM. DTT (2 mM) substantially blocks (> 85% in 20 min) retinal responses to the nicotinic agonist dimethylphenylpiperazinium (DMPP) while the response of NMDA receptors is enhanced 2-8 fold (Aizenman et al, Neuron 2:1257, 1989). Single applications (2 sec) of DT-ACh (EC50 20 μ M) or DT-DMAP (EC50 30 μ M) restored the DMPP responses of DTT-treated retinas while leaving the NMDA responses undiminished. Both DT-ACH and DT-DMAP displaced the binding of the neuronal nicotinic antagonist, 123 I-neuronal bungarotoxin ($^{1.2}$ 1-NBT), to homogenates of chick retina with $^{1.2}$ 1-neuronal bungarotoxin ($^{1.2}$ 1-NBT), to homogenates of chick retina with $^{1.2}$ 5 of $\approx 10^{-5}$ M. DT-ACh was tested for the ability to reoxidize DTT-reduced receptors from chick retina or Torpedo by preventing affinity alkylation by bromoacetylcholine (BAC). Alkylation by BAC was indirectly measured as the permanent inhibition of $^{1.2}$ 1-NBT binding in washed retina homogenates. DT-ACh ($^{1.2}$ 1-NBT) binding in washed retina homogenates. DT-ACh ($^{1.2}$ 1-NBT) binding in washed retina homogenates. DT-ACh ($^{1.2}$ 1-NBT) binding in washed retina homogenates. DT-ACh ($^{1.2}$ 1-NBT) binding in washed retina homogenates. The permanent inhibition of $^{1.2}$ 1-NBT binding in washed retina homogenates. The permanent inhibition of $^{1.2}$ 1-NBT binding in washed retina homogenates. The permanent inhibition of $^{1.$

PHARMACOLOGY OF THE NEURONAL NICOTINIC ACETYLCHOLINE RECEPTOR α4β2 EXPRESSED IN XENOPUS OOCYTES. Pilar. G., P. Charnet*, C. Labarca*, B. Cohen*, N. Davidson, and H.A. Lester. Div. Biology, Caltech, Pasadena, CA 01125

191125.

Two to 7 days after co-injection with 12-25 ng apiece of mRNA from α4 and β2 cDNA clones (S. Heinemann), macroscopic conductances were induced by superfusion of ACh (0.5-5 μM) at 13° C. Responses desensitized by about 1/3 with a time constant of 30 sec and displayed a Hill coefficient near unity. ACh-induced conductance decreased at less negative potentials and there was little outward current at positive potentials. Voltage-jump relaxations (+50 mV → -10 to -150 mV) were described by a single exponential; the rate constant decreased slightly at less negative voltages. Hexamethonium (Hx) decreased ACh-induced currents by 50% at 4-8 μM. Hx also increased the rate constant of voltage-jump relaxations in a dose-dependent fashion, consistent with open-channel blockade with a forward binding rate of 2 x 10⁷ M-1s⁻¹. This resembles channel blocking rates, e.g. for QX-222, at muscle receptors. However, QX-222 (20-40 μM) had little or no blocking effect on the receptors. In repetitive jumps to more negative voltages, the Hx blockade was increased, suggesting that the channel can close on the bound Hx molecule; this Hx use dependence was not observed with expressed muscle receptors. In single-channel data (100 mM KCl), predominant conductances were 21.7, 12.5, and (less frequently) 34 pS. Average channel open time was quite variable (0.5-10 ms) with little voltage dependence. The α4β2 pharmacology shares some of the characteristics of the muscle of ganglionic receptors; but the differences suggest a distinct functional receptor class that may be present on CNS neurons. Support: NS-11756, NS-10338, and MDA.

STAUROSPORINE DECREASES THE EXTENT OF RECOVERY FROM DESENSITIZATION AT SNAKE TWITCH FIBER NICOTINIC RECEPTOR-CHANNEL COMPLEXES. <a href="mailto:learner: learner: lea

Burlington, VT 05405.

Desensitization of nicotinic receptor-channel complexes occurs during prolonged exposure to cholinergic agonists such as carbachol. The recovery from desensitization, following removal of agonist, is a biphasic process with an initial fast phase followed by a slower component. Further, as recovery proceeds, the rate of desensitization produced by subsequent exposure to agonist is increased. The present study was done to test whether protein phosphorylation was involved in either the recovery from desensitization or the acceleration of desensitization with subsequent agonist exposure. Snake twitch fiber endplates, maintained in an isotonic potassium proprionate solution and voltage-clamped to +30 mV, were perfused with 540 µM carbachol to initiate the activation-desensitization sequence. The endplate region was then washed and re-perfused with agonist at different times to determine the time course and extent of recovery. Pretreatment with the protein kinase inhibitor staurosporine (10 nM to 0.5 µM) for 15 min produced a concentration-dependent decrease in the final extent of recovery of both carbachol-induced currents and MEPC amplitudes without any significant effect on the initial fast phase of recovery. Staurosporine had no effect on the initial peak carbachol-induced current, initial rate of desensitization, or the acceleration of desensitization occurring with subsequent applications. Also, staurosporine had no direct effect on MEPC amplitude or timecourse in fibers voltage-clamped to either -100 mV or +30 mV, indicating that activation kinetics were not altered. We conclude that recovery from desensitization has at least two components; a rapid staurosporine-insensitive component and a slower component which requires phosphorylation and is staurosporine esnesitive. EFFECTS OF REDUCING AGONISTS ON NICOTINIC RECEPTORS. Y. Xie, R.H. Loring and G.S. Jones, Jr.* Dept. of Pharmaceutical Sciences, Northeastern University, Boston, MA 02115

The vicinal disulfide bond found in the nicotinic agonist binding site is believed to be strained and therefore, is easily susceptible to reduction by dithiothreitol (DTT) and other agents (Kao and Karlin, J. Biol., Chem., 261:8805, 1986). However, nicotinic agonists, but not antagonists, protect against DTT reduction of the disulfide by inducing a conformational change in the receptor (Damle and Karlin, <u>Biochemistry</u> 19:3924, 1980). We asked whether a reducing group present on an agonist itself would have access to the susceptible disulfide bond. Reduction of dithio-bisacetylcholine (DT-ACh) by DTT or ditho-bis(1,1 dimethyl-4-acetylpiperazinium) (DT-DMAP) by NaBH₄ yielded products with strikingly different characteristics than the parent compounds, when tested in the chick retina preparation (Loring, <u>Br. J. Pharm.</u>, 99:207, 1990). Unlike DT-ACh, the presumed reduction product, mercaptoacetylcholine (ACh-SH) was susceptible to the action of acetylcholinesterase, but in the presence of 10^{-6} M neostigmine, ACh-SH was more efficacious than DT-ACh. The presumed reduction product of DT-DMAP, 1,1-dimethyl-4-mercaptoacetylpiperazinium (DMAP-SH), was at least 10 fold more potent than DT-DMAP (EC₅₀ DMAP-SH = $500 \, \mu$ M). DMAP-SH and ACh-SH were equipotent (10^{-6} M N) with the parent oxidized compounds in displacing the binding of the neuronal antagonist, 10^{-6} H neuronal bungarotoxin, to chick retinal homogenates. Both DMAP-SH and ACh-SH activated nicotinic receptors. Experiments are underway to see if desensitization by ACh-SH or DMAP-SH gives evidence of reducing nicotinic receptors.

TIME-DEPENDENT MATURATION OF ACETYLCHOLINE RECEPTOR CHANNEL ACTIVITY IN THE PLASMA MEMBRANE. L. Li* and M. G. McNamee. Dept. of Biochem. & Biophys., Univ. of California, Davis, CA 95616.

Time-dependent maturation of acetylcholine receptor (AChR) channel activity in the plasma membrane was studied using Xenopus laevis oocytes injected with in vitro synthesized Torpedo californica AChR RNA transcripts. The surface ¹²⁵I-α-bungarotoxin (α-BGT) binding assay showed that the surface-expressed AChR level was similar on Day 2 and Day 3 following microinjection of RNAs into the oocytes. In contrast to their toxin binding ability, the expressed AChRs were slower to acquire their ion channel activity. Voltage-clamp experiments at holding potentials of -80 mV showed that for the same individual oocytes the whole cell current response to 1 µM ACh increased by 10 to 33 fold from Day 1 to Day 2, and by another 2 to 4 fold from Day 2 to Day 3. The normalized channel activity of surface expressed AChRs, measured as the ACh-induced conductance per fmol of surface $\alpha\text{-BGT}$ binding sites, increased by 3 to 5 fold from Day 2 to Day 3. These results suggest that maturation of AChR ion channel function may require processes that occur after the receptor is inserted in the plasma membrane. (Supported by USPHS Grant NS 22941).

MOLECULAR DYNAMICS OF ION CHANNEL FORMING TRANSMEMBRANE SEGMENTS OF THE NICOTINIC ACETYLCHOLINE RECEPTOR

V B Cockcroft,* D J Osguthorpe,* F J Barrantes1* and G G Lunt. Molecular Graphics Unit, Department of Biochemistry, University of Bath, Bath, UK, BA2 7AY. Instituto de Investigaciones Bioquimicas, c.c. 857, 8000 Bahia Blanco, Argentina.

High-temperature (800K) molecular dynamics was performed on the transmembrane segments of the <u>Torpedo</u> nicotinic acetylcholine receptor (nAChR) in define a structural template model of this region within ligand-gated ion-channels (LGICs). A 20 picosecond trajectory was computed for the alpha subunit M1 to M3 region, using a starting structure with residue positions 209-236, 244-265 and 275-299 in a helical conformation (phi -60, psi -40), and the intervening linker regions in an extended conformation (phi -120, psi 120). Within the first 10 picoseconds of the dynamics trajectory the three helical segments folded into an antiparallel bundle. Several features of the final structural model are consistent with experimental data that indicate a partly hydrophilic surface of the M2 segment contributes to the wall of the ion-channel. The packing of annular phospholipids around the pentameric transmembrane region of the receptor has also been modelled. The number of phospholipid molecules predicted from the modelling studies is in accordance with previous measurements made on Torpedo receptor-enriched membranes (Barrantes, Crit. Revs. Biochem. Mol. Biol. 24: 437, 1989).

93.11

REGULATION OF FOUR DISTINCT NICOTINIC ION CHANNEL TYPES IN SYMPATHETIC NEURONS POLLOWING INNERVATION IN VITRO. A.B. Brissaard & ...W. Role, Dep. of Anat. & Cell Biol. in the Ctr. for Neurobiol. & Behav., Columbia Univ., P. & S., 630 West 168th St., New York, NY 10032.

We have studied neuronal nicotinic acetylcholine receptors (nAchRs) of chick sympathetic ganglion neurons following innervation in vitro. Before their in vivo innervation these neurons respond to Ach with three different classes of channel openings, referred to as S(mall), M(edium) and L(arge) openings (Moss et channel openings, referred to as S(mall), M(edium) and L(arge) openings (Moss et al., Neuron 3 (1989), p. 597). Following innervation in the animal, there is (a) an increase in frequency of all channel openings, (b) a shift in the conductances of S and M, (c) a shift in the major contributing classes from S & M in ED 10 to M & L in ED 17 and (d) a new class of higher conductance ACh activated channel openings (called extra-large; XL). To determine whether these changes were due to innervation per se we removed neurons prior to innervation in vivo (ED 10/11) and innervated them by preganglionic neurons in vitro. Under these conditions, ED 17-like single channel characteristics are detected in innervated neurons within ED 17-like single channel characteristics are detected in innervated neurons within 48 hours. To directly examine the properties of newly inserted AChRs we have treated neurons with an inveresible ligand, bromoacetylcholine-bromide (BAC), to selectively block nicotinic AChRs. Based on macroscopic current analysis, we found that the nAChR turnover rate is ~ 2 % per hour (Gardette et al., in prep). Monitoring the recovery of single channel openings at various times after BAC treatment of non-innervated ED 10/11 neurons, reveals that the proportional contribution of the different channel classes was altered such that the neurons had less S and M, but more openings of the L- type and in addition some XL openings. Thus, even before innervation in vivo, sympathetic neurons can express nicotinic receptors characteristic of later stages of development (eg. ED17-like) so that innervation may increase the rate of expression of "mature" AChR types rather than trigger these events de novo. Supported by NIH and the McKnight foundation to L.W.R. and a NATO grant (#81-415) to A.B.B.

CALCITONIN GENE-RELATED PEPTIDE (CGRP) MODULATES NICOTINIC ACETYLCHOLINE RECEPTORS IN CHICK SYMPATHETIC NEURONS. D.C. Valenta & L.W. Role, Dept. of Anat. & Cell Biol. and Ctr. for Neurobiol. & Behav., Columbia Univ. P & S, 630 W. 168th St., NY, NY 10032.

Chick sympathetic ganglion neurons receive input from both ACh- and CGRP-containing nerve fibers (New & Mudge, 1986; Tessier-Lavigne, unpub.). We have examined whether CGRP can regulate neuronal nicotinic acetylcholine receptor (nAChR) channel function by assaying effects of CGRP on whole-cell nicotinic (nAChR) channel function by assaying effects of CGRP on whole-cell nicotinic sensitivity and agonist-induced desensitization in voltage-clamped chick sympathetic neurons in vitro. Incubating sympathetic neurons with CGRP (100-500 nM for > 3-5 mins.) increases the mean peak amplitude of nAChR-mediated currents by 1.5-2-fold vs. control (n = 13). CGRP, when coapplied with submaximal concentrations of nicotinic agonist, also induces an -30% increase in the mean rate of agonist-induced current decay (n = 16). These data suggest that CGRP enhances nicotinic sensitivity and the rate of nAChR desensitization. Since CGRP activates adenylate cyclase in other systems (cf Laufer & Changeux, 1987), we have assayed effects of elevating cyclic AMP levels on nAChR function in sympathetic neurons in parallel experiments. We find that treating sympathetic neurons with cholera toxin (CTX, 10 µg/ml, 60 min. preincubation) and cyclic AMP analogues (chlorophenylthio-cAMP, CPT-CAMP, 1 mM, 90 min. preincubation + coincubation; adenosine 3',5' monophosphorothioate S_p-isomer, S_p-cAMPS, 1 mM, 120 min preincubation) elicits a 1.6-2.1-fold increase in peak nAChR-mediated currents (n=25), results similar to those obtained in chick parasympathetic neurons (cf Margiotta et al, 1987). CTX can induce a 45% increase in the rate of current decay (n=5), however, both CTX and Sp-cAMPS significantly decreased the rate of current decay in some experiments (by 15-39%, n=10). Since neuronal nAChRs mediate synaptic transmission in sympathetic ganglia, the modulation of nAChR channels by CGRP and cyclic AMP may regulate synaptic function in vivo. RECTIFICATION OF NEURONAL NICOTINIC ACETYLCHOLINE RECEPTOR CURRENTS. S.B. Sands 1 and M.E. Barish 1.2, 1 Department of Physiology and Biophysics, University of California, Irvine, CA 92717, and 2 Division of Neurosciences, Beckman Research Institute of the City of Hope, Duarte, CA 91010.

We studied nicotinic acetylcholine receptor (nAChR) currents in embryonic Xenopus spinal neurons and rat pheochromocytoma (PC12) cells using whole cell and single channel patch clamp techniques. In cell attached patches, single channel conductances were 21 pS for Xenopus neuron nAchR (amphibian solutions, 86 mM Na), and 48 pS for PC12 cell nAchR (mammalian solutions, 160 mM Na). Whole cell inward currents were carried by mono- and divalent cations, and were blocked by curare. Unlike nAChR currents in muscle, those in neurons and PC12 cells show inward rectification. We observed in whole cell recordings that peak current I-V relations during brief applications of 50-100 uM ACh or nicotine were almost linear at voltages more negative than -10 mV, but showed a sharp bend at positive voltages such that outward current was virtually absent.

We investigated the possible role of Mg-dependent block of nAChR channels in generating this rectification by recording whole cell nAChR currents during dialysis with Mg-free solutions containing 10 mM EDTA and 5 mM Na-ATP. I-V relations were determined at the peak of nAChR current using voltage ramps from -50 to +60 mV, or voltage steps from -70 mV to +60 mV. We observed partial relief of rectification during dialysis, as indicated by gradual development of a small amount of outward current at positive voltages. However, even after extensive dialysis with Mg-chelating solutions (up to 40 min), substantial rectification remained. We did not observe rectification of single channel nAChR currents in outside-out patches using the same Mg-free internal solutions. These observations suggest that an additional mechanism(s) is responsible for the rectification seen in whole cell current. We are presently characterizing channel opening probability as a function of voltage in the absence of Mg.

NICOTINIC RECEPTOR SUBUNIT EXPRESSION IN CHICK CNS CORRELATES WITH ACH GATED SINGLE CHANNEL ACTIVITY, <u>I.P.Doyle*</u>, S.E.Huck, A.B. Brussaard, M.D.Listerud, L.W.Role, Dept. of Anat. & Cell Biol, Ctr for Neurobiol. & Behav.,

Columbia Univ. P. & S., 630 W. 168th St., NY, NY 10032.

Both molecular (Wada et al., 1988) and recent biophysical (Mulle et al., 1990) data indicate that the habenular nucleus (HAB) of the rat is a rich source of 1990) data indicate that the habenular nucleus (HAB) of the rat is a rich source of neuronal nicotinic acetylcholine receptors (AChR). Our studies on peripheral neurons reveal important developmental changes in AChRs (Listerud et al., Brussaard & Role, this vol.), leading us to examine similar regulation of AChR channel expression in the chick CNS. We identify the chick HAB and lateral spiriform nucleus (LSN) by combined anti-choline acetyltransferase (gift of M. Epstein) and anti-AChR (gift of J. Lindstrom) staining. Northern blot analysis with an α3 probe detects hybridization to RNA from the LSN and the HAB, but not from cerebellum or optic tectum of EDI6-19 chicks. We assayed subunit expression in adult LSN and HAB with the polymerase chain reaction using oligonucleotide primers which amplify α2, α3, α4, α5, and β2 and β4 cDNA sequences. α3 and α5 probes amplify cDNA sequences from both the LSN and HAB. Probes to β subunits amplify a product from HAB cDNA whose size and restriction map correspond to the β2 product. These probes also amplify a smaller product from both regions corresponding to neither β2 nor β4.

and restriction map correspond to the β2 product. These probes also amplify a smaller product from both regions corresponding to neither β2 nor β4.

This diversity of subunits suggests the possibility of different channel classes. After papain dissociation, cells from the HAB and LSN survive for several days in culture. We have monitored ACh gated single channel activity in cell attached patches from isolated HAB neurons of ED11 and ED17 chicks. A single conductance class of about 34 pS was seen at both stages of development with approximately a ten fold increase in frequency observed in patches from ED17 neurons. A larger conductance class in patches from ED17 neurons was also observed in one set of recordings. Thus, neurons of the chick habenula express a variety of AChR subunits which may contribute to multiple classes of ACh activated channels and could provide a model for the developmental regulation of AChRs in the central nervous system. Supported by NIH and the McKnight foundation to L.W.R.

NEURONAL NICOTINIC ACETYLCHOLINE RECEPTOR GENE EXPRESSION

NEURONAL NICOTINIC ACETYLCHOLINE RECEPTOR GENE EXPRESSION AND FUNCTIONAL BLOCK IN CHICKEN SYMPATHETIC GANGLIA NEURONS. M. D. Listerud, A. B. Brussaard, P. Devay, D. Colman & L.W. Role, Department of Anatomy & Cell Biology, Center for Neurobiology and Behavior, Columbia University P & S. 630 W 168th, NY, NY 10032.

Our lab is interested in the acetylcholine gated ion channels expressed by chick sympathetic neurons and the subunits that comprise these channels. Using sequence information (provided by M. Ballivet, U. Geneva) we have assayed AChR gene expression in RNA from sympathetic ganglia by the polymerase chain reaction (PCR) technique. We observe cDNA dependent PCR products in reactions containing synthetic oligonucleotide primers specific for the α3, α5, and β4 AChR subunit genes and have confirmed their identity by detailed restriction enzyme maps. Radioactive probes generated from these fragments and a β2 clone (M. Ballivet) hybridize under stringent conditions to four RNA species respectively (α3: 3kb, α5: 4kb, β2: 4.6kb, and β4: 2.7kb) in Northern blots of total RNA taken from embryonic sympathetic ganglia (EDI1 and EDI7).

To examine function, two tandem antisense oligos were designed against the 5' end of the unspliced β4 message. Isolated sympathetic neurons maintained in culture were first treated in a manner that covalently blocks over 90% of the surface AChRs (Brown & Kwiatkowski, Br. J. Pharmac. 1976, 65:128) and were then incubated with the oligos (20μm). After 48hrs, cells exposed to the antisense β4 oligos (n=15) had

(Stown & Kwiakowski, <u>Pr.). Frantise.</u> 1970, 30:120) and were tueln included with the oligos (20μm). After 48hrs, cells exposed to the antisense β4 oligos (n=15) had a dramatic reduction in ACh induced channel activity as compared to both a sense α3 oligo (n=10) and control media (n=14) co-cultures. These data suggest the molecular correlates for the several ACh channels we observe in these neurons (Moss et al. <u>Neuron</u> 1989 3:597). Supported by NIH and McKnight Foundation (LWR), NSF Predoctoral Fellowship (MDL), NATO grant #81-415 (ABB).

INTRACELLULAR CALCIUM ION TRANSIENTS ASSAY CHICK CILIARY GANGLION ACH SENSITIVITY. Jeremy B. Tuttle. Dept of Neuroscipene Libity of Na Hith Sci. Cat. Charthesville. VA 23008

Neuroscience, Univ of Va Hith Sci Cntr, Charlottesville, VA 22908
Ciliary ganglion neurons regulate ACh receptors via retrograde intercellular interactions (Jacob & Berg, J. Cell Bio, 105:1847 (1987), McEachern et al, J.Neurosci, §:3899(1989)), but study of the mechanisms and signals responsible has been hampered by lack of a non-electrophysiological assay for ACh receptor function, necessitated by the large proportion of "silent" receptors in the neuronal membrane. ACh receptor regulation in vivo is mimicked by neurons in solitary culture, where ACh responses are retained if a solubilized muscle membrane fraction is included (J.B. Tuttle, Soc Neurosci Abs, 15: Pt 2, 1260, 1989). An assay for ACh responses was developed using receptor-mediated transient increases of intracellular free Ca ion imaged via the fluorescent Ca indicator INDO. Freshly isolated neurons or neurons on collagen in solitary culture for <24 hrs respond to ACh with dose-dependent Ca transients (1-100 µM ACh) which were blocked by curare and by removal of extracellular Ca, suggesting receptor activation is required to detect the Ca transients. After 4-5 da in vitro without active factors, responses were not obtained, paralleling electrophysiological measures of lost sensitivity. However, Ca responses to depolarization in high K saline were intact, demonstrating competent Ca channels and detection in the older cultures. Appropriate optics and culture density allow groups of neurons to be imaged simultaneously. While the Ca ion flux assay is less sensitive and less precise than measurements of single cell ACh-activated currents or voltage transients, it allows simultaneous data collection from many neurons and thus screening of extract fractions for activity. Also, using high spatial and temporal resolution. Ca transients and receptor localization by non-blocking fluorescent immunoprobes might be combined in live cells. Supported by the Muscular Dystrophy Association.

EFFECT OF METAPHIT ON THE PERIPHERAL NICOTINIC ACETYLCHOLINE (ACh) RECEPTOR. T. Tano^{1,2}, K. Rice³, R.S. Aronstam⁴, A.C. Oliveirå², Y. Aracava^{1,2} & E.X. Albuquerque, E.X.^{1,2} Lab. Mol. Pharmacol. II, IBCCF, UFRJ, Rio de Janeiro, RJ 21941, Brazil, ²Dept. Pharmacol. Exp. Ther., Univ. Maryland Sch. Med., Baltimore, MD 21201, ³Lab. Chem., NIH, NIDDK, Bethesda, MD 29892 & ⁴Dept. Pharmacol. Toxicol., Med. Coll. Georgia, Augusta, GA 30912. The actions of metaphit (1-[1-(3-isothiocyanatophenyl)cyclohexyl]-piperidine), a phencyclidine (PCP) analog, on peripheral nicotinic ACh receptors were studied using electrophysiological and biochemical techniques. Metaphit (50-100 μM) depressed the peak amplitude more markedly than it shortened the decay time constant of endplate currents recorded from the sartorius muscles of Rana vineiras. The current-

The actions of metaphit (1-[1-(3-isothiocyanatopheny]) cyclohexyl-piperidine), a phencyclidine (PCP) analog, on peripheral nicotinic ACh receptors were studied using electrophysiological and biochemical techniques. Metaphit $(50-100~\mu\text{M})$ depressed the peak amplitude more markedly than it shortened the decay time constant of endplate currents recorded from the sartorius muscles of Rana pipiens. The current-voltage relationship was nonlinear from -60 to -200 mV. In cell-attached single channel recordings obtained from the perijunctional regions of interosseal muscle fibers of frog, a decrease of the frequency of channel openings was observed in the presence of metaphit $(0.5-3.0~\mu\text{M})$. Mean open time, burst time and single channel conductance remained unaltered. The sensitivity of denervated mammalian skeletal muscle to iontophoretic application of ACh was reduced by metaphit $(2-16~\mu\text{M})$. This effect was dependent on the concentration of metaphit and on the frequency of ACh pulses. Binding experiments using Torpedo electroplax membranes showed that metaphit inhibited the binding of [³H]perhydrohistrionicotoxin, and this effect was further enhanced by the presence of the agonist carbachol. These data suggest that, in contrast to PCP which has multiple effects at peripheral nicotinic receptors, metaphit primarily enhances agonist—induced desensitization. Supported by FINEP, CNPq & NIH #P50-MH44211.

NICOTINE DIFFERENTIALLY AFFECTS THE SPONTANEOUS FIRING OF HIPPOCAMPAL PYRAMIDAL CELLS AND INTERNEURONS. D.A. Engstrom and G.M. Rose. Department of Pharmacology, UCHSC & Medical Research, VAMC, Denver CO 80262

Recent evidence suggests that changes in hippocampal nicotinic-cholinergic receptors occur with Alzheimer's disease. We are interested in understanding the functional consequences of such changes. A first step is to determine the physiological effects of nicotinic receptor activation upon different subclasses of hippocampal neurons.

Extracellular recordings of hippocampal CA1 pyramidal cells and interneurons were made using saline and drug-filled multi-barrel glass electrodes in male Sprague-Dawley and Fischer 344 rats. Animals were anesthetized with sodium pentobarbital (50-60 mg/kg, i.p.), placed in a stereotaxic apparatus and surgically prepared for acute recording. Pyramidal cells and interneurons within the hippocampus were isolated and identified using physiological criteria. Cell firing rates were sampled using a window discriminator and displayed on a stripchart recorder. Nicotine (barrel concentration: 1 mM) was applied using the technique of pressure microinjection.

The spontaneous firing rates of all pyramidal cells tested to date (36) were increased, and all interneurons (23) decreased, by nicotine. Preliminary results indicate that the effects of locally applied nicotine upon both pyramidal cells and interneurons can be blocked by curare, a neuromuscular-junction type nicotinic-cholinergic receptor antagonist. (Supported by NSF BNS8811486, the VAMRS and NIA AG04418).

EXTRACELLULAR ATP MODULATES THE FUNCTION OF THE PERIPHERAL NICOTINIC RECEPTOR. R.A.M. Reis, R. Rozental and E.X. Albuquerque. Lab. Mol. Pharmacol. II, IBCCF, UFRJ, Rio de Janeiro, RJ 21941, Brazil and Dept. Pharmacol. Exp. Ther., Univ. Maryland Sch. of Med., Baltimore, MD 21201.

Previous work suggested that some substances secreted from motor nerve terminals could modulate the peripheral nicotinic receptor—ion channel complex (nAchR) function (Albuquerque et al., 1979, J. Physiol. 297:423). ATP (adenosine—5'—triphosphate) is co—released at cholinergic synaptic junctions at concentrations up to 100 μM (Silinsky, 1975; J. Physiol. 247:145) with acetylcholine (ACh). To evaluate how ATP modulates the nAChR, single channel currents were recorded from junctional and perijunctional regions of the single fibers of the frog Leptodactylus occelatus interosseal muscle (patch—clamp technique, cell—attached configuration). ATP (0.01—0.1 μM) modified the kinetic properties of ACh—induced currents (0.4 μM); the major alteration observed was a marked increase in the mean number of events per burst. These effects were time— and voltage—dependent, i.e, they were enhanced by membrane hyperpolarization. Also, a slight decrease in the mean open time was noticed. It is worth noting that in contrast to previous report (Lu and Smith, 1989; Neurosci. Abs. 15:1300, 1989) ATP (0.01—0.5 μM) alone neither induced channel openings nor potentiated the agonistic effect of ACh. However, at higher concentrations (1–50 μM), a weak agonistic activity could be recorded. Our data suggest that ATP at nanomolar concentration range modifies junctional ACh activity which may be important in the modulation of the neuromuscular transmission. ANTAGONISM OF NEURONAL NICOTINIC RECEPTORS BY METHYL-LYCACONITINE. S Wonnacott¹, A Drasdo⁻¹ & M Caulfield⁻² Dept. Biochem., Univ. Bath, Bath BA2 7AY, UK and ²Dept. Pharmacol., Univ. College London WClE 6BT, UK.

Methyllycaconitine (MLA) possesses insecticidal and neuromuscular blocking activities. MLA competes for binding to muscle nicotinic receptors (nAChR) and brain [3H]nicotine sites at µM concentrations, but inhibits [125I]dbungarotoxin binding to rat brain at nM concentrations. We have examined its effects on functional neuronal nAChR in two preparations: (i) rat superior cervical ganglion, in which pre- and postsynaptic nicotinic responses were measured by extracellular recording (Brown & Marsh, Brain Res. 156: 187-191, 1978); (ii) rat striatal nerve terminals, in which the presynaptic nicotinic stimulation of [3H]-dopamine release was measured by superfusion (Rapier et al., J.Neurochem. 54: 937-945, 1990). MLA at 25µM reduced pre- and postganglionic responses to DMPP (30µM) by 80% and 62% respectively. In the perfused synaptosome preparation, 10µM MLA inhibited nicotine-evoked [3H]dopamine release by 80%. Thus ganglionic and brain nAChR are similarly sensitive to low micromolar concentrations of MLA, consistent with its K₁ for brain [3H]nicotine binding sites. MLA may be a useful novel antagonist for studying neuronal nAChR; its ability to discriminate between nAChR and brain abungarotoxin binding proteins make it a valuable probe for exploring the roles of these related proteins in nervous tissue.

CHARACTERIZATION OF A MOUSE DOPAMINE D2A RECEPTOR GENE AND DEVELOPMENTAL EXPRESSION OF THE RODENT mRNA D2A TRANSCRIPTS. K.J. Mack. R.D. Todd, and K.L. O'Malley. University of Wisconsin, Madison, WI 53792 and Washington University, St. Louis, MO 63110 Molecular techniques have identified at least three types of

bopamine D2 receptors. The rat D2A receptor gene is a large gene with multiple introns and an alternatively spliced exon, leading to the transcription of two alternatively spliced mRNA forms (O'Malley et al. Biochem. 29:1367, 1990). The D2B receptor gene product has the pharmacological profile of a D2 receptor, yet shares little sequence homology with the D2A receptor gene (Todd et al. PNAS 86:10134, 1990).

homology with the DZA receptor gene (Todd et al. <u>PNAS</u> 86:10134, 1989).

Using restriction endonuclease mapping, Southern blotting, and DNA sequencing, we have determined the organization of the mouse D2A receptor gene. Atypical for a G-protein coupled receptor, the mouse D2A gene spans at least 30kb of genomic sequence and contains 7 introns. There is at least 18kb of sequence between the first (noncoding) exon and the second (first coding) exon. This gene shares 99% amino acid homology with the rat gene and 95% homology with the human gene. The mouse gene can also be alternately spliced to form mRNAs for the D2A₄₁₅ and D2A₄₄₄ receptor proteins.

In order to understand the developmental regulation of the D2A gene, a PCR amplification technique was used to detect the multiple forms. An oligonucleotide primer set made from sequences in exon 7 and 8 was used to detect the total amount of D2A mRNA. A different primer set, which flanks the alternative exon (6), was used to detect the two forms of the D2 mRNA. Both D2A transcripts were detected as early as embryonic day 15 in the rat, at levels less than 15% of adult values. The D2A mRNAs then gradually increase to adult levels, as measured as a percentage of total mRNA.

ANTI-PEPTIDE ANTIBODIES LOCALIZE 125I-NAPS BINDING TO THE C-TERMINAL PORTION OF THE D₂ DOPAMINE RECEPTOR.

C. David* and S. Fuchs. Department of Chemical Immunology, The Weizmann Institute of Science, Rehovot

76100, Israel. 76100, Israel. $N-(4-azido-3-125I-iodophenethyl)-spiperone ($^{125}I-NAPS)$ is a potent derivative of the D₂ dopamine receptor antagonist, spiperone. Photolabelling of bovine striais a potent derivative or the D_2 oppontine receptor antagonist, spiperone. Photolabelling of bovine striatal or pituitary membranes, results in the specific labelling of a major 90 Kd protein band and 40 Kd. 20 Kd, and 14 Kd fragments, as well. In an attempt to develop specific reagents for the D_2 receptor, we raised antibodies against synthetic peptides of the rat D_2 receptor. Antibodies directed against peptides which correspond to cytoplasmic regions of the receptor, including the 14 amino acid C-terminal peptide, immuno-precipitate the 90 Kd band. Differential reactivity of the anti-peptide antibodies with various proteolytic fragments of the D_2 receptor indicates that L^2J -NAPS binds covalently to a carboxy terminal 140 amino acid fragment of the D_2 receptor. This implies that the photoaffinity ligand binds to a residue(s) located at the short extracellular stretch between the 6th and 7th transmembrane segment of the receptor or within these segments themselves. Further studies are being carried out to determine whether the receptor ligand binding site is located in this region or in another portion of the molecule which is conformationally in close proximthe molecule which is conformationally in close proximity to this area.

REGULATION OF DOPAMINE D2 RECEPTOR GENE EXPRESSION O. Civelli, L. Vallar, J. Meldolesi, H. Van Tol, Thambi, J. Bunzow and D. Grandy, Vollum Institute, CHSU, Portland, OR 97201 and University of Milan, Milano, Italy

Portland. OR 97201 and University of Milan, Milano, Italy We have characterized two isoforms of the D2 dopamine receptor which are generated by alternative splicing. Several aspects of expression and stimulation of these two isoforms have been studied. At the level of the gene it has been found that the 5'untranslated region of the mRNA is interrupted by a long intron. This intron may play a regulatory role in D2 receptor gene expression. The long isoform of the D2 receptor has also been expressed via recombinant vaccinia virus infection. This expression system may be of value in efforts to raise antibodies specific to the D2 receptor. At the cellular level dopamine stimulation of the receptor has been found to affect different second messenger systems depending on the environment of the receptor. In fibroblasts, the short isoform is able to inhibit adenylyl cyclase activity and phosphoinositol turnover. In lactotrophs, stimulation of the same isoform inhibits adenylyl activity and phosphoinositol turnover. In lactotrophs, stimulation of the same isoform inhibits adenylyl cyclase, has no effect on inositol phosphate levels and permits G protein-mediated coupling of the receptor to K+ channels. These second messenger effects were analyzed following stimulation of the long isoform and will be discussed in regard to the G proteins present in these cell lines.

DOPAMINE D-2 RECEPTORS AND ALTERNATIVELY SPLICED FORMS OF D-2 RECEPTOR mRNA IN RAT, BOVINE, AND HUMAN TISSUES. K.A. Neve. J.N. Joyce. V. Simonneaux, M. Ebadi, A. Spanoyannis, and R.L. Neve. VAMC, Portland, OR; Univ. of Pennsylvania Sch. Med., Philadelphia, PA; Univ. of Nebraska Coll. Med., Omaha, NE; and Univ. of Calif., Irvine, CA. Two molecular forms of D-2 receptors can be distinguished on the basis of the presence (D-2₄₄₄) or absence (D-2₄₁₅) of a 29-amino acid exon. Both mRNAs were widely distributed in rat, bovine, and human tissues, but the ratio of the alternatively spliced forms varied. For example, D-2₄₄₄ was expressed more abundantly than D-2₄₁₅ in rat pituitary and neostriatum, whereas a number of other rat tissues expressed both mRNAs at similar levels. Distribution of the two mRNAs in bovine and human tissues differed in several respects from distribution in rat. Using the Distribution of the two mRNAs in bovine and human tissues differed in several respects from distribution in rat. Using the ligand [125] pepidepride, we have characterized dopamine D-2 receptors in many tissues, including some with a low abundance of D-2 receptor mRNA. For some drugs, there were small but reliable differences in binding affinity among the tissues. For example, flupenthixol had an affinity of 2-3 nM in human cortex (frontal and temporal lobes) but an affinity of 0.5-1.0 nM in human putamen and accumbens. Also, the K_D of [125] pepidepride for D-2 receptors varied from 18-80 pM among tissues, with the lowest values observed in human cortex, intermediate values in human and rat caudate-putamen, and highest values in bovine cortex, hippocampus, and caudate. The possibility that differences in drug binding affinity are related to differences in the ratio of D-2415 to D-2444 is being investigated. (MH 45372, MH 43852, HD 18658).

CAN VOLTAGE-CLAMPED XENOPUS OOCYTES DETECT RECEPTOR-DRIVEN ALTERATION OF CYCLIC AMP LEVELS? Angela K, Birnbaum, Ping Y, Law. Sandra Roerig and George L, Wilcox, Dept. of Pharmacology, University of Minnesota, Minneapolis, MN 55455, U.S.A.

Xenopus oocytes form gap junctions with the follicular cells that surround them. The conductance of these gap junctions can be modulated by second messengers, such as cyclic AMP. The purpose of the present study is to exploit this phenomenon as an indicator of activation of receptors coupled to adenylate cyclase. The first part of the

as cyclic AMP. The purpose of the present study is to exploit this phenomenon as an indicator of activation of receptors coupled to adenylate cyclase. The first part of the study examined follicle-oocyte junctions in oocytes injected with mRNA for human α_2 adrenergic receptors; the second part of the study examined oocyte-oocyte junctions in oocyte pairs injected with mRNA for β_2 and α_2 adrenergic receptors. Stage V-VI folliculated oocytes were removed from mature female X. Laevis. Single oocytes were impaled with two 3M KCl-filled micropipettes (0.5 - 5 MΩ) and voltage-clamped with a two-electrode voltage clamp (0 to -100mV stepped or -10 to -25 mV constant). Currents were measured during and after application of ZK-62711, a phosphodiesterase inhibitor, isoproterenol, a β agonist, and tramazoline, an α_2 agonist. Sportoerenol elicited an outward current which reversed near -100mV. This effect was likely mediated by endogenous β receptors in the follicular cells. The current was presumably carried by K* ions through K*- channels in the follice cells. This effect of isoproterenol was enhanced by ZK-62711 pretreatment. Tramazoline did not appear to alter this current by itself, but co-administration of tramazoline with isoproterenol sometimes decreased the isoproterenol effect slightly. Stage V-VI oocytes were defolliculated by 2h collagenase digestion, injected with mRNA for β_2 and α_2 adrenergic receptors and mechanically devitillinized before juxtaposition. After three days, some coupling between oocytes was observed when each oocyte was independently voltage clamped. Coupling was variably affected by isoproterenol and tramazoline. Xenopus oocytes may be useful in expression of receptors using cyclic AMP as a second messenger. (Supported by NIDA R01 grants 01933 and 04274).

D2 DOPAMINE RECEPTOR mRNA IS EXPRESSED IN DORSAL ROOT D2 DOPAMINE RECEPTOR mRNA IS EXPRESSED IN DORSAL ROOT AND PETROSAL GANGLIA OF RAT. D.A. Bayliss, M. F. Czyzyk-Krzeska, K.B. Seroogy, E.R. Perl and D.E. Milhorn, Department of Physiology, University of North Carolina, Chapel Hill NC 27599

A number of primary sensory neurons of rat petrosal ganglia (PG) express tyrosine hydroxylase (TH) and are thought to be dopaminergic. In contrast, only a few dorsal root ganglia (DRG) cells of rat express TH. In situ hybridization was used to determine if neurons of PG and DRG might also express the mRNA for the FG and DRG might also express the mRNA for the presumptive dopamine autoreceptor (i.e. D2 receptor). Two synthetic oligonucleotides, complementary to different regions of D2 receptor mRNA, were labeled with $\begin{bmatrix} 5 & 5 \\ 5 & 5 \end{bmatrix}$ and applied as a cocktail to sections ($10 \ \mu m$) of fresh frozen ganglia. A number of PG neurons were found to contain D2 receptor mRNA; the topographic location of these cells within PG suggest that D2 receptor may be expressed in putative dopamine cells. In DRG, a substantial subpopulation of neurons also expressed D2 receptor mRNA. The number of D2 receptor mRNA-containing cells in DRG was much greater than the number of THexpressing cells. These latter results indicate that D2 receptor mRNA may be found in primary sensory cells which are not dopaminergic. (NIH HL33831)

QUANTITATIVE MEASUREMENT OF RAT DOPAMINE D2 RECEPTOR MRNA SPLICE VARIANTS BY SOLUTION HYBRIDIZATION. L.A. Snyder.*Y, Shifman, J.L. Roberts, S.C. Saalfon, Fishberg Center of Neurobiolov, Mt. Sinai Medical School, New York, NY 10029.

Neurobiology, Mt. Sinai Medical School, New York, NY 10029.

Two D2 receptor mRNAs which are splice variants of a single gene exist in the rat brain. In order to investigate the regional distribution and regulation of the two mRNA forms, we developed a sensitive and reproducible solution hybridization/nuclease protection assay. This assay was used to examine the subtype specific distribution of D2 mRNA in the brain and pituitary of adult male rats. The mRNA encoding the longer form of the D2 receptor is found in highest levels in the pituitary neurointermediate lobe, followed by levels in the naterior lobe, and in the striatum. Much lower levels are seen in other brain areas. In contrast, the mRNA encoding the shorter form of the D2R is found in highest levels in the striatum, followed by intermediate levels in the pituitary and low levels in other brain areas. Thus the ratios of the two D2 splice variant mRNAs varies widely across tissues, with the mRNA encoding the shorter form of the D2 receptor comprising 10-50% of the total D2R mRNA. The highest ratios of long to short D2R subtype mRNA is found in the pituitary (~9:1) while lower ratios (~2:1 and 1:1) are found in the striatum and the midbrain respectively. Using a probe that does not discriminate splice forms, we have demonstrated that haloperidol treatment increases the D2R mRNA level in the rat NIL, but not the anterior pituitary (Mol Cell Endo. 1989. 67:101-105) and are determining if this regulation is specific to either splice form.

DOPAMINE TYPE D, RECEPTOR-SPECIFIC ANTIBODIES. J.W. Brock, S. Farooqui, and C. Prasad. Neuroscience Lab, Pennington Biomed.Res.C., Baton Rouge; Dept. of Med., LSUMC, New Orleans, LA 70808.

Antibodies have been raised in preparation for mapping the location of dopamine type D₂ receptors in brain. Rabbits were innoculated with keyhole limpet haemocyanin-conjugated oligopeptide identical to amino acid sequence 77-86 of the D₂ receptor. In the D₂ receptor, this sequence is located between transmembrane domains 3 and 4. Monthly blood samples were taken and booster injections given. Antibody titer was determined by ELISA. The antibody was reactive only with amino acid sequence 77-86 (titer, 1:15,000 on ELISA). The antibody did not react with 2 analogues of the peptide or a peptide representing amino acid sequence 1-15. These data suggest that the antibody is selective against dopamine D₂ receptor protein. (Supported by Dept. of Army, grant #1788G8023)

A68930: A POTENT AGONIST SPECIFIC FOR THE D-1 DOPAMINE RECEPTOR. M.P. DeNinno. R. Schoenleber. R. MacKenzie. D.R. Britton. K.E. Asin. C. Brigos. J.M. Trugman and J.W. Kebabian. Neuroscience Research Division, Abbott Laboratories, Abbott Park, IL 60064 and Department of Neurology, University of Virginia, Charlottesville, VA 22908 (JMT).

A68930 [1B, 3S] 1-aminomethyl-5,6-dihydroxy-3-phenylisochroman HCI, is a potent (EC50 = 2.5 nM), partial (intrinsic activity = 66 percent of dopamine) agonist in the dopamine-sensitive adenylate cyclase model of the D-1 dopamine receptor. In contrast, A68930 is a much weaker (EC50 = 3,920 nM) full agonist in a biochemical model of the D-2 dopamine receptor. The orientation of the 3-phenyl substituent in the molecule is critical for the affinity and selectivity of the molecule towards the D-1 receptor. A68930 also displays weak alpha-2 agonist activity but the molecule is virtually inactive at the alpha-1- and beta-adrenoceptors. When tested in rats bearing a unilateral 60HDA lesion of the nigro-neostriatal neurons, A68930 elicits contralateral turning that is antagonized by D-1 receptor selective doses of SCH 23390 but not by D-2 receptor selective doses of haloperidol. When administered to these 60HDA lesioned rats, the molecule increases the accumulation of 2 deoxyglucose in the substantia nigra on the lesioned side of the brain. When tested in normal rats, A68930 elicits hyperactivity and, at higher doses, produces a forelimb clonus.

94.8

ANTIBODIES TO SYNTHETIC PEPTIDES CORRESPONDING TO SEGMENTS OF THE DOPAMINE (DA) D₂ RECEPTOR. <u>J.Y. Lew, K.Y. Lee, M. Goldstein</u> and A.Y. Deutch. Neurochem. Res. Lab., New York Univ. Med. Ctr, N.Y., N.Y. 10016 and Dept. Psych. and Pharmacol., Yale Univ. Med. Ctr., West Haven, CT 06516.

To characterize the DA D₂ receptor by immunochemical and immunohistochemical procedures, several peptides corresponding to discrete AA sequences of the DA D₂ receptor were synthesized and used as antigens for generation of polyclonal antibodies in rabbits. One peptide, D₂-1, containing the AA 10-20 from the N-terminal segment, and four peptides, D₂-3, D₂-4, D₂-4a and D₂-5, containing the AA 221-235, 261-270, 292-315, and 332-343 from the third cytoplasmic loop of the DA D₂ receptor, respectively, were synthesized. The synthetic peptides were coupled to bovine thyroglobulin or to a purified protein derivative of tuberculin and rabbits were immunized with conjugates corresponding to 50-200 µg of peptide. The antisera were tested by solid phase ELISA procedure and by Western immunoblots. Anti D₂-3, D₂-4, D₂-4a and D₂-5 interact with several solubilized striatal proteins (M.W. 34-120 KDa) and with one cerebellar protein (34 KDa). Preimmune serum does not recognize the immunoreactive proteins. Histochemical studies indicate that anti-D₂-4 and D₂-4a recognize neurons in the substantia nigra, pars compacta and medium size striatal neurons. The staining specificity for the DA D₂ receptor is now under investigation. These studies were supported in part by Grants NIMH 02717 and NINCDS 06801.

94.10

ORGANIZATION AND EXPRESSION OF THE HUMAN D2 GENE. K.Y. Gandelman, S. Harmon* K. J. Mack, R.D. Todd, and K.L. O Malley. Department of Anatomy & Neurobiology and Psychiatry, Washington University School of Medicine, St. Louis, MO 63110.

The dopamine D2 receptor has been implicated in the pathophysiology of a purpose of discrete Research and the St. Company of the C

The dopamine D2 receptor has been implicated in the pathophysiology of a number of disorders. Because detailed description of its gene locus will aid in understanding putative mutant alleles and polymorphisms in human, we have isolated the complete human D2, gene. Like the rat D2, gene (O'Malley et al. (1990) Biochemistry 29: 1367-1371), the human gene contains at least eight exons and spans at least 45 Kb. Exons 3-8 are clustered within 9 Kb of genome. Exon 2 is separated from exon 1 by at least 30 Kb. We and others have shown that alternative utilization of exon 6 gives rise to alternative D2, transcripts. Despite the extreme size of intron 1, no alternative transcripts can be detected in basal ganglia and pituitary using polymerase chain reaction analysis. The relative abundance and tissue distribution of the alternative D2, transcripts were examined in twenty different human brain regions. The relative expression of the two transcripts varied by at least 200-fold across the brain region surveyed. As expected, high levels of transcripts were detected in caudate, putamen and pituitary. Moderate levels were detected in the locus coeruleus and amygdala. In contrast to the rat brain, very low levels of transcripts were detected in cortical regions.

94.12

EXPRESSION AND CHARACTERIZATION OF D₂ DOPAMINE RECEPTOR ISOFORMS IN TRANSFECTED MAMMALIAN CELL LINES. <u>Mario S. Rinaudo. Frederick J. Monsma. Jr. Lauren E. Black, Lawrence C. Mahan¹. & <u>David R. Sibley.</u> ETB, NINDS, and LCB, NIMH, NIH, Bethesda, MD 20892. We recently described the cloning of two variants of the D₂ dopamine (DA)</u>

We recently described the cloning of two variants of the D₂ dopamine (DA) receptor which are derived from alternative RNA splicing (Nature 342: 926-929, 1989). To investigate the functional properties of the short (D_{2S}) and long (D_{2L}) isoforms of the D₂ receptor, we have stably expressed both cDNAs in CHO cells. Following transfection, several clonal cell lines were isolated which exhibited D₂ receptor binding with B_{max} values ranging from 0.5 to 5 pmol/mg protein as determined by ³H-methylspiperone (³H-MSP) binding. Cell lines expressing ~1-2 pmol/mg protein of each isoform were chosen for direct comparisons. Both receptor isoforms revealed a K_D for ³H-MSP of ~60 pM. Competition assays for ³H-MSP binding by DA antagonists to both D_{2L} and D_{2S} exhibited identical affinities and rank orders of potency. Inhibition of ³H-MSP binding by DA revealed the presence of high and low affinity agonist binding states with both receptor forms exhibiting similar values for the affinities (K_H and K_L) and proportions of the agonist binding states. In addition, both receptor isoforms show a complete loss of high affinity agonist binding with the addition of guanine nucleotides. Both of the D₂ receptor isoforms expressed in CHO cells exhibit DA-induced inhibition of forskolinstimulated cAMP accumulation by ~60% with EC₅₀ values of ~100 nM. In each case, the DA inhibition of cAMP accumulation is prevented by pretreatment of the cells with portussis toxin. Finally, for both receptor isoforms, pretreatment of the cells with 100 μM DA for 4 to 24 hrs results in desensitization of the ability of DA to inhibit cAMP accumulation. These data suggest that the D_{2L} and D_{2S} receptors are functionally similar in their ligand binding properties and linkage to adenylyl cyclase inhibition.

MOLECULAR CLONING OF A D1 DOPAMINE RECEPTOR LINKED TO ADENYLYL CYCLASE ACTIVATION. Frederick J. Monsma. Jr. Lawrence C. Mahan*, Loris D. McVittie, Charles R. Gerfen, and David R. Sibley. ETB, NINDS and LCB, NIMH, NIH, Bethesda, MD 20892.

We have used NS20Y cells, which express D₁ dopamine receptors linked to adenylyl cyclase activation, to investigate the molecular biology of this receptor subtype. In order to clone this D₁ receptor, the polymerase chain reaction (PCR) method was used to selectively amplify a D₁ receptor cDNA sequence from NS20Y cell mRNA. Poly (A)+ RNA was used to synthesize cDNA by reverse transcription followed by PCR amplification with sets of highly degenerate primers derived from the transmembrane sequences of the previously cloned adrenergic, D₂ dopaminergic, and serotonin receptors. This resulted in the amplification of a novel cDNA sequence which exhibits considerable homology to various members of the G protein-coupled receptor family. This cDNA is most homologous with β -adrenergic receptors followed by α -adrenergic and D₂ dopaminergic receptors. It also predicts a 3rd cytoplasmic loop consisting of 54 amino acids and one phosphorylation site for the cAMPdependent protein kinase. Most importantly, the predicted 5th transmembrane spanning domain contains conserved serine residues believed to be involved in catecholamine binding. Northern blot analysis reveals a transcript size of ~4 kb which is predominantly located in striatal tissue with lesser amounts in the cortex and retina. In contrast, no mRNA is observed in the cerebellum, hippocampus, kidney or pituitary. In situ hybridization analysis also indicates a high abundance of mRNA in the striatum as well as in the offactory tubercle. To establish the identity of this receptor, a full-length cDNA was isolated from a rat striatal library and transiently expressed in COS-7 cells. 3H-SCH23390, a D₁ selective radioligand, exhibited specific binding ($K_D=0.3$ nM, $B_{max}=400$ fmol/mg) only in transfected cells, thus confirming the D_1 identity of this clone.

OPIOIDS: BRHAVIOR

EVIDENCE FOR AN ENKEPHALINERGIC MECHANISM IN AMYGDALOID SUPPRESSION OF DEFENSIVE RAGE IN THE CAT. C.L. Lu

M.B. Shaikh and A. Siegel. Dept. of Neurosciences, UMDNJ-New Jersey Medical School, Newark, New Jersey 07103.

Recently, we have demonstrated enkephalinergic (ENK) inhibition of defensive rage behavior (DR) elicited from the periaqueductal gray (PAG) of the cat. The present study provides evidence that a major source of this inhibitory ENK input to the PAG arises from the amygdaloid complex Computer electrodec were impleated, into the PAG inhibitory ENK input to the PAG arises from the amygdaloid complex. Cannula-electrodes were implanted into the PAG for the elicitation of DR as well as for infusion of the opioid antagonist, naloxone. Monopolar stimulating electrodes were also implanted into central amygdaloid (CE) sites from which suppression of DR could be obtained. Initially, concurrent stimulation of the CE at very low, subscizure current levels (0.1mA, 60hz) and PAG resulted in an immediate suppression of this response after 2-4 trials. Total suppression of PAG elicited DR ranged from 30-60 min following CE stimulation. Secondly, naloxone (1.0, 7.0 and 10.0 ug/0.25 ul) was infused intracerebrally into PAG sites from which DR was elicited prior to CE stimulation. Naloxone treatment blocked the suppressive effects of CE stimulation in a dose and time dependent manner. These data strongly suggest that potent amygdaloid manner. These data strongly suggest that potent amygdaloid suppression of defensive rage utilizes ENK as its transmitter at the level of the PAG. [Supported by NIH grant NS 07941-20, the Fogarty International Center FO5TW04110, and the Foundation of UMDNJ].

COLD ACCLIMATION POTENTIATES HYPERTHERMIA AND OPERANT

COLLA ACCLIMATION POTENTIATES HYPERTHERMIA AND OPERAN HEAT ESCAPE OF RATS CENTRALLY INJECTED WITH DAGO.

J.R. Wilson and B.A. Howard*. Dept. of Psychology, Univ.Manitoba, Winnipeg, Canada, RST 2N2.

Centrally injected opioids evoke hyperthermia, a response potentiated following chronic cold exposure (Wong & Tse, Int.J.Peptide Protein Res., 24.74, 1984). To determine if these responses are multiple protein response to the protein respo receptor mediated, two studies examined the effects of intracerebro-ventricular (icv) DAGO, in cold- and non-cold-acclimated (CA,NCA) receptor mediated, two studies examined the effects of intracerebroventricular (icv) DAGO, in cold- and non-cold-acclimated (CA,NCA) sialoadenectomized rats on (a) core temperature at normal ambient temperature, and (b) operant escape from a mild heat challenge. In Experiment I, rats were implanted with an icv cannula and an abdominal Mini-Mitter temperature transmitter. The CA and NCA rats received ip saline (n=14) or naltrexone (NLTRAY), a mu-antagonist, (2mg/Kg) (n=14) followed 30 min by 1 of 3 icv doses of DAGO (0.0, 0.1, 1.0 µg/Kg). Preand post-DAGO core temperature and activity were monitored in a 21°C open field. Experiment II used the same drug protocol, however CA and NCA rats (n=28) were shaped to escape convective heat challenge by lever pressing and then tested during a mild heat (37°C) challenge. In Experiment I, DAGO induced a dose-dependent hyperthermia in NCA rats that was NLTRX reversible, independent of activity, and potentiated by CA. In Experiment II, CA enhanced the duration of heat escape for both pre- and post-DAGO injections. The greatest heat escape, obtained in CA rats at the 1.0 µg dose of DAGO, was NLTRX reversible. Thus, central opioid-induced hyperthermia appears to be mu-receptor mediated and CA potentiates the mu thermal reactivity. These findings supplement reports (Uehara, A., et al., Am.J.Physiol., 257:E336, 1999; Travis, K.A. & Boulant, J.A., Am.J.Physiol., 256:R560, 1989) that CA increase hypothalamicadrenocortical responsiveness, and cross tolerances emerge between thermal and nonthermal homeostatic processes. (Supported by NSERC Grant A6404 to JRW).

ACUTE AND LONG-TERM BEHAVIORAL, GLUCOCORTICOID AND OPIOID ADAPTATION TO SOCIAL STRESS K.A. Miczek, I. Fier *, I.M. McNamara*, G.F. Koob, C. Rivier. Dept. Psychology, Tufts University, Medford, MA 02155, Neuroscience, Res. Inst. Scripps Clinic; Peptide Biology Lab, Salk Institute, La Jolla, CA 92037.

Exposure to the stress of being attacked and threatened by a dominant opponent prompts rats to engage in a range of affective, behavioral and hormonal responses. The magnitude, sequence and time course of these responses, as monitored by audio- and videorecords, cardiovascular telemetry and blood samples, reveals the integration of glucocorticoid steroids, opioid peptides and catecholamines in brain and periphery. Immediately at the start of the social confrontation, ACTH and corticosterone rise, and this elevation as well as tachycardia, hyperthermia, ultrasonic distress calls, submissive postures and behavioral immobility persist for 1-2 h. Glucocorticoid and cardiovascular responses to repeated exposures to social stress remain unattenuated in the submissive rat. In dominant animals that engage in aggressive behavior, the glucocorticoid stress response is limited to the first 30 minutes of the encounter. Diazepam (0.3, 1 mg/kg) prevents the ACTH and corticosterone response in submissive rats, but they keep emitting ultrasounds. When challenged during the acute social stress with opiates, a potentiation of analgesia is seen. Within 24 h after exposure to the social stress, tolerance to the analgesic effects of mu opioid agonists becomes detectable that lasts for several months. However, within the same animals the morphine "cue" remains unaltered as assessed by the drug discrimination method. In contrast to the large release of glucocorticoids and opioids during the acute social stress response, central opioid receptor-mediated changes in pain perception persist for months.

REPRODUCTIVE EXPERIENCE ALTERS OPTOID-MEDIATED MATERNAL BEHAVIOR AND PROLACTIN SECRETION IN LACTATING RATS P.E. Mann, C.E. Lupini*, P.M. Ronsheim*, & R.S. Bridges,

Dept. Anat. & Cell. Biol., Harvard Med. Sch., Boston, MA.
Sensitivity to opiate disruption of maternal behavior
(MB) declines as a function of reproductive experience. The aims of this study were to determine whether central sensitivity to beta-endorphin (BE)-induced disruption of MB as well as naloxone (NAL) inhibition of suckling-induced prolactin (PRL) release changes with reproductive experience. Multigravid and age-matched primigravid rats were implanted with bilateral MPOA cannula on days 13-15 of gestation. On postpartum days 5 (saline) and 6 (BE: 0.5 ug/0.4 ul/side), dams were tested for MB 30 min after infusions. Animals were catheterized on day 7. On days 8-9, pups were removed and 4 hr later blood samples were taken before saline (day 8) and NAL (day 9; 5 mg/kg, i.v.) injections. Pups were returned and blood was sampled 10-30 min postinjection. Pups were removed again at 30 min and samples were taken for 60 min. Multiparous (MULTIP) animals were significantly less sensitive to BE than primiparous (PRIMIP) rats. Suckling-induced PRL levels were significantly higher in PRIMIP than MULTIP rats. Moreover, in PRIMIP rats, NAL reduced suckling-induced PRL release, while failing to affect PRL release. in MULTIP rats. These results indicate that alterations (tolerance) develop in the endogenous opioid system as a consequence of previous pregnancies and/or lactations. Supported by NIDA (DA04291) & NIH (HD19789).

EJACIJIATION INCREASES POSTICTAL BEHAVIORAL DEPRESSION IN MEDIAL PREOPTIC AREA KINDLED RATS: EVIDENCE FOR OPIOID INVOLVEMENT. R. Paredes*, C. Manero*, A.E. Haller*, R. Alvarado* and A. Agmo. Escuela de Psicología, Universidad Anahuac y Laboratorio de Formación Reticular INNN. México D.F.

It has been postulated that ejaculation is achieved when a reward threshold is reached through the release of opioid peptides during sexual activity. Others have postulated that the activation of GABA produces the inhibition of sexual behavior normally ocurring after ejaculation. The present experiments tested these hypothesis measuring the opioid dependent postictal behavioral depression (PBD) that ocurs after electrical kindling.

Sexually experienced male rats were kindled in the medial preoptic area (MPOA) or the amygdala (AMG). Once kindling had been established the PBD was measured after a standard kindling stimulus applied 2 min after ejaculation. The PBD was significantly increased after ejaculation. This effect was seen in MPOA but not in AMG kindled rats. The effects of ejaculation on PBD were blocked by naloxone. No effect was observed on seizure intensity and afterdischarge duration after ejaculation. It appears that opioid release during sexual behavior enhances the effects of those release after a kindled seizure, increasing the duration of the PBD. These results confirm that opioid peptides, rather than GABA, are release after ejaculation.

DIFFERENTIAL EFFECTS OF SPECIFIC ENDOGENOUS OPIOID SYSTEMS ON AFFECTIVE BEHAVIORS IN NEONATAL RATS. P. KEHOE, C. BOYLAN*, AND W. SHOEMAKER. Trinity College and Univ. of Conn. Health Center, Hartford, Ct. 06106.

Previous results show that endogenous opioid systems mediate affective responses in neonatal rats. Opioids modulate isolation-induced vocalizing and analgesia in infants. Morphine decreases calls and produces analgesia as well as promotes positive associations with novel stimuli in rat pups. The opioid systems consist of different receptor types (mu, delta and kappa) and morphine may exerts its effects primarily as a mu receptor agonist. Functional effects of these subsystems may vary producing differential behavioral outcomes. To assess the influence of the kappa receptor system on these neonatal behaviors, the kappa agonist, U-50,488H, was tested in both the positive conditioning paradigm and response to pain and isolation stress. In contrast to morphine's effects, the kappa agonist produced no positive associative conditioning. Moreover, U-50,455H significantly increased vocalizations but did produce an analgesic response that was naltrexone-reversible. Mu receptor functioning seems to have a positive valence in the above behaviors as opposed to a somewhat negative one for the kappa system. These differential effects may be in part due to the interaction of the dopaminergic and opioidergic systems.

BEHAVIORAL INTERACTIONS BETWEEN MORPHINE AND MK-801: ANALGESIA, TOLERANCE, DEPENDENCE AND LETHALITY. K. A. Trujillo and H. Akil, Mental Health Research Institute, University of Michigan, Ann Arbor,

The non-competitive NMDA receptor antagonist MK-801 has been found to have a unique and interesting profile of behavioral actions, suggesting that this drug might be of use in the treatment of a number of clinical disorders. In the present studies we examined behavioral interactions between MK-801 and the prototypical opiate agonist morphine, following acute or chronic treatment. Adult, male Sprague Dawley rats were administered saline or MK-801 (0.03, 0.1, or 0.3 mg/kg i.p.) followed 30 minutes later by saline or morphine sulfate (1.0, 3.0, or 10.0 mg/kg s.c.). Analgesia was assessed by the tail flick assay 60 minutes following the second injection. In chronic studies animals were treated twice daily for 9 days, as above, with MK-801 followed 30 minutes later by morphine (10 mg/kg s.c.), and analgesia determined on days 1, 3, 5, 7 and 9. On day 10, withdrawal was precipitated by naloxone (2.0 mg/kg s.c.) 60 minutes following morphine treatment (10 mg/kg s.c.).

Acutely, MK-801 had no significant effects on analgesia, nor did it significantly

affect the analgesic actions of morphine. At 0.3 mg/kg, MK-801 dramatically potentiated the lethal effects of morphine, shifting the apparent LD50 approximately 10-fold, from 100 mg/kg to 10 mg/kg. In chronic studies MK-801 dose-dependently attenuated the development of tolerance to morphine. Although 0.03 mg/kg had no effect on the development of tolerance, animals pretreated with 0.1 mg/kg showed significant morphine analgesia on days 7 and 9, when saline pretreated animals were approaching complete tolerance. Additionally, MK-801 dose-dependently attenuated the number of escape jumps observed on day 10 during naloxone-precipitated withdrawal. These results suggest that excitatory amino acid systems may be important in several opiate-mediated behaviors. This work was supported by NIDA NRSA DA05336 (K.A.T.), and NIDA DA02265 and NIMH MH422251 (H.A.).

INTERFERENCE BETWEEN OPIOID AND NONOPIOID MECHANISMS OF CALMING IN 10-DAY-OLD RATS <u>E.M. Blass & L. Brunson*</u>. Depts. of Psych. & Nutrition, Cornell University, Ithaca, NY 14853

To better understand mechanisms underlying adjustments to maternal separation, 10-day-old rats were separated from their mother for six consecutive 3-min. epochs at 34°C. Between each epoch rats contacted their anesthetized dam for either 1 min. (N=10) or 5 min (N=10). Rate of ultrasonic vocalization was the dependent measure. Ultrasonic vocalization peaked during the third isolation period and then declined for both contact groups. Rats that had only 1-min. contact between separation epochs vocalized more than 5-min. contact

To determine whether the vocalization decrease was opioid-mediated, rats is each contact group were injected (i.p.) with either naltrexone (0.5 mg/KG BW) or isotonic saline vehicle (experimenters were uninformed as to syringe contents) and tested as above. Rather than increase vocalization, naltrexone markedly decreased vocalization for both 1-min. and 5-min. contact groups (p< .001) suggesting that quieting influences during the separation epochs were cast by the mother through nonopioid pathways and that antagonizing endogenous opioid pathways enhanced the maternal effect.

It followed that a low dose of morphine should enhance rate of vocalization. Rats injected with .0625 mg/Kg BW emitted significantly more vocalizations than did control rats (p<.001) for both 1- and 5-min. groups.

Under circumstances of considerable duress, opioid and nonopioid mediated coping systems act antagonistically in Day 10 rats.

EFFECT OF β-CYCLODEXTRIN ON ANALGESIA PRODUCED BY INTRATHECALLY ADMINISTERED OPIOIDS. J. JANG. H. HILL* & T.L. YAKSH. Dept. of Anesth., Univ. of Calif., San Diego. CA 92093 & Fred Hutchinson Cancer Center,* Seattle, WA 98104
Hydroxypropyl-β-cyclodextrin (CDEX), a crown ether, forms inclusion complexes in its hydrophobic cavity with the lipophilic portion of drug molecule by a non-covalent bond. This may increase water solubility of lipid soluble drugs and thereby reduce their vascular redistribution after intrathecal (IT) administration. CDEX may thus prolong the analgesic action and reduce the supraspinal actions of IT opioids. In this study, opioids (morphine, lotentanil, altentanil and sufentanil) with and without CDEX (20%, 2%, 0.2%, 0.02% and 0.002% in sterile water) were administered in rats with chronic IT catheters. CDEX prolonged the duration of analgesia (52.5 hot plate: HP) produced by opioids and reduced the catalepsy otherwise produced by a supermaximal dose of IT morphine. The magnitude of the facilitatory effect was dependent upon CDEX concentration and varied with drug lipid partition coefficient. Drug levels in plasma and spinal cord at time of peak effect confirmed delayed redistribution. No toxicity was observed at highest CDEX (40%) concentration. Data indicate CDEX may be a useful IT vehicle for poorly soluble drugs. soluble drugs .

ARE CHANGES IN AMYGDALOID OPIATE BINDING CONTROLLED BY GONADAL STEROIDS, PHOTOPERIOD, OR A COMBINATION OF THESE VARIABLES? M.L. Tubbiola and E.L. Bittman, Dept. of Zoology, University of Massachusetts, Amherst, MA 01003

Short days (SD) reduce binding of ³H-naloxone (NAL), an opiate antagonist, in the medial armygdala (M) of male golden hamsters (Mesocricetus auratus). This reduction may be due to SD-induced decreases in circulating testosterone (T), a steroid independent effect of photoperiod, or an interaction between T and daylength. To answer this question specific NAL binding was measured by quantitative autoradiography in 9 groups of male golden hamsters after 12 weeks exposure to long (LD) or SD. Hamsters were left intact (Int), castrated (Cas), castrated and immediately given T implants to maintain T (Cas+T), castrated and given T implants after 5 weeks of LD to reinstate (Cas...T), or pinealectomized (Pinx). Short days reduced NAL binding in M, but not other amygdaloid nuclei or in the bed nucleus of the stria terminalis, of intact hamsters (p<0.05). Pinealectomy reversed this effect (p<0.05). Castration elevated NAL binding in M and other amygdaloid nuclei (p<0.05). T reversed the rise in NAL binding only in Cas+T hamsters housed in LD. Although short days increased NAL binding in M of Cas+T hamsters (p<0.05), photoperiod had no influence on NAL binding in Cas or Cas...T groups

These findings indicate that T regulates NAL binding in several amygdaloid nuclei. Daylength affects opiate receptor concentrations in M only if T is maintained; however the photoperiod effect is reversed in Cas+T as compared to intact hamsters. Changes in M opiate binding may explain deficits in copulatory behavior of SD hamsters with T maintenance, and diminished responsiveness to exogenous androgens in chronic castrates. NALTREXONE DOES NOT DISRUPT ACQUISITION OR EXPRESSION OF PAVLOVIAN CONDITIONED INHIBITION OF FEAR J. Landeira-Fernandez, M. S. Fanselow, J. P. DeCola, & J. J. Kim, Dept. of Psychology, UCLA, Los Angeles, CA 90024

Naltrexone (NTX) enhances acquisition of excitatory fear conditioning but its effect on inhibitory conditioning is untested. A neutral stimulus becomes a conditioned inhibitor (CI) when it is presented without reinforcement in conjunction with another stimulus that is usually reinforced. On alternate days of a 16 day procedure, rats were exposed to either a tone paired with shock or a simultaneous tone/light compound that was not paired with shock. Half the rats were injected with NTX prior to the training sessions on days where they received tone/light compounds (CI Training Days). No drug was given on tone shock days. To assess CI, a fear baseline was established by exposing rats to a few shocks in the novel context. CI was indicated by a reduction in freezing during presentation of the the light. For this test, half of the subjects in each training drug condition received NTX; the others received saline. A separate control group was used to assess acquisition of CI. There was reliable CI but NTX did not reduce acquisition or expression of CI. These results indicate that endogenous opioids do not play a role in conditioned inhibition of fear.

CONDITIONED WITHDRAWAL BEHAVIOR AFTER FOCAL BRAIN STIMULATION. B.E. Thorn, T. Nicholson, G.E.Jone and C. Runge. Univ. AL, Tuscaloosa, AL 35487. Previous reports indicate that "chronic" (2 hr.) focal brain stimulation (FBS) of the periaqueductal gray (PAG) followed by naloxone results in with opiate-like withdrawal (Williams & Thorn, 1984). In that study, animals served as their own controls, lst given sham FBS & 4 days there-after, given real FBS for 2 hrs followed by nalo-xone. This study examined whether the order of presentation of the sham vs. real FBS trial would influence the behaviors obtained. 16 rats received electrode implants electrodes into the ventral Half the animals were 1st given sham FBS, while the other half were 1st given 2 hrs of real FBS at the current intensity previously shown to Following the trial, produce analgesia. animals were injected with lmg/kg naloxone and observed for opiate withdrawal signs. Animals receiving sham stimulation lst showed a significant difference between the sham trial and the real trial in the number of opiate withdrawal signs, animals receiving the sham trial 2nd did not. These results may be explained as a classical conditioning effect of brain stimulation.

MORPHINE HYPERALGESIC EFFECTS AGAINST CHEMO-INFLAMMATORY PAIN IN LEGHORN COCKERELS. R. A. Hughes and K. J. Sufka. Dept. of Psychology, Iowa State University, Ames, IA 50011-3180.

We recently identified a biological model in which responses to a noxious thermal stimulus were enhanced by morphine. This atypical hyperalgesic effect is naloxone reversible (Hughes, R. A., Pharmac. Biochem. Behav., 35: 567, 1990) and has dose and temporal characteristics of morphine analgesia (Sufka, K. J. & Hughes, R. A., Physiol. Behav., 47:385, 1990. The present study extends this unusual opioid hyperalgesic effect to include chemoninflammatory nociception. Formalin (1% sc) in the plantar region of the foot reliably elicited discrete footlifts in young leghorn cockerels. This effect was enhanced by morphine sulfate (2.5 mg/kg, im.) and reversed by naloxone (5.0 mg/kg, im). Other opioid mediated responses were not atypical. Body temperature and respiration were reduced by morphine; naloxone reversed these effects.

05 10

MU OPIOID RECEPTOR ANTAGONISTS ENHANCE PAVLOVIAN FEAR CONDITIONING. M. S. Fanselow¹, J. J. Kim¹, S. Young*¹, J. P. DeCola*¹, J. Landeira-Fernandez¹, D. J. Calcagnetti², & F. J. Helmstetter². ¹Dept. of Psychology, UCLA, Los Angeles, CA 90024 & ²Dept. of Psychology, Dartmouth College, Hanover, NH 03755.

Opioid antagonists have two major affects on Pavlovian fear conditioning. First, they attenuate expression of fear-induced analgesia if given prior to testing. Second, they enhance acquisition of fear conditioning if they are given prior to training. Previous research using selective opioid antagonists, administered intracerebroventricularly, has implicated mu and delta but not kappa opioid receptors in the analgesia. The present studies used intracerebroventricular application of these selective antagonist treatments to determine which opioid receptor types result in the enhancement of conditioning. Two selective mu receptor antagonists, Cys2Tyr3Orn5Pen7-amide and naloxonazine dramatically enhanced fear conditioning as measured by the freezing response. Neither the delta opioid antagonists, 16-Methyl Cyprenorphine and naltrindole, nor the kappa opioid antagonist, nor-Binaltorphimine, enhanced conditioning. These data are consistent with our earlier suggestion that the μ_1 receptors mediating fear-induced analgesia also modulate acquisition of conditional fear.

THE EFFECTS OF LOW CURRENT TRANSCRANIAL ELECTROSTIMULATION & MORPHINE ON SOMATOSENSORY EVOKED POTENTIALS IN THE SOMATOSENSORY CORTEX & THALAMUS, C. Hymel* & M. Skolnick, Neurophysiology Res Center, Univ Texas Hlth Sci Cntr, Houston, 1343 Moursund, Houston, TX 77030 Application of low current transcranial electrostim-

Application of low current transcranial electrostimulation (TE) produces naloxone-reversible analgesic effects on Sprague-Dawley rats. Alternate forms of TE have also been shown to potentiate the analgesic effects of morphine. The aim of this research is to determine the combined effects of TE and morphine on somatosensory evoked potentials (SEP's) in specific nuclear regions of the thalamus and somethetic cortex using single recording electrodes to test the ability of TE to potentiate the analgesic effects of morphine.

Sites for SEP recordings were taken from pilot data in which specific nuclear regions were found in the somatosensory cortex and thalamus in which SEP responses to electric shock applied to the rat tail were significantly suppressed after TE treatment. In-brain SEP potential recording techniques were exploited to record the aggregate electrical activity of the neurons in close proximity to the probe in response to tail shock stimulation.

The results show both TE and morphine, acting alone, suppress SEP's in target nuclei. The combination of TE and morphine at various doses increases SEP suppression above that of TE or morphine alone.

95.16

OPIOID-RECEPTOR MEDIATION OF MORPHINE-INDUCED HYPERALGESIA IN DOMESTIC FOWL. K. J. Sufka, R. A. Hughes, and J. Giordano. Dept. of Psychology, Iowa State Univ., Ames, IA 50011-3180.

Recent research in this lab demonstrated that morphine produced a strain-dependent, naloxone-reversible hyperalgesic response to a noxious thermal stimulus in domestic fowl. The present study attempted to identify opioid-receptor mediation of this atypical opiate effect. Patterns of morphine (1.25 - 5.0 mg/kg/ml, im) hyperalgesia were examined against pretreatment with the selective mu antagonist beta-funaltrexamine, delta antagonist naltrindole, or kappa antagonist nor-binaltorphamine (10 ug/Sul, icv) on a hot-plate test (60°C) in 14-day old domestic fowl. Morphine produced a dose-dependent hyperalgesia. Beta-FNA attenuated this hyperalgesic effect, while nor-BNI only partially reduced hyperalgesia at the highest morphine dose tested. Pretreatment with NTI failed to block morphine effects. These results suggest that atypical morphine hyperalgesia is mediated, in part, by mu and kappa receptors in domestic fowl.

ENHANCEMENT BY AMNIOTIC FLUID OF DIFFERENT LEVELS OF VS-INDUCED ANALGESIA. A.C. Thompson, P. Abbott, J.C. Doerr, E.F. Ferguson* and M.B. Kristal. Dept. of Psychology, University at Buffalo, Buffalo, NY 14260.

A substance (POEF) in amniotic fluid (AF) and placenta has been shown to enhance analgesia produced by morphine, late-pregnancy, footshock, and vaginal/cervical stimulation (VS). Several of our studies suggest that the degree of enhancement is a function of the amount of analgesia being generated. We have examined this effect further in non-pregnant rats by testing the effect of AF ingestion on several levels of VS-induced analgesia.

Rats received AF (1/4 mt) or saline by orogastric intubation. Ten min later, pain threshold (measured as tail-flick latency) was determined before and during application of VS pressures of either 75g, 125g, 175g, or 225g.

The statistical analysis of the pain threshold data found AF to enhance VS-induced analgesia at the 125-g level (average increase in pain threshold from baseline was 36.6% [\pm 13.8] among control rats and 75.1% [\pm 17.67] among AF-treated rats). No significant effects were produced by AF mingestion on stimulation of 75g, 175g, or 225g. As expected, the effect of 1/4 ml AF on VS-induced analgesia depended on the dose of VS. An unexpected effect of AF on the induction of pseudopregnancy (PSP) among rats receiving 225g of VS was found such that fewer AF-treated rats became PSP (10%) than control rats (44%).

Results are considered in light of the role of amniotic fluid ingestion and vaginal/cervical stimulation in periparturitional analgesia.

Supported by NSF grant BNS88-19837 awarded to M.B.K.

95.18

AMNIOTIC-FLUID INGESTION ENHANCES ANALGESIA PRODUCED BY THE CENTRAL ACTION OF MORPHINE. J.M. Di Pitro. A.C. Thompson and M.B. Kristal. Dept. of Psychology, University at Buffalo, Buffalo Ny 14260.

Ingestion of amniotic fluid (AF) and placenta has been shown to enhance

Ingestion of amniotic fluid (AF) and placenta has been shown to enhance the analgesia produced by morphine, late-pregnancy, footshock, and vaginal/cervical stimulation in the rat. The present studies examined whether the active substance in amniotic fluid (Placental Opioid-Enhancing Factor, POEF) affects the central or peripheral actions of morphine. First, quaternary naltrexone (QN), an opiate antagonist that does not readily cross the blood-brain barrier, was used (8mg/kg, sc, or saline) to block peripheral opiate receptors. Rats were given QN 20 min prior to measuring baseline pain threshold (using a tail-flick latency [TFL] test). Immediately after, MS (3mg/kg, ip) or saline was given. AF (0.2ml) or beet bouillon was intubated orogastrically 15 min after MS injection. Pain threshold was then measured 15 min after intubation. The results indicate that QN attenuated MS-induced analgesia (by eliminating the peripheral effect), but did not prevent enhancement by AF.

Second, the effect of AF on analgesia induced by centrally-administered MS was assessed, both with and without systemic QN. Rats were given icv injections of MS (2.5µg/2.0µl) or saline. AF or control intubation occurred 10 min later. TFL was measured 20 and 40 min after intubation. The results show that AF significantly enhanced the analgesia produced by icv MS (about 92% above baseline at 20 min, about 98% above baseline at 40 min; our dose of MS, alone, induced only about a 10% elevation in pain threshold from baseline.

threshold from baseline.

These results are consistent with the hypothesis that amniotic fluid ingestion primarily enhances the central action of morphine.

Supported by NSF grant BNS88-19837 awarded to M.B.K.

BRAIN GLUTAMATE SYSTEMS

ENDOGENOUS INHIBITORS OF BRAIN GLUTAMATE DECARBOXYLASE. J.-Y. Wu, J. Bao*, M. Yarom, X.-W. Tang*, Y. H. Lee* and Y. Yan*. Department of Physiology and Cell Biology, University of Kansas, Lawrence, KS 66045.

The steady state level of GABA is believed to be determined by its synthetic enzyme, L-glutamate decarboxylase (GAD). Although GAD has been purified and studied extensively in terms of its cellular and subcellular distribution, little is known about its regulation. Hence, this has been purified and studied extensively in terms of its cellular and subcellular distribution, little is known about its regulation. Hence, this study was designed to search for endogenous brain substances that can regulate GAD activity. Briefly, GAD was prepared from pig brain as previously described [J. Neurochem. 44, 957 (1985)]. The P₂ membranes thus obtained were suspended in 50 mM Tris-Citrate (pH 7.0) and subjected to freezing and thawing, followed by extensive extraction with 5 mM Tris-Cl, (pH 7.0). The extract was filtered through hollow fiber PM 10 (exclusive limit: 10,000 daltons) and the filtrate obtained was concentrated and used as the starting material for endogenous inhibitors (Els). It was found that 50 µl of crude El preparation inhibited 73% of soluble GAD activity. Similar results were obtained with membrane associated GAD. Els were purified through Bio-Gel P2 column (exclusion limit: 2000-dalton), one was eluted after the void volume but slightly ahead of standard L-glutamate and GABA and the other one was eluted considerably behind the standard amino acids indicating that they are smaller than 2000-dalton. These inhibitors were excluded by cation exchanger but retained by anion exchanger suggesting that they are negatively charged. Els were heat stable, were not chelated by EDTA and behaved as competitive inhibitors since they increased the K_m of L-glutamate for GAD without changing the V_{max}. The exact chemical structure of Els remains to be determined. (Supported by NIH Grant NS20978 and BNS-8820581 from NSF).

GABA TURNOVER AND GAD IN CULTURED GABAERGIC NEURONS FROM RAT CORTEX. K. Rimvall and D.L. Martin. Wadsworth Center for Labs. and Res., NY State Dept. Health, Albany, NY 12201.

Dissociated cells from prenatal (E20) rat cortex were cultured in serum-free, defined medium. Cells did not survive unless coverslips were inverted at 1 DIV, thus apparently providing them with a suitable microenvironment. Immunocytochemistry indicated that at least 80% of cells grown in serum-containing medium were GABAergic. Studies of the fraction of GABAergic neurons in serum-free medium are not yet complete. Biochemical studies were carried out with inverted, serum-free cultures. GABA turnover rates, as inverted, serum-free cultures. GABA turnover rates, as measured by inhibiting GABA-T with gabaculine, were approximately 20% of GAD activity, as measured by ¹⁴CO₂-trapping. Two anti-GAD antisera 1440 (Lab. Clin. Sci., NIMH) and K2 (Houser et al., Abst. Soc. Neurosci., 15:488, 1989) and a monoclonal antibody GAD-6 (Chang and Gottlieb, J. Neurosci., 8:2122, 1089) received the control of the 8:2123, 1988) recognize the three forms of GAD described in the literature (59, 63 and 67 kDa) to varying degrees. Immunocytochemistry of inverted, serum-free cultures revealed that neuronal cell bodies and neurites are stained by 1440, K2 and GAD-6. Western blots of homogenized cultures with the same antibody/antisera confirm the presence of the 63- and the 67-kDa forms of GAD and possibly the 59-kDa form. The significance and in vitro development of the various GAD forms will be the subject of further investigations using this model system of GABAergic function. Supported by Grants MH35664 and NS853102 from USPHS-DHHS

THE APOENZYME OF GAD IS PRESENT PREDOMINANTLY AS THE 63-kDa FORM OF GAD IN SYNAPTOSOMES AND RAT BRAIN.

D. L. Martin, S.B. Martin, S.J. Wu, and N. Espina. Wadsworth Center for Labs. and Res. NY State Dept. Health, Albany, NY 12201-0509, and Dept. Environ. Health and Toxicology, SUNY Albany.

Glutamate decarboxylase is regulated, at least in part, by the interconversion of inactive apoenzyme (GAD without bound cofactor, pyridoxal-P) and active holoGAD. Previous studies from several groups have shown the presence of 59, 63 and 67-kDa forms of GAD in brain. We have investigated which forms are present as apoGAD in synaptosomes and in cortex, caudate, hippocampus and cerebellum of rat brain. Endogenous apoGAD was labeled by incubating synaptosomes or 2mm punches of each region for 15 min with ³²P-pyridoxal-P in Triton X-100-containing lysis buffer followed by reduction with NaBH₄ to covalently link the ³²P-pyridoxal-P to GAD. Proteins were separated by SDS-PAGE. Punches were obtained from 1mm slices of frozen brain from heads decapitated into liquid N₂. Synaptosomes contained a major labeled band at 63 kDa and remarkably few other strongly-labeled proteins. The 63-kDa band was identified as GAD by immunoaffinity chromatography with the GAD-1 antibody, and its labeling was blocked by 4-deoxypyridoxine-P, which inhibits labeling of purified GAD. Labeling at 59 and 67 kDa was barely discernable. More proteins were labeled in punches. Western blots of punch extracts were stained proteins were labeled in punches. Western blots of punch extracts were stained with 3 anti-GAD antibodies [1440 (Oertel et al., Neurosci. 6:2681, 1981), K2 (Houser et al., Abst. Soc. Neurosci.) and GAD-6 (Chang and Gottlieb, J. Neurosci. 8:2123, 1988] which recognize the 59-, 63-, and 67-kDa bands to varying degrees. The 63-kDa band was intensely labeled and corresponded to the major band stained with 1440 and GAD-6. A minor labelled band corresponded to the major K2-stained band. Labeling of each band was blocked by deoxypyridoxine-P and the labeled 63-kDa band was identified by immunoaffinity purification with GAD-1. Supported by Grant MH35664 from NIMH.

96.4

DISTRIBUTION OF IRON IN CHICK BRAIN: OVERLAP WITH GABA DISTRIBUTION OF IRON IN CHICK BRAIN: OVERLAP WITH GABA.

TRANSFERRIN LOCALIZATIONS. M.M. Beck and J.M. Hill¹.

Dept. of Animal Sci., Univ. of Nebraska, Lincoln, NE
68583, and Peptide Design, 12321 Middlebrook Rd.,

Germantown, MD 20874.

The role of brain iron is not well understood even though many facts about its distribution in mammals are known. It has been suggested that iron-rich areas of rat brain correlate with, among others, metabolic activity (Hill, J.M. and Switzer, R.C., III, Neurosci., 11, 1984) and GABA utilization (Hill, J.M., Brain Res., 342, 1985). To date, iron has not been demonstrated histochemically in appreciable amounts in avian brain. In the present study, brains of 10-day-old White Leghorn chicks were sectioned at 30 μ m, thaw-mounted onto slides, air-dried, and stained with Perls'-DAB. Nuclei high in iron belonged, generally, to three functional groups: Auditory: An, La, MCC, FPL, PP; <u>Vestibular</u>: VeM, VeL, Ta, Cb; and <u>Oculomotor</u>: ROT, BCS, AL, QF, SAC, SGC. Extensive overlap was found between these areas and GABA localization in the chick (Lewis, P.A. and M.M. Beck, Neurosci. Abstr. 15, 1989). Both iron and GABA were primarily in glial cells, although several of the iron-containing nuclei also had many GABAergic terminals. Preliminary scans of 1231-transferrin receptors in chick brain indicate that a similar distribution pattern exists. The results provide additional support for an interactive relationship between brain iron and GABA metabolism.

THE UPTAKE OF N-ACETYLASPARTATE INTO PRIMARY MURINE BRAIN CELLS IN CULTURE. O.H. Saab* and J.H. Department of Biology, Georgetown University, Neale. Washington, DC 20057.

N-Acetylaspartate (NAA), which is present in very high concentrations in the central nervous system, is produced by acetylation of aspartate and by the action of a dipeptidase on N-acetylaspartylglutamate (NAAG), and has been implicated in myelin biosynthesis. The objective of this research was to determine the fate of NAA in the extracellular/synaptic space following the neural release and hydrolysis of NAAG. Murine brain cells were maintained in dissociated cell culture for 14-17 days. The cells were then incubated with 3H-NAA under different conditions in order to characterize the metabolism and transport. The results indicate a carrier mediated, sodium dependent transport mechanism for NAA with a K_M of about 1.5 uM. The neurons rather than the glial cells seemed most responsible for the uptake. The transport mechanism appears to be similar, but not identical, to other acidic amino acid transporters. Little evidence was obtained for the extracellular deacetylation of NAA.

TRANSFER AND EXPRESSION OF GLUTAMATE DECARBOXYLASE CDNA IN MAMMALIAN CELLS. C.H.J. Ruppert, N.J.K.

Tillakaratne, M.G. Erlander, A. Torbati, and A.J.

Tobin, Dept. of Biology, UCIA, Los Angles, CA 90024.

Two cDNAs, coding for two different forms of the Two cDNAs, coding for two different forms of the GABA-synthesizing enzyme glutamate decarboxylase (GAD₆₅ and GAD₆₇) have been isolated in this laboratory. The availability of these cDNAs allowed us to design GAD-expressing cell lines. We cloned the coding regions of both cDNAs into the retroviral vector system of Miller and Rosman (<u>Biotechniques 7</u>, 980, 1989) and into plasmid vectors with inducible Stable clones of PC-12 and NIH3T3 cells show GAD activity, at about 10% the level present in brain homogenates. Retroviral vectors provide an efficient integration system with a wide host range that should enable us to program GABA production in many types of neuronal and non-neuronal cells, both in wive and in vitre. This capability would allow us to approach questions concerning the specific functional properties of the two GADs in different cell types and the influence of GABA production on developmental processes in the nervous system. Supported by NS 20256 to AJT and a fellowship from the Deutsche Forschungsgemeinschaft to CHJR.

CHARACTERIZATION OF SODIUM-DEPENDENT GLUTAMATE UPTAKE BY CLONAL CELL LINES. J.D. Sinor, J.S. Shumsky and M.B. Robinson. Children's Seashore House, Depts. Ped. and Pharm. Univ. of PA, Philadelphia PA,19104.

Previous studies have demonstrated that dihydrokainate (DHK) and α-aminoadipate (α-AAD) are region specific inhibitors of brain high affinity sodium-dependent glutamate uptake (Robinson, Soc Neurosci. Abs. 15 (1989) 602). Cerebellar uptake is insensitive to inhibition by DHK and is more sensitive to inhibition by α -AAD than brainstem and forebrain regions. The goal of these studies is to identify cell lines that express these pharmacologically distinct sodium-dependent uptake processes. The two cell lines characterized were a medulloblastoma, CHP 707, and C6 glioma. In both of these cell lines, greater than 80% of the accumulation of L-[3H]-glutamate was sodium-dependent. Eadie-Hofstee analysis of sodium-dependent glutamate uptake was Eadie-Hotstee analysis of sodium-dependent glutamate uptake was consistent with a single site in C6 glioma with Km of $26 \,\mu\text{M}$ and a Vmax of 980 pmol/mg protein/min whereas the concentration dependence of glutamate uptake in CHP 707 supports the presence of high and low affinity sites. The sensitivity of the sodium-dependent glutamate uptake to DHK, α -AAD, and cysteine sulfinate (CS) was examined at a low concentration of glutamate (0.5 μ M). In C6 glioma, the IC50's were as follows: DHK = 1300 μ M, α -AAD = 720 μ M, and 7.1 µM. These inhibition curves were consistent with a single site. In preliminary data, the sensitivity of sodium-dependent uptake by CHP 707 to these inhibitors was similar to that observed in C6 glioma. The ranked potencies of these inhibition data are more consistent with the uptake observed in forebrain or brainstem and are inconsistent with that observed in cerebellum.

TONIC STIMULATORY EFFECT OF THE DOPAMINERGIC INNERVATION ON THE SYNTHESIS OF GABA IN SUBSTANTIA NIGRA PARS RETICULATA AND NEOSTRIATUM IN THE RAT. J.Aceves, B. Florán*, J.Benitez* and D.Martínez-Fong*. Dept. Physiology. CINVESTAV-IPN. 07000 México, D.F. México. Dopaminergic innervation seems to stimulate the synthesis of GABA. Thus a decrease of GAB activity occurs in

sis of GABA. Thus a decrease of GAD activity occurs in basal ganglia of Parkinsonian patients (McGeer and McGeer, J. Neurochem. 26:25, 1976), and chronic blockade of dopaminergic receptors with haloperidol reduces GAD activity in s. nigra reticulata and entopeduncular nucleus (Itoh, <u>Psychopharmacology</u> 79:169, 1983). Here we tested if the <u>dopaminergic</u> influence on the synthesis of GABA could be shown by unilaterally lesioning the dopaminergic nigrostriatal system with 6-hydroxydopamine and comparing the GAD activity in slices of s. nigra reticulata and neostriatum of the lesioned and intact sides. GAD activity was assessed by the accumulation of GABA after inhibiting GABA transaminase with aminooxyacetic acid (10 µM). After 2 weeks of the lesion, GABA accumulation in the lesioned side was markedly reduced in s. nigra reticulata (lesioned: 7.9 ± 0.3; intact: 18.9 ± 0.8 µg/mg prot., (lesioned: 7.9 ± 0.3; intact: 18.9 ± 0.8 $\mu g/mg$ proc., n=4, after 20 min of AOAA), and slightly but significantly (P < 0.02) reduced in neostriatum (lesioned 2.1 ± 0.1; intact: 2.9 ± 0.2; n=8). In s. nigra reticulata, GAD activity was reduced even 2 months after lesioning. These results support the idea of a tonic modulation of the synthesis of GABA by dopamine in the basal ganglia.

CARDIOVASCULAR REGULATION: BULBOSPINAL MECHANISMS

97.1

TONIC SYMPATHETIC CONTROL OF THE KIDNEY, SPLEEN AND HEART ORIGINATING FROM VENTROLATERAL PONTINE NEURONS IN RATS.

K. Hayes, D.J. Beluli and L.C. Weaver. The John. P. Robarts Research Institute and Department of Physiology, University of Western Ontario, London, Ontario, Canada.

Recent studies have demonstrated that regions outside the

restral ventrolateral medulla (RVIM) may contribute to tonic excitation of sympathetic nerves. We explored the ventrolateral pons to search for regions providing tonic control of arterial pressure (AP), heart rate (HR) and activity of renal and splenic sympathetic nerves. In rats anesthetized with urethane or Saffan, discharge of neurons in this region was inhibited by unilateral microinjections of glycine (50nl). Seven injections in urethane rats decreased AP by 17±7 mmHg, HR by 9±3 bpm and discharge of renal (17±8%) and splenic (19±9%) nerves. Eight injections in Saffan rats decreased AP by 19±7 mmHg, HR by 25±9 bpm and activity of renal (47±17%) and splenic (59±26%) nerves. These responses were evoked from sites 0.5-2.0 mm dorsal to the ventral surface and 1-3 mm rostral to the RVIM. In contrast, five injections of glycine (either anesthesia) into sites close to the A5 cell group caused increases in renal (22±2%) and splenic (14±1%) nerve activity with little or no change in AP or HR. These experiments demonstrate that tonic excitatory influences on sympathetic outflow affecting AP, HR and abdominal sympathetic nerves can be generated by rostral ventrolateral medulla (RVLM) may contribute to tonic excitation of sympathetic nerves. We explored the AP, HR and abdominal sympathetic nerves can be generated by neurons significantly rostral to the RVLM. These influences are particularly evident in Saffan-anesthetized rats. Moreover, tonic inhibition of renal and splenic sympathetic discharge may originate from neurons in the ventrolateral pons. (Support: Ontario Heart & Stroke Foundation).

97.2

DIFFERENTIAL CONTROL OF RENAL AND SPLENIG NERVES IS NOT DUE TO TOPOGRAPHICAL REPRESENTATION IN VENTROLATERAL MEDULLA.

DIFFERENTIAL CONTROL OF RENAL AND SPLENIC NERVES IS NOT DUE TO TOPOCRAPHICAL REPRESENTATION IN VENTROLATERAL MEDULIA. Beluli, D.J.* and L.C. Weaver. Robarts Research Inst. and the Dept. of Physiol. Univ. of Western Ontario, London, CAN The capacity of the sympathetic nervous system to discharge differentially may be due to topographical organization within medullary vasomotor neurons. To search for topography in anesthetized rats, 15 nl (25 nMol) of the excitatory amino acid D.L-homocysteic acid (DLH) was microinjected into the ventrolateral medulla (VLM). The sympathetic discharge of either renal nerves (n-6), splenic nerves (n-7), or both nerves (n-6), splenic nerves (n-7), or both nerves (n-6) bull over a large area of the VLM, but the largest increases in renal and splenic activity occured after injection into the rostral VLM, while all the decreases in activity occured after injection into the caudal VLM. Although no topographical organization was found, a specific relationship in the magnitudes of responses between renal and splenic nerves was observed. Mean excitatory and inhibitory responses of splenic nerves were about half as large as those of renal nerves in all animals. When activity of both nerves was recorded simultaneously, splenic excitatory (rostral VLM) responses to DLH were only 44% of the renal responses and splenic inhibitory (caudal VLM) responses were 61% of the renal responses. In summary, mechanisms providing differential medullary control of renal and splenic nerves do not involve spatial organization of neuronal groups in the VLM. Support: MRC Canada & Rick Hansen Legacy Fund.

RESPONSES OF ADRENAL SYMPATHETIC PREGANGLIONIC NEURONS (SPNs) TO STIMULATION OF THE ROSTRAL VENTROLATERAL MEDULLA (RVL): EVIDENCE FOR FUNCTIONAL SPECIFICITY IN MEDULLOSPINAL SYMPATHETIC CONTROL. S.F. Morrison and D.J. Reis. Cornell University Medical College, Div. of Neurobiol., Dept. of Neurol. and Neurosci., New York, NY 10021.

University Medical College, Div. of Neurobiol., Dept. of Neurol. and Neurosci., New York, NY 10021.

Although reticulospinal sympathoexcitatory inputs from the RVL play a major role in regulating the discharge of sympathetic nerves innervating the heart and vasculature, the influence of these inputs on nerves innervating the adrenal gland is less well characterized. Thus, we examined the responses to single RVL stimuli (50-200 μA) of SPNs in spinal segments T7-T8 that innervate the adrenal gland in urethane/chloralose-anesthetized rats. Within the population of SPNs with axons in the greater splanchnic nerve, those antidromically activated from the adrenal nerve had significantly higher basal firing rates and slower axonal conduction velocities. Our previous results indicated that the RVL stimulus-evoked responses of splanchnic SPNs may be divided into four distinct patterns. The RVL-stimulus evoked responses of 80% of adrenal SPNs corresponded to a unique response pattern which was observed in only 10% of splanchnic SPNs. The response pattern of most adrenal SPNs was biphasic: an initial decrease in spontaneous firing lasting from 50-100 ms after the RVL stimulus was followed by an excitation which often consisted of several spikes over a 60-100 ms interval with a mean latency to peak activity of 136 ms. These results (a) support the hypothesis that differences in their function and (b) suggest the existence of unique inputs from the RVL to adrenal SPNs which may be consistent with the slow time course of glandular responses. Supported by NIH HL19874.

SEPARATE MECHANISMS BY WHICH SEROTONIN DEPRESSES INTRASPINAL AND GANGLIONIC SYMPATHETIC TRANSMISSION D.N. Franz. S.C. Steffensen*, and L.C. Miner*, Dept. of Pharmacology, Univ. of Utah Sch. of Med., Salt Lake City, UT 84132.

The marked increase in intraspinal transmission to sympathetic preganglionic neurons (SPGNs) produced by PDE inhibitors in spinal cats was nearly prevented by pretreatment with 5-HT precursors, S-HTP or L-tryptophan, apparently by activating 5-HT receptors that are negatively coupled to adenylate cyclase. Microinjection of 5-HT (5 ug) into the SPGN neurophil also produced selective, marked depression with full recovery within 2 hr. Marked increases (100%) in intraspinal transmission to SPGNs followed microinjection of 1-2 ug of cyclic AMP analogs, forskolin, or RO 20-1724 into the SPGN neurophil. Transmission through isolated stellate ganglia in spinal cats was markedly depressed by serotonin (30-100 ug/kg, i.v.) for about 10 min. Prolonged depression (hours) was produced by i.v. 5-HTP (6-25 mg/kg) or by L-tryptophan (10-50 mg/kg, after 10 mg/kg of pargyline). 5-HTP did not affect postganglionic discharges from direct stimulation of did not affect postganglionic discharges from direct stimulation of ganglia blocked by mecamylamine, indicating that 5-HT must act presynaptically to depress release of acetylcholine from SPGN preganglionic terminals. In contrast to SPGNs, ganglionic transmission was not affected by i.v. RO 20-1724 or by microinjection of cyclic AMP analogs or forskolin into the ganglia. Although 5-HT appears to depress SPGN perikarya by inhibiting adenylate cyclase and reducing cyclic AMP levels, it depresses ganglionic transmission by reducing transmitter release from SPGN terminals through mechanisms that do not involve cyclic AMP.

PATHWAYS MEDIATING AUTONOMIC RESPONSES ELICITED BY STIMULATION OF TONGUE AFFERENTS. S.J. Chen. M.M. Sawchuk*, G.V. Allen and D.F. Cechetto. Robarts Research Inst./Dept. of Physiology, Univ. of Western Ontario, London, Ontario N6A 5K8. Nociceptive and gustatory stimuli evoke autonomic responses. The pathways mediating these responses are not completely known. Injection

nociceptive and gustatory stimuli evoke autonomic responses. In pathways mediating these responses are not completely known. Injection of horseradish peroxidase into the anterior left quadrant of the tongue was used to identify sites of afferent termination in the nucleus of the solitary tract (NTS) and the caudal spinal trigeminal nucleus (SNVc). In chloralose-anesthetized (150 mg/kg) rats electrical stimulation of the tip of the tongue increases arterial pressure, heart rate and sympathetic (renal) nerve discharge (SND). SND responses were evaluated using peristimulus-time histograms generated by single pulse stimulation. An initial increase in SND was observed at 71.2 (± SE 1.9) ms after the stimulation of the tongue. A synaptic blocking agent, cobalt (COB), was injected (10 mM, 300 nl) into areas of the NTS and SNVc identified by the anatomical results. Injections of COB were also made into the parabrachial nucleus (PB), the pontine A5 region and the ventral lateral medulla (VLM) which are likely sites of the second synapse mediating these responses. Only injections into the SNVc and A5 blocked the autonomic responses. It is concluded that autonomic responses are elicited by activation of pain receptors whose sequential pathway involves the SNVc, A5 and spinal cord preganglionic neurons. (Supported by the Heart and Stroke Foundation of Ontario).

AORTIC DEPRESSOR NERVE STIMULUS-EVOKED INHIBITION OF SYMPATHOEXCITATORY NEURONS IN THE ROSTRAL VENTROLATERAL MEDULLA (RVL). I. Jeske, S. Morrison, S.L. Crayo*, and D.J. Reis, Cornell University Medical College, Div. of Neurobiol., Dept. of Neurol. and Neurosci., New York, NY 10021.

NY 10021.

Baroreceptor stimulation inhibits the activity of reticulospinal sympathoexcitatory neurons in RVL through a polysynaptic pathway from the nucleus of the tractus solitarius (NTS) and involving unidentified neurons of the caudal ventrolateral medulla (CVL). To determine the temporal characteristics of this intramedullary pathway, we recorded the responses of antidromically-identified RVL-spinal neurons and postganglionic splanchnic sympathetic nerve activity (SNA) following paired-pulse stimulation of baroreceptor afferents in the aortic depressor nerve (ADN) of urethane-anesthetized, ventilated rates, RVL-spinal neurons exhibited arterial nulse-grapted activity and either slow. depressor nerve (ADN) of urethane-anesthetized, ventilated rats. RVL-spinal neurons exhibited arterial pulse-related activity and either slow (0.5-1.5 m/s; n=8) or rapid (3.4-8.3 m/s; n=14) antidromic conduction velocities. Stimulation of the ADN inhibited the spontaneous discharge of RVL neurons with an onset latency of 57 ms (range:40-76 ms) and a latency to complete silence of 67 ms. The duration of inhibition was directly related to stimulus intensity. ADN stimulation inhibited SNA with an onset latency of 96 ms and time to peak inhibition of 138 ms. Since (a) the RVL stimulus-evoked increase in SNA has an onset latency of 41 ms and peak latency of 68 ms and (b) the ADN to NTS delay is less than 10 ms, the intramedullary conduction time is approximately 55 ms. Given the distance between NTS and RVL, such a long delay is consistent with a multisynaptic intramedullary pathway mediating arterial baroreflex inhibition of RVL-spinal sympathoexcitatory neurons. Supported by NIH HL18974.

PROJECTIONS FROM THE ROSTRAL VENTROLATERAL MEDULLA TO IDENTIFIED SPINAL SYMPATHETIC PREGANGLIONIC NEURONS AND SEROTONERGIC MEDULLARY RAPHE NEURONS IN RAT A.Zagon & A.D.Smith University Dept. of Pharmacology, Oxford OX1 3QT U.K.

The ventral part of the medulla plays an important role in the control of blood pressure. Both the rostral ventrolateral medulla (RVLM) and the caudal raphé nuclei in this area have been shown to project towards the intermediolateral cell column in the thoracic spinal cord. We have previously described a monosynaptic projection from the medullary raphé nuclei onto sympathetic preganglionic neurons (SPNs) (Bacon et al. Exp. Brain Res. 1990 79-587). In the present study we investigated if those parts of the RVLM which project to SPNs also project into the medullary raphé nuclei and if they have any connections with serotonergic neurons.

Axons arising from neurons of the medial part of the RVLM were labelled with Phaseolus Vulgaris Leuco-agglutinin (PHA-L). Cholera B-chain conjugated HRP (CB-HRP) was introduced into the left adrenal gland to retrogradely label SPNs. Sections of the spinal cord were processed to reveal CB-HRP and immunoristochemistry and visualized using DAB to produce a brown reaction product. Then the sections were processed for 5-HT immohistochemistry, visualized with benzidine giving a blue reaction product or with silver enhanced pre-embedding gold-staining.

Varicose PHA-L labelled axons of RVLM neurons were found in the intermediolateral cell column in close apposition to somata and proximal dendrites of retrogradely labelled SPNs. Occasionally labelled axons were found around more distal dendritic parts of SPNs in the intermediate and central gray regions of the thoracic spinal cord. Existence of direct monosynaptic connection between the labelled descending axons and the identified SPNs was established in the electron microscope. In all animals PHA-L labelled axons from the same injections were also seen in the caudal raphé nuclei. The greatest number of labelled

The project was supported by a grant from Bristol-Myers Squibb Co.

BASELINE ANDREFLEX SYMPATHETIC ACTIVITY FOLLOWING COBALT INJECTIONS INTO THE VENTRAL LATERAL MEDULLA (VLM) AND SPINAL CORD. D.F. Cechetto and S.J. Chen. Robarts Research Inst./Dept. of Physiology, Univ. of Western Ontario, London, Ontario N6A 5K8.

Previous investigations suggested the VLM is primarily involved in maintainance of sympathetic tone and mediation of baroreceptor reflexes. In chloralose anesthetized (150 mg/kg) rats a presynaptic blocking agent, cobalt (COB), was injected into either the VLM or the spinal cord; baroreceptors were tested by either i.v. injection of phenylephrine or electrical stimulation of the aortic depressor nerve (ADN). Blood pressure, heart rate and sympathetic (renal) nerve discharge (SND) were continuously monitored. COB injection (10 mM, 300 nl) into the VLM (-1.0 mm caudal to 2.5 mm rostral to obex) did not change baseline SND at any site; however, injection into the rostral VLM (1.0 mm to 2.5 mm rostral to obex) attenuated (21% ± SE 5.9) baroreceptor reflexes, although complete reflex blockade was never obtained. Kynurenate (a postsynaptic excitatory amino acid blocker) injections (250 mM, 300 nl) evoked a large increase (87%) in baseline SND from rostral VLM sites and resulted in apparent block of baroreceptor reflexes. Intrathecal spinal cord injections (4 mM, 200 µl) of COB did not alter baseline SND but completely blocked baroreceptor reflexes. These results demonstrate that VLM afferents do not alter tonic SND and that intrinsic SND remains after removal of brain inputs to spinal preganglionic neurons. In addition, the rostral VLM is at least partially responsible for mediating baroreceptor reflexes. partially responsible for mediating baroreceptor reflexes. (Supported by the Heart and Stroke Foundation of Ontario).

COCAINE INHIBITS GREATER SPLANCHNIC NERVE ACTIVITY IN ANESTHETIZED CATS. <u>VFC Raczkowski</u>**, <u>YM Hernandez</u>*, <u>KL Dretchen, RA Gillis</u>* Department of Pharmacology, Georgetown University; & Children's Hospital*; Washington, DC 20007

We have shown that intravenous (IV) cocaine (COC) inhibits spontaneous

cardiac sympathetic nerve activity (SNA) (FASEB JL 4:A1204,1990). These data contradict the commonly-held assumption that the sympathomimetic actions of COC result in part from increased central sympathetic outflow. They also appear to contradict the conclusion that COC increases centrally mediated SNA to the adrenal medulla (JPET 205:148-154,1978). Therefore, we recorded spontaneous SNA from the right greater splanchnic nerve, which innervates the adrenal medulla, during the administration of COC (4 mg/kg IV) in anesthetized (pentobarbital), paralyzed (vecuronium), mechanically ventilated cats with acutely denervated cardiovascular reflexes. Heart rate

ventilated case with according to the variety of t or SNA occurred 69 \pm 16 sec after orug administration. Initially, the mean BP decreased from 130 \pm 12 mmHg to a minimum of 61 \pm 14 mmHg (p<0.01). The maximal drop occurred at 91 \pm 21 sec. A secondary increase in BP to a maximum of 153 \pm 17 mmHg (p<0.05) occurred at 10.9 \pm 3.7 min. HR was unaltered. In two other experiments, an equimolar dose of lidocaine (3.2 mg/kg IV) decreased SNA by an average of only 1.6%. The mean BP decreased from 113 mmHg to a minimum of 71 mmHg. The maximal drop occurred at 30 sec. The HR decreased from 164 to 149 bpm. These data indicate that, consistent with its ability to decrease cardiac preganglionic sympathetic outflow, COC also decreases sympathetic outflow to the adrenal medulia. These effects do not appear to be related to a local anesthetic action of the drug. Supported by NIH grant RO1 DA-05333.

SPINAL NINDA RECEPTORS CONTRIBUTE TO CARDIOVASCULAR RESPONSES EVOKED BY HYPOTHALAMIC STIMULATION, J.P.

Dept. of Physiol., Univ. of Louisville, L'ville, KY 40292 Spinal glutamate receptors participate in the pressor response evoked by activation of the ventrolateral In the present investigation, the effect of spinal NMDA receptor blockade with DL-2-amino-phosphono-valeric acid (AP5) on hemodynamic effects produced by hypothalamic stimulation was determined. In urethane anesthetized Sprague-Dawley rats, the changes in mean arterial pressure (MAP), heart rate (HR), and relative renal (RR) and hindquarter (HQR) vascular resistances produced by electrical stimulation of the paraventricular nucleus (PVN) or posterior hypothalamic area (PH) were determined, before and after intrathecal injection of AP5 (200 nmole in $10~\mu l$). The AP5 significantly decreased baseline MAP and HR (n=6). Baseline RR tended to increase and HOR tended to decrease, but neither effect was significant. The increase in MAP and RR produced by hypothalamic stimulation of both sites was markedly reduced by the AP5. The decrease in HOR was reversed in 4 of 5 rats receiving FVN, and 2 of 4 rats receiving FH stimulation. These data suggest that spinal NMTA receptors participate in the engingers of the processor of the produced by hypothalamic in the cardiovascular responses evoked by hypothalamic stimulation. Whether the pathways mediating the effect involve activation of the ventrolateral medullary neurons that project to the spinal cord or direct hypothalamicspinal projections is yet to be determined.

97.13

ROLE OF THORACIC INTERNEURONS IN CERVICALLY-EVOKED SYMPATHOINHIBITION IN THE RAT.

L. R. Poree and L. P. Schramm; Department of Biomedical Engineering, Johns Hopkins University School of Medicine, Baltimore, MD 21205

We have previously described a cervical sympathoinhibitory system that inhibits both pre- and postganglionic sympathetic activity. We have been able to activate this system by electrical or chemical stimulation of the rostral cervical spinal cord only after C1 spinal transection or after inhibition of the rostral ventrolateral medulla with mucimol, leading us to hypothesize that this system is tonically active in the intact rat. Recordings from sympathetic preganglionic neurons (SPGN) suggested that the sympathoinhibition was due to the inhibition of presympathetic interneurons, not preganglionic neurons. In the present study, we tested the hypothesis that spinal interneurons which received somatic and visceral sensory information, and which might conceivably be excitatory antecedents to SPGN, were inhibited by cervical stimulation. Working in anesthetized, spinally-transected, and artificially-respired rats, we identified spinal interneurons which were excited by both somatic and visceral afferent stimuli. Most of these neurons also exhibited ongoing activity. Both the ongoing and evoked activities of the large majority of these neurons were inhibited by cervical electrical stimulation which also inhibited renal sympathetic activity. We conclude that the cervical "sympathoinhibitory system" may have a more general descending inhibitory function. Indeed, its sympathoinhibitory function may be mediated by inhibition of afferent activity which, in turn, excites SPGN. Supported by NIH Grant HL 16315.

NEUROCHEMICAL EVENTS IN THE SPINAL CORD DURING STIMULATION OF THE ROSTRAL VENTROLATERAL MEDULLA. G.A. Iwamoto, L.C. Abbott and T.G. Waldrop, Department of Veterinary Biosciences and Department of Physiology and Biophysics, University of Illinois, Urbana, IL 61801

Rostral ventrolateral medulla (RVLM) contains cells

which project to the spinal cord (SC) and are responsible for maintaining blood pressure as well as participating in pressor responses. Several substances may mediate synaptic transmission of RVLM cells at the level of the SC. The purpose of this study was to determine if monoamines were involved.

Adult cats were anesthetized with alpha chloralose (60 mg/kg). The SC was exposed at T2-3. A concentric, flowthrough microdialysis probe was placed just lateral to the dorsal root entry zone with the dialyzing portion of the probe (2 mm length x 0.25 mm dia.) localized to include the intermediolateral cell column. The medulla was exposed to allow placement of a stimulating electrode just ventral to the retrofacial nucleus. Control samples (15 min duration) were collected during stabilization of the probe for a period of 2 to 3 hr prior to stimulation. The RVLM was then stimulated for 15 min using repeated trains (40 Hz, 0.7 msec duration, 25 to 75 μA pulses) of 10 sec duration followed by 10 sec of no stimulation. Increases in 5HT and/or 5HIAA accompanied the pressor response to RVLM stimulation in 6 of 9 animals. There were no changes observed in epinephrine or norepinephrine. through microdialysis probe was placed just lateral to the

ROLE OF SPINAL N-METHYL-D-ASPARTIC ACID (NMDA) RECEPTORS IN SYMPATHOEXCITATION EVOKED BY GLUTAMATE STIMULATION OF THE ROSTRAL VENTROLATERAL MEDULLA (RVM) AND BY CEREBRAL ISCH-Michelle K, Bazil & Frank J, Gordon. Dept. of Pharmacology, Emory Univ., Sch. of Med., Atlanta, GA 30322.

Rats were anesthetized with urethane, paralyzed, vagoto-ted and artificially respirated. Sympathetic nerve mized and artificially respirated. activity (SNA) was recorded from the splanchnic nerve. The NMDA receptor antagonists D-AP7 (100 nmol) or CPP (12.5 nmol) were administered to the spinal cord via intrathecal (IT) catheters. Blockade of spinal NMDA receptors reduced mean arterial pressure (MAP) 29 ±4 mmHg and SNA 58 ±5%. Microinjections of L-glutamate (15 nmol/50 nl) into the RVM increased MAP 28 ±2 mmHg and SNA 97 ±29%. Pharmacologic blockade of spinal NMDA receptors reduced RVM pressor responses to 8 ±2 mmHg and evoked sympathoexcitation to 23 ±5% of control. In other experiments, cardiovascular and SNA responses were elicited by transient cerebral ischemia (CI). CI increased MAP 32 ±4 mmHg and SNA 75 ±19%. IT D-AP7 reduced CI pressor responses to 14 ±3 mmHg and SNA responses to 59 ±13% of control without affecting CIinduced increases in heart rate. IT administration of D-AP7 or CPP abolished the pressor and tachycardic effects of IT NMDA but not those of kainic acid or the quisqualate agonist AMPA. These results indicate that NMDA receptors in the spinal cord play an important role in the maintenance and bulbospinal regulation of sympathetic neural control of the circulation.

Functional evaluation of cardiac, vasoconstrictor and renal sympathetic nerve activity (SNA) in the conscious spinal rat. K. Trostel* and J. Osborn, Dept. of Vet. Biol., U. of Minnesota, St. Paul, MN 55108

In anesthetized rats, cervical spinal transection (CST) increases renal SNA 2-3 fold resulting in decreased urinary sodium (Na) and water excretion (Osborn et al., AIP 253:R619-R625, 1989). To determine whether there is functionally significant SNA in <u>conscious</u> spinal rats we conducted the following studies. First, mean arterial pressure (MAP), heart rate (HR) and plasma renin activity (PRA) were measured before and 24 hours after CST in 15 chronically instrumented Sprague-Dawley rats. Second, in the same rats, the response of functional indicators of SNA to combined alpha- and beta-adrenergic blockade (N=8) or saline vehicle (N=7) were evaluated 24 hours after CST. MAP, HR, urine flow (V), urinary Na excretion (UNaV), urinary potassium excretion (UKV) and PRA were determined before and after two hours of combined administration of phentolamine (2mg/kg + 1mg/kg/hr) and propranolol (2mg/kg + 1 mg/kg/hr). CST resulted in significant decreases of MAP (102.1±2.7 to 75.1±1.7 mm Hg), HR (338±12 to 292+7 bpm), and PRA (3.0+1.6 to 1.7+1.3 ng AI/ml/hr). Subsequent alpha- and beta-adrenergic blockade resulted in a small but significant increase in MAP (4mm Hg). There was no significant effect of adrenergic blockade on HR, V, UNaV, UKV or PRA. Based on these results, we conclude that sympathetic nerve discharge to the vasculature, heart, and kidney is either absent or ineffective in conscious spinal rats. NIH grant HL 39619.

SPINAL CONTROL OF CARDIAC FUNCTION IN THE RAT: ROLE OF DIFFERENT EXCITATORY AMINO ACID RECEPTOR SUBTYPES.

K. Sundaram*, J. Murugaian and H.N. Sapru, Departments of Neurosurgery & Pharmacology, UMDNJ-New Jersey Medical School, Newark, NJ 07103.

In different groups of pentobarbital-anesthetized male Wistar rats (immobilized and artificially ventilated), L-glutamate (Glu; 0.9-1.77 nmole), N-methyl-D-aspartic acid (NMDA; 1-100 pmole), kainic acid (KA; 1-10 pmole), quisqualic acid (QA; 0.1-100 pmole) and (a-amino-3-hydroxy-5-methyl-4-isoxazole-propionic acid (AMPA; 10 pmole) were microinjected into the right intermediolateral column (IML) at the T2 level. All these agonists produced tachycardia with level. All these agonists produced tachycardia with little or no change in blood pressure. The effects of D-AP7 (5 nmole) were blocked by microinjections of D-AP7 (5 nmole). Kynurenic acid (2-4 nmole) blocked the effects of KA (3 pmole) and QA (1 pmole) but not Glu (1.77 nmole). The effects of Glu were blocked by glutamic acid diethylester (GDEE; 80 nmole); this dose of GDEE did not block the effect of carbachol (440 pmole). These results indicate that different subtypes of excitatory amino acid receptors, located in the IML at T2 level. may have a role to play in the spinal at T2 level, may have a role to play in the spinal control of cardiac function.

PHARMACOLOGICAL STUDIES ON THE CARDIOVASCULAR RESPONSES TO INTRATHECAL ADMINISTRATION OF L- AND D-BACLOFEN IN THE RAT. Y. Hong and J.L. Henry, Depts. of Physiology and Psychiatry, McGill University, Montréal, Qué. H3G 1Y6
We have previously demonstrated that the intrathecal administration of

L-baclofen (7-700 nmol) to the thoracic spinal cord induces a decrease in arterial pressure and heart rate; D-baclofen (7-70 nmol), on the other hand, increases arterial pressure but has no effect on heart rate. Reports that D-baclofen antagonizes effects of L-baclofen and that phaclofen is an antagonist of baclofen prompted the present study. Anaesthetized (urethane; 2.5 g/kg, i.p.) male Sprague Dawley rats (300-350g) were used. In all cases, administration was intrathecal; control groups received vehicle. Effects of 70 nmol of L-baclofen were not modified by pretreatment 10 min beforehand with 700 nmol of D-baclofen (n=12). In contrast, 70 (n=10), but not 7 (n=7), nmol of L-baclofen blocked the cardiovascular effects of 700 nmol of D-baclofen. As a test for desensitization, D-baclofen was administered twice, 7 min apart, in one group of rats (n=5); the full-blown effect was observed with each of the two administrations. Phaclofen (2.5μ mol) increased arterial pressure and heart rate [T9 (n=18) > T2 (n=14)]; these effects developed slowly over 5-10 min and persisted for 30 min, and produced total and partial block of the effects of 70 (n=9) and 350 (n=10) nmol of L-baclofen, respectively. EFFECTS OF 5,7-DIHYDROXYTRYPTAMINE ON CARDIOVASCULAR REGULATION IN THE AWAKE RAT.

R. Melinek and V.R. Holets. The Miami Project, Dept. of Neurological Surgery, University of Miami, Miami, FL 33136.

The effect of 5,7-dihydroxytryptamine (5,7-DHT) on cardiovascular regulation was studied in the male rat during normal activity and during applied cold stress. Blood pressure and heart rate were measured via tail artery cannulation one week following intrathecal administration of 5,7-DHT. The mean arterial pressure (MAP) was significantly less for the unstressed 5,7-DHT-lesioned rats than for the vehicle-injected controls. Preliminary results indicate that one month vehicle-injected controls. Preliminary results indicate that one month post-lesion this difference was no longer apparent. Cold stress caused a significant increase in MAP over the basal level in both the control

a significant increase in MAP over the basal level in both the control and the experimental group.

Immunohistochemical analysis confirmed the loss of serotonin-immunoreactive fibers in the lesioned rats. Moreover an increase in calcitonin gene-related peptide (CGRP) immunoreactivity in fibers in the intermediolateral column of the spinal cord was observed a few months after the 5,7-DHT lesions. Studies are underway to determine the relationship between the apparent neuronal plasticity and change in

cardiovascular function.

GLUTAMATE-CONTAINING AXON TERMINALS SYNAPSE DIRECTLY ON CHOLINE ACETYLTRANSFERASE-LABELED SYMPATHETIC PREGANGLIONIC NEURONS. J. Callaway. S.F. Morrison, T.A. Milner, and D.J. Reis. Comell Univ. Med. Coll., Div. of Neurobiol., Dept. of Neurol. and Neurosci., New York, NY 10021.

We have proposed (Prog. Brain Res., 1989;81:159) that glutamate mediates the sympathoexcitatory effects of the vasomotor pathway from the rostral ventrolateral medulla (RVL) to the intermediolateral nucleus (IML): (A) glutamate-like immunoreactivity (GLU-LI) is in axon terminals making asymmetric synapses on IML neurons (B) neurons in the RVL are a source of this glutamatergic innervation, and (3) RVL stimulus-evoked excitation of sympathetic preganglionic neurons (SPNs) is blocked by glutamate receptor antagonists. To determine whether terminals with GLU-LI synapse upon cholinergic SPNs, coronal sections from the upper thoracic spinal cord were labeled immunocytochemically with antibodies to choline acetyltransferase (ChAT) (Crawford et al., Proc. Natl. Acad. Sci., 1982;79:7031) identified by the ABC reaction product and hemocyanin-conjugated glutamate (Hepler et al., J. Histochem. Cytochem., 1988;36:13) identified by silver-intensified immunogold labeling. Ultrastructurally, GLU-LI in the IML was in axon terminals containing a few mitochondria and numerous small, clear vesicles. Terminals with GLU-LI formed primarily asymmetric (excitatory) synapses on the shafts of medium and small dendrites as well as on dendritic spines of ChAT-labeled neurons. Frequently, more than one terminal with GLU-LI contacted the same target. These data indicate that SPNs are innervated by glutamate-containing terminals, suggesting a direct influence of glutamate on SPN membrane excitability. This finding is also consistent with a monosynaptic connection from vasomotor neurons of the RVL to thoracic SPNs. Supported by NIH HL18974. thoracic SPNs. Supported by NIH HL18974.

ADRENAL MEDULLARY SECRETION WITH SPLANCHNIC STIMULATION IN SPINALLY TRANSECTED CATS. S.L. Stoddard. G.M. Tyce and T.L. Yaksh. Dept. of Anatomy, Indiana U. Sch. of Medicine, Ft. Wayne, IN 46805, and Depts. of Physiol. & Biophys. and Neurologic Surgery Res., Mayo Clinic, Rochester, MN 55905.

This project was undertaken to determine whether previously observed adrenal medullary hyperactivity that developed following high spinal cord transection in the cat (Stoddard, J. Auton. Nerv. Syst. 23:175-179, 1988) could be explained by increased sensitivity of the splanchnic nerve-chromaffin cell synapse. The splanchnic nerve was stimulated in acute (2-3 hr; N=7) or chronic (61-64 da; N=7), spinally transected (T3) cats that were decerebrate and unanesthetized. Stimulation (30V; 1 msec pulses) was applied at 2 and 30 Hz to deliver the some number of sulses in 3 min 3 and 30 Hz to deliver the same number of pulses in 3 min. Adrenal medullary secretion (ng/min) of catecholamines (CAs), [Met]enkephalin (ENK), and neuropeptide Y was measured. Both stimuli increased the secretion of CAs and neuropeptides in both acute and chronic animals. Low frequency stimulation increased the ratio of NE/EPI in acute animals; this ratio was unchanged by either stimulation in the chronic animals. Secretion of EPI and ENK at low frequency was greater in the chronic than in the acute animals. These data suggest there is some facilitation of the splanchnic nerve-chromaffin cell synapse that occurs over time following high spinal transection. However, it is likely that spinal mechanisms also contribute to adrenal medulary hyperactivity.

REPETITIVE FIRING PROPERTIES OF NEURONS WITHIN THE MEDIAL NUCLEUS OF THE SOLITARY TRACT IN RATS. S.M. Johnson and R.B. Felder. Cardiovascular Center, Univ. of Iowa

College of Medicine, Iowa City, IA 52242.

The medial portion of the nucleus tractus solitarius (NTS) receives sensory information from baroreceptors and chemoreceptors located in the heart and great vessels We examined the repetitive firing properties of medial NTS neurons by recording intracellularly from neurons using an $in\ vitro\ brainstem\ slice\ preparation.$ The p synaptic response resulting from electrical stimulation of the ipsilateral solitary tract was also studied. Our results (n=18 cells) showed that the resting membrane poresults (n=10 certs) showed that the resting memorane tential was -54 \pm 8 mV (mean \pm std. dev.) and the membrane resistance was 68 \pm 38 MM (range = 23-164 MM). action potential amplitude and undershoot were 70.0 \pm 10.4 mV and 8.3 \pm 4.6 mV, respectively. The action po tential duration at half-height was 778 ± 166 ms. Afterhyperpolarization was found in 8/15 cells, post-in-hibitory rebound was found in 9/14 cells, and delayed ex-citation was found in 1/15 cells. In 9 of 10 cells tested, an action potential was evoked by stimulating the ipsilateral tractus solitarius. This is the first systematic examination of the repetitive firing properties of medial NTS neurons. These intrinsic neuronal properties, in addition to synaptic mechanisms, are important for afferent processing by NTS neurons. Supported by AHA 89-1017 and AHA 85-235.

N-METHYL-D-ASPARTATE (NMDA) RECEPTOR BLOCKADE AND

N-METHYL-D-ASPARTATE (NMDA) RECEPTOR BLOCKADE AND AFFERENT SYNAPTIC TRANSMISSION IN RAT MEDIAL NUCLEUS TRACTUS SOLITARIUS IN VITRO. M.C. Andresen and M. Yang. University of Texas Medical Branch, Galveston, TX 77550.

A variety of visceral afferents synapse on NTS neurons. Medial NTS receives substantial numbers of synaptic contacts from arterial baroreceptors. Reflex studies of the control of blood pressure and heart rate have implicated all three classes of excitatory amino acid receptors in these responses, but little is known about their cellular basis. Here, we studied the effects of blockade of NMDA receptors with the selective antagonist AP5 (2-amino-5-phosphonovalerate) on afferent synaptic transmission in mNTS. Neurons were recorded antagonist AP5 (2-amino-5-phosphonovalerate) on afferent synaptic transmission in mNTS. Neurons were recorded intracellularly from medial portions of NTS in a longitudinal slice of the rat medulla. The solitary tract (TS) was stimulated approx. 1-3 mm from NTS recording site at 0.5 Hz. Recording was limited to mNTS from the obex to 500 μ rostral to the obex bounded laterally by TS and the 4th ventricle. Some neurons were hyperpolarized to prevent spiking. TS stimulation evoked a short latency (2 msec) EPSP. AP5 was added to the slice surface near the recording electrode at 0, 1, 10, & 100 $\mu\mathrm{M}$ and measurements made at 2-3 min. We previously found that CNQX (non-NMDA blocker, 6-cyano-7-nitro-quinoxaline-2,3-dione) suppressed tract evoked EPSPs within 60 sec. AP5, however, had negligible effects on the EPSP even at 100 $\mu\mathrm{M}$ (n=8, p>0.23), but CNQX addition rapidly eliminated μ M (n=8, p>0.23), but CNQX addition rapidly eliminated these EPSPs. Our results suggest that a non-NMDA receptor mediates these excitatory synaptic responses.

EVIDENCE THAT VAGAL AFFERENTS ARE NOT

EVIDENCE THAT VAGAL AFFERENTS ARE NOT GLUTAMATERGIC. M.G. Backes and A.F. Sved. Department of Behavioral Neuroscience, University of Pittsburgh, Pittsburgh, PA 15260.

It has been suggested that baroreceptor afferent nerves release glutamate, or some other excitatory amino acid (EAA), at their terminals in the nucleus tractus solitarius (NTS). Glutamate analogs such as 'H-D-aspratate ('H-D-ASP), can be used to retrogradely label EAA-releasing neurons in the CNS. In the present study, this method was used to examine whether vagal afferents will transport 'H-D-ASP retrogradely from the NTS to the nodose ganglion. 'H-D-ASP (20-50 uCi in 25-100 nl) was injected into the NTS of rats at the level of the obex. In control rats 'H-D-ASP was injected into the spinal trigeminal nucleus (Sp5). Following 14-48 hours, rats were anesthetized and perfused with 5% glutaraldehyde. Brains and nodose, petrosal, and trigeminal ganglia were removed. Cryostat sections (20 u) were direct-mounted onto gelled slides. Slides were defatted and dipped in Kodak NTB-2 emulsion. After various exposure times (1-6 months), slides were developed in D-19 and counterstained with cresyl violet. In 4 of 9 rats in which the injection was centered on the NTS, no retrogradely labeled cells were observed in the nodose or petrosal ganglia. In the other 5 rats, a small number (<10/ganglion) of retrogradely labeled cells were found in the ipsilateral nodose ganglia. Many labeled neurons were always observed in the ipsilateral trigeminal ganglion following 3H-D-ASP injection into Sp5 (n=5). These data indicate that vagal and glossopharyngeal afferents do not specifically transport 3H-D-ASP retrogradely from the NTS, providing evidence that baroreceptor afferents are not glutamatergic.

L-HOMOCYSTEIC ACID (LHCA), A POTENTIAL ENDOGENOUS TRANSMITTER IN THE BAROREFLEX. H. Ohta, S. Eversmann*, and W.T. Talman. Dept. of Neurol., VAMC and Univ. of Iowa, Iowa City, IA 52242. We have hypothesized that glutamate is a transmitter at NMDA receptors in the baroreflex

we have hypothesized that glutamate is a transmitter at NMDA receptors in the baroreflex arc. NMDA antagonists block responses to NMDA and to baroreflex activation but not those to glutamate. Thus, an agent other than glutamate may be the endogenous agonist. We sought to evaluate the role of one such agent LHCA in cardiovascular regulation through the nucleus tractus solitarii (NTS) in 37 anesthetized rats, instrumented for recording arterial pressure (AP), heart rate (HR), and, in some, sympathetic nerve activity (SNA). Microinjections were made into NTS through micropipettes. Like NMDA, LHCA produced dose-related decreases in AP, HR, and SNA. The maximal response (decreased AP of 20.3±2.2 mmHg and HR of 26±2.8 bpm; p<0.05) occurred after a dose of 200 pmol; ED₅₀=20 pmol. The NMDA antagonists 2-APV and MK-801 significantly reduced responses to 20 pmol of LHCA and cardiovascular responses to baroreflex activation; MK-801, but not 2-APV, attenuated activation; MK-801, but not 2-APV, attenuated reflex responses of SNA. These data are consistent with a role for LHCA in baroreflex neurotransmission.

98.4

GLUTAMATE RELEASE IN THE NUCLEUS TRACTUS SOLITARIUS IS NOT AFFECTED BY BARORECEPTOR AFFERENTS. A.F. Sved and J.N. Salter. Department of Behavioral Neuroscience, University of Pittsburgh, Pittsburgh, PA 15260.

Previous studies have suggested that glutamate (Glu), or some other excitatory amino acid neurotransmitter, is the neurotransmitter of baroreceptor afferent nerves that project to the nucleus tractus solitarius (NTS). We have examined this hypothesis by determining the effect of afferent vagal stimulation or specific baroreceptor stimulation on release of endogenous Glu and aspartate (Asp) in the NTS. Microdialysis probes (200u diameter, 400u length of exposed dialysis membrane) were placed into the NTS of urethane anesthetized rats. Artificial CSF was perfused through the probe at 2 ul/min and 20 minute fractions were collected and analyzed for amino acids. By two hours after implantation of the probe, Glu and Asp levels in the dialysate fluid were stable (1.9±4 pmol/20 ul and 3.5±8 pmol/20 ul respectively). Neither bilateral electrical stimulation of vagal afferent nerves (2msec pulses, 500 uA, 10 Hz, for 20 minutes) nor increasing arterial pressure by 40 mmHg with an infusion of phenylephrine significantly altered the dialysate fluid levels of Glu, Asp, or any other measured amino acid (n=5 for each treatment). In contrast, increasing the K* concentration of the CSF perfused through the dialysis probe to 60 mM significantly increased the concentration of Glu (4.2±7 fold) and Asp (3.2±6 fold) in the dialysate fluid. Increasing the K* concentration increased the dialysate concentration of several other amino acids (i.e., GABA, taurine, glycine) and decreased the concentration of glutamine. Other amino acids were not affected. These data provide evidence that Glu is not the neurotransmitter of baroreceptor afferent nerves. Previous studies have suggested that glutamate (Glu), or some

AMINO-TERMINAL SUBSTANCE P FRAGMENTS IN CENTRAL CARDIO-VASCULAR REGULATION: STRUCTURE SPECIFICITY AND BINDING SITES. M.E. Hall*, C.L. Miller*, N. Zahniser, J.M. Stewart. Dept. of Biochem., Biophys. & Genetics and of Pharmacology, Univ. of Colorado Medical School, Denver, CO 80262.

Substance P (SP) is a putative neurotransmitter (NT) of the baroreflex in the nucleus of the solitary tract (NTS). Recent work suggests that SP(1-7) produced by endopeptidase 3.4.24.11 is the NT, producing bradycardia and hypotension upon microinjection into the medial NTS of rats. Inhibition of 24.11 by phosphoramidon blocks depressor action of SP but not of SP(1-7). Classical tachykinin agonists such as the widely used metabolically stable C-terminal analog DiME-C7 and other C-terminal SP fragments are pressor in the NTS. Intra-NTS injections of SP N-terminal fragments and analogs show considerable structure specificity for hypotensive action, suggesting combination with a specific receptor. Incubation of membranes from rat brainstem (including the NTS) with 500 picomolar 125 I-Tyr-SP(1-7) showed specific binding of 5 fmoles/mg protein. This result provides initial evidence for a basis of action of SP(1-7) and related N-terminal SP peptides in the central nervous

EXCITATORY AMINO ACID (EAA) MODULATION OF CAROTID SINUS BARORECEPTOR ACTIVITY. G. Hajduczok, S.J. Lewis, M.J. Brody, and F.M. Abboud*. Depts. Internal Medicine, Pharmacology, and CV Center, Univ. of Iowa College of Medicine, Iowa City, IA 52242.

Recent studies from our laboratory have demonstrated that intravenous injection of the EAA analogue kainic acid (KA) and the control of the EAA analogue kainic acid (KA) and the control of the EAA analogue kainic acid (KA) and the control of the EAA analogue kainic acid (KA)

produces a vasopressin mediated increase in arterial pressure in conscious ganglion-blocked animals. These responses to KA are abolished by chronic sinoaortic denervation. The purpose of the present study was to determine whether KA inhibits afferent present study was to determine whether KA inhibits afferent baroreceptor discharge. In four chloralose anesthetized dogs, the left carotid sinus (CS) was vascularly isolated and multiunit baroreceptor activity (BA) was measured from the CS nerve during increases in carotid sinus pressure (CSP) before and during exposure of the CS to KA. Values below represent the percent of maximal BA during control.

Exposure of the CS to KA resulted in a reversible inhibition of BA at all pressures. BA was also inhibited by KA at doses of 10⁻⁷ M and 10⁻⁰ M. This inhibitory effect appeared to be dose related. We conclude that the EAA analogue KA may suppress the baroreflex by inhibiting afferent baroreceptors.

IS THERE A CENTRAL PATTERN GENERATOR IN THE MEDULLA FOR CONTROLLING CARDIO-VASCULAR ACTIVITY? J.F.R. Paton.J.S. Schwaber,W.T. Rogers. Neural Computation Group, E.I. duPont Co., Wilmington, DE 19880-0352

In order to gain a better understanding of the baroreceptor reflex we are attempting to model the central neural mechanisms involved. Intracellular recordings of cells were made from rat brainstem slices within the dorsomedial and dorsal commissural nucleus tractus solitarius (NTS), the major regions receiving baroreceptor afferents and the NTS subgroups specifically concerned with cardiovascular control. Many cells in this area showed rhythmic ongoing discharge at a frequency of 5-10 Hz (mean 7.48, SEM +/-0.5 Hz) and were synaptically driven by electrical stimulation of both the ipsilateral tractus solitarius (ts; 2-5ms latency) and ventrolateral medulla (VLM; 3-7ms latency). In cases tested the neuronal discharge rate could be entrained by the frequency of ts and/or VLM stimulation within a preferred range. Inactivation of the VLM by cooling decreased the discharge frequency in some cells. Intracellular labeling of these active neurones demonstrated dendrites projecting medially and dorsomedially within the NTS and laterally into the ts. Their axons coursed out of the NTS ventrolaterally and in a rostral direction. The data provide some evidence for an oscillatory network between the NTS and VLM.

EXCITATORY AMINO ACID RECEPTORS IN THE ROSTRAL DEPRESSOR AREA OF CAT MEDULLA DO NOT MEDIATE BAROREFLEX. C. W. Dempesy, D. E. Richardson, and C. J. Fontana. Lab. of Neurosurgery, Tulane University School of Medicine, New Orleans, LA 70112.

We have previously reported (Neurosci. Abst. 14:192, 1988) in anesthetized, atropinized cat a glutamate-responsive sympathoinhibitory area lying superior to the rostral ventral lateral medulla. When this region, designated as the rostral depressor area (RDA), is bilaterally inactivated by toxic microinjections of kainic acid, cardiovascular tone rises and PeSBR, the sympathetic component of phenylephrine-induced baroreflex, is 80% diminished. The present study was aimed at discovering if N-methyl-D-aspartic acid (NMDA) and alpha-amino-methylisoxazole-proprionic acid (AMPA) receptors mediate the tonal and baroreflexive functions of the RDA. Microinjection (40 nl) of either NMDA (20 pmol) or AMPA (3 pmol) into unilateral RDA produced acute hypotension and bradycardia lasting 5-10 min. Subsequent microinjection of the NMDA-complex glycine-site antagonist 7-chlorokynurenic acid (7CK, 50 pmol) blocked the NMDA-response and elevated heart rate for 30 min, but did not change PeSBR even when administered bilaterally. Microinjection of the AMPA-site antagonist dinitroquinoxalinedione (DNQX, 40 pmol) blocked the AMPAresponse, but did not affect either tone or PeSBR. We conclude that NMDA- and AMPA-receptor mediation in the RDA is not significantly involved in these functions.

COMPUTATIONAL MODELING SHOWS PRIMA-RY BARORECEPTOR AFFERENTS PRESENT PARALLEL, THRESHOLD-RECRUITED, DISTRIBUTED INPUTS TO THE NTS. J.S. Schwaber, J.F.R. Paton, W.T. Rogers, K.M. Spyer, Neural Computation Group, E.I. duPont Co., Wilmington, DE 19880-0352 and Royal Free Hospital School of Medicine, London NW3 2PF.

We are creating a computational model of the baroreceptor vagal reflex based on the literature and our own ongoing experiments. Modeling of baroreceptor A-fiber transduction and signal transmission properties has revealed a new and quite different perspective on the coding of cardiovascular information. The distribution of distinct pressure thresholds of these fibers yields a recruitement series across the pressure pulse that optimally encodes the shape, height and timing of the pulse as a parallel population response across the primary afferents. The rise time of the pulse pressure causes this recruitment series to be temporally dispersed. time series is enhanced by an inverse correlation of conduction velocity with threshold. Thus, pulse pressure data are presented to the brain as a temporally dispersed population code. Interestingly, this computational result on the information coding of primary afferents matches well with (a) the dynamical, frequency-dependent response properties described for their second-order target cells in the NTS and (b) their apparently spatially distinct targets.

98.10

ELICITATION OF THE CAROTID SINUS BAROREFLEX AT LOW INTRASINUS PRESSURES. Ou. L. and Stuesse, S.L. Neurobiology Department, Northeastern Ohio Universities College of Medicine, Rootstown, OH 44272.

Department, Northeastern Ohio Universities College of Medicine, Rootstown, OH 44272.

In previous studies, we reported that baroreceptor fiber discharge can be elicited during low intrasinus pressure (ISP). In the present study, carotid sinus baroreceptor activity and its reflex effect were further investigated when ISP was varied in the range of 0-50 mmHg. In urethane-anesthetized rabbits with cut cervical sympathetic nerves, the carotid sinus region was isolated vascularly and perfused with Locke's solution equilibrated with 95% O₂ and 5% CO₂. Single unit discharges from baroreceptor or chemoreceptor fibers were tested for a response to pressure stimulation. Two groups of baroreceptors were identified: one had a mean pressure threshold of 47.8 mmHg and a maximal gain 0.238 impulses/sec/mmHg, and the other had a maximal gain of 0.13 impulses/sec/mmHg but no pressure threshold. Chemoreceptor discharges were also altered by changing ISP, but their activity was inhibited. Reflex changes in heart rate (HR), mean arterial blood pressure (MAP) and cardiac contractility were examined during bilateral carotid sinus perfusion in vagotomized rabbits with bilaterally cut aortic depressor nerves. Altering pulsatile ISP from 50 to 0 mmHg in 25 mmHg steps significantly increased MAP and decreased HR (Least squares liner regression, Pc0.05). Increasing CO₂ in the perfusate by equilibrating the Locke's solution with 6% CO₂ or 12% CO₃ in 20% O₃ attenuated MAP responses but increased the cardiac responses, HR and cardiac contractility. Thus during carotid sinus hypotension, circulatory reflexes may be elicited which differ from those during normal blood pressure or hypertension. Supported by a grant from the American Heart hypertension. Supported by a grant from the American Heart Association.

98.12

SINO-AORTIC DENERVATION ELIMINATES PRESSOR RESPONSES ELICITED BY MUSCIMOL INJECTIONS INTO THE NUCLEUS TRACTUS SOLITARIUS. A.M. McDonald and A.F. Sved. Department of Behavioral Neuroscience, University of Pittsburgh, Pittsburgh, PA 15260.

Local injection of muscimol (MUS), a GABA, agonist, into the nucleus tractus solitarius (NTS) of chloralose-anesthetized ventilated rats increases arterial pressure (AP) presumably by inhibiting tonically active neurons driven by baroreceptor afferents. The present study examined the effect of arterial baroreceptor denervation on this response to MUS. Male Sprague-Dawley rats were sino-aortically denervated (SAD) by bilaterally painting the carotid sinus with phenol and cutting the superior laryngeal nerve and the cervical sympathetic chain. Baroreceptor reflexes (phenylephrine-induced bradycardia and nitroprusside-induced tachycardia), tested in conscious rats one week following surgery, were totally absent in the SAD rats. Rats were then anesthetized with chloralose, artificially ventilated, and prepared for injections into the NTS (Catelli et al., Brain Res., 1987). In sham-denervated control rats, bilateral microinjection of MUS (100 pmol in 100 nl artificial CSF) into the NTS increased AP from 114±6 mmHg to 163±6 mmHg (n=7, P<0.01). In contrast, injection of MUS into the NTS of SAD rats did not influence AP (99±8 mmHg before, 99±8 mmHg after; n=6). Since MUS is known to inhibit neurons, the ability of MUS to increase AP in control rats indicates that it inhibits tonically active neurons in the NTS. The failure to elicit an increase in AP in the SAD rats suggests that, in the absence of arterial baroreceptor afferents, these neurons are not tonically active. These data imply that, in SAD rats, other inputs do not tonically excite NTS neurons that influence AP.

SELECTIVE INTERACTIONS OF ETHANOL WITH MEDULLARY NMDA AND GABA-A RECEPTORS INVOLVED IN BAROREFLEX REGULATION. Varga* and G. Kunos. LPPS, NIAAA, Bethesda, MD 20892

The effects of drugs and ethanol on blood pressure (BP), heart rate (HR) and baroreflex bradycardia were studied in urethane anesthetized rats. Ethanol, 1 g/kg i.v., or 0.2 µmol microinjected into the nucleus tractus solitarii (NTS) or the caudal ventrolateral medulla (CVLM), inhibited the reflex bradycardic response to i.v. phenylephrine. Intra-NTS injection of muscimol, 10-80 pmol/side, increased BP, HR, and inhibited baroreflex bradycardia. Intra-NTS ethanol markedly potentiated the pressor and tachycardic responses to intra-NTS muscimol. Glutamate, 0.5-2 nmol, microinjected into the NTS or the CVLM decreased BP and HR, and the effects in the CVLM but not in the NTS were inhibited by microinjection into the same site of 30 pmol of the NMDAantagonist, MK-801. The effects of intra-NTS glutamate were inhibited by i.v. and intra-CVIM but not by intra-NTS ethanol. The effects of intra-CVLM glutamate were inhibited by i.v. and intra-CVLM ethanol. Thus, ethanol appears to inhibit NMDA-receptor function in the CVLM and to potentiate GABA-A receptor responses in the NTS, while non-NMDA glutamate receptors in the NTS are not directly affected. We propose that these selective and localized effects of ethanol on GABA-A and NMDA receptors account for the inhibition of the depressor baroreflex response, and could thus contribute to the well documented hypertensive effects

98.15

THE CYTOARCHITECTURE OF THE CAUDAL NUCLEUS OF THE SOLITARY TRACT IN THE HUMAN MEDULLA. T.M. Hyde, S.K. Sigworth* and R.R. Miselis. CBDB, NIMH at St. Elizabeths Hospital, Wash., D.C., 20032.

In many species, the caudal nucleus of the solitary tract (NTS) has been divided into subnuclei on the basis of cytoarchitectural characteristics. In our study, sections from 8 normal human medullas were examined and computerized cell morphometry was performed on neurons within each subnucleus. Lying most caudally, the commissural subnucleus (Com) spans the midline, just behind obex, and contains small rounded neurons. The Com merges with the medial subnucleus (Med) anteriorly, and at this level other subnuclear divisions become apparent. The ventrolateral subnucleus (VL) lies in a triangular zone and contains large neurons. Rostrally, the VL is bounded medially by the interstitial subnucleus, which contains small cells intermingling with fibers of the tract. The intermediate subnucleus (Int) is largest at the midpoint of the rostrocaudal extent of the area postrema (AP), lies between the dorsal motor nucleus of the vagus (DMN) and the tract, and contains scattered large pigmented neurons. The dorsal subnucleus, containing densely packed large and medium-sized neurons, extends up and around the subnucleus gelatinosa (Sg). The Sg is a rounded cell-poor subnucleus lying ventrolateral to the AP, maximal in size at the rostral end of the AP. Composed of medium and small neurons, the Med is the largest subdivision, bounded by the Int, the dorsal subnucleus, the DMN, the AP, and the fourth ventricle. In conclusion, multiple subnuclei are identifiable in the caudal human NTS.

98.17

Baroreflex Function in Hypotensive Transgenic Mice Overexpressing Atrial Natriuretic Factor (ANF). Karen L. Cochrane and Loren J. Field*. Cold Spring Harbor Laboratory, Cold Spring Harbor, NY 11724.

Conscious, chronically cannulated transgenic mice that have a 10 fold increase in ANF have mean arterial pressures (MAP) that are 30 mmHg lower than their nontransgenic littermates (Steinhelper, et al., 1990). Plasma renin activity and catecholamine concentration were not elevated. To determine if the baroreflex slope (BRS; interbeat interval (IBI) VS systolic arterial pressure (SAP)) is altered, arterial and venous cannulas were placed in 6 transgenic and nontransgenic mice and MAP and BRS (during phenylephrine infusion; 3 ug/kg, iv) assessed 1 day later. The MAP of transgenic mice was lower than the control mice (76±3 mmHg VS 102±3 mmHg). The transgenic mice (5±1 VS 11±1 msec/mmHg). The increase in SAP was comparable in both groups (93±2 to 151±3 and 125±4 to 190±5 mmHg) while the maximum IBI achelved was less in the transgenic mice (110±3 to 272±24 VS 109±4 to 341±28 msec). The blunted BRS was probably due to a lack of sympathetic withdrawal because BRS was abolished in transgenic mice (n=2 each) pretreated with atropine while those pretreated with atenolol had little alteration in BRS. (Supported by HL-38605).

CONVERGENT EXCITATORY INPUTS FROM AREA POSTREMA AND AORTIC BARORECEPTORS ONTO NEURONS IN NUCLEUS TRACTUS SOLITARIUS (NTS). A.C. Bonham, Univ. California, Davis, Davis, CA 95616. E.M. Hasser, Univ. Missouri, Columbia, MO. C.M. Heesch, Univ. Kentucky, Lexington, KY.

Circulating arginine vasopressin (AVP) has been proposed to augment baroreflex-mediated sympathoinhibition by exciting area postrema neurons which project, ultimately, to baroreceptor-responsive neurons in the NTS which project, ultimately, to baroreceptor-responsive neurons in the NTS (Bishop et. al., Circ. Res. 61:4 Suppl II:1-76-81,1987). If true, then some NTS neurons should receive convergent excitatory inputs from both area postrema and arterial baroreceptors. To test that hypothesis, we performed extracellular recordings of single unit activity in the NTS of anesthetized, artificially-ventilated rabbits. Area postrema neurons were activated by brief electrical stimuli (50-420µA, 0.03-0.07ms, 1.51+2). Aortic baroreceptors were activated by single or twin electrical pulses (1-10v, 0.3-1ms, 1.51+2) applied to the aortic depressor nerve (ADN). We recorded action potentials from 14 single postsynaptic cells excited by area postrema stimulation (onset latencies, 3-20ms). The cells were located - 0.2-0.7mm caudal to obex, 0.5-0.9mm ventral to the dorsal surface, and 0.1-0.6mm lateral to midline. Six of 10 cells tested were also excited by ADN stimulation (onset latencies, 60-120ms). In each of trese cells, the waveform of the action potential evoked by stimulation of area these cells, the waveform of the action potential evoked by stimulation of area postrema or ADN was Identical. Furthermore, summation of inputs to individual NTS neurons was demonstrated during simultaneous threshold or subthreshold stimulation of area postrema and ADN.

In summary, brief electrical stimuli applied to area postrema evoked action potentials from NTS neurons, some of which also received excitatory input from aortic baroreceptors. These data suggest an excitatory interaction between baroreceptor and area postrema inputs to the NTS and provide a mechanism for AVP acting in area postrema to augment baroreflex-mediated cumpatibilities.

CAROTID BODY AFFERENT PROJECTIONS TO THE NUCLEUS CAROTID BODY AFFERENT PROJECTIONS TO THE NUCLEUS TRACTUS SOLITARIUS (NTS) IN THE RAT: NEUROCHEMICAL HETEROGENEITY OF TARGET SUBNUCLEI. J.C.W. Finley and D.M. Katz, Depts. of Medicine and Neuroscience, Case Western Reserve Univ. Sch. of Med., Cleveland, OH 44106 Despite widespread interest in brainstem control of peripheral chemoreflexes, the anatomic and neurochemical organization of carotid body afferent pathways remains poorly defined. In the present study as treasured to what terreserved in the present in the second of the present of the

carotid body afferent pathways remains poorly defined. In the present study, anterograde transport of wheat germ agglutinin- horseradish peroxidase (HRP) was used to define projections from the carotid body to NTS; in addition, immunocytochemical staining was used to begin characterizing neurochemical properties expressed by neurons in the projection area. HRP (Sigma VI, 5-10% w/v) was injected unilaterally into the carotid body via glass micropipettes after vascular isolation of the tissue. 2-4 days later the carotid body, petrosal ganglion (PG) and brainstem were fixed, sectioned and processed for HRP histochemistry using modifications of Mesulam's (1976) TMB method. Labeled sensory neurons were segregated in the distal portion of the PG. The central processes of these neurons entered the medulla rostral to the obex, descended in the ipsilateral TS and ended in a highly restricted region of the caudal nTS. A dense network of fibers rostral to the obex, descended in the ipsilateral TS and ended in a highly restricted region of the caudal nTS. A dense network of fibers was present bilaterally in the nucleus commissuralis; at the level of the obex, fibers were also present in the medial and dorsal subnuclei of NTS. Immunocytochemical staining demonstrated that NTS regions receiving carotid body afferent projections contained both tyrosine hydroxylase- and beta-endorphin-positive neurons. Although postsynaptic targets of the sensory fibers remain to be defined, these findings indicate that carotid body inputs to the brainstem may interact with neurochemically diverse subpopulations of NTS neurons. CENTRAL VASOPRESSIN-INDUCED PRESSOR RESPONSES IN RATS WITH IMPAIRED BARORECEPTOR REFLEXES. B.Bagdan, Y.Takahashi*, Q.J.Pittman. Neuroscience Research Group, University of Calgary, Calgary, Alberta, CANADA

Arginine vasopressin(AVP), given intracere broven tricularly (ICV) elevates blood pressure (BP) and Heart Rate (HR) via neural mechanisms. We have asked if AVP activates the sympathetic system directly or if its pressor action results from an interruption of baroreceptor reflex control mechanisms. Rats anesthetized with Pentobarbital received electrolytic or sham lesions (verified histologically upon autopsy) in the nucleus tractus solitarius (NTS). After one week recovery rats were anesthetized with urethane and femoral artery and vein were cannulated. Methoxamine was given iv and 1/HR plotted against BP to provide an assessment of sensitivity of baroreceptors. Rats with low baroreceptor sensitivity (LBS; <0.6 msec/mmHg) had MAP of 72±4 mmHg, not significantly different (73±8mmHg) than sham lesioned rats with high sensitivity (HBS). LBS rats (n=9) given 100pmoles AVP ICV displayed pressor responses of 20±8mmHg and increases of HR of 44±9bpm. HBS rats (n=5) displayed pressor responses of 11±4 mmHg and increases in HR of 53±27bpm. Responses of the two groups were not significantly different. We conclude that the integrity of baroreceptor mechanisms is not required for AVP to exert its central pressor actions. Thus AVP may activate sympathetic mechanisms directly rather than produce increases in BP through creation of an anomalous baroreceptor signal.

AORTIC BARORECEPTOR FUNCTION IN LONG TERM STREPTOZOTOCIN

AORTIC BARORECEPTOR FUNCTION IN LONG TERM STREPTOZOTOCIN DIABETIC RATS. P.J. Reynolds, M. Yang,* M.C. Andresen and S.K.S. Chang*. Oregon Health Sciences Univ., Portland, OR 97201 and Univ. Texas Medical Branch, Galveston, TX 77550. Patients with diabetes mellitus have impaired autonomic control of heart rate. We have shown an impairment of the baroreflex control of heart rate in long-term streptozotocin (STZ) diabetic rats (J. Mol. Cell. Cardiol. 18:617-624, 1986). To determine if the defect is in the afferent limb of the baroreflex arc, activity of regularly discharging harprecentors in relation to pressure and afferent limb of the baroreflex arc, activity of regularly discharging baroreceptors in relation to pressure and vessel diameter was studied in an in vitro aortic archaortic nerve preparation from 4 rats 52 weeks after the onset of STZ diabetes (D) and 5 age-matched control (C) rats. The baroreceptor threshold pressure (P_{th}) and suprathreshold pressure sensitivity (S_{th}) did not differ between groups. When related to vessel wall strain (e), between groups. When related to vessel wall strain (ε), however, the receptors of diabetic rats had a significantly lower threshold (ε _{th}) and higher sensitivity to suprathreshold strain (S)(See table). Supported in part by grants from V.A. and ADA, Oregon Affiliate.

BARORECEPTOR-MEDIATED VASOPRESSIN RELEASE IN HUMAN AUTONOMIC FAILURE. H. Kaufmann*, E. Oribe*, M. Miller*, M. Wiltshire-Clement* and

M. D. Yahr. Department of Neurology and Department of Geriatrics, Mount Sinai School of Medicine of the City University of New York, N.Y. 10029.

To investigate the role of vasopressin in the genesis of orthostatic hypotension of patients with primary autonomic failure we determined baroreceptor-mediated vasopressin release in 6 patients with this disorder. Three patients had pure autonomic failure (PAF) and 3 patients had multiple system atrophy with autonomic failure (MSA). Patients with MSA had a blunted vasopressin release in response to orthostatic hypotension whereas patients with PAF had a pronounced rise in the plasma concentration of vasopressin in response to orthostatic hypotension. The fall in blood pressure was more pronounced in the patients with MSA. Our preliminary results suggest that: 1) afferent baroreceptor pathways are spared in PAF, 2) blunted baroreceptor-mediated vasopressin release may be a marker for MSA, 3) the vasoconstrictor effect of vasopressin, released in response to baroreceptor stimulation, may moderate the fall in blood pressure in patients with PAF.

SUBCORTICAL SOMATOSENSORY PATHWAYS

ANATOMICAL INVESTIGATIONS OF AFFERENTS TO THE CERVI-CAL INTERNAL BASILAR NUCLEUS IN THE RAT: ANTERO-GRADE, INTRA-AXONAL and IMMUNOCYTOCHEMICAL LABEL-LING STUDIES. D.P. Crockett, S.L. Harris*, S. Maslany, J. Zhang* and M.D. Egger. Dept of Neuroscience & Cell Biology, UMDNJ-Robert Wood Johnson Med. Sch., Piscataway, NJ 08854-5635.

The internal basilar nucleus (IBN) of Cajal, extending medially in the cervical dorsal horn from C4 to the cuneate nucleus (CN), receives a diverse input of afferent fibers. Intradermal injections of B-HRP into the palmar digits labelled primary afferents projecting to the IBN, as did intra-axonal injections of HRP into cutaneous and proprioceptive primary afferents. Spinal injections of *Phaseolus vulgaris* leucoagglutinindemonstrated dense projections of postsynaptic dorsal column fibers to the IBN. Antibodies to substance P (SP) labelled numerous fine terminals in the IBN in contrast to the CN, which contained fewer terminals with SP-like immunoreactivity. The SP-like immunoreactive fibers that were found in CN were most abundant caudally, near the pyramidal decussation. On the other hand, antibodies to CGRP (calcitonin gene-related peptide) labelled only a few terminals in the IBN and the caudal CN. Within the gracile nucleus, a few widely scattered fibers and terminals with SP-like or CGRP-like immunoreactivity were detected, particularly in the caudal pole of the nucleus. The IBN appears to be an important site of sensory integration and transmission to more rostral structures.

99.2

THE RACCOON LATERAL CERVICAL NUCLEUS: A SINGLE UNIT D. A. Simone and B. H. Pubols Jr. Good Samaritan Hospital & Medical Center, Portland, OR 97209.
Raccoon lateral cervical nucleus (LCN) neurons with

receptive fields (RFs) located totally (N = 41) or partially (N = 19) on glabrous skin of the forepaw were

examined for their response to light tactile stimuli.

88% of the neurons were in the ventral 1/2 of the nucleus, 12% in the dorsal half. 80% of those tested were antidromically activated from the contralateral

thalamic ventrobasal complex or medial lemniscus.
Percentages of neurons classed as rapidly (77%) or slowly adapting (23%) did not differ significantly from those found among spinocervical tract (SCT) neurons. 8 were classed as light tactile and 15% as multireceptive units, also comparable to percentages found among SCT neurons. Exponents of power functions relating discharge rate during displacement ramp stimulation to ramp velocity (range for RA units = .710-.919; that for SA units = .448-.883) were similar to those found for SCT neurons. RF areas of neurons with RFs restricted to glabrous skin were significantly smaller for digital $(N = 19; range = 10-129 mm^2)$ than for palmar units $(N = 15; range = 38-257 mm^2)$, and, in both cases, were significantly larger than those for SCT neurons.

These results suggest that, except for increases in RF areas, properties of raccoon LCN neurons are similar to those of SCT neurons. [Support: NS-19486, USPHS.]

PROJECTIONS FROM LUMBOSACRAL DORSAL ROOT GANGLIA TO THE DORSAL COLUMN NUCLEI OF RATS. R. Giuffrida. P. Alario and A. Rustioni. Instituto di Fisiologia, Universitá di Catania, Italy, and Department of Cell Biology & Anatomy, University of North Carolina at Chapel Hill, NC 27599.

In a previous work we reported percentages and morphometric features of cervical dorsal root ganglion (DRG) neurons projecting to the dorsal column nuclei. We extended now the investigation to lumbosacral levels. Colloidal gold-labeled wheat germ agglutinin conjugated to inactive HRP (WGAapoHRP-Au) was pressure-injected (up to $0.8-1~\mu 1$) in cuneate and gracile nuclei of anesthetized rats. After two to three days the animals were perfused and ipsilateral DRGs were postfixed and embedded in paraffin. Retrogradely labeled neurons were identified after by silver enhancement of the gold particles. From counterstained 5 μ m-thick sections, neurons displaying the nucleolus were considered for quantitative estimates. The percentage of labeled neurons varied in different ganglia and was highest, up to 15%, at L4. The greatest majority of retrogradely labeled neurons were of large size. The percentage reported for lumbosacral projections is considerably lower than that reported for cervical projections (up to 65%). Whether this results from a lower contribution to the gracile nucleus of all afferents or from the selective absence of one or more functional group of primary afferents in the gracile funiculus remains to be established.

OPTIMIZING IMMUNOGOLD E.M. DOUBLE-LABELING FOR AMINO ACIDS. K.D. Phend, R.J. Weinberg and A. Rustioni, Dept. of Cell Biology and Anatomy, University of North Carolina, Chapel Hill, NC 27599.

Double-label immunocytochemistry using colloidal gold particles of different sizes has been used for electron

microscopic visualization of two antigens in different or the same nervous elements. We have experimented with various protocols to use this technique for the demonstration of amino acid neurotransmitters, particularly glutamate, aspartate and GABA. The following preparatory steps seem to be required for optimal results: good perfusion (as judged by the EM tissue preservation) with 2.5% glutaraldehyde (EM grade), 0.5% paraformaldehyde (Sigma) and 0.1% picric acid, postfixation for four hours in same fixative, and overnight rinse in buffer. We routinely osmicate for one hour in 1% 0s04, stain en bloc with 1% uranyl acetate, and embed in Epon-Spurr. Etching of sections is unnecessary with the use of 0.1% Triton in TBS, as suggested by DeZeeuw et al. (1988). Hot paraformaldehyde vapors have been used for double-labeling with primary antibodies raised in the same species, but this may impair staining for the second antigen, and treatment with heat alone (80°C) or with 10% formalin at room temperature is satisfactory. Reaction order of primary antibodies and choice of particle size may be crucial; this must be determined empirically.

PROJECTIONS OF PRIMARY AFFERENTS FROM THE DIGITS TO THE DORSAL HORN AND DORSAL COLUMN NUCLEI: WGA-HRP VS. B-HRP. S. Maslany. D.P. Crockett, J. Zhang and M.D. Egger. Dept. of Neuroscience & Cell Biology, UMDNJ-Robert Wood Johnson Med. Sch., Piscataway, NJ 08854-5635.

Piscataway, NJ 08854-5635.

Projections from cutaneous afferents to the dorsal horn (DH) and dorsal column nuclei (DCN) in the rat were examined using the following intracutaneously injected tracers: 25% free HRP, 2.5% WGA-HRP, a mixture of 25% free HRP and 2.5% WGA-HRP (WGA-HRP/HRP), or 0.1% B-HRP. After 3 days, the rats were perfused transcardially, transverse sections (60-μ m thick) were cut and the HRP was reacted using the TMB-method. Data from 58 rats were analyzed. Injections of 25% free HRP produced no labelling, WGA-HRP and WGA-HRP/HRP produced similar projection patterns. In the DH, WGA-HRP and B-HRP labelled different subpopulations, with WGA-HRP labelling based toward smaller diameter fibers. For both forelimb and hindlimb digits, WGA-HRP labelled cutaneous afferents projected to Rexed's laminae I-III, with the densest label in laminae III-IV. Comparisons of each digital projection map, using either WGA-HRP or B-HRP, indicated that, in the spinal cord, there was extensive overlapping among the labelled afferent fibers from these digits. Projections from forelimb digit 1 from caudal L3 to caudal L4. Projections from forelimb digit 5 extended from caudal C6 to rostral C8; for hindlimb digit 5 from caudal L3 to caudal L4. Projections from forelimb digit 5 extended from caudal C6 to rostral C8; for hindlimb digit 5 from caudal L4 to rostral L6.

In the DCN, WGA-HRP and the B-HRP labelled afferents projected more or less to the same locations for each digit, but B-HRP labelling was more intense. The DCN labelling was precisely restricted mediolaterally, with little or no overlap into adjacent areas. Labelling in the cuneate nucleus was less variable than that in the gracile nucleus. Projections from cutaneous afferents to the dorsal horn (DH) and dorsal

AFFERENT PROJECTIONS FROM THE FACE TO THE BRAIN STEM OF MACAQUE MONKEYS. S.L. Florence and J.H. Kaas. Dept. Psych., Vanderbilt Univ., Nashville, TN 37240.

The topography of somatosensory inputs from receptors in the face to the trigeminal complex of the brain stem was examined by placing one or more injections of HRP conjugated to cholera toxin subunit B subcutaneously in different locations on the face of anesthetized macaque monkeys (Macaca fascicularis). Following brief transport periods, the animals were perfused, the brain stem was cut, and sections were processed for HRP, cytochrome oxidase (CO), or stai for cell bodies. Injections resulted in labeled afferent terminals in the pars caudalis, oralis and stained principalis. A somatotopy was evident in the pars caudalis so that projections from the eyelids were caudal while those from the lips were rostral. In the pars oralis, smaller projections than those seen in the pars oralis, smaller projections than those seen in the pars caudalis appeared to reflect a second projection pattern, with the representation of the lips medial to the eyelid representation. The topographic representation of the face in the pars principalis may be oriented similarly. The CO preparations revealed dark and light regions in the complex that may relate to functional subdivisions and the locations of body part representations. Supported by NS16446 & NS08062.

EFFECT OF RETROGASSERIAN RHIZOTOMY ON NERVE GROWTH FACTOR

EFFECT OF RETROGASSERIAN RHIZOTOMY ON NERVE GROWTH FACTOR RECEPTOR IMMUNOREACTIVITY IN THE FELINE IRIGEMINAL NUCLEI. M.A. Henry', L.R. Johnson', C.D. Kullas', L.E. Westrum', and M.A. Bothwell. Univ. of Washington, Seattle, WA 98195, 'Univ. of Colorado, Denver, CO 80262. We are studying the normal organization and response to injury within the trigeminal nuclei (TN) following lesions. Here, we present observations following unilateral trigeminal rhizotomy in adult felines on nerve growth factor receptor (NGFn) immunoreactivity (IR) within TN. Ten days following rhizotomy. Fink-Heimer, stained TN. Ten days following rhizotomy, Fink-Heimer stained sections revealed massive degeneration in the ipsilateral TN and modest degeneration in the caudal contralateral TN. Using a monoclonal antibody to the human NGFr, the contra-lateral TN showed a normal pattern of discontinuous pockets of IR. The pattern within the ipsilateral TN was drastically reduced, with the remaining IR most likely from the IX and X cranial nerves. Somata within the ipsilateral trigeminal motor nucleus (Vmo) showed an increase in NGFr-IR as compared to the contralateral side. This study indicates that NGFr-IR within the TN is associated with a specific subset of primary trigeminal afferents and Vmo shows increased NGFr-IR following rhizotomy. TRIGEMINAL PRIMARY AFFERENT PROJECTIONS TO "NON-TRIGEMINAL" AREAS OF THE RAT CENTRAL NERVOUS SYSTEM (CNS). C. Marfurt and D. Rajchert, Northwest Center for Medical Education, Indiana University School of Medicine, Gary, IN 46408.

The central projections of rat trigeminal primary afferent neurons to various "non-trigeminal" areas of the CNS were examined by labeling the fibers with wheat germ agglutinin-horseradish peroxidase (WGA-HRP) transported anterogradely from the trigeminal ganglion. Terminal labeling was observed in the ipsilateral dorsal horn of the cervical spinal cord from C1-C7, and in contralateral pars caudalis and the dorsal horn of the spinal cord from C1-C5. Dense terminal labeling was observed in the ipsilateral paratrigeminal and solitary nuclei, whereas more moderate labeling was seen in the supratrigeminal nucleus and in the dorsal reticular formation. Small numbers of fibers were also observed in the cuneate, trigeminal motor, lateral and superior vestibular nuclei, and in the cerebellum. The latter fibers entered the cerebellum in the superior cerebellar peduncle and projected to the posterior and anterior lobes as well as to the interposed and lateral deep cerebellar nuclei. Most of the projections seen in this study originated from fibers in the dorsal part of the spinal tract of V, suggesting a largely mandibular origin. This study has demonstrated that somatosensory information from the head and face is transmitted directly to widespread areas of the CNS. These projections may function in trigeminospinal reflexes (dorsal horn from C1-C7), fusion of the sensory maps of the right and left sides of the head (contralateral projections), trigeminovisceral integration (paratrigeminal and solitary), control and integration of oral motor behavior (supratrigeminal and motor V), orofacial reflexes (reticular formation), and the coordination and stabilization of head posture and gaze (cuneate, vestibular and cerebellum).

EFFECT OF RETROGASSERIAN RHIZOTOMY ON THE LOCALIZATION OF EFFECT OF RETROGASSERIAN RHIZOTOMY ON THE LOCALIZATION OF CALCITONIN GENE-RELATED PEPTIDE AND GRIFFONIA SIMPLIFOLIA IN FELINE TRIGEMINAL NUCLEI. L.R. Johnson¹, M.A. Henry², C.D. Kullas² and L.E. Westrum². Univ. of Colorado, Denver, CO 80262, Univ. of Washington, Seattle, WA 98195 We are studying the normal organization and remodeling within trigeminal nuclei (TN) following trigeminal nerve lesions. Ten days following rhizotomy in adult felines, sections from TN were stained with the Fink-Heimer method, or reacted with the isolecting Griffonia simplifolia (L.R.)

sections from TN were stained with the Fink-Heimer method, or reacted with the isolectin Griffonia simplifolia $(I-B_{\rm d})$ that co-localizes with FRAP, or antibody to calcitonin gene-related peptide (CGRP). Terminal and axonal degeneration is seen throughout the ipsilateral TN with lesser amounts in contralateral caudal TN. I-B₄ and CGRP label was dramatically reduced throughout the ipsilateral consony TN and remained assertiable unchanged on the label was dramatically reduced throughout the ipsilateral sensory TN and remained essentially unchanged on the contralateral side. The ipsilateral trigeminal motor nucleus showed increased label for CGRP. $I-B_4$ and CGRP residual label have a similar distribution in the ipsilateral TN and are apparently in both degenerating fibers and a few normal axons. This study demonstrates that a significant portion of the CGRP and $I-B_4$ labeling is associated with a subset of trigeminal afferents. Ipsilateral residual labeling may be from cranial nerves IXlateral residual labeling may be from cranial nerves IX and X or reactivity associated with degenerating tri-geminal afferents. 99.10

ORGANIZATION OF AXONS IN THE RAT'S TRIGEMINAL SPINAL TRACT. R.S. Crissman, D.A. Siciliano*, N.L. Chiaia, C.A. Bennett-Clarke, and R.W. Rhoades. Dept. of Anatomy, Medical College of Ohio, Toledo OH 43699.

Trigeminal (V) nucleus caudalis (SpC) receives input from a variety of different primary afferent fiber types that have distinct laminar distributions within this nucleus. We carried out several experiments to determine whether any such laminar organization was also present in the V spinal tract at the level of this nucleus. Immunocytochemistry for substance P and calcitonin gene-related peptide, and histochemistry for the lectin <u>Bandierea simplicifolia-I</u> (markers for small caliber and primarily unmyelinated fibers) all labelled numerous axons in the outer portion of the V spinal tract. Conversely, a monoclonal antibody directed against the 200 kD subunit of neuofilament protein (a marker for larger myelinated axons) labelled axons throughout the depth of the tract. The axons) labelled axons throughout the depth of the tract. The organization of the V spinal tract suggested by these experiments was confirmed by electron microscopy. In the outermost portion of the tract, the average ratio of unmyelinated to myelinated axons was 1.95:1; in the innermost portion of the tract, this ratio fell to 0.57:1. This decrease resulted almost completely from a reduction in the number of unmyelinated fibers in the inner part of the tract. Both our immunocytochemical, histochemical, and electron microscopic data thus indicate that the V spinal tract at the level of SpC has a clearly laminar organization. Supported by RNS 85 17537. DE 0.7734 clearly laminar organization. Supported by BNS 85 17537, DE 07734, RR 05700, and the State of Ohio Research Challenge.

ORIGINS AND TERMINATIONS OF TRIGEMINAL PROJECTIONS TO RAT SPINAL CORD. W. M. Falls, L. A. Smith*, M. S. Cook* and J. Stuk*. Dept. of Anatomy, Michigan State University, East Lansing, MI 48824.

Utilizing retrograde transport of WGA-HRP, neurons projecting to cervical and thoracic portions of rat spinal cord were labeled in trigeminal nuclei interpolaris (Vi) and oralis (Vo). Cell density was greatest following upper cervical injections and decreased significantly with each successive caudal injection. Cervical injections yielded bilateral cell labeling in ventrolateral magnocellular (vlVimc), border (brVi) and intermediate regions of rostral Vi and ventrolateral (VL), middle dorsomedial (MDM) and border (B) regions of caudal Vo. Thoracic injections produced bilateral cell labeling ventrally in rostral vlVimc and brVi and in caudal VL and B. Spinal projections of Vi and Vo neurons were studied using anterograde transport of PHA-L. Neurons in vlVimc projected contralaterally to cervical dorsal horns and thoracic ventral horns. MDM, VL and B cells bilaterally innervated cervical dorsal and ventral horns. DM neurons projected to these same areas at thoracic levels, but VL cells innervated only the dorsal horns. Vi and Vo efferents terminating at spinal levels were of three morphologically distinct types. These studies suggest complex interactions between neurons in specific portions of Vi and Vo and cells located in definitive regions of cervical and thoracic spinal cord. (Supported by N.I.H. Grant DEO6725)

2-DG LABELING PATTERNS IN THE TRIGEMINAL BRAINSTEM COMPLEX FOLLOWING SELECTIVE VIBRISSAL STIMULATION IN THE ADULT HAMSTER. P.A. Young, J.S. McCasland, T.A. Woolsey, R.W. Rhoades and M.F. Jacquin. Dept. of Anat. & Neurobiol., St. Louis Univ. Sch. Med., St. Louis, MO 63104; Div. of Exp. Neurol. & Neurosurg. & McDonnell Center for Studies of Higher Brain Function, Washington Univ. Sch. Med., St. Louis, MO 63110; Dept. of Anat., Med. Coll. of Ohio, Toledo, OH 43699.

Prior studies have shown that single vibrissa stimulation results in restricted foci of increased glucose utilization at all levels of the trigeminal (V) neuraxis. However, these patterns have been directly related to aggregates of cells and axon terminals corresponding to the vibrissae only at the cortical level. In the present study, we combined 2-DG labeling and cytochrome oxidase (CO) staining in individual sections to directly evaluate this relationship in the V brainstem complex. Ten hamsters had all of their large mystacial vibrissae trimmed, except for the left C3, and the right A1 and E4, vibrissae. After overnight fasting, 2-DG was injected and the animals behaved freely in the dark for 45 min. (McCasland & Woolsey, JCN, '88). Brainstems were processed for both CO staining and 2-DG autoradiography. CO patches were patterned in a vibrissal-like fashion in all of principalis' rostrocaudal extent and in caudal portions of subnuclei interpolaris and caudalis. 2-DG silver grains were densest above those CO patches corresponding to the left C3, and the right A1 and E4, vibrissae. There were, therefore, no consistent 2-DG foci in subnuclei oralis, or rostral interpolaris and caudalis. These data show clearly that patterns of increased glucose utilization following single whisker stimulation are well matched with CO patterns that reflect distributions of cells associated with that same vibrissa in the V brainstem complex. COMPARATIVE MAGNIFICATION OF THE VIBRISSA REPRESENTATION IN THE SUPERIOR COLLICULUS OF RODENTS AND CATS. C.-Q. Kao. J.G. McHaffie. M.A. Meredith, H.R. Clemo and B.E. Stein. Depts. Physiol. & Anat., Medical Coll. Va., Va Commonwealth Univ., Richmond, VA 23298

The vibrissa representation is an exquisite adaptation of the trigeminal system, reaching its zenith in the rodent, whose vibrissae are critical for survival. One might then expect that the essential role of vibrissae in facilitating the rodent's attentive and orientation behaviors via the superior colliculus (SC) would be reflected in an expanded representation of the cutaneous area encompassing them (the vibrissa pad) beyond that evident in species that make less use of vibrissae, such as cat. This has proved to be the case, with the proportions of the SC representing the vibrissa pad in mouse (44.4%) and rat (35.8%) being far larger than in cat (13.7%), and the proportion of the body devoted to the vibrissa pad being greater in mouse (1.12%) and rat (1.24%) than in cat (0.47%). When a relative index of magnification in the SC is calculated (% of body surface vs. % of SC devoted to it), the rat (28.9) and cat (29.2) appear to be the same, but the mouse exhibits a substantially greater expansion (42.2). Thus, the rodent vibrissa specialization can be reflected both in the nature of the stimuli that can activate SC neurons, and in an expanded representation of the perioral area containing them. BRAINSTEM CONNECTIONS OF THE PARATRIGEMINAL ISLANDS IN THE RAT: A FLUORESCENT TRACER STUDY WITH TETRAMETHYLRHODAMINE DEXTRAN AND FLUORO-GOLD. D.W. Saxon* and D.A. Hopkins. Dalhousie University, Halifax, NS, B3H 4H7

The paratrigeminal islands (PTI) of the dorsal trigeminal tract, which are involved in thermosensation and hibernation (Kilduff, 1988), receive afferent projections from the pharynx and oral cavity (Altschuler et al., 1989). In order to study the efferent projections of the PTI, injections of 5-10% tetramethylrhodamine dextran (TMR) (Schmued and Heimer, 1989) or a mixture of 10% TMR and 0.4% Fluoro-gold (FG) were made into the PTI. After injections of TMR into the PTI, anterograde labelling was present in the contralateral PTI, and in the nucleus of the tractus solitarius (NTS) intermediate, interstitial, ventrolateral and ventral subnuclei, primarily ipsilaterally. The PTI also project to the ipsilateral parabrachial complex, particularly the external medial and ventral lateral subnuclei. TMR was also present in the medial and external lateral subnuclei. After injections of TMR and FG in the PTI, anterograde and retrograde labelling were present in the contralateral PTI. Retrogradely labelled cells were present in the external lateral subnucleus of the PBN and Kolliker-Fuse nuclei; some of these cells were in fields of labelled axons. The results show that afferents to the PTI project directly and indirectly, via the NTS, to specific subnuclei of the parabrachial complex. Supported by MRC of Canada (Grant MT-7369).

TRIGEMINOCEREBELLAR PROJECTIONS IN THE ADULT RAT.

J.J.A. Arends, T.J.H. Ruigrok*, T.A. Henderson and M.F. Jacquin. Dept. of Anatomy and Neurobiology, St. Louis University School of Medicine, St. Louis, MO 63104, and Dept. of Anatomy, Erasmus University, 3000 DR Rotterdam, The Netherlands (TJHR).

HRP, WGA-HRP and PHA-L tracing methods in conjunction with Zebrin-1 (mab0113) immunohistochemistry, were used to study trigeminocerebellar projections in the rat. Massive HRP injections into the entire cerebellum retrogradely labeled cells in every trigeminal brainstem subnucleus. They were most numerous in subnucleus interpolaris (SpVi); subnucleus caudalis (laminae III-V) contained the smallest number.

Anterograde transport following tracer injections in SpVi labeled multiple patches of short parasagittal strips of mossy fiber rosettes in the cerebellar cortex. This discontinuous, patchy projection pattern may be the basis for prior electrophysiological demonstrations of 'fractured somatotopy' in the cerebellum (Welker, W.I., New Concepts in Cerebellar Neurobiology, Alan R. Liss, New York 1987, pp 239-280). Bilateral, but predominantly ipsilateral, terminations were observed in vermis (dorsal uvula; proximal lobules V-VIII) and in the hemispheres (Crura I and II, the simple lobule, the paramedian lobule, dorsal paraflocculus and lateral lobules II-V). Following injections at different dorsoventral levels of SpVi, differential projections were observed (as measured against the background of the Zebrin staining pattern), most notably in the uvula, the paramedian lobule and Crura I and II. Support: NIH DEO7662, DEO7734.

SOMATOTOPIC COMPONENT OF THE MULTISENSORY MAP IN CAT DEEP SUPERIOR COLLICULUS. M. A. Meredith, H. R. Clemo and B. E. Stein. Depts. Anatomy and Physiology, Med. Coll. Va., Va. Commonwealth Univ., Richmond, VA 23298.

While the somatosensory representation in the cat superior colliculus (SC) is well established, this region also contains maps of visual and auditory space and it is not known if, or to what extent, the somatosensory map participates with these others to form a comprehensive, multisensory representation. To examine this question, the receptive fields (RF) and patterns of modality convergence were examined in 198 somatosensory neurons in 21 chronically prepared, anesthetized (Ketamine/Acepromizine) cats. The somatosensory map was examined using procedures modified from McIlwain (J. Neurophysiol. 38:219, 1975), whereby dermal images were constructed by determining the histological distribution of neurons whose RFs encompassed a given body region. This process accommodated not only the relative largeness of some RFs encountered, but also their variations with depth in the SC. Although previously unreported representations of certain body regions were now revealed (e.g., tall, ventrum), the general organization of the somatosensory map is the same as described before (Stein et al., J. Neurophysiol. 39:401, 1976). When the pattern of convergence from other sensory modalities was evaluated, it was found that the overwhelming majority (125/198; 63%) of somatosensory neurons received visual and/or auditory inputs. These data strongly suggest that many features of this somatosensory map are similar to the visual representation also found here (Meredith and Stein, Soc. Neurosci. Abstr. 14:831, 1988), and this somatosensory representation is best considered a component of a multisensory functional unit that plays a critical role in effecting behavioral responses to a wide variety of stimuli. Supported by grants NS-22543 and BNS 8719234.

SOMATOSENSORY CORTICAL (SIV) INPUTS TO DEEP LAYER EFFERENT NEURONS IN CAT SUPERIOR COLLICULUS H.R. Clemo, M.A. Meredith and R.F. Spencer Depts. Physiology and Anatomy, Med. Coll. Va., Va. Commonwealth Univ.,

Richmond, VA, 23298.

While the afferents to as well as efferent targets of the superior colliculus (SC) are well established, the role of somatosensory cortical inputs in the control of specific SC output neurons is not known. Of the identified somatosensory cortices, SIV and para-SIV (which are located in the dorsal bank and fundus of the anterior ectosylvian sulcus) give rise to the heaviest corticotectal projection. As for output neurons of the SC, the involvement of tecto-reticulo-spinal neurons in the initiation of orientation behaviors is well documented. Therefore, by using double-labelling techniques, we sought to determine whether axons originating in SIV and para SIV contact tecto-reticulo-spinal neurons. Tecto-reticulo-spinal neurons were identified with the retrograde transport of HRP from injections into the dorsal tegmental decussation, while terminals of corticotectal axons were localized in the same animal (n=8) using PHA-L placed in SIV and para-SIV. Preliminary results show terminal labelling of cortical axons on the distal dendrites of HRP-filled neurons located in both the intermediate and deep grey laminae. These data demonstrate that somatosensory cortex has direct access to SC output neurons and thereby can modulate the activity of neurons that initiate orienting behaviors. SOMATOSENSORY EVOKED RESPONSES IN VENTROBASAL THALAMIC NEURONS: AN INTRACELLULAR STUDY IN THE RAT. A. Noñez*. C. Barrenechea* and C. Avendaño. Dept. of Morphology. Medical Sch., Autónoma Univ., 28029 Madrid. Spain.

Intracellular recordings of thalamic relay neurons were obtained in order to study the spontaneous and stimulus-related activity in rat ventroposteromedial nucleus (VPm). Sprague-Dawley rats, weighing 200 g, were anesthetized with i.p. pentobarbital, paralyzed with i.p. vecuronium and artificially respired. Micropipettes filled with a 4% solution of HRP in 0.5 M KCl were lowered vertically into VPm. Sensory stimulation consisted of manually applied strokes or hair displacement on the receptive field. Impaled neurons showed stable membrane potentials below -50 mV and overshooting spikes. A few of them were successfully labeled, drawn, and photographed. Peripheral stimuli elicited two kinds of response: 1, a depolarizing potential with a fast-rising slope (<5 ms) and low amplitude (<10 mV), with one or two spikes rising on it; 2, a slow depolarizing wave of larger amplitude (up to 20 mV) and longer duration (up to 100 ms), which triggered a burst of spikes. Both responses could occur spontaneously or locked to the stimuli and their amplitude fluctuated. Depolarizing current pulses elicited neither of these activities, whereas hyperpolarizing pulses increased the amplitude of both, thus suggesting that both kinds of response have a synaptic origin. a synaptic origin.

ANTIDROMIC IDENTIFICATION OF "COLD"-SPECIFIC LAMINA I CELL TERMINATIONS IN THE CAT THALAMUS. J.O. Dostrovsky and A.D. Craig. Dept. of Physiology, Univ. of Toronto, Toronto, Canada, M5S-1A8 and Div. of Neurobiology, Barrow Neurological Institute, Phoenix, AZ 85013.

Previous anterograde tracer studies have demonstrated several spinal and

trigeminal lamina I projection sites in the thalamus, including a specific input to the n. submedius (Sm); previous physiological studies utilizing antidromic activation have suggested that lamina I cells that project to Sm include cells specifically responsive to innocuous cooling. The aim of the present study is to identify the terminal thalamic projections of "cold" spinothalamic and trigeminothalamic neurons by antidromic mapping with a mobile array of stimulation electrodes. In nine barbiturate-anesthetized cats an array was inserted into the region of Sm based on functional localization of the boundaries of ventrobasal thalamus. Single-unit extracellular recordings in lamina I were obtained from the contralateral medullary or cervical dorsal horn. Following antidromic activation of a "cold"-specific neuron, the array of stimulating electrodes was moved dorsoventrally at successive rostrocaudal locations in order to determine the focal sites from which the neuron could be antidromically activated. Complete histological reconstructions were done in each case. Twelve "cold" cells were activated from Sm. In all seven cells that were sufficiently well mapped, it was possible to demonstrate an additional separate projection to the putative thermoreceptive site on the dorsomedial aspect of VPM. Six cells also projected to the ventral aspect of VMb. These results demonstrate that specific thermoreceptive lamina I projections are distributed to several thalamic sites, including Sm. (supported by NIH grants to J.O. Dostrovsky and A.D. Craig)

THE EFFECTS OF COOLING CORTICAL SOMATOSENSORY AREAS I (SI) OR II (SII) ON THE RESPONSIVENESS OF VENTROBASAL (VB) THALAMIC NEURONS TO FOREPAW MECHANICAL STIMULATION IN THE THATAMIC NEDWORS TO FOREFAM THATAMICAL STITUTATION IN THE CAT. S. Ghosh, A.B. Turman*, G.M. Murray+, and M.J. Rowe*. School of Physiol. and Pharmacol., Univ. of NSW, and +Faculty of Dentistry, Univ. of Sydney, Sydney, Australia. The functional significance of the descending

projection from SI and SII to VB thalamus is poorly understood. This study's aim was to see if reversible inactivation by cooling of SI or SII affected the response properties of VB neurons to mechanical stimulation. In properties of VB neurons to mechanical stimulation. In halothane anesthetized cats (n=15), the responsiveness of VB neurons to controlled mechanical stimuli (sinusoidal vibrations, step indentations) delivered to hairy or glabrous skin of the contralateral forepaw was studied before, during and after cooling of the forepaw representations of SI and/or SII. Response levels (imp./s) were unaffected in 75% of neurons (n=30); in 25% of neurons a reduction in response level was noted following inactivation of SI or SII. In all neurons responding to vibrotactile stimuli (n=29), the extent of phase locking to the vibration was unaffected by cortical cooling, whether or not response levels were changed. We conclude that the responses of VB neurons to low threshold mechanical stimuli are mainly unaffected by reversible inactivation of SI or SII; but in a proportion of neurons, a facilitatory corticothalamic influence was revealed. ORIGIN, COURSE, AND ULTRASTRUCTURAL TERMINATION OF DORSAL COLUMN NUCLEAR PROJECTIONS TO THE ROSTRAL PORTION OF THE POSTERIOR THALAMIC NUCLEUS IN THE RAT. R.J. Kosinski, P. Hlavac, E.L. Bold and E.J. Neafsey. Depts. of Anatomy, The Chicago College of Osteopathic Med., 555 31st St. Downer's Grove, IL, 60515 and Loyola Univ. of Chicago, Sch. of Med.

The present study verified that the dorsal column nuclei (DCN) project to rostral portions of the posterior thalamic mucleus (Po) in rats by using the retro- and orthograde transport of WGA/HRP at light and electron microscopic levels. While anesthetized, black hooded rats were injected with a 2% solution of WGA/HRP (0.01-0.04ul) either within the DCN or rostral portions of Po, unilaterally. Animals survived for 24 - 48 hrs. Other animals received aspiration lesions of the DCN and were allowed to survive for 3 - 10 days. All animals were reanesthetized and perfused with a standard EM/HRP fixative. Brains were removed, sectioned, and processed for light and/or electron microscopy.

Results indicated that DCN projections to Po primarily

originate from rostral and ventral portions of the contra-lateral DCN. These projections course with the medial lemniscus until the midbrain, where they diverge dorsally to distribute within Po, somatotopically. Degenerating or WGA/HRP-containing synaptic boutons were identified ultrastructurally to contain small, round vesicles and to form asymmetrical synapses with dindritic profiles and/or dendritic spines in a manner similar to that observed for other DCN projections.

WHISKER-EVOKED RESPONSES IN THE POSTERIOR NUCLEUS (PO) OF RAT. M. E. Diamond, M. A. Armstrong-James and F. F. Ebner, Center for Neural Science, Brown Univ., Providence, RI 02912

Center for Neural Science, Brown Univ., Providence, RI 02912 In rat, parallel 'lemniscal' and 'paralemniscal' pathways from the whisker follicles relay in VPM and PO, respectively, before terminating in separate zones of the somatic sensory cortex (barrels and septa). To learn more about the 'paralemniscal' pathway, we have compared the whisker-evoked responses of PO cells to those of VPM and cortical cells studied under similar conditions. The responses of 55 PO cells to controlled whisker deflection were measured in urethane-anesthetized rats. With a response criterion of ≥ 0.1 spikes/trial across 50 trials (after compensation for the high levels of spontaneous activity). 48 PO cells (87%) had an excitatory RF spontaneous activity), 48 PO cells (87%) had an excitatory RF, 2 cells had an inhibitory RF, and 5 cells did not respond to whisker movement. The average excitatory RF was 4.3 whiskers (range 1-13). The mean response to the 'best' whisker was 0.45

(range 1-13). The mean response to the 'best' whisker was 0.45 spikes/trial; VPM cells gave a stronger response to the 'best' whisker: 1.12 spikes/trial (In Press).

The most striking finding was the long latency of PO cells even in response to the 'best' whisker (mean 22 ms; range 5-47 ms). Evoked activity in VPM (latency range 4-7 ms) thus initiates activity in cortex (latency range 7-25 ms) before the majority of PO cells discharge. This sequence of activation suggests that PO may influence the "late" communication among cortical barrel-columns. (Supported by NIH grant #NS 25907).

RESPONSE OF MONKEY VPM NEURONS TO AIR-PUFF STIMULATION DURING DISCRIMINATION AND ATTENTION TASKS. N. Tremblay*, N.

Bastrash*, M.C. Bushnell, G.H. Duncan, Univ. Montréal, Canada H3C 37.

Many studies have reported slowly adapting (SA) and rapidly adapting (RA) neurons in ventrobasal thalamus, but no study has quantitatively investigated the discriminative properties of these neurons or their modulation by attention. Thus, the present study assesses the activity of single units in ventroposterior medial thalamus (VPM) of monkey during performance of air-puff discrimination and attention tasks.

One Rhesus monkey was trained to detect small changes in the intensity of air-puff and light stimuli. In the air-puff task, twenty-ms puffs of fixed intensity were delivered at 1Hz via a 2mm-diameter tube positioned 2mm from the were universed at 1712 via a 2 min-dualited tude positioned 2 min from the monkey face. After 47s, the puff intensity changed, cueing the monkey to release a lever for liquid reward. In the attention task, identical air-puff stimuli were presented on all trials, but for half the trials, the monkey earned reward only for attending to and detecting changes in the intensity of a light. Single units were recorded during the tasks and their receptive field and rate of adaptation to tactile stimulation were determined.

Within VPM, both RA and SA neurons were observed that responded to air-puff stimulation. Usually the response was excitatory, but clear examples of inhibition were observed time-locked to the air-puff stimuli. Both RA and of inhibition were observed time-locked to the air-puff stimuli. Both RA and SA neurons responded differentially to various air-puff intensities and responded to the smallest intensity detectable by the monkey. In 10 neurons tested for attentional modulation, there was no indication that activity was enhanced when the monkey attended to the air-puff (p=0.44), confirming results of previous multi-unit studies (Poranen and Hyvarinen, 1980).

Our results indicate that some SA and RA neurons in VPM are sufficiently sensitive to account for the fine tactile discrimination seen in primates. However, we have observed no evidence that the ventrobasal thalamus plays an important role in attentional modulation of tactile discrimination.

ELECTRON MICROSCOPY OF 5-HT AND TH IMMUNOREACTIVE AXON TERMINALS IN THE VP NUCLEUS OF CAT AND MONKEY THALAMUS. X.-B. Liu and E.G. Jones. Dept. of Anatomy and Neurobiology, Univ. of California, Irvine, CA 92717.

Physiological and morphological studies have shown that relay nuclei of the thalamus receive brainstem afferents and immunocytochemistry has revealed serotonin (5-HT) and noradrenaline fibers in the ventral posterior (VP) nuclei. However, the synaptic connections of these fibers in VP have nor been described. In the present study we have combined immunocytochemistry and EM analysis of serial thin sections to localize serotonin and tyrosine hydroxylase (TH) immunoreactivities in VP of cat and monkey.

Adult cats and monkeys were perfused with 4% paraformaldehyde in 0.1M phosphate buffer or in 2% paraformaldehyde and 0.2% glutaraldehyde in 0.1M phosphate buffer. Immunocytochemistry was carried out using polyclonal antisera and the ABC method. 5-HT immunoreactive fibers and terminals were distributed evenly in the lateral thalamus of cat and monkey. Within VPL, immunoreactive fibers were typically thin and bore many varicosities; in some instances the fibers or their fine branches closely surrounded neuronal somata. TH staining was not obtained in cat thalamus. In monkey, TH and 5-HT immunoreactive fibers had a similar staining pattern in VPL. Irregularly distributed varicosities could be seen along the immunoreactive fibers and their branches. Ultrastructural characteristics of 5-HT and TH immunoreactive elements are similar. About 100 immunoreactive terminals of both types were chosen for serial section EM study. Only 10% of 5-HT terminals and no TH terminals could be shown to form conventional synapses These few formed asymmetrical synapses with proximal dendrites of relay cells and presynaptic dendrites of interneurons. The remaining immunoreactive terminals recognized by containing synaptic vesicles and mitochondria made contact with dendritic shafts and somata, but no synaptic contacts could be demonstrated. Supported by NIH grant no. NS22317.

EFFECTS OF ATTENTION ON VP THALAMIC NEURONAL RESPONSES IN AWAKE MONKEY. T.J. Morrow and K.L. Casey, Depts. of Neurology and Physiology, Univ. of Michigan and V.A. Medical Ctr., Ann Arbor, Mi 48105. A key question in neuroscience concerns the mechanism(s) by which the central nervous system filters incoming sensory signals and assigns importance or relevance to specific pieces of the sensory information being received. Previously we showed that the somatically evoked discharges of many primate ventral posterior (VP) thalamic neurons covary with the level of arousal (Brain Res. Bull, 21:433-438, 1988). Accordingly we chose to study the effects of attention on the responses of VP neurons in the awake monkey. One African green monkey was trained to pull a bar to obtain a fruit reward under different experimental conditions: one involving attention to a visual cue, the other to a specific somatosensory stimulus. The responses of single neurons in the VP thalamus to somatic stimuli and to electrical stimulation of the spinal lemniscus (SL) were recorded during the behavioral task. Movements and EEG were monitored to identify periods of drowsiness, quiet waking and waking movement. Neural responses were separately analyzed by computer for changes related to elements in the behavioral paradigm and to shifts in arousal. to shifts in arousal.

Five of the 8 neurons tested showed changes in somatic or SL evoked responses which correlated with behavioral task performance. During attention in the visual task, 3 units showed increased responsiveness and two were unaffected. Three units showed either an increased or decrease two were unaffected. Three units showed either an increased or decreased responsiveness during attention to a somatic cue applied concurrently to an area of the body outside of the unit's receptive field. One cell showed increased responsiveness during young to trials. Modulation occurring during shifts in the state of arousal was mixed with respect to the direction of change in response to somatic stimuli. Modulation of VP thalamic responsiveness can be attributed specifically to changes in attention and is distinct from those changes occurring during shifts in the general state of arousal.

ULTRASTRUCTURE OF SYNAPTIC CONNECTIONS IN THE THALAMUS FROM FIBERS ARISING FROM THE MEDIAL PARABRACHIAL NUCLEUS (MPB) OF THE RAT. A.M. Williamson, and H.J. Ralston, III. Dept. of Anatomy, UCSF, San Francisco, Ca. 94143.

Recent work by our laboratory (Ahlgren et al., Soc. Neurosci. Abst. 15:157.2, 1989) and others (Yasui et al., J. Comp. Neurol. 290:487, 1989) has shown that the MPB of the rat contains fibers which project rostrally into the thalamus and cortex. While the function of this projection is not known, the MPB contains cell bodies which are labelled by antibodies to calcitonin gene-related peptide (CGRP).

We examined this fiber projection to determine whether or not the varicosities in the thalamus, visible at the level of the light microscope, formed synaptic contacts and to define the nature of these contacts.

These experiments were conducted on male Sprague-Dawley rats which were injected with Phaseolus vulgaris leucoagglutinin (PHA-L) in the MPB. The animals were sacrificed after 7-10 days survival time, and the tissue was processed to demonstrate PHA-L using standard immunohistochemical techniques. The tissue was then processed for EM analysis. All procedures were in accordance with UCSF and NIH animal care guidelines.

Preliminary results suggest that PHA-L containing fibers in the gustatory nucleus and rostrally in the dorsal midline of the thalamus form both symm and asymmetric synaptic contacts onto small and large dendrites. No contacts onto other presynaptic elements or cell bodies have been seen. All labelled axonal elements were unmyelinated. Many appositions without synaptic specializations were also present.

This work was supported by NS-21445 from the NIH.

INPUT-OUTPUT ORGANIZATION OF VPM RODS IN MONKEY THALAMUS. E. Rausell and E.G. Jones. Dept of Anatomy and Neurobiology, University of California, Irvine, Ca 92717.

The principal trigeminal nucleus of the monkey brainstem gives rise to fibers that terminate in elongated rod-like cell clusters within the ventral posterior medial (VPM) nucleus of the thalamus. The rods provide the physiological basis for the place and modality specific projection onto the first somatic sensory area, SI (Jones et al, Exp. Brain Res., 62: 438, 1986). We have further characterized the organization of the afferent and efferent connections of the VPM rods, by means of the anterograde transport and immunocytochemical detection of iontophoretically injected <u>Phaseolus vulgaris</u> leucoagglutinin (Pha-L). Our findings demonstrate: a) The axonal terminations of electrophysiologically identified principal trigeminal neurons are restricted to the rods. b) In VPM, adjacent neurons that have the same stimulus-response characteristics lie in the same rod, and extend 800-950 µm in the anteroposterior dimension. c) Pha-L labeled fibers arising from the same rod enter SI perpendicularly from the white matter and each arborizes widely in a 4 to 6 mm long medio-lateral strip-like fashion. The terminations concentrate in the deeper part of layer III and in layer IV in the fundus of the central sulcus, extending 800-1500 μ m anteroposteriorly. Within the strips, column-like foci of dense terminations alternate with foci of weak terminations in the same cytoarchitectonic field.

These data suggest that the thalamocortical input to SI from the VPM rods is provided by widely arborized axons that terminate in strips. Within the same cytoarchitectonic field, the strips contain areas of differential innervation density. This may provide the anatomical substrate for multiple representations within SI and the basis for activity dependent plasticity of the representation Supported by NIH Grant Number NS 22317 and by a Fogarty fellowship to E.R.

THALAMOCORTICAL PROJECTIONS CORRELATE WITH STIMULUS-EVOKED METABOLIC ACTIVITY IN CAT SOMATOSENSORY CORTEX. W. Ma, D.E. Eslin, S.L. Juliano. Anatomy, USUHS, Bethesda, MD 20814.

We previously described the coincidence of evoked metabolic activity with cortico-cortical connections in the somatosensory cortex (SSC) and with retrogradely labeled neurons in the ventroposterior nucleus (VP) of the thalamus in primates. Those studies indicate the significance of connectivity in predicting functional activity. The current study seeks to determine the predicting functional activity. The current study seeks to determine the relationship between stimulus-evoked metabolic activity and thalamocortical projections in the SSC of the cat, although the precise functional and connectional relations may differ from those in primates. Double-barreled micropipettes were used to record thalamic units in VP responding to somatic stimuli, followed by iontophoretic injection of WGA-HRP into physiologically identified thalamic sites. Two days later, cats were injected with 2-deoxyglucose (2DG) and received the somatic stimulation found to best excite the thalamic neurons during recording. WGA-HRP injections led to column-like clusters of label in area 3b. Labeled fibers and terminals occurred primarily in layers IV and III and to a lesser extent in layer V; labeled cells were located largely in layer V. Following stimulation to the limbs, column-like metabolic patches coincided with the WGA-HRP label in somatotopically appropriate regions of area 3b. The metabolic patches generally overlapped with the WGA-HRP labeled fibers and terminals in layers IV and III. In addition, somatic stimulation to the limbs elicited metabolic activity in area 3a, where no WGA-HRP label was observed. The configuration of the evoked metabolic label was usually identical to the morphology of the WGA-HRP label. This finding suggests that evoked metabolic activity in SSC strongly correlates with cortical projections from VP neurons, although the functional roles played by corticocortical connections versus thalamocortical connections are yet to be elucidated.

100.13

THALAMIC CONNECTIONS OF THE FIRST (S-I), SECOND (S-II) AND PARIETAL VENTRAL (PV) SOMATOSENSORY AREAS IN NEW WORLD MARMOSETS (CALLITHRIX JACCHUS). Jon H. Kaas & Leah A. Krubitzer, Vanderbilt Univ., Nashville, TN 37240. Small amounts of anatomical tracers were placed into three electrophysiologically defined representations (S-I, S-II, and PV) in seven marmoset monkeys. Using multiunit mapping methods, the receptive fields for much of the body surface were quickly defined, physiological boundaries were lesioned, and anatomical tracers including WGA-HRP and fluorescent dyes were injected into specific representations of body parts in these fields. Three types of injection strategies were used. First, numerous small injections of WGA-HRP were closely spaced within the entire mediolateral extent of S-I to form one long injection. In this way, the entire extents of thalamic nuclei projecting to S-I could be determined. Second, different anatomical tracers were placed into different body parts in the same representation so that the topographic organizations of thalamic nuclei could be determined. Finally, different anatomical tracers were placed in the representations of the same body parts of different cortical areas, allowing connectional similarities and differences to be readily assessed.

S-I receives topographic input predominantly from the ventroposterior nucleus (VP) of the thalamus and receives less dense input from the inferior (VPI) and superior (VPS) divisions of VP. In cases where strip injections filled almost the entire extent of S-I, VP was almost completely filled with labelled cell bodies and axon terminals. However, small unlabelled strips of cell sparse zones separating body part representations in VP were observed. Connections of S-II are most dense with VPI, VPS and the posterior nucleus (PO) of the thalamus, while connections of PV are most dense with PO, VPI and VPS and less dense with VP.

100.15

CO-LOCALIZATION OF RETROGRADELY-LABELED NEURONS AND LEU-ENKEPHALIN CYTOCHEMISTRY IN THE POSTERIOR NUCLEUS OF THE THALAMUS IN GREY SQUIRREL. <u>H.J. Gould, III, R.H. Whitworth, Jr. and R.W. Rieck.</u> Department of Anatomy, L.S.U. Medical Center, New Orleans, LA 70112-1393.

L.S.U. Medical Center, New Orleans, LA 70112-1393.

Thalamic nuclei connected with the parietal dysgranular cortex (PDC) (Gould et al., '89, J. Comp. Neurol., 287:38) were studied in the grey squirrel using a combination of retrograde transport of rhodamine microspheres and immunocytochemistry for localization of leu-enkephalin.

Neurons labeled with rhodamine were found in a narrow zone of thalamus along the dorsal border of the ventral posterior nucleus, including parts of both Pom and Pol described by Krubitzer and Kaas ('87, J. Comp. Neurol., 265:549). Within the field of retrogradely-labeled neurons, immunocytochemical techniques revealed a very sparse pattern of leu-enkephalin- immunoreactive fibers. sparse pattern of leu-enkephalin- immunoreactive fibers. Enkephalin labeling was also noted in the reticular nucleus of the thalamus (which is known to receive a dense projection from the PDC), within lateral portions of the ventral posterior nucleus related to the limbs, trunk and tail, and in the central lateral, central medial, and anterior group of thalamic nuclei.

These results are consistent with those of our earlier connectional studies. The co-localization of leu-enkephalin immunocytochemistry and neurons labeled with tracer injected into PDC, suggests that enkephalin may play a role in the modulation of interhemispheric circuits. THALAMOCORTICAL CONNECTIONS RELATED TO RESPIRATORY MUSCLE AFFERENTS IN THE CAT. J. L. Sallach, R. L. Reep and P. Davenport*. Dept. of Physiological Sci., Univ. Florida, Gainesville, FL 32610.

Previously we reported cortical responses to stimulation of respiratory muscle afferents in the cat. In conjunction with defining the pathways associated with these responses, the specific aim of this study was to identify thalamocortical connections within this system.

Respiratory muscle afferents were activated by stimulation of the left C5 portion of the phrenic nerve. Cortical activity was recorded in right SI using a silver ball electrode and/or tungsten microelectrode. After the region of primary activation was located, a microinjection of WGA-HRP or retrograde fluorescent tracer (DY or FB) was made, often with ³H-leucine-proline. Injections were also made 2.0mm rostral and caudal, or 2.0mm medial and lateral to the primary area using different fluorescent tracers. The animals survived 2-7 days, were perfused, and their brains sectioned at 30-40 µm. To facilitate localizing injection sites, a portion of the right hemisphere including

SI was sectioned sagittally. The remaining brain was sectioned coronally.

The primary area is located in area 3a of SI, close to the 3a/3b border. The primary area is located in area 3a of SI, close to the 3a/3b border. Thalamic labeling associated with injections in the primary site is largely confined to the ventrobasal complex, particularly the ventromedial aspect of VPL (VPLm) mostly adjacent to the external medullary lamina, especially in the caudal aspect of VPL. The intralaminar and posterior nuclei also showed some labeling from injections in the primary site. Injections caudal or medial to the primary area produced labeling in the dorsolateral aspect of VPL (VPLI), also adjacent to the external medullary lamina. Rostral injections showed labeling in the ventrolateral and ventromedial nuclei. Anterograde labeling was comparable in location to that seen with the retrograde labeling from the primary area. Supported by NIH grant #HL37596.

EVIDENCE FOR TRANSNEURONAL DEGENERATION OF INTERNEURONS IN THE VENTROPOSTERIOR
NUCLEUS (VP) OF THE THALAMUS FOLLOWING
CORTICAL ABLATIONS OF PRIMARY SOMATOSENSORY
CORTEX IN MACAQUES (M. mulatta). J. Chmielowska,
T.P. Pons and M. Mishkin. Laboratory of Neuropsychology, NIMH, Bethesda, MD.

NIMH, Bethesda, MD.

An antiserum against the inhibitory transmitter gamma aminobutryic acid (GABA) was used to investigate the distribution of GABAergic cell bodies in VP of 2 normal and 3 operated hemispheres. In the operated hemispheres aspiration ablations of either all (areas 3a, 3b, 1 and 2) or portions (3a, 1 and 2 or 3b, 1 and 2) of the hand representations in to processing the tissue. In the normal hemispheres Nissl staining of cells and cytochrome oxidase (CO) activity was dense and uniform throughout the hand representation in VP and counts of GABA-positive neurons were on the order of 78.4/mm². In the operated hemispheres many of the cells in the hand representation in VP that project to cortex underwent the hand representation in VP that project to cortex underwent degeneration and these regions stained only lightly for CO activity. Cell counts of ABA-positive neurons in these regions were 28.9/mm². Since it is unlikely that a large population of GABA-positive cells project directly to primary somatosensory cortex, their reduction after cortical ablation is most likely due to retrograde transneuronal degeneration of interneurons which have lost their local projection targets.

CLAUSTRAL PROJECTIONS TO FIRST SOMATOSENSORY CORTEX IN MACAQUE MONKEYS: A MULTIPLE RETROGRADE TRACING STUDY
A.Granato*, P.Barbaresi*, and D.Minciacchi, Inst. of Anatomy, and Lab. of
Experimental Neurology, Catholic Univ., Rome, and Inst. of Physiology, Univ.

Experimental Neurology, Catholic Univ., Rome, and inst. of Physiology, Univ. of Ancona, Ancona, Italy.

The claustrum (CI) is a subcortical structure reciprocally connected with the cerebral cortex. Previous anatomical and electrophysiological studies have demonstrated the existence of a somatotopic map in the cat's CI. Claustral projections to primary somatosensory cortex (S1) have been also described in primates, but little is known about their topographic organization.

described in primates, but little is known about their topographic organization. In the present study we have investigated the somatotopic organization of Cl projections to S1 in macaque monkeys.

After electrophysiological identification of the face (S1fa) and hand (S1ha) representations in S1, fluorescent tracers were injected in these cortical regions. Tracer injections involved both areas 3b and 1. Two separate populations of retrogradely labeled neurons were observed in Cl: a first cell population surrounded dorsally the insular cortex, with S1fa neurons located laterally to S1ha neurons. More ventrally, a second cell population was observed in which S1fa cells were located rostrally to S1ha cells.

The ratio between the number of cells labeled in Cl and in the ventroposterior thalamic complex was significantly higher than that obtained

ventroposterior thalamic complex was significantly higher than that obtained in our previous studies in the cat (monkey: about 0.5; cat: about 0.3) (Granato et al., Eur. J. Neurosci. S. 2: 74, 1989). The monkey's Cl shows also a relative preference of projections to S1ha in respect to S1fa.

These data provide the first demonstration of ordered and possibly

multiple somatosensory representations in the monkey's Cl. Furthermore, our comparison with projections arising from the thalamic relay indicate that the Cl represents, in monkeys, one of the major subcortical inputs to S1.

PARVALBUMIN AND CALBINDIN HISTOCHEMISTRY OF THE HUMAN THALAMUS, K.M. Harrington and N.W. Kowall. Neurology Service, Mass.

General Hospital, Boston MA, 02114.

We examined the distribution of calbindin and parvalbumin immunoreactivity

in normal adult human thalamus using monoclonal antibodies (Sigma). The anterior nucleus contained scattered parvalbumin and calbindin positive neurons and parvalbumin terminals. The medial dorsal nucleus contained many parvalbumin neurons and few calbindin neurons. The ventral anterior-lateral complex had parvalbumin terminals and a moderate number of weakly stained calbindin neurons. A few parvalbumin neurons were present in the reticular nucleus. Intralaminar and midline cell groups contained prominent calbindin neurons but few parvalbumin neurons. The lateral posterior nucleus had moderate numbers of parvalbumin and calbindin neurons. Scattered parvalbumin neurons and terminals and moderate numbers of lightly stained calbindin neurons were present in the lateral dorsal nucleus. Ventral posterior nucleus had a moderate population of parvalbumin neurons and a few calbindin neurons. Parvalbumin positive terminals and calbindin positive neurons were seen in the lateral genicu-late. Parvalbumin and calbindin terminal fields defined the subthalamic nucleus and substantia nigra respectively. Our results show that parvalbumin and calbindin reactive neurons are generally segregated in the thalamus. Intralaminar and midline cell groups contain prominent calbindin neurons while parvalbumin neurons are concentrated in the medial dorsal and, to a lesser degree, the ventral posterior nucleus. The distribution of calbindin neurons in superficial cortical layers parallels the terminal fields of intralaminar thalamic nuclei which contain ayes paranets une terminal reuses of mutantina matamia funcia wince contain prominent calbindin positive cell groups. Similarly, parvalbumin local circuit neurons are concentrated in layer IV of cerebral cortex where projections from thalamic nuclei containing parvalbumin neurons terminate. Widely distributed but connectionally related nuclei may, therefore, be linked by shared biochemical features such as their content of specific calcium binding proteins.

CHEMOARCHITECTONIC DELINEATION OF VENTRAL TIER NUCLEI IN MACAQUE THALAMUS. L.J. Martin, J.C. Hedreen, D.L. Price and M.R. DeLong. Neuropathology Laboratory, The Johns Hopkins University School of Medicine, Baltimore, MD 21205.

The cytoarchitecture of the macaque thalamus is well characterized, but chemoarchitectonic definitions of characterized, but chemoarchitectonic definitions of thalamic nuclei are less clear. To characterize the chemoarchitecture of ventral tier nuclei (i.e., ventral anterior pars magnocellularis and parvocellularis; ventral lateral pars oralis [VLo]; ventral lateral pars medialis; ventral lateral pars caudalis [VLc]; area X; ventral posterior lateral pars oralis [VPLc]; ventral posterior medial [VPM]) in macaque thalamus, serial sections were stained for Nissl; acetylcholinesterase (AChE); cytochrome oxidase (CO); and glutamic acid decarboxylase (GAD). Ventral tier nuclei had distinct decarboxylase (GAD). Ventral tier nuclei had distinct patterns of AChE staining. VLo had clusters of very dense, large, coarse boutons and fine varicose fibers surrounding AChE-positive neurons. VLo extended caudally and dorsally into the region usually labeled VLc. VPLo and dorsally into the region usually labeled VLC. VPLO had a dense AChE innervation, with a pattern different from that of VLo, VLc, area X, and VPLc. CO and GAD staining delineated VLo and VPLo clearly from contiguous nuclei. Therefore, chemoarchitectonic patterns help to delineate thalamic ventral tier nuclei when cytoarchitectonic features are not distinct.

SOMATOSENSORY CORTEX AND THALAMOCORTICAL RELATIONSHIPS II

INTRINSIC SYNAPSES OF CALLOSAL PROJECTION NEURONS IN MOUSE SOMATOSENSORY CORTEX. <u>E.L.WHITE</u> AND <u>D. CZEIGER</u>, DEPT OF MORPHOLOGY, BEN-GURION UNIV. BEER SHEVA, ISRAEL.

Neurons in areas 1 and 40 of mouse Sml cortex were labeled by the retrograde transport of horseradish peroxidase (HRP) transported from severed callosal axons in the contralateral "Intrinsic" terminals of the local axon collaterals of these neurons were identified in areas 1 and 40, and their distribution and synaptic connectivity were examined.

A post-lesion survival time of 3 days was chosen because by this time extrinsic callosal terminals were all degenerating, whereas the intrinsic terminals were labeled by HRP.

Intrinsic callosal axon terminals formed only asymmetrical

Intrinsic callosal axon terminals formed only asymmetrical synapses. Analyses of serial thin sections through layers II and III in areas 1 and 40 show 97 % of the intrinsic terminals (1215 total sample) synapse onto dendritic spines, likely those of pyramidal neurons; the remainder synapse onto dendritic shafts of both spiny and nonspiny neurons. The high proportion of axospinous synapses formed by intrinsic callosal terminals differs significantly (p<<0.0001) from the proportion of asymmetrical, axospinous synapses that occur in the surrounding neuropil where only about 80% of the asymmetrical synapses are onto spines. This result is in accord with previous quantitative studies of the synaptic connectivities of both extrinsic and intrinsic axonal pathways in the cortex (e.g. White and Keller, 1989): In all instances, axonal pathways are highly selective for the types of elements axonal pathways are highly selective for the types of elements with which they synapse. NIH 20149 and BSF 86000-41 with which they synapse.

LAMINAR DISTRIBUTION OF THE EFFECTS OF NOREPINEPHRINE ON SINGLE NEURONS IN THE CAT SOMATOSENSORY CORTEX. R.A. Warren and R.W. Dykes, Dept. Neurol. Neurosurg., McGill Univ., Montréal, Canada, H3A 284; Dept. Physiol., Univ. Montréal, Montréal, Canada, H3C 347.

Norepinephrine (NE) was administered iontophoretically to 117 neurons in the cat somatosensory cortex. Upon ejection, NE produced both inhibition and excitation (Dykes, R.W. and Warren, R.A., Soc. Neurosci. Abstr., 15:1052, 1989). In several cases, effects were observed that outlasted the ejection of NE for several minutes (Warren, R.A. et al., <u>Soc. Neurosci. Abstr.</u>, 15:1053, 1989). The present report describes the laminar distribution of those effects of NE.

present report describes the laminar distribution of those effects of NE. At the end of each penetration in an ensthetized cat cortex, a dye was ejected iontophoretically from the recording electrode at two sites along the trajectory; those marks were used to identify the penetration in the histology and to correct for shrinkage. The tracks were reconstructed from NissI-stained sections and each neuron was assigned to a lamina.

Thirty eight (35%) of the neurons located from histological sections were studied with NE. During NE ejection, 80% of the neurons located in the middle layers were inhibited while 78% of the neurons found in the upper and lower layers were excited. Within 5 min of the presention of NE. Interconceptions of

layers were excited. Within 5 min of the cessation of NE, larger proportions of neurons in the upper and lower layers as contrasted to the middle layers had their ongoing and evoked activities affected. More than 5 min after the cessation of NE, ongoing and evoked activities of all the neurons found in the cessation of Ne., origoning and evoked activities or all the neurons round in the upper and lower layers had both their origoning and evoked activities significantly affected. In contrast, the ongoing and evoked activities were affected in not more than 50% of the cases found in the middle layers. The results were confirmed when the neurons located using the readings on the micromanipulator were analysed in addition to those located in the histology. These results suggest that the role of NE varies as a function of cortical layers. This will be discussed in light of the organization of the somatosensory cortex. (Supported by the Medical Research Council of Canada).

EFFECTS OF REPETITIVE AFFERENT DRIVE ON RESPONSIVITY OF SENSORIMOTOR CORTICAL SLICES C.-J. Lee*, B.L. Whitsel, M. Tommerdahl, and C. Wong*, Dept. Physiol., Univ. of North Carolina, Chapel Hill, NC 27599

Evoked potential recordings obtained from layers II-V of cortical slices indicate that the responsivity of local neuronal populations to repetitive low-frequency, low-intensity input drive varies prominently with stimulus repetition. Stimuli (bipolar, squarewave, 0.2 msec duration) were delivered to a single locus at the layer VI/white matter junction. At frequencies between 3-5 Hz, responsivity to this type of stimulation typically modified progressively to attain a new level that was maintained with continued stimulation. Observations obtained from different layers in the same slice under identical stimulus conditions suggest strongly that repetitive stimulation leads to similar changes in responsivity at all levels of the same cortical column, with the largest changes in responsivity coccuring in layers II-III and the smallest in layer IV. In addition, the alterations in responsivity observed to accompany such repetitive stimulation (i) were transient (complete recovery routinely occured in less than 1 min after termination of stimulation); and (ii) were either progressive (either incrementing or decrementing), or were complex and non-monotonic. High-density mapping of the responsivity changes evoked by repetitive afferent drive within individual slices clearly revealed a nonrandom spatial distribution of those cortical neuronal populations which exhibit different responsivity alterations to the same repetitive stimulation leads to the formation of column-shaped blocks of cortex whose neurons (on average) exhibit essentially the same alteration in responsivity with the working hypothesis that the intrinsic network of the somatosensory cortex accomplishes a major transformation of its input pattern; and that with repetitive stimulation these interactions dynamically enhance any local differences present in th

EFFERENT NEURONS AND SUSPECTED INTERNEURONS IN S-2 OF THE AWAKE RABBIT. H. A. Swadlow. Dept. of Psychology, Univ. of Connecticut, Storrs, CT 06269-1020.

Efferent populations studied in the vibrissa and sinus

hair region of S-2 included: callosal (CC) and ipsilateral corticocortical (C-IC) neurons, and descending corticofugal neurons of layer 5 (CF-5) and layer 6 (CF-6). Suspected interneurons (SINs) responded with a hi-frequency (>600 hz)

burst of spikes to thalamic stimulation.

Receptive fields were larger in S-2 than previously seen SINs had the largest receptive fields and the highest spontaneous firing rates of any population in S-2. CF-5 neurons had high axonal conduction velocities (median > 10 m/s), intermediate spontaneous firing rates (most 4-8/sec), and had the largest receptive fields of any efferent population. In contrast, CC, C-IC and CF-6 populations each had low axonal conduction velocities (medians < 3 m/s), low spontaneous firing rates (medians < 0.5/sec), and had relatively small receptive fields. Whereas all SINs and CF-5 neurons responded to peripheral stimulation, many CC, C-IC, CF-6 neurons did not

These differences among efferent neurons and SINs of S-2 $\,$ mirror similar differences among corresponding populations studied in S-1 and V-1 (Swadlow, H. A., J. Neurophysiol., 59:1162, 1988; 62:288, 1989, in press). These data suggest that a common physiological plan underlies the operations of functionally and morphologically diverse neocortical regions.

IPSILATERAL CORTICOCORTICAL CONNECTIONS OF SI SUBDIVISIONS IN MONKEYS. K.Alloway, M.Fabri and H.Burton. Department of Anatomy & Neurobiology, Washington University School of Medicine, St. Louis, MO 63110. (Supported by NS22012)

Ipsilateral cortical connections were studied using small amounts (75-400 nl) of different fluorescent tracers that were injected simultaneously, under electrophysiological control, in two or three body representations of areas 1 and/or 3b of SI.

Reciprocal connections exist between one subdivision of SI and numerous areas: 1,2,3a,3b, second somatic sensory area (SII), and retroinsular area (Ri). Local connections within the injected area involve related regions of the body map (i.e., proximal part of a digit with tracer injected into digit tip zone). Connections between injected areas and other parts of SI are mostly topographical and appear to interconnect homotopical zones. Few double labeled cells were seen

Projections from major body zones in SII and Ri did not display a somatotopy totally consistent with previous views. Each injection labeled multiple, interdigitated patches, especially within adjacent digit tip regions in SII. This interposed pattern of labeled cells and fibers obscured which area served as the primary representation for that body zone.

101.7

NERVE DOMINANCE COLUMNS IN THE PRIMATE PRIMARY SOMATOSENSORY [AREA 3b] CORTEX. <u>J.T. Wall</u>. Department of Anatomy, Medical College of Ohio, Toledo, OH. 43699.

The primary visual cortex of many primates contains columnlike aggregates of neurons which are dominantly activated by inputs from one optic nerve (or eye). Does the primary somatosensory cortex contain analogous column-like aggregates which relate to mechanoreceptor inputs from cutaneous nerves? To address this question, estimates of the low threshold mechanoreceptor innervation territories of the three nerves to the hand were derived either from summation of the receptive fields of multifiber recordings made from the nerves, or from summation of residual receptive fields of neurons in the cortical hand map after injuryrelated loss of one or two nerves. Estimates of the spatial distribution of aggregates of cortical neurons that are activated by low threshold tactile inputs from these nerve territories were then derived from maps of the hand representation by relating multineuronal receptive fields at individual cortical sites to the nerve territories. The results indicate that low threshold inputs from hand nerves activate column or patch-like aggregates of area 3b neurons. In addition, it appears that nerve injury alters the size of these aggregates. Supported by NS21105.

CONNECTIVITY PATTERNS OF PRIMARY SOMATOSENSORY CORTEX (SI) IN AN OLD WORLD PRIMATE, <u>Cercopithecus aethiops. Susan Warren.</u> Dept. of Anatomy, U. of Mississippi Med. Ctr., Jackson, MS 39216.
Although four diverse cytoarchitectural areas have been identified

Although four diverse cytoarchitectural areas have been identified within the primary somatosensory cortex (SI) of <u>C. aethiops</u>, the function of each area remains undefined. Application of micromapping techniques to study the topography of the SI hand area in this species (Warren & Carlson, '86) has demonstrated the occurance of complex and variable receptive field (rf) properties which disregard individual SI subdivision boundaries. Furthermore, the topographic organization of thalamocortical inputs to the SI hand area in <u>C. aethiops</u> (Warren, '90) reveals an apparent lack of submodality segregation, and no obvious morphological segregation of cutaneous and proprioceptive inputs into a 'core' and 'shell' arrangement. Identifying connections between individual areas of SI, as well as, SI connections with other cortical targets, including SII cortex, is essential for defining the functional role of each cortical subdivision. Patterns of SI cortical connectivity were defined by making separate injections of different retrograde neuroanatomical tracers into functionally defined SI hand areas for ten animals. Tissue was processed for fluorescence and WGA-HRP histochemistry. Corticocortical labelling in SII cortex, resulting from injections in either area 3b or area 1, was usually restricted to the inner face of the frontoparietal operculum, with the majority of labelled neurons principally located in Layers V and VI. Intracortical connectivity patterns in this species appears to differ from other Old World Monkeys implying that many of the fine details of the somatosensory system in <u>C. aethiops</u> are species specific. Support:BRSG #2SORR5386 and NIH #NS27998.

101.6

MULTIPLE IPSILATERAL CORTICAL CONNECTIONS OF SI IN RATS. M.Fabri, K.Alloway and H.Burton, Department of Anatomy & Neurobiology, Washington University Sch. of Med., St. Louis, MO 63110. (Supported by NS22012)

Ipsilateral cortical connections were studied using small amounts (50-150 nl) of different fluorescent tracers that were injected simultaneously, under electrophysiological control, in two or three zones of the SI body map.

Local connections within SI involve neighboring regions of the body map (i.e., digits and arm or within face areas). Ipsilateral reciprocal connections exist between SI and numerous areas: motor cortex (MI), cortex possibly homologous to area 3a, second somatic sensory area (SII), parietal ventral area (PV), parietal rhinal area (PR), and parietal medial area (PM) (Krubitzer et al., J Comp Neur, 250: 403, 1986). The first four cited areas maintain topographical connections with SI. In PR and PM, overlap was observed between projection zones from different regions of SI. Although such overlap was not extensive in other SI-connected areas, it was greatest amongst infragranular connecting cells. There were almost no double labeled cells.

Finding two maps lateral to SI in which the representations face each other (up-right in SII and upside-down in PV) may explain previous discrepancies regarding orientation of the SII map in rodents.

101.8

INTRINSIC CORTICOCORTICAL CONNECTIONS OF CAT PRIMARY SOMATOSENSORY CORTEX. H. Esteky* and H.D. Schwark. Dept Biological Sciences, Univ. North Texas, Denton, TX 76201.

We have examined the intrinsic corticocortical connections of the forepaw representation in primary somatosensory cortex of the cat. Various amounts of HRP, WGA-HRP, or PHA-L were delivered by pressure injection or by iontophoresis into physiologically-defined regions of the posterior sigmoid gyrus of barbiturate-anesthetized cats. Survival times ranged from 24 hours (HRP injections) to 4 days (PHA-L injections). Analyses were based on sections cut in frontal, sagittal, or tangential planes.

Injections into area 3b resulted in retrograde and anterograde labeling within area 3b and in nearby cortical regions, including areas 3a and 1. These projections were often quite widespread, spanning more than 2 mm in the longest dimension. The 3b injections also resulted in more focal labeling in the anterior wall of the ansate sulcus in a region which appears to be area 2.

Injections into the anterior wall of the ansate sulcus resulted in retrograde and anterograde labeling in areas 1, 3b, 3a and motor cortex. In some cases, such as following a large injection of WGA-HRP (0.5%, 360 nl) into area 2, anterograde and retrograde labeling appeared in distinct patches in each of these regions. Some of these patches were quite restricted in the anterior-posterior dimension (0.5 - 1 mm), but spread 2-3 mm in the mediolateral dimension. In every case analyzed so far, the corticocortical projections originate from neurons in layer III.

These widespread corticocortical connections may be involved in the SI somatotopic reorganization which follows peripheral input restriction. Supported by NS 25729.

THE ORGANIZATION AND CONNECTIONS OF SOMATOSENSORY CORTEX IN THE MEGACHIROPTERA BAT (PTEROPUS POLIOCEPHALUS). Mike B. Calford and Leah A. Krubitzer, Dept. Physiol. and Pharm. University of Queensland, QLD. 4072 Australia In this study, the areal pattern of connections of the primary somatosensory area (S-I) was investigated in in the flying fox. The flying

In this study, the areal pattern of connections of the primary somatosensory area (S-I) was investigated in in the flying fox. The flying fox was chosen for several reasons. First, because of its close relationship to primates, we expect some features to be similar to Toketherian mammals in general. Thus, the flying fox could serve as an important link between primates and non primate mammals. Second, the flying fox has a smooth neocortex so that all somatosensory areas are on the cortical surface and readily accessible for microelectrode mapping and connectional studies. Finally, the flying fox is a flying mammal and may possess cortical specializations related to flight, some of which have been reported previously by our laboratory. In these experiments, receptive fields were localized in S-I, lesions were placed at functional boundaries, and different anatomical tracers were injected into separate body part representations within S-I. In all cases, cortex was completely flattened and sectioned parallel to the cortical surface. By relating sections containing transported tracer to adjacent sections stained for myelin or reacted for cytochrome oxidase, the total pattern of connections could be related to architectonically defined fields. Since multiple tracers were used in the same animal, the topographic pattern of interconnected somatosensory areas could be readily assessed. Topographic connections were noted with areas 3a, 1, SII and two other areas rostral and caudal to S-II. We provide evidence that the somatosensory cortex of the flying fox has primate-like features as well as general mammalian features. In addition our results demonstrate at least six somatotopically organized cortical fields in the flying fox.

NEURAL CONTRAST SENSITIVITY. Andrew B. Watson. Vision Group, NASA Ames Research Center, Moffett Field, CA 94035-1000.

Contrast sensitivity is a useful measure of the ability of an observer to distinguish contrast signals from noise. For an individual linear neuron, it is given by

$$C(\mathbf{u},w) = \frac{\sqrt{T} G(\mathbf{u},w)}{\sqrt{2} \eta \sqrt{M(w)}}$$

where ${\bf u}$ and ${\bf w}$ are spatial and temporal frequencies, ${\bf G}$ is contrast gain, ${\bf M}$ is the noise power spectrum, ${\bf T}$ is the measurement duration, and ${\bf \eta}$ is the performance criterion. This principle is used to show how the contrast sensitivity of a given neuron depends upon that of neurons earlier in the visual pathway. The general theory is then applied to the specific problem of relating the sensitivities of parvocellular geniculate neurons to their target cortical neurons.

102.3

NETWORK MODELING OF SPATIAL PROPERTIES OF UNITS IN STRIATE CORTEX. Sidney R. Lehky!, Robert Desimone¹, and Terrence Sejnowski² ¹NIMH Bethesda, MD ²Salk Institute La Jolla, CA

We have used the back-propagation learning algorithm to model single unit data from macaque V1 cortex. Stimuli were 400 spatial patterns, including bars, sinusoidal gratings, textures, and 3-D shaded objects. The algorithm was used to integrate these data to produce a model of the cell's response properties. To create the network, the same images used as stimuli were repeatedly presented to the network's input layer, which consisted of several hundred units with receptive fields similar to those of retinal ganglion cells. The output layer had one unit, representing the neuron being modeled, and the middle layer had from 4-10 units. The network was trained so that its output in response to each image reproduced the activity of the actual neuron, using average firing rate as a measure of activity.

The resulting network was able to reproduce responses of the cortical neuron with a correlation of 0.8-0.85, when tested with images that were not included in the training set but for which we had data. This ability of the network to generalize well to images not part of the training set shows that it has captured most of the spatial properties of the cell, including nonlinear ones. We believe that this is the first use of back-propagation to directly model neurophysiological data. This technique may be useful as a more comprehensive and objective means of determining neural response properties, especially in extrastriate cortex, where receptive fields are particularly complex.

NEURAL CONNECTIVITY AND PHASE COHERENCE IN TWO DI-MENSIONAL SIMULATIONS OF STRIATE CORTICAL NEURONS. D. M. Kammen, E. Niebur and C. Koch. CNS Program, Division of Biology, 216-76, California Institute of Technology Pasadena, CA, 91125. Stimulus specific collective oscillations have been reported in olfac-

Stimulus specific collective oscillations have been reported in olfactory (Freeman, W. J., Elect. Clin. Neurophys., 44:169, 1979) and more recently in visual cortical (Gray, C. M., Nature, 338:334, 1989) areas. The oscillations observed in the striate cortex of anaesthetised cats (Area 17) are remarkable in that cells tuned to similar orientations but spatially widely separated on the cortical surface (up to 7mm) exhibit stimulus dependent frequency locking with no apparent phase delay.

dependent frequency locking with no apparent phase delay.

We have extended our previous integrate and fire-type model (Kammen, D. M. et al., In Models of Brain Function, R. M. J. Cotterill (ed.), Cambridge University Press, 273, 1989) to a two dimensional array of 8192 neurons. The array models a neural population such as a patch of cortical cells receiving coherent visual input from an associated population of geniculate neurons.

Our aim is to determine the patterns of axonal and dendritic connectivities necessary to subserve the frequency and phase coherence observed in populations of visual cortical cells. We present data for a wide variety of arborization radii and connectivity densities. A simple next-neighbor model is inconsistent with the data of Gray et al. 1989. Networks with sparse connectivity (typically 5%) do not exhibit long-range order while fully connected local networks exhibit synchronized activity over areas 2 to 3 times larger than the arborization radius.

102.2

NONLINEAR MODEL OF CAT STRIATE PHYSIOLOGY.

<u>David J Heeger</u>. NASA-Ames Research Center, ms 239-3, Moffett
Field, CA 94035 and Stanford Psychology Dept, Stanford, CA 94305

The goal of modeling striate physiology is to predict the response of a cell to any stimulus, based on a limited number of measurements. Simple-cells are often depicted as halfwave-rectified linear-operators and complex-cells as energy-mechanisms, constructed from the squared-sum of the outputs of quadrature-pairs of linear-operators. However, this linear/energy model falls short of a complete account of striate physiology. One of several major objections to this model is the fact that striate cells saturate at high contrasts, whereas linear- and energy-mechanisms do not.

I modified the linear/energy model in two ways to account for a significantly larger body of physiological data. The first modification is to include a feedback, contrast-normalization nonlinearity, and the second is to replace halfwave-rectification with half-squaring (half-squaring is halfwave-rectification followed by squaring) at the output of the model simple-cells. With these modifications, model cells respond similarly to real cells for measurements (using drifting and counterphase grating stimuli) of response vs. contrast (Albrecht and Hamilton, J. Neurophys., 48:217-237, 1984), contrast adaptation (Ohzawa et al., J. Neurophys., 54:651-667, 1985), cross-orientation and cross-frequency inhibition (Bonds, Visual Neurosci, 2:41-55, 1989), and direction selectivity (Reid et al., Proc. Nat. Acad. Sci., 84:8740-8744, 1987).

102.4

A SIMPLE QUANTITATIVE MODEL FOR SPATIO-TEMPORAL INTERACTIONS IN RECEPTIVE FIELDS OF VISUAL CORTICAL CELLS G. Holt and F. Wörgötter Computation and Neural Systems Program, CALTECH, 216-76, Pasadena, CA, 91125.

Most single cell models of visual cortical receptive fields (RFs) neglect spatio-temporal mechanisms. We present an analytical model of such interactions in which activity from a stimulated receptive field region is distributed into adjacent parts of the RF (adjacent regions of visual cortex), which were not directly stimulated. The receptive field is treated as a continuum because of the large number of converging inputs to cortical cells.

The model involves two stages of cortical cells. The cells of the first stage

The model involves two stages of cortical cells. The cells of the first stage have Gabor-type receptive fields (modeling orientation and spatial frequency uning), and their output is smoothed temporally by a low pass filter. They show weak directional tuning to bar stimuli (direction asymmetry) and velocity low pass behavior. The output from these cells is thresholded and fed into the second stage neuron, which has a similar low pass filter and threshold. Activity distribution is implemented by determining the pattern of connections from the first to the second stage. The second stage neuron shows strong directional tuning (direction selectivity) and velocity tuned behavior. The response of both types of cells to dot stimuli is similar to responses recorded from cortical cells (Wörgötter and Eysel, Exp. Brain Res., 76:307-314, 1989). Also, the model predicts that the optimal velocity for dot stimuli should be higher than that for bar stimuli, and the direction tuning strength should increase with velocity for a dot and decrease with velocity for a dot and decrease with velocity for

for a dot and decrease with velocity for a bar.

In conclusion: Our model is simple, thus, analytically tractable and implements a neurophysiological plausible mechanism. Most aspects of spatial frequency, orientation, direction and velocity tuning of simple cells are reproduced with this approach.

CIRCULAR INHIBITION: ISOTROPIC CONNECTIONS THAT GENERATE ANISOTROPIC BEHAVIOR IN THE VISUAL CORTEX. F. Wörgötter, E. Niebur, & C. Koch, Computation and Neural Systems Program, CALTECH, 216-76, Pasadena, CA, 91125.

Structural cross-orientation inhibition is defined as inhibition that arises from cells with preferred orientation orthogonal to their target cell. Our theoretical analysis shows that, due to the 2-dimensional organization of the orientation columns, this mechanism leads to unequal orientation tuning strengths for populations of differently oriented receptive fields. This situation is inconsistent with the experimental data. To resolve this problem we propose an isotropic arrangement of connections arising from a circle of cells at a distance of half a hypercolumn to the target cell (Circular Inhibition).

Circular inhibition is unspecific, thus, no Hebb type enhancement of connections is required. It is developmentally advantageous because only distance information is necessary to establish a connection.

We present an analytical model for the description of the cortical orientation column system and demonstrate the effects of circular inhibition within this model. We show that circular inhibition results in a weak net functional cross-orientation inhibition which corresponds to recents reports indicating the tuning strength of cross-orientation inhibition (Bonds, A.B., Vis. Neurosci., 2:41-55, 1989). Furthermore a significant directional bias is generated from this completely isotropic mechanism. The directional bias results from the location of the circle of connected cells in the column structure relative to the target cell which leads to unequal amounts of inhibition for both direction associated with the preferred axis of stimulus motion.

Thus, an isotropic connection scheme (circular inhibition) leads to two anisotropies: orientation tuning and even more surprisingly a directional bias.

102.7

CHAOS AND THE SINGLE NEURON IN AREA V1 OF THE CAT. R.M. Siegel. IBM Research Center, Yorktown Heights, New York 10598.

Visual perception can be described as the activation of sets of neurons in the cortex with properties that correspond to the qualia of the visual input (Edelman, 1990). Indeed, neurons appear to fire in synchrony after visual stimulation (Gray and Singer, 1989; Grinvald et al., 1989). What constitutes "sets of neurons" and how can the interactions in systems of large numbers of neurons be described? Non-linear dynamical theory (i.e. chaos theory) analyzes physical systems of similar complexity. We apply chaos theory to single neuron activity recorded in V1 of the anesthetized, paralyzed cat. The receptive field of a cell was mapped; optimal oriented rectangular light bars, modulated by a square wave with a 50% duty cycle, were used to probe for patterns of activity. With the stimulus period in the range of 100 to 2000 msec, temporal rhythms in the interspike intervals (ISIs) could be heard. Phase plots are used in chaos theory to extract predictive representations for temporal patterns (Glass and Mackey, 1988). The neural phase plot, generated by graphing each ISI against the next ISI, had clusters of points indicating preferred sequences of ISIs (c.f. Strehler and Lestienne, 1986). Some of these clusters were simply, and others more complexly related to the stimulus period. No such patterns were seen with spontaneous activity.

A neural model was used to test hypothetical physiological mechanisms for these experimental temporal patterns in V1. The neuron was modeled by a single variable for membrane potential. Poisson distributed spontaneous lSIs were simulated by an integrated random fluctuation of the membrane potential reached threshold. The membrane potential then rapidly returned to rest. The sum of the synaptic dendritic inputs to the cell was simulated by adding periodically varying values to the membrane potential then rapidly returned to rest. The sum of the synaptic dendritic

DETERMINING THE INDEPENDENCE OF MESSAGES CARRIED BY MULTI-PLE SIMULTANEOUS NEURONS T. J. Gawne and B. J. Richmond. Lab of Neuropsychology, National Institute of Mental Health, Bethesda, MD 20892.

Why are there so many neurons in each layer of a cortical colu the neurons carry redundant messages, then the signal-to-noise ratio (SNR) of that layer would increase. If all the neurons carry independent messages, then the layer would carry more information, but individual messages would have a low SNR. One way to increase the SNR of multiple messages would be to have a redundant sub-population for each message. When recording from multiple neurons simultaneously, how can we determine whether they are carrying redundant or independent messages?

We have used information theory to determine the independence of the messages carried by multiple neurons recorded simultaneously. If N neurons are redundant, then the influence of noise on the transmitted information will decrease by \sqrt{N} . If, however, the neurons transmit independent messages, then the information transmitted jointly by the neurons would be the sum of the information transmitted by the neurons individually.

We inserted a microelectrode into the superficial layers of striate cortex in an awake behaving rhesus monkey, and isolated pairs of neurons from the electrode using a template-matching technique. The set of 64 B&W 2-dimensional Walsh patterns were presented a minimum of six repetitions per stimulus in an area covering the common receptive field of both neurons in the pair. We computed the information transmitted by the magnitude of the response for each neuron separately, and for both neurons jointly. Preliminary results show pairs of neurons that are redundant, and other pairs that are independent. Therefore, this technique can indicate how information is coded by multiple neurons, and can be used to determine the functional groupings of the many neurons in cortical layers.

GLOBAL PROCESSING OF VISUAL STIMULI IN A NEURAL NETWORK OF COUPLED OSCILLATORS. D. Kleinfeld, D. Golomb* and H. Sompolinsky*. AT&T Bell Laboratories, Murray Hill, NJ 07974 and The Hebrew University, Jerusalem, Israel 91904.

A model neural network is presented that is capable of linking activity in disparate visual receptive fields in a manner that depends on extended features of the stimulus. The network is comprised of neurons that act as oscillators. Local features in the stimulus are encoded in the average firing rate of the neurons while the relationships between these features can modulate the temporal structure of the neuronal output. The model incorporates three aspects of the architecture of primary visual cortex: [1] The average firing rate of neurons is a strong function of the orientation of a bar that passes through the receptive field of the cell. [2] Nearby neurons have overlapping fields and appear to be highly interconnected. [3] Neurons with

non-overlapping fields form a sparse set of long-range connections.

The model will be discussed in the context of processing visual stimuli that are coded for orientation. Our results suggest that the recent experimental evidence on coherent oscillatory activity in the cat visual cortex (†) has important implications regarding the underlying pattern of neuronal connectivity: [1] The effective interaction between the phases of the neuronal output depends on the level of activity in both the pre- and post-synaptic cell. [2] Cells with substantially overlapping receptive fields form connections that do not depend strongly on the orientation preference of the pre- and post-synaptic cell. Connections between cells with non-overlapping fields have a strong dependence on their respective orientational and directional preference.

[3] The connections formed by cells with overlapping receptive fields are significantly stronger than those between cells with non-overlapping fields.

102.8

HOW THE UTILITY OF NEURAL MAPS INFLUENCES THEIR DEVELOPMENT IN A SELF-ORGANIZING MODEL OF VISUAL PROCESSING. R. Linsker. Watson Research Center, Yorktown Heights, NY 10598.

To what extent can we derive the functional properties and organization of a exceptual system from partial knowledge of (a) biological design constraints and (b) the adaptive value (to the animal) of discriminating among various environmental situations? To explore this question, I construct and analyze multilayered networks in which signaling activity and synaptic modification arise in a novel and biologically plausible way from feedforward, lateral (intralayer), and feedback interactions.

In the absence of feedback connections, it has been shown that Hebbian modification, combined with cooperative and competitive lateral interactions among cells, can generate networks whose output responses capture statistically and informationally salient properties of the sensed input environment [R. Linsker, Annu. Rev. Neurosci. 13:257-81 (1990)]. However, statistical saliency is not synonymous with utility to the animal.

propose a way in which network development and modification process are local to each layer (or processing stage) can favor the emergence of useful cell response properties and neural maps. A 'reward' (or 'penalty') value is ascribed to the final output layer of a simplified network model, in a way that depends upon the output signals and the state of the environment at that time. (There is no need for a 'desired' or 'correct' output to be specified to the network.) The 'utility' of the final layer is defined in terms of the time-averaged value of the reward. In each intermediate layer, the response properties of each cell (or functional group of cells) are incrementally modified according to three factors: (a) the extent to which the output provided by the cell to other layers contributes to the utility of the cells that receive this output; (b) a Hebbian rule acting on feedforward connections; and (c) lateral inthis output; (b) a necolan rule acting on recoroward connections; and (c) lateral interactions that influence the extent to which nearby cells of the same layer have similar response properties. Factor (a) in turn determines the "utility" of the cell or group being modified. The process is carried out for many network layers at once. A distinctive feature is that no detailed signal values need to be "back-propagated" to earlier processing layers. Cell response properties and organization generated by the method are compared with observations in visual cortex.

CORTICAL DYNAMICS OF MOTION SEGMENTATION: DIRECTION FIELDS, APERTURES, AND RESONANT GROUPING. Stephen Grossberg † and Ennio Mingolla‡. Center for Adaptive Systems. Boston University. 111 Cummington Street, Boston, MA 02215.

A neural model, called a motion Boundary Contour System, explains data about visual motion perception, and clarifies computational differences between parallel cortical streams for processing static visual forms $(V1 \to V2 \to V4)$ and moving visual forms $(V1 \to MT, V2 \to MT)$. Simulations clarify how ambiguous lo- $(VI \to MI, VZ \to MI)$. Simulations clarify now ambiguous cal movements (the aperture problem) on a complex moving shape are reorganized into a global motion representation. Properties of induced motion, motion capture, and apparent motion of illusory boundaries are clarified. The work analyses how a coherent motion signal is imparted throughout a moving figure, not only at loca-tions where unambiguous motion signals exist. Preprocessed inputs from concentric receptive fields (LGN) go to oriented receptive fields (simple cells) which are then endstopped and rectified. These outputs are temporally averaged over neighboring orientations and position. They are gated by the rectified outputs of transient cells, then spatially averaged again to generate signals that are insensitive to direction-of-contrast but sensitive to direction-of-motion. These signals are then fed into a competitive-cooperative feedback network (CC Loop) whose interactions choose and complete the most globally consistent motion signals across the figure data.

A COMPUTATIONAL MODEL OF SPACE-TIME SIGNAL PROPAGATION IN THE VISUAL CORTEX. P.Patton, E.Thomas, and R. Wyatt. Dept. of Chemistry, Univ. of Texas, Austin, TX 78712. • In order to simulate the vertical spread of evoked activity through the laminae of the visual cortex, a computational model of a slab of active tissue in the mammalian primary visual cortex has been constructed using anatomical and physiological data derived from the cat. The model will be used to investigate the dynamics of cortical activity flow and in planned studies of cortical self-organization. Up to 1000 model neurons are distributed through the 3-D slab in accordance with realistic cell densities and assigned schematic arbors corresponding to 17 cortical cell classes. Connectivity is determined based on this morphology and on literature data. Each neuron is treated as a single physiological compartment whose activity is describable by a first order, non-linear differential equation. Preliminary results show that our connection algorithm generates connection densities closely matching that reported for cat area 17. We have compared the spatial pattern and time course of activity following afferent stimulation in the model with the behavior of a dummy slab containing only a single cell type. In both the model and dummy slabs, oscillatory behavior was observed. In the $\,$ later case, oscillations appeared when a fraction of the cells were made inhibitory.

EFFECTS OF CAPSAICIN AND RESINIFERATOXIN ON ANTINOCICEPTION AND MICTURITION THRESHOLD IN RATS. Antonia Mattia and Frank Porreca, Department of Pharmacology, University of Arizona Health Sciences Center, Tucson,

Capsaicin has been shown to cause desensitization of primary afferent neurons producing long-term biological effects on sensory systems including antinociceptive and micturition reflexes in rats. This study compared the actions of capsaicin (CAP) with resiniferatoxin (RTX), a potent diterpene with desensitizing properties, in adult female Sprague-Dawley rats. Groups of rats (n=8) were injected s.c. with graded doses of CAP (12.5, 25 and 50 mg/kg), RTX (12.5, 25 and 50 µg/kg) or vehicle. Antinociception was assessed after 4 d using the 55°C warm-water tail flick and hot plate tests (cut-off latencies of 15 and 60 sec, respectively). Effects on micturition were studied using transvesicle perfusion of the bladder in the urethane anesthetized rat. After a 15 min equilibration, the bladder was continuously infused with saline at 50 µl/min and the detrusor response was recorded. As indicators of toxicity, body weight and bladder weight were recorded. Hot plate, but not tail flick, latencies were elevated by approximately 10% after CAP at 25 and 50 mg/kg in agreement with previous reports. Similarly, RTX elevated hot-plate, but not tail-flick, latencies at all doses tested, showing an approximately 60% increase. Changes in micturition threshold were noted only at the highest doses of CAP or RTX. At these doses, the number of contractions per min significantly decreased by approximately 30% without alteration of contraction amplitude. The volume threshold to micturition was increased by approximately 100% at the highest doses of CAP and RTX. Body and bladder weights were not significantly altered by CAP or RTX. These results indicate that RTX is approximately 1000-fold more potent than CAP in producing changes in sensory function and that additionally, the magnitude of the RTX effect on antinociception is substantially greater than that seen with CAP.

CAPSAICIN, OR THE ANALOGUE NE-21610, APPLIED TO THE TRANSECTED PRIMATE NERVE MARKEDLY INHIBITS HEAT SENSITIVITY OF THE DEVELOPING NEUROMA. R. H. Cohen, and J. N. Campbell. Dept. of Neurosurgery, Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205.

Baltimore, MD 21205.

These studies were conducted to determine if fibers in the developing neuroma are sensitive to heat and whether heat sensitivity can be blocked by pretreatment with capsaicin or the analogue, NE-21610. In anesthetized monkeys, the superficial peroneal nerve was crushed, ligated, and cut. Three to 14 days later, action potential activity was recorded from a site proximal to the ligature. Repeatable, short latency (<5s), short duration (51 min) responses to heated oil (40°C - 75°C) were observed in 27 of 35 multiunit recordings from the 3 untreated neuromas. Responses were observed in both A6 and C-fibers. To determine the effects of vanilloids, the naturally-occurring fascicles in the transected nerve were exposed and soaked for 1 hr in a small cup containing 1% capsaicin in the inactive vehicle, olive oil, or 1% NE-21610 in an active vehicle (10% Tween 80, 10% ethanol, and acetate buffer). When examined 3 to 14 days later, short latency, repeatable, responses to heat in neuromas pretreated with capsaicin (n=2) were found in only 2 of 20 strands and none of the 18 strands responded when neuromas (n=2) had 2 of 20 strands and none of the 18 strands responded when neuromas (n=2) had been pretreated with NE-21610. We conclude, therefore, that application of vanilloid to the transected nerve profoundly reduces the heat sensitivity of fibers in the developing neuroma. Another type of heat reaction was also observed in the untreated neuromas, but only after repeated applications of noxious heat. The inability to re-evoke the response, its delayed onset (10-30 s) and longer duration (1 to 5 min) support our interpretation that these reactions were mediated by the release of algesic chemicals. Responses of this nature were also evident in vanilloid pretreated neuromas and, thus, some chemical sensitivity probably remains probably remains.

103.5

MULTIPLE ACTIONS OF CAPSAICIN ON SPINAL SENSORY SYSTEMS, L. Urban and A. Dray. Sandoz Institute for Medical Research, 5 Gower Place, London WC1E 6BN, England.

An action on primary afferent neurons at the spinal cord level is important for the acute antinociception produced by capsaicin (Ashwood et al J.Physiol. 1990, 423, 77P). We now show, using a mouse spinal cord-dorsal root ganglion (DRG) preparation maintained in vitro, that several mechanisms may contribute to the

capsaicin induced antinociception.

Bath applied capsaicin (100-400nM) depolarized and enhanced synaptic activity in deep spinal dorsal horn neurons. These effects were abolished by removal of extracellular calcium but activation of primary afferent fibres persisted. In the DRG, capsaicin (100nM) depolarized and evoked action potentials in C-neurons. Higher concentrations also depolarized A δ neurons without evoking APs. Larger A-neurons were generally insensitive, though 2-10µM capsaicin sometimes produced a brief hyperpolarization followed by a depolarization. Electrical stimulation of dorsal roots often failed to evoke APs during the depolarization of small or large cells.

These observations confirm that capsaicin acts on primary afferent elements and not directly on intrinsic spinal neurons. The propagation of nociceptive signals generated from the periphery may therefore be impaired by a) capsaicin-induced depolarization of afferent nerve terminals b) possible conduction block in dorsal root fibres c) block of spike generation due to the slow depolarization of small DRG

PHARMACOLOGICAL CHARACTERIZATION OF THE RESINIFERATOXIN/CAPSAICIN RECEPTOR. A. Szalasi* and P.M. Blumberg. Molecular Mechanisms of Tumor Promotion Section, Lab. of Cellular Carcinogenesis and Tumor Promotion, National Cancer Institute, Bethesda, MD 20892.

Our demonstration of specific binding of resiniferatoxin (RTX), an ultrapotent analog of capsaicin, provided a new opportunity for the pharmacological characterization of the RTX/capsaicin receptor (Szallasi & Blumberg, Brain Res., in press). Competition between [H]RTX and capsaicinoids, RTX-analogs and other vanilloids to binding sites in rat dorsal root ganglion membranes was examined. Both the homovanilly! substituent and the diterpene moiety seemed to play an important role in the high binding affinity of RTX. If the homovanilly! substituent was missing (resiniferonol 9,13,14-orthophenylacetate, the 20-deacylated parent structure of RTX) the affinity for the RTX/capsaicin receptor was lost. Modification of the diterpene moiety (e.g. removal of the orthoester group, such as found in 12-deoxyphorbol 13-phenylacetate 20-homovanillate) also dramatically reduced the affinity. Replacing the homovanilly! (4-hydroxy-3-methoxyphenyl) substituent with a 4-hydroxyphenyl group, such as found in tinyatoxin, resulted in a 3-fold decrease in the K, value. The use of direct analysis of receptor binding and novel insights provided by the resiniferatoxin class of vanilloids may promote rapid progress in our understanding of vanilloid structure-activity requirements.

103.4

A CORRELATION BETWEEN CAPSAICIN EVOKED INWARD CURRENT, VOLTAGE-ACTIVATED Ca-CURRENTS AND CELL BODY SIZE IN SENSORY NEURONS.

 $\underline{M.\,Petersen}$ and R.H. LaMotte, Dept. of Anesthesiology, Yale University School of Medicine, New Haven, CT 06510

The somata with C- and A& fibers are restricted to the small cells within the dorsal root ganglia. Capsaicin, which excites nociceptors, evokes an inward current in a subpopulation of these sensory neurons.

We examined the correlation between cell body size, capsaicin evoked inward current and voltage activated Ca-currents in cultured DRG neurons of adult rat and guinea-pig. The currents were recorded using the whole cell patch clamp technique in solutions containing 10 mM Ba++. Capsaicin (10 uM) was applied for 15-30 sec.

The cross-sectional area of the cells which responded to capsaicin with an inward current varied widely and ranged from about 400 um² to about 3000 um². The peak of the distribution of areas was below 1000 um², for both species. The mean amplitude of the capsaicin evoked inward current was 0.67 pA/um², in cells maintained in culture up to 3 days. There was no difference between small and large cells, but in rat cells, we showed that the amplitude of the inward current decreased with time in culture. In guinea-pigs all recorded cells exhibited the high-threshold, L-type Ca-current while only 30% exhibited the low-threshold, T-type Ca-current. A correlation with cell size showed that the T-type Ca-current seemed to be restricted to those with larger diameters. Although capsaicin induced an inward current in about 26% of the cells with diameter greater than 1000 um², no cell with a capsaicin evoked inward current showed a T-type Cacurrent. Supported by P.H.S. Grant NS 14624

103.6

RESPONSES OF DORSAL HORN NEURONS IN CATS TO INTRACUTANEOUS INJECTIONS OF HISTAMINE AND CAPSAICIN. $\underline{\mathbf{H}}$ Hirata, H. Uchida*, K. Kishikawa, J.G. Collins, and R.H. LaMotte. Dept. of Anesthesiology, Yale Univ. Sch. of Med., New Haven, CT 06510 Previous psychophysical studies demonstrated that histamine injected

intradermally in humans produced a pure sensation of itch that can last se minutes and is not contaminated by other sensory qualities such as pain. Thus, by the use of this chemical we hoped to find central neurons mediating itch. Seventeen dorsal horn neurons (DHNs) (11 wide dynamic range: WDR; 6 high

threshold:HT) were studied in pentobarbital anesthetized cats via a chronically implanted lumbar spinal cord recording chamber. Two HT neurons responded to intracutaneous injections of histamine and subsequently to capsaicin for at least 3 min after injection. None of the other 13 nociceptive neurons (9 WDR, 4 HT) tested responded to histamine, although all but 2 responded vigorously to capsaicin. Lightly stroking the skin surrounding the injection, known to produce itch in humans, did not evoke enhanced responses in most neurons. However, one HT neuron that responded to histamine had unusually long and vigorous afterdischages that outlasted each stimulus. The depth of recording sites from the surface of the spinal cord for units responding to histamine was shallow (730 μ m for one unit) while the average depth for the units not responding to histamine was deeper (1457 μ m; n=6).

These results suggest the existence of a subpopulation of nociceptive DHNs responsive to intracutaneous injection of "itch" producing chemicals. How activity in these nociceptive DHNs contributes to itch sensation is yet to be determined. (Supported by PHS grant 14624 and NIH grant GM29065).

INFLAMMATORY MEDIATORS ENHANCE THE EFFECTS OF CAPSAICIN AND OLVANIL ON PERIPHERAL NOCICEPTORS. A.Dray, L.Urban, I. Patel*, A. Rueff* and M. Perkins. Sandoz Institute for Medical Research, Gower Place, London, England.

Capsaicin and its analogue olvanil (NE-19550) have similar capsaicm and its analogue of vanif (NE-1930) have similar antinociceptive potency in vivo (Campbell et al, Br. J. Pharmac. 1989, 98, 907P). However capsaicin activates peripheral nociceptors (EC₅₀ 300nM) and at 20-50μM concentrations reduces their responsiveness to noxious stimuli whereas similar concentrations of olvanil are inneffective (Bettaney et al, J. Physiol. 1990, press). We now show that inflammatory mediators enhance the effects of both

In a preparation of the neonatal rat spinal cord with the functionally connected tail maintained in vitro, activation of peripheral fibres by noxious stimuli (capsaicin, bradykinin, heat) was assessed by recording a spinal ventral root response. In the presence of sensitizing concentrations of PGE₂ (0.5-5µM), capsaicin-induced activation of peripheral fibres was enhanced and low concentrations of capsaicin (2µM) now reduced responses to other noxious stimuli. Under these conditions olvanil (100-500nM) activated peripheral other noxious stimuli. PGI₂ produced a similar but less consistent

office to whereas PGD₂ was inactive.

These data suggest that specific products of inflammation enhance the actions of capsaicin and olvanil. This may contribute to the efficacy of capsaicin-like compounds as antinociceptive and antiinflammatory agents.

NEUROPEPTIDE DEPLETION BY NEONATAL CAPSAICIN CORRELATES WITH ALTERATIONS IN VISCERAL AND CUTANEOUS NOCICEPTION.

T.J.Ness, V.Kumar* and G.F.Gebhart. Depts. Anesthes. and
Pharmacol., College of Medicine, Univ. of Iowa, Iowa Pharmacol., Coll City, IA 52242.

Newborn (48 hrs) Sprague-Dawley rats were injected s.c. Newborn (48 hrs) Sprague-Dawley rats were injected s.c. with vehicle (VEH) or capsaicin (CAP; 50 mg/kg in VEH). At 10 weeks of age the tail flick latency (TF_L; time (s) from onset of tail heating to withdrawal reflex), hot plate latency (HP_L; time (s) from placement on $55^{\circ}\mathrm{C}$ hotplate to licking of hindpaw), visceromotor threshold (VM_T; minimal pressure (mm Hg) in colorectal distending balloon evoking abdominal contracture) and cardiovascular responses to colorectal distension (80 mm Hg, 20 s; change in mean arterial pressure (Δ MAP in mm Hg); change in heart rate (Δ HR in bpm) measured via chronic femoral arterial catheters) were determined. Following testing arterial catheters) were determined. Following testing, the content of substance P (sP), calcitonin gene-related peptide (CGRP) and vasoactive intestinal polypeptide (VIP) of the lumbar spinal cord was determined using radioimmunoassay (expressed as pg/mg spinal cord tissue). The results are as follows:

VIP TF_L 10.7±.5 4.5±.4* 10.9±.7 3.4±.2 CORP HP_L 17+3* VM_T 45+5* Δ MAP 38+4* 301+28* 36+3 76+7 76<u>+</u>6 614+29 12+1 24+2 38+2

Neonatal capsaicin leads to significant (*p<0.05) sP and CGRP depletion and increased thresholds responses to noxious visceral and cutaneous stimuli.

THE CONSEQUENCES OF LONG TERM TOPICAL CAPSAICIN APPLICATION IN THE RAT. S McMahon*, G Lewin. St Thomas Hospital Medical School (UMDS), London, UK. (SPON: BRA)

Capsaicin has long been used as an experimental tool and more recently as a clinical treatment for several pain disorders where it is usually administered topically for periods of several weeks. It is the consequences of such treatment that we have studied here in the rat. Capsaicin cream (0.075% or 0.75%), or vehicle, was applied twice daily to the hindpaws of rats for ten weeks. The hindpaws treated with 0.75% capsaicin (but not 0.075%) became transiently hyperalgesic, but there were no signs of discomfort or distress associated with the treatment. After ten weeks of treatment, C-fibres produced significantly less neurogenic extravasation. This fully returned in 0.075% capsaicin treated animals after 4 weeks recovery, but only partially returned in the 0.75% group after 12 weeks. The levels of substance P and CGRP in the sural nerve supplying the treated skin area were unchanged after the 0.075% capsaicin treatment. One interpretation of these results is that topical capsaicin application produces a reversible block of the terminals of C-fibres in the skin, but at low concentrations does not have actions on the cell soma.

The number of afferent neurones in the L5 dorsal root ganglion projecting through the sural nerve was unchanged after 0.75% capsaicin treatment, suggesting that the topical capsaicin treatment does not produce any cell death in the adult animal.

THE ENDOTHELIUM-DERIVED RELAXING FACTOR (EDRF) CANDIDATE S-NITROSOCYSTEINE (S-NC) ACTIVATES CAPSAICIN SENSITIVE AFFERENTS IN CONSCIOUS RATS. M.J. Brody, S.J. Lewis, S.T. Meller, T.J. Ness, J.N. Bates* and G.F. Gebhart. S.T. Meller, T.J. Ness, J.N. Bates* and G.F. Gebhart.
Dept. of Pharmacology & Cardiovascular Ctr., Univ. of
Iowa, Iowa City, IA 52242.

Recent evidence suggests that S-NC may be an endogenous EDRF. The aim of the present study was to examine the cardiovascular effects of S-NC in conscious rats. The injection of S-NC (25-1000 µg/kg, iv) produced reductions in arterial pressure (AP) via reductions in per-ipheral vascular resistance which were accompanied by tachycardia. These responses were essentially identical to those produced by equimolar doses of sodium nitro-prusside (SNP), an agent whose actions may involve release of nitric oxide. Higher doses of S-NC (1500-2500 µg/kg, iv), but not SNP, produced profound atropine-sensitive rapid reductions in AP, heart rate and regional blood flows which were similar to the cardiopulmonary afferent mediated responses produced by serotonin. The transient S-NC-induced cardiovascular responses were markedly diminished in rats treated neonatally with capsaicin. These results suggest that S-NC but not SNP produces a reflex reduction in arterial pressure via stimulation of small diameter unmyelinated C-fibre afferents originating from cardiopulmonary regions.

BASAL GANGLIA AND THALAMUS I

104.1

LOCATION OF KAINIC ACID LESION WITHIN THE BASAL GANGLIA DETERMINES THE DIRECTION OF ROTATION IN RESPONSE TO APOMORPHINE. L.M. Wyatt, P.R. Sanberg, J.P. Hildebrand, and A.B. Norman. Division of Neuroscience, Departments of Psychiatry and Anatomy, University of Cincinnati College of Medicine, Cincinnati, OH 45267.

Quantification of drug-induced rotation behavior after unilateral lesions is a commonly used means of assessing dysfunction and recovery of the basal ganglia. Kainic acid (KA) destroys intrinsic neurons of the striatum that express dopamine receptors. Consequently, after unilateral lesion, only the intact striatum is capable of responding to dopamine agonists such as apomorphine. This unequal response leads to an asymmetry in locomotion which is usually manifested as rotation behavior towards the side of the lesion. However, we have previously reported that rats given KA lesions rotated contralateral to the side of the lesion. Close histological examination of the lesion site indicated that these rats had lesions of the anterior striatum and within the nucleus accumbens. We, therefore, determined if the KA lesion site could influence the direction of rotation subsequent to apomorphine challenge. Male Sprague-Dawley rats received unilateral KA lesions at either 1.5 or 0.3 mm anterior to bregma. There was a significant difference in the direction of apomorphine (1 mg/kg s.c.)-induced rotations with respect to A/P location of the lesion (p=0.037) and also in the total number of rotations for rats rotating in each respective direction (p<0.001). The more anterior lesions produced contralateral rotations while the posterior lesions produced in each respective direction (p<0.001). The more anterior lesions produced contralateral rotations while the posterior lesions produced ipsilateral rotations. Thus, the site of the lesion within the basal ganglia determines the direction of apomorphine-induced rotation behavior. [supported by NINDS]

CHANGES IN CIRCLING PERFORMANCE AND STRIATAL UNIT ACTIVITY IN FREELY MOVING RATS LESIONED WITH 6-HYDROXYDOPAMINE AND TRANSPLANTED WITH FETAL DOPAMINE CELLS. P. Patino, M. Garcia-Munoz, C.J. Hutt*, E.H. Kriek, and C.R. Freed. Depts. of Med. and Pharm., U. Colo. Sch. Med., Denver, CO. Studies in our laboratory have shown that rats trained to run on a circular treadmill show increased

firing of ventromedial striatal cells particularly on the side contralateral to the circling direction. We have now studied the effect of dopamine depletion on behavioral performance and cell firing. Male Sprague-Dawley rats were unilaterally lesioned in the nigrostriatal bundle were unilaterally lesioned in the nigrostriatal bundle with 6-hydroxydopamine (6-OHDA). Normal animals circled at 31 + 2 rpm by the third day of training. Lesioned animals circled at 14 + 4 rpm ipsilateral and 13 + 4 rpm contralateral to the lesion only after 11 days of training. Animals lesioned then transplanted circled at 21 + 2 rpm ipsilateral and 29 + 3 rpm contralateral after 21 + 2 rpm ipsilateral and 29 + 3 rpm contralateral aries of days of training. Unit recording from ventromedial striatum showed a basal firing rate of 0.7 hz which increased to 3.4 hz during contralateral circling and 2.2 hz with ipsilateral circling. By contrast, lesioned animals showed increased basal firing of 5.0 hz which fell to 1.3 hz when animals circled either contralateral or ipsilateral to the side of the recording. We conclude that unilateral 6-0HDA lesions change behavioral performance and striatal firing which is partly corrected by fetal dopamine cell implants.

EFFECTS OF STRIATAL, TECTAL, AND THALAMIC LESIONS ON CIRCLING ELICITED BY INTRANIGRAL INJECTION OF THE KAPPA OPIATE U50,488. L. A. Thompson and J. M. Walker. Dept of Psychology, Brown University, Providence, RI 02912.

Striatonigral prodynorphin opioids may influence movement through actions on kappa receptors in the substantia nigra pars reticulata (SNR). Previous experiments indicate that intranigral microinjection of the kappa opiate U50,488 produces dose-dependent contralateral rotation due to inhibition of nondopaminergic nigral efferents. In this study, the relationship between movement induced by intranigral U50,488 and output stations of the SNR was examined. Unilateral ibotenic acid lesions of the superior colliculus (SC), ventromedial thalamus (VM), or striatum (STR) were made in the hemisphere ipsilateral to the SNR injected with U50,488. No lesions were made in control animals.

Tectal, thalamic, and striatal lesions differentially influenced kappa opiate-induced motor activation. Lesions of the SC and VM tended to decrease circling compared to control animals, while striatal lesions tended to increase circling. These results suggest that nigral kappa opioids may influence movement through actions on the nigrotectal and nigrothalamic pathways. Striatal lesions may increase circling due to kappa receptor supersensitivity in the SNR or due to interference with the inhibitory effect of kappa opioids on the nigral dopamine system.

PLASTICITY OF FORELIMB-RELATED STRIATAL ACTIVITY DURING ACQUISITION AND MAINTENANCE OF A TONE-DISCRIMINATION TASK IN THE RAT. R.M. Carelli, Wolske, M. and M.O. West. Dept. Psychology, Rutgers Univ., New Brunswick, NJ 08903.

The objective of the present study was to determine the relationships

The objective of the present study was to determine the relationships among right forelimb-related unit activity, biceps EMG activity and lever pressing behavior during the acquisition and maintenance of a tone-discrimination task involving lever pressing with the right forelimb. Long-Evans male rats (300g) were chronically implanted with a detachable microdrive for recording in the lateral striatum (+2.0 to 0 mm A-P, 3.6 to 4.5 mm M-L, and 3.0 to 6.0 mm D-V from bregma). Water-deprived rats were trained to obtain water reinforcement by lever pressing with the right (contralateral) forelimb during tone presentation (one reinforcement/tone presentation). To reduce trial-to-trial variability in reaching toward the lever, rats were trained to stand facing the lever, with the right forepaw on the floor prior to initiation of each trial. Each day, forelimb-related cells (n=114) were identified by means of passive examination. Increased discharge time-locked to lever pressing (relative to background firing) was termed "Signal:Noise" (S:N). Results indicate that forelimb-related striatal activity varied as a function of number of days on the task. S:N was large (range 2-16) on days 1-4, during early acquisition, but decreased substantially and remained low (range 0.5-1.5) on days 5-14, during maintenance of stable responding. In contrast, biceps EMG remained related to reaching toward the lever throughout acquisition and maintenance. These findings suggest that striatal activity may participate in movement execution during the acquisition of skilled movements, but not during their routine maintenance when they are repeated in the same manner across days of overtraining. Supported by NSF BNS-8708523, DA 04551 and PHS RR 07058-21.

SINGLE UNIT ACTIVITY IN THE RAT CAUDATE-PUTAMEN DURING STEREOTYPICAL GROOMING SEQUENCES. <u>J.W. Aldridge, K.C. Berridge, M. Herman.</u> Univ. Michigan, Dept. Neurology, Dept. Psychology, 1103 E. Huron, Ann Arbor, MI 48014.

The purpose of this study was to investigate the neural correlates of neostriatal activity and instinctive behavior. In rodents, a syntactical chain of movements connects up to 25 actions in a stereotypical transition between face and body grooming. Single unit activity was recorded from the neostriatum (Bregma AP 1.0) in 13 rats while behavior was videotaped. Unit activity was compared during 1) syntactic grooming chains, 2) isolated grooming movements, 3) body-orienting movements (stepping, rearing, head-turning) and 4) cutaneous and visual sensory tests. Of 25 units, 14 (56%) had unit activity related to at least one behavior studied. The most frequent response (9 units, 64%) was to grooming during the syntactic chain. These units generally did not respond in the same way to similar grooming actions that occurred outside of the grooming chain. Most commonly, chain grooming units had a slow decreased tonic discharge at the onset of grooming and a phasic increase in activity at the end of chain grooming. Five units (36%) had responses to grooming movements that occurred apart from syntactic chain grooming. Body orienting and sensory stimulation each activated 50% (7/14) of the responsive units. In contrast to syntactic chain units, units with non-chain grooming, body orienting and sensory responses typically had responses in more than one behavioral category. In summary, a significant proportion of neostriatal units are functionally related to a particular sequential pattern of instinctive movements. These units do not have a functional overlap with other striatal units that related to elemental actions or sensory events. Supported by the University of Michigan Biomedical Research Council and Office of the Vice President for Research.

GRAFT-INDUCED RECOVERY OF FUNCTION FOLLOWING EXCITOTOXIC LESIONS OF THE STRIATUM, IN A VISUAL REACTION TIME TASK IN THE RAT. E. Mayer*, V.J. Brown, S.B. Dunnett & T.W. Robbins. Department of Experimental Psychology, University of Cambridge, Cambridge, CB2 3EB, U.K.

Rats were trained to move their heads away from an eccentrically presented visual stimulus, before receiving unilateral excitotoxic lesions of the striatum governing their preferred side. Testing recommenced six months later when profound deficits in response bias and stimulus control of responding were evident in animals having received lesions alone. They also exhibited attentional changes secondary to their tendency to over respond towards the side of their lesion. By contrast rats that had received implants of E15 embryonic striatal cell suspensions, subsequent to lesioning, showed recovery in certain aspects of their performance, which also precluded the attentional changes found in the lesion group. However the striatal graft group did show an initial lengthening of time taken to complete the head movement away from the side of the lesion.

The results indicate the utility of employing a complex reaction time procedure, with poor stimulus-response compatibility, not only for the study of normal striatal function, but also for assessing the function of grafted striatum and its functional integration into the host.

104.6

ANTERIOR LESIONS OF THE CORPUS STRIATUM PRODUCE A DISRUPTION OF STEREOTYPED GROOMING SEQUENCES IN THE RAT. <u>H.C. Cromwell and K.C. Berridge.</u> The University of Michigan, Department of Psychology, Ann Arbor, MI., 48109. The corpus striatum (caudate nucleus, putamen, and globus pallidus)

The corpus striatum (caudate nucleus, putamen, and globus pallidus) has been suggested to be crucial for the sequencing of actions into motor programs (Marsden, 1984, Cools, 1980). Even natural grooming sequences become sequentially disordered after large striatal lesions (Berridge and Fentress, 1987). Small bilateral lesions were made into the corpus striatum to localize the subregion involved in producing the disruption.

Microinjections of quisqualic acid or kainic acid were made in the anterior portion of the caudate nucleus and putamen in the dorsolateral region, and into the posterior caudate nucleus, putamen, and globus pallidus in the dorsolateral, ventromedial, and dorsomedial regions. Control animals had surgical procedures identical to lesioned animals with only vehicle injected. Grooming was videotaped. The focus of the evaluation was upon syntatic sequential transition pattern between face and body grooming that organizes up to 25 actions in to 4 distinct phases (Berridge and Fentress, 1987).

Rats with anterolateral lesions completed the four phases of the

Rats with anterolateral lesions completed the four phases of the grooming only 48% of the time while controls had a 80% completion rate. Rats with posterior lesions did not differ from controls. Nonsyntatic transitions from face to body grooming were preserved. This significant decrease in the ability to sequence the 4 phases of the grooming pattern is consistent with the findings that lateral lesions of the rostral striatum impair coordinated forelimb patterns, (Pisa, 1988) and supports a special role for this region in controlling sequences.

104.8

BILATERAL LOCAL METABOLIC EFFECTS INDUCED BY HIGH CONCENTRATION OF MUSCIMOL INJECTED INTRANIGRALLY. H.E. Savaki, V. Raos* and C.R. Dermon*. Lab. of Physiology, Div. of Medicine, Univ. of Crete, 71409 Iraklion, Greece.

The bilateral effects of unilateral intranigral muscimol (1 M) injection on local cerebral glucose utilization were investigated, by means of the autoradiographic 14C-deoxyglucose method, in conscious awake rats. Intranigral injections of 1 M muscimol induced: [1] increased glucose consumption within the injected substantia nigra reticulata, [2] bilateral metabolic decrease within collicular, thalamo-cortical and striatal relays, with the ipsilateral side displaying more pronounced depression. Previous studies have demonstrated that lower concentrations (10-6, 10-3M) of muscimol applied intranigrally induced disinhibition of nigral efferents through presynaptic GABAergic autoreceptors on the striato-nigral terminals (Dermon, C.R., et al., J. Neurosci. in press). It is presently suggested that muscimol applied intranigrally in higher concentration (1 M) induces inhibition of nigro-thalamic and nigro-collicular efferent pathways through postsynaptic GABAergic receptors on the nigral cells.

CHRONIC LEVODOPA ALTERS BASAL AND DOPAMINE AGONIST STIMULATED CEREBRAL GLUCOSE UTILIZATION. T.M. Engber, Z. Susel*, S. Kuo* and T.N. Chase. Exptl. Therapeutics Branch, NINDS, Bethesda, MD 20892.

The effect of chronic levodopa administration on the functional activity of the basal ganglia and its output regions was evaluated by means of the 2-deoxyglucose tosasi gangia aim its britiput regions was evaluated to means of the 2-deoxyginetoses (2-DG) autoradiographic technique in rats with a unilateral 6-hydroxydopamine lesion of the nigrostriatal pathway. The rates of local cerebral glucose utilization were studied under basal conditions as well as in response to challenge with a selective D1 or D2 dopamine receptor agonist. Levodopa (100 mg/kg/day, i.p.) was administered or D2 dopamine receptor agonist. Levodopa (100 mg/kg/day, i.p.) was administered for 19 days either continuously via infusion with an osmotic pump or intermittently by twice daily injections. Following a 3 day washout, glucose utilization was decreased by both levodopa regimens in the nucleus accumbens; intermittent levodopa also decreased glucose utilization in subthalamic nucleus, ventrolateral thalamus, ventromedial thalamus and lateral habenula. In control rats (lesioned and treated with saline), the D1 agonist SKF 38393 (5 mg/kg, i.v.) increased 2-DG uptake in the ipsilateral substantia nigra pars reticulata and entopeduncular nucleus by 84% and 56%, respectively. Both continuous and intermittent levodopa blunted the SKF 38393 induced elevation in glucose metabolism in the substantia nigra pars reticulata, while intermittent levodopa also attenuated the increase in the entopeduncular nucleus. The D2 agonist quinpirole (0.4 mg/kg, i.v.) did not increase glucose utilization in any brain region in controls; following intermittent levodopa treatment, however, quinpirole increased 2-DG uptake by 64% in the subthalamic nucleus and by 39% in the deep layers of the superior colliculus on the ipsilateral side. These findings indicate that chronic levodopa administration has long lasting effects on the functional activity of brain regions within the basal ganglia as well as in regions which are targets of basal ganglia output and that the effects of chronic levodopa reatment differentially alters D1 and D2 receptor mediated striatal output, decreasing D1 output through the striatonigral and striatoentopeduncular output, decreasing D1 output through the striatonigral and striatoentopeduncular pathways and increasing D2 output through the striatopallidal pathway.

THE EFFECT OF MEDIAL FOREBRAIN BUNDLE (MFB) STIMULATION ON STRIATAL DOPAMINE AND SEROTONIN RELEASE AS MEASURED BY MICRODIALYSIS. L. D. Manley, R. Kuczenski, S. J. Young, D. S. Segal and P. M. Groves. Dept. of Psychiatry, University of California, San Diego, Sch. of Med, La Jolla, CA 92093.

Intracerebral microdialysis was used to examine the effect of MFB stimulation on extracellular concentrations of dopamine (DA), serotonin (5HT) in rat striatum. Urethane-anesthetized Sprague-Dawley rats were implanted with a 4mm concentric dialysis probe and a bipolar stimulating electrode. Ninety minutes after implantation, baseline concentrations were assessed by HPLC-EC at implantation, observed concentrations were assessed of PFLC-EC at ten minute intervals for an additional hour before stimulation. Equal numbers of stimuli (1mA, 0.5ms; 5-20 per 1.2 sec: 4-33 Hz) were presented continuously or in equally spaced bursts of 75-600ms duration over the ten minute period. Measurements were made both in the absence and presence of cocaine in the perfusion buffer, so as to achieve an extracellular cocaine concentration of 2.5 mM. Cocaine increased basal extracellular DA levels from approximately 15 to 75nM and 5HT from below levels of quantification to approximately 7nM. MFB stimulation linearly increased DA concentrations, both in the presence and absence of cocaine, in a frequency dependent manner. 5HT concentration was also linearly dependent on the frequency of stimulation. The concentrations of both neurotransmitters rapidly returned to baseline levels upon cessation of stimulation. Stimuli delivered as a burst caused enhanced DA, but not 5HT, release as compared to stimuli presented in a continuous fashion. This work was partially supported by NIDA grant numbers DA02854, DA04151, DA01568.

ENHANCED POSTSYNAPTIC DOPAMINE EFFECTS AFTER CHRONIC COCAINE. S.P. Banerjee, E. Alter*, M. Nathan, T.I. Lidsky CUNY Med and NYS IBR.

COCAINE. S.P. Banerjee, E. Alter*, M. Nathan, T.I. Lidsky CUNY Med and NYS IBR.

Chronic use of cocaine (Coc) alters the pharmacology and physiology of dopamine (Da) systems. The present study investigated the nature of some of these changes.

After 7-9 days of Coc (10 mg/kg/day, i.p.), striatal somatosensory field potentials were recorded in urethane anesthetized rats. Rats that received Coc showed enhanced sensitivity to the post-synaptic effects of Da as evidenced by suppression of striatal field potentials at lower than normal intensities of substantia nigra (SN) stimulation. In addition, haldol, which mainly acts presynaptically in controls (1), had strong postsynaptic effects in Coc exposed rats. Specifically, i.v. haldol (0.1 mg/kg) in controls attenuated striatal potentials (as did Da release from SN stimulation) and failed to block the inhibitory effects of SN stimulation. In Coc rats, haldol alone had no effect on striatal fields and attenuated the inhibitory influence of SN stimulation. These changes were functional; increased receptor binding was not detected.

MICRODIALYSIS IN AMAKE RATS SUGGESTS THAT THE SUBSTANTIA NIGRA IS THE MAJOR SITE OF ACTION OF L-DOPA IN A RAT MODEL OF PRECLINICAL HEMIPARKINSOM'S DISCASE. Dora Oroscz (1) and James P. Bennett, Jr. (1,2,3). Departments of (1) Meurology, (2) Behavioral Medicine and Psychiatry (2) and Pharmacology (3). University of Virginia School of Medicine, Charlottesville, VA 22908.

Medicine, Charlottesville, VA 22908.

Idiopathic Parkinson's disease (PD) in humans arises from progressive, marked loss of midbrain dopamine (DA) neurons in the substantia nigra compacta (SNC), whose axons form the nigrostriatal pathway (NSP) and innervate the corpus striatum (caudate-putamen). These nigral neurons also release DA from their dendrites into the nigra reticulata (SNR) where DA interacts with D1 receptors on terminals of striatonigral neurons. L-DDPA therapy of PD seeks to replace lost DA. In earlier microdialysis work in urethane anesthetized rats, we showed that pharmacological L-DDPA doses did not lead to increased DA in striatal extracellular fluid (ecf) in either control striata or striata ipsilateral to a 6-hydroxydopamine (6-0HDA) lesion of the NSP. Because L-DDPA treatment of rats with unilateral 6-0HDA NSP lesions markedly increases glucose utilization in SNR, we sought to determine if L-DDPA selectively raised ecf DA in the nigra compared to striatum. Adult male rats had either sham of 6-0HDA lesions of the NSP, followed one week later by implantation of dialysis probe holders above ipsilateral dorsolateral striatum and SNC. After recovery, simultaneous dialysis of striatum and SNC was performed while the animal's activity was electronically monitored, before and after carbidopa 25 mg/kg i.p./L-DDPA methylester 25 mg/kg i.p. Baseline DA ecf levels in striatum were several fold higher than in SNC. Mereas striatal ecf DA levels at most doubled after L-DDPA, nigral DA receptors may be exposed to DA levels higher than in striatum and may be the preferential site of action of L-DDPA in this animal model of PD. (Supported by NINDS NS26581, RCDA to JPB and the American Parkinson Disease Association)

104.12

CONTRASTING TISSUE FACTORS PREDICT HETEROGENEOUS STRIATAL DOPAMINE (DA) NEUROTOXICITY AFTER MPTP OR METHAMPHETAMINE TREATMENT. J.F. Marshall and R.J. Navarrete*.

Psychobiology, Univ. California, Irvine, CA 92717.

Recent studies have demonstrated the heterogeneous striatal distribution of markers (e.g.[3H]mazindol binding) for the high-affinity DA transport (HADT) in several species. In idiopathic Parkinson's disease, the extent of the DAergic degeneration varies greatly between striatal regions; similar differences in susceptibility to the neurotoxic effects of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) have been described in treated primates, mice, and carnivores. The present work examines whether the regional variations in dopaminergic injury relate to those of the HADT. In male Swiss-Webster mice given four injections of MPTP HCl (20 mg/kg, i.p.), the extent of the DA depletion, as measured in 11 micropunch regions of the by depletion, as measured in () micropunch regions of the striatal complex, corresponded closely (r = +0.82, P < 0.005) to the specific [Himazindol binding and less well to the DA content (r = +0.50, N.S.) of these regions in intact mice. In contrast, the striatal DA depletions of a separate group of mice treated with a neurotoxic regimen of methamphetamine HCl (2.5 mg/kg, i.p., 4 times) corresponded to the regional DA content (r=+0.81, P < 0.005) but not to the [3 H]mazindol binding values (r=+0.50, N.S.) in intact mice. Thus, the concentration of HADT may determine the susceptibility of mouse striatal DA terminal populations to MPTP but not to methamphetamine.

104.14

NEURONAL ACTIVITY RELATED TO EXPECTATION OF EXTERNAL SIGNALS AND REWARD IN DORSAL AND VENTRAL STRIATUM OF THE MONKEY. P. Apicella*, E. Scarnati*, W. Schultz* and T. Ljungberg* (SPON: European Neuroscience Association). Institut de Physiologie, Univ. Fribourg, CIL 1200 Eighborg. Springeled. CH-1700 Fribourg, Switzerland.

The striatum receives afferents from cortical association areas and limbic structures, suggesting its involvement in cognitive and motivational processes. We investigated neuronal activity in dorsal striatum (caudate nucleus and putamen) and ventral striatum (anteroventral putamen and nucleus accumbens) in relation to predictable environmental event

Three monkeys were trained in a delayed go-nogo task in which they were required to make a visually-triggered arm movement (go) or to withhold it (nogo) according to the color of a preceding instruction light. Correct go and nogo responses were rewarded with liquid. Impulses were recorded from striatal neurons together with electromyograms of mouth and arm muscles.

Two types of anticipatory neuronal changes were observed: 1) Activations preceding the onset of trigger signal or movement were more frequently found in dorsal (82/542, 15%) than in ventral striatum (10/213, 5%). This activity could be related to expectation of trigger signal or preparation of limb movement. 2) Activations preceding the reward in both go and nogo trials were seen in both dorsal (78/542, 14%) and ventral (38/213, 18%) striatum. They may reflect the expectation of the appetitive consequence of the heavings! groups of the services of the precisions. expectation of the appetitive consequence of the behavioral response.

Thus, neurons in dorsal and ventral striatum are activated in advance of predictable,

specific events. The fact that most neurons with anticipatory activity in ventral striatum are related to reward may suggest that this region is particularly involved in the expectation of events with motivational properties.

POSSIBLE ROLE OF NIGRAL GABA-T IN STRAIN DIFFERENCES IN VACUOUS CHEWING MOVEMENTS. S.E. Bachus, A. Summerfelt & C.A. Tamminga, Maryland Psychiat. Res. Ctr., P.O. Box 21247, Baltimore, MD, 21228.

Rat strains differ in incidence of chronic neuroleptic-induced vacuous chewing

Rat strains differ in incidence of chronic neuroleptic-induced vacuous chewing movements (VCM), which have been proposed as an animal model for tardive dyskinesia. Since we have implicated a GABAergic deficit in VCM*-3, we have compared levels of activity of the GABA synthetic enzyme glutamate decarboxylase (GAD), and the GABA degradative enzyme GABA transaminase (GABA-T) in basal ganglia regions among rat strains that vary in VCM rates: Long-Evans (LE) (high), Wistar (W) (variable) and Sprague-Dawley (SD) (low). Samples were dissected bilaterally from striatum, globus pallidus, substantia nigra (SN) and the nigrotegmental target area, and assayed radioenzymatically for GAD*. SN was large enough to also enable us to use an enzymatic-fluorometric assay for GABA-T*. Statistics were by MANOVA.

For GAD across brain regions, there was a strain effect (p≤.001), and also a strain by region interaction (p≤.001), indicating different profiles of GAD across regions for the 3 strains. Within SN, there was also a strain effect (p≤.001) and a strain by enzyme interaction (p≤.005) for GAD and GABA-T. The SD rats, with the lowest VCM, for which we had predicted protection of nigral GABA by high GAD or low GABA-T, were lowest in both nigral GAD (81% LE, 89% W) and GABA-T (74% LE, 79% W). There was a significant correlation between VCM and nigral GABA-T, we are now using in vivo intracerebral microdialysis to estimate nigral synaptic GABA. estimate nigral synaptic GABA.

EFFECTS OF MPTP-INDUCED DOPAMINE DEPLETION ON STRIATAL AND PALLIDAL ELECTROPHYSIOLOGY IN PARKINSONIAN AND RECOVERED CATS. D.W. Duffield, D.S. Rothblat and J.S. Schneider, Dept. of Neurology,

nann University School of Medicine, Philadelphia, PA. 19102.

Administration of MPTP to cats results in greater than 90% loss of dorsal Administration of MPTP to cats results in greater than 90% loss of dorsal striatal dopamine (DA), extensive loss of substantia nigra pars compacta neurons, and behavioral/motor impairment characterized by akinesia, rigidity, and decreased responsiveness to environmental stimuli. These behavioral deficits, while initially very severe, recover to a great extent by 6 wks. after MPTP exposure. The present study examines the electrophysiological correlates of the parkinsonian and recovery conditions in the dorsolateral caudate (DL CD) nucleus and the globus pallidus (GP) in awake cats. Two adult cats have been recorded from under normal and expressions and these cats the part of the parkinsonian conditions and these cats have been recorded from under normal and parkinsonian conditions and three cats have been recorded from under normal, parkinsonian, and recovered conditions. In the DL CD, mean spontaneous firing rates increased 47% while animals exhibited parkinsonian symptoms (with 99% DL rates increased 47% while animals exhibited parkinsonian symptoms (with 99% DL CD DA loss) and reverted to near-normal rates during motor recovery (94% DL CD DA loss). In contrast to DL CD neurons, spontaneous firing rates of GP neurons decreased 62% during parkinsonism. In the normal DL CD, approximately 20% of neurons sampled responded to somatosensory or proprioceptive stimuli. In parkinsonian cats, approximately 5% of sampled neurons were responsive to such stimuli, while during recovery, this increased to approximately 15%. Responses to cortical and thalamic inputs during the MPTP syndrome have also been recorded and will be discussed as will nallified responses to somatosensory and proprioceptive stimuli. discussed as will pallidal responses to somatosensory and proprioceptive stimuli. Thus far, the data indicate that distinct changes in striatal and pallidal spontaneous firing rates and in responsiveness to external stimuli occur accompanying parkinsonian symptoms. As striatal neurochemistry changes during motor recovery, apparently so does the electrophysiology of the DL CD and GP. Supported by NIH grant NS 23980.

104.19

DEFICITS IN TASK-RELATED EYE MOVEMENTS INDUCED BY UNILATERAL INFUSION OF MPTP IN THE MONKEY CAUDATE NUCLEUS. N. Miyashita*, M. Matsumura*, S. Usui*, M. Kato*, A. Kori*, T.W. Gardiner, O. Hikosaka National Institute for Physiological Sciences, Okazaki 444, Japan.

In two monkeys treated unilaterally with MPTP in the caudate nucleus, we examined two types of saccadic eye movements: visually guided saccades (visual-saccade) and memory-guided saccades (memory-saccade). The target was turned on at the same time (visual-saccade) or 600 ms after (memory-saccade) the central fixation point went off. In the memory-saccade task, the position of the future target was flashed while the monkey was fixating, position of the target was chosen randomly out of 32 possible locations on the screen.

Changes in saccades during these tasks began to appear 2-3 days after starting MPTP injection, along with changes in spontaneous eye movements. Saccades to targets contralateral to the injection became delayed in latency, slower in peak velocity, and hypometric. The changes were more marked for memory-saccades than for visualsaccades. Memory-saccades to contralateral targets were sometimes misdirected toward the ipsilateral side.

These results suggest that dopamine plays an important role in the initiation of task-specific saccades, especially those guided by the memory of target position. This effect could be explained by a blockade of saccade-related signals in the caudate that would normally be transmitted to the superior colliculus through the substantia nigra pars reticulata.

WHY DO CATS RECOVER FROM THE EFFECTS OF MPTP? A NEUROCHEMICAL ASSESSMENT. D.S. Rothblat. G.V. Smith*, L. Cerone*, and J.S. Schneider. Dept. of Neurology, Hahnemann University School of Medicine, Philadelphia, PA. 19102.

Administration of MPTP to cats results in a parkinsonian syndrome characterized by rigidity, akinesia, extensive loss of striatal dopamine (DA), and permanent loss of substantia nigra pars compacta neurons. Interestingly, cats show significant motor recovery by 4-6 weeks after MPTP. The present study was performed to assess the neurochemistry of the acute and recovery phases of the MPTP-induced syndrome in the cat in greater detail. Cats with severe parkinsonian symptoms and motor impairment (as assessed by several behavioral/motor and reflex tests) and sacrificed 7 days after 1 wk. of daily MPTP (5-7.5 mg/kg, s.c.) had DA losses of 96% in dorsal medial caudate (DM CD), 99% in dorsal lateral caudate (DL CD), and similar losses in ventral striatal regions. HVA levels were decreased to a slightly lesser degree in all striatal regions (ex., 94% and 93% decreases in DL and DM CD, respectively). By 6 wks. after MPTP, most animals had recovered motor function to a near normal level. In these animals. DA was decreased 87% in DM Administration of MPTP to cats results in a parkinsonian syndron function to a near normal level. In these animals, DA was decreased 87% in DM CD, and 94% in DL CD, while HVA levels had recovered to a greater degree (ex, decreases of only 56% and 41% decreases in DL and DM CD). In contrast to the decreases in DA, serotonin (5-HT) levels were increased in dorsal striatal regions in both parkinsonian and recovered cats. 5-HIAA levels were decreased in parkinsonian animals but were normal in recovered animals. Analysis of amine metabolites in cisternal CSF samples taken during normal, parkinsonian, and recovered phases of the syndrome did not reflect the changes observed in striatal tissue samples. CSF metabolites seemed to reflect more the status of brainstem catecholamine activity. The results suggest that recovery from MPTP-induced parkinsonism in the cat may the results suggest that recovery from MP1P-induced parkinsonism in the cat may be due to a small increase in striatal DA with a significant increase in turnover and/or an increase in striatal 5-HT levels also accompanied by an increase in turnover. The apparent discrepancy between striatal tissue and CSF data will also be discussed. Supported by NIH grant NS23980.

DEFICITS IN SPONTANEOUS EYE MOVEMENTS INDUCED BY UNILATERAL INFUSION OF MPTP IN THE MONKEY CAUDATE NUCLEUS. S. Usui*, M. Kato*, A. Kori*, M. Matsumura*, N. Miyashita* and O. Hikosaka, National Institute for Physiological

Sciences, Okazaki 444, Japan.

To study the role of dopamine in the control of saccadic eye movements we injected MPTP unilaterally into the central part of the caudate nucleus of two Japanese monkeys.

MPTP was infused using an osmotic mini-pump for a period of 1-2 weeks. Using the scleral search coil method, eye movements were recorded in three conditions: in light, dim and total darkness. The monkey sat in a chair facing a tangent screen.

After MPTP injection the frequency of saccades decreased and the range of eye movements decreased. The mean eye position shifted toward the side ipsilateral to the injection by 10-20 degrees. Saccades toward the side contralateral to the injection (contrasaccades) were fewer in number than ipsilateral saccades. Contrasaccades became significantly shorter in amplitude, slower, and longer in duration; changes in ispi-saccades were less pronounced. Immunohistochemistry of tyrosine hydroxylase (TH) showed that activity of the enzyme decreased locally around the injection site. The contralateral side was not affected. In the substantia nigra, TH activity was decreased in its rostral-dorsal part.

The present study indicates that unilateral dopamine deficiency produced suppression of spontaneous saccades toward the contralateral side. This could result from a change in the level of tonic GABAergic inhibition of the superior colliculus by the substantia nigra pars reticulata.

RESPONSES OF MONKEY DOPAMINE NEURONS TO EXTERNAL STIMULI DEVELOP DURING LEARNING AND DECREASE AFTER OVERTRAINING. W. Schultz*, T. Ljungberg* and P. Apicella* (SPON: European Brain and Behavior Society). Institut de Physiologie, Univ. Fribourg, CH-1700 Fribourg, Switzerland

Previous studies have shown that dopamine (DA) neurons respond to external

stimuli with known behavioral significance. This study investigated how responses of DA neurons change when the behavioral significance of stimuli was modified

of DA neurons change when the behavioral significance of stimuli was modified with task acquisition and overtraining.

We recorded impulses from DA neurons with typical electrophysiological characteristics from areas A8, A9 and A10, in 2 awake Macaca fascicularis monkeys, and obtained the following results: (1) Before behavioral reactions were demanded, DA neurons (n=130) typically lacked responses to opening of a small door and to illumination of a light located ahead of them at eye level and at reaching distance. (2) When a small food morsel was presented behind the opening door, monkeys reached out for it, and most of 76 further DA neurons responded with a chort burse of impulses to door opening but lacked responses to the citi lauted. monkeys reached out for it, and most of 76 lurther DA neurons responded with a short burst of impulses to door opening, but lacked responses to the still neutral light. (3) Then the light was used to trigger an arm movement for touching a lever located immediately below the light for liquid reward. Most of 67 DA neurons responded to light illumination in a similar way as to door opening. (4) During acquisition of this task, half of 21 DA neurons responded to the delivery of liquid reward. These responses were lost after task acquisition. (5) After extensive training with 30 000 trials, the task was performed faster, but only 34 % of 82 DA neurons showed significant responses, which also had lower magnitudes.

The present data show that DA neurons respond predominantly to salient

external stimuli that are associated with behavioral reactions and require the attention of the animal. Responsiveness is reduced with more automatic task performance, suggesting that DA neurons are less activated during routine or habitual behavioral acts.

SUBDIVISIONS OF THE SUBSTANTIA NIGRA RETICULATA (SNr) REVEALED BY CYTOCHROME OXIDASE (CO) HISTOCHEMISTRY: CORRELATION WITH LEVELS OF GLUTAMIC ACID DECARBOXYLASE (GAD) GENE EXPRESSION.
L.T. Weiss-Wunder, M. Mercugliano, C. Gonzales and M-F. Chesselet

Dept of Pharmacology, U. of Pennsylvania, Philadelphia, PA 19104
The activity of CO, an endogenous marker of neuronal activity, was examined in the SNr of the adult rat at the light microscopic level. The pattern of histochemical staining observed for CO activity was correlated with immunohistochemistry for tyrosine hydroxylase (TOH, a marker of dopaminergic neurons) and for dynorphin (a peptide present in afferents from the striatum). In addition, the level of GAD immunoreactivity detected with an antibody labelling GAD-containing cell bodies (A. Tobin) and the level of GAD messenger RNA (mRNA) detected with a 35S-radiolabelled cRNA probe (A. Tobin) were measured in neurons of the SNr. The SNr showed a heterogeneous distribution of CO activity that was characterized by denser staining in the ventrolateral than the that was characterized by denser staming in the ventrolateral than the dorsomedial part of the nucleus throughout its rostrocaudal extent, with the exception of the most rostral levels. This pattern of CO activity was inversely correlated with the density of ventrally descending TOH positive dendrites arising from the medial portion of the SNc, as well as with the density of dynorphin immunoreactivity. The region of dense CO activity contained neurons that expressed higher levels of GAD mRNA and GAD immunoreactivity than those neurons located in the region of low CO activity. The results suggest that, within the SNr, different levels of CO activity characterize subpopulations of neurons which may be differentially regulated by both striatal and dopaminergic influences. 105.3

NEUROTRANSMITTER STATUS OF ELECTROPHYSIOLOGICAL SUBTYPES IN THE SUBSTANTIA NIGRA PARS COMPACTA. W.H Yung* and M.A. Häusser* (SPON: Brain Research Association). University Lab. of Physiology, Parks Rd., OXFORD OX1 3PT, U.K.

Recent studies have demonstrated the existence of at least two distinct classes of neurons in the substantia nigra pars compacta (SNC; Grace and Onn, J. Neurosci. 9, 3463; Lacey et al., J. Neurosci. 9, 1233; Häusser and Yung, J. Physiol. 420, 27P). The cells were classified based on electrophysiological properties as non-bursting (principal) and bursting (secondary). The aim of the present study was to determine the transmitter status of these two classes of neurons in the guinea pig SNC in vitro. Double labelling of identified SNC neurons combining biocytin labelling with tyrosine hydroxylase (TH) immunofluorescence revealed that non-bursters (n=24) were consistently double-labelled while none of the bursters (n=12) was TH-positive. Retrograde labelling of SNC neurons with striatally-injected Fluorogold followed by intracellular recording and labelling confirms that non-bursters project to the striatum and indicates that they represent the classical dopaminergic nigrostriatal neurons. Dual color TH and GAD immunostaining was performed on midbrain sections and revealed that GAD-positive neurons were located largely in the dorsal and rostral SNC, which corresponded closely with the distribution pattern of the bursting neurons. This result strongly suggests that the bursting neurons are GABAergic, although the possibility that they use other transmitters such as CCK cannot be excluded.

105.5

CONVERGENCE OF PALLIDAL AND STRIATAL INPUTS TO NEURONES IN THE ENTOPEDUNCULAR NUCLEUS AND SUBSTANTIA NIGRA OF THE RAT: APPLICATION OF A NEW DOUBLE ANTEROGRADE LABELING METHOD AT ELECTRON MICROSCOPIC LEVEL, Y. Smith & J.P. Bolam, MRC Anatomical Neuropharmacology Unit, Dept of Pharmacology, OXFORD,

U.K.

The aim of this experiment was to determine whether single cells in the entopeduncular nucleus (EP) or the substantia nigra reticulata (SNr) receive convergent inputs from the globus pallidus (GP) and the striatum (STR). The approach was to combine the anterograde transport of Phaseolus-vulgaris Leucoagglutinin (PHA-L) and of biocytin (BIO). The PHA-L was injected in GP and the BIO injected into STR. After perfuse-fixation the PHA-L was revealed by immunocytochemical means using benzidine dihydrochloride as chromogen for the peroxidase reaction whereas the BIO was revealed by incubation in avidin-biotin-peroxidase complex using diaminobenzidine as chromogen. Neurones of the EP and SNr were then selected and examined in the electron microscope for synaptic inputs from PHA-L- and BIO-positive boutons. In the SNr, the cells were further characterized by retrograde transport of lectin-conjugated horseradish peroxidase (WGA-HRP) from the superior colliculus (SC), revealed using tetramethylbenzidine as chromogen. In the EP and SNr the PHA-L-labeled varicosities (pallidal) were very large and formed pericellular baskets whereas the BIO-labeled terminals (striatal) were much smaller and formed a rich plexus without any apparent neuronal association. In the electron microscope EP and SNr cells were identified that received symmetrical synapses from both pallidal (PHA-L-labeled) and striatal (BIO-labeled) boutons. Some of the nigral cells that received convergent inputs were identified as nigrocolicular neurones by retrograde labeling. In conclusion, the present findings: (1) suggest the existence of a prominent projection from the GP to the EP and the SNr and (2) reveal that there is a convergence of GP and STR terminals onto neurones in EP and SN. (Supported by the MRC of Canada). The aim of this experiment was to determine whether single cells in the

NEUROTRANSMITTER(S) OF THE AMYGDALO-NIGRAL PATHWAY: AN IMMUNOHISTOCHEMICAL AND IN SITU HYBRIDIZATION STUDY. C. Gonzales, W.R. Patterson* and M.-F. Chesselet, Dept. Pharmacology, University of Pennsylvania School of Medicine Phila PA 101004 Medicine, Phila. PA 19104.

We have previously shown (Gonzales and Chesselet, J. Comp. Neurol. 297:2-20, '90) that the amygdalo-nigral pathway originates in a restricted region located both within and dorsal to the central nucleus of the amygdala (CeN). Previous studies did not detect a significant number of peptidergic neurons in this area. (Veening et al. Brain Res. 303:337-357 84; Cassell et al. J. Comp. Neurol. 246:478-499 86) In an effort to identify the neurotransmitter(s) present in this pathway, sections of rat brain were processed either for immunohistochemistry (IH) using antibodies against glutamic acid decarboxylase (GAD, from A. Tobin, UCLA) and somatostatin 28 (SOM, from Incstar) or in situ hybridization histochemistry (ISHH) using 35-S radiolabelled cRNA probes for GAD (A. Tobin, UCLA) and SOM (R. Goodman, Tufts). Numerous weakly labelled cells were detected in the entire CeN by ISHH with the GAD probe. In contrast, more densely labelled GAD-cells were found in the area of origin of the amygdalonigral pathway both by IH and ISHH. Fewer cells labelled for SOM were found in this area using either technique. Preliminary experiments combining retrograde tracing with fluorogold and ISHH for GAD have shown that GAD cells in this region project to the brainstem. The evidence is compatible with the hypothesis that GABA may function as the neurotransmitter of the amygdalo-nigral pathway. Supported by BNS 86-07645 and MH 44894.

AN EM STUDY OF THE RELATIONSHIP BETWEEN ENK+ BOUTONS AND NIGRAL NEURONS IN PIGEONS. K.D. Anderson, E.J. Karle and

A. Reiner. Dept. Anatomy and Neurobiology, Univ. of TN, Memphis. The substantia nigra (SN) in birds and mammals contains abundant enkephalinergic (ENK+) fibers and terminals. Although various studies indicate ENK is involved in regulating the activity of nigral dopaminergic (DA+) neurons, the specific role of ENX+ nigral afferents in the regulation of DA neurons is unknown. To help clarify this role, we used an EM double-label immunohistochemical technique to determine the relationship between ENK+ terminals (visualized with anti-Leu-ENK using PAP/DAB) and DA+ neurons (visualized with anti-tyrosine hydroxylase, TH, using silver-intensified immunogold). We observed numerous contacts between LENK+ terminals and both TH+ perikarya and TH+ dendrites. Synaptic membrane specializations, some of which were symmetric and others of which were asymmetric, were often observed at the axo-dendritic contacts. LENK+ terminals contacting TH+ neurons contained clear, round, densely-packed vesicles, and also typically contained one or more dense-core vesicles. Segments of TH+ neurons contacted by LENK+ terminals were also contacted by many unlabeled terminals of various morphologically distinct types. LENK+ terminals (with features similar to those of LENK+ terminals contacting TH+ neurons) also contacted unlabeled perikarya and dendrites in regions containing both TH and LENK labeling. These results indicate that ENK+ nigral afferents have a direct influence on the activity of DA+ nigral neurons, and that these ENK+ afferents together with other types of nigral afferents regulate the activity of individual DA+ neurons. PROJECTIONS FROM PEDUNCULOPONTINE NUCLEUS (PPN) TO BASAL GANGLIA IN PRIMATE. B. Lavoie. C. Desiardins* and A. Parent. Neurobiol. Lab., Laval Univ., Québec, Canada.

Tritiated amino acids (AA) and the lectin *Phaseolus vulgaris*-leucoagglutinin (PHA-L) were used as anterograde tracers to study the innervation of the basal ganglia from the PPN in the squirrel monkey (Saintic Giusen). A free result unit trace to recome institute of A A. 2 (Saimiri sciureus). After small unilateral pressure injections of AA (2 animals) or iontophoretic injections of PHA-L (4 animals) in PPN, anterogradely-labeled fibers were found in several basal ganglia components, both ipsi- and contralaterally. The ascending fibers first appeared as a diffuse bundle along the dorsal surface of the substantia nigra pars compacta (SNc), but collected as a more compact fascicle as they run within the lateral hypothalamic area. At midbrain level numerous labeled fibers occurred in SNc and, in sections immuno-stained for both tyrosine hydroxylase and PHA-L, these fibers were found to arborize principally around the cell bodies and primary dendrites of dopaminergic neurons. More rostrally, labeled fibers were dendrites of dopaminergic neurons. More rostrally, labeled fibers were noted in the subthalamic nucleus, particularly in its dorsomedial portion, and in ansa lenticularis, and internal and external medullary laminae. In dorsal pallidum fibers arborized much more profusely in the internal than external segment. The ventral pallidum was devoid of labeled fibers whereas the underlying substantia innominata was densely innervated. In the striatum a small number of labeled fibers occurred especially in the rostroventral part of the caudate nucleus where they terminated in the form of patches. Current studies involving NADPH-diaphorase histochemistry and ChAT immunostaining will serve to evaluate the possible contribution of cholinergic neurons in PPN to the basal ganglia innervation in primates. [Supported by MRC].

AN IN VITRO INTRACELLULAR ANALYSIS OF PEDUNCULOPONTINE INPUTS TO SUBSTANTIA NIGRA PARS COMPACTA NEURONS. J. A. Whittaker and S. T. Kitai. Department of Anatomy and Neurobiology, College of Medicine, The University of Tennessee, Memphis, Memphis, TN 38163.

Response characteristics of substantia nigra pars compacta (SNc) neurons to electrical stimulation of the Pedunculopontine (PPN) area transitional internal participated in vitra vising conventional intracellular seconding.

neurons to electrical stimulation of the Pedunculopontine (PPN) area were investigated *in vitro* using conventional intracellular recording techniques. In parasagittal slices (400-500µm) containing both SNc and PPN, stimulation (10-300µA) of the PPN area produced depolarizing potentials in SNc neurons at latencies of 2.0-3.0msec. with amplitudes over 10mV. Stimulus was applied through bipolar stainless steel electrodes insulated to within 0.2mm from the tips and separated by a distance of 0.3mm. The synaptic responses were identified as excitatory postsynaptic potentials (EPSPs) by intracellular current injection and were considered monosynaptic since their latencies remained constant in spite of changes in stimulus intensities. The morphology and location of recorded since their latencies remained constant in spite of changes in stimulus intensities. The morphology and location of recorded neurons were identified via intracellular biocytin injection and their transmitter phenotype revealed by tyrosine hydroxylase (TH) immunoreactivity. The results demonstrate PPN has predominant excitatory synaptic inputs to both Type I and Type II SNc dopaminergic neurons and may play a role in modulating SNc function. (Supported by NIH grants NS 20702 and NS 23886 to S. T. Kiri) S. T. Kitai).

MULTI-CHANNEL SINGLE-UNIT RECORDINGS FROM AWAKE, FREELY MOVING RATS WITH 6-OHDA-INDUCED DAMAGE TO THE DOPAMINERGIC NIGROSTRIATAL PROJECTION. S.F. Sawyer, C.D. Myre, B.N. Maddux and D.J. Woodward. Department of Cell Biology and Neuroscience.
University of Texas Southwestern Medical Center, Dallas, TX 75235

Damage to the dopaminergic nigrostriatal projection from intracerebral injection of 6-hydroxydopamine (6-OHDA) has proven to be a useful animal model for Parkinson's disease. The behavioral and neurochemical consequences of this lesion have been studied extensively, providing insights into the cellular basis for Parkinsonian symptomatology, but little is known concerning the electrophysiology of neurons in the dopamine-depleted neostriatum of awake, freely moving animals. We report here our preliminary findings using chronic extracellular single unit recording of neostriatal neuronal activity in 6-OHDA treated rats. Male Long-Evans rats received injections of 6-OHDA (8 µg in 4 µl) into the left medial forebrain bundle and substantia nigra pars compacta, and an array of 16 microwires was implanted in the left neostriatum. Damage to the dopaminergic nigrostriatal projection was assessed by orienting deficits to tactile stimuli applied to the contralateral body surface and from contralateral circling to apomorphine (0.05 mg/kg, s.c.). The position of microwires was determined from X-rays and histological reconstruction. Neostriatal neurons in dopamine-depleted rats tended to exhibit higher firing rates than neostriatal neurons in intact animals. In addition, neurons in 6-OHDA-treated animals often exhibited an altered firing pattern consisting of an increased tendency for action potential burst firing with intra-burst rates approaching 500 Hz. In addition, the activity of many neostriatal neurons in 6-OHDA treated rats was episodic to a degree not observed in intact animals. The disruption of the modulatory effects of dopamine on neostriatal synaptic circuits may underlie the observed alterations in firing rates and patterns, and may contribute to the motor impairments observed in Parkinson's disease. Supported by NIDA Grant DA-05352, MH-44337, AFOSR 90-0416 and Biological Humanics Foundation.

ORGANIZATION WITHIN THE RAT SUBSTANTIA NIGRA OF VENTRAL STRIATAL EFFERENT PATHWAYS AND DOPAMINERGIC CELLS PROJECTING TO MOTOR- OR LIMBIC-RELATED STRIATUM. L. Majumdar, S. Haber. Departments of Neurology and Neurobiology and Anatomy, University of Rochester School of Medicine, Rochester, NY 14642.

Integration of motor- and limbic-related parallel circuits through the rodent basal ganglia may occur within the substantia nigra. This study was undertaken to investigate the relationship between limbic-related ventral striatal efferent terminals

investigate the relationship between limbic-related ventral striatal efferent terminals and the dopaminergic cells within the substantia nigra which protect to either motor-related dorsolateral striatum or association-and limbic-related dorsomedial striatum. The anterograde tracer, PHAL, was iontophoretically injected into the ventral striatum and the retrograde tracer, cholera toxin (subunit B), was pressure-injected into dorsolateral or dorsomedial striatum in the same animal. Sections were double stained using antibodies to PHAL and cholera toxin B. Dopaminergic cells within the nigra were identified using a antibody against tyrosine hydroxylase and a flourescent second antibody.

PHAL-labelled fibers from the ventral striatum entered the medial substantia nigra pars compacta rostrally and spread laterally in the caudal nigra. Fibers entered

nigra pars compacta rostrally and spread laterally in the caudal nigra. Fibers entered the ventral tegmental area caudally. Dorsolateral injections labelled the middle third of the substantia nigra with a tendency toward medial and lateral clumping of labelled cells within this region. Double label studies demonstrated significant intermingling throughout the nigra and ventral tegmental area of PHAL-positive ventral striatal efferent terminals and dopaminergic cells which project to association- and limbic-related dorsomedial striatum. PHAL-positive terminals and dopaminergic cells which project to the motor-related dorsolateral striatum were separate in their distributions except within the medial clump of labelled nigral dopaminergic cells. In this region PHAL-positive terminals intermingled extensively with the dopaminergic cell bodies. These results suggest that limbic-related striatal afferent systems may influence the motor-related efferent projection systems of the nigra by virtue of their anatomic interactions within the substantia

UNIT RESPONSES RECORDED IN THE SUBSTANTIA NIGRA AFTER STIMULATION OF THE FRONTAL CORTEX. K. Fujimoto and H. Kita Dept. of Anatomy and Neurobiology, College of Medicine, Univ. of Tennessee Memphis, Memphis, TN 38163.

The subthalamic nucleus (STH) receives excitatory input from the frontal cortex (Cx) and sends excitatory output to the substantia nigra (SN). The neostriatum (Str) also receives excitatory input from the Cx. However the Str sends inhibitory output to the SN. In order to study the function of these pallarel circuits, we assessed unit responses of the SN to stimulation of the Cx. Male Sprague-Dawly rats were anesthetized with urethane (1.2 g/kg, 1.p.). Stimulus electrodes were placed in the Cx. Single unit responses of the SN to the stimulation of the Cx were recorded using glass electrodes filled with 2M NaCl. Some rats were anesthesized with Ketamine (30 mg/kg) and Xylazine (0.9 mg/kg), and received ibotenic acid (60M) lesion of the STH 7-10 days before recording. In some other rats, the Str was lesioned similarly by injection of quinolinic acid (200 nmol). In normal rats, 10-20% of the units recorded in the SN showed excitation followed by inhibition after the stimulation of the Cx, while the rest showed only inhibition. After lesion of the Str, the proportion of the inhibited units in the SN decreased. The proportion of the excited units was not affected by Str lesion. After lesion of the STH, excited units were not observed in the SN and the proportion of inhibited units was also decreased. Therefore evidence suggests that the two pallarel circuits converge upon single SN neurons, and the excitatory response, via the STH, precedes the inhibitory response, through the Str. The reason why lesion of the STH decreased inhibitory responses is not clear. (Supported by NIH Grant NS-25783)

SELECTIVE SUBREGIONAL DOPAMINE DEPLETIONS IN THE RAT CAUDATE-PUTAMEN FOLLOWING NIGROSTRIATAL LESIONS. E.A. Pehek and B.K. Yamamoto. Dept. of Psychiatry, Case West. Reserve Univ. Sch. of Med., Cleveland, Ohio 44106

The rat striatum is heterogenous with respect to dopamine (DA) content, degree and pattern of innervation, and responsiveness to the DA-releasing drug amphetamine The present study examined whether subregions of the striatum would be differentially sensitive to destruction of the nigrostriatal pathway by the DA neurotoxin 6-OHDA. 6-OHDA was injected into the substantia nigra pars commacts. After one month. the substantia nigra pars compacta. After one month, brains were assayed by HPIC/FC for tissue levels of DA, DOPAC, HVA, 5-HT, and 5-HIAA. Four striatal sub-

regions (anterodorsomedial, anterodorsolateral, posterodorsomedial, and posteroventrolateral) and the nucleus accumbens were examined. DA and DA metabolite levels, but not 5-HT or 5-HTAA levels, were reduced in all four striatal subregions but not in the nucleus accumbens. However, compared to other subregions, this accumbens. However, compared to other subregions, this depletion was greatest in the anterodorsolateral area. This relative difference between subregions was most apparent in those animals with partial lesions (40-89% DA depletions). These findings may reflect differences in the pattern of innervation of striatal subregions by nigrostriatal afferents. Furthermore, this research may have implications for the pathogenesis of Parkinson's disease. Supported by PHS NS24814.

CIRCLING INDUCED CHANGES IN GABA RELEASE IN THE SUBSTANTIA NIGRA RETICULATA AND GLOBUS PALLIDUS. R.E. Maloney, C.R. Freed. Dept. of Med., Div. of Clin. Pharm. Univ. of Co. Health Sci Center, Denver, Co 80262.

In our ongoing efforts to understand the relationship between movement and the release of neurotransmitters we have used in-vivo microdialysis to measure GABA release from the substantia nigra pars reticulata(SNR) and globus pallidus(GP) of rats trained to run on a circular treadmill for a water reward. Male Sprague Dawley rats were trained to an FR10 schedule in both directions. After subjects reached criteria they were surgically implanted with guide tube cannulae in either the SNR(Paxinos & Watson coordinates AP:-5.3, LAT:2.78, VENT:-7.4) or GP(AP:-9.5, LAT:3.2, VENT:-5.15). 3 days after surgery animals were retrained and then a 300 um x lmm dialysis probe was inserted which extended into either the SNR or GP. Animals were perfused with Ringers solution at a flow rate of 1.5ul/min. Twenty min. samples were taken. After a 3 hr. baseline period animals were placed on the circular treadmill for 80 mins and allowed to run in one direction only for a water reward. One week later animals were tested in the opposite direction. Perfusate was analyzed by HPLC/EC with precolumn derivatization with orthophthalaldehyde. There was a 249% increase in GABA release from the SNR when animals circled contralateral to the dialyzed side. There were no significant changes in SNR GABA release ipsilateral or in either side of the GP.

MOTOR EFFECTS OF SUBSTANTIA NIGRA PARS RETICULATA (SNR)
STIMULATION IN THE RAT: LESIONS OF SNR EFFERENT TARGETS,
CORTICOFUGAL AND RUBROFUGAL PATHWAYS DO NOT ATTENUATE THE
MOTOR EFFECTS. S.I. Lentz and D. Asdourian, Dept. of
Psychology, Wayne State Univ., Detroit, MI 48202.
Unilateral lesions disrupting substantia nigra pars

Unilateral lesions disrupting substantia nigra pars reticulata (SNr) efferent targets, and fibers of passage coursing through SNr were made to determine the source of neck and shoulder muscle activity observed during unilateral electrical stimulation of SNr in anesthetized adult male rats. Muscle activity in trapezius, biventer cervicis, and rectus capitis was recorded electrically. In the intact animal, unilateral stimulation of SNr (twin square wave pulses, 1 pulse/sec, duration 1.0 msec, interpulse interval 1.0 msec, at 0.5 mA) drove bilateral muscle activity in all 3 muscles with ipsilateral muscle activity always greater in amplitude than contralateral activity. Lesions to SNr efferent targets: Unilateral lesions in the superior colliculus (SC) and pedunculopontine tegmental nucleus (PPtg) did not have a significant effect on muscle activity driven with SNr stimulation. Lesions to fibers of passage through SNr: In separate groups, unilateral lesions to: (1) ipsilateral motor cortex, (2) ipsilateral pyramidal tract and (3) contralateral red nucleus, to the stimulation did not have a significant effect on muscle activity driven by SNr stimulation. The inability to block muscle activity with lesions of SC, PPtg, corticofugal and rubrofugal systems leaves unanswered the question as to which pathway(s) is involved in driving muscle activity with SNr stimulation.

ULTRASTRUCTURE OF CHOLINERGIC NEURONS OF THE NUCLEUS TEGMENTI PEDUNCULOPONTINUS IN THE RAT. B. Spann and I. Grofova. Dept. of Anat., Mich. State Univ., E. Lansing, MI 48824

Choline acetyltransferase (ChAT) immunohistochemistry studies have indicated the nucleus tegmenti pedunculopontinus (PPN) as a center of the Ch 5 cell group in human and experimental animal species (Mesulam, M.-M. et al., J. Comp. Neurol., 281:611-633, 1989). The present immunocytochemical study describes light and electron microscopic features of ChAT-positive neurons and synaptic arrangements of both cholinergic and non-cholinergic cells of the PPN.

Both subdivisions of the PPN, the subnucleus compactus (PPNc) and

Both subdivisions of the PPN, the subnucleus compactus (PPNc) and dissipatus (PPNd) contain cholinergic neurons that are either fusiform or multipolar in shape and vary in size from 20 μ m to 60 μ m along the longest axis. While the ChAT-positive somata are most numerous in the PPNc, the ChAT-positive dendrites are present in both subnuclei with a particularly dense concentration in the medial portion of the PPNd. In a previous study on the normal ultrastructure of the PPN, we have identified three morphologically distinct types (I-III) of terminal boutons. Electron microscopic examination of the present material reveal all three types synapsing on the ChAT-positive dendrites. Type III terminals are, at least partially, of nigral origin and we have previously reported that they terminate mostly on dendrites within the PPNd. Consequently the present observations suggest, indirectly, that nigral afferents may terminate on the dendrites of PPN cholinergic neurons. (Supported by N.I.H. grant NS 25744).

105.17

GABA NEURONS IN THE VENTRAL TEGMENTAL AREA PROJECT TO THE MEDIAL PREFRONTAL CORTEX: A NON-DOPAMINERGIC MESOCORTICAL SYSTEM. M. H. Gillham¹, L. Jennes², and A. Y. Deutch¹. ¹Departments of Psychiatry and Pharmacology, Yale University School of Medicine, New Haven, CT 06510 and ²Department of Anatomy, Wright State University, Dayton, OH 45435.

The dopaminergic projection from the ventral tegmental area (VTA) to the medial prefrontal cortex (mPFC) has been extensively studied. However, less than half of the VTA neurons which project to the mPFC are dopaminergic. We now report a GABAergic projection from the VTA to the mPFC.

Combined retrograde tracer-immunohistochemical methods revealed GABA-like immunoreactive (GABA-li) neurons in the VTA which were retrogradely labeled with fluorogold (FG); these were most often observed in the nucleus parabrachialis pigmentosus. FG-labeled GABA-li neurons were typically small round cells and contrasted with FG-positive non-GABA-li neurons which were medium-sized. GABA-li axonal pericellular arrays were frequently observed to surround non-GABA-li FG-positive neurons, but were rarely seen in apposition to the GABA-li mesocortical cells.

These data suggest that GABA may regulate mPFC function in two ways: through direct GABAergic projections from the VTA to the mPFC, and via local GABAergic regulation of dopaminergic mesocortical neurons.

PATTERNS OF CALCIUM CHANNEL ANTAGONIST BINDING IN RAT CNS. L.P. Fortier*, B. Lavoie and J.P. Tremblay. Lab. of Neurobiol., Fac. of Med., Laval Univ., Quebec, Canada.

Quebec, Canada.

The term voltage-sensitive calcium channel (VSCC) refers to a family of ionic channels characterized by individual kinetic properties. Their multiple roles, level of cell excitability, neurotransmitter release and growth probably derive from their respective characteristics. Using as a probe the omega-conotoxin (ω-CgTX), a specific antagonist of the VSCC, we revealed populations of neurons in coronal sections of rat brain. A population of particular interest for us was located in the substantia nigra. Labelling of the probe binding sites with our monoclonal antibody mab anti-CgTX was found mainly on cell bodies and proximal processes. The labelled cells were not uniformly distributed throughout the substantia nigra. Whether these cells represent a subpopulation remains to be determined. Current studies combining the use of retrograde fluorescent tracers injected into the thalamus and/or superior colliculus with immunohistochemistry should help to better characterized this subpopulation of nigral neurons expressing ω-CgTX immunoreactivity.

PREFRONTAL CORTICAL TERMINALS SYNAPSE WITH DOPAMINERGIC NEURONS IN THE VENTRAL TEGMENTAL AREA AND WITH UNLABELED NEURONAL TARGETS OF DOPAMINERGIC TERMINALS IN THE NUCLEUS ACCUMBENS SEPTI. S.R. Sesack and V.M. Pickel. Dept. Neurology and Neuroscience, Cornell Univ. Med. Coll., New York, NY 10021.

We sought to determine possible ultrastructural bases for known modulatory interactions between the prefrontal cortex (PFC) and the mesolimbic dopaminergic (DA) system, either in the ventral tegmental area (VTA) or in the nucleus accumbens senti (Act). Terminals from

We sought to determine possible ultrastructural bases for known modulatory interactions between the prefrontal cortex (PFC) and the mesolimbic dopaminergic (DA) system, either in the ventral tegmental area (VTA) or in the nucleus accumbens septi (Acb). Terminals from the PFC were identified in rats either by anterograde degeneration following electrolytic lesions or by immunoperoxidase labeling of anterogradely transported *Phaseolus vulgaris* leucoagglutinin. In single sections processed for degeneration or transport, presumed DA neurons and processes were identified by immunoperoxidase or immunogold labeling, respectively, for the catecholamine synthesizing enzyme, tyrosine-hydroxylase (TH). In the VTA, PFC-terminals made asymmetric synaptic junctions with TH-labeled or unlabeled dendrites. In the Acb, PFC-terminals formed asymmetric synapses with dendritic spines, some of which also received symmetric synapsic contact from TH-labeled terminals. PFC and TH-labeled terminals were also directly apposed to each other, but did not form conventional axoaxonic synapses. We conclude that efferents from the PFC monosynaptically modulate, and most likely excite, DA neurons in the VTA and spiny targets of DA terminals in the Acb. Additionally, PFC and DA terminals are anatomically positioned to facilitate presynaptic modulation in the Acb. These findings have important implications for understanding the mechanisms linking cortical and mesolimbic DA pathophysiology in schizophrenia. (Supported by NS08193, MH40342).

DO ENTOPEDUNCULAR NEURONS PROJECTING TO THE HABENULA RECEIVE A SUBSTANCE P INPUT FROM THE STRIATUM? N. Rajakumar, K. Elisevich and B.A. Flumerfelt. Depts. of Anatomy and Clinical Neurological Sciences, University of Western Ontario, London, Canada, N6A 5C1.

The entopeduncular nucleus (EPN) of the rat is homologous to the internal segment of the primate globus pallidus and forms an important output pathway of the basal ganglia. Anatomical studies have demonstrated a large projection from the rostral two-thirds of the EPN to the ipsilateral habenular nucleus. Unlike other neostriatal output systems, these fibres terminate in the lateral habenula (LHB) which is known to receive its afferents mainly from limbic centres. The EPN receives its main input from the neostriatum via a projection that contains substance P (SP). However, it remains to be determined if the SP containing synaptic input terminates in relation to the EPN-LHB projection neurons. In this study, the WGA-HRP retrograde tracing method was employed to label the EPN-LHB neurons, and immunocytochemical methods were used to investigate the presence of SP containing synaptic profiles on the labeled cells. Reactive profiles were identified with the PAP technique using the chromogens TMB, DAB, and BDHC in various combinations. SP immunoreactive terminal axons were frequently observed with the L.M. in apposition to EPN neurons retrogradely labeled from the LHB. These results suggest that the LHB receives a large projection from EPN neurons which in turn receive an SP-containing synaptic input, probably from the neostriatum. THE PRIMATE NUCLEUS OF THE FIELD OF FOREL: NEURONS TYPES AND AFFERENT FIBERS. J.A. Rafols, Y. Anavi* and S. Mintz*. Dept. of Anatomy, Wayne State Univ. Sch. of Med. Detroit, MI 48701

Dept. of Anatomy, Wayne State Univ. Sch. of Med. Detroit, MI 48201

The neuronal organization of the nucleus of the Field of Forel(nFF) in the monkey (Macaca mulatta) was examined in Golgi impregnated brains(N=50) sectioned in the frontal, horizontal, and sagittal planes. Four(types I-IV) different neuronal types were distinguished based on morphological features of the cell body, dendrites, and the axon. Type I was the most commonly impregnated neuron. It had large(24-63µm), fusiform or polygonal cell bodies and long, tapering dendrites which radiated preferentially in the dorsoventral and mediolateral planes. Only the hillock and initial segment of the axon were impregnated suggesting that it may be of the long variety. Type II neurons had medium(13-21µm), fusiform or polygonal cell bodies and thin, varicose dendrites. The axon was of the long type and gave rise to a few intrinsic collaterals. Type III neurons were local interneurons with small (8-17µm), round somata and long, nontapering dendrites which gave rise to numerous bulbous appendages and axon-like processes. The rarely observed type IV neurons had small(8-12µm), round somata, few tightly coiled dendrites and a short axon. In addition, five different types of afferent fibers, some of which were fibers of passage, gave rise to synaptic boutons which terminated in nFF. In horizontal and sagittal sections some of these fibers were followed into the internal capsule, dorsal and ventral midbrain tegmentum, Forel's H2 Field and hypothalamus. The present results show, for the first time, evidence of cell type heterogeneity, as well as diversity of extrinsic and intrinsic neural networks in nFF.

THE PROPORTION OF THE STRIATUM STAINED POSITIVE FOR CHOLINE ACETYLTRANSFERASE (CAT) INCREASES IN A UNILATERAL RODENT MODEL OF PERINATAL HYPOXIA-ISCHEMIA.RE Burke and N Kenyon², Dept of Neurology, Columbia University, NY, NY 10032.

Little is known of the effect of hypoxic-ischemic injury during development on the neurochemical anatomy of the brain. We have focused on effects on the striatum, because it often shows the predominant pathology in human perinatal asphyxial injury, and it plays a major role in motor control. We and others have previously shown that striatal cholinergic neurons are relatively spared following hypoxic-ischemic injury; their density (neurons/mm³ striatum) increases. We have here investigated what changes occur in the density and distribution of CAT-positive striatal neuropil staining. Rat pups underwent left carotid ligation and exposure to 8% O₂ at 7 days of age, and brains were prepared for immunohistochemical staining of CAT at 3-4 or 8-12 weeks. Cryostat cut sections were stained with a monoclonal ant-CAT Ab (Bochringer). Representative sections were taken from Paxinos-Watson 10.2, 9.7, 9.2, and 8.2. The area of the striatum stained CAT-positive was determined by segmented field analysis; specific staining was defined as density values between a maximum specific OD and 75% of that value. At 3-4 weeks there was a trend towards an increase in the absolute value of CAT-positive area on the injured side: C:3.4±0.5; E:4.7±0.8 (mm² = SEM)(p=0.1). There was a significant increase in percent striatal area stained: C:8.6±1.3; E:13.7±2.1 (%)(p=0.5, N=11). The effect was uniform in the rostro-caudal dimension. Similar changes were observed in adults; there was a significant increase in the percent area stained CAT-positive: C:14±2.2; E:20.2±3.5 (%)(p=0.5, N=9). These results support our earlier finding that striatal cholinergic systems are resistant to hypoxic-ischemic injury. NINDS NS26836.

EFFECT OF UNILATERAL PERINATAL HYPOXIA-ISCHEMIA ON CHOLINERGIC RECEPTORS IN THE RAT STRIATUM. Y. Kostic, S. Przedborski, Y. Jackson-Lewis, J.L. Cadet R.E. Burke. Department of Neurology, Columbia University, New York, N.Y. 10032

Little is known of the effect of hypoxic-ischemic (HI) injury during development on the neurochemical anatomy of the brain. We have previously shown in a unilateral rodent model that perinatal HI injury results in an increased density of morphologically-defined cholinergic pre-synaptic elements, both neurons (Ann Neurol, 1990) and neuropil. Little is known of effects on post-synaptic cholinergic markers. We therefore used quantitative autoradiography to investigate effects on total (3 HQNB) and M1 (3H Pirenzepine [PZ]) muscarinic receptors. In one-week old rat pups, unilateral HI was induced by carotid ligation followed by exposure to 8% oxygen. Pups were sacrificed at 3-4 weeks. 3H-QNB autoradiography revealed no changes in Bmax or Kd on the HI-injured side. In contrast, saturation experiments using 3H-PZ showed a significant decrease in Bmax in the injured striatum ipsilateral to the ligation, compared to the contralateral side (134.5 ± 4.9 vs 153.9 ± 8.2 fmol/mg tissue; p<05). No change was observed in Kd. M1 mapping experiments revealed that the observed decrease occurred mainly in the dorsal part of the lesioned striatum (-23%; p<05). These findings suggest that HI injury may result in an increase in striatal M2 sites, a possibility to be explored with selective M2 ligands. NINDS NS26836, PDF.

RELEASE OF THE SUBTHALAMIC NUCLEUS (STN) FROM GABAERGIC INHIBITION IS AN ELEMENT IN THE DEVELOPMENT OF PARKINSONIAN SIGNS. T. Wichmann', H. Bergman', M.R. DeLond Dept. of Neurology, The Johns Hopkins Hospital, Baltimore, MD, USA. Studies in MPTP treated primates suggest that parkinsonian signs may be

Studies in MPTP treated primates suggest that parkinsonian signs may be linked to increased activity of the STN, due to release from GABAergic inhibition from the external pallidal segment. The present study was designed to further investigate the role of STN activity and its control by GABAergic mechanisms in the development of parkinsonian signs.

Two African green monkeys were rendered parkinsonian by the injection of MPTP (i.m., 4 - 10 mg/kg). After the development of severe parkinsonian signs, the subthalamic area was mapped first with microelectrode recordings and later with a combined injection/recording device. With this, the GABA receptor agonist muscimol and the GABA receptor antagonist bicuculline were injected into the STN to transiently influence STN activity in two monkeys. Injections of normal saline served as a control.

Injection of 0.6 - 1 ul muscimol (1 mg/ml) into the "arm area" of the STN decreased the neuronal activity, reduced rigidity and tremor, and led to the appearance of voluntary and involuntary movements of the contralateral arm, which then spread to the contralateral leg. Injection into the 'leg area' induced the same effects, starting in the leg and spreading to the arm. Injection of 0.6 - 1.0 ul bicuculline (0.25 - 1 mg/ml) increased the neuronal activity. Bicuculline injections did not elicit dyskinetic movements and the parkinsonian signs remained largely unchanged. In both animals, saline had no effect.

These findings support further the notion that increased STN activity due to decreased GABAergic inhibition is important in the development of parkinsonian signs.

EFFECTS OF UNILATERAL PERINATAL HYPOXIA-ISCHEMIA ON DOPAMINE (DA) DI-and D2-RECEPTORS AND UPTAKE SITES IN RAT. V. Jackson-Lewis, S. Przedboski, Y. Kostic, J.L. Cadet, R.E. Burke, Columbia University, New York, New York 10032

The striatum is a major site of pathology following perinatal hypoxic-ischemic (HI) brain injury. Little is known of alterations in neurochemical anatomy Johnston (1983) had previously shown that pre-synaptic biochemical indices of striatal dopaminergic systems are relatively spared. We have confirmed this morphologically by finding an increased density of tyrosine hydroxylase-positive neuropil in the injured striatum (Soc Neurosci, 1989). However, little is known of effects on post-synaptic dopaminergic elements. We therefore studied effects of perinatal HI on striatal DA-receptors, as well as uptake sites, in rats using quantitative autoradiography. In 7-day-old rat pups, HI was induced by unilateral carotid ligation with subsequent exposure to 8% oxygen. In animals sacrificed at 3-4 weeks of age, radioligand binding saturation experiments revealed significant decreases in Bmax for ⁵H-SCH 23390-labeled D1 (-23%; P<0.001) and ³H-spiperone labeled D2 receptors (-28%; P<0.011) on the side of the injury. In addition, a significant increase in the Kd for D1 receptors was observed(P<0.05). Mapping experiments showed that these changes were present along the rostro-caudal axis of the striatum and predominated in the dorsal aspect. On the other hand, no changes in either Bmax or Kd were observed in ³H-mazindol labeled DA uptake sites. In 8 to 12-week-old rats, similar changes in D2 receptors were observed; however, both the Bmax and the Kd for D1 receptors had returned to normal. NINDS NSZ6836, PDF.

GABA_RECEPTOR IMMUNOREACTIVITY IN ADULT AND DEVELOPING MONKEY SENSORY-MOTOR CORTEX. G.W.Huntley, A.L.de Blas and E.G.Jones. Dept. of Anatomy and Neurobiology, Univ. of California, Irvine, CA.92717 and Division of Molecular Biology, Univ. of Missouri, Kansas City, MO. 64110.

The areal and laminar distribution of GABA_A receptor immunoreactivity was examined in fetal, early postnatal and adult mankey sensory more cortex by using a moneological antibody to

immunoreactivity was examined in fetal, early postnatal and adult monkey sensory-motor cortex by using a monocional antibody to the purified GABA_A receptor complex (Vitorica et al., J.Neurosci.8,1988). If adult cortex, immunoreactivity was distributed throughout the neuropil and in each area layers I-IIIA exhibited the most intense immunostaining. In deeper layers of SI, layers IIIB and V were lightly stained and alternated with more intensely stained layers IV and VI. In area 4, staining in layers IIIA-VA was light, but was more intense in layers VB-VI. In areas 4,1,2, parallel, radially oriented chains of densely stained nuncta resembling small fasciculi were present. Each of the In areas 4,1,2, parallel, radially oriented chains of densely stained puncta resembling small fasciculi were present. Each of the developing sensory-motor cortices examined (E110-PND125) possessed receptor immunoreactivity. At early stages, staining was present in a diffuse band occupying the middle layers of all areas and in the subplate. With increasing age, changes in the distribution of staining occurred resulting in an adult-like pattern by early postnatal ages. It is suggested that laminar changes seen in development are associated with the establishment of afferent connections and inhibitory circuits in the sensory-motor cortex. MOLECULAR SPECIFICATION OF PRIMATE CORTICAL NEURONS REVEALED BY MONOCLONAL ANTIBODIES. A. Guimaraes, P.L. Strick and P. Levitt. Dept. of Anatomy. Med Coll of PA, Philadelphia, PA 19129 and VA Med Ctr./Depts of Neurosurg.& Physiol, SUNY-HSC @ Syracuse, Syracuse, NY

Monoclonal antibodies have been useful in demonstrating rare antigenic determinants expressed by select subsets of neurons in the central nervous system. A new monoclonal antibody was generated by immunizing Balb/c mice with homogenized monkey motor cortex. These mice were immunotolerized neonatally with monkey hippocampus and subsequently treated with cyclophosphamide. Monoclonal antibody 8B3 is an immunoglobulin of the IgM subclass and crossreacts with an epitope in rodent, cat and monkey. Immunocytochemical analysis in the rhesus monkey brain revealed an immunoreactive subpopulation of neurons in all cortical areas except the hippocampus. The distribution of staining is characterized by a single row of neurons on the border of layers I/II, a scattered population in deep aspects of layer V and thoughout layer VI, and a large number of interstitial neurons located in the subcortical white matter. Very few positive neurons are seen in layers II through upper V. The immunohistochemical staining pattern suggests that 8B3 recognizes a surface epitope on the somata and proximal dendrites of a population of cells that include stellate neurons. The distribution of labelled cell classes that are immunoreactive are identical between cortical areas, but the number of 8B3-stained neurons varies substantially depending upon the region examined. This might reflect the relative contribution of this neuron population to distinct functional regions of the primate cerebral cortex. Supported by NIMH grant MH45507 and March of Dimes Basic Research Grant 1-919.

CORTICOSPINAL PROJECTIONS IN THE INFANT AND MATURE MACAQUE MONKEY. Galea, M.P.* and Darian-Smith, I. Brain Research Laboratory, Univ. of Melbourne, Parkville, 3052, Victoria, Australia.

Postnatal regressive neuronal changes have been observed in callosal (Innocenti et a 1.86, J.Neurosci. 6, 1384) and thalamocortical projections to the macaque's sensorimotor cortex, (Darian-Smith et al., 90 in press), and also in corticospinal projections in non-primate mammals (O'Leary and Stanfield, 86, Dev. Brain Res. 27, 87). We describe the changing postnatal corticospinal projections in the macaque monkey, which also reflect regressive changes. Fluorescent, retrogradely transported dyes [Fast Blue, Diamidino Yellow, Rhodamine and Green Latex Microspheres] were injected into the surgically-exposed cervical cord of each macaque, and the cortical distributions of labeled cells mapped and correlated with the cytoarchitecture in serial coronal sections. In each macaque, either newborn or mature, Fast Blue injections extended through much of the dorsal quadrant of C_2 - C_3 on one side, whereas smaller injections of the other dyes were made at the level of C_7 - C_1 on the other side. In mature monkeys, Fast-Blue-labeled cells were found almost exclusively in

Lamina V and mainly in the contralateral prefrontal, premotor, supplementary area, motor area 4; areas 3a, 3b, 1, 2, 5, 7a and 7b, the cortical folds of the cingulate sulcus through much of its length, SII and adjacent insular cortex. With injection sites mainly in the dorsal horn, labeled neurons were concentrated in postcentral cortex, while injections centered on the spinal intermediate zone also labeled many precentral cells.

In the newborn macaque additional corticospinal neurons were regularly in the lateral and orbital parts of the inferior frontal gyrus, and the lower lip of the lateral sulcus, with spread into the superior temporal gyrus. The cingulate projection was also denser than that observed in the mature brain, and while corticospinal neuron somas were mainly within lamina V, this was not always so. How these differen corticospinal projections in newborn and mature macaques relate to sensorimotor performance is not clear.

A MICROCOLUMNAR STRUCTURE OF MONKEY CEREBRAL CORTEX REVEALED BY IMMUNO-CYTOCHEMICAL STUDIES OF DOUBLE BOUQUET CELL AXONS. J. DeFelipe, S.H.C. Hendry, and E.G. Jones. Dept.

of Anatomy and Neurobiology, Univ. of California, Irvine, CA 92717.

Immunocytochemical methods were used to study 28 Kd calbindin and tachykinin immunoreactivity in the monkey cerebral cortex. The staining of long, vertically-oriented bundles of processes - identical to classical double bouquet cell axonal arborizations - is the most prominent feature of both calbindin and tachykinin immunoreactive staining. These bundles form a widespread and regular columnar system descending from layer II through layers III-V. The bundles are most evident in layer III where, in tangential sections, they have a density of 7 to 15 bundles per $10,000 \, \mu \text{m}^2$ with a center-to-center spacing of 15 to 30 um.

Somatic sensory, auditory, and visual areas display a large number of calbindin immunoreactive bundles but tachykinin immunoreactive bundles are numerous only in the auditory areas and in area 18 of the visual cortex. In the precentral motor cortex (area 4) few or no immunoreactive bundles are visualized

Tachykinin-positive axons of the bundles form symmetrical synaptic contacts with dendritic shafts (57%) and spines (43%). Despite the virtually identical morphological features of tachykinin and calbindin immunoreactive bundles, colocalization studies demonstrate little coexistence of the two antigens in somata and none in the axonal bundles of double bouquet cells.

These data suggest that the double bouquet cell is a chemically between the property of the control o

heterogeneous, but ubiquitous morphological type of cortical interneuron. Its uniquely bundled axonal system, which is probably GABAergic, imposes a fundamental microcolumnar organization upon the cerebral cortex. Supported by NIH grant no. NS21377.

106.4

ORGANIZATION OF NEURAL ELEMENTS IN MOTOR SPEECH AREAS.

T.L. Hayes and D.A. Lewis. Departments of Behavioral Neuroscience and Psychiatry, University of Pittsburgh, Pittsburgh, PA 15216.

Motor speech functions are believed to be localized to the region known as Broca's area, located within the left inferior frontal gyrus rostral to the motor region. However, little is known about the intrinsic organization of this area, or about how that organization compares to the homologous region in the right hemisphere. Three control human brains were examined immunohistochemically using Nissl stains and antibodies directed against non-phosphorylated neurofilament proteins (NFP) and calbindin. Nissl stains revealed considerable heterogeneity within this area. The rostral portion of the area was granular, with evenly sized and distributed pyramidal neurons in layers III and V. A distinct population of large layer III pyramidal neurons appeared more caudally, concomitant with a narrowing of layer V. The region was dysgranular at its most caudal extent. Different populations of neurons were NFP- and calbindin-immunoreactive (IR). The soma and proximal applical and hasilar dendrites of a subpopulation of pyramidal neurons in organization of this area, or about how that organization compares to were NFP- and calbindin-immunoreactive (IR). The soma and proximal apical and basilar dendrites of a subpopulation of pyramidal neurons in the large layer III pyramidal neurons. In contrast, calbindin was present in the soma and apical dendrites of the smaller pyramids in layer III, as well as in nonpyramidal neurons of layers II, III and VI. Numerous processes in layers II and superficial III were calbindin-IR, as were bundles of radial fibers in layers III-VI. These findings provide a basis for comparing the organization of Broca's area with that of its homologue in the right hemisphere.

CONNECTIONS OF ELECTROPHYSIOLOGICALLY DEFINED LOCATIONS IN PRIMARY MOTOR CORTEX, MI, OF OWL MONKEYS (AOTUS TRIVIRGATUS). Iwona Stepniewska, Anne Morel and Jon Kaas. Vanderbilt Univ., Nashville, TN 37240.

Microstimulation and anatomical techniques were combined to reveal connection patterns of MI in owl monkeys. Three or four different tracers (WGA-HRP and fluorescent dyes) were placed in the representations of the hindlimb, trunk, forelimb and face in MI. Labeled connections revealed parallel somatotopic inputs from areas 3a, 3b, and 1, with the input from 3b being sparse, especially for the forelimb. Connections with the hindlimb, trunk, and forelimb regions of MI formed a caudorostral sequence in the supplementary motor area. Dense inputs to MI originated from cortex in the lower bank of the lateral sulcus, and sparse label in cortex of the upper bank may have been in SII and the parietal ventral area. Callosal connections were with matched parts of MI, with the forelimb representation having sparse connections. Thalamic input zones in the ventrolateral complex formed a hindlimb, trunk, forelimb and face dorsolateral to ventromedial sequence. Other labeled structures included intralaminar nuclei, the reticular nucleus, CM, the putamen, claustrum, nucleus basalis, and nucleus of the diagonal band. (Supported by NS 16446.)

EFFECTS OF EXPERIMENTAL INFANTILE HYDROCEPHALUS AND VP SHUNTS ON MOTOR CORTEX CONNECTIONS. J.S. Way, S.D. Katz*and J.P. McAllister. Depts of Anatomy and Neurosurgery, Temple Univ. School of Medicine, Philadelphia, PA. 19140

Since previous neurotransmitter studies suggest that cortical afferents are altered irreversibly by ventriculomegaly, an axon tracer study was initiated on motor cortex connections. Hydrocephalus was induced in 10-11 day old kittens by intracisternal injections of 25% kaolin and monitored by ultrasound. Some hydrocephalic animals receimonitored by ultrasound. Some hydrocephalic animals received VP shunts at 11-12 days post-kaolin. Normal age-matched animals served as controls. WGA-HRP injections were made unilaterally in cortical area 4 in: hydrocephalic animals at 9-15 days post-kaolin; shunted animals at 1,2 & 4 weeks post shunt; age-matched control animals. Sections were processed by TMB histochemistry. Post-shunt ventriculomegaly was much reduced and accompanied by marked neurological improvement. Hydrocephalic brains had fewer labeled cells in contralateral active, insilateral claustry. in contralateral cortex, ipsilateral claustrum, nucleus basalis, thalamic nuclei, dorsal raphe, ventral tegmental area and midbrain reticular formation, but no decrease in the locus coeruleus. Axonal label was reduced in thalamus, internal capsule, crus cerebri, pons, dorsal column nuclei, pyramids. All shunted animals exhibited labelling similar to controls. These results indicate damage to cortical pathways occurs during hydrocephalus, but decompression allows some structural restoration of these connections. Supported by HD21527 to JPM

106.9

CONNECTIONS OF MEDIAL AGRANULAR CORTEX WITH PRIMARY MOTOR AND SOMATOSENSORY CORTICES IN RATS. J.J. Diehl and M.F. Huerta. Center for Neurological Sciences and Dept. BioStructure & Function, Univ. Conn. Health Ctr., Farmington, CT 06032.

While oculomotor-related functions of the medial

agranular cortex (AGm) have been emphasized in recent studies, this region is also known to have strong studies, this region is also known to have strong connections with somatosensory and somatomotor structures. In order to study this aspect of AGm, the connections between AGm and primary somatosensory (S-I) and motor (M-I) cortical areas were determined using the fluorescent tracers fast blue (FB) and diamidino yellow (DY). Injections of FB in the hindlimb representation of M-I and DY in more rostral M-I in the same case revealed the topography of the AGm projection to M-I; these data suggest that the same zone of M-I receives input from two widely separated regions within AGm. Other experiments were designed to reveal the laminar patterns of AGm which project to S-I and M-I; injections of FB and DY in the same animal showed that cells projecting to S-I were concentrated in layer V, but also present in VID, while cells projecting to M-I were dense in layers II, V and VID, but also present in layers III and VIa. These preliminary findings indicate that AGm has highly organized connections with somatosensory and somatomotor cortex. with somatosensory and somatomotor cortex.

106.11

PREFRONTAL CONNECTIONS WITH THE PREMOTOR AREAS.

M.T. Lu and P.L. Strick. VA Med. Ctr. and Depts. of Neurosurg.

& Physiol., SUNY-HSC @ Syracuse, Syracuse, NY, 13210.

We placed multiple injections of one tracer (e.g., diamidino yellow) in the arm area of the primary motor cortex in macaques to define the premotor areas in the frontal lobe. Then, in the same monkeys, we placed multiple injections of another tracer (e.g., WGA-HRP) in and around the principal sulcus (Walker's area 46) to determine which premotor areas are interconnected with the prefrontal cortex. Neurons projecting to prefrontal cortex (PF neurons) were unevenly distributed in the premotor areas. In fact, over 62% of these neurons were found in the arm representation of a single premotor area, the the premotor areas. In tact, over 62% of these neurons were found in the arm representation of a single premotor area, the arcuate premotor area (APA). A smaller number of PF neurons (22%) were found within specific portions of the rostral and caudal cingulate motor areas (CMAr and CMAc) which are buried in the banks of the cingulate sulcus. Finally, about 13% of the PF neurons were found in the arm representation of the supplementary motor area (SMA). Most of these neurons were confined to a small region of the SMA which lies rostral to the genu of the arcuate sulcus. genu of the arcuate sulcus.

These observations suggest that the APA represents a major site for interactions between the prefrontal cortex and the motor system. Our results also suggest that input from the prefrontal cortex is focused on specific portions of the premotor areas on the medial wall of the hemisphere (i.e., the SMA, CMAr and CMAc). Support: VA Med. Res. Serv.; USPHS 2957, 24328.

MESIAL AREA 6 IN MACAQUE MONKEY IS FORMED BY TWO DIFFERENT CYTOARCHITECTONIC AND PHYSIOLOGICAL AREAS. M. Matelli *, G. Luppino*, R. Camarda* and G. Rizzolatti* (SPON:European Brain and Behaviour Society) Istituto di Fisiologia Umana Universita' di Parma Via Gramsci 14 I-43100 Parma Italy.

Although there is no agreement on whether the mesial part of area 6 is a single cytoarchitectonic area, this large cortical region has been generally considered coextensive with the so called supplementary motor area (SMA). Recently we demonstrated that a sector of mesial area 6 (area F3) shows a specific pattern of

demonstrated that a sector of mesial area 6 (area F3) shows a specific pattern of cytochrome-oxidase staining different from that of the dorsal convexity immediately lateral to it (area F2). Area F3 occupies the caudal two thirds of the whole mesial area 6 (Matelli et al.,Behav. Brain Res. 18:125-137,1985).

In the present experiments we investigated the cytoarchitectonic features of mesial area 6 in celloidin embedded macaque brains. Two regions were identified: a larger region, caudally located, which basically coincided with histochemical area F3; a smaller region (which will be referred to as area F6), located in the rostral third of mesial area 6. Lateral to area F6, on the dorso-lateral convexity, a third cytoarchitectonic area was identified (area F7). In order to see whether physiological differences do exist among these areas, intracortical microstimulation (ICMS) was refrormed in three macaque monkeys. Area F3 was found to be easily excitable and differences do exist among these areas, intracortical microstinuliation (LCMs) was performed in three macaque monkeys. Area F3 was found to be easily excitable and movements were obtained in 493 out of 600 tested sites. A complete somatotopic map similar to that described by Mitz and Wise (J.Neurosci. 7:1010-1020,1987) was demonstrated. ICMS of area F6 was also effective although its excitability was lower than that of area F3 (108 out of 214 cortical sites). Slow displacements of the arm, which somehow mimicked natural movements or postural adjustements, were observed in 85% of excitable sites. No clear somatotopic organization was observed. Eye movements were elicited from area F7.

In conclusion, mesial area 6 comprises two different areas. One of these (area F3) coincides with the SMA. The other one (area F6) appears to be involved in the arm control at a rather high level. Cortico-cortical connections of this last area and its single neurons properties (Exp. Brain Res., in press) suggest this conclusion.

106.10

CHARACTERIZATION OF PARVALBUMIN NEURONS AND AXONS IN THE PRIMATE PREFRONTAL CORTEX. S.M. Williams, P.S. Goldman-Rakic, and C. Leranth . Sec. of Neuroanatomy and Dept. of Obstetrics and Gynecology, Yale

Univ. School of Med., New Haven, CT 06510.

Previous studies have demonstrated that the primate neocortex possesses a population of non-pyramidal neurons (chandelier and basket cells) that contain the calcium-binding protein, parvalbumin (PV). We have conducted light and electron microscopic analyses of PV-immunoreactive (PV-IR) neurons in the prefrontal cortex (PFC) of the macaque. With the exception of layer I, all cortical laminae contained (PPC) of the macaque. With the exception of layer I, all cortical laminae contained PV-IR somata; however, immuoreactive cells were concentrated in layers IIIB and V. Electron microscopy revealed that PV-IR axon terminals heavily innervate the soma and axon hillock of layer III/III pyramidal neurons. Interestingly, PV-IR boutons also established synaptic contact with large spines that emerged from the initial segments of these pyramidal cell axons. Furthermore, PV-IR axons formed dense basket-like networks of terminals on layer V pyramidal somata, occasionally contacting the axon billock of these neurons.

hillock of these neurons.

To further characterize the target cells of parvalbumin-containing axons, horseradish peroxidase injections were made in the dorsolateral prefrontal cortex of monkeys. The contralateral PFC was processed for both the detection of retrograde labeling and PV-IR. EM analysis demonstrated that PV-IR processes densely innervate retrogradely labeled large pyramidal neurons of the contralateral hemisphere (i.e. commissural neurons). Furthermore, myelinated PV-IR axons were often observed in both the cortical grey and white matter. This observation has led to the hypothesis that the PFC receives an extrinsic, possibly commissural, parvalbumin input. Preliminary experiments combining retrograde tracing and PV-immunohistochemistry in the rat strongly suggest that a population of commissural neurons are PV-IR. These studies are currently being conducted in primate PFC. Thus, PV-IR neurons may subserve both local circuit and projection roles in the interhemispheric transfer of cortical information. PREMOTOR AREAS: CORTICOSPINAL PROJECTIONS TO UPPER AND LOWER CERVICAL SPINAL CORD. S.Q. He. R.P. Dum and P.L. Strick. VA Med. Ctr. and Dept. of Neurosurg. & Physiol., SUNY-HSC @ Syracuse, Syracuse NY, 13210.

We have recently presented evidence that the frontal lobe of macaques contains at least 6 premotor areas which project to both the primary motor cortex and the spinal cord. In this experiment, we have examined the topographic organization of experiment, we have examined the topographic organization of the corticospinal projections from the premotor areas by injecting a fluorescent tracer (e.g. DY) into upper cervical segments (C2-4) and a second tracer (e.g. FB) into lower cervical segments (C7-T1) of the spinal cord.

Five of the six premotor areas contained neurons which project to lower cervical segments and neurons which project to upper cervical segments. Only the arcuate premotor area had a

segmental termination limited largely to upper cervical segments. Most neurons projected to either upper or lower segments; only 5% of the sample was 'double labeled.' In the premotor areas, as well as in the primary motor cortex, regions which project to upper cervical segments overlapped those which project to lower upper cervical segments overlapped those which project to lower cervical segments. However, in each cortical area, the regions with the highest density of neurons projecting to a segmental level were spatially separate. Our results suggest that the topographic organization of arm representation in 5 of the 6 premotor areas has characteristics which are similar to that in the primary motor cortex.

EMERGING PATTERNS OF CONNECTIVITY IN CAT SENSORIMOTOR CORT-EX. L.L.Porter, Dept. of Anatomy, USUHS, Bethesda, MD 20814

The manner in which information is processed in cat somatosensory cortex is reflected in the network of fiber pathways linking its functionally speciallized subregions, each of which may provide motor cortex with different sensory input. Both area 2, which may integrate input and area 3a, which receives muscle afferents project directly to motor cortex. The distribution of area 3a afferents to MI were studied following injections of PHA in area 3a and compared to that of area 2 afferents. Labeled axons branched in the superficial laminae of discrete regions of motor cortex, similarly to axons arising in area 2. Labeled fibers, evenly distibuted through the cortical laminae were noted in area 2 where their input may be integrated with others before being relayed to motor cortex. To further study the flow of information, 2 fluorescent tracers were injected in identified forelimb regions of areas 3a and 4. Clusters of retrogradely labeled neurons were located in adjacent or overlapping regions of area 2 but individual cells were not double labeled, indicating that separate groups of cells project to the target sites. Neurons projecting to area 4 are in superficial laminae; those which project to 3a often exhibit a bilaminar arrangement. Variations seen in laminar distributions of axon terminals (which are being confirmed with EM) and differences in laminar distribution of retrogradely labeled cells may indicate a directional flow of information processing in the sensorimotor cortex.

CORRELATIONS BETWEEN PHYSIOLOGY, MORPHOLOGY AND PARVALBUMIN CONTENT IN RAT NEOCORTICAL NEURONS. J.F.M van Brederode * and A.E. Hendrickson, Depts. of Biological Structure & Ophthalmology, Univ. Washington, Seattle WA 98195.
Neocortical neurons have been classified according to their firing

Neocottical neurons have been classified according to their firing patterns in response to intrasomatic depolarizing current injections into regular-spiking (RS), intrinsic bursting (IB), or fast-spiking (FS). Each correlates to distinct morphological cell types (TINS 13:99-104,1990). Some of these firing properties could be due to intracellular calciumbinding proteins such as parvalbumin (PV). This study examines the correlation between the physiology, morphology, and PV immunoreactivity in single cells of rat neocottex in in vitro brain slices. After recording the response to intracellular current injections of successfully impaled cells, biocytin was injected into the cells. Following fixation biocytin was visualized using avidin/rhodamine (RITC). The issue was then reacted immunocytochemically for PV using fluorescein (FITC)/IgG. Two-wavelength excitation appropriate for RITC and FITC was used to examine injected cells for the presence of PV. Biocytin was transformed into a permanent label for light-microscopic analysis by binding biocytin to avidin/peroxidase and reacting with diaminobenzidine. Our results indicate that most RS cells were unaminopenzione. Our results indicate that most RS cells were pyramidal cells with varying morphology and laminar localization. FS and IB cells were impaled infrequently. FS cells consisted of smooth stellate and inverted pyramidal cells. Preliminary results suggest that PV immunoreactivity is found in a physiologically and morphologically heterogeneous group of cells. This study was supported by grants EY 01208 and EY07031.

SPIKE AFTERPOTENTIALS OF HUMAN NEOCORTICAL NEURONS. Lorenzon, N.M. and Foehring, R.C., Dept of Anatomy and Neurobiology Univ. of Tenn., Memphis, TN 38163

Intracellular recordings were made from human cortical neurons in an in vitro slice preparation. Neurons were manipulated pharmacologically in order to study Ca2+-dependence of AHPs, the role of K+ currents in these

potentials, and modulation of AHPs by neurotransmitters.

Three afterhyperpolarizations (AHPs) have been studied. Following single action potentials, fast and medium duration AHPs are produced. Repetitive firing episodes result in AHPs of medium and slow durations. The slow AHP had a reversal potential similar to the predicted Nernstian rine slow AHP had a reversal potential similar to the predicted herristian value for K+ equilibrium. This AHP was Ca²⁺-dependent and showed sensitivity to norepinephrine and serotonin. The fast and medium duration AHPs reversed polarity at more depolarized membrane potentials than the K+ equilibrium potential. Both AHPs were Ca²⁺-sensitive. Studies in which extracellular Cs+ (2-3mM) was applied suggest that the medium AHP has contributions from outward K+ current(s) and an anomolous rectifier (Q) current. Some cells exhibited an afterdepolarization following a single spike which was Ca+-dependent and overlapped temporally with the medium AHP. The conductances underlying the AHPs affect several aspects of cell excitability; for example, spike repolarization and duration, and spike frequency adaptation and habituation. The effects of several substances on these AHPs have been studied: extracellular Cd^{2+} , Co^+ , Cs^+ , K^+ , NE, and

HORIZONTAL LAYER I INPUTS TO PRIMARY SOMATOSENSORY (BARREL-FIELD) NEOCORTEX OF RAT. L.J. Cauller and B.W. Connors, Section of Neurobiology, Div. of Biology & Medicine, Brown University, Providence, RI 02912.

SII and MI cortex were injected with rhodamine-dextran (10k MW), and anterogradely labeled axons were followed into SI (identified with cytochrome oxidase staining). Within SI, axons ascended directly to layer I, where they often extended >1 mm horizontally and gave off numerous terminal branches. These projections resemble the backward system in the visual cortex of cats and monkeys (Rockland & Virga, JCN 1989). Layer I pathways were isolated in coronal slices in vitro with a vertical cut that preserved only layer I. Layer I was then stimulated >0.3 mm lateral to the cut while recording medially. Current-source density analysis revealed current sinks restricted to layer I, with smaller current sources distributed in layers II and III. While the layer I-evoked sinks lasted no more than 20 ms, intracellular recordings from layer Vb pyramidal cells showed long-lasting EPSPs (50-200 ms) without any obvious IPSPs. Layer I-evoked fields and EPSPs were blocked by CNQX (5 μM). Only the long-latency (>50 ms), possibly polysynaptic, EPSPs were blocked by APV (50 μM). We conclude that primary sensory cortex may be strongly activated by backward glutaminergic projections to layer I, and that synapses on the most distal apical dendrites can strongly excite neurons as deep as layer Vb. strongly excite neurons as deep as layer Vb.

INTRACORTICAL LOCATION SYNAPTICALLY INTERACTING CELLS IN PRIMATE PRECENTRAL MOTOR AREAS M. Matsumura*, D.-F. Chen & E.E. Fetz. Regional Primate Research Center and Dept. of Physiology & Biophysics, University of Washington, Seattle, WA 98195.

Synaptic interactions between pairs of neurons in precentral gyrus were documented by spike-triggered averages (STAs) of membrane potentials in 3 monkeys. Extracellular trigger spikes were recorded from "EC" cells with carbon-fiber electrodes, while intracellular recordings were obtained from neighboring "IC" cells with K-methylsulfate electrodes. EC trigger spikes could be evoked in anesthetized monkeys by iontophoretic injection of glutamate and were also obtained in awake monkeys during performance of a step-tracking task. STAs revealed serial EPSPs, IPSPs, common synaptic input or their combination. Successive extracellular recordings demonstrated convergent input from multiple EC cells to the same IC cell. Successive intracellular penetrations showed the divergent connections of single EC cells to multiple neighboring IC cells; for example, one inhibitory neuron produced IPSPs in 7 of 10 IC cells. To date, the relative locations of 94 cell pairs recorded under these conditions were determined by reposition of microelectrodes and their cortical tracks confirmed by histological reconstruction. Common synaptic input was found in 68 pairs; a given EC cell could share common input with IC cells up to 2.4 mm away, and located in all cortical layers. In 19 cases EC cells produced serial EPSPs in IC cells located in more superficial layers (II & III) and/or in deeper layers (V & VI), and up to 2.2 mm away. Similarly, in 17 cases EC cells produced serial IPSPs in IC cells located in more superficial and/or deeper layers, and up to 1.4 mm away. These results elucidate the synaptic interactions between cells in a column and confirm the existence of excitatory and inhibitory connections from deeper to upper layers as well as the reverse.

IONIC BASIS FOR BURST-FIRING BEHAVIOR IN HUMAN NEOCORTEX USING IN-VITRO SLICE PREPARATION: POSSIBLE ROLE OF M AND Q CURRENTS. R.S. Waters, and R.C. Foehring. Dept. of Anatomy and Neurobiology, Univ. of Tennessee, Memphis, Col. of Medicine, Memphis, TN 38163.

Two types of firing behavior have been described in human neocortical cells

in-vitro. Regular spiking neurons respond to a suprathreshold injection of current with repetitive firing throughout the stimulus, while burst-firing neurons respond with an initial short burst of 2-5 spikes that ride upon a slow wave of depolarization. The burst response is voltage-dependent, occurring only from membrane potentials negative to -60mV. Burst-firing neurons also exhibit afterdepolarizations (ADP) and voltage- and time-dependent post-stimulus rebound. Application of TTX in the bath voltage- and unre-dependent post-stimulus rebound. Application of 11X in the bath eliminates action potentials leaving only the slow wave of depolarization. This wave has been shown to be Ca-dependent in a number of species since blockage occurs with inorganic Ca channel blockers. These Ca channel blockers do not appear to totally block the slow wave in human neocortical cells, suggesting that other ionic currents may also contribute.

To test this hypothesis, human neocortical tissue that had been removed during epilepsy surgery was placed in a chamber containing artificial CSF bubbled with carbogen at 36°C. Pharmacological agents were gravity fed into the bath or pressure injected in the vicinity of the recording electrode. Using these techniques the following results were obtained: 1. Co²⁺ blocked the ADP.

- 2. In the presence of TTX, inorganic Ca-blockers greatly reduced the slow depolarizing wave underlying the burst and rebound following hyperpolarizing stimuli.
- 3. The remaining wave form could be reduce or eliminated by 2mM extracellular
- The possible involvement of M current was also examined. (Supported by grants

 The possible involvement of M current was also examined.) from NSF, BNS 88-02766; NINDS, NS287180; The Epilepsy Foundation.)

MORPHOLOGY OF PHYSIOLOGICALLY IDENTIFIED HUMAN CORTICAL NEURONS. P. Herron, R. C. Foehring, and C. J. Wilson. Dept. of Anatomy and Neurobiology, The University of Tennessee, Memphis, Memphis, TN 38163

A primary aim of this study was to determine if physiological classes can be related to particular morphological classes of neurons in the human neocortex. These experiments were conducted on slices of cortical tissue removed from occipital, frontal, and temporal lobes during the course of surgeries for the relief of epilepsy. Data from 27 neurons were used in this study. Glass microelectrodes containing 1M acetate and 2% biocytin were used for the intracellular recording and labeling of neurons. Three-dimensional reconstruction and morphometric analyses of filled neurons were accomplished using an Eutectic Electronics Neuron-Tracing System.

Three physiological classes were identified: burst-firing neurons, regularspiking neurons, and fast-spiking neurons. Fourteen of the 27 neurons were characterized as regular-spiking neurons. Regular-spiking neurons were almost exclusively pyramidal neurons (12 of 14, 86%) with 72% (10 of 14) of these located in layer V. The two remaining regular-spiking neurons were large pyramidal-like spiny stellate neurons located in layers Ill and IV. Burst-firing neurons were equally divided between pyramidal and nonpyramidal classes. Three of the nonpyramidal neurons were identified as spiny stellate neurons in layers III through V. Only two of the

27 neurons were fast-spiking neurons. One was a nonpyramidal neuron.
These results suggest that the neuronal substrates for different types of physiological behaviors are differentially distributed amongst the morphological classes of neurons in the human neocortex. Supported by NINCDS #NS27180 and The Epilepsy Foundation (to RCF).

CORTEX II

TRANSCALLOSAL EFFECTS ON MOTOR CORTICAL EXCITABILITY IN MAN. A. Ferbert, A. Priori, J.C. Rothwell, J.G. Colebatch, B.L. Day and C.D. Marsden. MRC Human Movement & Balance Unit, Institute of Neurology, Queen Square, London WC1N 3BG, U.K.

Electric or magnetic transcranial stimulation over the motor cortex can produce evoked potentials over the contralateral hemisphere. Here we show that this is accompanied by a pronounced inhibition of the excitability of the contralateral cortex. The experiments used two Novametrix Magstim 200 stimulators. One of the stimulators was connected to a figure-of-eight shaped coil (loop diameter 7cm) placed with its mid-region over the motor cortical hand area of one hemisphere. This provided the conditioning stimulus. At intervals from 1-160ms later, a test stimulus was given to the opposite hemisphere using a 9cm diameter round coil, or another figure-of-eight coil. Surface EMG responses were recorded from the slightly pre-activated first dorsal interosseous muscles of each hand. The main effect of the conditioning stimulus was to inhibit the test response. The inhibition began at intervals of 6ms, peaked at 10-15ms, and recovered slowly up to 50-100ms. In some subjects, the inhibition was preceded by a short period of facilitation at conditioning-test intervals of 4ms. The average depth of the maximum inhibition was of the order of 50%. In contrast to the pronounced effect on the size of magnetically-evoked EMG responses, the same conditioning shock in three subjects had little or no effect on responses evoked by electrical stimulation of the motor cortex. Assuming that the electrical and magnetic test stimuli activate the same motor output pathways from the cortex, then this differential effect of the conditioning shock indicates that inhibition was occurring at a cortical level. In view of its onset latency, we suggest that this inhibition was mediated via a trans-callosal pathway.

PHYSIOLOGICAL ANALYSIS OF REORGANIZATION FOLLOWING LOWER PHYSIOLOGICAL ANALYSIS OF REORGANIZATION FOLLOWING LOWER LIMB AMPUTATION IN HUMANS. P. Fuhr*, L.G. Cohen, T.W. Findley*, J. Macedo* and M. Hallett. Human Cortical Physiology Unit, Human Motor Control Section, Medical Neurology Branch, National Institute of Neurological Disorders and Stroke, National Institutes of Health, Bethesda, MD 20892, and Kessler Institute for Rehabilitation, West Orange, NJ 07052

We studied the locus of motor reorganization after amputation in 5 subjects who had loss of a lower limb. A Cadwell MES-10 stimulator was used to deliver a magnetic stimulus through a round coil centered on the sagittal line 4 cm anterior to Cz and through an 8-shaped coil positioned over locations 1 cm apart along the coronal axis. Surface EMG was recorded bilaterally from quadriceps femoris. Excitability of the spinal alpha-motoneuron pool to I a afferents was evaluated by comparing the maximal H reflex with the maximal M wave (H:M ratio).

Motor reorganization after lower limb amputation was similar to that previously observed after upper limb amputation (Cohen, L.G. and Hallett, M. Soc. Neurosci. Abstr., 15:1239, 1989). In all 5 subjects, stimuli of equal intensity in both hemispheres recruited a larger percentage of the alphamotoneuron pool in muscles ipsilateral to the stump than in contralateral muscles (46.8% vs 7.7%, $p \le 0.05$) and mean onset latencies were 2 ms shorter (p \leq 0.01). Muscles ipsilateral to the stump were activated from a larger number of scalp positions than contralateral muscles ($p \le 0.05$). There was no difference in the H:M ratio between the legs (8.0% ipsilateral vs 11.0% contralateral). The apparent absence of a change in the excitability of the alpha-motoneuron pool after amputation suggests that reorganization occurs at a suprasegmental level.

EFFECTS OF TRANSCRANIAL MAGNETIC STIMULATION ON IPSILATERAL MUSCLES IN HUMANS, E. M. Wassermann, P. Fuhr*, . G. Cohen and M. Hallett. Human Cortical Physiology Unit, Human Motor Control Section, National Institute of Neurological Disorders and Stroke, NIH, Bethesda, MD 20892.

We studied the effects of focal transcranial magnetic stimulation on ipsilateral muscles in 6 normal volunteers. An "6"-shaped coil was used to deliver stimuli to different scalp positions over one hemisphere. EMG recordings were made from muscles of both upper extremities, at rest and at several degrees of voluntary ipsilateral muscle activation.

No ipsilateral responses were observed with the arm at rest. During muscle activation, stimuli evoked a transient attenuation of ongoing voluntary EMG activity (ipsilateral silent period, ISP). ISPs were highly reproducible and could be evoked in scalp locations which activated corresponding contralateral muscles. The ISP in abductor pollicis brevis had an onset latency of 35±4msec (12 msec longer than the onset of the contralateral excitatory response), and a duration of 46±15msec. At 50% muscle activation, the peak attenuation was 71±18%. In wrist flexors, biceps and deltoid ISPs tended to be less prominent. On some occasions excitatory responses preceded the ISPs.

This study demonstrates the existence of a powerful inhibitory

influence of sensorimotor cortex on ipsilateral upper extremity muscles and on distal muscles in particular.

107.4

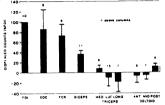

ARELONG LATENCY CUTANEOUS REFLEXES TRANSCORTICAL IN MAN? P. Ashby. E. Palmer. Playfair Neuroscience Unit, Toronto, Canada We tested the hypothesis that the late reflex activity occurring in small hand muscles following stimulation of cutaneous afferents is a long loop reflex involving the cortex.

Cutaneous afferents of the index finger were stimulated electrically at 1.5-2 x perception threshold. Cortical neurons were excited using magnetic stimulation. Single motor units were recorded with a needle electrode in the first dorsal interosseous. Three simultaneous post-stimulus time histograms were generated following submaximal stimuli to cutaneous afferents, the cortex, and to both sites at a suitably timed interval. We assumed that the short latency facilitation produced by magnetic stimulation is due to monosynaptic activation of spinal motoneurons. Convergence on a common pool of upstream neurons would be suspected if the facilitation produced by both stimuli was different from the sum of the facilitation produced by both stimuli awas different from the sum of the facilitation sproduced by a burst of cutaneous stimulai at 50 Hz beginning 500 msec prior to magnetic stimulation. Thus although both stimuli results in less facilitation. There are a number of possible explanations for this. 1. Failure to superimpose the facilitation between the two fiber systems activated.

These data do not support the hypothesis that the late reflex activity from cutaneous stimuli is a transcortical reflex.

CORTICOSPINAL PROJECTIONS TO UPPER LIMB MOTONEURONS IN MAN E.Palmer , P. Ashby, Playfair Neuroscience Unit, Toronto. Canada

Magnetic stimulation of the motor cortex was used to excite corticospinal pathways in normal human subjects. The characteristics of the shortest latency post synaptic potentials (PSPs) generated in individual motoneurons were derived from PSTHs of single motor units. The number of displaced counts in a period of increased or decreased firing probability was used to estimate the amplitude of the underlying composite EPSPs or IPSPs. The amplitudes of PSPs produced in various motoneurons were expressed as a percentage of the amplitude of the EPSP generated in the first dorsal interosseous muscle (FDI) of that subject, under the same conditions. The means of these generated in the tirst dorsal interosseous muscle (PDI) of that subject, under the same conditions. The means of these percentages were used to determine the overall strength of the short latency corticospinal projections to upper limb motoneurons (shown with 1 SE in fig.). We conclude that the short latency corticospinal pathways have a recognizable projection pattern in man, which closely resembles that of other primates.

107.7

THE EFFECT OF IMAGINARY MAXIMAL MUSCLE CONTRACTION TRAINING ON THE VOLUNTARY NEURAL DRIVE TO MUSCLE. G. Yue, Dept. of Exercise Science, University of Iowa, Iowa City, IA 52242

Studies have demonstrated that initial strength gains in a strength training program are primarily due to the changes in the nervous system because muscle hypertrophy cannot take place as rapidly. This finding suggests that neural factors alone may be able to produce strength increases providing that the central neural states can be altered. Other studies have shown that the neural output from the cortex to spinal motor neurons may be altered by mental practicing of skilled movements. This evidence indicates that similar neural changes obtained through strength training may be yielded during mental training. Given that neural changes alone are able to produce voluntary strength gains and such neural changes may be achieved in mental training, it is reasonable to hypothesize that imaginary maximal muscle contraction (IMMC) training can increase voluntary neural drive to the trained muscle and produce strength increases. Subjects were asked to imagine 15 maximal contractions of the left abductor digiti minimi (ADM) in each training session for a total of 20 sessions. EMG recordings during training indicated that the trained muscle was inactive. After training there were increases in maximal strength and integrated EMG of the ADM muscles of both hands. Such increases were not found in the control group and control muscles of the subjects who were trained by the IMMC method. These results suggest that training which utilizes imaginary muscle contractions may yield neural events that are similar to those which yield increased strength in strength training before muscle hypertrophy occurs. Moreover, cross-training effect may also result from these neural events.

107.9

MOVEMENTS IN HUMANS. J. Artieda*, S.M. Papa*, J. A. Obeso*. Dpt. of Neurology, University of Navarra, Pamplona-Spain.

We recorded in 10 normal subjects (mean age 27±4) the readiness potential (RP) preceding self-paced and externally induced sequential hand movements. Using the first EMG discharge (wrist extension) to trigger averaging showed a typical RP starting 1 second before self-induced movements but absent RP for externally referenced movements. Using the second EMG burst (wrist supination) for triggering revealed a motor potential timelocked to the externally referenced movement and preceding it by some 200 ms. Brain mapping analysis showed its origin restricted to motor areas. These results indicate that for sequential motor acts the first movement may act as a "go" signal for the second one and that the earlier component of the RP can be dissociated from the actual motor potential.

CORTICAL ACTIVITY PRECEDING SEQUENTIAL HAND

DYNAMICS OF SOMATOSENSORY-MOTOR INTEGRATION IN HUMAN NEOCORTEX. Steven Bressler, Brian Cutillo* and Alan Gevins. EEG Systems Lab., San Francisco, CA 94117. Neurosurgery patients at the UCSF Epilepsy Center, with 64-contact electrode grids implanted subdurally to localize seizure foci, performed several hundred trials of a somatosensory discrimination task. Trials began with a fixation point on a CRT screen. After 1 sec, constant voltage pulses of 3 different durations were presented to the little finger of 1 hand. Subjects responded to the low and medium duration stimuli with index finger flexions

pulses of 3 different durations were presented to the little finger of 1 hand. Subjects responded to the low and medium duration stimuli with index finger flexions of the same hand to produce required pressures of 0.2 and 0.8 kg. They were required not to respond to the high duration stimulus. Visual feedback of the exerted response pressure was presented 0.5 sec after completion of the response in response trials. Somatosensory Evoked Potentials (SEPs) were averaged for each stimulus type and low-pass filtered at 7 Hz. Event-Related Covariance (ERC) functions were computed between all electrode pairs in 187-msc overlapping intervals covering the SEP for 1 sec poststimulus. The maximum ERC value and the time delay to maximum were derived for each electrode pair. Results from 1 patient are reported. In the first poststimulus interval, the pattern of covariance following all 3 stimulus types was focused on 2 somatosensory sites believed to represent the little finger. The early cortical SEP peaks (N22-P37-P54) were only found at those sites, and P90 was maximal there. The ERC patterns for the 3 stimulus types then diverged. For the 2 conditions requiring a pressure, the patterns went through a similar progression in which ERCs were first established between the little finger area and a group of temporal sites, then between these temporal sites and a motor site, possibly representing the index finger. This sequence was delayed preceding the hard pressure, which also was delayed in reaction time. Possible signs of signalling from the motor to sensory representation of the index finger were also evident. In the no-response condition, the sequence did not progress beyond the temporal sites show the sequencing of sensory-motor integration in the human neocortex with unprecedented spatiotemporal precision, and demonstrate that the ERC method can measure signs of cortical functional relation.

107.8

MOTOR AND FRONTAL CORTEX INVOLVEMENT IN PLANNING AND EXECUTION OF MOVEMENT DIRECTION IN HUMANS. K, L. Kerman*, J.

EXECUTION OF MOVEMENT DIRECTION IN HUMANS. K.L. Kerman*. J. Martin*. J. N. Sanes. J. P. Donoghue. Department of Clinical Neuroscience and Center for Neural Science, Brown University, Providence, RI 02912.

Recent studies suggest that the primary motor (MI) and frontal cortex are important in coding movement direction. To explore this issue further, we examined whether MI and frontal cortex have separate roles in planning and executing two-dimensional arm movements by studying humans with distinctive pathology of the two regions.

Arm kinematics were measured in 7 normal subjects and in 6 patients each with pathology, localized on CT scan, in frontal cortical areas. Subjects moved a hand-held stylus across a horizontally oriented digitizing tablet as quickly and as accurately as possible through a three point course displayed on a video monitor. The start and end points had the same X but different Y coordinates. The pattern had a direction reversal point with displaced X and mid Y coordinates relative to the start and end points. The target position was always visually available on the video monitor, and the hand was visible. The movements primarily required elbow and shoulder joint rotations.

Normal subjects moved through the path with a near ideal parabolic trajectory performing a continuous, smoothly executed movement having two velocity peaks and a non-zero-trough at direction reversal. Their trajectories closely fit a minimum jerk profile. With MI lesion, contralateral arm movements had frequent small changes in

a non-zero-trough at direction reversal. Their trajectories closely fit a minimum jerk profile. With MI lesion, contralateral arm movements had frequent small changes in direction, concomitant multiple peaked velocity profiles, and longer movement times. The frequent direction shifts helped to maintain an overall, but jerky, parabolic trajectory. By contrast, with lesions rostral to MI, movements were decomposed into 3 straight segments, one being parallel to the start and end points, and each with sharp direction changes. Segments executed by these patients had smooth velocity profiles. With both lesions, the ipsilateral hand followed a normal path. These results suggest that MI and frontal cortex have different roles in coding movement direction. Since MI lesion disrupted movement smoothness, but not the overall movement path, these data suggest that MI controls movement execution, but not movement planning. In contrast, cortical areas anterior to MI seem necessary for organizing optimal movement strategy, while contributing little to execution.

107.10

EFFECTS OF POSTERIOR ASSOCIATION CORTEX ESIONS ON BRAIN POTENTIALS PRECEDING SELF-INITIATED MOVEMENTS

Jaswinder Singh and Robert T. Knight Dept. of Neurology, University of California, Davis. VAMC: Martinez CA.

Movement Related Potentials (MRPs) were recorded in patients with unilateral lesions centered in temporal-parietal junction (T-PCx, n = 5; male; mean age = 59. 1, SD = 4.6; damaged areas 22, caudal 39 and 40; lesion volume 38.5cc), lateral parietal (ParCx, n = 5; male; mean age = 52. 1, SD = 15. 7; damaged areas 5, 7, rostral 39 and 40; lesion volume = 35.3cc), posterior association cortex (T-PCx and ParCx; n = 5; 4 male; mean age = 65. 2, SD = 6.9; damaged areas 22, 39, 40, 41 and 42; lesion volume 88.1cc) and normal controls (n = 10; 7 male; mean age = 56. 4, SD = 7. 4). Subjects performed a self-paced button press task. Data epochs beginning 1400 msec prior to and 600 msec after each motor response were extracted from scalp sites over precentral, central and parietal regions. Controls and patients with temporal lesions generated comparable Readiness potentials (RPs, onset 1000 msec), Negative shifts (NS's, 500 msec) and Motor potentials (MPs, onset 100 msec). In contrast, unilateral lesions involving the lateral parietal cortex markedly reduced MRPs. The findings indicate that parietal association cortex contributes to MRP generation.

DIRECT CORTICAL RECORDINGS FROM HUMAN MOTOR CORTICES: EVIDENCE FOR DIRECTIONAL TUNING IN TWO DIMENSIONAL MOVEMENTS. C. Toro*, C. Cox*, RE. Maxwell*, JR. Gates*, TJ. Ebner. Depts of Neurology, Neurosurgery and Physiology Univ of Minnesota, Minneapolis, Mn 55455.

Chronic unit data suggests that movement direction is represented in premotor, motor and parietal cortices of monkeys. Attempting to extend these findings to humans we analyzed the electroencephalographic activity from 32 subdural electrodes in eight epileptic patients during two dimensional arm movements. The task consisted in displacing a hand controlled cursor from a start position in the middle of a video screen to one of 18 possible targets in six different directions and three different distances. Changes in signal power in the 8-12 Hz band related to the task were calculated for each electrode computing a Fast Fourier Transformation (FFT) on a 1.0 sec moving window shifting over the raw data at increments of 250 msec. The probabilities for power change between the baseline period (start position) and different time cross-sections during the task were determined. Groups of electrodes displayed probabilities for power change broadly "tuned" to movement direction. A pattern of greater power decline when moving into contralateral space (to the hand performing the task) was present in all patients. These findings suggest that kinematic variables are represented in the human motor cortex. Supported by UMHC and MINCEP.

COMPARATIVE NEUROANATOMY: REPTILES, BIRDS, MAMMALS

CALCIUM BINDING PROTEIN IMMUNOREACTIVITY IN REPTILIAN DORSAL THALAMUS. M.B. Pritz and M.E. Stritzel*. Div. of Neurol. Surg., Univ. Calif. Irvine Med. Ctr., Orange, CA 92668

Neurons in mammalian thalamus can be characterized by their immunoreactivity for certain calcium binding proteins. We investigated the analagous situation in reptiles, Caimma crocodilus, using antibodies to a variety of calcium related proteins. These included: calbindin, parvalbumin, calmodulin, calcitonin gene-related peptide (CGRP), troponin-T, and caldesmon. Experiments employed both monoclonal (calbindin, parvalbumin, troponin-T, caldesmon) and polyclonal (calbindin, parvalbumin, calmodulin, and CGRP) antibodies. In some cases, colchicine pretreatment was used. Free floating 30µm sections were cut on a sliding microtome and processed utilizing the avidin-biotin complex technique. Preliminary data is the following. Neurons in nucleus rotundus, nucleus diagonalis, and the medialis complex were found to be immunoreactive for parvalbumin, calbindin, and CGRP. By comparison, parvalbumin immunoreactivity in these areas was less intense than either calbindin or CGRP. Cells in nucleus reuniens were immunoreactive for calbindin and CGRP. Neurons in nucleus dorsolateralis anterior expressed immunoreactivity for calbindin. Although immunoreactivity to calmodulin, troponin, and caldesmon was found elsewhere in the brain, neurons immunoreactive for any of these three antibodies have yet to be found in any dorsal thalamic nucleus. Further experiments to complete this analysis are presently underway.

108.3

COMPARATIVE DISTRIBUTION OF MELATONIN RECEPTORS IN THE AVIAN BRAIN. Teresa A. Kelm* and Vincent M. Cassone. Department of Biology, Texas A&M University, College Station, TX 77843.

The role of the pineal gland and its hormone melatonin in the regulation of circadian rhythmicity and photoperiodism appears to vary among avian species. To determine if there is an anatomical correlate of this diversity, we have employed in vitro binding of 2[12] Tijodomelatonin (IMEL) and autoradiography to ascertain an analogous diversity in the distribution of putative brain receptors for melatonin. Brains from Psitticaformes, Columbiformes, Galliformes, and Passeriformes were sectioned on a cryostat at 20 µm, thaw-mounted on gelatin-coated slides and dried. Sections were incubated in either 50 pM IMEL or 50 pM IMEL plus 1µm melatonin. Sections were exposed to X-ray film for 7 days. Film was developed, fixed and dried. Sections were stained with cresyl violet. The identity of structure specifically binding IMEL was determined by computer-aided image analysis. IMEL binding is present in the retinorecipient aspects of the visual system in all species. Secondly, thalamic relay nuclei of the visual system, n. rotundus, and tectofugal integrative areas, ectostriatum, bind IMEL to varying degrees. The brain of the budgerigar bound little else than the above structures and the negostriatum in addition, Columbiform species indicated a great deal of binding in the telencephalic neostriatum, n. Edinger-Westphal (EW) and n. isthmoopticus (IO). However, there was relatively little binding in the ventrolateral geniculate (GLv) complex. In the chicken, binding was similar to the doves and pigeons, although there was binding in GLv and no binding in IO. In passerine species, all structures, with the exception of EW, described above bound IMEL. In composite, the data indicate a wide array of sensory and integrative function under melatonin influence. Further work is directed at studying a wider taxonomic transect and at unveiling general anatomical principles of IMEL binding. Supported by NSF Grant 88-96225

108.2

AXONAL ARBORIZATIONS OF PYRAMIDAL AND NON-PYRAMIDAL NEURONS IN THE CEREBRAL CORTEX OF THE TURTLE. P. H. Desan and A. R. Kriegstein. Dept. of Neurology, Stanford University, Palo Alto, CA 04035

CA, 94305. We examined the axonal morphology of neurons in the medial areas DM and M of the cerebral cortex of the pond turtle (Pseudemys scripta elegans). Neurons were filled with the tracer biocytin using whole-cell patch-clamp recording, a technique enabling the visualization of axonal arborizations. The axons of pyramidal cells gave rise to a relatively dense arborization within a tangential radius of 500-800 um about the soma. The peak density of axonal varicosities, presumably synapses, per square 100 um of tangential cortical area was as high as 20-40/100 um². Long, seldom branching collaterals with infrequent varicosities extended great distances in all directions from the soma. Some were traced as far as 2300 um. Within this area the density of varicosities was remarkably constant in the range of 4-8 varicosities/100 um². In addition all pyramidal cells possessed one or more axon collaterals entering the fornix. By contrast, the axons of non-pyramidal cells arborized densely within a radius of 600-800 um about the soma. The density of varicosities reached a maximum of 150-170/100 um² close to the cell body and declined smoothly with distance from the soma. These results suggest that intracortical excitation extends over a large area, while intracortical inhibition is limited to a smaller area but may be more powerful.

108.4

ORIGIN OF PROJECTIONS UPON THE PALEOSTRIATAL COMPLEX IN THE MALLARD, ANAS PLATTRHYNCHOS L. J.L. Dubbeldam* (Spon: European Brain and Behaviour Society). Dept. of Organ. Zoology, Leiden Univ., 2300 RA Leiden, The Netherlands. In a study on the afferent and efferent connections

of n.basalis (Bas) (Dubbeldam, J.L. & Visser, A.M., Neurosci. 21: 487, 1987) also projections from the overlying layers upon the frontal part of the paleostriatal complex (PC) were observed. We analysed the sources of these projections using the combination of HRP-WGA for retrograde tracing and Phaseolus-agglutinin for anterograde tracing. Injections were made in hyperstriatum ventrale (HV), the dorsal and ventral zones of the frontal neostriatum (NF,d and NF,v), n.basalis (Bas), the paleostriatum augmentatum and primitivum (PA and PP) and the n.intrapeduncularis (INP). The anterograde experiments suggest that only Nf,d and Nf,v project upon PA and INP, but not upon PP. Bas projects upon Nf and HV, but not upon parts of PC. PA is a thin lamellar area and it was not possible to place injections exclusively in this area. Injections in either INP or the combination of INP/PP/PA always labeled cells in Nf,d. Injections including Bas, PA and PP labeled a few cells in Nf,v. Only an HRP/WGA injection in the deepest part of INP labeled some cells in HV and the dorsal hyperstriatum.

In conclusion, an intermediate zone of Nf,d is the main source of projections upon the frontal part of the paleostriatal complex in the mallard.

TELENCEPHALIC AND THALAMIC INPUTS TO THE STRIATAL PORTION OF THE PIGEON BASAL GANGLIA. C.L. Veenman and A. Reiner. Dept. of Anatomy & Neurobiology, Univ. of Tennessee, Memphis, TN 38163.

The little available data on the sources of telencephalic and diencephalic input to the avian striatum are largely based on the use of HRP as a retrograde marker. We have used injections of the highly sensitive retrograde markers fluorogold, fast blue, and rodomine latex beads into the striatum to examine the sources of corticostriatal and thalamostriatal projections in pigeons.

Our results indicate that the connectivity of the striatum in pigeon is similar to that of mammals. In pigeons, the equivalents of the isocortex, namely the Wulst and the dorsal ventricular ridge (DVR) project topographically to the striatum. The rostral Wulst and DVR preferentially project to medial striatum. Lateral parts of the DVR, including the temporo-parieto-occipital area (TPO) and the dorsolateral corticoid area (CDL), project preferentially to the lateral striatum. The caudolateral DVR (caudolateral neostriatum) projects to the entire striatum. The archistriatum also projects heavily to the striatum, with the rostral part of the archistriatum projecting to all of the striatum, the rim of the archistriatum preferentially to the lateral striatum, and the core of the archistriatum to the medial striatum. Within the thalamus, the dorsomedial and dorsolateral thalamic nuclei (which may be comparable to the mammalian intralaminar nuclei) were found to project heavily to the medial striatum, but sparsely to the lateral striatum. Our results indicate that forebrain projections to the avian striatum are more extensive than hitherto shown. Supported by NS-19620 (A.R.)

108.7

INTRATELENCEPHALIC PROJECTIONS OF THE VISUAL WULST IN BIRDS Columba livia): A phaseolus vulgaris leucoagglutinin study. T. Shimizu, H. J. Karten and K. Cox*, Department of Neurosciences, University of California, San Diego, La Jolla, CA 92093.

The visual wulst of birds is a laminated dorsomedial telencephalic elevation with many similarities to the mammalian visual cortex. The major laminar components of the visual wulst, from dorsal surface inward, include HA, IHA, HIS, and HDI. An anterograde tracer, PHA-L, was used to study the intratelencephalic connections of these laminar components. The following major projection areas were found. The IHA (the major target area of the visual thalamic input) and HIS project to HA. Efferents of HA were observed in the lateral portion of LPO and a restricted region in PA (the avian equivalents of basal ganglia), as well as the visual nuclei in the brainstem via the tractus septo-mesencephalicus. At least some regions of HA, HIS, and possibly HDI were found to project to several areas of the neostriatum, including the neostriatum frontale pars laterale, the periectostriatum, and the lateral edge of the neostriatum caudale (NC). The HDm projects to the medial LPO, area parahippocampalis, and area corticoidea dorsolateralis. When PHA-L was injected into HVdv, immediately ventral to the wulst, labelled fibers and terminals were found in NC and some portions of archistriatum, but not in the wulst. These results indicate that the visual wulst projects upon multiple targets within the telencephalon. These include projections upon the more massive tectofugal pathways, indicating the possibility of interaction of channels of parallel visual information processing within the telencephalon of non-mammals. (Supported by ONR N00014-88-K-0504 and NINCDS PHS NS24560-03).

108.9

"NEUROLIPOMASTOCYTE" OF THE RAT BRAIN: A MISNOMER. R.V.W. Dimlich. Departments of Emergency Medicine and Anatomy/Cell Biology, University of Cincinnati, Cincinnati, OH 45267. Certain cells associated with the vasculature of the brain were named "neurolipomastocytes" (Ibrahim, M.Z.M., et al., Acta Anat., 104:134, 1979). Although there is evidence to the contrary (Kiernan, J.A., J. Anat., 121:303, 1976; Edvinsson, L., et al., Neurology, 27:878, 1977), these cells are still considered by some investigators to be a special type of mast cell (Dimitriadou V., et al., Neuroscience, 22:621, 1987; Theoharides, Life Sci., 46:607, 1990). The similar vascular association of "neurolipomastocyte" and typical connective tissue mast cells in the brain as well as species variability may account, at least in part, for these opposing views. In this study, immunoreactivity, fluorescence, and routine histochemistry were used to verify that "neurolipomastocytes" in the rat brain do not contain heparin (Kiernan, Ibid.) or histamine (Edvinsson, Ibid.). In addition, this study demonstrated that these cells also do not contain 5-HT. Therefore, these cells have been misidentified as a type of mast cell and for that reason, "neurolipomastocyte" is an inappropriate name for these cells. Supported in part by NIH Grant NS-25635.

108.6

AUDITORY PROJECTIONS TO THE ANTERIOR TELENCEPHALON IN THE BUDGERIGAR. S.E. Brauth, W.S. Hall*and P. Cohen; Dept. Psychology, Univ. of Maryland, College Park, MD. 20742

The connections of a higher order auditory area in the neostriatum intermedium pars ventrolateralis (NIVL) of the neostriatum intermedium pars ventrolateralis (NVC) of the budgerigar (Melopsittacus undulatus) were mapped with pathway tracing techniques. Previous research (Brauth and McHale, 1988) has shown that NIVL receives projections from Field "L" as well as adjacent portions of the dorsolateral neostriatum intermedium and may be comparable to the "shelf" nucleus around HVc as described in songbirds.
The results show that NIVL neurons project to the

rostromedial archistriatum (RAm) in agreement with prior work and also show that NIVL neurons project to the medial frontal neostriatum and hyperstriatum ventrale. Injections of HRP into this part of the telencephalon labeled many neurons in NIVL, the dorsal and ventral archistriatum, RAm, the core nucleus of the ectostriatum and within a medial crescent shaped area in the nucleus dorsomedialis thalami. HRP injections centered more laterally, within nucleus basalis, labeled neurons within a different auditory nucleus, the ventrolateral nucleus of the lateral lemniscus. This latter pathway may be comparable to that reported in pigeons from the intermediate nucleus of the lateral lemniscus (Arends and Ziegler, 1986). Taken together, these results support the notion that many pathways exist in the budgerigar telencephalon for correlation of auditory and non-auditory information.

The Distribution of Cholinergic Neurons in the Central Nervous System of the North American Opossum, Didelphis Virginia. Lili Huang, R.H. Ho and G.F. Martin. Department of Anatomy and Neuroscience Program, The Ohio State University, Columbus, OH 43210.

The distribution of cholinergic neurons in the central nervous system of the opossum was studied by PAP immunohistochemistry for choline acetyltransferase (ChAT) and acetylcholinesterase (AchE) histochemistry ChAT-immunoreactive neurons were detected in four major cell groups: (1) striatum, where they were scattered within the caudate, the putamen, the nucleus accumbens, and olfactory tubercle, (2) the magnocellular basal nuclei, which included the medial septal nucleus, the nucleus of diagonal band, the magnocellular preoptic nucleus, the substantia innominata, and the globus pallidus, (3) the pontomecencephalic tegmentum, which included the pedurculopontine tegmental nucleus, the parabrachial complex and the presumptive laterodorsal tegmental nucleus, and (4) all cranial and spinal nerve motor nuclei. In addition, ChAT-immunoreact cells were seen in the supraoptic nucleus, the medial habenula, the parabigeminal nucleus, the locus ceruleus, the ventral nucleus of lateral lemniscus, the reticular formation, the substantia nigra, the red nucleus and the superior olivary complex, the last three of which were weakly stained. All of the nuclei which contained ChAT-immunoreactive cells also contained AchE-positive cells. However, in the hypothalamus and the thalamus there were many AchE-positive neurons, but none that immunostained for ChAT. AchE-positive cells were also found in the raphe nucleus, the ventral part of gigantocellular reticular nucleus and the mesencephalic nucleus of the trigeminal nerve, where ChAT-immunoreactive cells were rare. Our results suggest that the distribution of cholinergic neurons in this marsupial is similar to that in placental mammals. (Supported by NS-25095).

THREE DIMENSIONAL DIGITAL BRAIN ATLAS FOR MACACA NEMESTRINA

E.M. Santori, J. Quintana J.C. Mazziotta, D. Valentino B.A. Payne, and A.W. Toga. Laboratory of Neuro Imaging, Depts of Neurology and Radiological Sciences, UCLA, Los Angeles, CA 90024

Digital imaging techniques for the three dimensional (3D) reconstruction and display of serial data provide powerful new tools for studying neuroanatomy. Our development of a computerized rat brain atlas provided a proof-of-concept for this approach (1). In the current study we have applied these imaging techniques towards the visualization of monkey brain anatomy.

The data set used to build this atlas consists of 1200 digital images of the specimen blockface captured during cryostat sectioning of a whole head. This method of data collection eliminated the problem of image alignment. In addition, it allows for visualization of bony landmarks and other structure as cranial nerves, that are not usually preserved in histological studies. The bony landmarks provided reference to published stereotaxic atlases. Structures were defined by series of contours. Models of the cortical surface, basal ganglia, thalamus, and hippocampal formation were reconstructed and rendered.

These rendered displays enable the viewer to appreciate the shape and locations of anatomic structures within the monkey brain. In addition, the digital atlas provides the opportunity for quantifying a variety of morphometric feat of the anatomy.

WARPING 3D MODELS FOR INTERBRAIN COMPARISONS A.W. TOGA, P.K. BANERJEE* & E.M. SANTORL Laboratory of Neuro Imaging, Department of Neurology, UCLA School of Medicine. Los Angeles, CA. 90024

Three dimensional (3D) reconstructions of whole brain anatomy are routinely derived. The results of these computations are spatially accurate and realistic 3D models of brain. However, these results are based upon the serial sections of a single subject. Because the size, shape and location of various structures can vary between brains, 3D statistical comparisons are difficult or impossible to compute. To facilitate visual and statistical inspections of multiple brains, we have developed a method to warp one 3D volume so that it maps into a second.

The problem was solved in two steps. First a global registration followed by a global warp was performed. Second, local deformations were computed to correct for structure to structure differences. Calculations were performed on voxels using a continuous inverse mapping function. The global registration and warp were restricted to affine transformations. The local deformations, on the other hand, were the results of elastic displacements of grid points under the influence of local forces derived as the negative gradient of the local similarities between the two models. These displacements were obtained by solving the elastic equilibrium equations in

These algorithms have been applied to 3D models of rat brain anatomy and the resulting warped data sets rendered to produce realistic displays.

MIDSAGITTAL AND CORONAL FEATURES OF THE NORMAL HUMAN BRAIN: A QUANTITATIVE MRI ANALYSIS. M.L. Collaer. C. Karatekin* and J. Beatty. Behavioral Neuroscience Program, Dept. of Psychology, UCLA, Los Angeles, CA 90024.

The resolution of magnetic resonance imaging (MRI), combined with its safety, permit a detailed examination of the healthy human brain for research purposes. Quantification of normal neural features provides a perspective for better understanding the effects of pathological processes. Magnetic resonance images were obtained in normal adults, ranging in age from 19 to 34 years, from a 0.04 tesla Instrumentarium Magnaview MRI using a saturation recovery sequence (TR 600 / TE 60). Morphological measures were made on midsagittal (28 subjects) and coronal (16 subjects) scans of 10 mm thickness. The coronal slice was located at the anterior boundary of the thalamo-fornical junction. Prominent features from the midsagittal analysis include (overall group means, uncorrected for brain size): cerebral area (112.9 cm2), cerebellar area (16.0 cm2), maximal pons crosssectional width (26 mm) and distance from the frontal to occipital poles (171 mm). Selected results from the coronal analysis include: cerebral area (102.4 cm²), maximal frontal width (122 mm) and maximal temporal widths (right, 47.9 mm; left, 46.8 mm). Results are analyzed for each gender and presented in absolute and allometric forms.

PSYCHOTHERAPRUTIC DRUGS: ANTIPSYCHOTICS I

CHRONIC GABA AGONIST EFFECTS ON HALOPERIDOL-INDUCED VACUOUS CHEWING MOVEMENTS AND D1 AND D2 DOPAMINE RECEPTOR DENSITY. F. Tarazi, O. Shirakawa, L. Goodman*, and C.A. Tamminga, Maryland Psychiatric Research Center, University of Maryland at Baltimore, Baltimore, MD 21228

Tardive dyskinesia (TD) is a hyperkinetic movement disorder in humans associated with chronic neuroleptic treatment. Chronic blockade of dopamine (DA) receptors resulting in DA receptor supersensitivity and secondary changes in other brain areas are to be involved in the pathophysiology of TD. We have previously reported that the coadministration of a GABA agonist, progabide with haloperidol significantly reduced the development of vacuous chewing movements in rats (Shirakawa, O., et al., Soc. Neurosci. Abst. 15:1989). To clarify the neurochemical mechanisms of this progabide effect in VCMs, we studied the changes in D2 receptors labeled by ³H-spiperone using in vitro quantitative autoradiography. The rats were perfused and their brains were rapidly removed, frozen by immersion in isopentane, mounted and cut into 20-um-thick coronal sections. ⁸H-spiperone binding in the caudate-putamen (medial and lateral) was significantly increased after 6 months treatment with haloperidol (H) and with haloperidol plus progabide treatment with natopertuol (H) and with natopertuol pipe progenite (H+P) (medial; W: 63.1 ± 10.0 fmol/mg tissue (6), H: 89.4 ± 9.4 (12, H+P: 97.1 ± 12.0; lateral; W: 94.5 ± 8.6 (6), H: 125.5 ± 8.6 (12), H+P: 131.4 ± 12.4 (6); mean ± S.D. (N)). No significant correlations were found between VCMs and ³H-spiperone binding in caudate-putamen. Correlations between VCMs and changes in D1 and D2 receptors in other brain regions will be reported as well as changes in 5HT-2

109.3

NICOTINE POTENTIATION OF HALOPERIDOL-INDUCED CATALEPSY: STRIATAL MECHANISMS. P.R. Sanberg. D.F. Emerich, S. Lamb., C. Latkin, B.J. McConville and A.B. Norman. Division of Neuroscience, Department of Psychiatry, University of Cincinnati College of Medicine, Cincinnati, Ohio 45267.

Previously it was demonstrated that the co-administration of low doses of nicotine and haloperidol in rats caused an almost ten-fold increase in cataleptic behavior, as compared to haloperidol alone. Subsequently, Tourette's patients treated with haloperidol and nicotine gum showed remarkable improvement of their motor tics. In order to determine if the potentiation by nicotine of haloperidol catalepsy is mediated via the striatum, we tested whether nicotine could potentiate the haloperidol response in animals devoid of intrinsic striatal neurons. Rats were injected bilaterally with quinolinic acid (150 nmols) into the striatum. At least one month later, the rats were tested for catalepsy following administration of nicotine (0.1 mg/kg i.p.), haloperidol (0.3 mg/kg), nicotine plus haloperidol, or vehicle. In control animals nicotine plus haloperidol produced a significantly greater catalepsy than haloperidol alone. In animals with striatal lesions, there were no significant differences between groups. The nicotine alone or vehicle groups did not produce catalepsy in either control or lesioned animals. The amount of catalepsy produced by haloperidol in the lesioned group was significantly reduced, as demonstrated by earlier research. This not only supported our previous research demonstrating that haloperidol catalepsy is reduced by striatal lesions, but more importantly that nicotine could not potentiate cataleptic behavior without an intact striatum. This supported a role for the striatum as the site of interaction for these potentiate cataleptic behavior without an intact striatum. This supported a role for the striatum as the site of interaction for these two drugs on cataleptic behavior. Supported by Smokeless Tobacco Research Foundation, Tourette Syndrome Association and Merrell Dow.

CHRONIC GABA AGONIST EFFECTS ON HALOPERIDOL INDUCED VACUOUS CHEWING MOVEMENTS AND GABA-A-RECEPTOR DENSITY. O. Shirakawa, F. Tarazi, L. Goodman and C.A. Tamminga, Maryland Psychiatric Research Center, University of Maryland at Baltimore, Baltimore, MD 21228

Vacuous chewing movements (VCMs) in rats induced by chronic neuroleptic treatment are thought to be an animal analogue of human tardive dyskinesia. We have previously reported the prophylactic effect of a GABA agonist, progabide in haloperidolinduced VCMs (Shirakawa, O., et al., <u>Soc. Neurosci. Abst.</u> 15:1989). In an attempt to examine the involvement of GABAergic mechanisms in TD, we have studied changes in GABA-A receptors labeled by 3H-muscimol using quantitative <u>in vitro</u> autoradiography. We treated rats orally with water alone (W), haloperidol alone (H), progabide alone (P) and haloperidol plus progabide (H+P) for 6 months. The rats were perfused and their brains were rapidly removed, frozen by immersion in isopentane, mounted and cut into 20-um-thick coronal sections. 8H-muscimol autoradiographic method was based on Palacios, J.M. et al. (Brain Res., 222:285, 1981) and Penney, J.B., Jr. et al. (Science, 214:1036, 1981). ³H-muscimol binding was significantly increased in substantia nigra reticulata after 6 months significantly increased in substantia largia returbate after 6 months of treatment with H and H+P (W: 301.9 ± 41.9 fmol/ mg tissue (7), H: 354.9 ± 37.3 (12), H+P: 368.9 ± 37.1 (6): mean ± S.D. (N)). In subthalamic nucleus, ³H-muscimol binding was significantly increased with H, but not significantly increased with H+P. No significant correlations were found between VCMs and 3H-muscimol binding in these two brain areas. Correla-tions between VCMs and changes of GABA-A receptors in the other brain regions will be reported

109.4

DIFFERENTIAL EFFECT OF NICOTINE ON D₁ VS D₂
ANTAGONIST-INDUCED CATALEPSY. D.F. Emerich, P.R. Sanberg.
P.Z. Manderscheid, B.J. McConville, J.M. Rich, M.M. El-Etri, M.T.
Shipley and A.B. Norman. Division of Neuroscience, University of Cincinnati College of Medicine, Cincinnati, OH 45267.

Nicotine produces a 10-fold increase in haloperidol-induced catalepsy. Furthermore using nicotine gum as an adjunct to haloperidol produced a remarkable improvement in motor tics in Tourstet's

catalepsy. Furthermore using nicotine gum as an adjunct to haloperidol produced a remarkable improvement in motor tics in Tourette's patients. In order to determine whether these effects of nicotine interact with D₁ or D₂ dopamine (DA) receptor mechanisms, we examined whether nicotine could potentiate the catalepsy produced by the selective D₁ antagonist SCH23390.

Male Sprague-Dawley rats were randomly assigned to one of four treatment groups: SCH23390 plus nicotine, SCH23390 alone, nicotine alone, or vehicle control. SCH23390 (D.5 mg/kg, ip) was administered 30 minutes prior to nicotine (0.1 mg/kg) and rats were tested for catalepsy using the bar test.

Although nicotine produced approximately a 40% increase in

catalepsy using the bar test.

Although nicotine produced approximately a 40% increase in SCH23390-induced catalepsy during the first hour, this did not reach statistical significance. Thus, it appears that striatal D2 rather than D1 receptor mechanisms are predominantly involved in nicotine's profound potentiation of neuroleptic-induced catalepsy.

We also investigated whether nicotine, in conjunction with haloperidol, synergistically increased striatal DA turnover. Nicotine alone produced a small increase while haloperidol produced a marked increase in DA turnover. However, the combination of nicotine and haloperidol did not produce any significantly greater effect on DA turnover. Thus, it is unlikely that the remarkable behavioral effect of nicotine and haloperidol co-treatment was due to any change at the level of DA turnover. Supported by Smokeless Tobacco Research Foundation, Tourette Syndrome Association and Merrell Dow.

Topographical Imaging of the Rabbit Electroencephalogram: Differential classification of major CNS drug classes

Differential classification of major CNS drug classes. G. P. ALBERICI, J.-L. GASKILL, L. COOK, AND G. F. STEINFELS. E. I. DuPont de Nemours & Co., Med. Prod. Dept., Wilmington, DE 19880-0400 USA.

Topographical analysis of EEG provides a 2 dimensional image of electrical brain activity. This study sampled 16 electrodes, 8 per hemisphere, placed symmetrically across the skull of the rabbit. EEG activity was collected online (60, 4 sec intervals) and then transformed into power spectra via a fast Fourier transform (FFT). The results were then grouped into EEG bandwidths, (delta 1-5 Hz, theta 5-9 Hz, alpha 9-13 Hz, and beta 13-35 Hz), averaged and then compared to control for each subject. The change from control values for relative power (RP) for each subject where then averaged and processed, using TMAP (Nicolet Instruments Corp), into topographical images. each subject where then averaged and processed, using TMAP (Nicolet Instruments Corp), into topographical images. The drugs tested included; morphine, chlorpromazine, diazepam, and 3 putative cognitive enhancers; physostigmine, THA (tetrahydroacridine, Cognex, Warner Lambert) and DuP996. Morphine and chlorpromazine both increased frontal alpha and beta RP. However, morphine tended to increase parietal and occipital delta RP whereas chlorpromazine tended to decrease frontal delta RP. Diazepam increased alpha RP across all cortical regions with minimal effects on other bandwidths. Finally the cognitive enhancers showed an increase in occipital beta RP and a decrease in frontal alpha RP. This model has thus far distinguished several classes of pharmacologic agents and in some cases these changes parallel those reported in clinical topographical EEG studies.

BRIFF MATERNAL SEPARATION INTERACTS WITH PARENTAL DRUG SENSITIVITY TO INFLUENCE AKINESIA IN ADULT RATS. H Schreiber Dept. Psychol., Univ. Texas at Tyler, Tyler, TX 75707. M. Coffman*, C. Maes* and M. Juarez-Turner*.

Dept. Behav. Sci., Highlands Univ., Las Vegas, NM 87701.

Briefly removing the dam from the nest in the neonatal period can alter haloperidol induced akinesia in rats and mice (Gallegos, et al., Behav Neural Biol, 53,172-183,1990).

Akinesia was assessed in male and female hooded rats.

Akinesia was assessed in male and female hooded rats. Matched pairs of highly sensitive females were mated with highly sensitive males, less sensitive females with less sensitive males, etc. For 7 days after birth, one member of a matched pair was removed from her nestcage (30 min) while the control dam was not. The offspring received forepaw on dowel testing 90 min after haloperidol (2mg/kg,IP) or saline injection on days 56 and 58. The offspring of highly sensitive parents showed greatly enhanced akinesia at their second exposure to the drug

ly enhanced akinesia at their second exposure to the drug in comparison with the others. The effect of maternal separation was to reverse this increase among only the offspring of the highly sensitive parents, while increasing the akinesia of the offspring of the least sensitive parents. While this experiment does not separate innate from other parental influences, it suggests that neonatal manipulations of the dam may influence powerfully the adult response to neuroleptic drugs.

Supported by NIH-MBRS grant RR08066-13.

SERTINDOLE - A NEW ATYPICAL NEUROLEPTIC J. Arnt. T. Skarsfeldt. J. Hyttel, J. Perregaard*. C. Sánchez*. Research Departments, H. LUNDBECK A/S, Ottiliavej 7-9, DK-2500 Copenhagen Valby,

In a study of neuroleptic activity within a series of 1-aryl-3-(4-piperidyl) substituted indoles1 sertindole (Lu 23-174), 1-[2-[4-[5-chloro-1-(4fluorophenyl)-1H-indol-3-yl]-1-piperidinyl]ethyl]-2-imidazolidinone, was found to be a potent neuroleptic with prominent selectivity for brain limbic areas. In vitro sertindole has a very high affinity for central 5-HT2 receptors (IC₅₀ = 0.72 nM, displacement of [3H]ketanserin), but also high affinity for central DA D-2 receptors (IC50 = 4.1 nM, displacement of [3H]spiperone) and central α_1 adrenoreceptors (IC₅₀ = 3.4 nM, displacement of [3H]prazosin). The compound is non-cataleptic and does not antagonize dopaminergic induced stereotypies (methylphenidate, amphetamine) in proposed clinical doses. Potent 5-HT2 antagonism with long duration of action was found in rats (antagonism of LSD cue and quipazine-induced head twitches). A selective and dose dependent decrease in the number of spontaneously active DA neurones in A10 versus A9 area was induced by sertindole after 21 days po treatment (ED₅₀'s = 0.015 and 1.6 μmol/kg/day, respectively) 2. These results will be compared to data obtained for haloperidol and

ACUTE HALOPERIDOL-INDUCED DEPOLARIZATION BLOCK OF ACUTE HALDPERIDOL-INDUCED DEPOLARIZATION BLOCK OF DOPAMINERGIC REWARD NEURONS IN PARTIALLY 6-OHDA-LESIONED RATS. M. D. Doherty and A. Gratton, Douglas Hosp. Res. Ctr., McGill Univ., Montréal, CANADA, 14H 1R3.

The present study was designed to examine the behavioral significance of depolarization block (DB) of dopamine (DA) cells and, in particular, how with the control of the properties
The present study was designed to examine the behavioral significance of depolarization block (DB) of dopamine (DA) cells and, in particular, how partial loss of DA neurons affects the inhibitory effects of acute haloperidol (HAL) on brain stimulation reward (BSR). Male rats were each implanted with a chronic stimulating electrode in the medial forebrain bundle and with bilateral guide cannulae in the lateral ventricles. A psychophysical method was used to measure changes in the animals' responsiveness to BSR following HAL (50-150 ug/kg, i.p.) and apomorphine (APO, 25-100 ug/kg, s.c.) administered either alone or during HAL blockade. The animals then received bilateral intraventricular infusions of the DA neurotoxin, 6-OHDA (80-100 ug/ventricle). In animals exhibiting normal baseline BSR 21-28 days post-lesion, HAL, at doses that caused only a moderate decrease in responsiveness to BSR before the lesion, now caused a complete cessation of BSR. Normal responsiveness to BSR could be reinstated during HAL blockade with APO, at doses that caused an inhibition of BSR before the lesion. These behavioral data are consistent with electrophysiological data (Grace et al., 1989) showing that; 1) DA cells that survive 6-OHDA lesions are more active and thus more likely to be driven into DB by acute HAL treatment, 2) APO, a hyperpolarizing agent of DA cells at low, autoreceptor selective doses, can repolarize DA cells driven into DB. The present data also suggest that although partial DA depletion has, by itself, little effect on reward functions, the surviving reward-relevant DA cells may be more susceptible to inactivation by a variety of stimuli that increase DA cell firing. Our preliminary data suggest that acute stress may also cause DB in partially DA-depleted animals. Funded by the MRC of Canada.

CHLOPROMAZINE INDUCED WEIGHT GAIN. W.B. Lawson Ida Michele Williams, and J. Hill. Department of Psychiatry, Vanderbilt University School of Medicine, Nashville, TN 37232.

Obesity related to neuroleptic use is a common problem among the chronically mentally ill. Animal research has shown that many neuroleptics will cause increased eating and weight gain by D_2 blockade. Chlopromazine (CPZ) consistently fails to cause weight gain in rats in contrast to clinical observation in humans. We studied food intake and body weight in adult male and female Sprague Dawley albino rats on a diet of 50% chow and water for 42 days. Groups of 7 rats were injected i.p. with either vehicle or chlopromazine 2,4, or 8 mg/kg. Female rats showed increased weight gain past the tenth day for all Male rats gained proportionally less weight with higher doses. Total food intake and energy utilization were significantly higher for females on CPZ. Amount of adipose tissue increased with CPZ dose for both males and females. CPZ may cause weight gain in females by increasing food intake and adiposity.

DISCRIMINATIVE STIMULUS PROPERTIES OF CLOZAPINE. H.F. Villanueva, S. Arezo*, J.A. Rosecrans* & J.H. Porter, Depts. of Pharm./Tox. and Psych., Va. Commonwealth Univ., Richmond, VA 23298.

Due to the lack of extra-pyramidal side effects of the atypical antipsychotics and therefore the

lack of adequate screening procedures for new atypical antipsychotic compounds, a two-lever operant drug discrimination paradigm was investigated as a possible screening technique for atypical antipsychotic compounds. Also, the drug discrimination paradigm offers an opportunity to investigate the mechanisms of action of the atypical antipsychotic clozapine. Male Spragueinvestigate the mechanisms of action of the atypical antipsychotic clozapine. Male Sprague-pawley rats were trained to discriminate 5 or 10 mg/kg clozapine from vehicle using a VI-15 second schedule of food reinforcement. Following drug discrimination training, the following compounds were substituted to test for generalization to clozapine: thioridazine, an atypical antipsychotic, haloperidol, a D2 antagonist and SCH 23390, a D1 antagonist. Rats trained to discriminate 5 mg/kg clozapine from vehicle demonstrated partial generalization to thioridazine, while those trained at 10 mg/kg showed no generalization. while those trained at 10 mg/kg showed no generalization. Neither haloperidol nor SCH 23390 substituted for clozapine, suggesting that the discriminative cue is not mediated through D1 or D2 receptors.

EFFECTS OF DOPAMINE PARTIAL AGONISTS ON FIRING RATES OF DOPAMINE NEURONS IN SUBSTANTIA NIGRA PARS COMPACTA. W.E.Hoffmann, J.T.Lum, and M.F.Piercey. CNS Research, The Upjohn Company, Kalamazoo, MI 49001 USA.

The aminoergolines, SDZ 208-911 (S911) and SDZ 208-912

The aminoergolines, SDZ 208-911 (S911) and SDZ 208-912 (S912), have been characterized as potent D2 receptor partial agonists that, because of low intrinsic activities, act as dopamine (DA) receptor antagonists in behavioral assays (D.M.Coward *et al.*,

JPET 252:279, 1990). The dopamine autoreceptor, because of spare receptors (Meller *et al.*, Eur. J. Pharmacol, 123:311, 1986), is very sensitive to dopamine agonist effects. We have examined S911 and S912 on DA neuron firing rates and antagonism of DA agonists amphetamine (AMPH) and apomorphine (APO). Using dye-filled glass microelectrodes, DA neurons in SNPC were identified by classical electrophysiological/neuroanatomical criteria (Bunney *et al.*, JPET 155:560, 1973). S911 depressed DA neuron firing, but only partially (maximum effect = 38%, ED₅₀ = 38 μg/kg). AMPH and APO agonists were partially reversed by S911. S912 was much weaker as an agonist. Maximal depression was 15%. In contrast, TDHL (Piercey and Hoffmann, JPET 243:391,1987), (-)-3-PPP and APO depressed firing by 50%, 80% and 100%, respectively. S912 completely reversed that S912 is a partial agonist at the DA autoreceptor with an intrinsic activity near the level of detectability.

THE IN VIVO PHARMACOLOGY OF THE NOVEL ANTIPSYCHOTIC HP 873. M.R. Szewczak, R.W. Dunn*, R. Corbett*, H.M. Geyer*, D.K. Rush*, J.C. Wilker*, J.T. Strupczewski*, G.C. Helsley*, and M.L. Comfeldt. Department of Biological Research, Hoechst-Roussel Pharmaceuticals, Inc., Somerville, NJ 08876.

HP 873, 1-[4-[3-[4-(6-fluoro-1,2-benzisoxazol-3-yl)-1-piperidinyl] propoxyl-3-methoxyphenyl] ethanone, an antagonist with potent 5HT₂ receptor binding activity, displays an atypical antipsychotic profile in *in vivo* assays predictive of clinical efficacy. It was effective in blocking apomorphine-induced climbing behavior in mice (ED₅₀ = 0.10 mg/kg, ip). HP 873 also potently blocked intracranial self-stimulation behavior in rats (ED₅₀ = 0.15 mg/kg, ip), pole-climb avoidance in rats (avoidance ED₅₀ = 1.4 mg/kg, ip, escape failure ED₅₀ = 6.0 mg/kg ip), and continuous Sidman avoidance in monkeys (ED₅₀ = 3.6 mg/kg, po). Acute administration of HP 873 to rats caused an increase in the number of active dopamine neurons sampled in both the ventral tegmental area (A10) and substantia nigra (A9), whereas chronic administration resulted in significantly fewer active dopamine neurons in the A10 with increased numbers until observed in the A9. In a social interaction test in rats, HP 873 significantly increased social interaction time between rats at 1.0 mg/kg ip, without significantly reducing motor activity. HP 873 displays an *in vivo* profile consistent with that of an atypical antipsychotic agent and is predicted to be clinically effective with fewer neurological side effects than classical antipsychotic agents.

109.15

REGIONAL SPECIFIC EFFECTS OF CLOZAPINE AND HALOPERIDOL ON GABA RELEASE IN RAT BASAL GANGLIA. K.L. Drew, W.T. O'Connor*, J. Kehr* and U. Ungerstedt*. Department of Pharmacology, Karolinska Institute, Stockholm, Sweden.

The release of Y-aminobutyric acid (GABA) from dorsolateral striatum, fundus striati (a ventral region of the striatum) and globus pallidus was measured following subcutaneous administration of haloperidol or clozapine using in vivo microdialysis in halothane anaesthetized rats. Clozapine (5.0 mg/kg) increased GABA release in fundus striati while haloperidol (0.5 mg/kg) increased GABA release in globus pallidus. In contrast, clozapine (2.5 to 40 mg/kg) failed to increase GABA release in globus pallidus and haloperidol (0.1 to 2.0 mg/kg) failed to increase GABA release in the fundus. Thus, haloperidol and clozapine are clearly distinguished by their effects on GABA release in fundus striati and globus pallidus. Both drugs increased GABA release in dorsolateral striatum. Drug-induced increases in GABA release were reversed by the addition of 1 µM tetrodotoxin to the perfusion medium. These data suggest that regional differences in the effects on GABA release in the basal ganglia may parallel the unique clinical profiles of haloperidol and clozapine.

109.12

THE NEUROCHEMICAL PROFILE OF HP 873, A POTENTIAL ATYPICAL ANTIPSYCHOTIC WITH D₂/5HT₂ RECEPTOR ANTAGONIST ACTIVITY. C.A.Wilmot, A.M. Szczepanik, L.R.Brougham*, J.E.Roehr*, G. Bores*, H.B. Hartman*, P.G. Conway, J. Chernack*, J.T. Srupçzewski*, E.J. Glamkowski*, D.B. Ellis* and G.C. Helsley*. Dept. Biol. and Chem. Res. Hoechst-Roussel Pharmaceuticals Inc., Somerville NJ 08876.

Hoechst-Roussel Pharmaceuticals Inc., Somerville NJ 08876. HP 873, 1-4[3-[4-(6-fluoro-1,2-benzioxazo1-3-yl)-1-piperidinyl]-propoxy]-3-methoxyphenyl]ethanone, has a preclinical behavioral and electrophysiological profile of an atypical antipsychotic. *In vitro*, HP 873 had moderate to high affinity for SHT₂, α_2 and α_1 receptors (IC₅₀= 9.3, 60, 0.4 nM, respectively) with lower affinity for D₂, SHT_{1A}, σ and D₁ (IC₅₀= 109, 210, 180, 750 nM, respectively). *Ex vivo*, HP 873, 2.5 to 20 mg/kg, ip, inhibited cortical and subcortical SHT₂ receptor binding by 50-94% with a duration greater than 4 hrs. in contrast to a peak effect of 10-20% inhibition of D₂ receptor binding at 1 hr. *In vivo*, HP 873 inhibited 5HTP-induced head twitch in rats at doses below those active against apomorphine-induced stereotypy. HP 873 increased DA turnover in rats at 0.3 to 10 mg/kg, ip, and partially reversed the apomorphine inhibition of GBL-induced DOPA synthesis at 3 and 10 mg/kg. Chronic treatments with 10 mg/kg, ip, for 19 days produced no change in the Bmax for Deceptors in the n. accumbens or 6 regions of the striatum, however the Bmax for 5HT₂ receptors was reduced to 41% of control in the frontal cortex. These studies suggest that potent 5HT₂ receptors as an atypical antipsychotic.

109.14

COMPARISON OF ACUTE EFFECTS OF HALOPERIDOL AND CHLORPROMAZINE ON EEG WITH BRAIN WAVE FACTOR SCANS

N.C. Paquette, H. Stamidis.*L.Mayo-Michelson.*R.P. Gussio*, and G.A. Young. Dept. of Pharmacol. and Tox., Univ. of Maryland Sch. of Pharmacy, 20 N. Pine St., Baltimore, MD 21201.

Various compounds of different structural classes are used to treat psychoses. In this study the electrophysiological effects of haloperidol, a butyrophenone, and chlorpromazine, a phenothiazine, were examined. Female Sprague-Dawley rats were prepared with chronic EEG recording electrodes and permanent indwelling i.v. cannulae. EEG data were analyzed with a Nicolet Pathfinder 1 computer. Animals were administered haloperidol (0.1 mg/kg) and chlorpromazine (0.5 mg/kg). Multivariate analyses of EEG spectral parameters demonstrated differences between these antipsychotic compounds. haloperidol administration, one bipolar factor emerged which described decreases in slower EEG frequencies and increases in faster EEG frequencies and the edge frequency. Chlorpromazine, however, contained a comparable factor which was monopolar and described increases in faster EEG frequencies and the edge frequency. The differential EEG effects may reflect differences in chemical structure or mechanism of action. (Supported by NIDA DA01050).

109.16

CLOZAPINE AND THIORIDAZINE, BUT NOT MOST OTHER ANTIPSYCHOTIC DRUGS, PRODUCE LARGE ELEVATIONS IN BRAIN GLUCOSE CONCENTRATIONS. L.D. Kreamer* and C.F. Saller. ICI Pharmaceuticals Group, ICI Americas Inc., Wilmington, DE 19897.

Previous studies indicated that the stimulation of brain dopamine receptors can increase brain glucose concentrations which can in turn suppress dopaminergic activity. Thus, brain glucose vas measured after a variety of antipsychotic drugs, which block DA receptors. In addition, the effects of several antipsychotic drugs with low affinities for DA receptors were also measured. Only clozapine and thioridazine, antipsychotic drugs with atypical properties, produce very large increases (i.e., >100% at 20 mg/kg, i.p.) in brain glucose. None of a variety of compounds, such as: d-butaclamol, chlorpromazine, fluphenazine, haloperidol, pimozide, remoxipride, rimcazole, SCH 23390, and setoperone produce more than a 30% change in brain glucose. Loxapine, a typical antipsychotic, was intermediate between clozapine and thioridazine and the other drugs tested. Depletion of catecholamines completely prevented clozapine-induced increases in brain glucose. These data are discussed with regard to how increases in brain glucose might contribute to the therapeutic effects of clozapine and thioridazine.

EFFECTS OF CI-943, A POTENTIAL ANTIPSYCHOTIC AGENT, ON CEREBRAL GLUCOSE UTILIZATION IN RATS. L.P. Raymon, A.S. Kimes, L.T. Melizer, T.G. Heffner, and E.D. London. NIDA Addiction Research Center, Baltimore, MD 21224 and Parke-Davis Pharmaceutical Research Division, Warner-Lambert Co., Ann Arbor, MI 48105.

CI-943 is a unique antipsychotic drug candidate in that it is not a dopamine (DA) receptor antagonist and does not bind to a variety of other neurotransmitter receptors. However, CI-943 has modulatory effects on dopaminergic and serotonergic neural systems, and exhibits an antipsychotic profile in a variety of preclinical behavior tests in rodents and primates (Heffner, T. et. al., JPET, 251:105, 1989). We used the 2-deoxy-D-[1-14C]-glucose method (Sokoloff, L. et al., J. Neurochem., 28:897, 1977) to study the effects of CI-943 on local cerebral glucose utilization (LCGU) in 22 male Sprague Dawley rats. CI-943 (40 mg/kg, i.p.) was administered 10 or 60 min before the radiotracer. Compared to saline-treated controls, CI-943 increased LCGU in the lateral habenula at both time points, and in the globus pallidus and substantia nigra, pars reticulata at 60 min. CI-943 decreased LCGU in dopamine projection areas (e.g., caudate-putamen, accumbens n., frontal and anterior cingulate cortical areas, subthalamus) and several additional areas; but the drug had no effect on LCGU in areas of dopamine cell bodies (e.g., substantia nigra, pars compacta, ventral tegmental area). Thus, CI-943 produces haloperidol-like effects on LCGU in some brain areas (e.g., lateral habenula), but not in others (e.g., globus pallidus). The results support the view that CI-943 has a different profile of CNS effects than clinically available antipsychotics.

Supported in part by a grant from the Warner-Lambert Co.

109.19

THE EFFECT OF ICI 204,636, A POTENTIAL ANTIPSYCHOTIC AGENT, IN A BATTERY OF BEHAVIORAL TESTS PREDICTIVE OF ANTIPSYCHOTIC ACTIVITY AND TARDIVE DYSKINESIA.

Migler, J.B. Malick, and E. J. Warawa. ICI Pharmaceuticals Group, ICI Americas Inc., Wilmington, DE 19897.

ICI 204,636, a dibenzothiazepine, was tested in a

ceuticals Group, ICI Americas Inc., Wilmington, DE 1989.

ICI 204,636, a dibenzothiazepine, was tested in a variety of behavioral tests predictive of antipsychotic activity, including a) conditioned avoidance in squirrel monkeys; b) antagonism of apomorphine-induced blinking in squirrel monkeys; c) antagonism of apomorphine-induced visual searching in cats; d) antagonism of apormorphine-induced climbing in mice; e) antagonism of amphetamine-induced hyperactivity in rats; f) restoration (normalization) of apomorphine-induced disruption of swimming in mice; and g) restoration (normalization) of amphetamine-induced disruption of swimming in mice; and g) restoration (normalization) of standard antipsychotic agents and suggest that ICI 204,636 is a potential antipsychotic agent. In addition, ICI 204,636 was tested in haloperidol-sensitized cebus monkeys and in drug-naive cebus monkeys for the induction of dyskinetic reactions. The results were compared with the results obtained with standard agents. The data suggest that ICI 204,636 has a markedly reduced potential to produce dyskinetic reactions in cebus monkeys. We conclude that ICI 204,636 is a potential antipsychotic agent with a marked reduction in the potential to produce BPS and tardive dyskinesia in humans.

109.21

ICI 204,636, A POTENTIAL ANTIPSYCHOTIC WITH AN "ATYPICAL" BIOCHEMICAL PROFILE. C.F. Saller and A.I. Salama. ICI Pharmaceuticals Group, ICI Americas Inc., Wilmington, DE 19997

19897.

ICI 204,636 and the atypical antipsychotic clozapine (CLZ) were compared using measures in rats which may indicate antipsychotic activity and extrapyramidal side-effect (EPS) liability. These compounds are low potency D-2 dopamine (DA) antagonists and are much more potent 5-HT2 antagonists. Both produce similar elevations in DA metabolites. Like CLZ, ICI 204,636 produces a short-lasting increase in plasma prolactin. Unlike CLZ, ICI 204,636 lacks activity at D-1 DA and muscarinic receptors. After chronic administration, at doses which produce large increases in DA metabolites, both fail, unlike typical antipsychotics, to increase striatal D-2 receptors, but do decrease 5-HT2 receptors in frontal cortex. These data are discussed with regard to the hypothesis that 5-HT2/D-2 receptor interactions may account for the low propensity of ICI 204,636 to produce behavioral and electrophysiological indices of EPS.

109.18

EFFECTS OF CI-943, A POTENTIAL ANTIPSYCHOTIC DRUG, AND HALOPERIDOL ON REGIONAL BRAIN NEUROTENSIN CONCENTRATIONS.

B. Levant, G. Bissette, M.D. Davis, T.G. Heffner, and C.B. Nemeroff. Depts. of Pharmacology and Psychiatry, Duke Univ. Med. Ctr., Durham, NC 27710 and Parke-Davis Pharm. Res. Div., Warner-Lambert Co., Ann Arbor, MI 48105.

Treatment with efficacious antipsychotic drugs, such as

Treatment With efficacious antipsychotic drugs, such as haloperidol, selectively increases the concentrations of neurotensin (NT) in the nucleus accumbens and caudate nucleus of the rat. These increases in NT concentrations may be associated with the therapeutic and side effects of antipsychotic drugs. CI-943, a novel antipsychotic clinical candidate, produces behavioral effects in animals which suggest that it may possess antipsychotic activity but is not a dopamine antagonist. This study evaluated the effects of CI-943 and haloperidol on regional brain NT concentrations. Adult, male, S-D rats were treated with CI-943 (40 mg/kg, ip) or haloperidol (1 mg/kg, ip) for 23 days. NT concentrations of discrete brain regions were determined by a sensitive and specific RIA. NT concentrations in the nucleus accumbens, anterior caudate and posterior caudate were significantly increased by both drugs. Unlike haloperidol, CI-943 also increased the concentrations of NT in the substantia nigra/ventral tegmental area and hypothalamus. These data provide further evidence that putative antipsychotic drugs increase NT concentrations in the nucleus accumbens and other brain regions. (Supported by NIMH MH-39415 and Parke-Davis).

ELECTROPHYSIOLOGICAL PROFILE OF ICI 204,636: A NEW AND NOVEL ANTIPSYCHOTIC DRUG. J. M. Goldstein, L. C. Litwin, E. B. Sutton and J. B. Malick. ICI Pharmaceuticals Group, ICI Americas Inc., Wilmington, DE 19897 USA.

Extracellular single unit recording techniques were used to compare the effects of ICI 204,636 (ICI) with the

Extracellular single unit recording techniques were used to compare the effects of ICI 204,636 (ICI) with the reference antipsychotic (AP) agents clozapine (CLZ) and haloperidol (HAL) in electrophysiological tests considered predictive of either AP activity or extrapyramidal side effects (EPS). ICI and CLZ were differentially more active in reversing d-amphetamine inhibition of mesolimbic (A10) than nigrostriatal (A9) DA-containing neurons, whereas HAL exhibited the opposite selectivity. In cell population studies, acute administration of ICI and CLZ produced selective increases in the number of spontaneously active A10 DA cells, which correlated with the ability of both these drugs to cause depolarization inactivation (DI) of only A10 DA cells following chronic administration. This profile of activity was unlike that of HAL, which acutely caused a nonselective increase in the number of actively firing A9 and A10 DA cells, associated with its ability to cause DI of both A9 and A10 DA cells after chronic administration. Inasmuch as DI of A10 DA cells may be correlated with AP efficacy whereas DI of A9 DA cells may predict EPS, ICI may be a potential AP with a reduced likelihood for producing EPS.

REPEATED ADMINISTRATION OF COCAINE DECREASES DOPAMINE SYNTHESIS AND DIALYSATE DOPAC BUT NOT TISSUE DOPAMINE OR DOPAC IN THE NUCLEUS ACCUMBENS. J.W.Brock, J.P. Ng. and J.B. Justice, Jr. Department of Chemistry, Emory University, Atlanta, GA 30322.

Using microdialysis, reduced steady state formation of dihydroxyphenylalanine (DOPA) (47%) was found in the nucleus accounts (N.) CO of rate restrict with ten days of represent accounts.

accumbens (N ACC) of rats treated with ten days of repeated cocaine injections (10 mg/kg i.p.) as compared to saline controls after NSD 1015 perfusion (0.1 mM). In addition, prior to NSD 1015 perfusion, basal extracellular levels of the dopamine (DA) metabolite, dihydroxyphenylacetic acid (DOPAC) in the N ACC were 33% lower in the chronic cocaine treated animals. The serotonin metabolite, 5-hydroxyindole acetic acid (5-HIAA) examined under the same conditions as DOPAC was found to be unaffected by repeated cocaine administration. The results indicate the rate of DA synthesis in the

AVAIC is significantly reduced by repeated cocaine administration.

Preliminary results also indicate a challenge injection of cocaine (20 mg/kg i.p.) further reduced the DOPA levels from steady state in both saline and cocaine treated animals.

In an additional experiment, tissue levels of DA, DOPAC, 5-HIAA were measured in the N ACC, striatum (STR), and prefrontal cortex (PFC) of rats treated for 10 days with either saline or cocaine (10 mg/kg i.p.). Tissue levels of norepinephrine were also examined in the PFC. No statistically significant difference was found for any of the analytes in the N ACC, STR, or PFC between cocaine and saline treated groups.

110.3

ENHANCED RESPONSE OF MESOLIMBIC DOPAMINE SYSTEM TO COCAINE FOLLOWING PREEXPOSURE TO CAFFEINE: AN IN VIVO MICRODIALYSIS STUDY P.J. Wellman, B. Davies* and S. Schenk, Texas A&M Univ., Dept. Psychol., College Station, TX, 77843

Rats were preexposed with 9 daily injections of either caffeine (20 mg/kg, IP) or the saline vehicle. On the tenth day, the rats were injected with cocaine (10 mg/kg, IP) and the response of the mesolimbic dopamine system was measured through the use of in vivo microdialysis. Cocaine-induced increases in extracellular dopamine levels were apparent in both saline and caffeine precreases in extracellular dopamine levels were apparent in both saline and caffeine pretreated rats. However the caffeine pretreated animals demonstrated greater increases in accumbens dopamine. This enhanced response of the mesolimbic dopamine system to cocaine following caffeine preexposure parallels behavioral indices of sensitization to cocaine observed under identical preexposure parameters.

110.5

EVALUATION OF CHANGES IN DOPAMINERGIC FUNCTION FOLLOWING CHRONIC COCAINE: AN IN VIVO MICRODIALYSIS STUDY.
A. Mele, P. Glue, D.J.Fontana and A. Pert. BPB/NIMH and LCS/NIAAA,

Some of the behavioral effects of cocaine increase in intensity with repeated administrations. A variety of neurochemical mechanisms have been postulated to underlie this behavioral sensitization. The purpose of this study was to evaluate alterations in dopaminergic processes with *in* vivo microdialysis following exposure to chronic cocaine. Rats were administered 30 mg/kg cocaine or saline daily for 7 days. On day 8 all animals were anaesthetized with chloral hydrate and challenged with cocaine administered either systemically or through microdialysis probes cocaine administered either systemically or through microdialysis probes situated in the striatum or nucleus accumbens. A cocaine (10 mg/kg) challenge administered systemically on day 8 produced a somewhat greater increase in DA overflow in both the striatum and nucleus accumbens of rats pretreated chronically with cocaine. On the other hand, when rats were challenged with cocaine (0.01 mM or 1 mM) through the dialysis probe, there was no difference in DA overflow between the two groups in either structure. We have found that injections of apomorphine into the substantia nigra decrease levels of DA in the striatum, presumably through interaction with somatodendritic autoreceptors. No differences were found in apomorphine-induced decreases in striatal DA between groups of rats treated chronically with saline or cocaine. These findings groups of rats treated chronically with saline or cocaine. These findings suggest that the enhancement in DA overflow induced by systemic cocaine in cocaine-pretreated rats is not due to alterations in presynaptic DA functions or to DA autoreceptor subsensitivity. Experiment are in progress to determine whether the differences between the two groups can be attributed to differences in the disposition of cocaine and cocaine metabolite in the brain.

REPEATED COCAINE ADMINISTRATION INCREASES STIMULATED RELEASE AND UPTAKE OF DOPAMINE IN NUCLEUS ACCUMBENS AS MEASURED BY INVIVO VOLTAM-METRY. J.P. Ng, G.W. Hubert, and J.B. Justice Jr.; Emory University; Dept. of Chemistry; Atlanta, Georgia 30322.

Electrically-stimulated dopamine (DA) release (overflow) and

reuptake were measured with in vivo voltammetry in nucleus accumbens of anaesthetized rats given repeated administration of cocaine. Electrically-stimulated DA release was induced by a 10 sec stimulation in the medial forebrain bundle (2-ms, 200uA biphasic, 100 Hz). DA overflow and uptake were quantified with fast chronoamperometry using Nafion-plated carbon fiber electrodes. Animals (N=7/grp) given repeated cocaine (10 mg/kg s.c. from day 1-5, 20 mg/kg s.c. from day 6-10) showed a 185% increase in uptake rates compared to saline controls (6.1±1.0 uM/s vs. 3.3±0.8 uM/s) and a 151% increase in stimulated overflow over 10 day controls (27.3±2.9 uM vs. 18.1±3.2 uM). This effect was found to be temporary as cocaine-treated animals showed no difference in uptake or release vs. controls following a10 day abstinence period (N=7/grp). GBL (300 mg/kg) administered to controls (N=5) showed a 200% augmented DA release with no change in uptake indicating that enhanced uptake rates observed in cocaine treated animals were independent of augmented stimulated release of DA. These results suggest that alterations produced by repeated cocaine adminstration may be a compensatory response to prolonged uptake blockade of synaptic DA. These alterations of the dopaminergic nerve terminal may be important during withdrawal from repeated cocaine use.

110.4

EFFECTS OF COCAINE ON DOPAMINE AND ITS METABOLITES IN THE STRIATUM BETWEEN WKY AND SHR: A MICROLIALYSIS STUDY. T. Inada, R.W. Rockhold, K. Polk, C. Jin, B. Hoskins and I.K. Ho. Dept. Pharmacol. and Toxicol., Univ. of Mississippi Med. Ctr., Jackson,

The present study examined effects of intraperitoneal injections of cocaine (20 and 40 mg/kg) on the extracellular levels of dopamine (DA) and its metabolites in the striatum of halothane-anesthetized 20-30 weeks WKY and SHR using an *in vivo* microdialysis technique. The baseline levels (pg/20µl) of DA and its metabolites were as follows:

DOPAC

SHR (n=14) 19.3±4.6 1638±418 2119±404 WKY (n=12) 22.9±6.3 1985±542 2498±592 There were no significant differences in the baseline levels of DA and its metabolites between WKY and SHR. The extracellular DA levels increased significantly following injections of cocaine (46% WKY, 52% SHR for 20mg/kg, p<0.05; 74% WKY, 78% SHR for 40mg/kg, p<0.01). However, there were no significant differences between strains. No significant changes were observed after cocaine administration in levels of DOPAC and HVA. Our previous findings showed brace and HVA. Our previous indings showed significant differences in binding characteristics of both D-1 and D-2 receptors in the striatum between SHR and WKY. The present results indicate that acute challenge with cocaine does not differentially alter striatal DA release between anesthetized SHR and WKY. (Supported by DA04264)

BEHAVIORAL AND NEUROCHEMICAL INTERACTIONS BETWEEN COCAINE AND BUPRENORPHINE: IMPLICATIONS FOR PHARMACOTHERAPY OF COCAINE ABUSE. E.E. BROWN. J.T.F. WONG*, J.M., FINLAY, C., WILSON* and H.C., FIBIGER. Div. of Neurol. Sci., Dept. of Psychiatry, Univ. of British Columbia, Vancouver B.C., V6T 1W5 Canada.

Buprenorphine (BUP) is a synthetic opiate that attenuates opiate self-administration. Recently, it has been reported that BUP also suppresses cocaine self-administration, suggesting that BUP might be useful in the pharmacotherapy of cocaine abuse. However, BUP is a drug of abuse as shown by epidemiological and self-administration studies. The conditioned place preference (CPP) paradigm was used to address two specific questions. First, does BUP induce CPP? Second, is cocaine-induced CPP affected by BUP?

Cocaine-induced CPP was linearly related to the dose administered. BUP also elicited CPP in a dose-related manner; an inverted-U shaped function was obtained. Subthreshold doses of BUP and cocaine, individually incapable of eliciting CPP, produced significant CPP's when given together. Moderate doses of BUP and cocaine individually capable of eliciting a CPP, produced a significantly larger effect in combination.

effect in combination.

effect in combination.

A large body of evidence suggests that mesolimbic dopamine (DA) is implicated in the rewarding properties of drugs of abuse. The effects of BUP, cocaine, and a combination of both drugs on DA and its metabolites in the nucleus accumbens were measured using in vivo microdialysis. BUP (10 µg/kg) caused a progressive increase in DA, reaching 200% of basal levels at five hr. A rapid increase in DA, reaching 200 basal levels at five hr. A rapid increase in DA, or a complete the property of basal values) was observed following cocaine (5.0 mg/kg), which returned to baseline in 2-3 hr. BUP potentiated the effects of cocaine on extracellular DA (260% of basal values), providing neurochemical corroboration of the CPP results. Taken together, these data suggest that BUP can interact synergistically with cocaine.

MARKEDLY REDUCED STRIATAL DOPAMINE LEVELS IN BRAIN OF A CHRONIC COCAINE ABUSER by J.M. Wilson, J. Deck*, K. Shannak*, L.J. Chang*, L.M. DiStefano* and S.J. Kish, Clarke Institute of Psychiatry, Rotman Research Institute of Baycrest Centre and Toronto General Hospital, Toronto,

To our knowledge, no information is available concerning the behaviour of the major neurotransmitter systems in brain of human chronic cocaine abusers. We measured the brain or numan chronic cocaine abusers. We measured the levels of dopamine (DA) and dopamine D_2 receptor binding in autopsied basal ganglia of a chronic cocaine abuser (age 26). DA levels were markedly decreased outside of the normal control (n=8) range in subdivisions of the caudate (-51 % to -59%), putamen (-53% to -70%), and nucleus accumbens (-67%), but were normal in substantia nigra. DA accumbens (-0/3), but were normal in substantia nigra. DA (D₂) receptor binding density and affinity were within the normal control range in caudate and putamen. We suggest that the marked reduction of striatal DA levels may be due to either a reversible cocaine-induced inhibition of DA synthesis, or may represent an actual loss of dopaminergic nerve terminals. We emphasize the preliminary nature of our data and the importance of extending our findings in a greater number of cases.

EFFECTS OF INTRAVENOUS COCAINE ON SINGLE UNIT ACTIVITY IN THE NUCLEUS ACCUMBENS OF FREELY-MOVING RATS. L.L.

Peoples* and M.O. West. Dept. Psychol, Rutgers U., New Brunswick, NJ.

This study characterized the effects of intravenous cocaine on single unit activity in the nucleus accumbens of freely-moving rats. Male Long-Evans rats were chronically implanted with either microwires or a detachable microdrive, positioned for accumbens recording; a stimulating wire in the fimbria; and a jugular catheter. That recorded units were accumbens neurons was verified by stimulating the fimbria to evoke unit discharges at monosynaptic latencies and by histological analysis. During self-administration training, a 0.2 ml infusion of 1.65 mg/kg cocaine followed each lever-press. To control for the potential effects of cocaine-induced motor behaviors on accumbens unit activity, pre- vs post-cocaine comparisons were made with behavior held constant across conditions. Two approaches were taken to create stable behavioral baselines: 1) periodically, rats were forced to locomote at a constant rate on a moving treadmill preand post-drug; and 2) neural activity was measured in relation to particular behavioral events with a computer-synchronized videotape analysis. In all cells thus far tested (i.e., 11 cells in four rats), mean firing rate increased during the pre-drug period of treadmill-walking and following the initial cocaine infusions. In nine cells, the cocaine-induced increase in mean firing rate exceeded the increase induced by treadmill-walking. For the majority of cells characterized across the entire self-administration training session (n = 8): 1) the initial cocaine-induced increase in unit activity dissipated with continued cocaine infusions so that unit activity at the end of the session approached pre-drug levels; and 2) unit activity appeared related to number of cocaine infusions but not to either the timing of lever-presses, or the occurrence of cocaine-induced stereotypies. THE D1 ANTAGONIST SCH 23390 AND THE D2 ANTAGONIST RACLOPRIDE SELECTIVELY DECREASE BEHAVIOR MAINTAINED BY COCAINE OR FOOD IN THE RAT. S.B. Caine, M. Berhow*, M. Amalric and G.F. Koob. Department of Neuropharmacology, Research Institute of Scripps Clinic, La Jolla, CA 92037.

The purpose of this study was to determine whether a specific D1 or D2 dopamine receptor antagonist selectively alters cocaine self- administration in the rat. Male Sprague-Dawley rats equipped with chronic jugular catheters were food-deprived and placed on an FR 15/2min. time-out schedule. Half-hour components of the two-hour session were alternately reinforced with food or cocaine (.075 mg/kg/inj.). Once baselined, animals were injected with SCH 23390 (2.5, 5, 10, 20 ug/kg sc) or raclopride (50, 100, 200, 400 ug/kg sc) 30 min. prior to the session.

At lower doses SCH 23390 dose-dependently decreased responding for cocaine down to 41% of baseline, yet had no effect on responding maintained by food. Higher doses of SCH 23390 reduced responding for both reinforcers, but more potently inhibited responding for cocaine. SCH 23390 is also reported to decrease responding for cocaine in the rhesus monkey (Woolverton and Virus, Pharm. Biochem. & Behav. 32:691, 1989) at doses which minimally affect responding for food (Kleven and Woolverton, Soc. Neurosci. Abs. 322.8, 1989). In contrast, the D2 antagonist raclopride failed to inhibit responding for cocaine at doses which decreased responding for food. Other studies in our laboratory have shown that raclopride in this dose range disrupts motor performance on a reaction time task while SCH 23390 fails to alter performance in this task at doses which suppress cocaine self- administration. Taken together these results may suggest that at low doses D1 antagonists selectively block the mesocorticolimbic dopamine system and D2 antagonists selectively block the nigrostriatal system.

EFFECTS OF CHRONIC COCAINE TREATMENT, WITHDRAMAL AND RECHALLENGE ON ANIMAL BEHAVIOR AND SYMPTIC DOPAMINE METABOLISM IN MUCLEUS ACCUMBENS. Matthew W. Robertson, Ill (1,2), Catherine A. Leslie (2), Eric W. Lothman (1) and James P. Bennett, Jr. (1,2,3). Departments of Neurology (1), Behavioral Medicine and Psychiatry (2) and Pharmacology (3), University of Virginia School of Medicine, Charlottesville, VA 22908.

We studied the time course of development and duration of behavioral sensitization to cocaine in adult rats, and the effects of chronic cocaine administration and withdrawal upon subsequent cocaine-induced behavior and synaptic dopamine metabolism in vivo, measured with microdialysis. Audit male rats were implanted with microdialysis probe holders (Carnegie-Medicin) aimed to terminate 3 mm above ventromedial striatum/nucleus accumbens. After recovery, two groups of animals received either daily saline i.p. (SAL) or daily occaine KCl 30 mg/kg i.p. (COC) for 18 days. On every third day, each animal's activity was monitored for 60 minutes before and after saline (SAL group) and some cocaine injection (COC group). Animals received no injections from days 19-24 (washout). On day 25 a 3 mm microdialysis probe (Carnegie-Medicin) was inserted into the holder and perfused at 1 uL/min with artificial csf; 2 hours later activity monitoring was begun and consecutive 20 min dialysis samples were collected. After 60 min of baseline monitoring and dialysate collection, each animal received 30 mg/kg i.p. cocaine; monitoring and dialysis continued for 240 min.

Behavioral sensitization to cocaine was present by Day 13, persisted through Day 18, and was not present on Day 25. Day 25 baseline DA and MVA levels in extracellular fluid (cef) were reduced 30% in the COC group, suggesting synaptic DA deficiency. Ecf DA levels rose to 340-360 % of baseline in both SAL and COC group; ecf HVA fell less in the COC group.

Total activity after cocaine in the SAL group was greater than in the GOU-group.

Sensitization to cocaine occurs in rats and does not persist after one week of drug withdrawal. 18 days of cocaine followed by 7 days of withdrawal.1) reduced baseline ecf DA and HVA Levels, suggesting synaptic DA deficiency; 2) decreased behavioral response with similar increase in ecf DA after cocaine rechallenge, suggesting decreased DA receptor function, and blunted the fall in ecf HVA, suggesting autoreceptor desensitization. (Supported by NIMM-PSA to CAL and NINOS-RCDA and NS26581 to JPB).

ACTIVITY OF NEURONS IN NUCLEUS ACCUMBENS DURING COCAINE SELF-ADMINISTRATION IN FREELY MOVING RATS. 1.Y. Chang, S.F. Sawyer,

SELF-ADMINISTRATION IN FREELY MOVING RATS. J.Y. Chang, S.F. Sawer, R.S. Lee, B.N. Maddux and D.J. Woodward, Dept. of Cell Biology and Neuroscience, Univ. of Texas Southwestern Medical Center, Dallas, TX 75235.

A consensus has evolved that the nucleus accumbens (NAc) plays an important role in rewarding behaviors, including drug self-administration. Most of the experimental studies to date have focused on pharmacological and behavioral aspects experimental studies to date have focused on pharmacological and behavioral aspects of this issue. The present study employed chronic extracellular recording techniques in a cocaine self-administration paradigm in rats to explore the physiological mechanisms that underlie cocaine self-administration. Two bundles of eight stainless steel teflon-insulated microwires were chronically implanted in the NAc of male Long-Evans rats (275-300 g) and silastic tubing was inserted in the right jugular vein. Single bar presses activated a pump that infused 1 mg/kg cocaine (in 0.1 ml PBS) into the jugular vein. Daily 3 hour experimental sessions were conducted over periods of 7 to 28 days. Approximately 30% of the neurons recorded in NAc responded to drug self-administration, with most neurons exhibiting a decrease in firing rate following cocaine infusion. In some animals, simultaneous recordings obtained from 3-4 NAc neurons revealed heterogenous but reciprocal anticipatory responses, with some neurons increasing impulse activity 10-20 seconds prior to bar pressing and other neurons seven also present when drug infusion was given randomly under computer control. The increase in firing rate observed during approach to the bar may be unrelated to locomotion since increased unit activity was not observed under computer control. The increase in tring rate observed during approach to the bar may be unrelated to locomotion since increased unit activity was not observed during treadmill-enslaved locomotion. The dopamine D_2 receptor antagonist, pimozide (0.25 mg/kg, i.p.), blocked the decreased firing in some NAc neurons after bar pressing, but had no effect on anticipatory responses that preceded bar pressing. These preliminary results suggest that the NAc may be involved in the processes that initiate or control cocaine self-administration and that dopamine receptor activation appears to play a role in the responses that follow cocaine infusion. LOCOMOTOR ACTIVITY INDUCED BY INFUSIONS OF COCAINE INTO THE CA3 REGION OF THE HIPPOCAMPUS: MEDIATION BY DOPAMINERGIC SUBSTRATES. H.O. Pettit, M.S. Hooks and J.B. Justice Jr.; Emory University, Department of Chemistry, Atlanta, Georgia 30322.

Studies have revealed that behavioral effects can be produced by infusions of cocaine into the nucleus accumbens, the medial prefrontal cortex, and (more recently) the CA3 region of the hippocampus. In a series of four experiments locomotor activity was examined following bilateral infusions of cocaine directly into the CA3 region of the hippocampus. In the first experiment infusions of cocaine into the hippocampus were found to significantly increase locomotor activity (0.0, 6.8, 13.6 and 27.2 μ g/0.5 μ L/cannula, F=13.5, df=3/24, P<0.0001). Significant effects were primarily produced by the 27.2 μ g dose. In a second experiment the increase in iocomotor activity produced by cocaine was not affected by bilateral 6-hydroxydopamine lesions of the nucleus accumbens (F=1.0, df=1/25, NS). The third experiment revealed that infusions of higher doses of cocaine into the CA3 region of the hippocampus can increase locomotor activity in a dose dependent manner (0.0, 25, 50 and 100 μ g/0.5 μ L/cannula, F=6.1, df=3/32, P<0.003). In the last experiment the administration of a dopamine antagonist (cis-flupentixol, 0.125 and 0.25 mg/kg, I.P.) blocked the hyperlocomotion produced by infusions of cocaine into the hippocampus in a dose dependent manner (F=15.5, df= 2/24, P<0.0001). Present pus in a dose dependent manner (r=15.5, di= 2/24, r<0.0001). Present findings indicate that the effects of cocaine in the CA3 region of the hippocampus can produce locomotor activity that is mediated by dopaminergic mechanisms. The parallel relationship between drug-in-duced locomotor activity and reinforcement indicates that reinforcing effects produced by infusions of cocaine directly into the hippocampus are possible and warrant further study.

ASSESSMENT OF CHRONIC COCAINE-INDUCED CHANGES IN ASSESSMENT OF CHANGE COCAINE-INDUCED CHANGES IN DOPAMINE MEDIATED BEHAVIORS DURING AND AFTER COCAINE TREATMENT. C.M. Joyner*, T.H. Lee*, E.H. Ellinwood, S.T. Cain. Dept. of Psychiatry, Duke University Medical Center, Durham, NC
Using electrophysiological techniques we have in the past demonstrated that

the dopamine systems undergo time dependent changes in sensitivity following chronic stimulant (amphetamine) administration. It is important to characterize these time dependent changes behaviorally; therefore, we have initiated an examination of various behaviors which allow distinguishing different groups of animals.

Male Sprague Dawley rats weighing 100 to 125 grams are pretreated with either continuous cocaine (40 mg/kg/day) via Alzet osmotic minipumps, daily cocaine injections (40 mg/kg/day) via Alzet osmotic minipumps, daily cocaine injections (40 mg/kg/day s.c.), or chronic saline. Following 14 days of pretreatment, these animals were behaviorally examined based on a number of rating scales developed in this lab as well as others. To assess development of sensitization or tolerance their response to cocaine was tested (20 mg/kg i.p.) the day after pretreatment and with apomorphine (80 µg/kg s.c.) seven days after withdrawal.

The daily injection group exhibits sensitization and the infusion group tolerance as shown by us and others in past studies. Our preliminary results show there are certain behaviors which may correlate with functional changes following differential modes of pretreatment. We will be presenting optimal drug regimes for producing sensitization versus tolerance as well as other distinguishing behavioral measures.

110.15

SELECTIVE DOPAMINE ANTAGONISTS DEVELOPMENT OF BEHAVIORAL SENSITIZATION TO APOMORPHINE. B.A.Mattingly, J.K.Rowlett, J.Graff*, and G.Lovell*.

Department of Psychology, Morehead State University, Morehead, KY 40351.

The purpose of the present study was to determine the involvement of specific dopamine receptor subtypes (D1, D2) in the development of behavioral sensitization to apomorphine. In 3 experiments, male rats received 10-21 apomorphine. In 3 experiments, male rats received 10-21 daily injections of a selective D1 (SCH23390) or .5 mg/kg IP) or D2 (sulpiride; 0, 30, or 100 mg/kg IP) antagonist followed by an apomorphine (APO; 0 or 1.0 mg/kg SC) injection. In 2 experiments, the rats were tested for locomotor activity in photocell arenas after the daily injections. In all experiments, the rats were tested for sensitization to APO following the subchronic pretreatments. The results indicated that APO produced a progressively greater increase in activity with each injection, and this APO-induced increase in activity was completely blocked by both sulpiride and SCH23390 treatments. However, although both sulpiride and SCH23390 ments. However, although both sulpiride and SCH23390 blocked APO-induced activity, only SCH23390 injections blocked the development of behavioral sensitization to APO. That is, rats treated with APO and sulpiride dis-played significant sensitization when subsequently tested with APO-alone. These findings suggest that the development of behavioral sensitization to apomorphine is related specifically to the stimulation dopamine Dl receptors.

110.17

EVIDENCE FOR INVOLVEMENT OF BOTH D1 AND D2 RECEPTORS IN MAINTAINING COCAINE SELF-ADMINISTRATION. Britton, P. Curzon and J.W. Kebabian, Neuroscience Research, 47U, Pharmaceutical Discovery, Abbott Laboratories, Abbott Park, IL 60064.

Laboratories, Abbott Park, IL 60064.

We have extended testing of the hypothesis that D1 receptors are involved in cocaine reward (Koob et al. 1987) by using the D1 antagonist A69024 which has high affinity for the D1 site and is highly selective relative to D2 as well as to 5HT1c sites (Kirkman et al., 1989). We have also extended the testing of D2 antagonists with YM-09151-2. Rats trained to self-administer cocaine (0.75 mg/Kg/infusion) on an FR-5 schedule were treated with selective D1 and D2 antagonists. The D1 antagonist, A69024 (2.5. 5.0 or 10.0 umol/Kg. sc) increased A69024 (2.5, 5.0 or 10.0 umol/Kg, sc) increased cocaine self-administration by 47, 71 and 56 % respectively. SCH-23390 (.007, .015 and .030 umol/Kg) increased self-administration by 16, 47 and 65%, respectively. Both D1 antagonists decreased responding in some animals at the highest dose tested. The D2 antagonist, YM-09151-2, showed a tested. The D2 antagonist, YM-09151-2, Showed a similar profile, increasing cocaine self-administration at doses of .003 and .01 umol/Kg and producing either further increases or suppression of responding at the dose of .03 umol/Kg. These data give further support to the hypothesis that both D1 and D2 receptors are involved in maintaining cocaine self-administration. self-administration.

FEFECTS OF HALOPERIDOL PRETREATMENT DURATION ON COCAINE INDUCED ACTIVITY. P.A. LeDuc and A.G. Golden. Dept. of Psychology, Austin Peay State Univ., Clarksville, TN 37040.

Three haloperidol (HAL) pretreatment durations produced different effects on cocaine induced locomotor activity measured in photocell cages. Rats were given IP injections of haloperidol (0.2 mg/kg) or bacteriostatic water (BW) for 6, 12, or 18 days prior to the start of testing with cocaine hydrochloride. All rats received cocaine (0.0, 7.5, 15.0 mg/kg) in a semi-randomized order, every other day for 36 days. Daily injections of HAL or BW were continued during testing. The animals that received 18 days of HAL pretreatment were significantly more active than the 18 day controls at the 7.5 and 15.0 mg/kg levels of cocaine. Neither 6 or 12 days of HAL pretreatment produced significant increases in activity. HAL injections were continued throughout cocaine testing. When the 6 and 12 day pretreatment groups reached a total of 18 days of HAL injections their cocaine induced activity levels were significantly lower than the group pretreated for 18 days prior to cocaine exposure. These findings suggest that the critical factor in the modification of cocaine induced activity with haloperidol is the pretreatment duration prior to but not following cocaine exposure.

Behavioral and cardiovascular effects of cocaine alone and in combination with the novel D1 antagonist SCH 39166. V. Research, Dept. of Pharmacol., Bloomfield, NJ 07003. Cocaine was studied alone and in combination with SCH 39166 in mice, rats and cebus monkeys in several test procedures. Cocaine produced stimulant effects in mice (10-30 mg/kg sc), rats (100-300 mg/kg sc) and monkeys (3 mg/kg sc) using either a locomotor activity monitor or observational measures. These effects were blocked by relatively low oral doses of SCH 39166 (0.3 - 3.0 mg/kg po), doses which had little if any behavioral effects on locomotor activity. Cocaine also produced dose-related increases in mydriasis, exophthalmus and lethality in rats (100-300 mg/kg sc), effects which could be blocked or delayed by SCH 39166. Cocaine given iv (0.02 -1.25 mg/kg) produced dose-related increases in diastolic pressure in conscious rats. Acute or chronic pretreatment up to two weeks with SCH 39166 did not potentiate or alter the pressor effect of cocaine. Potentiation of cocaine's effects or the emergence of new adverse actions were never observed under any of the different paradigms or species studied. Instead, SCH 39166 attentuated a number of behavioral and neurological functions produced by cocaine including lethality.

110.18

EFFECTS OF DOPAMINE RECEPTOR-SELECTIVE DRUGS IN RATS TRAINED TO DISCRIMINATE COCAINE FROM SALINE. J.L. Katz,

Baltimore, MD 21224 and Purdue Univ. West Lafayette, IN.
The involvement of dopamine receptor subtypes in the behavioral effects of (-)-cocaine was evaluated by the dopamine receptors to produce behavioral responses comparable to cocaine. Male, Sprague-Dawley rats were trained to discriminate 10 mg/kg (-)-cocaine HCl from saline (IP, 15 min prior) in a two-lever discrimination procedure. Both D1 and D2-selective agonists with diverse structures partially generalized to cocaine; these procedure. structures compounds produced responding that was not significantly different from that produced by either cocaine or saline. The D1 agonists studied were SKF 38393, SKF 75760, and CY 208-243. Dihydrexidine, a full agonist for induction of 208-243. Dihydrexidine, a full agonist for induction of adenylate cyclase activity, also partially generalized to cocaine. The peripherally-acting D1 agonist, fenoldopam, produced only minimal cocaine-like responding which was unrelated to dose. The D2 agonists tested were pergolide, quinpirole, (-)-NPA, N0434, and N0437. Neither the D2 antagonist haloperidol nor the D1 antagonist SCH 23390 consistently blocked the discriminative stimulus effects of cocaine. These results suggest that both D1 and D2 receptors may play a role in the discriminative stimulus effects of cocaine but that stimulation of either dopamine receptor subtype alone is not sufficient. receptor subtype alone is not sufficient.

THE EFFECTS OF INTRA-A10 PERTUSSIS TOXIN INJECTIONS ON COCAINE-INDUCED MOTOR ACTIVITY. <u>J.D. Steketee and P.W. Kalivas</u>. Department of VCAPP, Washington State University, Pullman, WA 99164-6520.

Behavioral sensitization to psychostimulants, such as cocaine or amphetamine, has been suggested to result from an alteration of the inhibitory control of A10 dopamine neurons. The inhibitory mechanisms consist mainly of dopamine D₂ autoreceptors and GABA_B receptors which are coupled via G proteins to K⁺ channels. Activation of the D₂ and GABA_B receptors leads to a hyperpolarization of the neuron. The G protein which couples the D₂ autoreceptors to K⁺ channels is reported to be pertussis toxin (PTX)-sensitive. In order to investigate the potential role of G proteins in behavioral sensitization, we injected PTX (1.0 μ g/ μ l, 0.5 μl/side) into the A10 region 2 weeks before testing the behavioral response to cocaine. Both saline control and PTX rats showed similar motor activity responses to saline. However, PTX rats exhibited a significantly greater motor activity response to cocaine relative to control animals receiving cocaine. In vivo microdialysis revealed that PTX rats had a significantly augmented release of dopamine in the nucleus accumbens which paralleled the augmented behavioral response to cocaine. Intra-A10 pretreatment with the GABA_B agonist baclofen, which has been shown to block the acute response to cocaine, was unable to block the cocaine response of PTX rats. These data suggest that PTX-sensitive G proteins may play an important role in the development of behavioral sensitization by in part uncoupling the GABA_B receptor from its G protein.

SUPERSENSITIVITY TO THE INITIAL REWARD PROPERTIES OF COCAINE FOLLOWING 6-OHDA LESIONS TO THE MEDIAL PREFRONTAL CORTEX IN RATS. S. Schenk, B.A. Horger, R. Peltier, K. Shelton* and H. Vercesi-Bonavera*. Dept. Psychol., Texas A&M Univ., College Station, TX, 77843.

Acquisition of intravenous cocaine self-administration (0.25, 0.5 or 1.0 mg/kg/infusion) was measured in separate groups of rats 14 days following either a sham or 6-Hydroxy-dopamine lesion to the medial prefrontal cortex. For sham rats, the dose/response curve was an inverted U with the 1.0 and 0.5 mg/kg doses supporting reliable self-administration. Reinforced response rates were reduced when 0.25 mg/kg was the available dose and there was a loss of discriminative responding suggesting that it was subthreshold for acquisition of self-administration. For rats that sustained a 70% depletion of dopamine in the medial prefrontal cortex, the dose/response curve was an inverse function across the entire dose range tested. They demonstrated good discrimination for all doses including 0.25 mg/kg/infusion, suggesting a supersensitive response to the initial reward effect of cocaine.

DRUGS OF ABUSE: COCAINE, SEROTONIN

111.1

TROPANE ANALOGUES INHIBIT COCAINE TOXICITY TO RAT FETAL 5-HT NEURONS IN CULTURE. V. Williams, E.C. Azmitia, X. Hou, D.I. Schuster, and R.B. Murphy. Depts. Biol. and Chem., New York University, New York, NY 10003.

Cocaine is toxic to fetal rat 5-HT neurons in primary dissociated tissue culture. Structural analogues of cocaine were studied as antagonists of its neurotoxicity. The selective 5-HT, antagonist ICS-205-930 at 10-9 M provided protection against cocaine toxicity (10-6 and 10-7 M) in cells treated 3 days in culture, whereas various other dopaminergic, adrenergic, and serotonergic antagonists did not. We synthesized a series of tropane analogues from tropanone and evaluated their activity in this system. Equivalent protection to ICS-205-930 was provided by 2-thienyl-tropan-2-ol and several indolyltropanones, which were potent at nanomolar concentrations. These results suggest that further refinement of structure-activity relationships within this series of compounds will produce even more highly potent antagonists of cocaine neurotoxicity. Supported by NIDA contract 271-87-8144 (ECA) and NIDA RO1 DA 05728 (RBM)

111.3

EFFECTS OF REPEATED COCAINE ON MONOAMINE TRANSPORTERS STUDIES IN VITRO WITH SEROTONIN AND DOPAMINE TRANSPORTER SUBSTRATES AND INHIBITORS R.S. Salah, M.J. Keegan*, B.N. Mathews*, E. A. Novak*, and M.P. Galloway, Lafayette Clinic, Cell. & Clin. Neurobiol. Prog., Dept. Psychiatry, Wayne State Univ Sch Med, Detroit MI

Repeated use of psychomotor stimulants such as cocaine (COC) or amphetamine (AMPH) produces a behavioral and neurochemical sensitization of DA systems to subsequent stimulant challenges. Additionally, recent behavioral studies suggest that increased 5HT neuronal tone decreases the rate of drug self-administration in rats. We sought to determine if repeated COC treatment in vivo (20 mg/kg/ip/day, for 7 days, 7 days off) altered either the 5HT or DA transporter by examining 1) the ability of transporter substrates (eg. (+)MDMA, AMPH) to release 5HT or DA from brain slices <u>in vitro</u>, and 2) the ability of transporter inhibitors (eg. COC) to block these effects. Expressed as percent control, striatal DA released by AMPH (0.3-10 µM) was greater in treated animals, whereas striatal 5HT released by AMPH was not altered. Similarly, AMPH induced 5HT release from cortical slices was not different. However, (+)MDMA induced 5HT release was enhanced in cortical slices obtained from treated subjects. The ability of cocaine to reverse either AMPH or TFMPP (a 5HT releaser) did not appear to be altered by the above treatment protocol. Although further studies are currently in progress, these preliminary data suggest that transporter function (ie the releasing effect of substrates) and the inhibition afforded by cocaine at its receptor may be differentially regulated by repeated treatment with cocaine. Further, enhanced releasability of SHT may be related to development of either tolerance or behavioral sensitization associated with DA systems. ALLOSTERIC MODULATION BY PAROXETINE OF THE $[^3h]$ COCAINE BINDING SITE ASSOCIATED WITH THE SEROTONIN TRANSPORTER IN GUINEA PIG BRAIN

H. C. Akunne¹, B. R. de Costa², A. E. Jacobson², K. C. Rice² and R. B. Rothman¹, ¹Unit on Receptor Studies,LCS, NIMH, Bldg 10, 3D41 Bethesda, MD 20892; ²Laboratory. of Medicinal Chemistry, NIDDK, Bethesda, MD 20892.

We studied the characteristics of [³H]cocaine binding in membranes prepared from whole guinea pig brain. Cocaine binding was specific and saturable. Binding surface analysis demonstrated that a two-site binding model fit better than a one-site binding model. The Kd values for [³H]cocaine were 15.2 and 650 nM with Bmax values of 183 and 1880 fmol/mg protein. In competition studies, serotonergic reuptake inhibitors (paroxetine, clomipramine, fluoxetine) were more potent than dopaminergic (GBR12909, benztropine, mazindol) or noradrenergic (desipramine) reuptake inhibitors. Both high affinity serotonin and dopamine uptake inhibitors produced dose-dependent wash-resistant (pseudoirreversible) inhibition of [³H]cocaine binding. However, serotonerigc uptake blockers were more potent than dopaminergic uptake inhibitors. The pseudoirreversible inhibition produced by paroxetine was due to an increase in the Kd of [³H]cocaine, accompanied by an increase in the dissociation rate of [³H]cocaine. These studies suggest that using membranes prepared from whole guinea pig brain, [³H]cocaine labels two binding sites associated with serotonin transporter and that paroxetine binds to a site which allosterically controls the conformation of the [³H]cocaine binding site.

COCAINE EFFECTS ON SEROTONIN AND DOPAMINE RECOGNITION SITES IN RAT BRAIN: IN VITRO AND IN VIVO STUDIES F. Tung, A.M. Bonadonna, P.A. Rittenhouse, E. Bakkum, L.D. Van de Kar. and G. Battaglia. Department of Pharmacology, Loyola Univ. of Chicago, Stritch School of Med., Maywood, IL 60153.

This study focuses on the in vitro and in vivo effects of cocaine at brain 5-HT and DA recognition sites. An in vitro pharmacological profile at these sites demonstrated that cocaine had an extremely low affinity (Ki > 100 uM) for striatal D-1 and D-2 dopamine receptors and cerebral cortical 5-HT₁ and 5-HT₂ serotonin receptors. In contrast, cocaine exhibited relatively high affinity for the uptake sites for DA (Ki=0.75 uM) and 5-HT (Ki=0.14 uM). To assess the effects of cocaine on the modulation of DA and 5-HT receptors, presumably via indirect actions on uptake blockade, rats were treated with cocaine (15 mg/kg, i.p. b.i.d) or saline for 7 days and sacrificed 36 hours after the last injection. With respect to dopaminergic systems, cocaine caused no change in D-1 receptors in cerebral cortex or striatum but slightly reduced the binding to D-2 receptors in striatum. DA uptake sites in the same brain region were unaffected by cocaine. Similarly, cocaine had no affect on 5-HT_1 or 5-HT_2 receptors in cerebral cortex or hippocampus. In contrast, cocaine significantly decreased 3H-paroxetinelabeled 5-HT reuptake sites, but only in striatum; no changes were observed in cerebral cortex, hippocampus or hypothalamus. These results provide preliminary data which suggest that cocaine may "down regulate" 5-HT transporters or may be toxic to striatal 5-HT axons and/or terminals. (Supported by NIDA DA 04865)

AUTORADIOGRAPHIC AND BEHAVIORAL ANALYSIS OF LONG-TERM EFFECTS OF CHRONIC COCAINE AND AMPHETAMINE. Steve Zeigler, Jack Lipton, and Gaylord Ellison. Dept of Psychology, UCLA, Los Angeles, CA, 90024. Rats were given continuous amphetamine(AMPH), or cocaine(COC) via subcutaneous pellets for 5 days, or were given five days of once-daily COC injections. 40 days after drug discontinuation, rats were observed after drug discontinuation, rats were observed in open field and then sacrificed for autoradiography. Coronal brain sections were prepared for autoradiography using the following receptor ligands: [3H]spiperone for D-2, [3H]SCH23390 for D-1, [3H]QNB for ACH, [3H]ketanserin for 5-HT2, [3H]5-HT for 5-HT1, and [3H] flunitrazepam for benzodiazepine. While AMPH rats did not differ from controls in open field behavior, they showed large reductions in S-2 binding in most brain regions. Chronic COC rats were the most fearful in open field, yet showed less dramatic reductions in 5-HT2 binding than AMPH rats, and only in selected regions.COC injection rats showed the least fear and highest activity in open field but did not differ from controls in 5-HT2 binding. No differences between groups were found for 5-HT1 receptor binding.Analysis of results for the other 4 ligands will be discussed.

111.7

COCAINE: BEHAVIORAL SENSITIZATION AND SEROTONIN (5-HT) IMMUNOREACTIVITY IN THE RAT FOREBRAIN. J.M. Paris, P.M. Callahan. I.M. Lee¹ and K.A. Cunningham. Dept. Pharmacol., Univ. Texas Med. Branch,
 Galveston, TX 77550; ¹Dept. Pathol., Mass. General Hosp., Boston, MA 02114
 With repeated exposure, rodents become sensitized to the motor-activating

properties of cocaine and amphetamine derivatives while humans develop psychoses and sensory hallucinations. Behavioral sensitization to cocaine appears to be associated with an enhanced sensitivity of 5-HT systems in the absence of any overt alterations in central 5-HT and metabolite levels. This is in contrast to some amphetamine derivatives which are 5-HT neurotoxins. The purpose of the present study was to assess whether behavioral sensitization is associated with perturbations of 5-HT-immunoreactive processes in the rat forebrain. Male Sprague-Dawley rats were administered (ip) either saline (1 ml/kg;N=10) or cocaine (15 mg/kg;N=11) twice daily for 7 days. Following the last injection, behavioral sensitization was expressed in cocaine (median:6, range:6-8) but not saline-treated rats (median:3, range:2-6; Kilby-Ellinwood scale; p<0.0002). Twenty-four hours following the final injection, rats were treated with pargyline (30 mg/kg, ip) 60 min prior to sacrifice and perfusion. 5-HT immunoreactivity was visualized in brain sections using a rabbit anti-5-HT antibody and an avidin-biotin peroxidase system. Behaviors and intensity of 5-HT immunoreactivity were scored by a rater blind to the animals' treatment. No consistent alterations in 5-HT fibers in cortex (frontal, cingulate, parietal), septum, hippocampus and striatum were observed in cocaine-treated rats. The data lend further support to the hypothesis that, al-though psychomotor stimulants share similar behavioral profiles, behavioral sensitization to cocaine is not associated with neurotoxicity of 5-HT neurons. Furthermore, we will show data to indicate that the variability of 5-HT fiber staining in control animals justifies the need for careful interpretation of drug-induced 5-HT fiber loss. DEVELOPMENT OF TOLERANCE TO ACUTE ADMINISTRATION OF COCAINE IN THE DORSAL RAPHE SEROTONERGIC NEURONS OF SUB-CHRONIC COCAINE-TREATED RATS. E.W. Black and J.M. Lakoski. Dept. of acology and Toxicology, Univ. of Texas Medical Branch, Galveston TX 77550 The effects of subchronic cocaine administration on serotonergic cell firing

in the dorsal raphe nucleus (DR) was examined using an in vivo, extracellular slice preparation. Male Sprague-Dawley rats were administered either cocaine or saline (30 mg/kg, ip) for a period of 7 days prior to experimentation. Following a washout period of 24 h, the rats were anesthetized and decapitated. DR slices (400 µm) were obtained using a vibrotome and were allowed to equilibrate in oxygenated ACSF (37°) for a period of at least 1 h. Recorded slices were superfused with ACSF containing 1 µM phenylephrine and 1 µM 5-hydroxytryptamine (5-HT). This concentration of 5-HT was found to inhibit basal firing rates of both cocaine and saline treated animals by 10.5% ± 2.23. In addition, inhibition responses to acute applications of 5-HT showed no differences between treatment groups and there were also no indications of a developed tolerance to 5-HT application. However, animals treated subchronically with cocaine do show an apparent tolerance to acute cocaine application as compared to saline controls. Animals treated subchronically with cocaine required an acute cocaine treatment of 5.5 \pm 0.5 μ M to inhibit firing by 50% versus 2.4 \pm 0.4 μM for saline controls. In both treatment groups, repeated superfusion of the slice with equal concentrations of cocaine produced a dose-dependent inhibition which remained constant with each application indicating no development of an acute tolerance to cocaine application. Finally, ligand binding studies using hippocampal tissue and the 5-HT $_{1A}$ specific ligand 8-OH-DPAT indicated that there were no differences in either the K_d or B_{max} between the treatment groups. In summary, these results indicate that the inhibitory effects of cocaine are not due to direct effects upon the presynaptic autoreceptor but are instead produced by its interactions with the 5-HT reuptake system. Supported by DA04296 and a Research Career Development Award from NIA to JML

LACK OF PROTECTIVE EFFECTS OF CHLORPROMAZINE (CPZ) ON 3.4-METHYLENEDIOXYMETHAMPHETAMINE (MDMA) INDUCED-NEUROTOXICITY ON BRAIN SEROTONIN (5-HT) NEURONS IN RATS. S.Y. Yeh, Neurobiology Laboratory, NIDA Addiction Research Center, Baltimore, MD 21224

MDMA, a ring-substituted derivative of methamphetamine (MA), is a potent neurotoxin. Mechanisms of MDMA-induced neurotoxicity are not CPZ has been shown to decrease the lethality induced by amphetamine (A) and stress, to prevent MA-induced depression of striatal tyrosine hydroxylase activity. Furthermore, CPZ has been used effectively to treat the poisoning of A, MA, and the interaction of meperidine and MAO inhibitors. The present study examined whether CPZ antagonized the toxic effects of MDMA in rats on brain serotonin neurons. ere injected with CPZ (10 mg/kg, i.p), or MDMA (10 mg/kg, s.c.), CPZ + MDMA (CPZ was given 30 min prior to the injection of MDMA) and saline every 12 h for 5 doses. The rats were killed at 24 h after the last injection and brain tissues were dissected. Monoamine levels in the brain tissues were assayed by HPLC-EC. 5-HT and 5-hydroxyindoleacetic acid concentrations in the frontal cortex and hippocampus were comparably decreased in the MDMA and MDMA + CPZ treated rats (60% of the saline decreased in the MDMA and MDMA + CPL treated rats (60% of the sainter or CPZ control group). No significant differences in brain indolamine levels were noted between CPZ- and saline-treated rats. These data suggest a lack of neuroprotective effects of CPZ on neurotoxic effect of MDMA treatment on brain 5-HT neurons in rats.

111.8

COCAINE INHIBITION OF SEROTONIN (5-HT) DORSAL RAPHE (DR) NEURONS: EFFECTS OF HABENULAR LESIONS. K. A. Cunningham, J. M. Paris, P. M. Callahan. Department of Pharmacology and Toxicology, University of Texas Medical Branch, Galveston, TX 77550.

Pathways which originate in and pass through the habenular nuclei provide a major source of regulatory afferents to mesencephalic 5-HT systems. Cocaine potently inhibits the activity of 5-HT DR neurons probably as a consequence of local reuptake blockade and potentiation of 5-HT somatodendritic autoregulatory processes. The purpose of the present study was to ascertain whether the suppressive effect of cocaine on the activity of 5-HT DR neurons may also be dependent upon the integrity of the habenula. Bilateral radiofrequency lesions of habenula were made in chloral hydrate-anesthetized rats. Conventional single-unit extracellular recording techniques were used to identify spontaneously-active 5-HT DR neurons 1-4 hrs post-lesion. Cocaine (0.125-2 mg/kg,IV) rapidly and reversibly suppressed cell firing (n=7; ID₅₀=0.54 mg/kg) in sham-lesioned and unoperated controls. In rats with habenular lesions and partial damage of the dorsomedial thalamus, the cocaine-induced depression (n=6; ID₅₀=3.75 mg/kg) was significantly attenuated [F(4,27)=2.99, p=0.036]. For example, cocaine at a dose of 2 mg/kg completely inhibited cell firing in control rats but elicited an average 40% depression in lesioned rats. The firing rate (# spikes/sec) observed in lesioned rats (1.33±0.55) did not differ from that of control rats (1.13±0.14). Electrical stimulation of habenula suppresses the spontaneous activity of 5-HT DR neurons. Thus, the present data suggest that the observed suppressive effects of cocaine may be mediated in part by a local action in habenula or via feedback pathways from limbic forebrain that relay or course through the habenula. SELF-ADMINISTRATION & NEUROTOXICITY OF 3,4-METHYLENEDIOXY-AMPHETAMINE IN RATS. L.E. Markert, D.C.S. Roberts. Department of Psychology, Carleton University, Ottawa, Ontario, KIS 5B6.

The reinforcing properties of 3,4-methylenedioxyamphetamine (MDA), a drug known to be toxic to the central serotonergic system of rats, have rarely been examined experimentally. The present study investigated whether rats would self-administer MDA and whether MDA would be neurotoxic at self-administered doses. were permitted access to MDA at doses of 0.25, 0.50, or 1.0 mg/injection on an FR 1 schedule of reinforcement for 5 hrs/day. Results showed that animals would selfadminister MDA in a dose-dependent manner and that after access to the drug for 5-7 days, 5-HT was depleted in the hippocampus but not the cortex. The data indicate that neurotoxicity is associated with MDA selfadministration in rats.

LOW DOSE EFFECTS OF 3,4-METHYLENEDIOXYMETHAMPHETAMINE (MDMA) ON BRAIN AMINE LEVELS. TH Champney and D Dischler*. Dept Anat, Coll Med, Texas ARM Univ, College Station, TX 77843-1114.

Acute and chronic injection of high doses of MDMA in rats markedly depress serotonin (5HT) and 5-hydroxyindoleacetic acid (5HIAA) levels and transiently alter dopamine (DA) and 3,4 dhydroxyhenylacetic acid (DOPAC) levels in numerous brain regions. Low dose, discontinuous administration of MDMA to rats has not been reported even though this is the primary type of administration utilized by humans. Singly housed male rats were injected at 1000 hr twice per week (on Mondays and Tuesdays) with saline or 2 mg/kg of ± MDMA (sc) for up to 8 weeks. Body weight was determined weekly and overt behavior after injection was noted. After two weeks, groups of saline- and MDMA-injected rats were killed 24 hr after the last injection (n=5/group). After eight weeks, groups of saline- and tDMA-injected rats were killed 3 hr, 12 hr, 24 hr and 48 hr after the last injection (n=5/group). Cortical, hippocampal, hypothalamic and striatal brain regions were collected and assayed for amine content by HPLC-EC. No differences in cortical and striatal 5HT levels were observed between the MDMA and saline treated rats. DA and DOPAC levels were depressed in the striatum 48 hr after the last injection (32 and 54%, p<0.01). 5HT levels were increased (p<0.05) in the hypothalamis (26%) and the hippocampus (33%) at the two week time point, while 5HIAA levels were depressed (34%, p<0.05) in the hippocampus 12 hr after the last injection. Hypothalamic 5HIAA levels were increased at 12 and 24 hr after the last injection (40 and 29%, p<0.05). Body weight was decreased slightly (F=6.2, p<0.05) in MDMA-treated rats with no major behavioral effects observed at this dosage. The observed changes in amine levels in this study are small compared to the major declines in 5HT content observed in previous studies utilizing high doses of MDMA. These results indicate that even smal

EFFECTS OF CHRONIC METHYLENEDIOXYMETH-AMPHETAMINE (MDMA) ON LOCOMOTOR ACTIVITY, LEARNING AND MEMORY, PAIN PERCEPTION AND MAINTENANCE OF BODY WEIGHT. D.B. Miller, K.F. Jensen and J.P. O'Callaghan. U.S. Environmental Protection Agency, Res. Tri. Pk., NC 27711

Acute and chronic treatment with MDMA produces serotonin (5-HT) depletions that last many months. 5-HT is involved in cognition, pain perception and feeding. Locomotor activity in home-cage monitors and figure-8 mazes, Morris-water maze learning, colonic temperature, tail-flick response, as well as body weight and associated food and water consumption were measured lasting functional alterations. Long- Evans male rats were administered MDMA by a chronic regimen (5 - 30 mg/kg, s.c., twice daily for 7 days). MDMA caused the development of doserelated hyperactivity during dosing but resulted in no permanent activity alterations. Morris-water maze acquistion and performance were not affected by prior exposure to MDMA. MDMA did not affect the tail-flick response during or after dosing. Body weight as well as food and water consumption were reduced during the period of dosing. Food and water consumption recovered after the cessation of dosing but no rebound feeding occurred. Thus, food intake and rate of weight gain were equivalent in MDMA and control rats in the period following dosing but body weights of MDMA rats were still below those of the controls 60 days after dosing. MDMA, like the known anorectic - fenfluramine, may alter metabolic set point. Supported by NIDA IAG ND89-4

EVIDENCE FOR THE NEUROTOXICITY OF METHYLENE-DIOXYMETHAMPHETAMINE (MDMA) USING A CUPRIC SILVER STAIN FOR NEURONAL DEGENERATION. K.F. Jensen, D.B. Miller, J.K. Olin*, and J.P. O'Callaghan. Neurotoxicology Division, U.S. Environmental Protection Agency and *NSI Technology Services Co., RTP, NC 27711

MDMA (80 mg/kg, s.c.) was administered to rats twice a day for 2 days and the animals were sacrificed by transcardial perfusion with fixative under deep pentobarbital anesthesia 48 hours after the first dose. Frozen sections of the brains were stained for degenerating terminals, axons and cell bodies with a recent modification of the DeOlmos cupric silver stain for neuronal degeneration. Evidence of neuronal damage was observed in frontal and parietal regions of the neocortex and included terminal and perikaryl degeneration in upper layers as well as axonal degeneration in both the upper and lower layers. These observations support the hypothesis that MDMA induces neuronal damage. This work was supported by NIDA IAG ND-89-4.

EFFECT MDMA ANALOGUES ON THE EXTRACELLULAR CONCENTRATION OF DOPAMINE (DA) IN THE STRIATUM AS MEASURED BY IN VIVO MICRODIALYSIS. J.F. Nash and D.E. Nichols.
Dept. of Psychiatry, Case Western Reserve Univ.,
Cleveland, OH 44106 & Dept. of Med. Chemistry & Chemistry &

Pharmacognosy, Purdue Univ., W. Lafayete, IN 47907.

The effect of the racemic mixture of MDMA (3,4-methylenedioxymethamphetamine) and its alpha- and N-ethyl analogues, MBDB and MDE, respectively, on the extracellular concentration of DA and its major metabolites DOPAC and HVA was measured in the rat striatum using in vivo microdialysis. Acute administration of these compounds increased the extracellular concentration of DA in the striatum. The rank order of potency of these drugs to increase DA concentrations was: ${\rm MDMA} > {\rm MDE} > {\rm MBDB}$. The concentrations of DOPAC and HVA were reduced following administration of these drugs. consistent with in vitro studies which demonstrate that extending the alpha-carbon and amine substitutions from methyl to ethyl groups decreases the effect of these phenethylamines on dopaminergic systems. The rank order of potency of these drugs to decrease brain serotonin content 7 days following a single administration was the same as that to increase the extracellular concentration of DA. These data are supportive of the hypothesis that DA may play a role in the serotonin depleting effects of these drugs. Suported by Ohio Board of Regents RIF(OBR).

SEROTONIN DEPLETIONS ARE NOT PREDICTIVE OF NEURO-TOXICITY: EVIDENCE FROM INCREASES IN GLIAL FIBRIL LARY ACIDIC PROTEIN INDUCED BY METHYLENDIOXY-METHAMPHETAMINE (MDMA) AND 5,7-DIHYDROXYTRYP-TAMINE (5,7-DHT). J.P. O'Callaghan, D.B. Miller, K.F. Jensen and C.J. Schmidt¹. U.S. Environmental Protection Agency, Res. Tri. Pk., NC 27711 and ¹Merrell Dow Research Inst., Cincinnati, OH 45215.

Astrocytes hypertrophy following chemical damage to the CNS and the hallmark of this response is enhanced expression of the intermedthe hallmark of this response is ennanced expression of the intermediate filament protein, glial fibrillary acidic protein (GFAP). In this study we used assays of GFAP to determine if MDMA is neurotoxic. Rats were administered MDMA by acute (20 mg/kg, s.c.) or chronic (5-30 mg/kg, s.c., twice daily for 7 days or 80 mg/kg, s.c., twice daily for 2 days) regimens. Another group of rats received the serotonergic neurotoxicant, 5,7-DHT (200 µg, i.c.v.) as a positive control. Rats were killed at intervals between 2 hours and 2 months post dosing. Brain halves were dissected into 4 - 6 regions and assayed for GFAP or serotonin (5-HT). Acute or chronic MDMA resulted in 5-HT of serotonin (3-H1). Active of cirronic MDMA resulted in 3-H1 depletions in all areas with decrements as great as 95% (striatum). GFAP was increased (50%) only in cortex and only after 4 x 80 mg/kg MDMA; 5-HT levels in cortex from the same rats were decreased by 60%. 5,7-DHT caused brain-wide decreases in 5-HT that were less than those seen with MDMA but it increased GFAP in several regions by as much as 50%. Long-lasting 5-HT depletions due to MDMA may not be indicative of neurotoxicity. Supported by NIDA IAG ND-89-4.

MDMA'S EFFECT ON THE FIRING RATES OF MEDIAL PREFRONTAL CORTICAL (mPFc) NEURONS IS MEDIATED THROUGH THE SEROTONERGIC (5-HT) SYSTEM. H.S. Pan and R.Y. Wang. Dept. of Psychiatry and Behavioral Science, SUNY, Stony Brook, N.Y. 11794.

The designer drug MDMA (3,4-methylenedioxymethamphetamine; "Ecstasy") enhances emotion and cognition but is nonhallucinogenic. It releases 5-HT and blocks its reuptake; it has a similar but less potent effect on the dopamine system. We used standard single unit recording and microiontophoretic techniques to study the mode of action of MDMA on mPFc cells of chloral hydrate anesthetized male Sprague-Dawley rats. When MDMA was given intravenously, it dose-dependently inhibited the majority (86%) of the mPFc cells (IC₅₀ = 5.3 ± 1.8 mg/kg, n = 12). A minority (14%) of the cells were modestly excited. The coadministration of 5-HT receptor antagonists such as metergoline and granisetron reversed majority (84%) of the mFrc cells (IC₅₀ = 3.3 ± 1.8 mg/kg, n = 12). A minority (14%) of the cells were modestly excited. The coadministration of 5-HT receptor antagonists such as metergoline and granisetron reversed the effect of MDMA. When administered directly onto the cells by microiontophoresis, MDMA inhibited the firing of mFrc cells (IC₅₀ = 27 nA, n = 10). In PCPA (p-chlorophenylalanine, 400 mg/kg, i.p., 24 hr before recording)-pretreated animals whose brain 5-HT levels had presumably been depleted, MDMA, either given intravenously or by microiontophoresis, failed to inhibit the neurons. In these PCPA-treated rats, the i.v. administration of 5-hydroxytryptophan (5-HTP, the immediate precursor of 5-HT; 50-200 mg/kg, n=4) but not L-DOPA (the immediate precursor of dopamine, 50-100 mg/kg, n=4) reinstated the inhibitory action of MDMA. In contrast, in AMPT (α-methyl-p-tyrosine, 250 mg/kg, i.p., 4 and 2 hr before recording)-pretreated animals whose brain dopamine content had presumably been depleted, MDMA inhibited the cells with an IC₅₀ of 2.2 ± 1.0 mg/kg (n = 5), which is not statistically different from that seen in control rats. The data suggest that MDMA affects the firing rates of spontaneously active mPFc cells indirectly via the release of endogenous 5-HT, not dopamine.

THE MECHANISMS OF NEUROCHEMICAL CHANGES INDUCED BY 4-METHYLAMINOREX (4-MAX)-A NEW STIMULANT OF ABUSE. C.F. Bunker, M. Johnson, G.R. Hanson, and J.W.GIBB. Dept. Pharmacology and Toxicology, University of Utah, Salt Lake Utah 84112

A-MAX is a new stimulant of abuse which has recently gained significant attention. Although classified as a Schedule I drug, little is known about its neurochemical or neurotoxic properties. We have reported that 4-MAX is an extremely potent convulsant in rats and mice; a single dose (10 mg/kg) of 4-MAX elicits an immediate dramatic rise in the dopamine metabolite dihydroxyphenyl acetic acid, and a decline in tryptophan hydroxylase (TPH) activity in striatal tissues 3 h after treatment. In order to determine the mechanism of 4-MAX-induced neurochemical order to determine the mechanism of 4-MAX-induced neurochemical changes, this drug was given as single or multiple (5 doses; 6-h interval) administrations. TPH activity which declined 3 h following a single dose (20 mg/kg) was completely reactivated to control enzyme activity by a 20-h preincubation in vitro under strong reducing conditions as has been reported for other amphetamine analogs. The neurotoxic properties of 4-MAX were assessed by evaluating TPH and tyrosine hydroxylase (TH) activity 7 d after both single and multiple doses. Following both treatment paradigms, striatal TPH activity declined significantly to approximately 80% of control but TH activity was unchanged. This long-term decrease in TPH activity likely reflects selective damage to serotonergic neurons; however, after single and multiple doses, 4-MAX does not appear to be as neurotoxic as MDMA or methamphetamine but may be comparable to MDE. (Supported by grants DA 00869 and DA 04222).

DIFFERING EFFECTS OF ACUTE AND CHRONIC COCAINE TREATMENT ON 5-HT2- MEDIATED HEAD-TWITCH RESPONSE IN MICE. N.A. Darmani¹, M.G. Hadfield² and B.R. Martin*¹. Departments of Phamacol/Toxicol¹. and Pathology², MCV/VCU, Richmond VA 23298.

Cocaine inhibits the uptake of dopamine (DA), norepinephrine (NE) and serotonin (5-HT) and is reported to be a more potent inhibitor at the 5-HT uptake sites than at the DA or NE sites. Radioligand binding studies have identified at least four types of 5-HT receptors (5-HT1, 5-HT2, 5-HT3 and 5-HT₄). Recently, we reported that acute cocaine administration inhibited DOI-induced 5-HT₂ receptor mediated head-twitch response(HTR). This inhibition appeared to result from the stimulation of the inhibitory α_2 and

5-HT_{1A} receptors.

5-MeO DMT was used to induce HTR in mice and the behavior was scored for 10 minutes post injection. 5-MeO DMT produced HTR in a scored for 10 minutes post injection. 5-MeO DMT produced HTR in a dose-dependent manner up to 16 mg/kg (i.p.). Higher doses did not further increase the behavior. For drug interaction studies a dose of 8 mg/kg 5-MeO DMT was used to induce HTR. After acute pretreatment, cocaine (1.2-20 mg/kg, i.p.) dose dependently inhibited HTR. Another group of mice was chronically treated with either cocaine (10, 20 and 40 mg/kg, i.p.) or saline twice daily for 12 days and once at 9:00 am on day 13. On day 13 (2-5 pm), the animals were injected with 8 mg/kg 5-MeO DMT, and the HTR was scored as above. The 10 and 20 mg/kg cocaine treated mice exhibited 2.6 and 1.7 times (p<0.05) more HTR than saline treated control. Although cocaine lacks affinity for 5-HT2 receptors, these data suggest that it does modify 5-HT2 receptor function differentially after acute and chronic administration. NIDA grants DA-02396 and DA-05274. acute and chronic administration. NIDA grants DA-02396 and DA-05274.

EFFECTS OF THE HALLUCINOGEN, DOI, UPON REGIONAL BRAIN ACTIVITIES OF RATS. B.E. Morton and F.M. Fujimoto*, Univ. of Hawaii School of Medicine Honolulu, HI 96822

Determining the mechanism of classic hallucinogens, such as LSD, has been difficult because they have affinities for several neurotransmitter sites. Recently, hallucinogens, such as DOB and DOI have been synthesized which have high affinity for only one neurotransmitter receptor, the 5HT2-5HTlc class, appearing to act as agonists, although there is conflict regarding this point.

agonists, although there is conflict regarding this point. In an attempt to determine the site of action of the potent hallucinogen, (+/-)-1-(2,5-dimethoxy-4-iodopheny1)-2-aminopropane HCl (DOI), we have used 2-deoxyglucose-1-14C (2DG) to measure its effects upon regional brain activities in rats. Ten min. after rats were injected, i.p., with 0.3 or 3.0 mg/kg DOI, they were injected with 125 uCi/kg 2DG, i.p. Both DOI concentrations caused back twitches. After 45 minutes, brains were removed and frozen. Autoradiograms of 20 um sections were prepared and film densities were quantitated at 30 brain sites.

As reported for LSD and 50H-0-Methyl DMT. DOI (0.3

As reported for LSD and 50H-0-Methyl DMT, DOI (0.3 mg/kg), caused a marked generalized reduction of brain glucose uptake, which was more pronounced at 3.0 mg/kg. Densitometric analysis of regional activity ratios is underway. Assuming the reductions of regional glucose uptake prove to be as globally uniform for DOI as for classic hallucinogens, one conclusion is that it is a on element in hallucinosis. The brain site causing this overall depression remains to be identified.

111 18

CHRONIC COCAINE MODIFIES GROWTH HORMONE RELEASE AFTER 5-Dax*. Addiction Res. Ctr., NIDA, Baltimore, MD 21224.

More growth hormone (GH) is released between 0500-0900

hr in human males who voluntarily abstain from cocaine use than in males who do not use cocaine habitually. To determine if the chronic administration of cocaine could alter GH release, we infused male Lweis rats with cocaine (1 mg/kg IV) or 0.15 M NaCl (0.1 ml/kg IV) every 12 min for 2 hr for 10 days. The rats were also injected with 5-hydroxytryptophan (10 mg/kg ip) 30 min after the last infusion on days 1, 5 and 10. Blood was removed from an industrial of days 1, 3 and 10. Blood was removed from an industrial jugular catheter before and after the session on these days and its GH content was determined.

A wide range of concentrations of GH were measured at each time, reflecting the operation of an independent circadian rhythm that in part governs its release. The pre-session concentrations of GH were similar in both groups of rats on each day. Post-session GH was reduced and less variable in cocaine-treated rats by Day 5, but did not differ from that of the 0.15M NaCl-treated rats. Although the administration of 5-hydroxytryptophan always markedly increased GH in both groups of rats, this response was significantly blunted (P < 0.03) by Day 5 in rats given cocaine. These results suggest that an alteration in responsiveness to serotonergic agents occurs in cocaine-treated rats.

BETA-ADRENERGIC ADAPTATION TO COCAINE: ROLE OF SEROTO-

Medical Sch., Houston, TX 77225.

There is little information about monoamine effects of repeated cocaine. Cocaine blocks reuptake of norepinephrine (NE), dopamine (DA), and serotonin (5HT), initially increasing synaptic concentrations of these Cocaine increases synthesis of DA and NE but decreases that of 5HT. Adaptation of NE or DA to repeated cocaine may be impaired by 5HT depletion. Repeated cocaine has been reported to increase beta-NE receptor (DHA) binding (24 h later) in brain, either from adapta tion to NE depletion during cocaine treatment, from NE decrease during cocaine withdrawal, or from 5HT depletion, which has been reported to increase, and to prevent adaptive decreases in, NE receptor binding. We have investigated the role of 5HT in effects of cocaine on NE receptors. Cocaine (9 mg/kg bid for 2 weeks) resulted (2 h later) in decreased metabolites of NE, DA, and 5HT, and increased beta-receptor binding in several brain regions. Treatment with the 5HT precursor 5-hydroxytryptophan prevented the cocaine-induced increase in DHA binding. There was no effect on MHPG, showing that the ability of cocaine to block NE uptake was not impaired. These data suggest that potentially increased sensitivity to NE develops during cocaine treatment and is prevented by treatments that enhance 5HT synthesis.

THE HYPOTHERMIC AND ATAXIC EFFECTS OF ETHANOL: EVIDENCE

THE HYPOTHISMIC AND ATAXIC EFFECTS OF EHMAND: EVIDENCE FOR MODULATION BY CENTRAL ALPHA2—ADRENOCEPIORS.

M.J. Durcan, R.G. Lister and M. Linnoila. Laboratory of Clinical Studies, NTAAA, Blglo 3Cl02, 9000 Rockville Pike, Bethesda, MD 20892, USA.

The hypothermic and ataxic effects of ethanol can be

attenuated by alpha₂-adrenoceptor antagonists in mice. The present study examined whether these effects are mediated by central or peripheral alpha₂-adrenoceptors. The administration of 1-10 mg/kg L 659,066, a selective alpha2-adrenoceptor antagonist which poorly penetrates the brain, had no effect on the hypothermia induced by a the brain, had no effect on the hypothermia induced by a 2.4 g/kg dose of ethanol or the ataxia induced by a 2.4 g/kg dose of ethanol. Whereas the centrally active antagonist atipamezole (1 mg/kg) significantly attenuated both ethanol-induced hypothermia and ataxia.

Many alpha2-adrenoceptor ligands have affinity for an imidazoline binding site in addition to the alpha2-adrenoceptor itself. In order to investigate the role the imidazoline binding site might play in attenuating the imidazoline binding site might play in attenuating ethanol's hypothermic and ataxic effects RX 821002, an alpha2-adrenoceptor with low affinity for the imidazoline binding site was compared with atipamezole. Both atipamezole (1 mg/kg) and RX 821002 (0.06-0.2 mg/kg) significantly attenuated the hypothermic and ataxic effects of ethanol. These results suggest that central alpha2-adrenoceptors and not the imidazoline binding site are implicated in the ethanol attenuating properties of alpha2-adrenoceptor antagonists.

112.3

OF GABA-STIMULATED 36CL FLUX PICROTOXIN AND DMCM IS NOT ALTERED IN CHRONIC ETHANOL RATS. D.W.Sapp, N.Kokka and R.W.Olsen. Dept. of Pharmacology, UCLA, Los Angeles, CA

Chronic exposure to ethanol increases the binding of benzodiazepine inverse agonists in cultured spinal cord neurons (Mhatre and Ticku, JPET,251:164, 1989). We examined whether the inhibition of GABA-stimulated ³⁶Cl flux by inverse agonists was also increased in the brains of rats chronically exposed to ethanol. In our model rats chronically exposed to etnanol. In our mount were intubated with 6 g/kg ethanol on an alternate capa-stimulated 36Cl day schedule for 3 months. GABA-stimulated $^{36}\text{Cl}^{-}$ flux was measured in brain microsacs of both control and chronic-ethanol rats. GABA (100 μM)stimulated flux was inhibited with the betacarboline inverse agonist DMCM or the antagonist picrotoxin, both at concentrations of 0.1-100 μM. The inhibitory concentration-dependence curves were similar in control and chronic ethanol rats, were similar in control and chronic ethanol rats, with IC50 of 1.0 µM for DMCM and 5.0 µM for picrotoxin. GABA stimulated ³⁶Cl flux by itself was also unchanged in the ethanol rats. These results indicate that sensitivity to picrotoxin or benzodiazepine inverse agonists was not increased in chronic ethanol rats when measured by Cl flux. Supported by Grant AA07680.

5-HT3 BUT NOT 5-HT2 RECEPTORS IN THE NUCLEUS ACCUMBENS MAY MEDIATE ALCOHOL DRINKING IN ALCOHOL-PREFERRING (P) RATS. A.D. Levy, J.M. Murphy, W.J. McBride, L. Lumeng*, & T.-K. Li*. Psychiatric Res. & Regenstrief Insts., Indiana Univ. Sch. Med., VAMC, & Psychology Dept., Purdue Sch. Science, Indianapolis, IN 46202.

Sch. Science, Indianapolis, IN 46202.

The serotonin (5-HT) system in the nucleus accumbens (ACC) has been implicated in ethanol (EtOH) drinking of P rats. To determine if 5-HT2 and/or 5-HT3 receptors in the ACC might be involved in regulating oral EtOH intake, adult female P rats (N=13-19/group) received bilateral microinjections into the ACC of ICS205-930 (5-HT3 antagonist; 0.1-0.5 ug/side), DOI (5-HT2 agonist; 0.1-1.0 ug), ketanserin (5-HT2 antagonist; 0.05-0.5 ug) or vehicle prior to scheduled 1-hr access to 10% EtOH. Food and water were always available. EtOH intake averaged 1.9 g/kg following vehicle injections. ICS205-930 (0.25 ug) increased EtOH drinking by 28% (p<.05), while the 0.5 ug dose did not alter EtOH intake, but reduced general motor activity. DOI (1 ug) reduced EtOH intake by 50% (p<.05). activity. DOI (1 ug) reduced EtOH intake by 50% (p<.05), but also disrupted ongoing activity. Lower doses did not alter drinking. Ketanserin did not alter EtOH consumption at any dose tested. The findings implicate ACC 5-HT3 but not 5-HT2 receptors in EtOH drinking of the P rat. (AA03243, AA07611, & AA07462)

IN VIVO MEASUREMENTS OF DOPAMINERGIC ACTIVATION IN BRAINS OF ALCOHOL PREFERING (P) AND NON-PREFERING (NP) RATS FOLLOWING ORAL SELF ADMINISTRATION OF ETHANOL. C.A. Cohen, E. Vavrousek-Jakuba, W.J. Shoemaker. Alcohol Res. Ctr, U. of Conn. Health Center, Farmington, CT 06032.

Dopaminergic activation has been shown to play a role in response of the organism to various drugs of abuse, including alcohol. In the present investigation we assessed in vivo dopamine D2 receptor binding in the nucleus accumbens (NA) and caudate-putamen (CP) of P and NP rats that have been trained to drink alcohol during a single daily 30 min. session. The experiment was divided into two phases. Phase one compared animals that received either water or a 10% ethanol solution. In Phase one compared animals that received either water or a 10% ethanol solution. In order to increase the amount of alcohol consumed, a solution of 10% sucrose and 20% alcohol was presented to the animals receiving alcohol during phase two. To assess dopaminergic activation after presentation and consumption of the experimental drink, 3H-raclopride was injected via the tail vein 10 minutes after the presentation of the drink. Rats were sacrificed 35 min later and receptor binding determined by liquid scintillation counting of tissue digests of the aforementioned brain regions. Binding in the cerebellum was used as a measure of nonspecific

A significant decrease in binding (reflecting a release and binding of the endogenous transmitter in response to the presentation and/or consumption of the ethanol drink) was observed in the NP rats when both phases were combined (NA: -23%; CP: =35%, p<0.05), but not in either phase in the P rat. While these data suggest that the NP rats were more responsive to the daily presentation of the ethanol drink (regardless of the presence or absence of sucrose), a 15% decrease in nonspecific binding found in the ethanol receiving NP rats may be a potential confound to this observation. To help clarify this issue, in vivo microdialysis experiments are currently underway.

ETHANOL STIMULATES [3H]5-HT ACCUMULATION BY RAT FOREBRAIN SYNAPTOSOMES: ROLE OF 5-HT RECEPTORS AND VOLTAGE CHANNEL BLOCKERS.

T. Alexi and E.C. Azmitia, Dept. of Biology, New York University. Serotonin (5-HT) has long been associated with alcohol consumption. We proposed that ethanol might have specific effects on serotonin accumulation in vitro.

We report that 54 mM ethanol enhanced the accumulation of [3H]5-HT by rat forebrain synaptosomes by 15-54% when applied acutely for 5-10 minutes at 37C. Increasing intracellular Ca*+ levels ([Ca⁺⁺]_i) with ryanodine and the 5-HT₂ receptor agonist, DOI, also stimulated 5-HT accumulation. In combination with etOH, these substances did not supplement the etOH-induced accumulation of 5-HT. The 5-HT₃ antagonist, ICS 205930, as well as lidocaine and tetrodotoxin (TTX), which all block voltagedependent Na+ channels, were shown to have no effect on the accumulation of 5-HT. Tetraethylammonium (TEA), which blocks voltage-dependent K+ channels, also did not alter 5-HT accumulation. ICS 205930 and TEA did, however, block ethanol's action on accumulation. These results indicate that etOH's stimulation of 5-HT accumulation is due to increased [Ca++], and not inhibition of voltage Na+ and K+ fluxes, although it is sensitive to these Na+ and K+ fluxes.

QUANTITATIVE AUTORADIOGRAPHIC ANALYSIS OF BRAIN DOPAMINE RECEPTORS IN ETHANOL-PREFERRING RATS. S. Sigala*, C. Missale, P. Rizzonelli*, E. Zanelli*, M. Memo, P.F. Spano. Inst of Pharmacol Exp Ther, Sch of Med, Univ of Brescia, Italy.

Activation of brain dopamine (DA) neurons is considered to mediate the reinforcing properties of drugs of abuse, including ethanol. An ethanol-preferring line of rats was obtained through selective breeding (20th progeny). This progeny of alcoholpreferring rats, which never consumed ethanol during their lifetime, were killed at the age of six months together with waterpreferring rats from the same progeny. The distribution and the density of brain DA receptors was evaluated in binding studies on brain slices followed by quantitative autoradiography. 3H-SCH 23390 was used to label D-1 receptors and 3H-spiroperidol to study D-2 receptors. The density of D-1 receptors was similar in the two rat populations. In contrast, the analysis of 3Hspiroperidol binding revealed a decreased density of 0-2 receptors in the hippocampus, nucleus accumbens and amygdala of ethanol-preferring rats; no changes were found in striatal D-2 receptor density. The selective decrease of D-2 receptors in the areas associated with the rewarding mechanisms of ethanolpreferring rats could reflect an altered activation of DA neurons leading to compulsive alcohol consumption.

THE EFFECT OF GLYCINE ON THE ETHANOL INHIBITION OF N-METHYLD-ASPARTATE INDUCED TRANSMITTER RELEASE IN THE CORTEX, HIPPOCAMPUS AND STRIATUM. L. M. Brown, R. A. Gonzales and S. W. Leslie, Institute for Neuroscience, University of Texas, Austin, Texas 78712.

The ability of glycine to reverse the inhibitory effects of ethanol on N-methyl-Daspartate (NMDA) stimulated catecholamine release was examined. Brain slices from the rat cortex and hippocampus were prepared and labelled with ³H-norepinephrine and the striatum was labelled with ³H-dopamine. The slices were washed extensively with Mg²⁺ free Krebs-Ringers bicarbonate buffer and the release of ³H transmitter release. The maximal responses (NMDA 1000µM) were 5.42±0.27, 7.72±0.18 and 1.61±0.20 percent fractional tritium released from the cortex, hippocampus, and striatum, respectively. The maximal responses were proportional to the number of NMDA receptors reported for each brain region. Ethanol (30-60mM) caused a concentration-dependent inhibition of NMDA-stimulated transmitter release. Ethanol (30mM) inhibited release by 10-12% and at 60mM inhibited release by 17-22% in all brain regions. Glycine, an NMDA coagonist, caused a concentration-dependent increase in ³H-catecholamine fractional release in the slice preparation. Glycine (3µM) enhanced release by 17-21% in the cortex and hippocampus and by 47% in the striatum. The ethanol-induced inhibition of NMDA-stimulated release was reversed by glycine in all brain regions. However, no apparent statistical interaction of ethanol and glycine was observed. These results indicate that ethanol was a potent inhibitor of NMDA-stimulated release of transmitter release in several brain regions. The glycine reversal of ethanol was confounded by the enhancing properties of glycine on NMDA-stimulated release of transmitter. RESPONSES OF CEREBELLAR GRANULE CELLS SHOW DIFFERENTIAL SENSITIVITY TO ETHANOL. <u>G.LIU*, R.HUANG* And C.HUANG.</u> Div. Structural & Systems Biol., Sch. Basic Life Sci., Univ. Missouri-Kansas City, Kansas City, MO 64110.

The cerebellum is very sensitive to acute intoxication of ethanol (ETOH). ETOH increases dramatically the discharge rate of climbing fibers, however, its effect on the mossy fiber system has not been fully elucidated. We have recorded granule cells (GC) from the cerebellum of cats under low (0.3g/kg, IV) and high (1.2g/kg, IV) dosage of ETOH. ETOH severely inhibited GC's responses to auditory and visual stimuli. Complete or maximal inhibition occurred in 5-8 min. Recovery followed a near exponential time course, reaching a plateau in 60-90 min. ETOH had a more severe inhibition on long-latency responses (>40 ms) than short-latency ones (<25 ms). Within a given animal, patches of GC's with long latencies were more resistant to ETOH than patches with shorter latencies. Acute tolerance to ETOH caused marked reduction and a faster recovery in the inhibitory effect of a second injection if the second injection was given within 4 hrs of the first one. Such acute tolerance was clearly seen in short-latency responses. (Supported by PHS grant AA07643.)

LITHIUM-INDUCED INOSITOL MONOPHOSPHATE ACCUMULATION AS SENSITIVE MARKER FOR ACUTE AND CHRONIC ETHANOL IN BRAIN. <u>Navidi M.*, Lin T-N.*, Sun G.Y.</u> Dept. Biochem., Univ. Missouri, Columbia, MO, 65203.

It has been well demonstrated by Sherman (1985) that systemic injection of lithium results in a large increase in inositol monophosphates (IP), namely Ins(1)P and Ins(4)P. In this study, a radiotracer technique together with lithium treatment was used to assess acute and chronic effects of ethanol on poly-phosphoinositide (PI) turnover in brain. Typically, inositol metabolites in brains of control and ethanol treated C57/BI mice were labeled with ³H-inositol for 16 hr. This was followed by injection i.p. of lithium (6 meq/kg) 4 hr prior to analysis. In some experiments, isomers of inositol phosphates were quantitatively analyzed by ion chromatography. Using this experimental protocol, the lithium-induced accumulation of labeled IP was suppressed in mice given an intoxicating dose of ethanol (6 gm/kg) via intragastric intubation. On the other hand, mice that were administered ethanol chronically and subsequently lithium 4 hr before analysis showed a higher level of labeled IP as compared to the pair-fed controls. Analysis of the inositol phosphates in lithium-treated ethanol and control brain samples by ion chromatography indicated large increases in Ins(1)P, Ins(4)P and Ins(1,4)P₂ with respect to lithium treatment and furthermore, with respect to chronic ethanol treatment. Results thus revealed a sensitive procedure for assessing the effects of ethanol in brain.

EFFECTS OF CHRONIC ETHANOL ADMINISTRATION ON MUSCARINIC ACETYLCHOLINE RECEPTORS ASSESSED BY QUANTITATIVE LIGAND AUTORADIOGRAPHY AND IN SITU HYBRIDIZATION HISTOCHEMISTRY IN LONG- AND SHORT-SLEEP MICE. S. Vincent, L. Tsiokas, S.C. Zhang*, S.P. Aiken, J.J. McArdle and M. Watson. U. of Med. and Dent. of N.J.- N.J. Med. Sch., Newark, N.J. 07103 Ethanol (ET) alters muscarinic function and differences

Ethanol (ET) alters muscarinic function and differences in muscarine acetylcholine receptors (mAChR) have been reported in long—and short—sleep (Is/SS) mice that are differentially sensitive to hypnotic effects of FT. Study of a specific nonsubtype selective antagonist [³H](-)quinuclidinylbenzilate, an M1 selective antagonist [³H]hpirenzepine, a partial M2 selective antagonist [³H]AF-DX 116, an agonist [³H](+)cis—methyldioxolane (that selectively labels a super high affinity agonist state), and a blocker of sodium-dependent high affinity choline uptake [³H]hemicholinium—3, were done as previously described. In situ hybridization histochemistry (ISSH) was done with oligonuclectide probe complementary to 4–48 or 4–51 base sequence of m1-m5 mAChR mRNA by 3'-end labeling by 35-dATP (specific activity>2.4x10°dpm/ug) by terminal deoxynuclectidyl transferase. Slices were hybridized (25°C;36h), washed (Tm=55°C;2xSSC), air—dried and apposed to Hyperfilm—Bmax (4Wk;0-4°C). Autoradiograms were quantified by DUMAS image analysis. ET-induced sleep time (IS;4g/kg,ip=131m v SS;5g/kg=78m & 3g/kg=0m) varied. By 7d ET (3.8%v/v;Liquidiet) Rx -50% tolerance was seen in IS and SS by respective 4 or 5g challenge dose. Low SS m3 mRNA and 14d ET Rx data on IS/SS mice may relate to differential ET sensitivity. MH-43024.

CHRONIC EXPOSURE OF CULTURED SEROTONERGIC NEURONS TO ETHANOL INCREASES SEROTONIN UPTAKE. D. K. Lokhorst and M. J. Druse The Neuroscience Program, Loyola U. of Chicago, Stritch Sch. of Medicine, Maywood, IL. 60153.

In order to determine how ethanol influences the development of serotonergic neurons, we cultured rhombencephalic neurons which were obtained from rats on the 15th embryonic day. After 2 days, ethanol was added to the culture media at a concentration of 50, 150 or 300 mg/dl. Following 4 days in the presence of ethanol, the uptake of ${}^{1}_{3}H^{1}_{1}_{1}_{2}$ -serotonin (5-HT) was determined in cultured cells. The effect of acute ethanol exposure on ${}^{1}_{3}H^{1}_{1}_{2}_{3}$ -5-HT uptake was also determined. In the latter studies ${}^{1}_{3}H^{1}_{2}_{3}_{3}$ -18 T uptake was measured in ethanol-naive cells, exposed to ethanol only during the uptake experiment.

The results of these experiments demonstrate that the presence of 50, 100 and 150 mg/dl ethanol in the culture media for 4 days significantly increased [³H]-5-HT uptake in developing rhombencephalic cells. The stimulation in [³H]-5-HT uptake occurred in a dose-dependent manner. In contrast, acute exposure of cultured rhombencephalic cells to 50, 100, or 150 mg/dl of ethanol had no effect on [³H]-5-HT uptake. Thus, it appears that exposure of embryonic rhombencephalic cells to ethanol for 4 days significantly alters the development of 5-HT containing neurons.

112.12

CHRONIC ETHANOL EFFECTS ON PROTEIN KINASE C IN MOUSE BRAIN CYTOSOL AND MICROSOMES. P.M. Wixom and G.Y. Sun. Dept. of Biochem., Univ. Missouri, Columbia, MO 65203.

C57/Bl mice were maintained on an ad lib liquid diet of flavored Sustacal containing 5% ethanol for 8 weeks. A pair-fed control group was given an isocaloric amount of sucrose. After 12 hr withdrawal, the cerebrum was homogenized and centrifuged to isolate the cytosol and microsome fractions. The samples were partially purified on a DE-52 anion exchange column prior to phosphorylation with ³²P-ATP. Lipid activation was assessed by adding oleoylacetylglycerol (OAG, 3 ug/tube) and phosphatidylserine (PS, 4 ug/tube) to the incubation mixture. Using this procedure for assay of protein kinase C (PKC) activity on endogenous substrates, we observed that chronic ethanol group had specific and different effects on the lipid activated kinase activity in cytosol and in microsomes. In the cytosol fraction, the total phosphorylation was significantly less in the ethanol-treated mice as compared to pair-fed controls. This effect was observed regardless of the presence or absence of Ca²⁺. Under this condition, OAG activation of kinase activity was unchanged but the PS enhanced kinase activation in cytosol was less in the ethanol group as compared to controls. On the other hand, ethanol administration did not alter the microsomal PKC activity. It is concluded that chronic ethanol administration results in specific alterations on the activation of PKC activity in brain.

DIFFERENCES IN GABA-A RECEPTORS STUDIED BY EXPRESSION OF LS/SS MOUSE BRAIN MESSENGER RNA IN XENOPUS OOCYTES. D.M. Burnett, T.V. Dunwiddie, J.M. Sikela, and R.A. Harris. Dept. of Pharmacology, Univ. of Colorado Hlth. Sci. Cent. and V.A. Med. Cent., Denver, Co 80262.

Alterations in the functioning of the GABA-A receptor/chloride channel complex have been implicated as a mechanism of action for ethanol (EtoH) and benzodiazepine intoxication. The genetically selected LS and SS lines of mice differ markedly in their sensitivity to EtoH. We used Xenopus oocytes to express whole brain mRNA from LS and SS mice in order to study genetic differences in the sensitivity of the GABA-A receptors to modulation by EtoH, diazepam and pentobarbital. Oocytes were injected with 100 ng of either LS, SS, or a 50/50 mixture of LS and SS whole brain mRNA. Following a 2-3 day incubation, GABA-stimulated chloride currents were recorded under voltage-clamp conditions (-90 mV). Drugs were applied by perfusion incubation, GABA-stimulated chloride currents were recorded under voltage-clamp conditions (-90 mV). Drugs were applied by perfusion. Application of GABA (10-100 uM) elicited inward currents of similar magnitude in LS-, SS- and LS/SS-expressing oocytes. Pentobarbital (100 uM) potentiated GABA-stimulated currents to the same extent (500-600% of control) across oocyte groups, as did diazepam at 10 nM (140%) and 100 nM (250%). With EtOH, however, genetic differences were seen. In LS oocytes, EtOH (20 mM) potentiated GABA-stimulated currents to 230% of control, whereas it attenuated them to 50% of control in SS oocytes. In oocytes expressing a 50/50 mixture of LS and SS mRNA, the effect of EtOH was not a summation of the opposing phenomena; rather, LS/SS oocytes responded in SS fashion (50% inhibition). These results suggest that protein(s) translated from SS mRNA alters the effects of EtOH on GABA-A receptors and that this protein can convert LS GABA-A receptors to "SS-like" when co-expressed. Supported by the VA and Grant AA06399.

CHRONIC ETHANOL EXPOSURE OF XENOPUS OOCYTES EXPRESSING MOUSE BRAIN MRNA REDUCES GABA RECEPTOR-ACTIVATED CURRENT AND BENZODIAZEPINE RECEPTOR LIGAND MODULATION. K.J. Buck and R.A. Harris. Dept. of Pharmacology, UCHSC, Denver, CO, 80262; Veterans Admin. Med. Res. Serv., Denver, CO, 80222.

Med. Res. Serv., Denver, CO, 80222.

Xenopus oocytes microinjected with exogenous total messenger RNA isolated from mouse cerebral cortex express a variety of neurotransmitter-activated channels. We found that exposure of Xenopus oocytes to ethanol (50 mM) for 2 to 4 days during expression of mouse brain mRNA reduced the amplitude of current activated by the GABA_a receptor-selective agonist, muscimol (100 uM). Muscimolactivated durrents were reduced from 164 ± 21 nA (control) to 61 ± 10 nA after ethanol exposure. Allosteric modulation of muscimolactivated current by flunitrazepam (benzodiazepine agonist) and DMCM (benzodiazepine inverse agonist) was also reduced in ethanol activated current by flunitrazepam (benzodiazepine agonist) and DMCM (benzodiazepine inverse agonist) was also reduced in ethanol treated oocytes. Flunitrazepam (1 uM) enhanced muscimol-activated current by $195\pm23\%$ vs. $95\pm24\%$ in control and ethanol exposed oocytes, respectively (p < 0.01); DMCM (100 nM) reduced muscimol-activated current by $61\pm5\%$ vs. $30\pm8\%$, respectively (p < 0.01). Currents activated by kainate, NMDA, acetylcholine, serotonin and glycine were not significantly reduced by ethanol exposure. These results indicate that ethanol exposure may selectively reduce expression of the GABA/benzodiazepine/ chloride channel complex. Supported by the VA and grant AA06399.

ARE ETHANOL-INDUCED DEPRESSIONS OF NEURONAL ACTIVITY MEDITATED BY A GABA, MECHANISM OF ACTION? Ronald K. Freund, Maan Yuh Lin, Craig G. van Horne, J. Timothy Harlan, and Michael R. Palmer, Dept. of Pharmacology, Univ. of Colorado Health Sciences Center, Denver, CO 80262

Biochemical and behavioral studies indicate that ethanol (ETOH) will facilitate the activation of the GABA_B Cl^{*} channel. However, in the present study, we found that ETOH, when locally-applied by pressure ejection from micropipettes, caused only modest and infrequent potentiations of the depressant effects of locally-applied GABA on cerebellar Purkinje neurons and that local ethanol applications required very specific conditions in order to observe this effect. Longer, low-dose applications of ethanol, which caused small depressions of neuronal activity, appeared to antagonize rather than to augment the GABA-induced depressions. Even so, bicuculline, a GABA_A receptor antagonist, reversibly blocked the depressant effects of pressure-ejected ETOH when locally-applied from the same micropipette, and this antagonism appears competitive with our techniques. These data might suggest that GABA mechanisms play a permissive role in the expression of ETOH-induced depressions of single-neuron firing rate in the cerebellum. In apparent contrast to this hypothesis, a preliminary investigation indicates that local applications of picrotoxin, an agent which blocks the chloride channel response to GABA_B activation, did not consistently antagonize ETOH-induced depressant vs more subtle effects of ETOH which may alter GABA mechanisms. (Supported by USPHS grants AA 05915 and AA 00102. JTH is currently in the Department of Pharmacology, Univ. of Arizona Col. Med., Tucson, AZ. MRP is supported by an ADAMHA Research Scientist Development Award.)

ANTAGONISM OF ETHANOL ACTIONS BY GABA, ANTAGONISTS. S.J. McQuilkin*, D.M. Burnett, A.M. Allan, R.A. Harris, Denver VAMC, Denver, CO 80222; Dept. Pharmacol., UCHSC, Denver, CO 80262; Washington Univ. Med. Sch., St. Louis, MO 63110.

The ability of the GABA, receptor antagonist, phaclofen, to block some behavioral effects of ethanol (motor activity, hypothermia), has been shown (Life Sci. 45:1771,1889). Saclofen and phaclofen were tested to see whether these GABA, antagonists could block the effects of ethanol on the GABA, receptor/chloride channel complex in brain membranes and Xegnopus oocytes expressing whole brain mRNA. GABA-dependent ³⁶Cl uptake measurements were performed as previously described (Life Sci. 46:527,1990) using ICR mouse cortical microsacs. Long-sleep mouse whole brain mRNA was injected into defolliculated oocytes and GABA responses were measured using 2 electrode voltage clamp conditions. In microsacs, saclofen (100µM) and phaclofen (100µM), significantly blocked ethanol (15mM) augmentation of GABA(5µM)-dependent chloride flux, without having any effect on the GABA response alone. In oocytes expressing brain mRNA, ethanol (20mM) stimulated GABA(10µM)-mediated currents 5 fold. This effect of ethanol was reduced by 100µM saclofen. Although saclofen and phaclofen completely antagonized the ethanol effects in microsacs, the same concentration of saclofen (100µM), antagonized teethanoement of GABA actions on oocytes produced by diazepam or pentobarbital. These studies suggest that activation of GABA₆ receptors is necessary for ethanol potentiation of chloride conductance through GABA, operated channels. The mechanism responsible for this interaction remains to be defined. Supported by the VA and grant AA06399. the VA and grant AA06399.

ETHANOL REDUCES RESPONSES TO DENDRITICALLY APPLIED NMDA IN CA1 PYRAMIDAL NEURONS IN RAT HIPPOCAMPAL BRAIN SLICES. W.R. Proctor and T.V. Dunwiddie, Veterans Administration Medical Services and University of Colorado Health Science Center, Denver, CO 80262

Ethanol has a biphasic excitatory/inhibitory effect upon the amplitude of the population spike response recorded in the CA1 pyramidal cell layer of hippocampal brain slices. The mechanism(s) underlying this effect are unclear: intracellular recordings from CA1 pyramidal neurons show minimal or no changes in passive membrane characteristics during superfusion with 50-100 mM ethanol. Ethanol also had no significant effect on EPSPs or GABAergic IPSPs. Interneurons were similarly unaffected by ethanol superfusion. Since inhibition of NMDA receptor function has recently been implicated in the depressant effects of ethanol on extracellularly recorded responses (Lovinger et al. J. Neurosci. 10:1372, 1990), we studied the effects of (Lovinger et al. J. Neurosci. 10:15/2, 1990), we studied the effects of superfused ethanol on responses to local pressure application of NMDA (5-10 msec, 30-60 psi) onto pyramidal cell dendrites. In medium containing 0-0.1 mM Mg⁺⁺, the amplitude and duration of the depolarizing response to pressure ejection of NMDA in stratum radiatum were reduced by 80 mM ethanol (28±7% and 24±11%, respectively). When the Mg⁺⁺ concentration was raised (1.3 mM), the NMDA response was smaller, but was still depressed by ethanol. These results suggest that synaptically evoked EPSPs and IPSPs are not affected by ethanol, but that responses mediated by NMDA receptors are reduced in this preparation.

LOW CONCENTRATIONS OF ETHANOL INHIBIT LONG-TERM POTENTIATION IN RAT HIPPOCAMPUS. R.D. Blitzer, O. Gil and E.M. Landau. Psychiatry Svce., Bronx VAMC, Bronx NY 10468

In humans, ethanol (EtOH) impairs memory at concentrations associated with mild intoxication. A possible mechanism for this effect is the suppression of long-term potentiation (LTP) by EtOH. EtOH blocks responses mediated by NMDA-Etoh. Etoh blocks responses mediated by NMDA-type glutamate receptors, and intact NMDA receptors are required for LTP in various brain regions. We tested the effects of Etoh (5-100 mM) on LTP in the Schaffer collateral - CA1 pathway using extracellular techniques. Etoh reduced LTP with an IC₅₀ of 13 mM, and even 5 mM Etoh had a significant depressant effect. In voltage-clamped CA1 neurons, EtOH blocked NMDA-induced currents with a similar potency ($IC_{50}=23\,$ mM). EtOH was also found to block a component of the tetanic field potential which is sensitive to the NMDA antagonist APV. The inhibition of LTP by EtOH was intact in picrotoxin, indicating that the effect does not depend upon GABAergic transmission. The results indicate that EtOH transmission. The results indicate that EtOH inhibits LTP at concentrations in the low clinical range, probably by interfering with NMDA receptor-mediated processes. Supported by NIAA Grant AA06659 and the VA Merit Program.

ANTAGONISM OF 5-HT3 RECEPTORS ATTENUATES THE EFFECTS OF ETHANOL ON DOPAMINE. K.M. Wozniak, A. Pert and M. Linnoila. LCS/NIAAA and BPB/NIMH Bethesda, MD 20892. Serotonin has been implicated as a modulator of dopaminergic neuro-

transmission (Cheeselet, 1984). Recently, the identification of 5-HT3 binding sites in brain (Kilpatrick et al. 1987) has prompted a number of interesting studies, the results of which suggest a role for this receptor subtype in modulating dopamine (DA) release (Blandina et al. 1988). 5suotype in modulating dopamine (DA) release (blandina et al. 1988). 5-HT is thought to have a role in alcoholism and the motor effects of ethanol (Rockman et al. 1982). Liljequist et al. 1981). Interestingly, Grant et al. (1990) have recently reported that 5-HT3 antagonists attenuate the discriminative properties of ethanol. Moreover, morphine and nicotine induced place preference has been attenuated by 5-HT3 antagonists (Carboni et al. 1988) as has morphine-induced dopamine increase (Imperato and Angelucci 1989). Ethanol has been shown to increase extracellular DA (Di Chiara and Imperato 1988, Wozniak et al. in press). We therefore chose to investigate the effect of pretreatment with 5-HT3 antagonists on this ethanol-induced DA increase. Animals were anesthetized and placed into a stereotaxic frame. A microdialysis probe was then positioned in the striatum or accumbens. Following the attainment of stable DA values (2-3 h), ICS 205-930 (500 µg/kg) or saline was administered s.c. After 1 h, a 3% v/v solution of ethanol was perfused for 20 mins through the probe. Pretreatment with ICS attenuated the subsequent ethanol-induced DA response when compared to saline treated animals. ICS alone had little or no effect on DA. These data provide evidence that 5-HT may be involved in the effects of ethanol on DA. Furthermore, they suggest a possible application for the use of 5-HT3 antagonists in alcoholism and substance abuse.

CHRONIC ETHANOL TREATMENT DIFFERENTIALLY EFFECTS AFFERENT RESPONSE PROPERTIES IN RAT HIPPOCAMPUS. B.S. Rottberg, C.T. Smothers and B.E. Hunter. Dept. of Neuroscience, University of Florida, Gainesville, FL 32610.

We compared afferent fiber response properties in stratum radiatum(SR) and stratum oriens(SO) of the rat hippocampus after chronic ethanol treatment(CET). Ethanol-treated(Group E) and sucrose control(Group S) groups were fed a liquid diet containing ethanol or sucrose for 20 weeks. An 8 week abstinence period was introduced prior to experimentation. Slices from the dorsal and ventral hippocampus were maintained in a slice chamber. Stimulating electrodes were placed in either SR or SO and a recording electrode was placed in the synaptic layer(afferent volley[AV]; dendritic EPSP) or in the pyramidal cell layer(population spike[PS]) of CA1. Responses to afferent stimulation were studied by systematically varying electrode distance at 100, 250 and 500 microns. CET increased the size of the AV with stimulation of SR but not SO. Plotting the EPSP as a function of AV showed that CET significantly reduced synaptic transmission in a regionally specific manner confined to the ventral hippocampus. Finally, CET increased PS amplitude but this was also dependent upon source of afferents. These results suggest that CET produces regionally specific alterations in afferent volley magnitude and in synaptic response strength which varies as a function of the afferent source and position in the hippocampus. The results demonstrate a selectivity in the toxic actions of ethanol and emphasize the potential differences in the adaptive properties of the hippocampal formation. EFFECT OF CHRONIC ETHANOL CONSUMPTION ON SYNAPSES OF THE DENTATE PSychology, University of Colorado, Boulder, CO 80309.

Long- and Short-Sleep mice (LSIBG; SSIBG) were divided in groups and fed for 4

months with either a control isocaloric liquid diet or with isocaloric liquid diet containing ethanol . They were withdrawn from this diet for 1 month. Subsequently, the mice were prepared for electron microscopy. The GABA terminals were labeled with antibodies against GABA using a gold probe in a postembedding protocol. Two types of synapses which are essential for transmission through the hippocampus were studied: the cross sectional area of dendritic spines in the dentate molecular layer (DML) and the number of GABAergic synapses on dentate granule cell bodies.

The population of dendritic spines in the DML was divided into groups of simple and

concave spines, and the average cross sectional area was computed for each group separately. The cross sectional area of concave dendritic spines in the distal third of the separately. The cross sectional area of concave dendritic spines in the distal third of the DML, projection zone of the perforant path (PP), of alcohol treated mice was significantly smaller (by 21%) than in controls. This change could be caused by ethanol effect on the actin based cytoskeleton of dendritic spines. This possibility is supported by the observation in cultured neurons that a low concentration of ethanol disrupts actin filaments and causes cells to shrink (Hassler and Moran, Experientia, 42:575, 1986). Shrinkage of dendritic spines could adversely affect synaptic transmission in these spines in the DML. Given that concave spines represent 25% of the entire spine population in the DML and given that synapses in the projection zone of PP represent the first synapse in the

given that synapses in the projection zone of PP represent the first synapse in the trisynaptic hippocampal circuity, this change, resulting from alcohol consumption, could seriously affect the flow of information into the hippocampus.

The density of GABAergic terminals was not affected by ethanol exposure. However, comparison between the LS and SS controls revealed significantly fewer (by 23%) GABAergic contacts on dentate granule cell bodies in the SS line. This observation is in line with the suggestion that the LS and SS lines differ not only in their sensitivity to ethanol but also in their respective GABAergic systems. Supported by NIAAA #AA06196.

LEARNING AND MEMORY: PHYSIOLOGY I

113.1

OPPOSITE ACTION OF DOPAMINE AND GLUTAMATE IN OPERANT CONDITIONING OF HIPPOCAMPAL CA1 CELLS. X. B. Gang* and Stein. Department of Pharmacology, UCI School

Medicine, Irvine, CA 92717.

Previous work indicates that hippocampal CAl bursting activity may be reinforced by local micropressure application of dopamine (lmM) or cocaine (0.5mM) (Neurosci. & Biobehav. Rev. 13:69-80, 1989). However, there is concern that these agents may act merely by direct or indirect pharmacological stimulation of bursting. One approach is to attempt to reinforce hippocampal bursting with a relatively nonspecific depolarizing agent, such as glutamate. Unlike dopamine and cocaine, burst-contingent applications of glutamate (0.1 and 0.2mM) did not produce selective facilitation of cellular bursting when compared to random presentations; indeed, both contingent and random glutamate applications reduced the likelihood of bursts, while at the same time greatly increasing the frequency of individual spikes. In a second approach, excellent reinforcement was demonstrated with the highly specific dopamine D2 receptor agonist N-0923 (3 and 6mM), but not with its much lower affinity optical isomer N-0924. These results are consistent with the idea that

dopamine's reinforcing action on hippocampal bursting cannot be attributed to nonspecific stimulation and is exerted at dopamine D2 receptors.

DISSOCIATION OF BEHAVIORAL STATE - DEPENDENT SYNAPTIC GATING AND EXPLORATION RELATED SYNAPTIC EFFICACY CHANGES IN RAT FASCIA DENTATA. E. J. Green. Department of Psychology, University of Miami, Coral Gables, FL 33124.

Environmental exploration is associated with a number of moderately persistent alterations in perforant path - evoked population responses, including a large increase in evoked EPSP slope, and a substantial reduction in both the onset latency and area of the population spike. These changes have a gradual onset, and decay relatively slowly following exploration. The magnitude of perforant path evoked responses also vary as a function of the animal's behavioral state at the time of the stimulus - a phenomenon originally described by Winson and colleagues. The present experiments were designed to evaluate possible interactions between these two types of synaptic efficacy change.

Baseline evoked responses, hippocampal EEG, and EMG from the dorsal neck muscles were recorded for 3 - 12 hours from rats in a soundproof chamber, which served as the animals home cage. Following the baseline period, animals were allowed to explore an open field containing junk objects for 20 minutes, and were then returned to their home cage for an additional 3 - 12 hours of recording. Baseline responses fluctuated in accordance with the animal's behavioral state at the time of the stimulus. Exploration resulted in gradual, though substantial (30 - 50%), increases in evoked epsp slope and decreases in the onset latency and area of the evoked population spike. Epsp and spike values observed following exploration were larger and smaller, respectively, than any observed over the 3 -12 hour period preceeding exploration. During the post-exploration period in the home cage, the momentary alterations associated with sleep/waking states were superimposed upon the exploration related changes in evoked response values. This was particularly evident for the evoked spike, which remained relatively depressed for hours, but continued t

EFFECT OF REVERSIBLE INACTIVATION OF THE HIPPOCAMPUS ON A DELAYED NONMATCHING TO SAMPLE TASK IN THE RAT: EVIDENCE FAVORING THE CONSOLIDATION OF WORKING MEMORY. Edwin J. Barea and Douglas C. Smith, Dept. Psychology. Southern Illinois University, Carbondale, IL 62901.

While evidence has been accumulating in favor of Olton's theory that the hippocampal system in the rat plays an important role in working memory (WM), the persistence of WM in a spatial memory task remains controversial. Indeed. Knowlton, McGowan, and Olton (1985) reported disruption of WM even after an 8 hr delay in rats tested in a DNMTS task in a radial arm maze following seizure o in dealy in raise tested in a DIMNI's task in a radial arm mazer onlowing selective stimulation of the hippocampi (HPC) and concluded that the time course for consolidation of WM is very long or that it never occurs.

We now report the within animal effects of reversible inactivation of the HPC via bilateral microinfusion of 2% lidocaine HCl administered at various delays

in a DNMTS task in an 8 arm radial maze. Eleven rats were allowed to freely choose the first four arms of the maze and then removed from the apparatus for choose the first four arms of the maze and then removed from the apparatus for 3, 5, 10 or 20 min prior to choice 5. Once criterion level performance had been reached at each delay, Ss were tested with HPC inactivation beginning immediately (3 min delay), 2 min (5 min delay), 7 min (10 min delay), or 17 min (20 min delay) following the competion of choice 4. Our results demonstrate a temporal gradient of disruption of WM. In choices 5-8 the mean number of errors was 4.00 (3 min delay), 3.27 (5 min), 2.18 (10 min) and 1.18 (20 min) indicating that the greater the amount of the time between the choices to be remembered and the disruption of the HPC, the better

the memory is preserved. Such results are most consistent with the idea that WM consolidates over a much more rapid time course than has been previously been suggested. (Support in part by NIMH 1 T32 MH-1882 to E.J.B.)

A NEW ROLE OF INHIBITORY HILAR NEURONS IN FEEDBACK CIRCUITRY IN THE DENTATE GYRUS/HILUS/CA4/CA3 AREA IN THE GUINEA PIG HIPPOCAMPAL SLICE <u>U. Misgeld and W. Müller</u> Dept. of Neurophysiology, Max-Planck-Institut für Psychatrie, Am Neurophysiology, Max-Planck-Institut Klopferspitz 18a, D-8033 Martinsried F.R.G.

In paired extra- and intracellular recording from the guinea pig hippocampal slice, picrotoxin (ptx) induced time-locked rhythmically nippocampal slice, picrotoxin (ptx) induced time-locked rhythmically ocurring bursts of repetitive population spikes in the CA3, CA4 and hilar region but no extracellularly recorded activity in the granule cell layer. 4-aminopyridine (4-AP) induced rhythmically occurring positive field potential waves in the CA3, CA4 and granular layer coincident to negative field potentials in the hilus. Under intracellular recording, ptx induced bursts in CA3, CA4 and hilar neurons, but only K-dependent slow IPSPs in granule cells. 4-AP induced rhythmically occurring bursts in hilar neurons or CI- and K-dependent IPSPs in CA3, CA4 and granule cells. These events were time-locked to field occurring bursts in hilar neurons or CI- and K-dependent IPSPs in CA3, CA4 and granule cells. These events were time-locked to field potential activity in the CA3 layer. Ptx-induced activity originated in the CA3 area and subsequently appeared in the CA4 and hilar region, whereas 4-AP-induced activity appeared simultaneously in all subfields. Blockade of fast glutamatergic excitation by CNQX blocked the ptx-induced activity, but was ineffective on 4-AP-induced activity. Focal application of tetrodotoxin between CA3 and CA4 blocked the ptx-induced activity in the CA4 and bills region. activity. Focal application of tetrodotoxin between CA3 and CA4 blocked ptx-induced activity in the CA4 and hilar region, but reduced 4-AP-induced activity in the CA3 area. This study reveals that hilar neurons are excited by CA3/CA4 pyramidal neurons in addition to the well known excitation by granule cells and perforant path fibers, and, in turn, hilar neurons inhibit CA3, CA4 and granule cells. HIPPOCAMPAL PYRAMIDAL CELLS "THETA-BURST" DURING BEHAVIORAL EVENTS CRITICAL TO OLFACTORY LEARNING. H. Eichenbaum, T. Otto, S. Wiener, & C.G. Wible, Dept. of Biological Science, Wellesley College, Wellesley, MA 02181.

Long-term potentiation (LTP), a lasting enhancement of synaptic efficacy which can be induced in many monosynaptic pathways, has been proposed as a candidate mnemonic device due to its similarity in induction, and maintenance, characteristics, to those of memory.

been proposed as a candidate mnemonic device due to its similarity in induction and maintenance characteristics to those of memory. LTP in the hippocampus is preferentially induced by high-frequency bursts of stimuli repeated at 5-10 Hz, the theta frequency (Larson et al, 1986), and can be induced by a single burst if a single "priming" stimulus precedes that burst by 130-170ms (i.e. at a frequency of 6-7 Hz; Rose et al, 1986). We now report that these optimal activation patterns, called "theta-bursting", occur naturally in the hippocampi of rats, time-locked to behavioral events associated with mnemonic

processing.

The firing patterns of a subset of hippocampal cells previously found to have significant nonspatial behavioral correlates in a simultaneous odor discrimination paradigm (Eichenbaum et al. 1989) were reanalyzed for evidence of theta-bursting. A burst was defined as the occurrence of at least 2 spikes with an interspike interval of no more than 10 ms; a cell was considered to theta-burst if it had a predominance of interburst-intervals between 85 and 140 ms (i.e. between 12 and 7 Hz). Of 16 cells reanalyzed, all exhibited significant bursting; 11 of these burst repetitively within the specified theta range. In all instances, the bursts were well time-locked to periods of odor sampling or to discriminative responses.

These data provide compelling evidence that the conditions optimal for inducing hippocampal LTP are indeed occurring in the hippocampus of behaving rats during behavioral events critical to mnemonic processing.

HIPPOCAMPUS AND WORKING MEMORY: CONTINUOUS CONDITIONAL DISCRIMINATION AND T-MAZE R.Q.Wan, K.Pang and D.Olton, Dept. of ALTERNATION. Psychology, The Johns Hopkins University, Baltimore, MD. 21218.

Hippocampal function in working memory was tested in two tasks. (1) In the continuous conditional discrimination (CCD), rats were trained to press one lever when the current stimulus (a tone or light) was same as the previous one (match trial), and another lever when those two stimuli were different (nonmatch trial). Three delays, 2.5, 10 and 20 sec, were imposed between stimuli. (2) In the T-maze discrete trial alternation task, rats were trained to alternate choices between arms of a T-maze. After preoperative training in both tasks, rats were given either a hippocampal (HPC) lesion by radio frequency current or a control operation. In the CCD task, during the first few weeks, a severe impairment was found in HPC group. The size of impairment was dependent on the delays and the ratio of match to nonmatch trials. In the CCD task, performance in HPC group recovered to normal within 4 weeks. In the T-maze task, a severe impairment endured during all 7 weeks of postoperative testing. These data indicate that the hippocampus is involved in spatial and nonspatial working memory. The dissociation of performance in CCD and T-maze alternation tasks suggests that the hippocampus may have a different role in these two tasks.

BEHAVIORAL CORRELATES OF HIPPOCAMPAL UNIT ACTIVITY IN AN ODOR-GUIDED DELAYED NONMATCH TO SAMPLE TASK. T. Otto. H. Eichenbaum. & C.G. Wible. Dept. Biological Science, Wellesley College, Wellesley, MA 02181

The delayed nonmatch to sample (DNM) task has been used extensively in studies identifying the neural pathways critical to visual memory in primates. Continuing efforts toward designing for rats tasks similar to those commonly used with primates have resulted in our development of an odor-guided continuous delayed nonmatch to sample (cDNM) task that is suited ideally to both behavioral and electrophysiological studies of memory in rats.

Successful performance in the cDNM task required the rat to remember across a variable intertrial interval the odor presented on the preceding trial, and respond for water reinforcement only if the odor presented on the current trial was different, i.e. a nonmatch. Individual odors were selected randomly from a finite set, and were presented equally often on match and nonmatch trials. Performance in this task decayed with increases in either delay (intertrial interval) or interference imposed by reducing the size of the odor set from which samples were chosen, demonstrating that performance in this task is sensitive to manipulations that increase memory demand.

Of 22 CA1 pyramidal cells recorded to date from rats performing cDNM, 4 exhibited differential responses during odor sampling on match versus nonmatch trials. Three cells increased in firing rate during correct but not incorrect responses. The remaining cells had no identifiable behavioral correlate. Additional unit data from this study-in-progress will be reported; these preliminary data suggest that hippocampal pyramidal cells exhibit striking nonspatial mnemonic correlates, and further that the hippocampus participates in the comparison among representations of previous and present experiences.

comparison experiences.

MEMORY-RELATED RESPONSES IN RAT HIPPOCAMPUS DURING LEARNING PLACE ASSOCIATED WITH REWARDING ICSS. M. Fukuda, T. Ono, T. Kobayashi* and E. Tabuchi*. Dept. Physiol., Fac. Med., Toyama Medical and Pharmaceutical Univ., Sugitani, Toyama 930-01, Japan Single unit activity in the rat hippocampal CAl field

was recorded in a cylindrical field (diameter, 1.5m; depth, 0.7m) to study its function in place learning and If the rat alternately visited one of a pair of particular hidden areas (reward areas), brain electrical stimulation was delivered to the lateral hypothalamus as reward. Some hippocampal cells fired when the rat was in a particular part of the field. When the positions of the reward areas, or illumination in the experimental room were changed, some of these cells indicated a similar place field, but others fired more irregularly. When colored paper covered part of the wall in the apparatus, the place field and behavior were disturbed. The behavior of ICSS recovered after a few trials. Reconstruction of the place field was well-correlated to recovery of behavior. The results suggest that hippocampal neurons might code some particular positions within the environment depending on visual information, and formation of a place field might be correlated with place learning.

FUNCTION OF MONKEY HIPPOCAMPAL NEURONS IN MEMORY AND RECOGNITION. T. Ono, R. Tamura*, K. Nakamura* and M. Fukuda. Dept. Physiol., Fac. Med., Toyama Medical and

Pharmaceutical Univ., Sugitani, Toyama 930-01, Japan Neuronal activity in the hippocampus of conscious monkeys was recorded during performance of operant feeding, drinking, and active avoidance tasks coupled to the presentation of objects having positive (reward), negative (aversion), or unfamiliar implication.

Of 837 neurons recorded in the hippocampus, 155

responded to the sight of certain object(s) and 82/155 neurons responded differentially to different objects. Some differential neurons responded predominantly to rewarding, aversive, or unfamiliar objects. Some differential neurons responded selectively to only one object or one category of objects. Fourteen neurons that responded predominantly to rewarding or aversive objects were tested in reversal or extinction learning. Even after reversal or extinction was behaviorally evident, 12/14 neurons maintained their original responsiveness to the rewarding or aversive objects.

The results suggest involvement of the hippocampus in the preservation and recognition of past information of

PLACE FIELDS ARE ALTERED BY NMDA ANTAGONIST MK-801 DURING SPATIAL LEARNING. K.B. Austin, W.F. Fortin*, and M.L.

Shapiro, Department of Psychology, McGill University, Montreal, Quebec. Single unit activity recorded from complex-spike cells in the hippocampus correlates with selective locations occupied by rats behaving in spatial environments. These place cells may encode and store relationships among spatial stimuli. Hippocampal neurons have synapses which show NMDA-dependent plasticity, and blocking NMDA receptors impairs spatial NMDA-dependent plasticity, and blocking NMDA receptors impairs spatial learning in naive animals, but not performance of the same spatial memory task in trained animals. If place cells encode spatial information during learning via an NMDA-dependent form of plasticity, then NMDA receptor blockade may alter place fields during spatial learning, but not after learning has occurred.

Single unit activity was recorded from CA1 cells in the dorsal hippocampus of rats traversing an enclosed chamber. The rats were either naive to the chamber or had a minimum of 4 prior 20 minute exposures. NMDA antagonist MK-801 (0.0625 mg/kg) or an equivalent volume of normal saline was injected i.p., and the same units were recorded again 30 min, 4h, and 6h later. Both naive and experienced rats given saline had stable place fields during all recording sessions. MK-801 altered place fields in naive rats, changing the location of the firing fields. In some cases, the changes in place fields produced by MK-801 diminished 6 h after drug administration; in other cases, the changes persisted. However, MK-801 did not alter place fields in experienced animals. Thus, spatial encoding in the hippocampus may require NMDA-dependent synaptic changes that establish stable place fields. After these synaptic changes occur, place field stability in a given spatial environment may no longer depend upon NMDA receptors.

EFFECTS OF THE NMDA RECEPTOR ANTAGONIST, MK-801, ON ENVIRONMENTALLY INDUCED PLASTICITY OF DENTATE GYRUS EVOKED POTENTIALS. S.D. Croll, P.E. Sharp and E. Bostock. Dept. Psychol., Queens Coll., CUNY, Flushing, NY 11367. Research has demonstrated environmentally in-

Research has demonstrated environmentally induced plasticity (EIP) of hippocampal dentate gyrus evoked potentials (EP). Other research has shown a role of the NMDA receptor in long-term potentiation (LTP). We tested the role of the NMDA receptor in EIP. Rats were chronically implanted with stimulating electrodes in the perforant path and recording electrodes in the dentate gyrus bilaterally. Fig. were recorded orant path and recording electrodes in the dentate gyrus bilaterally. EPs were recorded from freely behaving rats for 20 min/week for 4 weeks; rats received 0, .05, .08, or .10 mg/kg MK-801 s.c. 30 min prior to recording sessions in either an ascending or descending dose series. Results showed that MK-801 produced a significant dose-dependent reduction of EPSP enhancement. The effects of MK-801 on spike depression varied as a function of dose-series and time within a as a function of userseries and time within a session, suggesting a long-term effect of MK-801 on spike depression. There was no detected effect of MK-801 on behavior. Results suggest a role of the NMDA receptor in EIP, with differential effects of NMDA receptor antagonism on EPSP enhancement and spike depression.

A TOPOLOGICAL REPRESENTATION OF SPACE BY A REALISTIC

A TOPOLOGICAL REPRESENTATION OF SPACE BY A REALISTIC NEURAL NETWORK. R.U. Muller and J.L. Kubie Depts. of Physiology and Anatomy. SUNY-Brooklyn, Brooklyn, NY 11203 Place cells are hippocampal pyramidal cells that show location-specific firing. Each cell has a firing field; it fires only if a rat's head is in the field. Computer models have focused mainly on how location-specific firing arises and less on how the set of place cells represents local space. We are using a model that takes place cells as given to ask instead how the structure of space is represented in CA3. The model uses 2 properties of CA3 pyramids. 1) CA3 cells make direct excitatory synapses with each other (Miles and Wong, 1986). Contact probability is low for random pairs but constant over large areas of CA3. 2) Synaptic strength grows when the pre- and post-synaptic cells fire in closely in time (Miles et al, 1987). The modifiable synapses do not affect firing; they only integrate conjoint firings of pre- and post-synaptic units.

A first aim is to show that the synaptic strengths can reflect the connectivity of local space to give a topological representation. Synaptic strengths are zeroed and the rat's position is initialized. A probability of firing (P) is calculated from the spatial firing pattern of each cell. A cell fires if P is higher than a random number. The rat's position is updated from a record of real motions and firing is again determined. Synapses between cells that both fire within 250 msec are strengthened.

Synapses between cells with over-lapping fields should increase in strength, whereas synapses between cells with distant fields will stay weak. The encoding of distance by synaptic strength arises because rats cannot move fast enough to make cells with distant fields fire in close temporal order. We will show how synaptic strength varies with field distance and running speed. Our next step is to investigate how the connections can be used to guide the rat's behavior.

113.12

EFFECTS OF THE NMDA RECEPTOR ANTAGONIST, MK-801, ON LTP IN FREELY BEHAVING RATS. E. Bostock, S.D. Croll, and P.E. Sharp. Dept. Psychol., Queens Col., CUNY, Flushing, NY 11367.

The hippocampus has been shown to be involved

in learning and memory. Long-term potentiation (LTP), a candidate learning mechanism, can be induced by high frequency stimulation of the perforant path(PP)-dentate gyrus(DG) system of the hippocampus, resulting in LTP of the EPSP and population spike(PS) of the evoked potential. LTP of DG evoked potentials is attenuated by NMDA receptor blockade in both hippocampal slices and anesthetized rats. We tested whether the NMDA antagonist MK-801 would also attenuate LTP in freely behaving rats. Rats were chronically implanted with stimulating electrodes in the PP and recording electrodes in the DG. Thirty min prior to recording sessions rats were injected with vehicle or .1 mg/kg MK-801 s.c. They were then recorded from for 15 min followed by high frequency stimulation of the PP and 40 min of subsequent recordings. Vehicle injected rats exhibited LTP of both the EPSP and PS. MK-801 tended to reduce LTP of the EPSP (X=13%) and significantly reduced LTP of the PS (X=47%), indicating that DG LTP in freely behaving rats is dependent on the NMDA receptor.

113.14

ASSOCIATIVE LEARNING ENHANCES [3H]MK-801 BINDING IN RABBIT HIPPOCAMPUS.

ASSOCIATIVE LEARNING ENHANCES [\$^3\text{HjMK-801} BINDING IN RABBIT HIPPOCAMPUS. L.T. Thompson. S.N. Murphy. S.G. Brown. D.J. Luchins, and J.F. Disterhoft. Depts. of Cell, Molecular, & Structural Biology, Northwestern University Medical School, and of Radiology and of Psychiatry, University of Chicago, Chicago, IL.
Hippocampal neuronal plasticity in learning may involve specific neurotransmitters or receptor subtypes. Glutamate binding, either to receptors or to uptake sites, has been shown to increase in the hippocampus of blink-conditioned rabbits (Mamounas et al., 1984). The NMDA receptor has been implicated in induction of other forms of hippocampal neuronal plasticity, including LTP. Recently, AMPA binding to quisqualate receptors in hippocampus was reported to be increased in the hippocampi of trained rabbits, but no enhancement of NMDA receptor binding was found (Tocco et al., 1989). The present study tested the effects of learning on binding of the highly specific non-competitive NMDA receptor antagonist MK-801 (dizocilpine).

Young adult male rabbits (n=5) were trained using standard techniques (Disterhoft et al., 1977) in a delay-eyeblink paradigm to a behavioral criterion of 80% conditioned responses per daily block of 80 trials. Conditioned animals were matched with equal numbers of handled control and pseudoconditioned animals were matched with equal numbers of handled control and pseudoconditioned animals. Rabbits were scrifticed 24 br after completion of training, and whole hippocampi were removed and immediately frozen in liquid nitrogen. All biochemical assays were then performed blind. Membranes were prepared in a manner similar to that previously described (Reynolds et al., 1987), although with only a single freeze-thaw cycle. 100 µM glutamate and 30 µM glycine were added to all samples. Membranes were incubated for 4 hr to assure binding reached equilibrium. All saturated MK-801 binding assay data was pooled within groups and analyzed with the LIGAND analysis program.

No significant differe

A MONOCLONAL ANTIBODY FACILITATES ASSOCIATIVE LEARNING IN RABBITS. J.F. Disterhoft, L.T. Thompson, S.W. Conroy and J.R. Moskal. Depts. of Cell, Molecular, and Structural Biology, Northwestern Univ. Medical School, Chicago, IL and of Neurosurgery, Albert Einstein College of Medicine, Bronx, NY. Recent work in other laboratories has demonstrated that glycine allosterically modulates biophysical properties of the NMDA receptor. A monoclonal antibody to dentate gyrus (B6B21) that modulates NMDA receptors in a glycine-like fashion has been described. Like glycine, B6B21 enhances NMDA and glutamate stimulation of [3H]-TCP binding but has no effect on D-AP5 inhibition of binding. B6B21 significantly elevates LTP when applied to CA1 pyramidal cells in rat hippocampal slices (Moskal et al., Soc. Neurosci. Abst., 1989, 15: 202). It has been suggested that LTP and associative learning may share common cellular mechanisms. We thus evaluated the effects of B6B21 on associative learning. The behavioral task used was long-interval trace eyeblink conditioning in rabbits, which other work from our laboratory has shown is hippocampally-dependent (Moyer et al., Behav. Neurosci., 1990, 104: 241-250).

Rabbits were surgically implanted with bilateral ventricular cannulae and fitted

laboratory has shown is hippocampally-dependent (Moyer et al., Behav. Neurosci., 1990, 104: 241-250).

Rabbits were surgically implanted with bilateral ventricular cannulae and fitted with restraining headbolts. After recovery and habituation, rabbits received daily 5 μg infusions of B6B21 in ACSF (treated) or of ACSF (controls) delivered by micropump at a rate of 1 μg/μl/min. Trace conditioning [using a 100 ms duration, 6 KHz, 85 db tone CS followed after a 500 ms race interstimulus interval by a 150 msec corneal air puff US] commenced immediately after infusion for 80 trials/day. Training continued until a criterion of 80% conditioned responses was attained. Pilot studies on 3 matched pairs of rabbits showed that infusion of B6B21 reduced the time required to reach the behavioral criterion. Ongoing experiments indicate that B6B21 treated rabbits require at least one-third less training trials than controls to acquire the task. These data suggest that glycine modulation of NMDA receptors may be important in associative learning. Pseudoconditioning procedures will be used to evaluate changes in nonspecific behavioral excitability in B6B21 treated rabbits. A goal of these experiments is to determine if monoclonal antibodies which interact with NMDA receptors affect associative learning in inact behaving animals. Supported by the Office of Naval Research, contracts N00014-88-K-0399 and N00014-88-K-0430.

CHOLINERGIC DIAGONAL BAND LESIONS AND LIMBIC CORTICAL AND THALAMIC UNIT ACTIVITY DURING LEARNING IN RABBITS. Y. Kubota, T. Holmbo*, A. Poremba, E. Kang and M. Gabriel. Dept. of Psychol. and Beckman Institute, Univ. of Illinois, Urbana II. 61801.

Previously systemic injection of scopolamine impaired performance of discriminative avoidance behavior and reduced training-induced unit activity in AV thalamic nucleus and posterior cingulate area 29 (Henzi, V., et al. Br. Res., in press). To test whether the neuronal decrement was a source of the behavioral impairment, we attempted to specifically reduce cholinergic function in cingulate cortex by making electrical lesions in the nucleus of diagonal band of broca. Marked reduction of acetylcholinesterase in cingulate cortex later confirmed cholinergic depletion. Ablated rabbits trained to step in an activity wheel to a tone, predictive of footshock US, and to ignore another tone acquired the task at a normal rate, but made significantly fewer CR's than sham lesion controls. Effects of lesions on CR and UR measurements were smaller than but consistent with effects of cholinergic blockade by scopolamine, e.g. unaffected Ussensitivity. The brief-latency (1-100 msec) cingulate cortical unit response to CS was reduced, whereas limbic thalamic units responded more to CS in ablated rabbits than in controls. The lesions had no effect on unit activity in dentate gyrus. These data suggest that reduced cholinergic input disturbs brief-latency cortical and thalamic CS processing. The depletion-related CR impairment suggests that the altered processing interfered with CR-triggering information flow from thalamus to motor system. (Supported by AFOSR and NIH grants to M.G.).

CS-RELATED HIPPOCAMPAL UNIT ACTIVITY DURING AVOIDANCE CONDITIONING IN RABBITS. A. Poremba, Y. Kubota, E. Kanq and M. Gabriel. Dept. of Psychol. and Beckman Inst., Univ. of Illinois, Urbana IL 61801.

This study tested the hypothesis that hippocampal circuits not essential for conditioned response (CR) acquisition nonetheless engender a mnemonic representation of task events that is used for novelty-induced CR suppression (Gabriel, M. et al., Exp. Br. Res., 67:131-152, 1987). Multi-unit and field potential (FP) activity in dentate gyrus (DG), CA3, CA1 and posterior subiculum (PS) was recorded as the CR (stepping in an activity wheel to a tone CS+ to prevent a shock US 5 sec. later) was acquired. Latencies (ms.) of initial and peak unit discharges respectively were: DG:15,25; CA1:15,95; PS: 15,115; CA3: 15,155. Rapid associative change in all areas except PS was indicated by significant firing increases in the first conditioning session, relative to pretraining with unpaired CSs and US. Firing diminished with further training and virtually ceased as the CR reached asymptote. DG and CA1 units showed modest CS+/CS- discrimination. Brief-latency DG FP components replicated those found in rats (Deadwyler, S.A. et al., Science, 211:1181-1183, 1981). Elicited DG theta amplitude increased with training and discriminated during asymptotic CR performance as a positive 55-ms. discriminative FP component emerged in CA3. These associative changes, consistent with the preliminary hypothesis, provide a basis for analysis of CR suppression mechanisms. (Supported by NIH and AFOSR grants to MG).

LOCUS COERULEUS CELL ACTIVITY AND POTENTIATION OF THE PERFORANT PATH EVOKED DENTATE GYRUS POPULATION SPIKE. C. W. Harley and S. J. Sara. LPN2, CNRS, 91190 Gif/Yvette, France

Single and multiunit activity in the locus coeruleus (LC) of urethane anesthetized rats was monitored concomitantly with the dentate gyrus (DG) potential evoked by perforant path (PP) stimulation at .1 Hz. LC cell firing was decreased by iv injections of clonidine (6-12 ug/kg). The DG evoked potential was unchanged during the LC silence induced by clonidine. LC cell firing was increased by several means. Injection of glutamate (500 mM, 100 nl) characteristically produced a strong increase in firing for 10 sec. followed by loss of action potential height, probably due to depolarization block. Minutes after glutamate injection LC activity appeared to return to baseline levels (1.2 Hz). The abrupt increase in LC activity was invariably correlated with an increase in the DG population spike. Typically a long-lasting increase in the population spike followed these manipulations despite the return to baseline LC activity. Similar effects were seen with iv injections of idazoxan (2 mg/kg), Idazoxan ejected locally in the LC rarely produced increased firing but when it occurred the population spike also increased. Introduction of an iv catheter was seen to produce increased LC firing lasting 10-20 sec. and, again, the cell firing increase was correlated with an increased population spike, however tail pinch which briefly excited LC neurons (<1 sec) did not induce changes in the evoked potential. EPSP slope increases were observed in some experiments but were not invariable. These data suggest (1) that short-term increases in LC firing are not invariable. These data suggest (1) and short-relimine teases in Ec. liming are correlated with and, probably, initiate potentiation of the DG population spike if a sufficient number of cells are activated for periods of at least several seconds; (2) that long-lasting potentiation does not depend on continued LC activation and (3) that short-term absence of LC firing does not reduce the DG population spike.

HIPPOCAMPAL LESIONS, LIMBIC CORTICAL AND THALAMIC TRAINING-INDUCED UNIT ACTIVITY, AVOIDANCE CONDITIONING, AND RESPONSE TO DIFFERENT FORMS OF NOVELTY IN RABBITS. E. Kang, Y. Kubota, A. Poremba and M. Gabriel. Dept. of Psychol. and Beckman Institute, Univ. of Illinois, Urbana IL 61801.

Psychol. and Beckman Institute, Univ. of Illinois, Urban IL 61801.

Past studies have implicated cingulate cortex and limbic thalamus in mediation of discriminative avoidance learning, wherein a conditioned response (CR) of stepping in an activity wheel to a tone CS+ prevents a footshock US scheduled to occur 5 sec. after CS+ onset. Lesions of the subicular complex, the hippocampal origin of efferents to cingulate cortex and anterior thalamus (AT), increased the magnitude of AT training-induced multi-unit discharges in response to the CS+ and reduced the cingulate cortical unit discharges. In addition, CR frequency was enhanced in novel training stages (the first sessions of conditioning and extinction, Gabriel, M., et al., EXD. Br. Res., 67:131, 1987). Here we test a hypothesis that hippocampal lesions will mimic the effects of subicular lesions. As after subicular lesions, hippocampal lesions increased AT unit discharges to CS+. However, the hippocampal lesions enhanced the cingulate cortical unit activity and did not increase CR-frequency during acquisition or during extinction with the standard or with a novel CS. Context (illumination and odor) change which suppressed CR performance in intact rabbits failed to do so in rabbits with lesions. These results suggest functional independence of subiculum and hippocampus: subicular neurons deprived of hippocampal inputs are sufficient to mediate CR-suppression in response to CS alterations; hippocampus is however needed for CR-suppression in response to contextual alterations. (Supported by NIH and AFOSR grants to MG).

BILATERAL INJECTIONS OF MORPHICEPTIN INTO THE MEDIAL PREOPTIC NUCLEUS PRODUCE A DRAMATIC DELAY IN THE INITIATION OF SEXUAL BEHAVIOR IN THE MALE RAT.

. Matuszewich* and W.A. Dornan. Dept. of Psychology, Illinois Wesleyan University, Bloomington, IL 61702.

Behavioral experiments examined the role of morphiceptin in male rat copulatory behavior. Male copulatory behavior was recorded subsequent to bilateral injections of either 10, 500, or 1000 ng of morphiceptin aimed at the medial preoptic nucleus (MPN) of the medial preoptic area (MPOA) in sexually vigorous male rats. In the first experiment, all three doses of morphiceptin injected bilaterally into the MPN produced a dramatic delay in the initiation of copulation. Both mount and intromission latencies significantly increased following injections of all three doses of morphiceptin when compared to saline injected controls. No other parameter was affected. In experiment 2, the inhibitory effects of morphiceptin on male copulatory behavior were abolished by pretreatment with specific opioid receptor antagonists 20 minutes prior to intracerebral morphiceptin injections. This study represents an attempt at pharmacological characterization of the inhibitory effects of opioids on male rat sexual behavior. The results of experiment 1 indicate that mu receptors located within the MPN mediate the initiation of male rat copulatory behavior.

EVIDENCE TOWARD A ROLE FOR CENTRAL ANGIOTENSIN II IN THE REGULATION OF SEXUAL BEHAVIOR IN THE MALE RAT. L.S. Myers and M.K. Steele. Psychology Dept. CSUS, Stanislaus, Turlock, CA 95380 and Physiology Dept., Univ. of Calif., San Francisco, CA 94143.

A recent study has shown that intracerebroven-

tricular (ICV) administration of angiotensin II (AII) increased the number of intromissions and intromission latency as well as increasing the length of the postejaculatory interval (Clark, Physio. & Beh., 45:221, 1989). The present study investigated the role of central AII in sexual behavior by using a specific AII receptor blocker, sarthran, and observing sexual behavior. After preliminary mating tests, rats were implanted with third ventricular cannulae. Only those rats that Testing was started an hour and a half intolights on. Using a counterbalanced design, rats received ICV injections of either sarthran (10ug/10ul) or vehicle immediately prior to mating tests. Sarthran injections significantly increased the number of mounts, while significantly decreasing the intromission latency. No other sexual behaviors were affected. These data suggest that the brain renin-angiotensin system may be playing a role in the regulation of sexual behavior in the male

114.5

ROLE OF CALCIUM IN THE EXPRESSION OF ACTH-INDUCED ROLE OF CALCIUM IN THE EXPRESSION OF ACTH-INDUCED STRETCHING, YAWNING AND PENILE ERECTION. A. Argiolas, M.R. Melis, R. Stancampiano* and G.L. Gessa*. B.B. Brodie Department of Neurosciences, Univ. of Cagliari, 09124 Cagliari (Italy). The effect of \(\Omega-conotoxin \) GVIA, a potent and selective inhibitor of N-type calcium channels and of the organic calcium channel inhibitors

nimodipine, verapamil and flunarizine, on stretcnimodipine, Verapamil and flunarizine, on stretching, yawning and penile erection induced by ACTH 1-24 was studied in male rats. Conotoxin (1-10 ng ICV 15 min before ACTH, 10 µg ICV) induced a dose-dependent prevention of all ACTH effects. In contrast, organic calcium channel inhibitors (20 mg/kg IP 30-60 min before ACTH) failed to modify ACTH-induced stretching and yawning but induced a 15% document in the number of penile erection 25% decrease in the number of penile erection episodes induced by the peptide, and prevented, like ICV conotoxin, oxytocin- and apomorphine-induced yawning and penile erection. When injected in the paraventricular nucleus of the hypothalamus, conotoxin prevented the above responses induced by appropriate and oxytocin but not by thalamus, conotoxin prevented the above responses induced by apomorphine and oxytocin but not by ACTH 1-24. The present results suggest that ACTH induces stretching, yawning and penile erection by mobilizing calcium through central ω -conotoxin-sensitive calcium channels in brain sites different from those sensitive to oxytocin and apomorphine.

114.2

THE EFFECTS OF INTRA-AMYGDALOID β-ENDORPHIN INFUSIONS ON THE SEXUAL BEHAVIOUR OF THE MALE RAT. A. McGregor and J. Herbert, Department of Anatomy, Cambridge University, Cambridge CB2 3DY, U.K. β-Endorphin infused into the amygdala of the male rat lengthened the

p-Endoppini infused into the amygdala of the male rat lengthened the intromission latency of the copulatory series in a dose dependent manner, but had no effect on the ejaculation latency itself or the post ejaculatory interval. This effect was naloxone (Smg/kg i.p.) reversible at the 60 pmol dose. Corticotropin releasing factor (CRF) infused into the amygdala had no effect on either the intromission latency or the ejaculation latency of the copulatory

To investigate the role of female specific information processing in the response, the first intromission of the series was allowed to proceed, followed response, the first intromission of the series was allowed to proceed, followed by a 60 pmol β -endorphin infusion before replacing the male with either the original female or a different female. The effect on the intromission latency following replacement was measured. When replaced with the original female β -endorphin had no effect on the intromission latency (i.e. on reinitiation of the copulatory series). However, when β -endorphin was infused prior to the replacement with a different female, the intromission latency was increased. This effect implies that the "newness" of the novel female is registered when β -endorphin is acting within the amygdala, but that the female specific information cannot be employed appropriately to engage the copulatory series immediately. immediately.

These results suggest that β -endorphin within the amygdala prohibits the incoming female specific information from gaining access to the neural circuitary responsible for initiating the copulatory series, or prevents the information from being classified appropriately within the amygdala itself. Furthermore, the lack of response following the action of another stress related peptide (CRF) suggests that the effects of β -endorphin on sexual behaviour are not part of a more global stress response

PREVENTION BY W-CONOTOXIN GVIA OF PENILE ERECTION AND YAWNING INDUCED BY APOMORPHINE AND OXYTOCIN.

PREVENTION BY ω-CONOTOXIN GVIA OF PENILE ERECTION AND YAWNING INDUCED BY APOMORPHINE AND OXYTOCIN.

M.R. Melis, R. Stancampiano* and A. Argiolas.

B.B. Brodie Department of Neurosciences, Univ. of Cagliari, Via Porcell 4, 09124 Cagliari (Italy).

The effect of the administration of ω-conotoxin GVIA on penile erection and yawning induced by oxytocin or by the dopaminergic agonist apomorphine was studied in male rats. Conotoxin, 1-10 ng given ICV 5 min before oxytocin (30 ng ICV) or apomorphine (80 μg/kg SC), but not its carboxymethylated (CM) derivative, prevented the above behavioral responses in a dose-dependent manner. Conotoxin (5 ng) unilaterally injected in the paraventricular nucleus of the hypothalamus (PVN), prevented penile erection and yawning induced by the microinjection of oxytocin (10 ng) or apomorphine (50 ng) in the PVN. ω-Conotoxin injected in the PVN, but not in the preoptic area, prevented also penile erection and yawning induced by systemic apomorphine (80 μg/kg SC). ICV ω-conotoxin was unable to prevent stereotypy induced by apomorphine (500 μg/kg SC). The present results provide further evidence that calcium plays a major role in the expression of penile erection and yawning and that apomorphine and oxytocin induce these behavioral responses by mobilizing calcium through ω-conotoxin-sensitive (N type) calcium channels. (N type) calcium channels.

NEUROPHYSIN PROJECTIONS FROM THE PARAVENTRICULAR NUCLEUS OF THE HYPOTHALAMUS TO LOWER LUMBAR SPINAL CORD AND THE DISTRIBUTION OF NEUROPHYSIN FIBERS IN THE REGION OF THE SPINAL NUCLEUS OF THE BULBOCAVERNOSUS. C.K. Wagner and L.G. Clemens, Neurosci. Prog. & Dept. Zool., Mich. State Univ., E.Lansing, MI 48824

The paraventricular nucleus (PVN) of the hypothalamus projects to the sexually dimorphic segments of the spinal cord, L5-L6 (Soc. Neurosci. Abstr. 15: 1089, 1989), which contain the afferents of the sensory pudendal nerve and the motor nuclei responsible for penile reflexes (J. Comp. Neurol. 248: 532, 1980). Neurophysin (NP) is found in fibers and terminals throughout the spinal cord and the PVN is the major source of neurophysin in the CNS. The present study examined the presence of NP in neurons of the PVN that project to L5-L6 segments of spinal cord, as well as the distribution of NP fibers in this region of the cord. Male rats received 0.5µl 4% Fluorogold into segments L5-L6. Following 1-2weeks, animals were perfused and immunohistochemistry for NP was performed on 30 µm sections through PVN. Double labelled neurons were found within the dorsal and lateral parvocellular subnuclei of PVN. In other male rats, 30µm sections through the lumbosacral enlargement were reacted for NP immunohistochemistry. NP fibers and terminals appeared to contact motoneurons within the spinal nucleus of the bulbocavernosus (SNB). Fibers were also found in the sympathetic nucleus in the lateral funiculus, at the lateral, medial and dorsal edges of the dorsal gray matter and in the dorsal horn between the central canal and the dorsal funiculus. These results demonstrate that oxytocin and/or vasopressin fibers, thought to arise from the PVN, are found in regions of the dorsal horn known to contain afferents from the sensory pudendal nerve and may directly modulate the activity of SNB motoneurons.

ELECTROPHYSIOLOGICAL RESPONSES OF PERIAQUEDUCTAL

ELECTROPHYSIOLOGICAL RESPONSES OF PERIAQUEDUCTAL GRAY NEURONS OF FEMALE RATS TO LHRH, SUBSTANCE P, OXYTOCIN, AND TRH IN VITRO. Sonoko Ogawa, L.-M. Kow & D.W. Piaff. The Rockefeller University, New York, NY 10021.

Lordosis behavior of estrogen-primed females rats and other behaviors are modified by certain neuropeptides in the periaqueductal gray (PAG). To study possible roles of neuropeptides in neural circuitry for female reproductive behavior, responses of PAG neurons to LHRH and substance P (SP), which facilitate lordosis in PAG, and also oxytocin (OT) and TBH was accorded in burin tierus elicer reproductive. and TRH were assessed in brain tissue slices prepared from estrogen-treated (OVX+E) or nontreated (OVX) ovariectomized females rats. treated (UVA+E) or nontreated (UVA) ovariectomized remales rats. Extracellular single-unit activity was recorded and changes in spikes/sec were analyzed. Responses to all four neuropeptides tested were virtually all excitatory. Both spontaneously firing neurons and silent neurons were affected. SP was most effective for exciting PAG neurons, and effectiveness was similar in OVX-E (29/48 cells) and OVX (25/34 cells) preparations at 10 M. OT and TRH were less effective than SP, and responses to them appeared to be affected by estrogen. OT tended to excite more neurons in OVX+E (19/45 cells) than in OVX (6/23 cells). In contrast, TRH tended to excite more neurons in OVX (10/13 cells) than in OVX+E (13/29 cells). LHRH was the least effective neuropeptide for direct excitation. It excited only a few PAG neurons even at 10°M and the magnitude of the changes only a few race neurons even at 10 M and the magnitude of the changes was small. Orderly dose-response relations in terms of the percent of excited neurons were obtained between the concentrations of 10 M and 10 M for SP, OT, and TRH. Cell populations responsive to SP, OT, or TRH overlapped: 23 out of 31 peptide-responsive neurons were excited by more than one. Thus, SP may have direct excitatory effects on lordosis-relevant PAG neurons whereas LHRH may modulate actions of other neurotransmitters on them.

HYPOPHYSECTOMY ALTERS THE MAGNOCELLULAR NEUROSECRETORY SYSTEM BUT SPARES VASOPRESSIN-DEPENDENT FLANK-MARKING BEHAVIOR IN GOLDEN HAMSTERS. C.G. Pilapil, E.T. Koh. and C.F. Ferris. Dept of Physiol, U. Mass. Med. Center, Worcester, MA 01655.

There is evidence that subpopulations of magnocellular neurons in and around the anterior hypothalamus (AH) of the hamster do not project to the neurohypophysis. It is hypothesized that these non-neurosecretory neurons provide vasopressin (VP) neurotransmitter to the hypothalamus for the control of flank-marking behavior. Therefore, it is predicted that hypophysectomy should disrupt neurosecretory function but spare flank marking and the magnocellular neurons that control this behavior. HYPOX (n=6) and CONTROL (n=6) animals displayed similar odor-induced flank marking behavior. However, HYPOX animals had 4% the urine flow and water intake of CONTROLS due to the absence of VP neurohormone. The HYPOX group had an overall loss of approximately 50% of the VP neurons in the hypothalamus. However, computer-aided cell counting and mapping showed a 63% reduction in VP immuno-reactive neurons in PVN, 52% in the lateral SON, 44% in medial SoN and 34% in the nucleus circularis as compared to CONTROL. These results suggest that there may exist functionally and anatomically distinct populations of VP magnocellular neurons in the hypothalamus of the golden hamster. (Work was supported by NIH grant #NS23557).

114.11

NOREPINEPHRINE (NE) BUT NOT NEUROPEPTIDE Y (NPY) BLOCKS ARGININE VASOPRESSIN (AVP) STIMULATED FLANK MARKING WITHIN THE MEDIAL PREOPTIC ANTERIOR HYPOTHALAMUS (MPOA-AH) OF THE HAMSTER. D.C. Whitman, A.C. Hennessey and H.E. Albers. Lab. of Neuroendocrin. & Behav., Depts. Biol. & Psych., Georgia State Univ., Atlanta, GA 30303.

AVP in the MPOA-AH is critical for the control

of flank marking. Since NE and NPY are found within projections to this region, the effects of within projections to this region, the effects of NE and NPY on AVP stimulated marking were investigated. Female hamsters (n=29) implanted with guide cannulas aimed at the MPOA-AH were tested for marking on 3 consecutive days. On day 1, 9.0 μ M AVP was microinjected; on day 2, AVP and NPY (250 μ M) or AVP and NE were co-administered; and on day 3, AVP was given alone. Co-administration of AVP with 4, 0.4 or 0.2, but not 0.04 or 0.004 nM NE, into the MPOA-AH, significantly (P<.05) reduced AVP induced marking. Co-administration of AVP and NPY did not significantly reduce AVP induced marking. Hamsters were administration of AVP and NPY did not significantly reduce AVP induced marking. Hamsters were injected with 50nl of rhodamine labelled microspheres to localize the injection site and identify afferent projections. These data indicate that NPY does not block AVP stimulated flank marking and NE may be involved in regulating this behavior. (Supported by NSF BNS-800962) (Supported by NSF BNS-890863)

114.8

EFFECTS OF PRENATAL ADMINISTRATION OF ACTH AND NICOTINE ON THE SUBSEQUENT SEXUAL BEHAVIOR OF FEMALE RATS. S.E. Alves and F.L. Strand. Department of Biology and Center for Neural Science, New York University, New York, NY

Previous studies have shown that prenatal administration of ACTH or nicotine alters the subsequent sexual behavior of adult male rats (Segarra and Strand, 1989: a. Br. Res., 480: 151.; b. ICPS XXXI, P3492). This study was undertaken to investigate whether the sexual behavior of the female offspring is affected. Sprague-Dawley rats were injected with either ACTH 1-24 (10µg/kg), nicotine hydrogen tartrate (0.25mg/kg) or saline vehicle twice daily from gestation day 14-21. Females were tested as virgins at approximately 110 days of age. Sexual behavior was measured by recording the lordosis quotient and the lordotic quality score. Animals prenatally treated with ACTH had lower lordotic quotients and quality scores when compared to control animals. Prenatal administration of nicotine did not alter the lordotic quotient in these animals, however the quality score was significantly decreased. Based on this study, we suggest that sexual differentiation of the brain in the female rat is also susceptible to prenatal manipulation with ACTH or nicotine. We are currently investigating plasma estradiol and progesterone levels. This study was supported by the Council for Tobacco Research.

114.10

MICROINJECTION OF ARGININE-VASOPRESSIN (AVP) INTO THE MIDBRAIN CENTRAL GRAY STIMULATES DOSE-DEPENDENT FLANK MARKING IN SYRIAN HAMSTERS. A.C. Hennessey, D.C. Whitman and H.E. Albers. Lab. Neuroendocrinol. & Behav., Depts. Biol. & Psych., Georgia State Univ., Atlanta, GA 30303.

AVP microinjected into the medial preopticanterior hypothalamus induces intense bouts of

flank marking in hamsters. Injection of AVP into the midbrain central gray elicits flank marking in female hamsters. The present study investigated whether AVP would stimulate flank marking in males at midbrain central gray sites that induce flank marking in females. Hamsters were implanted with guide cannulas aimed at the central gray and were injected with 0.9 μ M, 9.0 μ M, 90.0 μ M and 900 μ M AVP in 100 nL of saline on 4 consecutive days in a counterbalanced manner. After behavioral testing some animals were micro-After behavioral testing some animals were microinjected with rhodamine labelled microspheres (50 nL) to examine afferent projections to AVP sensitive sites. AVP stimulated flank marking in a dose-dependent manner for both male (p<0.01) and female hamsters (p<0.05). These data suggest that the neurochemical control of flank marking may involve vasopressin-sensitive neurons in the midbrain central gray in male and female hamsters. (Supported by NSF BNS-8910863)

114.12

DISTRIBUTION OF THYROTROPIN RELEASING HORMONE BINDING SITES IN THE AMPHIBIAN BRAIN. S.K. Boyd and J.A. Taylor*. Dept. of Biological Sciences, Univ. of Notre Dame, Notre Dame, IN 46556.

TRH alters sexual and locomotor behaviors of the frog <u>Xenopus laevis</u>. The precise neural sites where TRH acts are unknown however. We used <u>in</u> where TRH acts are unknown however. We used in vitro autoradiography to locate binding sites for ^{7}H -TRH in the brain of Xenopus. Brains were frozen-sectioned at 50 μ m (frontal) and sections incubated with 10 nM ^{3}H -TRH (NEN), with or without 10 μ M unlabelled TRH (Sigma) for 1.5 hr. Films were exposed for 4 months at room tempera-

Binding of ³H-TRH to <u>Xenopus</u> brain was displaced by unlabelled TRH and was reversible and saturable. Greatest densities of specific binding sites were observed in the preoptic and infundibular nuclei of the hypothalamus. In the telencephalon, binding sites were found in the striatum and dorsal and lateral pallia. Significant binding was also observed in the thalamus, optic tectum, and brain stem. The distribution of sites was similar in males and females.

Since some of these neural areas have been previously implicated in the control of amphibian sexual behaviors, they may represent the sites of TRH-induced behavioral changes.

MORPHOLOGY OF THE TERMINAL NERVE SYSTEM IN A TROPICAL FISH, THE DWARF GOURAMI: GARH IMMUNOCYTOCHEMISTRY AND ELECTRON MICROSCOPY. Y.Oka and M.Ichikawa. Zool. Inst., Fac. Sci., Univ. of Tokyo. Tokyo 113, and Dept. Anat. Embryol. Tokyo Metro. Inst. for Neurosci. Tokyo 183

It has recently been suggested that the terminal nerve (TN) system may be involved in the control of sexual behavior in teleosts and mammals. We have examined the morphological characteristics of the TN system in the dwarf gourami as the basis for a study of its involvement in the control of sexual behavior. The TN cells in the transitional area between the olfactory bulb (OB) and the telencephalon reacted strongly with a monoclonal anti-GRH (LRH13, Park & Wakabayashi, '86). The GRRH-ir fibers were abundant in the OB, ventral telencephalon (VT) and several other areas. A distinct bundle of axons emanating from the TN cells ran caudally through the VT and the preoptic area (POA). Some of the axons entered the optic nerve (ON) and innervated the retina. Thus, the GRRH-ir TN system may affect both olfactory and visual functions as well as function of the VT and POA (these areas have been suggested to be involved in the control of sexual behavior in teleosts) as a neuromodulator and/or neurotransmitter. We next examined the cytology and synaptology of the TN cells by EM. The TN cell bodies had morphological characteristics similar to those of peptidergic neurons. The frequent occurrence of coated vesicles in close vicinity of the plasma membranes of the cell bodies was suggestive of membrane retrieval of secretory granules after exocytosis. The adjacent TN cells were either in direct juxtaposition or made specialized "glomeruloid, the somatic processes of the TN cells received inputs from synaptic terminals that have spherical synaptic vesicles and some DCVs.

PRETREATMENT WITH CENTRAL SOMATOSTATIN (SS) ANTISERA BLOCKS GRF-INDUCED FEEDING. D. Feifel and F.J. Vaccarino, Dept.'s of Psychology, University of Toronto, Toronto, Canada, M5S 1A1.

Previously we have reported that both GRF and SS, administered icv in picomole doses, increase feeding acutely in sated rats. The current study examined the effects of icv pretreatments with rabbit antisera raised against GRF(abGRF) and SS(abSS) in order to determine whether the feeding effects of either peptide was contingent upon the

Male Wistar rats (300-400 gms) were housed in separate cages and given free access to food and water. Each was stereotaxically implanted with a chronic guide-cannulae aimed at the right or left lateral ventricle. Following recovery subjects were given a feedingeffective dose of icv GRF (4 pm) or SS (1 pm) or saline. Injections were preceded by an icv injection of abGRF or abSS or normal serum. Food intake for the following hour was recorded.

Both GRF and SS significantly increased feeding relative to saline injections (p<.05). Neither antisera had a significant effect on baseline feeding. abGRF blocked GRF-induced feeding but had no significant effect on SS-induced feeding. abSS, on the other hand, blocked both SS and GRF-induced feeding. These results suggest that somatostatin is involved in the expression of GRF-induced feeding. This conclusion is consistent with evidence that low doses of GRF induce the release of SS from hypothalamic neurons.

The Long-term Effects of Neonatal Exposure to Bombesin (BN) and a BN-antagonist. H. Piggins¹ and Z. Merali ^{1,2}. ¹School of Psychology, ² Dept. of Pharmac

¹School of Psychology, ² Dept. of Pharmacology University of Ottawa, Ottawa, Canada K1N 9A9

The longterm effects of neonatal exposure to the peptide bombesin (BN) and [D-Phe⁶, \PLeu \frac{13}{Cpa} \text{-Cpa} \frac{14}{\text{|BN}} (6-14) a BN-antagonist was assessed in all male litters (8 pups/litter) by treating pups subcutaneously (sc) with one of the following 2x/day for postnatal days 1-8: Untreated (handled), saline, BN (5mg/kg -LDB or 10 mg/kg -HDB), and BN-antagonist (5mg/kg -LDA or 10 mg/kg -HDA). At 65 days of age, the animals were implanted with 3rd ventricular cannulae and placed on a water access schedule (4 hrs of water access/day). Grooming and food and water consumed were assessed in the first 30 min following water presentation. No group differences were noted at baseline. Animals were administered BN centrally (0.0-1.0 ug; icv) or systemically (0.0-8 ug; ip) and the above measures noted. The rats neonatally exposed to the 10 mg/kg dose of BN were consistently more sensitive to the central as well as systemic effects of BN. This was reflected by increased grooming and decreased food and water intake at the 0.1 ug (icv) dose and by decreased food consumption at the 4 ug/kg (ip dose). In contrast to the long-lasting effects of of neonatal exposure to the agonist, exposure to the BN antagonist failed to significantly alter the response to central or peripheral BN in adulthood. This lack of effect may have been due to the dosage regimen or the testing intervals employed. However, since BN receptors develop earlier in ontogeny as compared to the synthesis of BN-like peptides, the pups may be more succeptable to effects of a receptor agonist. These data would indicate BN-receptor interactions early development may play a role in the synaptogenesis and/or development of systems utilizing BN-like peptides as neurotransmitters/neuromodulators. CENTRAL INJECTIONS OF GROWTH HORMONE-RELEASING FACTOR (GRF) ANTISERUM ATTENUATE THE INCREASED FEEDING ASSOCIATED WITH DARK ONSET FEEDING IN RATS. E. J. Vaccarino1, D. Feifel1, J. Rivier², W. Vale² Dept. of Psychology, University of Toronto. ²Clayton Foundation Laboratories for Peptide Biology, The Salk Institute, La Jolla, CA. Current findings indicate that GRF-induced feeding is

photoperiod-sensitive and is mediated by GRF actions in the MPOA and SCN, a critical brain region underlying circadian rhythms. These findings raise the possibility that endogenous GRF represents a feeding-stimulatory signal in the brain which is associated with circadian feeding rhythms

In order to examine this possibility, the effects of intra-SCN/MPOA injections of GRF antiserum (abGRF) on food intake at four time points across a 12:12 hour light-dark cycle were tested. The four time points

tested were: mid-light, dark-onset, mid-dark, and light-onset.
Results indicated that intra-SCN/MPOA abGRF treatment decreased feeding associated with onset of the active dark phase. None of the other time points tested revealed any significant effect of abGRF treatment. These effects appeared to be behaviourally specific as evidenced by the lack of abGRF effect on locomotor activity and the lack of any feeding effect following extra-SCN/MPOA abGRF treatment.

The present results suggest that endogenous GRF actions in the SCN/MPOA region contribute to the naturally increased feeding associated with the onset of the active phase of the circadian feeding cycle. This research was supported by a NSERC grant to F.J. Vaccarino

CORTICOTROPIN RELEASING FACTOR AND RESTRAINT STRESS REDUCE PREFERENCE FOR NOVEL FOODS IN SELF-SELECTING RATS. S.C. Heinrichs and G.F. Koob. Dept. of Neuropharmacology, Scripps Clinic and Research Foundation, 10666 N. Torrey Pines Rd., La Jolla CA, 92037.

Exogenous corticotropin releasing factor (CRF) produces behavioral responses in locomotor activity, conditioned suppression, operant conflict and shock-induced fighting tasks which reflect the postulated stress-like action of this peptide. For instance, locomotor/open Field results demonstrate CRF-induced behavioral suppression in an unfamiliar environment and delayed contact with novel stimuli. This reduced response to novelty was examined in the present study of CRF effects on ingestive behavior using a two-choice test of familiar vs. unfamiliar foods.

Fifty three rats were fed either protein-free or protein-replete diets for three days and on the fourth day were given a choice between this familiar maintenance diet and an unfamiliar alternative. Under such conditions, rats consuming protein-imbalanced diets show an increased preference for novel food choices. Neither I.C.V. infusion of 500 ng CRF nor physical restraint 30 min prior to the 1 hr choice test affected consumption of the two diets in protein-replete controls. In the nutritionally deprived group by contrast, both treatments reduced consumption of the novel diet without affecting familiar diet intake. Further, this dose of CRF did not produce a conditioned taste aversion suggesting that the reduction in consumption of a novel diet did not result from malaise. These results suggest a stress-like action of CRF in reducing intake of unfamiliar foods while sparing appetite for familiar foods.

PERIPHERAL RECEPTOR SUBTYPE SPECIFICITY FOR CHOLECYSTOKININ-INDUCED INHIBITION OF FEEDING. J.N. Crawley, S.M. Fiske*, C. Durieux*^1, M. Derrien*^1 and B.P. Roques^1*, Clinical Neuroscience Branch, NIMH, Bethesda, MD 20892 and ^Laboratoire de Chimie Organique, INSERM U266, CNRS UA 498, Universite Rene Descartes, Paris, France.

MD 20892 and ^Laboratoire de Chimie Organique, INSERM U266, CNRS UA 498, Universite Rene Descartes, Paris, France. New agonists and antagonists selective for the peripheral-type (CCK-A) and for the brain-type (CCK-B) cholecystokinin receptor were used to determine whether a peripheral or a central type of CCK receptor mediates the action of cholecystokinin (CCK) on reducing food consumption. Rats administered BC 264, a CCK-B receptor agonist, did not decrease consumption of a palatable meal in a 30 minute test session, after an overnight fast, when BC 264 was administered either intraperiteonally (5-50 ug/kg) or into the lateral ventricles (20 ng-5 ug) of the brain. CCK decreased feeding when administered intraperitoneally at the highest dose (5 ug). L-364,718 (50 ug/kg i.p.), an antagonist selective for the CCK-A receptor, completely blocked the action of centrally administered CCK. L-365,260 (50 ug/kg i.p.), an antagonist selective for the CCK-B receptor, did not affect the ability of centrally administered CCK to inhibit feeding. Propionyl CCK, administered with radiolabelled tracer, intraventricularly at a dose which inhibited feeding (5 ug), was detected in the plasma 30 minutes later at a concentration of 4 nM. CCK appears to inhibit feeding in the rat by a peripheral, not a central, CCK receptor subtype mechanism.

INTERACTION OF CCK-8 AND STRESS IN FOOD INTAKE

INTERACTION OF CCK-8 AND STRESS IN FOOD INTAKE IN RATS. M.Shuck. J.Prather, M.Mims, and E.Quinton. Lab. of Psychobiology, University of Louisville, Louisville, KY 40292.

Exogenous administration of the octapeptide fragment of cholecystokinin (CCK 26-33) inhibits feeding; stress that elicits an endogenous opiate response increases feeding in rats. This study compared the effects of CCK-8 on feeding in stressed and non-stressed rats. Male Sprague-Dawley rats were injected ICV with either 10 ul of physiological saline solution or 10 ug of CCK dissolved in the solution. Rats were deprived of food for 4 hrs. and then allowed to feed freely for 1 hr. immediadely prior to injection. On the first day the rats were injected and food intake was measured each were injected and food intake was measured each hour for 6 hrs. Three days later the rats were injected as before but 5 min. after injection received a 1mA footshock for 90 sec. and food intake was measured as before. Results show a significant increase in feeding during the first hour after stress, and a significant CCK after stress, and tion of feeding. inhibition of feeding. A significant CCK inhibition of feeding. A significant interaction effect supports findings that CCK inhibits stress induced feeding and may provide additional evidence of an opiate antagonist function of CCK.

EFFECTS OF FMRFamide AND SCP_B ON SPONTANEOUS AND INDUCED CONTRACTIONS OF THE ANTERIOR GIZZARD IN <u>APLYSIA</u>.

N. <u>Ewadinger & K. Lukowiak</u>, Dept. of Medical Physiology, University of Calgary, Calgary, Alberta, Canada T2N 4N1.

Biologically active peptides can function as transmitters, modulators, or hormones in the central nervous systems of both vertebrates and invertebrates. Previous studies on the anterior gizzard of the opisthobranch mollusc Aplysia revious studies on the anierior gizzard of the opisitiotratic monuse $\frac{E_{ij}}{E_{ij}}$ and $\frac{E_{ij$ of the possibility that peptides may co-exist with 'classical' neurotransmitters, such as acetylcholine (ACh), the co-perfusion of carbachol (an ACh analog) and SCP_B was also done to test for possible synergistic effects. FMRFamide at concentrations between 10⁻⁹ to 10⁻⁸ M inhibited spontaneous gut activity. In addition, carbachol alone produced tonic contractions of the gut at relatively high concentrations (e.g., 10⁻⁴ M). SCP_B did not significantly effect either the amplitude or the rate of contractions of the gut. When carbachol (10⁻⁴ M) and SCP_B (10⁻⁸ M) were co-perfused, the tonic contractions induced were shifted by SCP_B, leading to more rhythmic (phasic) contractions; thus, no synergistic effects were observed. These results suggest that both FMRFamide and SCP_B may function as neuromodulators of gut contractility in Aplysia.

LEARNING AND MEMORY: CONDITIONING

115.1

CEREBELLAR CORTEX LESIONS DISRUPT THE TIMING OF CONDITIONED EYELID RESPONSES. S.P. Perrett, B.P. Ruiz*, and M.D. Mauk. University of Texas Medical School, Houston, TX 77225.

Previous studies suggest that the cerebellum is a necessary component of the pathways that mediate classical conditioning of skeletal muscle responses. However, the precise role of the cerebellum, particularly the cerebellar cortex, remains unresolved. We report here that lesions of the cerebellar cortex have a very specific effect on the performance of conditioned eyelid responses in rabbits; the normal timing of the responses, in which eyelid closure peaks near the onset of the unconditioned stimulus (US), is disrupted in a characteristic manner.

To examine the effects of lesions on conditioned response (CR) timing, we use a differential conditioning paradigm in which individual animals are trained to elicit two differently timed responses. Two distinguishable conditioned stimuli (CS; 0.4 & 8 kHz tones) are paired with the US (air puff to the cornea), each using a different inter-stimulus interval (ISI). For example, CS1 may be paired with the US at an ISI of 150 ms, and CS2 may be paired with the US at a 750 ms ISI. These animals show high rates of conditioned responding (90-100%) and the timing of the responses elicited by the two CSs is significantly different. Rabbits were trained to asymptotic performance and subjected to aspiration lesions of the ipsilateral cerebellar cortex (ansiform and paramedian lobes).

We find that CRs are spared by the lesions (though in some animals there is a decrease in the percentage and amplitude of the responses elicited), however, their timing is significantly affected. Before the lesion the responses to the respective CSs were timed differently, each peaking near the onset of the US. The post-lesion responses, however, were similarly timed for both CSs and displayed an abnormally short latency to onset and to peak. The lesions produced decreases in latency to onset of up to 100 ms and latencies to

115.2

RECOVERABLE AND NON-RECOVERABLE DEFICITS IN CONDITIONED RESPONSES (CRs) AFTER CEREBELLAR CONDITIONED RESPONSES (CRS) AFTER CEREBELLAR CORTICAL LESIONS. J.A. Harvey, C.H. Yeo, J.P. Welsh and A.G. Romano. The Medical College of Pennsylvania/EPPI, Philadelphia, PA 19129 and University College London, London WCIE 7JG, UK. This study reexamined the effects of unilateral damage to cerebellar cortical lobule VI (HVI) on the rabbit's conditioned nictitating

membrane response. Animals received 15 conditioning sessions. Each session consisted of 60 pairings of a tone CS with a corneal air puff US and 6 tone alone test trials. Animals then underwent surgery and 3 weeks later were given 12 more conditioning sessions. Total removal of the state of t Total removal of HVI along with extensive damage to the medial ansiform cortex in 11 rabbits significantly impaired their ability to perform CRs as compared with 7 sham-operated controls or 14 animals with only partial damage to HVI. CR frequency was reduced by 52% and CR amplitude by 54% on the 1st post-operative session. CR frequency recovered to control levels but CR amplitudes were permanently reduced. Thus, HVI plays an important role in the retention and performance of learned responses, but is not essential for reacquisition. Supp. MH16841.

115.3

HARMALINE BLOCKS ASSOCIATIVE LEARNING IN RABBIT.

HARMALINE BLOCKS ASSOCIATIVE LEARNING IN RABBIT.
A. G. Romano and J. A. Harvey. Medical College of Pennsylvania at EPPI, Philadelphia, PA 19129. This study examined the effects of harmaline on acquisition of the conditioned nictitating membrane response. In Phase 1, harmaline (5, 10 or 20 mg/kg) or saline was injected s.c., 30 min prior to a single acquisition session consisting of 120 pairings of a tone conditioned stimulus (CS) with a corneal air puff unconditioned stimulus (US). In Phase 2, two days later, all animals received a second conditioning session except that no drug or saline was injected. Control animals demonstrated a significant acquisition of CRs in Phase 1 and CR retention acquisition of CRs in Phase 1 and CR retention in Phase 2. However, all three doses of harmaline blocked CR acquisition during Phase 1 harmaline blocked CR acquisition during Phase 1 and there was no evidence of retention during Phase 2. Control experiments established that harmaline (5 mg/kg): 1) altered the CS threshold for eliciting CRs 2) had no effect on the unconditioned response; and 3) did not alter non-associative responding. Given harmaline's known effects on the inferior olive, our results provide further evidence that associative learning is dependent on normal activity of the learning is dependent on normal activity of the inferior olive. Supported by Grant MH16841.

115.4

ASSOCIATIVE LEARNING REQUIRES THE FUNCTION OF THE INFERIOR OLIVE. <u>I.P. Welsh and I.A. Harvey.</u> Univ. Iowa, Iowa City, IA 52242 & Med. Col. of Pa/EPPI, Phila., PA 19129.

This study examined the role of the inferior olive (IO) in the acquisition and retention of conditioned nictitating membrane responses (CRs). Infusions of lidocaine (LID) into the dorsal accessory olive (CRs). Infusions of lidocaine (LID) into the dorsal accessory olive (DAO) immediately and reversibly abolished CRs acquired to either a tone or light CS. In order to determine the reason why CRs were abolished by DAO inactivation, a 3-phase procedure was employed. In Phase 1, rabbits were trained to make CRs to a light CS that was paired with an air-puff UCS. In Phase 2, rabbits received infusions of LID into the DAO during a conditioning session in which a tone CS was paired with the UCS. Interpolated light-CS trials monitored the degree to which performance of CRs was impaired by LID. In Phase 3, two days later animals received tone-CS alone trials to determine two days later, animals received tone-CS alone trials to determine whether learning had occurred in Phase 2 but was not observed due to a performance deficit resulting from inactivation of DAO by LID. Animals that received infusions of LID into the DAO during Phase 2 showed no CRs to the light CS and no evidence of CR acquisition to the tone CS. In Phase 3, when no LID was infused and performance was not impaired, these animals showed no retention of CRs to the tone. Therefore, in contrast to lesions of the cerebellum which abolish CRs by disrupting motor function, lesions of the IO abolish CRs through an action on associative learning. The results are interpreted to support a outative role for the IO in sensory function and/or timing. (Supp. NIMH Grant MH16841)

Effects of Age on Eyeblink Conditioning in Freely Moving Fischer-344 and F1 Hybrid Rats. C. Weiss, E. Savay, and R. F. Thompson, Neurosciences Program, University of Southern California, Los Angeles, California 90089-2520.

Classical conditioning of the eyeblink response in humans and rabbits shows progressive age related impairments. Contradictions in the literature are likely to be due to the specific paradigm being used. We have implemented a standard "delay" paradigm using a 350ms white noise conditioning stimulus and a 2mA, 60 Hz, 100ms coterminating unconditioned stimulus. Our results indicate that Fischer 344 male rats exhibit severe associative deficits as a result of aging. The two older groups, 18 & 30 months, exhibit significantly fewer conditioned responses (CRs) than the two younger groups, 3 & 12 months, F(3,20)=3.11, p<.05. In contrast to the F-344s, all ages (9, 18 & 24 months) of the F1 hybrids (F-344 x Brown Norway) exhibited substantial numbers of CRs. In fact, the oldest F1 hybrids exhibited more CRs than the youngest Fischer rats. These data indicate clear strain differences in rate of learning on this paradigm. These data also indicate that the delay paradigm is sufficiently demanding to demonstrate age related deficits in the Fischer rat.

IBOTENIC ACID LESIONS OF AREA 32 OF THE MIDLINE PREFRONTAL CORTEX GREATLY ATTENUATE CONDITIONED BRADYCARDIA IN THE RABBIT. D.A. Powell and Karen L. Watson*. Neuroscience Laboratory, VA Medical Center and University of South Carolina, Columbia, SC 29201.

Aspiration lesions of the midline prefrontal cortex (PFC) greatly attenuate the bradycardia elicited by classical conditioning contingencies (Buchanan & Powell, J. Comp. Physiol. Psych., 96, 1982, 755-774). In the present study, bilateral multiple injections of ibotenic acid in the midline PFC selectively destroyed: (a) the dorsomedial precentral agranular portion of the midline PFC (approximately Brodmann's area 24); (b) the more ventral anterior limbic area (approximately Brodmann's area 32); or (c) the infralimbic area (Brodmann's area 25) in separate groups of animals. After recovery from surgery, the rabbits received differential classical conditioning, in which two tones served as a reinforced CS+ or a nonreinforced CS-. A paraorbital electric shock train was the unconditioned stimulus. The more dorsal lesions of area 24 slightly impaired responding to the CS+ in the lesioned animals compared to sham operated animals. More ventral lesions in area 32 appeared to completely abolish conditioned bradycardia in most animals, but area 25 lesions had no effect. These findings thus suggest that conditioned bradycardia in the rabbit is dependent upon the anterior limbic area of the midline PFC.

115.9

LESIONS OF THE ROSTRAL FASTIGIAL N. AFFECT BRADYCARDIAC ORIENTING, BUT NOT CONDITIONED, RESPONSES IN RABBITS. C.M. Gibbs, K. Watson*, P. Shah* & A. Gibbs*, VA Med. Center & Univ. of South Carolina, Columbia, SC 29201.

Aversive Pavlovian conditioning procedures lead to the rapid development of bradycardiac adjustments (HR CRs) in rabbits that are dependent upon the integrity of corticolimbic mechanisms (e.g. Kapp et al: Physiol Behav Recent preliminary data (Supple et al: As: 109). Recent preliminary data (Supple et al: Soc Neurosci Abstr 15:640) have suggested that the anterior cerebellar vermis (Va) may also be involved in this learning process. Accordingly, the present studies were undertaken to determine the effects of lesions of the rostral fastigial n. (FA), the deep nuclear target of Va Purkinje cells, on the expression of bradycardiac orienting responses (ORs) and the subsequent development of discriminative MPCCPs. of discriminative HR CRs.

Following lesion or sham surgical procedures. animals received habituation training to two distinctive 4-sec tones (CSs), followed by three 40-trial sessions of differential conditioning (CS+/eyeshock pai interspersed with presentations of CS- alone). results to date indicate that bilateral FA lesions, in contrast to sham operations contrast to sham operations, markedly enhance HR ORs (ps<.01) but have minimal impact on HR CRs. Thus, the FA appears to be involved in the modulation of unconditioned, but not conditioned, cardiac adjustments.

115.6

MEDIODORSAL THALAMIC LESIONS AND CLASSICAL OF HEART RATE AND EYEBLINK RESPONSES CONDITIONING Shirley L. Buchanan and Richard H. Thompson. and University of South Carolina, Columbia 29201.

Rabbits received bilateral ibotenic acid injections in the mediodorsal nucleus of the thalamus (MD), were compared to sham control animals in a simple classical conditioning experiment, in which both eyeblink (EB) and heart rate (HR) conditioning were assessed over 4 acquisition and 1 extinction session consisting of 60 trials each. Lesions of MD enhanced the initial bradycardiac component of the HR conditioned response (CR) that appears in unoperated animals at the beginning of conditioning, and completely abolished the tachycardiac component of the HR CR that occurs later, after EB conditioning reaches maximum. animals, EB conditioning was delayed during the first session, when most animals begin to show EB CRs. These data suggest that MD's role in classical conditioning involve somatomotor response selection, based on information processed in other brain areas, e.g., prefrontal cortex. They also provide additional evidence that MD is involved in mediating sympathetic control. These two effects may be related, since the acquisition of a somatomotor response would be expected to involve engagement of sympathetic mechanisms.

PURKINJE CELL NUMBER RELATED TO RATE OF NM/ EYEBLINK CLASSICAL CONDITIONING IN THE TRACE

PARADIGM. D.S. Woodruff-Pak & J. F. Cronholm. Department of Psychology, Temple University, Philadelphia, PA 19122

Cerebellar Purkinje cells are likely to play a role in acquisition and retention of the classically conditioned NM response in rabbits. We demonstrated that Purkinje cell number and acquisition in the trace paradigm were highly correlated in a group of aging rabbits.
Here we report that in young rabbits there is a significant correlation of -.60 (p<.01) between Purkinje cell number and trials to learning criterion. Eighteen 3-month-old rabbits were conditioned in the trace paradigm with an 85 dB, 250 msec, 1 KHz tone CS and a 3 psi corneal airpuff US presented 750 msec after the onset of the CS. Animals were trained to learning criterion, sacrificed, and perfused. Brains were kept in formalin and then embedded in an albumin-gelatin mixture. Every fourth 80 um section was mounted and stained with cresyl violet. Purkinje cells were counted on 6 sections (18 micrographs/rabbit). Counts were made of Purkinje cells in the HVI area and in vermis and were limited to a single row of Purkinje cells 0.5 mm wide. Counters were blind to the performance of the rabbits. Inter-rater reliability was .95 (p < .001). These data provide additional evidence for the role of Purkinje cells in normal acquisition of the classically conditioned NM response in the trace paradigm. (Supported by NIH grant AG05312 and a grant from the American Federation for Aging Research).

LESIONS OF THE AMYGDALA DISRUPT REFLEX FACILITATION OF THE NICTITATING MEMBRANE (NM) RESPONSE IN RABBIT. D.G. Harden. Z. Xiang. J. Davis*. and D.J. Weisz. Dept. of Behavioral Neuroscience, Univ. of Pittsburgh, Pittsburgh, PA 15260.

The presentation of a previously neutral or conditioned stimulus (CS) at an appropriate interval prior to the delivery of a reflex-eliciting or unconditioned stimulus (US) to the cornea of a rabbit can facilitate the amplitude of the NM response that is elicited by the US (e.g. Ison and Leonard, JCPP, 75:157, 1971). In two experiments we investigated the role Leonard, JCPP, 75:157, 1971). In two experiments we investigated the role of the amygdala in reflex facilitation using an auditory CS (85 db) and an airpuff US (2.0 psi). In Experiment 1 animals with lesions that included approximately 70% of the central nucleus of the amygdala exhibited no significant reflex facilitation of NM amplitude at a wide range of interstimulus intervals (ISIs) (125-8000 msec) (12 presentations at each of 8 ISIs), whereas control animals demonstrated robust facilitation ranging from 1.5-3.0 mm. In Experiment 2, we tested the relation between reflex resilitation and the conscipition of conditional presentations. facilitation and the acquisition of conditioned responses (CRs) to CS presentation by using a fixed ISI (250 msec) throughout training. Both control and amygdala lesion groups showed comparable facilitation (2.0-2.5 control and amygdala lesion groups showed comparable facilitation (2.0-2.5 mm) for the first block of training (5 presentations of each trial type) and comparable CR acquisition rates. Whereas reflex facilitation was maintained in the control group across the first day of training, no facilitation was observed in the lesion group after the first block. As in Experiment 1 approximately 70% of the central nucleus of the amygdala was damaged in the lesion group. The results suggest that the amygdala plays a critical role in the maintainance of reflex facilitation but not in its initial appearance. (Supported by RO1MH42800)

THE EFFECT OF RUBROSPINAL TRACTOTOMY ON A CONDITIONED LIMB RESPONSE IN THE CAT. T.J. Voneida, Dept. of Neurobiology, Northeastern Ohio Universities College of Medicine, Rootstown, OH 44272.

Rootstown, OH 44272.

Cats were conditioned to perform a right forelimb response to a paired tone CS - shock UCS. Right rubrospinal section was carried out following criterion CR performance. Lesion sites were confirmed histologically and by demonstration of severe chromatolysis in the left red nucleus. Tractotomy resulted in total or near-total loss of the CR. The UCR remained unaffected, as did limb placing, accuracy of striking at moving objects, running and walking. Postoperative scores remained at zero or near-zero for 2000-3000 trials, at which time training of the left limb resulted in scores of 75-80% within 5 sessions. In 1963, Voneida reported right limb CR loss following left sensorimotor cortical lesions, and in 1967 demonstrated that pyramidal lesions had no effect on CR performance. These results, in combination with those reported here and with Tsukahara's findings, ('81), lend support to the contention that a non-pyramidal, corticorubral, rubrospinal pathway represents a critical part of an associative mechanism in conditioned learning. Together with studies demonstrating that cerebellar lesions also severely impair conditioned limb and alcitiating membrane responses, these data support a dual ("cooperative") control model recently proposed by Houk ('89), in which motor cortex/red nucleus represent an associative, memory-based a dual ("cooperative") control model recently proposed by Houk ('89), in which motor cortex/red nucleus represent an associative, memory-based system, and the cerebellum represents a motor programming, computational system. Interaction of these two systems, according to the Houk model, is mediated by various cortical and brain stem neuronal loops. Our findings, past and present, lend support to this model, and suggest further that at least in the case of a conditioned limb response, the rubrospinal tract represents a critical path by which the combined effect of these two mechanisms is expressed to final common pathway neuronal pools. (Supported by NINCDS Grant NS26053).

115.13

INVESTIGATIONS OF THE MODULATION OF THE R1 AND R2 COMPONENTS OF THE REFLEXIVE EYEBLINK IN RABBIT. D.J. Weisz, T. A. Blanpied, and D.G. Harden. Dept. of Behavioral Neuroscience, Univ. of Pittsburgh, Pittsburgh, PA 15260.

In this experiment we began our investigation of the neural sites in the reflex pathways at which an auditory stimulus modulates the amplitude of a subsequently elicited reflexive eyeblink. A prior auditory stimulus can inhibit the amplitude of these reflexes at short interstimulus (ISIs) (20-80 msec) and facilitate the amplitudes at longer ISIs (100 to over 1000 msec). in this study we examined the effects of prior auditory stimulation on the R1 and R2 components of the reflexive eyeblink. The presentation of a brief periorbital shock elicits two discrete EMG responses (R1 and R2) from the orbicularis oculi, which reflect the output of disynaptic and polysynaptic reflex arcs, respectively. The disynaptic arc is comprised of cells whose cell bodies are in the semilunar ganglion, spinal trigeminal nucleus, and the facial nucleus. The polysynaptic are is probably mediated by structures in the reticular formation in addition to those in the disynaptic loop. We found that both R1 and R2 exhibited significant facilitation at 250-8000 msec ISIs. No significant facilitation of R1 or R2 was seen at 30-125 msec ISIs; however, there was significant inhibition of R2 at a 30 msec ISI. These results indicate that the disynaptic reflex arc is facilitated by the prior presentation of an auditory stimulus and that inhibition of the behavioral eyeblink at short ISIs is probably mediated by the polysynaptic We found that both R1 and R2 exhibited significant facilitation at arc. In future studies we will determine which reflex arc is affected t lesions of structures that are critical for reflex facilitation (e.g. amygdala) or inhibition. (Supported by RO1MH42800)

EFFECTS OF COOLING INTERPOSITUS DURING ACQUISITION OF EFFECTS OF COULING INTERPOSITION DURING ACCOUNTS.

CLASSICAL CONDITIONING. D.G. Lavond, A.S. Kanzawa*, V. Esquenazi*, R.E. Clark & A.A. Zhang. Dept Psych & Bio Sci/HNB 501, Univ So Cal, Los Angeles, CA 90089-2520.

Rabbits were implanted with a cooling probe near the

Rabbits were implanted with a cooling probe near the cerebellar interpositus nucleus (IN) (Antr 0.5, Lat 6.5, Vent 14.0 mm from lambda), and implanted with multiple-unit recording electrodes in IN bilaterally and contralaterally in the red nucleus. After 1 wk recovery, they were adapted, and trained on 5 days for classical conditioning while the probe tip was cooled to +/-10 °C (CS-conditioned stimulus, 1KHz, 85 dB SPL, 352 msec tone; UCS-unconditioned stimulus, 2.1 N/cm², 100 msec corneal airpuff; CR/UCR-conditioned/unconditioned responses nictitating membrane extension measured with a Solomon minititating membrane extension measured with a Solomon minitreating membrane extension measured with a Solomon min-torque potentiometer; 12 blocks of CS, CS-UCS, CS-UCS, CS-UCS, UCS, CS-UCS, CS-UCS, CS-UCS, CS-UCS for a total of 108 trials per day; 20-40 sec intertrial interval). During cooling the rabbits had UCRs but no CRs. They were then trained on 5 days <u>without cooling</u>. There was no evidence for retention, and CRs developed as would be expected for naive rabbits. These results are discussed in relation to the idea that IN is a putative site for learning and memory, and related to lidocaine experiments by Chapman (1988 Stanford dissertation) and by Welsh & Harvey (Neurosci., 15:639, 1989). Supported by NSF BNS-8906612.

DISCRIMINATION OF BILATERAL INTER-SESSION UCS SHIFTS DURING NICTITATING MEMBRANE CLASSICAL TRACE CONDITIONING.

P.D. McAbee & M. M. Patterson. Department of Psychology and College of Osteopathic Medicine, Ohio University, Athens, OH 45701.

It has been hypothesized that the correlation between shifts in the frequency of conditioned responses (CRs) and bilateral shifts of the uncondiquestey of conditioned responses (CRS) and bratefal stritts of the discondi-tioned stimulus (UCS), in the rabbit nictitating membrane (NM) classical delay conditioning paradigm, is representative of some form of spatial learn-ing (Greiner, Wilson & Patterson, *Neurosci. Abst.*, 15:890, 1989). It has ing (Greiner, Wilson & Patterson, Neurosci. Abst., 15:890, 1989). It has also been hypothesized that trace conditioning of the NM preparation involves more hippocampal control than delay conditioning (Weisz, Solomon & Thompson, Bull. Psychonom. Soc., 16, 1980). Various theories of hippocampal function describe it as a spatio-temporal, or cognitive map. The goal of this study is to use a trace conditioning procedure, similar to Greiner's procedure, in order to engage these spatial functions. The resulting trace data could then be compared to the earlier delay data in order to determine any behavioral differences. determine any behavioral differences.

Subjects (n=4) received 80 paired stimuli/session on the left eye for odd numbered sessions, and on the right eye for even numbered sessions, for a

numbered sessions, and on the right eye for even numbered sessions, for a total of 16 sessions (not including an initial adaptation session). The stimuli consisted of a 100 msec 1 kHz tone conditioned stimulus (CS), and a 100 msec airpuff UCS. CS offset and UCS onset were separated by 400 msec. A comparison of the delay and preliminary trace data shows no significant difference in the level of discrimination (defined as stimulated eye %CRs minus unstimulated eye %CRs) of the UCS shift. However, there is a significant effect (p<.05) due to session. In fact, the level of discrimination unserverted by fluctuates in a regular meanure, with both prodicing a congregation. unexpectedly fluctuates in a regular manner, with both paradigms apparently synchronized, but not with the direction of the UCS shift.

CS/US PRE-EXPOSURE RETARDS ACQUISITION OF DISCRETE MOTOR RESPONSES USING HVI STIMULATION. A.F. Nordholm, R.A. Swain, and R.F. Thompson. Neurosciences Program, University of Southern California, Los Angeles, CA 90089

Prior studies have shown that paired presentations of tone CS and HVI stimulation produce robust classical conditioning (Brogden & Gantt, 1937; Shinkman, Swain & Thompson, 1989). Eight New England White rabbits were implanted with bipolar microstimulation electrodes in the white matter of HVI. Following 1 wk recovery, the animals were given five days of explicitly unpaired training prior to a maximum of twenty days of paired training. They were compared with a group of 8 animals that received only paired training.

The results indicated that baseline responding to CS alone presentations in unpaired training was $\leq 10\%$. Acquisition following CS/US pre-exposure was significantly retarded ($\underline{t}(14)$ --2.39, \underline{p} <.05). These results extend previous work using HVI stimulation as a US and emphasize that learning acquired in this paradigm fol-lows all of the rules of normal associative condition-

COOLING CEREBELLEAR HVI LOBULE DOES NOT ABOLISH COMDITIONED RESPONSES. A.A. Zhang, R.E. Clark & D.G. Lavond. Dept Bio Sci & Psych/HNB 501, Univ So Cal, I Angeles, CA 90089-2520.

A previous study has shown that temporary cooling of the interpositus nucleus reversibly abolishes learned responses (Lavond et al. Neurosci. 15: 889, 1989).

In the present study, rabbits were implanted with a cooling probe next to cerebellar lobule HVI. Multiple unit recording electrodes were implanted in HVI bilaterally and in red nucleus contralaterally. After recovery, the rabbits were overtrained for classical eyeblink conditioning. The conditioned stimults was 1 KHz, 85 dB SPL, 352 msec tone coterminating with 2.1 $\rm N/cm^2$, 100 msec corneal airpuff unconditioned stimulus, and nictitating membrane extension was measured as the response. A total of 108 trials were given each day.

We then attempted to inactivate cerebellar cortex HVI by injecting Freon into the probe implanted next to HVI. We tested with 27 normal trials, 54 trials with the cooling probe turned on, and finally 27 more normal This procedure was repeated on 5 days:

Results indicate that learned behaviors are not abolished for the duration of cooling. These results support previous observations that cerebellar cortex is not essential for classical conditioning. Supported by NSF BNS-8906612.

REACQUISITION OF CLASSICAL CONDITIONING AFTER REMOVAL OF CEREBELLAR CORTEX IN DUTCH BELTED RABBITS. R.E. Clark, D.J. Brown*, R.F. Thompson & D.G. Lavond. Dept Psych & Bio Sci/HNB 501, Univ So Cal, Los Angeles, CA 90089-2520.

While many agree that cerebellar interpositus lesions abolish or prevent classical conditioning, the role of cerebellar cortex is controversial. Yeo and colleagues report that HVI lesions also abolish conditioning (<u>Beh. Brain Res.</u>, 13:261-266, 1984). However, Lavond and colleagues report both retention and acquisition without cerebellar cortex (Exp. Brain Res., 67:569-593, 1987; Beh. Brain Res., 33:113-164, 1989). Of many possible explanations, only strain differences (Yeo's Dutch Belted vs Lavond's New Zealand White) remain untested.

In the present study we used Dutch Belted rabbits (n-3) and replicated Yeo's paradigm: 550 msec CS, either 90 dB SPL white noise or 190 lux light; 50 msec UCS, 2.5 mA, 60 Hz periorbital stimulation; 15 sec intertrial interval; 220 daily trials, 50% light CS and 50% noise CS; 5 days of training, cerebellar aspiration, 1 week recovery, retraining. The rabbits were retrained for 20 recovery, retraining. The rabbits were retrained for 20 days, and then trained for 20 more days using our usual paradigm (Thompson et al. <u>Am. Psych.</u>, 31:209-227, 1976). Preliminary evidence indicates that Dutch Belted rabbits relearned following the lesion using both paradigms.

ANATOMICAL RELATIONSHIPS BETWEEN THE CEREBELLAR VERMIS AND THE PARABRACHIAL NUCLEI IN THE RABBIT. W. F. Supple. Jr. and B. S. Kapp.
Department of Psychology, University of Vermont, Burlington, VT 05405.
The cerebellar vermal cortex is importantly involved in aversive

classically conditioned bradycardic responses in the rabbit. Lesions block acquisition and retention of bradycardia, and Purkinje cells in this region show electrophysiological changes which accompany the learned response. This study examined the connections between the anterior vermis and the parabrachial nucleus (PBN), a region recriprocally connected with the amygdaloid central n.(ACE) which is also involved in conditioned bradycardia.

New Zealand albino rabbits received 20 - 40 nl injections of WGA-HRP into either the lateral PBN (IPBN), anterior vermis or rostral fastigial nucleus. Following 1 to 2 d survival, the brains were processed using the TMB procedure of Mesulam. Injections into the IPBN resulted in anterogradely labeled fibers in lobules III, IV and V of the anterior vermis. These fibers were unusual as they appeared to be neither mossy nor climbing fibers, and were distributed to each layer of the cortex in a pattern similar to that observed by Dietrichs & Haines (Anat. Embryol.,173: 279, 1985) for hypothalamocerebellar fibers in the cat. These PBN injections also resulted in retrogradely labeled fastigial nucleus neurons. Injections into the vermis produced many retrogradely labeled neurons in the lateral and medial PBN, and there was evidence of anterograde terminal labeling in the IPBN. Fastigial injections resulted in terminal label in the PBN but no retrogradely labeled neurons were observed.

These findings suggest the existence of a neuroanatomical circuit from the PBN to anterior vermis to fastigial n. to PBN in the rabbit. The vermal connections with the PBN, which in turn is recriprocally connected with the ACE, suggests a potential important interrelationship between cerebellar and amygdaloid neurons in the acquisition of conditioned bradycardia in the rabbit.

MEASUREMENTS OF REFLEXIVE REACTIONS TO DIFFERENT UNCON-DITIONED STIMULUS INTENSITIES OVER THE COURSE OF CLASSI-CAL CONDITIONING. D. Ivkovich, D.G. Lavond, C.G. Logan, & R.F. Thompson, Neurosciences Program, University of Southern California, Los Angeles, CA 90089-2520.

Rabbits were classically conditioned with a 3 psi un-

conditioned stimulus (UCS) to the cornea, lesioned in the ipsilateral interpositus (IP) nucleus, and subsequently retrained. Reflexive eyeblinks to 4 different UCS intensity levels (1, 2, 3, & 4 psi) were measured over the course of training. These input/output (i/o) tests included amplitude, onset and peak latency, and amplitude-time area of the unconditioned responses (UR). The lesion completely abolished conditioned responses in all animals.

Amplitudes and latencies of URs in i/o tests varied significantly with airpuff intensity. After training, the UR amplitudes to 3 and 4 psi were significantly larger than prior to training. Immediately after the lesion, UR amplitudes at 3 and 4 psi were slightly reduced but returned to prelesion levels after retraining. The lesion did not affect onset or peak latencies.

Preliminary results with animals receiving random

unpaired training suggest that there was no training

potentiation of responses to 3 and 4 psi.

RED NUCLEUS PROJECTIONS TO THE ACCESSORY ABDUCENS NUCLEUS IN RABBIT REEXAMINED WITH WGA-HRP. M.E. Rosenfield and J.W. Moore. Dept of Psychol, Univ of Mass, Amherst, MA 01003.

The accessory abducens nucleus (AAN) is the main pool of motoneurons innervating eye ball retraction and the nictitating membrane response (NMR). Motor commands for the classically conditioned NMR presumably originate in the cerebellum and are relayed to AAN via the red nucleus (RN). We implanted WGA-HRP (Sigma L3892) unilaterally into the region AAN in 5 albino rabbits (method of Mori, J., et al, Brain Res Bull, 6:19, 1981). The pipette remained in situ for 53 hours before sacrifice. Animals were perfused transcardially (descending aorta clamped) with approximately 2 L of .9% saline followed by 1 L of 10% formalin and then 3 L of 12% sucrose solution at 4 degrees C. Brains were blocked immediately on extraction (saving only the brain stem and cerebellum), placed in 30% sucrose in .1 M phosphate buffer (pH = 7.2), and stored at 4 degrees C for 24 h. Brain stem and cerebellum were embedded in gelatin; frozen sections were cut transversely at 60 μ , mounted on subbed slides, and reacted with tetramethylbenzidine (TMB). All cases showed retrogradely labeled cells in the caudal portions of magnocellular RN, consistent with (a) projections from "eye/face" regions of the cerebellum to RN, (b) Rosenfield and Moore's RN lesion studies of NMR conditioning (Behav Brain Res, 17:77, 1985), (c) Desmond, J., et al's HRP implant study of AAN (Brain Res Bull, 10:747, 1983).

STRESS, HORMONES AND THE AUTONOMIC NERVOUS SYSTEM II

116.1

MICRODIALYSIS OF THE DORSOMEDIAL HYPOTHALAMUS (DMH) WITH NIPECOTIC ACID (NA) ATTENUATES STRESS-INDUCED TACHYCARDIA.

Indiana Univ. Sch. of Med., Indianapolis, IN 46202-5120.

Injection of muscimol, a GABAA receptor agonist, into the DMH blocks the increase in heart rate (HR) seen in air stress in rats. This study examined the effect of microdialysis of the DMH with NA, an inhibitor of GABA uptake, on extracellular levels of GABA and on HR and mean blood pressure (MBP) in an air stress paradigm. Rats were instrumented with a microdialysis probe in the DMH on one side (for perfusion with 0.5 mM NA or Ringer's solution starting 2-2.5 hr prior to stress) and a guide cannula (for injection of 88 pmol muscimol or saline 5 min prior to stress) in the contralateral DMH. Below are increases (mean \pm SEM, n=6) from baseline HR and MBP 5 min after the start of stress:

HR (bpm) MBP (mmHg) 132 ± 12* 107 ± 8* 17 ± 2* Ringer-saline NA-saline 14 ± 2 Ringer-muscimol 88 ± 5* 13 ± 2 28 ± 8* NA-muscimol * different from the other 3 groups by ANOVA (p<0.05).
Perfusion with NA elevated [GABA] in dialysates 6-8 fold.

These results suggest that elevating extracellular levels of endogenous GABA in the DMH reduces the tachycardia induced by stress. (Supported by NS 19883 and American Heart Association, Indiana Affiliate)

116.2

STRESS-INDUCED INCREASE IN GLUTAMATE UPTAKE AND RELEASE. V.H. Gilad, Y. Tizabi, R.J. Wyatt and G.M. Gilad. Neuropsychiatry Branch, NIMH Neuroscience Center at St. Elizabeths Hospital, Washington, DC 20032 and Dept. of Pharmacology, College of Medicine, Howard University, Washington, DC 20059.

We sought to determine if stressful stimuli cause changes in the activity of rat forebrain neurons that use glutamate rat forebrain neurons that use glutamate at their neurotransmitter. Measurements of glutamate high-affinity uptake and release in synaptosomal preparations served as indices. Restraint stress lasting 0.5 to 4 hours, but not shorter, led to a 40-50% increase in both indices in the frontal cortex, bippocampus and sentum but not in cortex, hippocampus and septum, but not in the striatum. The increase in uptake was observed with glutamate concentrations of up to 10 µM, but not higher. The results indicate that forebrain glutamatergic neurons are activated by stressful stimuli in a regionally selective manner.

CARDIOVASCULAR REACTIVITY TO NON-SIGNAL STIMULI: NORMAL AND CATECHOLAMINE-DEPLETED RATS. K.S. Quiqley, B.M. Potter*, G.G. Berntson and J.P. Bruno, The Ohio State Univ., Columbus, OH 43210.

Me examined the autonomic origins of cardiovascular response to non-signal stimuli in rats. Pharmacological blockade of sympathetic (atenolol) or vagal (scopolamine) innervation to the heart indicated that the acceleratory response to a high intensity tone (75 db) was largely of sympathetic origin, whereas the deceleratory response to a low intensity tone (55 db) appeared to arise from coactivation of both vagal and sympathetic controls. To examine the potential contributions of central catecholamines (CA) to cardiovascular responses, we also tested adult animals have been reported to exhibit deficits in the development of sympathetic control. In fact, CA-depleted animals exhibited a more robust acceleratory heart rate response to the high intensity stimulus which included an additional short-latency acceleratory component reminiscent of the startle response. Both components were blocked or attenuated by atenolol, but were unaffected by scopolamine. Contrary to previous speculation, these animals may evidence increased sympathetic lability.

116.5

TEMPORAL CHARACTERISTICS OF STRESS-INDUCED SECRETION OF PITUITARY-ADRENAL HORMONES AND BRAIN CATECHOLAMINES IN PRENATALLY STRESSED MALE RAT PUPS. L. K. Takahashi, N. Cai,* J. G. Turner,* and N. H. Kalin. Dept. Psychiatry, Univ. Wisconsin Med. Sch., Madison, WI 53792 and Middleton Veterans Hospital, Madison, WI 53705.

We showed that stressed pregnant rats produce pups with heightened stress-induced secretion of pituitary-adrenal hormones. We now report on the temporal characteristics of this potentiated stress-induced hormone release. We also measured brain NE and DA because they mediate

of this potentiated stress-induced hormone release. We also measured brain NE and DA because they mediate stress-induced hormonal and behavioral responses.

14-day-old prenatally stressed (PS) and control male Sprague-Dawley rats received 5 foot shocks (0.5 mA, 1 s) in a 10-min period. Plasma ACTH and corticosterone were measured by RIA 0, 0.5, 1.0, 2.0, and 4.0 h after shock. A no-shock control group provided basal values. NE and DA levels were determined by HPLC using EC detection.

Plasma ACTH was elevated (pc.001) in PS pups only at 0 h; plasma corticosterone was elevated not only at 0 h but also at 0.5 and 4.0 h (pc.01), suggesting increased

Plasma ACTH was elevated (p<.001) in PS pups only at 0 h; plasma corticosterone was elevated not only at 0 h but also at 0.5 and 4.0 h (p<.01), suggesting increased sensitivity of the adrenal to ACTH. In PS pups, basal, 0, and 4 h hypothalamic and cortical NE were elevated (p<.01), whereas cortical DA was reduced (p<.01). This may reflect compromised neural systems that facilitate coping which consequently may increase the vulnerability of PS offspring to the deleterious effects of stress. Supported by NIMH grant MH-43986.

RELATIONSHIP BETWEEN URINARY CATECHOLAMINE LEVELS AND SEVERITY OF POST-TRAUMATIC STRESS DISORDER

R. Yehuda*1,2, S.M. Southwick*2, E.L. Giller, Jr.1, and J.W. Mason*2

1 Psychiatry Dept, UCONN Health Center, Farmington, CT, 06032.

2 Psychiatry Service, West Haven VAMC, West Haven CT, 06516.

We have previously found elevations in urinary norepinephrine (NE) and epinephrine (E) concentrations in combat veterans with PTSD compared to other psychiatric groups. In the present study we set out to replicate these pilot results in a larger sample of veterans with PTSD (n=18) and to explore the relationship between catecholamine levels and severity of PTSD symptoms. The mean urinary NE concentration was significantly higher in the PTSD group compared with normal male controls (51.9 \pm 38.4, PTSD; 31.6 \pm 9.4, controls). No significant group differences were observed in mean E or dopamine (DA) levels. Correlational analysis showed that both NE and DA, but not E, were significantly related to scores on the Combat Exposure Scale and to overall PTSD symptoms as measured by the Impact of Events Scale (IES). In particular, NE was related to scores on the 'avoidance' subscale of the IES, while DA was related to scores on the 'intrusive' subscale. In contrast, none of the three catecholamine levels were found to correlate with depression of psychotic symptoms. The results support the idea of an enhanced sympathetic nervous system activation in PTSD, and suggest that increased sympathetic arousal may be closely linked to severity of PTSD symptoms.

116.4

AGE-RELATED DIFFERENCES IN STRESS-INDUCED ADRENAL HORMONE RESPONSES B.Buwalda*, S.M.Korte*, G.Bouwg*, P.G.M.-Luiten, J.M.Koolhaas* and B.Bohus*, Dept. of Animal Physiology, University of Groningen, P.O. Box 14, 9750 AA HAREN, The Netherlands.

There is no general agreement on the nature of sympatho-adrenal stress responses in aged mammals. The type and intensity of stressors and the behavioural responses they evoke may be the intervening factor. Mild stress of sudden silence imposed on background noise does not evoke overt behavioural changes and therefore seems suitable to compare catecholamine and corticosterone responses in young (3 mo. old) and aged (24 mo. old) male Wistar rats equiped with permanent venous catheters. Blood samples were taken in the home cage before and after exposure to the mild stress in another environment. Post-test samples were also taken with delay in order to investigate recovery rate to baseline.

Basal levels of norepinephrine (NE) and corticosterone (CORT) were elevated in the aged rats while no differences in epinephrine (E) levels were found. Stress-induced increases of E and NE were similar but CORT response was blunted in the aged animals. Finally, recovery of all three adrenal hormones were impaired in the aged rats. Although young and aged rats exhibit comparable increments in plasma levels of catecholamines, the blunted CORT response and the slower recovery rates suggest an age-related impairment in the regulation of adrenal function in relation to mild stress.

116.6

TYROSINE PROTECTS HUMANS FROM THE ADVERSE EFFECTS OF ACUTE EXPOSURE TO HYPOXIA AND COLD.

L. E. Banderet* and B. Shukitt-Hale*. U.S. Army Research Institute of Environmental Medicine, Natick, MA 01760.

In rodents, administration of tyrosine, a food constituent and precursor of the catecholamines, ameliorates some of the behavioral and neurochemical deficits caused by exposure to acute stressors. In an initial study, tyrosine (100 mg/kg, p.o.) protected humans from some adverse behavioral effects of exposure (4.5 h) to a combination of hypoxia (4200 m and 4700 m) and cold (15°C) (Banderet and Lieberman, Brain Res. Bull., 22:759-762, 1989). To extend these findings we conducted a dose-response study using similar environmental conditions (4700 m and 17°C) and increased the exposure to 7 h. Using a double-blind, placebo-controlled crossover design we administered 85 and 170 mg/kg of tyrosine p.o. to 21 male volunteers. Cognition, symptoms and affect were assessed using: Bakan vigilance task, visual pattern recognition, Environmental Symptom Questionnaire (ESQ) and Profile of Mood States (POMS). Among volunteers with the greatest response to the stressors, both doses of tyrosine significantly (p<.05) reduced the adverse behavioral effects of exposure to the stressors. Vigilance, pattern recognition, distress (ESQ), alertness (ESQ), depression (POMS) and confusion (POMS), were less impaired when tyrosine was given.

116.8

PHYSICAL STRESS, EPINEPHRINE, DEXTROSE, & INSULIN INCREASE BOUND SIALIC ACID OF MOUSE BRAIN. L. Cherian and W. R. Klemm. Dept. Veterinary Anatomy, Texas A&M University, College Station, TX 77843

Our previous research showed that ethanol can decrease total brain sialic acid (SA). Because ethanol can act as a physiological stressor, some of ethanol effect might be due to stressor action. In this present study we tested the hypothesis that stress could decrease brain SA by comparing brain SA levels in non-handled/non-injected mice with those given saline and various physical stressors and drugs.

Total whole-brain SA in male outbred mice decreased, compared to non-injected mice, at 3 and 4 hours after IP saline. This lagged behind an earlier increase in free SA. Physical stressors, such as tail and foot shock, increased total brain SA 4 hrs later. To explore mechanisms, we tested several stress-related drugs. In one study, total brain SA increased about 32%, compared to saline-injected controls, in mice sacrificed 4 hours after epinephrine (0.1 mg/kg). Prednisolone (8 mg/kg) and morphine (25 mg/kg) did not seem to change brain SA levels from the decreases seen in their respective saline-injected control groups. The epinephrine effect may be due to increased availability of glucose substrate for SA synthesis. Dextrose, given IP at 2 gm/kg, produced a similar increase in total bound brain SA 4 hrs. later. Insulin (10 units/kg) also caused a similar increase. Although insulin decreases blood glucose, glucose is more accessible for SA synthesis because of enhanced transport into cells. We discuss the possibility that brain SA may be a component of the classical pituitary-adrenal stress response. Supported partly by grant AA 06920, NIAAA.

HEMODYNAMIC AND HUMORAL RESPONSES TO ACUTE EMOTIONAL STRESS. M.H. Zink III* and R.H. Alper, The University of Kansas Medical Center, Kansas City, KS. 66103

The role of stress in the pathogenesis of hypertension has long been postulated. Several models are used to examine the cardiovascular and neuroendocrine responses to chronic and acute stressors. These experiments were designed to study concurrently hemodynamic and hormonal effects of emotional stress in conscious, unrestrained male Sprague-Dawley rats. After acclimation in an operant conditioning chamber, rats were exposed to a warning tone for 1 min followed by a 3 sec, 2 mV inescapable footshock (Stress) or no footshock (Control). Mean arterial pressure (MAP), heart rate (HR), renal blood flow (RBF), and renal vascular resistance (RVR) were continuously monitored. Plasma renin activity (PRA) was determined 5, 15 and 30 min after the tone. Exposure to tone only produced a mild increase in MAP and HR which returned to baseline within 1 min after cessation of the tone. The Stressed rats displayed elevated MAP and HR for 5 min after shock with a return to baseline by 15 min. PRA and RBF were not altered in either group. In Control rats tested 3 times on one day at 1 hr intervals, and then a fourth time on the following day, the increase in MAP observed during the tone was attenuated with each exposure; tachycardia was present during the tone in all four trials. In Stressed rats, the increase in MAP was greater with each of the four exposures to the tone. Tachycardia was observed only upon the initial exposure to the tone in the Stressed rats; the increase in HR was suppressed in subsequent trials. Stress did not increase PRA. In a limited number of rats RBF was not altered but RVR increased 40% due to the increase in MAP. Thus it appears that inescapable footshock produces a conditioned increase in MAP, decrease in HR and little or no effect on RBF or PRA.

116.11

EFFECTS OF MILD STRESS ON SEROTONIN TURNOVER AND OPEN-FIELD BEHAVIOR IN STREPTOZOTOCIN-DIABETIC RATS. <u>LL Bellush & SG Reid.</u> Dept. of Psychology, Ohio University, Athens, OH 45701. Chronically-hyperglycemic diabetic (D) rats

Chronically-hyperglycemic diabetic (D) rats have reduced turnover of 5-HT in several brain regions. Increased 5-HT turnover was recently implicated in restraint stress-induced effects on food intake and open field activity. In the present investigation, we noted increased 5-HT turnover in 3 brain regions (frontal cortex, amygdala and brain stem) of D and nondiabetic (ND) rats after 1/2 hr restraint stress. D also had significantly reduced turnover relative to had significantly reduced turnover relative to had significantly reduced turnover relative to ND, as well as smaller increments in turnover in response to restraint. Both restraint and diabetes were associated with enlarged adrenal glands and reduced adrenal epinephrine concentration, although plasma corticosterone elevations after restraint were similar in D and ND. In a second study, we evaluated the functional relevance of these changes by measuring open field activity in D and ND 24 hrs after 2 hr restraint in round plexiglass tubes. Restraint had no effect on the behavior of ND in Restraint had no effect on the behavior of ND in the open field, but led to significant reductions in both general activity and exploratory behavior in D rats.

ISCHEMIA II

117.1

THE EFFECT OF CGS-19755 ON LOCAL CEREBRAL pH (LCpH) AND CEREBRAL BLOOD FLOW (CBF) IN MIDDLE CERE-BRAL ARTERY (MCA) AND IPSILATERAL COMMON CAROTID ARTERY (CCA) OCCLUDED RATS.

S.Takizawa*, M.Hogan*, A.Hakim. Brain Imaging Center, Montreal Neu-rological Institute, Montreal, Canada, H3A 2B4.

Systemic administration of CGS-19755, a potent competitive NMDA receptor antagonist, has been reported to result in better clinical outcome and smaller infarct volumes. However, we observed that even in ischemia, CGS-19755 crossed the blood-brain barrier poorly. This suggested that the observed in-vitro binding of the drug may not be functionally relevant. We report here the effect of intravenous infusion of CGS-19755 (10mg/kg bolus + 5mg/kg/hr for 4 hours) on LCpH and CBF in Sprague-Dawley rats with MCA + CCA occlusion compared to ischemic controls without treatment and others receiving CGS-19755 carrier. LCpH and CBF were determined simultaneously using ¹⁴C-dimethyloxazolidinedione and ¹⁴C-iodoantipyrine by a double-label autoradiographic technique. Our data are as follows:

	Control G	roup (n=4)	CGS-19755 (n=4)		
Structure on	CBF	pН	CBF	pН	
Occluded Side	ml/hg/min		ml/hg/min		
Caudate-putamen	6.2 ± 1.5	6.67 ± 0.06	46.6 ± 26.4	6.98 ±0.10	
Hippocampus	74.2 ± 7.3	7.16 ± 0.02	130.8 ± 25.3	7.11 ± 0.03	
Parietal cortex	11.7 ± 8.1	6.86 ± 0.04	19.4 ± 8.8	6.98 ± 0.10	
Sensorimotor cortex	27.2 ± 8.2	6.93 ± 0.06	71.5 ±13.3	7.13 ±0.02	

Values are mean ± SEM

These preliminary data suggest that the neuroprotective effect of CGS-19755 in ischemia may be related to vasodilator properties and ability to correct post-ischemic cerebral acidosis.

116.10

INDOLE-MEDIATED ADAPTATION: DOES MELATONIN MEDIATE RESISTANCE TO STRESS IN HUMANS? K.G. Walton. G.M. Brown. N. Pugh.* C. MacLean* and P. Gelderloos.* Pleurochemistry Lab, Dept. of Chemistry, and Popt. of Psychology, Maharishi International University, Fairfield, IA, USA 52556 and Dept. of Biomedical Sciences, McMaster University, 1200 Main St. West, Hamilton, ON, Canada L8N 325. Studies in animals suggest the increase of melatonin in response to stressors is important in physiological adaptation. Some authors claim that, in addition to a timekeeping function, melatonin has a tranquilizing or "anti-stress" role. Since excretion of the metabolite 6-sulfatoxymelatonin (6SM) is a gauge of melatonin turnover, we investigated the relationship between 6SM excretion and stress in college students. Urinary 6SM was tested by radioimmunoassay. Levels of stress were indicated by scores on Profile of Mood States and Spielberger's State-Trait Anxiety Inventory as well as by status as practitioner (TM, n = 22) or non-practitioner (NonTM, n = 32) of the Transcendental Meditation and TM-Sidhi program, a program known to reduce stress. Use of drugs (alcohol, tobacco and caffeine) was monitored by questionnaire and was minimal in the entire TM group but high in some of the NonTM group. Excretion rates of 6SM were higher in the NonTM group and also were affected by drug use and by gender. For example, daytime 6SM for NonTM men was 566 ± 448 ngh (n = 8) while for TM men it was 164 ± 107 (n = 11; t = 2.9, p = .01). In women, nighttime levels differed most; e.g., NonTM drug-user women (799 ± 399, n = 14) were higher than the TM women (498 ± 235, n = 11; t = 2.21, p < .04). Psychological tests supported the presumption that drug users were high-stress, drug-free NonTM subjects were intermediate-stress and TM subjects low-stress. Anxiety and mood disturbances were highly correlated with 6SM excretion, but were often opposite for men and women. Positive correlations between 6SM and 5-HIAA also were found, suggesting the

EXTRACELLULAR GLUTAMATE IN GERBIL BRAIN FOLLOWING REPEATED ISCHEMIA EVALUATED BY IN VIVO MICRODIALYSIS. N. Saito*, C. Chang*, K. Kawai*, T. S. Nowak, Jr., M. Spatz and I. Klatzo. Lab. of Neuropathol. and Neuroanatom. Sci., NINDS, NIH, Bethesda, MD 20892.

Repeated brief ischemic insults result in cumulative brain injury, particularly evident as severe delayed edema at 24 h recirculation accompanied by widespread serum protein extravasation and morphological damage. A progressive reduction in tissue oxygen tension is observed during the intervals between repeated insults suggesting should be a second of the cumulative and suggesting that persistent hypoxia may play a role in the cumulative effect, but specific functional derangements have not yet been described. In the present study the time course of changes in extracellular glutamate was evaluated by cortical microdialysis in halothane anesthetized gerbils subjected to a series of three 5 min bilateral carotid artery occlusions at 1 h intervals. Preischemic and sham occluded animals showed stable baseline levels of 0.5-2 pmol/µl dialysate with the enzymatic cycling assay employed. A single 5 min occlusion resulted in modest glutamate release, rarely achieving more than 3-4 pmol/µl over baseline, which resolved in 30-60 min. Repeated occlusions generally resulted in several-fold further increments in glutamate release even when levels had returned to baseline between occlusions, often achieving concentrations of 10-20 pmol/µl in the dialysate, comparable to that seen after a longer 15 min single occlusion. Mechanisms responsible for this potentiation remain to be identified. Nevertheless, these results identify progressive increases in glutamate release as a specific component of the pathophysiology of repeated ischemic insults which may further contribute to their cumulative impact.

GLUTAMATE PLAYS A MINOR ROLE IN THE MEMBRANE EVENTS LEADING TO NEURONAL DEATH IN A PHARMACOLOGICAL MODEL OF ISCHEMIA *IN VITRO*. EMMA R. WOOD, and PETER B. REINER, Depts. of Psychology and Psychiatry, University of British Columbia, Vancouver, B.C., Canada.

A prominent hypothesis concerning the mechanism of ischemic damage is that of glutamate neurotoxicity. We examined the effects of glutamate antagonists in a pharmacological model of cerebral ischemia *in vitro*. 400 um rat hippocampal slices were maintained in standard ACSF, and intracellular recordings were obtained from pyramidal neurons in the CA1 subfield. Pharmacological ischemia was induced by the addition of 10 mM iodoacetic acid and 1 mM sodium cyanide to the bathing medium. This treatment mimics ischemia in vivo in that iodoacteic acid prevents the glycolytic production of ATP by blocking the enzyme 3-phosphoglyceraldehyde dehydrogenase, and cyanide blocks oxidative phosphorylation by inhibiting the mitochondrial enzyme cytochrome a_3 . Thus both the hypoglycemia and the hypoxia that occur during ischemia in vivo are reproduced. This treatment causes a characteristic hyperpolarisation, loss of membrane resistance, and depolarisation, eventually leading to loss of membrane function. A combination of 200 uM APV, 10 uM CNQX and 1 mM kynurenic acid, (which together block NMDA, AMPA and kainate receptors) was applied to the bathing medium for 10 minutes prior to, and during pharmacological ischemia. Experimental and control slices were always obtained from the same rat. Glutamate antagonists increased both the duration and the magnitude of the hyperpolarisation associated with pharmacological ischemia, and delayed the cell depolarisation significantly. These effects however, were not enormous, and cell death occurred rapidly in every case, implying that while glutamate may contribute to the pathophysiology of ischemia, it is only one of a number of mediators of cell death.

COMBINED NICARDIPINE AND MK-801 TREATMENT REDUCES CEREBRAL ISCHEMIC DAMAGE. <u>D. CORBETT AND K. E. HEWITT *</u>. Basic Medical Sciences, Faculty of Medicine, Memorial University, St. John's, NF, CANADA, A1B 3V6

Excessive calcium influx and prolonged activation of the N-methyl-D-aspartate(NMDA) receptor may contribute to cerebral ischemic damage. The present study examined the antischemic effects of the calcium channel antagonist, nicardipine and the NMDA antagonist, MK-801.

Forty gerbils were subjected to a 5 ' bilateral occlusion of the carotid arteries under halothane anesthesia. The MK-801 group received a 5.0 mg/kg (i.p.) injection 15 ' after occlusion. The nicardipine group was given a 0.5 mg/kg i.p. injection 15' after occlusion plus a 1.0 mg/kg/day infusion of the drug via an osmotic mini- pump. The NMK group received the above MK-801 and nicardipine drug treatments. A control group was treated identically to the NMK group except saline was used in place of MK-801 and nicardipine. Cell counts of CA1 revealed a protective effect of MK-801 and nicardipine given only in combination (F (3, 27) = 3.641, P < .05, Scheffe test). Combined drug therapy may be a useful approach in treatment of ischemic brain injury. Supported by MRC.

DEXTROMETHORPHAN PREVENTS HYPOXIA-INDUCED LOSS OF HIPPOCAMPAL FUNCTION. R. J. Radek and W. J. Giardina. Neuroscience Research Division, Abbott Laboratories, Abbott Park, Il 60064

Dextromethorphan (DEX), an opioid class antitussive, has neuroprotective effects in animal models of brain ischemia and hypoxic cortical cell cultures. The purpose of this study was to determine whether DEX prevents hypoxia-induced loss of synaptic function in an in vitro hippocampal slice preparation. The population spike (PS) was recorded from from the CA1 pyramidal cell layer of 400µ thick guinea pig-derived hippocampal slices. The PS was irreversibly blocked in slices that were superfused with N2(95%)/CO2(5%) gassed ACSF for 30 minutes at 37° C. The PS recovered in 9 of 10 slices that were superfused with DEX at 100µM during the exposure to hypoxia. The mean PS amplitude in these 9 slices was 42% of pre-hypoxic amplitude. The PS returned in 1 of 5 slices superfused with 10µM DL-2-amino5-phosphonovaleric acid (AP-5), an NMDA receptor antagonist. The mean PS amplitude of these 4 slices was 51% of pre-hypoxia amplitude. These results show that DEX, like the NMDA receptor antagonist AP-5, has neuroprotective properties in the hypoxia sensitive hippocampus.

GLUTAMATE-INDUCED NEUROTOXICITY AND THE CYTOPROTECTIVE PROPERTIES OF IFENPRODIL, A NOVEL NMDA ANTAGONIST. D. Graham* and S.Z. Langer. Synthélabo Recherche (L.E.R.S.), 58 rue de la Glacière, 75013 Paris, France.

In animal models of focal cerebral ischaemia ifenpro-

In animal models of focal cerebral ischaemia ifenprodil has been shown to exhibit cytoprotective activity (Gotti et al., J. Pharmacol. Exp. Ther. 247, 1211, 1989). Interestingly, recent data indicate that ifenprodil labels a polyamine-sensitive site associated with the MMDA receptor complex (Schoemaker et al., Eur. J. Pharmacol., 176, 249, 1990). We have therefore studied the effect of ifenprodil in a neurotoxicity cell culture model. Dispersed cocultures of neurones and glia were prepared from fetal mice cerebral cortices at 15-17 d gestation and maintained in a humidified CO2 atmosphere at 37°C for 15-19 d. Neurotoxicity was induced by acute L-glutamate exposure and cell-death assessed by measurement of the amount of the cytosolic enzyme, lactate dehydrogenase (LDH), released into the bathing medium after 20 h. L-Glutamate exposure produced a concentration-dependent increase in released LDH activity. This effect of L-glutamate was potentiated in the presence of glycine (10 μ M). L-Glutamate (500 μ M)-induced neurotoxicity was inhibited in the presence of the NMDA channel blocker MK801 and ifenprodil with IC10 values of 30 nM and 200 nM, respectively. These results support the view that the neuroprotective properties of ifenprodil are exerted through an interaction at the polyamine-sensitive site on the NMDA receptor complex.

THERAPEUTIC EFFICACY OF LY-233053, A COMPETITIVE GLUTAMATE ANTAGONIST, IN EXPERIMENTAL CNS ISCHEMIA. K.P. Madden, W.M. Clark, A. Kochhar, and J.A. Zivin. Department of Neurosciences, University of California, San Diego. Glutamate antagonists offer a promising new avenue of therapy for

Glutamate antagonists offer a promising new avenue of therapy for CNS ischemia. Non-competitive antagonists have provided neuroprotection in a variety of models of neuronal injury. However, these agents cause marked sedation, which confounds tests of functional outcome following CNS ischemia and limits potential clinical usefulness. We tested the clinical effect and therapeutic efficacy of LY-233053, a new competitive glutamate antagonist, in a well-established rabbit model of spinal cord ischemia. Reversible ischemic insult was induced with temporary compressive occlusion of the infrarenal aorta. Duration of ischemia was varied to provide a range of durations in each experimental group. The P50 represents the duration that resulted in permanent paraplegia in 50% of animals. Five minutes after onset of ischemia, animals received IV bolus of either 50 or 100 mg/kg of LY-233053. Fifteen animals receiving 50 mg/kg displayed ataxia without apparent sedation and had a P50 of 31.1 ± 1.9 minutes. Fifteen animals receiving 100 mg/kg displayed modest sedation and had a P50 of 39.4 ± 2.7 minutes. These values were significantly longer than the P50 of 25.2 ± 1.5 minutes for 14 control animals (t= 2.42 and 4.62, respectively). We conclude that competitive glutamate antagonists may provide significant neuroprotection in CNS ischemia without major sedative effects.

117.8

FUNCTIONAL NEUROPROTECTION WITH MK801: REDUCED RADIAL MAZE IMPAIRMENT IN GERBIL ISCHEMIA MODEL. C.A. Boast and S.A. Maurer*. Wyeth-Ayerst Research, Princeton, NJ 08543-8000. Forebrain ischemia results in selective CA1 hippocampal damage and disrupts radial maze performance (Volpe, et al, Stroke, 15:558, 1984). The noncompetitive NMDA antagonist, MK801, provides protection from ischemic brain damage (Foster, et al, Neurosci. Lett., 76:307, 1987). We assessed whether MK801 would reduce a radial maze impairment in ischemic gerbils. Female Mongolian gerbils were trained on an eight arm radial maze (four arms baited) until the criterion of 75% correct on both reference and working memory was met for three consecutive sessions. Gerbils were then subjected to 10 min of bilateral carotid occlusion under halothane anesthesia with and without MK801 (10 mg/kg, i.p. just prior to occlusion). Testing resumed 24 hr later and continued for 4 days. Ischemia significantly impaired radial maze performance, affecting both reference and working memory. MK801 significantly reduced hippocampal damage and prevented the ischemiainduced radial maze impairments. MK801 treatment alone transiently impaired radial maze performance 24 hr after These findings are consistent with previous data indicating that ischemia disrupts radial maze performance and that MK801 reduces ischemic brain damage. morphological neuroprotection provided by MK801 is now shown to be functional in that radial maze performance was unimpaired in ischemic gerbils treated with the drug.

THE ACTIVITY OF BMY 14802 IN MODELS OF NEURO-PROTECTION: A COMPARISON WITH SABELUZOLE AND IFENPRODIL. S. L. Moon, J. A. Stanley*, R. C. Lamy*, M.N. Duquette*, and J.M. Libera*. CNS Biology, Bristol-Myers Squibb Co., Wallingford, CT 06492.

BMY 14802 (Bristol-Myers Squibb), a phenyl-akyl-piperidine, is effective in animal models used to evaluate neuroprotective compounds.

effective in animal models used to evaluate neuroprotective compounds. In an anoxia test, adult Sprague-Dawley rats were exposed to an atmosphere of 100% nitrogen for one min. Without any protection, virtually all of the vehicle-dosed animals (>91.7%) died. A 50 mg/kg dose of BMY 14802 given 30 min. prior to nitrogen exposure protected 63% of the animals. BMY 14802 at 75 mg/kg antagonized NMDA-induced convulsions in Swiss Webster mice, shifting the CD₅₀ from 113 to 133 mg/kg NMDA. Also, when assessed by means of a rating scale to denote the severity of cell loss, BMY 14802 at 25 mg/kg one hour premand post-surgery significantly attenuated hippocampal neuronal damage and post-surgery significantly attenuated hippocampal neuronal damage induced by a 15 min. bilateral carotid occlusion in the Mongolian gerbil.

BMY 14802 was compared to two putative neuroprotective phenyl-BMY 14802 was compared to two putative neuroprotective phenylakyl-piperazines that also bind to sigma sites. Sabeluzole (Janssen) at 5 mg/kg protected 100% in the anoxia test and shifted the CD₅₀ for NMDA to 179 mg/kg. However, under the dosing regimen used, it was not active in the gerbil carotid occlusion model at 2.5 and 5 mg/kg. Ifenprodil (Synthelabo) showed a maximal protection of 17% against anoxia at 80 mg/kg. It did not alter NMDA-induced convulsions. In addition to showing activity across all three models of neuroprotection, BMY 14802 did not produce PCP-like effects. Unlike MK-801, BMY 14802 did not produce PCP-like catalepsy in the pigeon, nor did it substitute for PCP in pigeons trained to discriminate PCP.

FELBAMATE REDUCES NEONATAL HYPOXIC-ISCHEMIC BRAIN DAMAGE IN THE RAT. C. G. Wasterlain. P. H. Schwartz. L. M. Thompson* and H. H. Hattori. Epil. Res. Labs., VAMC, Sepulveda, CA 91343 and Brain Res. Inst., UCLA.

Felbamate, a dicarbamate anti-convulsant, has marked in vitro neuroprotective properties against hypoxic damage in the hippocampal slice (Wallis et al., Neurology 40 (Suppl. 1):193, 1990). We tested its effect on in vivo hypoxic-ischemic brain damage in a neonatal rat model. Ninety-four seven-day old Wistar (Simonsen) rat pups were subjected to bilateral carotid ligation under methoxyflurane anesthesia and, after four hours of recovery, were exposed for 1 hour to 6.5% 0./93.5% N₂. Temperature was carefully controlled before, during, and after hypoxic exposure. Sixty minutes before hypoxic exposure 37 rats received, i.p., felbamate, 300 mg/kg in DMSO (1 mL/kg), 37 vehicle controls received DMSO (1 mL/kg), and 20 received 0.9% NaCl (1 mL/kg). Animals were perfusion-fixed 3 days later and serial brain sections were stained with hematoxylin and eosin. The volume of neocortical infarction (above the rhinal fissure) was calculated from 6 standardized coronal sections and the percent infarcted cortex was determined. Saline controls had infarcts occupying 70 ± 10 % of the neocortex while vehicle controls had 65 ± 5 % cortical infarction, a value significantly lower than both control groups (p < 0.01). These data suggest that felbamate may have neuroprotective properties in vivo and deserves evaluation in cerebral ischemia and status epilepticus. A POST-HYPOXIC MODEL OF MYOCLONUS IN THE RAT. P. H. Schwartz, L. M. Thompson* and C. G. Wasterlain. Epil. Res. Labs., VAMC, Sepulveda, CA 91343 and Brain Res. Inst., UCLA. Myoclonus is a common consequence of episodes of cerebral hypoxia-ischemia arising from such causes as cardiac arrest. To date, although several chemically-induced or genetic models of myoclonus have been described, no model of post-hypoxic myoclonus has been available for study. Here we describe a model of post-hypoxic myoclonus induced in the rat by reversible cardiac arrest with long-term recovery. Cardiac arrest was induced by intracardiac KCl in temperature-controlled, ketamine anesthetized, paralyzed, and ventilated adult male Sprague-Davley rats. After ten minutes of zero blood pressure, the rats were restored to spontaneous circulation by cardiopulmonary resuscitation. For at least six days, they showed marked hindlimb extensor hypertonus and the EEG was abnormal and was characterized by a predominance of slow wave activity interspersed with sharp waves. Most animals displayed spontaneous myoclonus, involving the whole body, or startle myoclonus (acoustic), involving the whole body which, with repeated stimulation, could give rise to running seizures. Histopathological examination of the brains from these animals revealed selective neuronal necrosis in layers 3-5 of lateral neocortex, the CA, pyramidal cell layer and the septohippocampal nucleus. In addition, there was a selective loss of Purkinje cells near the dural surface of the cerebellum, and neuronal necrosis in the medial superior olive as well as a loss of larger cells throughout the rostro-caudal extent of the medullary reticular formation. This model of post-hypoxic myoclonus appears promising for studies of the pathophysiologic mechanisms of myoclonus as well as its pharmacological treatment. A video of the myoclonic animals will be presented.

ISCHRMIA II

PROTECTION AGAINST ISCHEMIC NEURONAL DEGENERATION IN VITRO OR IN VIVO BY HONGHUA, AN ANTI-EXCITOTOXIC CHINESE HERBAL MEDICINE. H. Y. Bai, H. Xiao*, M.T. Price, J.W. Olney. Washington University School of Medicine, St. Louis, MO. 63110.

CNS ischemia causes glutamate (Glu) and aspartate to accumulate extracellularly and trigger neuronal degeneration by excitotoxic interaction with N-methyl-D-aspartate (NMDA), kainic acid (KA) and/or quisqualate (Quis) receptors. We have shown in the *in vitro* isolated chick embryo retina that simulated ischemia (glucose/oxygen deprivation) causes a Glu-like pattern of neuronal degeneration which deprivation) causes a Gil-like pattern of neuronal degeneration which is not adequately prevented by anti-excitotoxic agents that block only NMDA or only non-NMDA receptors, but is completely prevented by agents that block both NMDA and non-NMDA receptors. Similarly, we found that a combination of NMDA and non-NMDA antagonists provided optimal protection against ischemic damage induced in the *in vivo* adult rat retina by a dye-photothrombosis approach. Here we used the same retinal ischemia models to test the neuroprotective used the same retinal ischemia models to test the neuroprotective properties of Honghua, a Chinese herbal medicine derived from safflower. In the isolated chick embryo retina, an extract of Honghua protected against the neurotoxic actions of NMDA, KA, Quis or Glu and against ischemic neuronal degeneration. When injected into the vitreous of the adult rat eye immediately before induction of photothrombosis, Honghua conferred excellent protection against ischemic degeneration of retinal neurons. We conclude that Honghua iscineriiic degeneration oi reunal neurons. We conclude that Honghua contains one or more anti-excitotoxic agents that, either alone or in combination, block both NMDA and non-NMDA receptors and, therefore, effectively protect against ischemic neuronal degeneration. Supported by EY 08089 and RSA MH-38894 (JWO).

DEPLETION OF ATP LEVELS IN THE HIPPOCAMPAL SLICE DOES NOT PREDICT SYNAPTIC FAILURE DURING HYPOXIA. R.A. Wallis, H Hattori, K. Panizzon, E. Csiszar and C.G. Wasterlain. Neuronal Recovery Laboratory, VAMC, Sepulveda, CA 91343 and Dept. of Neurology and Brain Research Institute, UCLA School of Medicine, Los Angeles, CA 90024.

Los Angeles, CA 90024.

ATP depletion during hypoxia has been thought to be responsible for synaptic transmission failure. To investigate this question, we examined ATP levels in relationship to synaptic activity in the CA1 area of hippocampal slices with dentate and CA4 regions trimmed. Using artificial cerebral spinal fluid containing 4 mM glucose, 1.3 mM magnesium, and 2.4 mM calcium, we exposed slices to 15 min. of hypoxia. ATP levels showed a progressive decline with baseline, 5, 10 and 15 min. of hypoxia yielding ATP values of 15.6±0.6 (SE), 13.0±1.0, 10.7±1.0 and 8.3±0.5 mmole/mg protein respectively. Phosphocreatine levels likewise showed decline throughout the hypoxic exposure with values of 29.4±1.2, 21.8±3.0, 12.9±1.8, 7.9±1.5, at baseline and 5,10 and 15 min. of hypoxia. Synaptic transmission, however, as measured by the mean percent amplitude of the original evoked potential, did not show a progressive decline but rather first declined at 5 min to 2%, then recovered to 36% at 10 min and then disappeared at 15 min. These data show that the initial fall of the evoked potential during hypoxia occurs while energy reserves are still sufficient to sustain major membrane pumps. Initial synaptic failure is unlikely to reflect profound energy failure, since evoked response amplitude later increase when ATP leases continue to decline. neering failure, since evoked response amplitude later increase when ATP levels continue to decline.

BARBITURATES ENHANCE CORTICAL NEURONAL INJURY UNDER CONDITIONS OF SUBSTRATE DEPRIVATION. J.H. Weiss¹, R.G. Giffard² and D.W. Choi¹. Depts. of Neurology¹ and Anesthesiology², Stanford Univ. Med. Sch., Stanford, CA 94305

Barbiturates have been extensively studied as potential neuroprotective agents in ischemia. We found that high concentrations of barbiturates can attenuate excitatory amino acid-induced neurotoxicity in murine cortical cell cultures (Neurology 38:214, 1988). In the current studies, we examined the effect of barbiturates on glucose deprivation-induced neuronal injury in the same system. Cultures exposed to 0 glucose for 6 - 10 hr developed substantial neuronal injury by the next day, apparent either by light microscopy or by the efflux of lactate dehydrogenase to the bathing medium. Addition of 300 - 500 µM secobarbital to the media was not protective; in contrast, neuronal injury was markedly increased. Even in cultures deprived of glucose for only 4 hr, an insult which produced little injury in control cultures, secobarbital addition increased neuronal damage. Similar potentiation of injury was found with thiopental or methohexital, or when barbiturates were added to cultures deprived simultaneously of both oxygen and glucose. Enhancement of neuronal injury under ischemic conditions might be a factor limiting the neuroprotective value of barbiturates in vivo.

CALPAIN INHIBITORS IMPROVE THE RECOVERY OF SYNAPTIC TRANSMISSION AFTER HYPOXIA IN HIPPOCAMPAL SLICES.

A. Arai, M. Kessler, K. Lee and G. Lynch, CNLM, University of California, Irvine, CA 92717 and Department of Anatomy, Thomas Jefferson Medical School, Philadelphia, PA 19107.

Recently, it was reported that transient ischemic episodes that produce

Recently, it was reported that transient ischemic episodes that produce delayed pathology in hippocampus cause an immediate increase in the degradation of spectrin, a primary component of the membrane cytoskeleton (Brain Res, 1989, 492:366). The breakdown products observed were identical to those resulting from activation of a calcium sensitive protease (calpain) suggesting that this enzyme is triggered by even relatively brief periods of hypoxia. In this study, we tested calpain inhibitors for their effects on hypoxia-induced synaptic dysfunction in hippocampal slices.

Synaptic transmission in hippocampal slices continuously declined after substituting N_2 for O_2 and was lost by 4-5 min; the fiber volley disappeared after 5-6 min of hypoxia. Recovery from hypoxia was complete if reoxygenation was begun before the loss of the fiber volley but became progressively more impaired past this point. Treatment with the calpain inhibitors leupeptin (1 mM) and calpain inhibitor I (200 μ M) significantly improved the recovery of the evoked response under conditions in which control slices did not show any recovery, i.e. the drug treated slices recovered 50-80% of their initial EPSPs. Calpain inhibitors did not delay the disappearance of the fiber volley and thus presumably do not affect the processes involved in energy and ion gradient dissipation. The data suggest, instead, that a brief activation of calpain may be sufficient to cause an immediate impairment of neuronal function. Thus, calpain may be involved in both acute and delayed neuronal damage when activated during hypoxia or ischemia episodes (supported by NIA AG00538).

FOCAL CEREBRAL ISCHEMIC INFARCTION AND BRAIN EDEMA ARE REDUCED IN TRANSGENIC MICE OVEREXPRESSING HUMAN SUPEROXIDE DISMUTASE. H. Kinouchi.* S. Imaizumi.* E. Carison.* C. Epstein* and P. H. Chan. CNS Injury & Edema Research Center, Depts. of Neurology & Neurosurgery, Pediatrics and Biochemistry/Biophysics, Univ. of Calif., San Francisco, CA 94143, U.S.A.

Oxygen radicals have been implicated in the pathogenesis of brain edema and cell death in cerebral ischemia. We have demonstrated that liposome-

of Calif., San Francisco, CA 94143, U.S.A.

Oxygen radicals have been implicated in the pathogenesis of brain edema and cell death in cerebral ischemia. We have demonstrated that liposome-entrapped SOD reduced the infarct size significantly in focal cerebral ischemia in rats. Transgenic mice overexpressing human CuZn-SOD (SOD-1) enzymatic activity (1.6-6.0 fold increase) in whole brain have been successfully established (Epstein et al., PNAS 84, 8044, 1987). We now compare the infarct size (IS; infarct area/hemisphere area) and ipsilateral hemisphere enlargement (IHE; ipsilateral hemisphere/opposite hemisphere) at various stereolactic coronal planes in focal cerebral ischemia produced by a combination of middle cerebral antery occlusion and bilateral common carotid artery occlusion (Chen et al., Stroke 17, 738, 1986) in transgenic mice and normal diploid mice littermates. Experiments were done blindly and physiological parameters were monitored throughout the studies. This model provides a reproducible infarct in ipsilateral cortex, as measured by 2,3,5,-triphenyltetrazolium chloride (TTC) stain for mitochondrial dehydrogenase activity at 24 hrs postischemia. The infarct size and the ipsilateral hemisphere enlargement (an indication of brain edema) of transgenic mice were significantly smaller than that of normal mice (coronal level from anterior 3 mm; IS: 15.3% vs 23.7%, IHE: 105% vs 114%). These data suggest that superoxide radicals play an important role in the pathogenesis of focal ischemic brain injury, because the overexpression of human SOD-1 enzymatic activities attenuates the infarct size and brain edema. INHIBITION OF PROTEOLYSIS PROTECTS HIPPOCAMPAL NEURONS FROM ISCHEMIA. K.S. Lee, S. Frank*, P. Vanderklish*, A. Arai and G. Lynch. Dept. of Anatomy Thomas Jefferson Univ., Philadelphia, PA 19107 and CNLM, Univ. of Calif., Irvine, CA 92717.

Transient forebrain ischemia has recently been shown to elicit a rapid and sustained proteolysis of the cytoskeletal protein, spectrin (Seubert et al., '89, Brain Res. 492: 366). Spectrin is a preferred substrate for the calcium-activated protease, calpain; and, the specific pattern of spectrin proteolysis by calpain is identical to that seen following ischemia. The current studies examined whether this proteolytic response to transient ischemia can be inhibited by in vivo treatment with a protease inhibitor and whether p

inhibitor and whether protease inhibition affects the process of neuronal death. Adult gerbils were administered saline or the protease inhibitor, leupeptin via a cannula implanted in the right lateral ventricle. Compounds were delivered over a three day period by an Alzet osmotic pump attached to the cannula. Animals were then subjected to a ten minute period of bilateral occlusion of the carotid arteries. Post-ischemic survival periods were 30 minutes for the spectrin assay experiments and 14 days for the histological analysis of cell death. Leupeptin treatment resulted in a substantial reduction in ischemia-induced spectrin proteolysis. The post-ischemic increase in spectrin breakdown products was inhibited by approximately 75% in leupeptin treated animals. Histological studies showed that leupeptin had a pronounced neuroprotective effect on the post-ischemic loss of selectively vulnerable CA1 pyramidal neurons. Saline-treated animals exhibited a 72% loss of CA1 neurons while leupeptin-treated animals showed only 15% cell loss.

Taken together, these observations indicate that neuronal proteolysis (presumably mediated by calpain) is a critical step in post-ischemic neuronal pathology. Moreover, suppression of this proteolytic response represents a promising avenue for limiting cell death following ischemia and perhaps other neurodegenerative responses. ANTIOXIDANT LEVELS INFLUENCE ASTROCYTE SURVIVAL IN HYPEROXIA. S.F. Chen. V.S. Woolworth.* and P. H. Chan. CNS Injury & Edema Research Center, Dept. of Neurology, University of California, San Francisco, CA 94143, U.S.A.

A model for astrocyte exposure to hyperoxia has been developed using primary cultures of cerebral cortical astrocytes from neonatal rats. Exposure of these cultures to 95% O2/5% CO2 in a modular incubator chamber resulted in cell death between 48 and 72 hours, as indicated by LDH release, morphology changes, and trypan blue nonexclusion. This model has enabled us to examine the effects of alterations in endogenous antioxidant levels on the outcome of hyperoxic treatment. Astrocyte intracellular glutathione (GSH) levels and survival times were measured in cells treated with 50 µM buthionine sulfoximine (BSO) or 35 mM 2-oxothiazolidine-4-carboxylate (OTC). BSO dropped GSH levels to less than 10% of normal and shortened survival times. OTC only slightly elevated GSH levels but significantly lengthened survival times. Treatment of astrocytes with 1 mM diethyldithiocarbamate (DDC) decreased levels of superoxide dismutase and GSH-peroxidase to 70% of normal and also decreased survival times under hyperoxic conditions. None of these compounds affected cell survival under normoxic conditions. Glucose utilization, as measured by the decrease in glucose levels in the medium, was more rapid under hyperoxic than normoxic conditions. OTC treatment slows the glucose utilization by astrocytes under hyperoxic conditions. These results imply that GSH is a critical metabolite in cytoprotection against the damage induced by hyperoxia and confirms that cell death is oxygen radical mediated. (Supported by NIH grants NS-14543 and NS-25372.)

HISTOLOGY AND SOMATOSENSORY EVOKED POTENTIALS FOLLOWING BASILAR ARTERY OCCLUSION IN THE RAT. JC Wojak. V DeCrescito. W Young. Dept. of Neurosurgery, NYU Med. Ctr., New York, NY 10016.

We surgically exposed and occluded the basilar artery in 25 rats. Basilar artery occlusion at any single point between the foramen magnum and the circle of Willis did not produce histologically detectable infarcts in the brain at 12-24 hours. Two point occlusions of the basilar artery produced variable infarcts between the occlusion sites but no ischemic lesions elsewhere. After either single or double point occlusions, the proximal basilar artery refilled within 2-3 minutes. When the basilar artery was occluded above and below the origins of the anterior inferior cerebellar arteries, the arteries between the occlusion points initially collapsed but refilled within 2-3 minutes. In two rats, bilateral carotid occlusion combined with basilar artery occlusion rostral or caudal to the anterior inferior cerebellar arteries did not completely eliminate proximal basilar flow. Basilar artery occlusions invariably suppressed somatosensory evoked potentials by >50%. Regardless of whether a brainstem infarct developed, somatosensory evoked potentials recovered above baseline levels by 4 hours in 7 of 17 rats and returned to baseline levels by 24 hours in every rat tested. We conclude that the occluded basilar artery receives extensive retrograde collateral flow and that somatosensory evoked potentials are exquisitely sensitive to basilar artery occlusion but are insensitive to whether brainstem infarcts develop.

IRIGEMINAL SEPS IN A REPERFUSABLE MCA OCCUSION MODEL IN RATS. Takeo Shimizu¹, Eric H. Chudler² and Michael A. Moskowitz¹. Stroke Research Laboratory and Laboratory of Pain Research², Dept. of Neurosurgery, Massachusetts General Hospital, Boston, MA 02114. We investigated the sequential changes of trigeminal somatosensory evoked potentials (SEPs) recorded over

We investigated the sequential charges of trigeminal somatosensory evoked potentials (SEPs) recorded over the somatosensory cortex and the consequential histochemical charges occurring after focal cerebral ischemia using transvascular occlusion of the middle cerebral artery (MCA) in rats. Adult Wistar rats (270-340 gm) were anesthetized with chloral hydrate (400 mg/kg, i.p.). Ischemia of the cerebral cortex was induced by the advancement of a thread cylinder through a coaxial catheter into the anterior cerebral artery (A₁). SEPs generated from the primary somatosensory cortex (P1) and thalamocortical radiation (IIIb) usually disappeared within 5 min after obstruction of the MCA. The amplitudes of P1 and IIIb returned to control values when ischemia lasted 15 min. Recovery of P1 and IIIb were delayed after 30 min of ischemia. After 60 min of ischemia, IIIb and P1 did not recover significantly. Histochemical evidence of an infarction involving the somatosensory cortex always coincided with cases that did not show recovery of P1. These data illustrate the correlation between the persistent abolishment of the cortical SEP and irreversible brain damage after ischemia and reperfusion.

OUABAIN INDUCES SPREADING DEPRESSION-LIKE DEPOLA-RIZATION. M. Balestrino°, S. Mazzari°°, A. Leon°°
**Department of Neurology, University of Genoa and
**Fidia Research Laboratory, Abano Terme PD, Italy

In rat hippocampal slices addition of ouabain (100 uM) to the perfusion medium caused the peculiar, sudden, 20-40 mV depolarization that is usually observed in spreading depression (SD). Usually tissue voltage slowly (1-3 min) recovered to baseline despite continuing ouabain perfusion. This did reflect cell repolarization (thus suggesting that the Na-K pump was not yet completely blocked): in fact, in some slices a second identical SD-like cycle occurred minutes later. A slower, profound and sustained depolarization followed, presumably reflecting progressive and complete block of the pump. Since SD-like events occurred well before this complete block, they appeared to be triggered by some intermediate factor. Nevertheless, failure of the Na-K pump (as induced by ouabain) is obviously a key factor in the chain of events that leads to SD-like depolarization. This further suggests that drugs depolarization. This further suggests that drugs that activate the Na-K ATPase (e.g. GM1 ganglioside: J. Neurochem. 37:350, 1981) may prevent or delay SD-like phenomena (e.g. anoxic depolarization: Neurosci. Abs. 12:1401, 1986).

ANOXIC DEPOLARIZATION OF NEOCORTICAL PYRAMIDAL NEURONS IN A.S. Rosen and M.E. Morris. Department of Pharm-

acology, University of Ottawa, Ottawa, Canada KlH 8M5.
Brief (<5 min) anoxic exposure of rat neocortical slices elicited depolarizing responses (AD) of 2.5-5 mV in 18/20 layer II-III neurons. Input resistance (R_N) was generally unchanged (but a 15-20% reduction observed in 2/18 neurons) and PSPs were depressed. AD, recorded at resting potentials between -55 and -100 mV, was reversed during reoxylais between -55 and -100 mV, was reversed during reoxygenation, which also elicited postanoxic hyperpolarization (PAH) — which has been attributed to Na⁺-K⁺ pump reactivation (Fujiwara et al. 1987, J. Physiol. 384: 131). An early pump failure as cause of AD has not yet been ruled out. During anoxia K⁺ sensitive electrodes record an increase in [K⁺]₀ of 1 mM. Moreover, at normal pO₂, ouabain 5 μ M also elicits a depolarizing response. Of further interest is the finding that AD can be almost entirely blocked in slices superfused for 25-30 min with kynurenic acid 100 µM; this suggests that a release of excitatory amino acids may be partly responsible for the effect.

Since with anoxia hippocampal pyramidal neurons undergo hyperpolarization and a decrease in R_N (a Ca $^{++}$ induced K $^+$ efflux proposed as the most likely mechanism (Leblond & Krnjevic 1989, J. Neurophysiol. 62: 1), it is concluded that different mechanisms appear to operate during anoxic responses of neocortical versus hippocampal pyramidal neurons.

ION CHANNEL INVOLVEMENT IN HYPOXIA-INDUCED SPREADING DEPRESSION IN HIPPOCAMPAL SLICES. P.G. Aitken, J. Jing*, J. Young*, G.G. Somien, Dept. Cell Biology and Div. Neurosurgery, Duke Medical Center, Durham, NC 27710.

When subjected to severe hypoxia in vitro, hippocampal tissue exhibits.

cellular depolarization and ionic redistribution very similar, if not identical, to classical spreading depression (SD). Because hypoxic SD is a causative cellular depolarization and ionic redistribution very similar, if not identical, to classical spreading depression (SD). Because hypoxic SD is a causative factor in neuronal injury and death, we are interested in the specific ion channels involved. We previously demonstrated that the K* channel blocker tetraethylammonium (TEA) decreases the latency and amplitude of hypoxic SD in the CA1 region of hippocampal slices (SNA, 1988, p. 185). We now report the effects of the K* channel blocker 4-aminopyridine (4-AP) and the Na* channel blocker tetrodotoxin (TTX). Rat hippocampal slices were kept at 35°C in an interface chamber. Two hypoxic periods were given, one in control artificial CSF and one in ACSF containing 1/M TTX or 50/M 4-AP. The hypoxic periods lasted just long enough to induce SD, and were 1 hour apart. The latency and amplitude of SD were monitored in st. pyramidale of CA1. 4-AP caused a significant reduction in the latency of SD, to 85% of control. TTX had the opposite effect, causing an increase in SD latency to 180% of control. Neither 4-AP nor TTX affected the amplitude of the DC voltage shift or the shape of the SD waveform. We interpret the latency differences as due to changes in neural excitability; 4-AP increases, while TTX decreases, excitability. That TTX and 4-AP do not decrease SD amplitude argues that neither the voltage-gated Na* channels nor the delayed rectifier or "A" K* channels are major contributors to hypoxic SD. Since TEA has been shown to decrease SD amplitude, Ca²-activated K* channels (blocked by TEA but not by 4-AP) may be important ion carriers during hypoxic SD. Since TEA does not completely block hypoxic SD, other channels must be involved as well. [Supported by NIH grants 17771, 18670, 06233]

ANOXIC-INDUCED CHANGES IN K⁺_o AND Ca²⁺_o IN NEONATAL RABBIT MEDULLA. M.E. Morris and T. Trippenbach*. Department of Pharmacology, University of Ottawa, Ottawa, Canada KIH 8M5. Changes in K⁺_o and Ca²⁺_o were measured in the brainstem of newborn rabbits (1-14 days old; 53-260 g; urethane ananesthesia; controlled ventilation/100% 0₂) during brief anoxia (1-3 min 100% N2). Ion-selective microelectrodes anota (1-3 min 100% my). Indiselective mittoelectrones recorded ion and tissue potentials at depths 350-700 μ m (1-1.4 mm lateral to obex). N₂ evoked reversible K⁺ †s (with small phase I and larger phase II) of ≤ 2.3 mM (>2.5 mM resting level), duration 30-90 s; and ≤ 5 mV tissue depolarization of similar time course. Brief K⁺ †s (<5 s, ≤ 12 mM) were frequently superimposed. K⁺ plateau changes In my were frequently superimposed. A plateau changes for Day 1-4 pups were consistently larger (0.7-2.3 mM) than those for Day 6-14 pups (\leq 0.7 mM) and times to onset and peak delayed. Ca²⁺0 +s were more variable, small (0.1-1.25 mM below 1.7 mM baseline) and brief (10-60 s). They were often associated with potential bursts and the time of early K⁺ change. K⁺ *s were generally less than those expected to depress synaptic transmission. The higher levels during the first post-natal week may be due to the absence of inhibitory synapses and/or the presence of voltage-independent NMDA responses. It is suggested that the burst activity and Ca^{2+} changes indicate a Ca^{2+} influx which may activate g_K and contribute to the sequence of excitation, gasping and apnea which forms the immature breathing response to hypoxia.

EFFECT OF ANOXIA ON INTRACELLULAR AND EXTRACELLULAR K+ IN HYPOGLOSSAL NEURONS STUDIED IN-VITRO. C. Jiang, G.G. Haddad and S. Agulian. Department of Pediatrics, Section of Respiratory Medicine, Yale University School of Medicine, New Haven, CT 06510.

Previous reports have shown that extracellular K+ (Ko) Previous reports have snown that extracellular K (KO) increases in brain slices during 02 deprivation. The source of Ko and the mechanisms by which K[†] leaks from cells are not well understood. To address these issues, we studied changes in Ko and intracellular K[†] (Ki) of hypoglossal (XII) neurons during 3-5 min anoxia in brain slices of adult rats using ion sensitive microelectrodes. Intracellular recordings with double barrelled microelectrodes showed that Ki ings with double barrelled microelectrodes showed that Ki decreased during anoxia in all XII neurons studied (n=20). The magnitude of drop was 44.5 ± 17.3 mM, (mean ± SD, n=6). To study the mechanisms by which K⁺ leaks from XII neurons, we used several pharmacological blockers. K⁺ leakage was reduced by 40-50% for each of TEA (20-50 mM), CsCl (4mM) and tolbutamide (1-3mM), an ATP-sensitive K⁺ channel blocker. In contrast 4-AP, Apamine, CoCl2 and TTX had little or no effect. Measurements of the extracellular space showed that its shrinkage with anoxia was less than 5%. These results its shrinkage with anoxia was less than 5%. These results strongly suggest that during anoxia, 1) neurons lose Ki and this could contribute to the increase of Ko; 2) Ki leakage is achieved through specific K⁺ channels, possibly related to ATP depletion but not to Ca⁺⁺ activation; and 3) K⁺ leakage does not depend on the increased neuronal activity observed in XII neurons.

POTASSIUM-INDUCED PROLONGED DEPOLARIZATION IN HIPPOCAMPUS IN SITU AND IN VITRO: LIMITS OF DELAYED RECOVERY. Q. Herreras. J. Jing. G.G. Somien. Div. Physiology, Duke Univ. Med. Ctr., Durham, NC 27710

We have reported that spreading depression (SD) of prolonged duration

We have reported that spreading depression (SD) of prolonged duration induced in hippocampal tissue slices by high K* was followed by depression of synaptic transmission for 1-3 hours (Kawasaki et al, Brain Res. 457: 322-329, 1988). We now tested prolonged SD in brain of rats anesthetized with urethane. SD was induced by microdialysis of artificial CSF with K* replacing Na*, and/or by superfusion of the surgically exposed hippocampus. Evoked potentials, DC potential and [K*], were recorded from CA1. 30 min or longer depolarization induced by 90 min high K* dialysis was followed by hyperexcitability, then depression, then full recovery of antidromic and partial recovery of orthodromic transmission in 3-5 hours. 60 min or longer irrigation combined with dialysis of high K* caused complete loss of evoked responses; shorter similar treatment was followed by slow partial or complete recovery. EPSPs recovered more than orthodromic population spikes. We then repeated the experiments on hippocampus in vitro, with longer postrepeated the experiments on hippocampus in vitro, with longer post-exposure observation. Some slices that were intially depressed, recovered slowly over 3-6 hours. We conclude: (1) hippocampal tissue normally perfused by blood tolerates severe depolarization of longer duration than the same tissue in vitro. (2) Depression of transmission for 1-3 hours is not necessarily "irreversible". (3) Antidromic conduction and EPSPs can recover to control level before the ability to fire orthodromic spikes is regained. (Supported by the NIH and the Spanish Min. Education)

CALCIUM/CALMODULIN-DEPENDENT PROTEIN KINASE II ISOLATED FROM CONTROL AND ISCHEMIC GERBILS. S.B. Churn, W.C. Taft, R.E. Blair and R.J. DeLorenzo. Departments of Neurology and Pharmacology, Medical College of Virginia, Richmond VA 23298.

Calcium/calmodulin-dependent protein kinase type II (CaM kinase II) activity has been shown to be especially sensitive to the effects of transient ischemia (Brain Res. 447:159,1988). However, it is not known whether the decrease in activity observed after ischemia is due to proteolytic digestion of CaM kinase II or some postranslational modification of the enzyme. To examine this question, CaM kinase II was purified, in parallel, from control and ischemic animals. Gerbils were given a 5 min ischemic insult by means of bilateral carotid occlusion and allowed to recover for 24 hrs. Whole forebrain homogenates were made and CaM kinase II purified by previously published methods (J. Biol. Chem. 258:12632, 1983). CaM kinase II enzyme levels were quantitated by a biotinylated-calmodulin binding assay in every step throughout purification. Total protein, calmodulin binding and percent recovery were not significantly different between control and ischemic fractions. However, ischemic CaM kinase II activity remained down relative to control activity in all fractions obtained. Kinetic studies, including exogenous substrate, ATP and Calcium/calmodulin-dependent protein kinase type II (CaM obtained. Kinetic studies, including exogenous substrate, ATP and calmodulin affinities, phosphorylation rate, and tests for the presence of inhibitors showed no significant differences between control and ischemic CaM kinase II. Ischemic CaM kinase II activity could not be restored by phosphatase treatment. The results support the conclusion that ischemia induces a post-translational modification of CaM kinase

HIGH Ca++ LOADING OUTSIDE PRIMARY AND PERI-INFARCT ISCHEMIC AREAS: TERTIARY INJURY PROCESS IN STROKE. S.E. Karpiak, A. Ortiz, C.G. Wakade, N. Hernandez, M. Durkin*, A.I. Barkai*, & S.P. Mahadik. NY State Psych. Inst., & Columbia U. (Physicians & Surgeons),

Ischemia is induced by middle cerebral artery (MCAo) & ipsilateral common carotid artery (CCAo) occlusion with a 1hr temporary contralateral CCAo. The ischemic damage is restricted to cortex. No tissue pathology occurs in subcortical tissues. Maximal Ca++ increases (primary & peri-infarct areas) occur 72hrs after ischemia. To study the anatomical distribution of these increases, 72hrs after ischemia, rats were injected (i.p.) with 100uCi [45]Ca++. After 5hrs rats were sacrificed & 20micron frozen coronal sections were taken throughout. Sections were exposed to x-ray film for 14 days. Autoradiographic analyses parallel our prior finding of Ca++ increases in primary & peri-infarct areas. Large [45]Ca++ increases were also seen in the ipsilateral thalamic nuclei, tracts & internal capsule. No tissue pathology has been observed in these areas. The longterm sequelae of this increased [45]Ca++ in areas not directly affected by the ischemic insult may be significant. High levels of Ca++ in tertiary areas may reflect injury processes heretofore not included in stroke pathology. Such tertiary damage may be the basis for psychopathologies associated with stroke (e.g. depression & cognitive disorders), and the primary locus for therapeutic interventions. These data provide a basis for studies of other injury processes associated with a singular focal neuronal insult. Supported in part by grants from NINDCS (NS-2525856) and FIDIA Research Foundation.

REGIONALLY-SELECTIVE EFFECTS OF BRAIN TEMPERATURE ON INSCHEMIC DAMAGE. K.H. Neill*, B.J. Crain and J.V. Nadler. Depts. Pharmacology, Pathology and Neurobiology, Duke Univ. Med. Ctr., Durham, NC 27710.

Transient forebrain ischemia preferentially destroys neurons in striatum, neocortex and hippocampal formation. We tested the dependence of this neuronal degeneration in the gerbil on brain temperature. A thermistor neuronal degeneration in the geroii on orain temperature. A mermistor probe implanted in the striatum monitored brain temperature before, during and after a 5-min bilateral carotid occlusion. During the occlusion, rectal temperature was maintained at 36.5 °C and the brain was maintained at various temperatures between 29 and 37 °C. All animals developed a mild postischemic hyperthermia $(0.6 \pm 0.1 \, ^{\circ}\text{C})$ for several hours. Ischemic damage to different neuronal populations varied with temperature. CAS hippocampal pyramidal cells were protected from damage by the smallest reduction in brain temperature, followed by striatal neurons, cortical pyramidal cells and CA1 hippocampal pyramidal tal neurons, cortical pyramical cells and CAT hippocampal pyramical cells. The experimental anti-ischemic drug MK-801 consistently reduced the mean postischemic brain temperature by about 2 °C and caused the brain temperature to oscillate between hyperthermic and hypothermic. Under these conditions MK-801 abolished striatal damage, but only modestly and inconsistently protected CA1 pyramidal cells. MK-801 did

not affect brain temperature in sham-operated gerbils.

The neuroprotective effect of hypothermia seems to depend on how far above threshold the ischemic insult is for the neuron in question. The inconsistent neuroprotective effects of MK-801 on CA1 pyramidal cells cannot be explained by differences in the degree or duration of postischemic hypothermia. (Supported by NIH grant NS 06233.)

CALCIUM UPTAKE AND PROTEIN SYNTHESIS AFTER GLOBAL ISCHEMIA OF RAT BRAIN. G. Mies*, N. Saito*, G. Naoashima*, K. Kawai*, T.S. Nowak, Jr., G.A. Dienel and I. Klatzo, LNNS, NINDS, NIH, Bethesda, MD 20892.

Postischemic selective vulnerability of the central nervous system not only develops in the hippocampal formation or in the striatum but also in other brain regions such as thalamus, substantia nigra and inferior colliculus. It was therefore of interest to investigate the regional relationship between charactherefore of interest to investigate the regional relationship between characteristic features observed during the progression of delayed neuronal injury and characteristic metabolic changes during postischemic recovery possibly associated with the maturation phenomenon. For this purpose, a double tracer technique was established which employs [45Ca]chloride for the detection of jeopardized brain regions and [31]leucine for the measurement of regional cerebral protein synthesis. Cerebral ischemia was studied in a 10 min cardiac arrest model in rats induced by the compression of intrathoracic large vessels, followed by survival intervals up to one month. During the early postischemic recovery period (6h to 1d), an inhibited cerebral protein synthesis but no 45Ca uptake was observed in brain regions which, at later postischemic stages (2h to 4d), developed morphological criteria of injured neurons and increased 45Ca uptake. At 4 d to 1mo postischemia, depressed protein synthesis was generally associated with 45Ca uptake in areas in which neurons were at risk or irreversibly damaged. Persistent deficits in regional protein synthesis, consequently, appear to predict areas of subsequent protein synthesis, consequently, appear to predict areas of subsequent 45Ca accumulation in which neuron damage may evolve at later postischemic stages. In contrast, the reticular nucleus of thalamus showed intense 45Ca uptake with apparently normal amino acid incorporation at 4d postischemic recirculation. Morphological alterations of these GABAergic neurons were slight or absent. The thalamus therefore is an area in which the contributions of specific pathophysiology in individual cell types to these different indexes of ischemic injury may be productively investigated.

HYPOTHERMIA DURING HYPERGLYCFMIC ANOXIA PREVENTS DIFFUSE BRAIN INJURY. K.R. Wagner, M. Kleinholz*, G.M. de Courten-Myers*, R.E. Myers. Research Serv., VAMC; Depts. Neurol. & Pathol., UC Coll. Med., Cincinnati, OH 45220. Hyperglycemia during anoxic/ischemic insults

exacerbates brain injury while hypothermia is markedly brain protective. Presently, we examined whether mild (33°C) or moderate (28-29°C) hypothermia would prevent the development of brain edema and diffuse injury that

occurs following similar hyperglycemic anoxic exposures at normal body temperature (38-39°C).

Hyperglycemic cats (serum glucose = 25-50 mM), anesthetized with pentobarbital (35 mg/kg), were made anoxic by respiration with 100% nitrogen. These exposures (range = 8 min in normothermic to 20 min in moderately hypothermic cats) produced markedly elevated lactic acid concentrations in cerebral cortex (22-28 µmoles/g). While postanoxic hyperglycemic normothermic cats developed neurologic signs (focal and tonic-clonic seizures), brain edema, blood-brain barrier damage (Evans blue penetration) and usually died within 24 hours, both

groups of hyperglycemic hypothermic cats survived and showed no or only minimal damage to brain.

In conclusion, hypothermia is remarkably brain protective even during hyperglycemic anoxia in which markedly elevated lactic acid accumulations occur in brain. Hypothermia modifies the biochemical mechanisms through which severe tissue lactic acidosis during anoxic/ischemic exposures injures the brain.

118.14

PROTEIN KINASE C BINDING TO CELL MEMBRANES IS STIMULATED BY CEREBRAL ISCHEMIA AND INHIBITED BY HYPOTHERMIA. M. Cardell*

CEREBRAL ISCHEMIA AND INHIBITED BY HYPOTHERMIA. M. Cardell F. Boris-Möller H. Birig-Ren and T. Wieloch. Laboratory for Experimental Brain Research, Lund University, 221 85 Lund, Sweden.
Cerebral ischemia is accompanied by a rapid decrease in energy phosphates, that triggers membrane depolarization leading to a massive increase in intracellular calcium ino concentration, transmitter release and elevation of brain tissue diglycerides and free arachidonate. Using polyclonal antibodies directed against PKC(α), (β|1), (γ), we investigated the changes in the distribution of protein kinase C in the cytosolic and particulate fractions of brain homogenates at 15 sec, 1, 2, 3, 5, 10, and 15 min after onset of cardiac arrest ischemia in the rat. Three to ten min after the onset of ischemia the PKC levels increase in the particulate fraction, concomitantly with a decease in the cytosolic fraction, suggesting a firm binding of PKC to cell membranes during ischemia. At 15 min of ischemia PKC levels decreased in both particulate and cytosolic fractions. The ischemia-induced changes in the subcellular distribution of PKC(γ) was marked, while PKC(β|1) was less affected, and PKC(α) only marginally affected.

Hypothermia protects neurons against ischemic damage. We found that hypothermia (27 °C) prevents the ischemia-induced increase in binding of

hypothermia (27°C) prevents the isofernia-induced increase in binding of PKC to cell membranes, and the decrease in the PKC levels.

We propose that PKC is translocated to cell membranes during ischemia due to elevation of intracellular calcium ion concentrations and/or modification the membrane lipid properties. The cerebro-protective effect of hypothermia may be due to its prevention of PKC translocation-activation.

DIAZEPAM INDUCED HYPOTHERMIA AND NEUROPROTECTION IN GERBIL FOREBRAIN ISCHEMIA. M.A. kapin, R.A. Myers. V.L. Brazee, G.W. Dent. Bristol-Myers Squibb Co., Wallingford, CT 06492 in the gerbil, moderate hypothermia results in an attenuation of neuronal injury associated with forebrain ischemia. Benzodiazepines, such as diazepam, have been previously shown to be neuroprotective in mild forebrain ischemia of the gerbil and to be hypothermic producing in the rat. We have previously demonstrated in the gerbil that a marked correlation exists (r=.91) between decreasing colonic temperature and attenuation of neuronal injury. Our goal in this study was to assess in a model of severe gerbil forebrain ischemia whether diazepam could induce a marked hypothermia and at these doses attenuate hippocambal pyramidal cell death. Following methoxyflurane anesthesia, male gerbils (55-80gm) underwent 15 min bilateral carotid occlusion and 96 hrs of reperfusion. At the end of the reperfusion period, the brains were histologically examined for pyramidal cell injury. Colonic temperatures (°C) for vehicle (V), and diazepam at 1 or 10 mg/kg,i.p. (V1/10) was pre-dose =38.0±.1/37.9±.3/38.3±.1; post-dose at 30 min = 37.2±.2/36.7±.2/33.6±.08 & 90 min 36.8±.2/36.7±.2/33.4±.3. The percent protection of hippocampal pyramidal cell injury by diazepam was 9% (n.s.) and 65% (sig.p<.001) for 1 and 10 mg/kg, respectively. Our data support the contention that diazepam-mediated hypothermia may in part account for the protective actions of this drug.

DURATION, TEMPERATURE EFFECTS IN FOUR-VESSEL OCCLUSION ISCHEMIA ON CA1-CA3 DAMAGE IN RATS. P. Bialobok*, C.J. Thomas, J.M. Ordy, T.M. Wengenack, and W.P. Dunlap*. Fisons Pharmaceuticals, Univ. of Rochester, Rochester, NY 14623, and Tulane Univ., New Orleans, LA 70118.

Patients with global cerebral ischemia (IS) in stroke

Patients with global cerebral ischemia (IS) in stroke and cardiac failure have memory loss and hippocampal CA1-CA3 damage. Studies with the rat 4-VO model of IS have shown memory loss and CA1-CA3 damage. Differences in CA1 and CA3 vulnerability have been associated with variations in duration of IS and temperature during IS and reperfusion (RP). The aims of this study were to compare the effects of 15 and 30 min. of IS on CA1-CA3 vulnerability at: 1) ambient temp., 2) 37.5°C. body temp. during IS, 3) 37.5°C. during RP, and 4) 37.5°C. during IS and RP. Thirty min. of IS resulted in significantly greater CA1 than CA3 damage, compared to 15 min. of IS. Fifteen min. of IS produced mainly CA1 damage. Temperature interaction effects on CA1-CA3 damage depended upon duration of IS. Valid assessment of neuroprotective drug effects on CA1-CA3 damage attributable to specific durations of IS and temperature during IS and RP.

REGIONAL VULNERABILITY TO HYPOXIA-ISCHEMIA DURING DEVELOPMENT OF IMMATURE RAT BRAIN. K.S.Blumenfeld and F.A.Welsh. Div. of Neurosurgery, Univ. of Pennsylvania, Philadelphia, PA 19104.

To investigate the effect of development on regional vulnerability to hypoxia-ischemia in the brain of immature rat, litters of rat pups aged

To investigate the effect of development on regional vulnerability to hypoxia-ischemia in the brain of immature rat, litters of rat pups aged 7, 15, and 23 days were subjected to unilateral hypoxia-ischemia, followed by recovery for one week. Unilateral hypoxia-ischemia was produced by permanently ligating one carotid artery and placing the pups in an atmosphere containing 8% oxygen for 90 min. After recovery for 1 week, the brains were sectioned, stained, and examined for histopathologic alteration. In the 7-day group, histologic injury was not detected in neocortex, striatum, hippocampus, or thalamus. In the 15-day group, histologic injury was present in neocortex and striatum in the majority of animals, and was occasionally evident in hippocampus and thalamus. In the 23-day group, all four regions suffered severe injury in the majority of animals. Thus, the regional extent and overall severity of ischemic injury was markedly increased in the older groups. However, it is not yet clear whether the rank order of regional vulnerability changes during this stage of brain development.

Hippocampal Damage following Ischemia: Temperature Maintainence Blocks Protective Effects of the Antiglucocorticoid Metapyrone. J.K. Morse and J.N. Davis, V.A. and Duke University Medical Centers, Durham, NC 27710

Metapyrone. J.K.Morse and J.N. Davis, V.A. and Duke University Medical Centers, Durham, NC 27710

Hypothermia has been shown to reduce ischemia-induced hippocampal CA1 damage. Metapyrone, an anti-glucocorticoid, has also been shown to lower temperature and to reduce hippocampal damage following transient forebrain ischemia in the gerbil. We hypothesized that metapyrone prevented CA1 cell death by lowering brain temperature. To test this theory we subjected gerbils to 5 minutes of bilateral carotid occlusion. One group (n=8) received 3 injections of 100 mg/Kg metapyrone and the other group (n=8) received 3 injections of saline. Both experimental groups underwent surgery and sacrifice in a heated room (30°C). During the 72 hours, from the time of carotid reperfusion until sacrifice, the gerbils were kept in a heated chamber, on one of 4 levels. The mean temperature on the top shelf was 32.9°C (± 0.3 SEM); the second shelf 31.9°C (± 0.3); the third shelf 30.6°C (± 0.4); the bottom shelf 29.6°C (± 0.4). There was no difference in the severity of hippocampal damage between experimental groups. However, damage in both metapyrone and control groups was more severe in those animals kept at the higher temperatures. These results suggest that the protective effect of metapyrone on hippocampal cell death may have been mediated by a reduction in brain temperature. (Sponsored by NS06233/NS07274)

DELAYED HYPOTHERMIA REDUCES INFARCT VOLUME FOLLOWING TRANSIENT FOCAL ISCHEMIA IN RAT BRAIN. D.J.Moyer and F.A.Welsh. Div. of Neurosurgery, Univ. of Pennsylvania, Philadelphia, PA 19104. The protective effect of hypothermia on

The protective effect of hypothermia on ischemic injury has been well documented. In the present study, the effect of delayed hypothermia on cortical infarct volume was investigated in a model of transient focal ischemia in rat brain. Focal ischemia was produced by permanent occlusion of the middle cerebral artery combined with transient (1 hr) occlusion of both carotid arteries. Immediately after occlusion, cerebral temperature was lowered from 37.5°C to 32°C over the course of 20 min, maintained at this level for the duration of the 1-hr insult, and returned to 37.5°C during reperfusion. Cerebral temperature was maintained at 37.5°C during ischemia and reperfusion in the normothermic group. After recovery for 24 hr, the brain was sectioned, stained, infarct volume determined by planimetry. Delayed hypothermia significantly reduced infarct volume from 93 ±15 mm³ (normothermic, N=4) to 13 ±7 mm³ (hypothermic, N=4, pc0.001). These results demonstrate that hypothermia, even when administered after the onset of ischemia, protects the brain against ischemic injury.

EFFECTS OF INCOMPLETE GLOBAL CEREBRAL ISCHEMIA ON CORTICAL EEG SPECTRAL ESTIMATES IN THE UNANESTHETIZED RAT. J. E. Moreton, E. Echevarria, L. Robles and F.C. Tortella. U. of Maryland, Sch. of Pharmacy, Baltimore, M.D. 21201 and Neuropharm. Br., Div. of Neuropsychiat., Walter Reed Army Inst. of Res., Washington, D.C. 20307.

Male S.D. rats were prepared with cerebrocortical EEG electrodes, i.v. jugular and i.a. tail cannulae, bilateral vertebral

Male S.D. rats were prepared with cerebrocortical EEG electrodes, i.v. jugular and i.a. tail cannulae, bilateral vertebral artery occlusion and common carotid artery (CCA) snares. 24 h later, CCAs were occluded for either 15 or 20 min and recovery evaluated for 24 or 72 h. EEG and physiological parameters were monitored. Four-vessel occlusion resulted in behavioral coma and an associated isoelectric EEG. Despite no convulsive behavior or ictal activity, during recovery the EEG resembled interictal epileptiform activity superimposed on low-voltage slow waves. During the initial 6 h of reperfusion, the frequency of occurrence and amplitude of these EEG complexes increased. By 24 and 72 h recovery they were absent, or much less frequent and low amplitude slow-wave EEG activity predominated. Computer-derived spectral shifts in peak frequency(PF), mean frequency(MF), total power(TP), complexity(COM), mobility(MOB) and edge frequency(EDF) from 0-20 Hz correlated with the direct EEG changes. For example, baseline vs 10 min reperfusion values, respectively, were: PF 5.08/1.5; MF 5.74/2.56; TP 68.8/7.5; MOB 6.9/3.0; COM 9.4/5.0; EDF 15.5/6.7. Although the EEG tended to normalize during recovery decrements persisted at 24 and 72 hr. These data indicate potential value of preclinical EEG spectral analysis in cerebral ischemia research.

Diazepam Decreases Cerebral Glucose Uptake During Status Epilepticus in Amygdala Kindled Rats: Reversal by Ro15-1788. B.E. Jones and G.G. Buterbaugh, Univ. of Maryland Sch. of Pharmacy, Dept. Pharmacology and Toxicology, Baltimore, MD 21201

Status Epilepticus was evoked in amygdala Status Epilepticus was evoked in amygdala kindled animals by pilocarpine (20mg/kg; i.p.) and amygdala stimulation. After ten min of SE, rats exhibit a bilaterally symmetric cerebral glucose uptake (CGU) except for the lower midbrain and brainstem regions. Diazepam (Dz; 6mg/kg; i.v.) 15 min after SE onset produced a omg/kg; 1.v.) 15 min after SE onset produced a profound loss of muscle tone, diminished CGU in the hippocampus, striatum and frontoparietal cortices but did not alter the EEG seizure. Ro15-1788 (Ro; 50mg/kg; i.v.) administered 5 min after diazepam completely reversed the behavioral effect of Dz; CGU in these rats was comparable to untreated rats. Ro (25mg/kg; i.v.) partially reversed the behavioral effect of Dz; CGU in these rats was also comparable to untreated rats. These results suggest that the effect of Dz to markedly reduce CGU during SE without attenuating the electrographic component of the seizure involves the GABA/Benzodiazepine receptor complex.

ACTIVATION OF SUPERIOR COLLICULUS, PRE-TECTUM AND ZONA INCERTA IN THE LATE STAGES OF STATUS EPILEPTICUS-AN ANTI-ICTAL MECHANISM? A. Handforth & D. M. Treiman*, VAMC Wadsworth and Dept. of Neurology, UCLA, Los Angeles, California 90024.

The later stages of status epilepticus characterized electrographically by a transition from fast spiking (FS) to periodic epileptiform discharges (PEDs), and behaviorally by a devolution from frank to subtle convulsions. To investigate the underlying mechanisms of SE devolution, we studied the late stages of SE in the lithium-pilocarpine model with the ¹⁴C-2-deoxyglucose (2DG) method. SE was induced in LiCl-pretreated rats with pilocarpine, 20 mg/kg i.p., then 2DG, 30 uCi, given as i.v. bolus at early FS, late FS, late FS with pauses (FS+P), early PEDs with jerks, late PEDs with jerks, or late PEDs with twitches (n=6 per group). Controls received both drugs but did not enter SE. 30 min after 2DG the brain was removed and sections applied to x-ray film. The resulting autoradiographs revealed in the first two FS stages intense generalized forebrain activity. The superior colliculus (SC), pretectum (PT) and zona incerta (ZI) remained low in activity. At the FS+P stage, however, which preceded PEDs, these areas displayed sharply increased activity, which continued to the latest stages of SE. It is proposed that the late activation of the SC-PT-ZI complex may be causally related to the devolution of SE.

EFFECTS OF HYPERGLYCEMIA ON SEIZURE INDUCED BRAIN DAMAGE IN THE RAT, W. Andrew Kofke, M.D.*, M.A. Barmada, M.D.,
Thomas Rudy, Ph.D., University of Pittsburgh Department of
Anesthesiology/CCM and Pathology (Neuropathology), Pittsburgh, PA 15261

<u>Objectives</u>. We tested the hypothesis that hyperglycemia

exacerbates seizure-induced damage to the substantia nigra pars reticulata (SNPR).

Methods. Rats were anesthetized with halothane, intubated, and mechanically ventilated for surgery. Halothane was stopped for 1h. Three treatment groups (N=20 each) were subdivided by duration of SZ and recovery period, as follows (n=5 each subgroup): Controls (Ct1); 40% mannitol (Man) 40% Glc. Infusions were started th PreSZ. Flurothyl SZ were induced for 45 or 75 m. Rats underwent perfusion fixation end SZ or after 2h. At end SZ thiopental 15 mg/kg IV was given. Brains were assessed for eosinophilic neurons (EN) in necortical areas and substantia nigra with severity of damage graded from 0-5 (0=no damage). SNPR was also graded (0-5) for degree of vacuolation (vac). Ridit analysis was used to test statistical significance.

Results. Clc was 59-107 mg% in ctl and Man groups and was 409 and 452 mg% in Glc groups. Glc administration decreased the SNPR grade (Glc vac = 2.8 vs control = 4.0, Glc EN = 3.3 vs control = 4.0; P. 05). No effect was evident for Man infusion or acute groups.

Conclusions. Hyperglycemia can be protective vs SZ-induced SNFR damage.

CHANGES IN INHIBITORY PROCESSES FOLLOWING RECURRENT SEIZURES INDUCED BY SYSTEMIC ADMINISTRATION OF KAINIC ACID. N.W. Milgram, T. Yearwood*, M. Khurgel, and R. Racine. Dept. Psychol., U. Toronto, Toronto, Ontario.

Paired pulse inhibition was monitored prior to, immediately following, and over a one month period after a single subcutaneous injection of kainic acid in rats chronically prepared with stimulation electrodes in the angular bundle and recording electrodes in the dentate gyrus. There was a progressive loss of inhibition in the openiod immediately following KA which predicted the development of seizures. This effect lasted for a maximum of 24 hours. Over subsequent testing inhibition recovered to levels significantly greater than baseline. Increased inhibition persisted for the duration of the experiment. The long-term increase was restricted to the early phase of inhibition. The late-phase of inhibition (analyzed at interpulse intervals between 200 and 300 msec) showed a transient decrease followed by recovery to baseline levels within 7 days. These findings are inconsistent with previous reports of a long-lasting decrease in inhibition produced by recurrent seizures. (Sloviter, R.S., Science, 235: 73, 1987).

SEIZURES INCREASE ACETYLCHOLINE AND CHOLINE IN RAT BRAIN. X. Gu and R.S. Jope. Dept. of Psychiatry, U. of Alabama, Birmingham, AL 35294

X. Gu and R.S. Jope. Dept. of Psychiatry, U. of Alabama, Birmingham, Al. 35294. Scizures induced by three convulsants, each causing status epilepticus, produced differential effects on acetylcholine (ACh) in rat brain. Status epilepticus induced by coadministration of lithium and pilocarpine caused increases in ACh in the cerebral cortex and hippocampus. Status epilepticus induced by a high dose of pilocarpine depleted ACh after 1 hr, followed by an increase. Status epilepticus induced by kainate increased ACh, but the magnitude of the increases were lower and the latencies were longer in comparison with lithium/pilocarpine, both of which may be reflective of the time course and characteristics of the electrical seizure activity. In contrast, ACh in the striatum was either unchanged or decreased by convulsant treatments. The finding that ACh increases in two models of status epilepticus in the cortex and hippocampus is direct contrast with many in vitro reports in which excessive stimulation causes depletion of ACh.

the cortex and hippocampus is in direct contrast with many in vitro reports in which excessive stimulation causes depletion of ACh.

The concentration of choline (Ch) increased during seizures in all three regions and with all three seizure models. This is likely to be due to activation of phospholipase C and/or D activity causing cleavage of Ch-containing lipids.

The excessive ACh, as well as the Ch, present during status epilepticus induced by Li and pilocarpine was responsive to pharmacological manipulation. Atropine tended to decrease ACh and increase Ch, similar to its effects in controls. The NMDA antagonist, MK-801, reduced the excessive concentrations of both ACh and NMIDA antagonist, MA-801, reduced the excessive concentrations of both ACn and Ch. Inhibition of Ch uptake by hemicholinium-3 administered icv reduced ACh in controls and when given to rats during status epilepticus.

These results demonstrate that the rat brain concentrations of ACh and Ch can increase during status epilepticus. The accumulated ACh was not in a static, inactive

compartment, but was actively turning-over and was responsive to drug treatments. Excessive concentrations of ACh and/or Ch may play a role in seizure maintenance and in the neuronal damage and lethality associated with status epilepticus.

RENAL DYSFUNCTION FOLLOWING REPETITIVE SEIZURES IN RATS. B.L. Peronne*, R.S. Hodson*, R.C. Vari*, and N.R. Kreisman. Dept. of Physiology, Tulane Univ. Sch. Med., New Orleans, LA 70112

To determine whether acute renal failure occurs in status epilepticus, seizures were induced periodically in anesthetized, paralyzed rats by i.v. injection of pentylenetetrazol. Measurements were made of arterial blood pressure (BP), hematocrit (Hct), glomerular filtration rate (GFR), renal plasma flow (RPF), renal blood flow (RBF), urine protein concentration, urinary Na+ and K+ excretion, and urine flow (v) both prior to and after 40 min of seizures. Following seizures, v increased from 11.3 to 29.3 µ/min, and Na+ excretion increased from 0.74 to 1.98 µeq/min. RBF decreased from 8.6 to 4.1 ml/min, RBF decreased from 15.6 to 4.5 ml/min, and GFR decreased from 2.6 to 1.1 ml/min. No significant differences were found in BP, urinary K+ excretion, or urine protein levels. The marked diuresis and large increase in Na+ excretion, coupled with decreased RBF and GFR, suggests that seizures can produce acute renal failure probably mediated by prerenal vasoconstriction and tubular damage. (Supported by the American Heart Association National Center and La. affiliate).

PERSISTENT ALTERATIONS OF DENTATE GYRUS INHIBITION FOLLOWING KAINIC ACID-INDUCED STATUS EPILEPTICUS IN MATURE, BUT NOT IMMATURE, RATS. K. Haas, E.F. Sperber, S.L. Moshé and P.K. Stanton. Albert Einstein Coll. of Med., Bronx, NY 10461. In adult rats, kindling and kainic acid-induced seizures produce sprouting of recurrent collaterals in the dentate supragranular layer and a persistant enhancement of inhibition of dentate granule cells. These changes recompany enhanced enjars avecaribility. In contract kainia exist in the dentate granule cells.

persistant ennancement or inhibition of dentate granule cells. These changes accompany enhanced seizure susceptibility. In contrast, kainic acid-induced seizures in immature rats do not lead to long term increases in seizure susceptibility. Hence, we determined whether kainic acid-induced status epilepticus in immature (14-15 day old) rats is associated with persistent alterations in dentate gyrus synaptic transmission in hippocampal slices. Thirty days after status epilepticus, extracellular recording were made in the granule cell body layer of hippocampal slices (400 µm) from seized rats and age-matched controls. Relative levels of inhibition and excitation were assessed by apied-nulse outbodeonic stimulation of the

seized rats and age-matched controls. Relative levels of innibition and excitation were assessed by paired-pulse orthodromic stimulation of the perforant path. In controls, afferent stimulation produced a triphasic response consisting of an initial fast inhibition (0-20 msec), excitation (20-200 msec), and a late inhibitory phase (200-6000 msec). The level of granule cell excitability is measured as the change in amplitude of a test pulse delivered at varying intervals after a conditioning stimulus. We measured recurrent, feedback innervation by antidromic-orthodromic pairedpulse activation, and feed-forward inhibition by preceding the test pulse with a weak, epsp-generating orthodromic stimulus.

Adults exhibited enhancement of the late inhibitory component of

paired-pulse responses four weeks after status was induced. In contrast, slices from 14-15 day old pups showed no significant changes in paired-pulse physiology four weeks post-status. These data suggest that the immature brain, though more seizure-prone than the adult, may be less susceptible to seizure-induced persistent alterations in neuronal excitability.

PATTERNS OF 2-DEOXYGLUCOSE UPTAKE AND FOS IMMUNOREACTIVITY ASSOCIATED WITH LIMBIC STATUS EPILEPTICUS IN THE RAT. LE. White and J.L. Price. Dept. Anat. & Neurobiol., Washington Univ., St. Louis, MO 63110.

Models of nonconvulsive and convulsive limbic status epilepticus were developed in the adult rat by 40 min of continuous electrical stimulation of either the basolateral amygdala, the anterior piriform cortex, or the olfactory bulb. Nonconvulsive status epilepticus is characterized by persistent low frequency (1-2 Hz), sharp wave discharges observed in depth EEG recordings during incessant exploratory behaviors. The associated 2-deoxyglucose (2-DG) uptake is concentrated in the basolateral amygdala and its efferent targets. Three olfactory areas, the anterior olfactory nucleus, the ventral tenia tecta, and the dorsal endopiriform nucleus, are also activated, but not the piriform cortex. Convulsive status epilepticus includes all of these same features, with the addition of emergent convulsive episodes manifested as discrete segments of high frequency (10-20 Hz), sharp wave activity and concurrent clonic behaviors. The accompanying pattern of 2-DG uptake consists of the nonconvulsive pattern, with the addition of several limbic and nonlimbic areas, especially the piriform and entorhinal cortices and the substantia nigra. In general, structures that exhibit high 2-DG uptake also contained many somata that were immunoreactive for the FOS protein, with the exceptions of the substantia nigra and the medial thalamus.

These findings demonstrate that common seizure circuits may be activated by stimulating different forebrain sites. Furthermore, they suggest that activation of the basolateral amygdala underlies nonconvulsive status epilepticus, while activation of other limbic and nonlimbic structures, particularly the piriform cortex and the substantia nigra, is required for the expression of convulsive status epilepticus. Supported by NIH DC00093 and NS07057.

SYNAPTIC REORGANIZATION FOLLOWING STATUS EPILEPTICUS IS AGE-DEPENDENT. E.F. Sperber, K. Haas, P.K. Stanton & S.L. Moshé. Depts. of Neurology & Neuroscience, Albert Einstein College of Medicine, Bronx, NY 10461

Lesions of hippocampal afferents induce synaptic reorganization of hippocampal mossy fibers and redistribution of synaptic terminals in the supragranular layer of the dentate fascia. A similar pattern of synaptic sprouting has been observed following seizures in adult rats, suggesting the presence of a seizure induced lesion

In previous studies, we reported that kainic acid induced seizures produce greater amounts of cell loss in the hippocampal CA3 region of adult rats as compared to pups. However, if undetected cell loss is present in the pup, we would expect synaptic sprouting to occur. To test this hypothesis, we exposed adult rats and 14-15 day old pups to kainic acid induced status epilepticus. Thirty days later, we determined whether sprouting occurred by using the Timm stain.

Consistent with previous studies of adult rats, the precent results.

Consistent with previous studies of adult rats, the present results indicate that kainic acid induced status epilepticus produced dense Timm staining in the supragranular layer of the hippocampal fascia dentate. In contrast, in rat pups, status epilepticus did not produce any aberrant Timm staining. This suggests that status epilepticus does not induce hippocampal mossy fiber reorganization early in life. These age related differences may be the result of the delayed maturation of the granular cell layer which is still developing and proliferating at 2-4 weeks of age.

FOREBRAIN DAMAGE INDUCED BY THE ACH-ESTERASE INHIBITOR SOMAN IS BLOCKED BY MK-801 EVEN WHEN GIVEN AFTER CONVULSION-ONSET. S. Sparenborg, L.H.Brennecke*, D.J. Braitman*, U.S. Army Medical Research Institute of Chemical Defense, APG, Maryland 21010.

Disease of the NMTA artegorist MK-901 was given to myine a principle of the property
Diazepam or the NMDA antagonist MK-801 was given to guinea pigs during soman-induced status epilepticus (SE) to determine the time course of inhibitory soman-induced status epilepticus (SE) to determine the time course of inhibitory and excitatory amino acid (EAA) involvement in the development of neuronal necrosis resulting from soman poisoning. Subjects were pretreated with pyridostigmine, challenged with soman (2xLD₂₀), and given atropine and pralidoxime chloride as therapy. MK-801 (0.3 or 1 mg/kg) or diazepam (1 or 3 mg/kg) was given at 5 or 120 min after the appearance of electrographic spikes. In other groups, MK-801 (0.3 mg/kg) or diazepam (1 mg/kg) was given at 50 min after spike appearance. The brains of all subjects that survived for 48 hours after soman challenge were prepared (with H & E stain) for light microsopic examination of the amygdala, hippocampus, thalamus, and the parietal and pyriform cortices.

SE and motor convulsions developed in each subject within five minutes of spike appearance. Neuronal necrosis, most severe in the amygdala and least severe in the thalamus, was observed in animals not given MK-801 or diazepam. MK-801 completely protected against necrosis and convulsions when given at the 5- and 50-completely protected against necrosis and convulsions when given at the 5- and 50-completely protected against necrosis and convulsions when given at the 5- and 50-completely protected against necrosis and convulsions when given at the 5- and 50-completely protected against necrosis and convulsions when given at the 5- and 50-completely protected against necrosis and convulsions when given at the 5- and 50-completely protected against necrosis and convulsions when given at the 5- and 50-completely protected against necrosis and convulsions when given at the 5- and 50-completely protected against necrosis and convulsions when given at the 5- and 50-completely protected against necrosis and convulsions when given at the 5- and 50-completely protected against necrosis and convulsions when given at the 5-convergence and 5-convergenc

completely protected against necrosis and convulsions when given at the 5- and 50-min delays. Severe necrosis was found in the amygdala, and mild to moderate

min delays. Severe necrosis was found in the amygdala, and mild to moderate necrosis was found in the thalamus, hippocampus, pyriform and parietal cortices of the MK-801 120-min delay groups and in all groups treated with diazepam. Previously, we had found that diazepam (2 mg/kg) given prior to soman completely prevented neuronal necrosis. In this experiment, however, when the administration of diazepam was delayed until only 5 min after the onset of electrical seizures, a substantial level of necrosis developed. It appears that the efficacy of diazepam was decreased when given after a critical period early in the development of SE, but the efficacy of MK-801 continued until 120 minutes after seizure onset. The relative superiority of MK-801 may be attributed to its ability to act directly on the EAA system, which has been shown to be critically involved in the induction of brain damage by several neurological insults.

ALZHEIMER'S DISEASE: BIOCHEMISTRY AND CLINICAL STUDIES

120.1

ELEVATION OF UNSATURATED FATTY ACIDS IN BRAIN MEMBRANE PHOSPHOLIPIDS IN ALZHEIMER'S DISEASE. <u>T. Nakada and I. L. Kwee</u>. Neurochem Res Lab, VA Med Ctr, Martinez, CA 94553 and Dept of Neurology, Univ of California, Davis, CA 95616.

Fatty acid constituents were analyzed in cerebral cortex of pathologically proven Alzheimer' brains and cortex of pathologically proven Alzheimer' brains and aged matched controls using conventional thin layer chromatography and gas liquid chromatography. Alzheimer's brains were consistently found to have higher mono- (16:1, 18:1) and poly-unsaturated (18:2, 18:3) fatty acids compared to age matched controls (p < 0.01). The elevation in essential fatty acids indicated that mechanisms other than diet are likely to be the cause of the observed elevation in unsaturated fatty acids in Alzheimer's cortex. The study strongly suggests that abnormalities in fatty acid metabolism and resultant membrane phospholipid abnormalities may play a role in the pathogenesis of abnormalities may play a role in the pathogenesis of Alzheimer's disease

120.2

TROPHIC EFFECT OF BRAIN HOMOGENATE CEREBROSPINAL ON NEURONAL CELLS FLUID ALZHEIMER'S DISEASE

S.Kittur.B.Weeks*.H.Kleinman*.G.Martin*.W.Adler> GRC,NIA,Baltimore,MD.21224,NIDR,NIH,Bethesda,MD.

In order to determine if there is a toxic or a tangle promoting factor in Alzheimer's disease(AD), we tested the effect of brain extract, cerebro spinal fluid (CSF) and serum from both AD patients and control individuals, on neuronal cell branching, process formation and adhesion. Pheochromocytoma (PC-12) cells and neuroblastoma-glioma NG108-15 cells were cultured in serum free defined media containing various concentrations of brain homogenates, CSF or serum from patients with AD and control subjects on substrates of plastic and laminin. We found the brain homogenates from both AD patients and control individuals enhanced neurite outgrowth in PC-12 and NG-108 cells in the presence of laminin. However only AD brain homogenate stimulated an increase in branching per neurite process in PC12 cells after approximately 4 hours of culture on laminin substrate.

The observed neurotrophic effect of Alzheimer's brain tissue extract on neuronal culture may be explained by the presence of a neurotrophic factor giving rise to abnormal sprouting and tangle promoting activity in Alzheimer's disease. Such a factor might be produced in response to neuronal loss or as a part of Alzheimer's pathology, characterization of such a factor may be useful in understanding the pathophysiology of the disease.

BASIC FIBROBLAST GROWTH FACTOR (FGF) IN ALZHEIMER'S DISEASE. A. Baird*, A.M. Gonzalez*, E.D. Bird#, R. Chorsky*, J. Alvarez*, R.J. Corona*, and E.G. Stopa#. The

R. Chorsky* J. Alvarez* R.J. Corona*, and E.G. Stopa#. The Whittier Inst., La Jolla, CA, McLean Hosp., Belmont, MA and #Dept. of Path., SUNY Health Science Center, Syracuse, NY Although nerve growth factor (NGF) has been considered for therapeutic use in the treatment of Alzheimer's disease (AD) (Neurobiol. of Aging 10:205-207, 1989), basic (FGF) has been shown to be equally as effective in supporting the growth of basal forebrain cholinergic neurons (Nature 332:306-361, 1988). In this study, we examined basic FGF in control and AD brains in an effort to characterize a possible role for the growth factor in the pathogenesis of AD. Immunocytochemical localization with a specific polyclonal antibody (773), revealed that basic FGF is widely distributed in astrocytes and neurons throughout the normal prefrontal cortex and hippocampus (n=5). In AD (n=4), immunoreactive FGF was substantially increased in these regions and could be localized in neuritic plagues and in association with neuronal neu-AD (n=4), immunoreactive FGF was substantially increased in these regions and could be localized in neuritic plaques and in association with neuronal neurofibrillary tangles. In situ hybridization for FGF mRNA suggested an increased expression of the FGF gene within the hippocampus of Alzheimer patients. Western blotting established the presence of basic FGF in all samples studied and quantitative RIAs performed on fresh frozen samples of cerebral cortex confirmed that the concentration of FGF was approximately 2-fold greater in Alzheimer patients. These observations support the hypothesis that basic FGF may have neurotrophic activity in the human brain and suggest that it is increased during the "injury" response of AD. By virtue of basic FGFs affinity for heparan sulfate-like proteoglycans, and the association of these GAGs with amyloid plaques, our data also suggest that the increased FGF observed in AD may not necessarily reflect the bioavailability of the growth factor to surrounding neurons. RVHPGSS00002, AG00295, DK-18811.

120.5

NA/CA EXCHANGE ACTIVITY IN CEREBRAL PLASMA MEMBRANE VESICLES IS INCREASED IN ALZHEIMER'S DISEASE. (AD) R.A. Colvin,* J.W. Bennett,* S.L. Colvin,* and G.D. Miner. Pharma-cology Dept., ORU School of Medicine and The Alzhiemer's Foundation, Tulsa, OK, 74137

Cerebral plasma membrane vesicles (PMV) were purified by sucrose density gradient centrifugation from frozen postmortem hippocampal/temporal cortex tissue slices derived from age matched brains of normal, AD and Non-Alzheimer dementia (NAD) origin. Na/Ca exchange of PMV increased rapidly at first and then maintained a steady plateau for up to 5 min. When the Ca ionophore A23187 (10µM) was added after 4 min, Ca content was immediately reduced by 90% Ruthenium red (10µM) had no effect on Ca content. Na/Ca exchange was increased in AD brains as evidenced by both an increase in the initial rise in Ca content and in elevated values of peak plateau Ca content. The Km and Vmax for Na/Ca exchange was obtained from Lineweaver-Burk analysis of the effect of increasing concentrations of Ca on Ca content after 30 sec. The values obtained for the K_m (μM) and V_{max} (nmol/mg/30 sec) were (respectively): normal (n=6) 57.9±28.1 and 2.23±.29; AD (n=6) 71.2±29.3 and 3.34±.794; NAD (n=4) 66.1±3.3 and 1.88±.75 (mean \pm S.D.). The V_{max} for Na/Ca exchange in AD brain tissues was significantly (p<.05) elevated when compared with normal or NAD brains. The results suggest that Na/Ca exchange activity is probably increased in AD brain in regions suffering the greatest degeneration.

120.7

ISOLATION OF A NOVEL 66 kD PHF PEPTIDE FROM ALZHEIMER'S BRAIN. F.P. Zemlan, G.D. Yogelsang, E.F. Schwab and G.E. Dean. Department of Psychiatry, Univ. of Cincinnati College of Medicine, Cincinnati, OH 45267-0559.

Electrophoretic purification and solubilization of PHF (Vogelsang et al., J. Neurochem. 54 1990 148) yields two groups of PHF peptides, a broad band of PHF peptides immunoreactive with the pAb PAM raised against an enriched PHF preparation and a group of 55-66 kD PHF peptide fragments not immunoreactive with PAM. These two groups of PHF fragments were independently isolated based on their differential affinity for nitrocellulose. The 55-66 kD peptide fraction with low nitrocellulose affinity demonstrated a ladder of 55-66 kD proteins on silver stained SDS-PAGE and no immunoreactivity with either PAM or the MAP-tau mAb Tau-1 on Western blots. This fraction was employed for pAb production in mice. Following immunoblot pAb screening against purified PHF; a pAb M1 was identified which labeled a primary 66 kD PHF peptide fragment on Western Immunocytochemical studies demonstrated that M1 pAb selectively labeled neurofibrillary tangles in formalin fixed AD brain with no labeling observed in age matched normal brain. The present data suggest that a novel 66 kD PHF peptide fragment has been isolated which appears unrelated to MAP-tau. Further characterization studies are ongoing to determine whether this 66 kD PHF peptide fragment represents a novel protein present in low abundance in normal brain.

120.4

PEPTIDE PROFILE VARIATIONS RESULTING FROM THE ADDITION OF KAINIC ACID TO FETAL RAT HIPPOCAMPAL CELL CULTURES. M.L. Zettel, J.R. Slemmon & P.D. Coleman. Dept. Neurobiology and Anatomy & Dept. Biochemistry, Univ. of Rochester, Rochester, N.Y. 14642

For about a century it has been known that nervous system injury leads to glial cell reaction. More recent evidence from studies in which cell death is limited to a neuronal population suggests that this glial reaction is a response to neuron death (Streit & Kreutzberg, 1988). We propose that this glial response may be mediated by altered release of signal peptides by dying or dead neurons. We have found candidate peptides whose release into the microenvironment is altered following manipulations designed to produce neuron death.

Mainic acid (KA) is a neuroexcitatory agent which has been shown to induce neuron death. We added four concentrations (.0, .1mM, .5mM, 1.0mM) of KA in DME to hippocampal and cerebellar microexplant cultures (Moonen, et al., 1990) derived from fetal day 18 rats as well as to media alone. Reverse phase HPLC showed that KA added to media alone abolishes one large peptide peak. Chromatograms obtained from defined media of explants in which there had been presumptive neuron death show peptide peaks which consistently differ in amplitude from control cultures. Identical experiments performed using cerebellar cultures from the same fetal rats do not show most of these changes. The peptides of some of these peaks are being isolated and added to glial cell culture preparations to examine the effects of the peptides on glial proliferation. Peptides of interest are also being sequenced. Supported by NIH grants: AG01121, AG03644, AG09016.

120.6

ALTERED PROTEIN TYROSINE PHOSPHORYLATION IN ALZHEIMER DISEASE. I.P. Shapiro, E. Masliah, T. Saitoh. Department of Neurosciences, School of Medicine (M-024), University of California, San Diego, La Jolla, CA 92093.

Since protein tyrosine kinases (PTKs) and their substrates are important in signal transduction and cellular regulation in the brain, alterations in protein tyrosine phosphorylation might be involved in Alzheimer disease (AD) pathology. The activity of PTKs was determined in extracts from AD autopsy brains and age and post-mortem time matched unaffected control brains using the PTK synthetic peptide substrate, $poly(Glu_4Tyr_1)$. The specific activity of PTKs in the particulate fraction was decreased two-fold (p< 0.005) in AD relative to controls. Cytosolic PTK activity was not significantly altered. Quantitative immunohistochemistry and morphometry of frontal cortex sections with anti-phosphotyrosine (anti-PTyr) antibody indicated increased anti-PTyr staining in neurons, although the number of anti-PTyr positive neurons per mm decreased. Also, increased anti-PTyr staining was observed in hippocampal neurons. Analysis of Western blots of proteins cytosol and particulate fractions revealed increases in cytosolic anti-PTyr immunoreactive polypeptides with molecular mass of 60 and 55 kDa. These results suggest that altered PTK activity and protein tyrosine phosphorylation are involved in AD pathology

120.8

COMPARISON OF A SANDWICH ENZYME IMMUNOASSAY FOR ALZHEIMER'S DISEASE ASSOCIATED PROTEIN (ADAP) IN HUMAN BRAIN AND THE PRESENCE OF A68 BY WESTERN Hossein A. Ghanbari and Barney E. Miller. ABBOTT LABORATORIES, DEPT 9MA/AP20-3, ABBOTT PARK, IL 60064

We have developed a sandwich enzyme immunoassay, ALZ-EIA (Brain) for measuring Alzheimer's Disease Associated proteins (ADAP) in human brain tissue. Although both of the antibodies used in this assay (PR1 and ALZ-50) cross-react with normal brain components (including tau proteins), the combination appears to minimize cross-reactivity and the assay has demonstrated a high level of specificity for Alzheimer's Disease (AD) cases. A-68 is one of the the proteins detected in the human AD brain as indicated by Western the proteins detected in the human AD orain as indicated by Western blot using ALZ50. This protein is absent in non-AD brains. We have compared ADAP reactivity by ALZ-EIA (Brain) and presence of A68 by Western blot using a total of 61 brain specimens. The brain specimens included: AD(n=21), AD/Down's (n=2), Normal (n=14), Parkinson's Disease (n=7), Huntington's (n=2), Korsakov (n=2), Wernicke (n=1) and Motor Neuron Disease (n=2). The non-AD cases (n=28) had no detectable ADAP by ALZ-EIA (Brain), and showed no A-68 band by Western blot using ALZ-50. The AD cases (n=23, including the two AD/Down's), all were positive for ADAP by the ALZ-EIA (Brain), but only 21 of 23 had visible A-68 band by Western ALZ-EIA (Brain) compared well with the presence of A-68 bands by Western blot and demonstrated very high specificity and sensitivity.

DISTRIBUTION OF ALZHEIMER'S DISEASE ASSOCIATED PROTEIN DISTRIBUTION OF ALZHEIMER'S DISEASE ASSOCIATED PROTEIN (ADAP) IN VARIOUS REGIONS OF HUMAN BRAIN. B.E. Miller¹, W.O. Whetsell, Jr.², H. Haigler¹, and H.A. Ghanbari¹. Dept. 9MA, AP20, Abbott Laboratories, Abbott Park, IL 60064¹ and Neuropathology, Dept. of Pathology, Vanderbilt University, Nashville, TN 37232-2561². The distribution of an Alzheimer's Disease associated protein

The distribution of an Alzheimer's Disease associated protein complex (ADAP) was studied by enzyme immunoassay (see Ghanbari, et al., JAMA, June, 1990, for details of the assay) in post-mortem brain tissue from a group of five Alzheimer'sDisease (AD) patients and a group of five non-Alzheimer's Disease (NAD) patients. In each of these ten brains, eighteen different brain regions were examined including frontal, temporal, parietal and occipital cortex, hippocampus, subiculum, amygdala, caudate nucleus, putamen, globus pallidus, thalamus, hypothalamus, subthalamus, basal nucleus of Meynert, substantia nigra, locus ceruleus, medulla, and cerebellum. ADAP is a protein complex of total molecular weight of more than 200 kDaltons which produces three major bands in SDS-PAGE Western blot using ALZ50 antibody. This enzyme immunoassay (ALZ-EIA) has been configured to minimize cross-reactivity with normal brain components by using the antibodies ALZ50 and PR1, a polyclonal antibody against ADAP (blod.) In all five NAD brains (including one case of multi-infarct dementia without Alzheimer's), no ADAP was detected by ALZ-EIA. ADAP was consistently detected in all five AD brains with highest levels being found in regions associated with cognition and memory. found in regions associated with cognition and memory.

CLASSICAL CONDITIONING OF THE EYEBLINK RESPONSE IN ALZHEIMER'S DISEASE AND MULTI-RESPONSE IN ALZHEIMER'S DISEASE AND MULTI-INFARCT DEMENTIA. R. G. Finkbiner, D. J. Libon, D. K. Sasse, J. M. Coffin, K. E. DeMott, & D. S. Woodruff-Pak. Dept. of Psychology, Temple Univ. and Philadelphia Geriatric Center, Philadelphia BA 10441 Philadelphia, PA 19141.

We reported striking differences in conditioning between patients diagnosed as probable Alzheimer's disease (AD) and non-demented elderly. For this study, it was predicted that AD patients with elderly. For this study, it was predicted that AD patients with impaired cholinergic input to hippocampus would all show poor conditioning. MID patients would show poor conditioning only if the vascular lesions affected relevant subcortical areas. Thus, mean MID scores should be higher than AD scores. We tested patients who met NINCDS-ADRDA criteria for the diagnosis of probable AD (N=17; age=84.9) or MID (N=8; age=83.3). They were agematched to non-demented elderly (N=16; age=83.4). Scores on the Blessed Memory-Information-Concentration test for AD. MID. and Blessed Memory-Information-Concentration test for AD, MID, and non-demented elderly were 17, 14, and 3, respectively. Subjects' hearing was tested, and they received 90 trials of 500 msec, 80 dB nearing was tested, and they received 90 trials of 500 msec, 80 dB tone CS paired with 100 msec, 5 psi corneal airpuff US in the delay paradigm (400 msec CS-US interval). Percent CRs (corrected for alpha responses) for AD patients were 12.1, for MID patients were 23.6. and for non-demented elderly were 30.7. Eyeblink conditioning differentiates among demented patients as predicted. (Supported by an Alzheimer's Association/NJAHCF Research Grant).

SYMPOSIUM. THE OLIVO-CEREBELLAR SYSTEM: ITS POSSIBLE ROLE IN LEARNING. J.A. Harvey, Med. J.A. Harvey, Col. of Pennsylvania (Chairperson); R.R. Llinás

Col. of Pennsylvania (Chairperson); R.R. Llinás New York Univ.; J.P. WELSH, Univ. of Iowa; C.H. YEO, Univ. Col. London, England; R.G. BAKER, New York Univ; S.G. LISBERGER, Univ. of California.

The purpose of this symposium is to review and critically evaluate recent data that have advanced our knowledge concerning the participation of the olivo-cerebellar system in the acquisition of motor skills. Cerebellar involvement in learning has been examined primarily within two motor systems: the vestibulo-ocular reflex and the classically conditioned nictitating membrane response. Sites of plasnictitating membrane response. Sites of plasticity for these examples of motor learning have been suggested to involve various loci within the olivo-cerebellar system. However, a growing body of data suggests that many of these conclusions about the cerebellum as a site of learning and memory have been premature and need to be modified. While the olivo-cerebellar system is clearly important for learning, there is mounting evidence that the actual site or sites of plasticity may be in other parts of the brain. This symposium will explore the recent data and the issues involved, and provide some suggestions for resolving the controversies in this field.

THE DISORGANIZATION OF VISUAL COGNITIVE FUNTION IN PATIENTS

THE DISORGANIZATION OF VISUAL COGNITIVE FUNTION IN PATIENTS WITH ALEMEIMER'S DISEASE(AD)—COMPARATIVE STUDY OF AD WITH DEVELOPING CHILDREN-. M.Fujii*, S.Murakami**, J.Miyazawa*, R.Fukataw*, N.Nakano*, Y.Aizawa*, T.Said*, N.Takahata*, T.Fukuda***, M.Yamada***. *Dept. of Neuropsychiatry, Sapporo Medical College., **Yamanoue Hospital, Sapporo,060. ***NHK Science and Technical Lab., Tokyo, 156.

There are some evidences suggesting disorganization of visual cognitive function plays an important role in occurance of neuropsychological disturbances, which are observed frequently in patients with AD. Our previous studies showed that a vision analyzer is useful in investigating the visual information processing and that subclinical findings are recognizable similar to unilateral neglect syndrome (UNS) and Balint's syndrome (BS) even in early stage of AD. On the other hand, it is well known that children complete the visual cognitive function during their development. In this study, we compare the visual information processing of AD with that of chilren. We examined 7 patients with AD (range 56-63) and 30 controls (range 6-81 including 6 children below 9), using a vision analyzer (TKK939). Results obtained are (i) in children below 9, each gazing time became shorter than the aged controls and gazing points were seen more on the copied figure than the model, and multisaccades were seen on the model, but BS (e.g. a tendency to be localized gazing points out of two figures) was not seen; (ii) in the elderly children and the other controls, the gazing points distributed both on the model and the copied figure equally; (iii) in the early stage of AD, each gazing time became shorter like children below 9, but in the moderate stage of AD, each gazing time became much shorter and few gazing points were seen on the model. Our results demonstrate some similalities and differences between visual information processing of AD, disorganization of visual cognitive function and that of children below 9 years old, undeveloped visual cogni

120.12

HIPPOCAMPAL GLUCOSE METABOLISM IN ALZHEIMER'S DISEASE. W.J. Jagust, J.L. Eberling, M.G. Baker*, T.E. Nordahl*, P.E. Valk*, B.R. Reed*, T.F. Budinger*. Donner Laboratory, Lawrence Berkeley Laboratory, University of California, Berkeley, CA 94720.

Measurement of glucose metabolism in mesial temporal lobe structures

in Alzheimer's disease (AD) has been limited by the spatial resolution of existing tomographs. We utilized a high resolution (2.6 mm in-plane) PET tomograph and ¹⁸F-fluorodeoxyglucose to study glucose metabolism in the temporal lobes in 7 patients with very mild to moderate AD and 6 age-matched controls. Beginning 30 min following injection of the tracer, age-matched controls. Beginning 30 min following injection of the frace 3 tomographic levels were scanned -200 to the canthomeatal line contiguously through the temporal lobes; a fourth scan was obtained at a level including the basal ganglia. Previously determined rate constants were used with an operational equation to calculate regional cerebral metabolic rates for glucose (rCMRglc), which were then averaged over three levels for temporal lobe structures.

AD patients showed lower rCMRglc than controls in all regions studied, with significant differences (p < .005) in all temporal lobe regions and in visual cortex. No significant differences were seen between the groups in frontal lobes or subcortical regions. The pattern of metabolism was similar, with the lowest metabolic rates seen in anterior temporal neocortical and mesial temporal lobes in both groups (AD patients averaged 26±8 µmol/100g/min in anterior temporal and controls 42±3 µmol/100g/min). There was no overlap between AD patients and controls in anterior temporal and mesial temporal regions. Thus, while AD involves a generalized decline in glucose metabolism which is most severe in temporal lobes, the anterior and mesial temporal lobe regions differentiate AD patients from controls best.

SYMPOSIA

SYMPOSIUM. DIRECT ION CHANNEL GATING BY INTRACELLULAR IONS AND MOLECULES. P.E. Hockberger, Northwestern Univ. Medical School (Chairperson); P. Gardner, Stanford Univ. School of Medicine; G. Matthews, SUNY - Stony Brook; L.D. Partridge, Univ. of New Mexico; S.Dryer, Florida State Univ.; P.R. Stanfield*, Univ. of Leicester.

The list of intracellular molecules and ions that can affect membrane

The list of intracellular molecules and ions that can affect memorane ionic conductances has been growing in recent years. This symposium will focus on examples of ion channels that are gated by intracellular ligands and supported by single-channel studies using isolated membrane patches. Dr. Gardner will describe a voltage-insensitive calcium channel that is opened by intracellular IP3 elevation in T-lymphocytes. Regulation of this channel is coupled to the T3-Ti antigen-major histocompatibility receptor complex, and activation of the complex results in clonal proliferation through a calcium-dependent mechanism. proliferation through a calcium-dependent mechanism. Dr. Matthews will describe a sodium current found in vertebrate photoreceptors, olfactory receptors, and invertebrate neurons that is regulated by the level of intracellular cGMP (or cAMP) which in turn is controlled by the level of phosphodiesterase activity. Dr. Partridge will describe a Ca²⁺-activated, non-specific cation channel that is important in excitation-secretion coupling and is involved in shaping neuronal firing patterns. Dr. Dryer will describe how elevation of intracellular Na⁺ opens a novel potassium channel in both vertebrate and invertebrate neurons that also contributes to shaping neuronal firing patterns. Dr. Stanfield will describe how intracellular ATP is responsible for regulating a novel potassium channel in nerve and muscle cells. Under conditions of energy depletion this channel would open, thereby preventing maintained excitation and possibly protecting the cell from extreme fatigue and/or excitotoxicity.

PROCESSING OF THE LHRH PRECURSOR IN THE GT1 CELL LINES DERIVED FROM TRANSGENIC MICE. W.C. Wetsel, P.L. Mellon*,

PROCESSING OF THE LERH PRECURSOR IN THE GT1 CELL LINES DERIVED FROM TRANSGENIC MICE. W.C. Wetsel, P.L. Mellon*, R.I. Weiner, and A. Negro-Vilar*. Lab. of Mol. & Integrat. Neurosci., NIH/NIEHS, Res. Tri. Pk., NC 27709; Reg. Biol. Lab., Salk Institute, La Jolla, CA 92037; Reprod. Endo. Center, Univ. of Cal., San Francisco, CA 94143.

Several cell lines (GT1-1, GT1-3 and GT1-7) were developed by genetically targeted tumorigenesis in transgenic mice (Mellon et al., Neuron, in press). These cells biosynthesize and secrete immunologically recognizable LERH. We have characterized this material using size-exclusion chromatography. LHRH-like immunoreactivity (IR) was measured by A772 antisera, while MC-2 antisera were used to measure pro-LHRH- and GAP-like IR. When extracts or media from GT1-1, GT1-3 and GT1-7 cells were separated according to molecular weight (MW), multiple peaks of immunoreactivity were detected. Cell extracts contained GAP-like materials at approximately 14000-16000, 8200 and 6500 molecular weight (MW). The LERH antisera bound materials at approximately 8200 and 1200 MW. By comparison, media contained GAP-like IR at approximately 6500 MW, while LERH-like material was bound at approximately 6500 MW. When the 1200 MW material was added to an anterior pituitary cell culture, secretion of LH was stimulated in a dose-dependent manner. These data indicate that processing of the pro-LERH precursor in the GT1 cells is similar to that found in the rat. The development of the GT1 cells is important because they allow the molecular mechanisms which underlie the biosynthesis, processing and secretion of pro-LERH peptides to be investigated. [Supported by the NIEES Intramural Program (MCW and ANV) and Grants HD 20377 (PLM) and HD 08924 (RIW)].

INHIBIN/ACTIVIN SUBUNITS ARE CO-STORED WITH GONADOTROPINS IN SECRETORY GRANULES OF THE RAT ANTERIOR PITUITARY GLAND. V.J. Roberts, C.A. Peto*, W.W. Vale and P.E. Sawchenko, The Salk Institute, La Jolla, CA 92037.

The gonads are the major source of circulating inhibin (α/β_A) or α/β_B) and activin (B/B). These protein dimers regulate FSH release from the anterior pituitary. Recently, we reported that the gonadotropes are also sources of inhibin and activin subunits (α and β_B) and mRNAs (Endocrinology 124:552, 1989). Here, we determined the extent to which the a- and BB-subunits might be colocalized with gonadotropins in secretory granules. Dual postembedding immunogold staining methods were used on pituitary from adult male rats, which were cryofixed, molecular distillation dried, and resin-embedded (LifeCell Corp., The Woodlands, TX). Sections were stained on one side with antiserum against either the α - or β_B -subunit and on the other with antiserum against FSH or LH. Secondary antisera were labeled with 5 nm or 15 nm colloidal gold. The inhibin- α subunit colocalized with FSH in 32% of all positively stained granules and with LH in 36% of the granules. The β_B -subunit was found with FSH in 28% of the granules and with LH in 25% of the granules. Approximately 50% of the granules contained only FSH or LH and 10% to 30% were positive only for the inhibin subunits. At least 30% of the granules that are immunopositive for the inhibin proteins show positive signals for both These results suggest that inhibin and activin may be packaged, and released, either alone or along with FSH and LH.

DISTRIBUTION AND NEUROENDOCRINE ROLE OF KAINATE AND OTHER EXCITATORY AMINO ACID RECEPTORS IN MONKEY HYPOTHALAMUS. A.J. Billy. R. Medhamurthy*. C., Shaw and T.M. Plant. Dept. of Physiology, Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA 15261 and Depts. of Physiology, Zoology and Ophthalmology, Univ. of British Columbia, Vancouver, Canada, V6T 1 W3.

Columbia, Vancouver, Canada, V6T 1 W3.

The finding that repetitive iv injections of NMDA elicit a sustained train of GnRH discharges from the hypothalamus of the prepubertal monkey prompted the present study to determine the distribution of Glu receptors throughout the primate hypothalamus. Serial, frozen, coronal sections (20µ) of the hypothalamus from a juvenile and adult male rhesus monkey were thaw mounted onto subbed glass slides for subsequent autoradiographic analysis of Glu receptor subtypes, using H3 labelled KA, MK-801 and CNQX as KA, NMDA, receptor subtypes, using H³ labelled KA, MK-801 and CNQX as KA, NMDA, and Q receptor ligands, respectively. Binding sites labelled with H³ KA, MK-801 or CNQX were found throughout the mediobasal hypothalamus (MBH). A striking feature of binding in this region of the primate brain was an extremely high density of KA receptors in the region of the arcuate nucleus and median eminence: this contrasted with a relatively unremarkable and diffuse pattern of NMDA and Q receptors in MBH. In addition, KA and Q receptors were heavily labelled in the SON, and KA receptor was detected in the lamina terminalis, the tuberal portion of the SON, and the PVN. To study the role of non-NMDA receptors in the regulation of hypothalamic fonRH release, the effects of iv KA and Q receptor agonists on GnRH release were examined in juvenile male monkeys utilizing LH release from a bioassay for the decapeptide. Injections of KA (0.5 mg/kg BW) elicited distinct discharges of LH. Q injections (0.5-2.5 mg/kg BW), however, produced a less robust and inconsistent response. Prior treatment with AP5, an NMDA receptor antagonist, failed to block KA induced LH release. Studies are in progress to confirm that KA exerts its action on LH release at a suprapituitary level. These findings suggest that KA receptors, most probably localized in the region of the arcuate nucleus and median eminence, play a role in regulating GnRH release from the primate hypothalamus.

DYNAMICS OF GRRH SECRETION FROM PERIFUSED GT1-1 CELLS. G. Martinez de la Escalera*, A. L. H. Choi* and R. I. Weiner. Reprod. Endocrinol. Ctr., Univ. of Ca., San Francisco, CA. 94143.

GnRH cell lines were developed in transgenic mice by genetically targeted tumorigenesis. The cells synthesize and release GnRH, express neuronal but not glial markers and have a neuronal We have examined the dynamics of GnRH release in phenotype. GT1-1 cells were cultured on coverslips for three days, placed in a Sykes-Moore chamber and perifused (0.3 ml/min) with Locke's medium containing bacitracin. Samples obtained every 2 min were radioimmunoassayed with the Nett R1245 GnRH-specific antiscrum. Basal secretion from GT1-1 cells varied between 5 and 10 pg/min. Over a 2 h collection period occasional pulses were observed with amplitudes 1.5 to 6 fold over basal. Removal of Ca^{2+} inhibited spontaneous pulses of GnRH release. Depolarization for 2 min with 56mM K⁺ caused a 50 fold increase in GnRH release. Maximal levels were reached within 2 min and returned to normal within 10 min. The time course of the response to 15mM K+ was similar but only approximately 10% the amplitude. The removal of Ca²⁺ blocked the response to K⁺. Increases in cAMP levels with 2.5mM 8-Br-cAMP or 10uM forskolin, induced a 3 or 10 fold sustained increase in GnRH, respectively. Basal secretion during relatively short term studies is characterized by the release of pulses of GnRH which are absent following removal of Ca2+. The release of GnRH from GT1-1 cells is stimulated by depolarization with K⁺ via a Ca²⁺ dependent mechanism and by increasing intracellular cAMP. Supported by NIH Grant HD08924(R.W.) and the Rockefeller Foundation (G.M.E.)

REPETITIVE IV INJECTIONS OF L-GLUTAMIC ACID, IN CONTRAST TO THOSE OF NMDA, FAIL TO SUSTAIN INTERMITTENT HYPOTHALAMIC GnRH RELEASE IN THE PREPUBERTAL RHESUS

TO THOSE OF NMDA, FAIL TO SUSTAIN INTERMITTENT HYPOTHALAMIC GARH RELEASE IN THE PREPUBERTAL RHESUS MONKEY. R. Medhamurthy*. V.L. Gay* and T.M. Plant. Dept. of Physiology, Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA 15261. In prepubertal male rhesus monkeys, repetitive iv injections of an NMDA receptor agonist (NMDA) elicit sustained trains of hypothalamic GnRH release as reflected by the LH response of the pituitary gland. The purpose of the present experiment was to determine whether similar stimulation with the putative endogenous ligand, L-glutamic acid (Glu), is also able to elicit intermittent hypothalamic GnRH release. An earlier study indicated that a single iv bolus of Glu at 150 mg/kg BW induced a robust GnRH discharge from the hypothalamus of prepubertal monkeys (Medhamurthy, et al., Ann. Meeting Am. Fed. Clin. Res., 1990). Four prepubertal males primed with exogenous GnRH to heighten the responsivity of the pituitary to this releasing homone, received an iv injection of Glu (150 mg/kg BW) every 3 h for 9 h. The mean (± SE) peak concentration of the LH discharge in response to the 1st, 2nd and 3rd injection of Glu was 68.5, 44.9 and 34.1 ng/ml, respectively. In a separate experiment (n=3), in which the iv intermittent Glu treatment was extended to 24 h, the LH releasing ability of Glu was abolished by the 9th injection. However, administration of NMDA (2-5 mg/kg BW) at the end of 9 or 24 h of intermittent Glu treatment resulted in a robust LH discharge, and the ability of repetitive NMDA administration to sustain GnRH release in these particular animals was confirmed during a 12 h study. One possible explanation for the finding that repetitive injections of Glu valva. possible explanation for the finding that repetitive injections of Glu fail to sustain GnRH release, without concomitant loss of sensitivity to NMDA stimulation, is that Glu induced GnRH release may be mediated primarily by non-NMDA receptors that are unable to respond to intermittent stimulation with a periodicity of 3 h. Experiments are underway to resolve whether prolonged activation of non-NMDA receptors, such a kainate or quisqualate receptors, also leads to a progressive loss in the ability to release GnRH.

126.6

EFFECTS OF N-METHYL-D,L-ASPARTATE (NMDA) ON THE REPRODUCTIVE AXES OF HAMSTERS IN LONG VS. SHORT-DAY PHOTO-PERIODS. J.M. Meredith, F.W. Turek, J.E. Levine. Dept. Neurobiol/Physiol, Northwestern Univ., Evanston, IL 60208 Hamsters exposed to short-day photoperiods (LD 6:18) develop a reversible inhibition of the reproductive axis which includes decreased LH pulse frequency, decreased FSH and testosterone (T) levels and testicular regression. This study examines the role of hypothalamic LHRH neurons in the short-day inhibition of the reproductive axis. Golden hamsters were housed for 10 wks under LD 14:10 and maintained for another 10 wks under either LD 14:10 or LD 6:18. Animals were bled every 10 minutes from 1300-1800 h and given 4 hourly injections of the LHRH secretagogue, NMDA (10 mg/kg). Long-day animals responded to successive NMDA administrations with mean LH pulse amplitudes of $2.65\pm.09$, $1.22\pm.50$, $1.22\pm.43$, and $1.15\pm.42$ ng/ml respectively. Short-day animals responded to NMDA with mean LH pulse amplitudes of $1.61\pm.31$, $2.89\pm.34$, $3.08\pm.59$ and 2.65 \pm .32 ng/ml. Baseline T levels and paired testes weights were significantly greater in long-day animals. Robust LH responses in short-day animals suggest that photoperiodic inhibition of the hamster reproductive axis is not due to a reduction in the secretory capacity of LHRH neurons, viz. a reduction in size of the releasable LHRH pool. Instead, inhibition of the reproductive axis by short-day photoperiods may occur at or above the level of the LHRH pulse generator. Supported by NIH grants RO1the LHRH pulse generator. Supported HD20677, PO1-HD21921, and KO4-HD00879.

N-METHYL-D, L-ASPARTIC ACID (NMDA)-INDUCED LH RELEASE IN HYPOGONADAL FEMALE MICE WITH FETAL PREOPTIC AREA GRAFTS (HPG/POA). Y. Saitoh, A.J. Silverman, and M.J. Gibson.Div.

Endocrinology, Mount Sinai Sch. of Med., New York,NY 1002
In order to clarify the mechanism of NMDA-induced LH
release, HPG/POA were challenged by venous injection of
NMDA, and the results were compared with those of normal female mice. Most HPG/POA showed persistent estrus and ovarian and uterine development by 60 days after successful grafts; a few started cycling after pregnancies by reflex ovulation. One group of normal and HPG/POA mice were ovariectomised (OVEX); a second group were OVEX and estrogen primed (OVEX/E2), and a third group included intact cycling normal and cycling HPG/POA that were tested in the estrous state. After blood sampling via intrajugular catheters HPG/POA were perfused for light and/or electron microscopic immunohistochemical studies. There were significant increases in plasma LH at +10 min after NMDA challenge in reases in plasma Ln at +10 min after NMA challenge in normal OVEX (baseline: 0.58±0.20; +10 min: 1.85±0.41 ng/ml) and OVEX/EZ (baseline: 0.33±0.02; +10 min: 0.80±0.21ng/ml). HPG/POA OVEX/EZ mice (n=7), which had 4-12 GnRH cells and GnRH axonal outgrowth, responded to NMDA with increased plasma LH (baseline: 0.36±0.03; +10 min: 1.03±0.24 ng/ml) HPG/POA OVEX/E2 mice (n=5) with sparse GnRH fiber outgrowth did not respond to NMDA. Neither normal estrous nor cycling HPG/POA estrous mice responded to NMDA. These results suggest that NMDA stimulation of GnRH cells is estrogensensitive and may be mediated by interneurons.

HYPOTHALAMIC GONADOTROPIN RELEASING HORMONE (GnRH) RELEASING DUINGARIAN HAMSTERS. AE Jetton, NB Schwartz and FW Turek. Dept. of Neurobiology & Physiology, Northwestern University, Evanston, IL 60208.

Following photoperiodically induced gonadal regression, circulating levels Following photoperiodically induced gonadal regression, circulating levels of the gonadotropins luteinizing hormone (LH) and follicle stimulating hormone (FSH) are low in Djungarian hamsters (Phodopus sungorus). The goal of this study was to investigate hypothalamic changes which may be involved in the photoperiodic response. Young male Djungarian hamsters were maintained on 6L:18D (short days) or 16L:8D (long days) for 4-6 wks. Following decapitation the hypothalami were removed, and the testes were weighed to confirm photoperiodic response. Hypothalami were placed 3 per chamber into a dynamic perfusion system and perfused for 4-5 hr. with supplemented Medium 199 with or without 10-6M melatonin. Three, 20 min. stimulations of 50 mM K⁺ were administered during each perfusion. Medium was collected in 5 min. fractions and assayed for GnRH by RIA using the EL-14 antibody. GnRH release in response to each stimulation was analyzed by 14 antibody. GnRH release in response to each stimulation was analyzed by ANOVA. There was no significant difference in GnRH release from short ANOVA. There was no significant difference in GnRH release from short day hypothalami compared to long day hypothalami. In the presence of melatonin, however, long day tissue had a significantly lower GnRH response to K+ stimulation than short day tissue (p<0.05). We conclude that there is little or no difference in readily releasable GnRH during photoperiodically induced inhibition of the neuroendocrine-gonadal axis. Following photic inhibition of reproductive activity, melatonin appears to have a reduced acute effect in blocking stimulation of GnRH release. Supported by P01-HD21921 and HD-00885.

THE STIMULATORY EFFECT OF METHOXAMINE ON *IN VIVO* LHRH RELEASE IS MEDIATED BY PROSTAGLANDIN E₂ (PGE₂) IN OVARIECTOMIZED UNPRIMED MONKEYS. <u>M. Gearing and E. Terasawa</u>. Neuroscience Transing Prog. and Wisconsin Reg. Primate Res. Ctr., Univ. of Wisc., Madison, WI 53715

Recently, we have reported that the α -agonist methoxamine (MTX) stimulated pulsatile LHRH release in ovariectomized rhesus monkeys in the absence of estrogen (*Endocrinology* 123:1808,1988). In the present study, the mechanism by which MTX stimulates LHRH release is investigated; specifically, the role of PGE₂ is examined. *In vivo* LHRH release in the stalk-median eminence (S-ME) was measured by push-pull perfusion in conscious, median eminence (S-ME) was measured by push-pull perfusion in conscious, ovariectomized monkeys, and perfusiate samples were collected on ice. MTX (10⁵ M) or PGE₂ (10⁷ M) was infused into the S-ME through the push cannula for 10 min at 90-min intervals. LHRH and PGE₂ in aliquots of the same perfusate samples were measured by RIA. Infusion of MTX significantly stimulated LHRH release (1.2±0.2 pg/ml before vs. 3.7±0.9 pg/ml after MTX; n=12; P<0.01) and PGE₂ release (76.1±8.5 pg/ml before vs. 112.1±18.7 pg/ml after MTX; P<0.05). Furthermore, infusion of PGE₂ through the push cannula significantly stimulated LHRH release (1.5±0.5 pg/ml before vs. 2.8±1.1 pg/ml after PGE₃; n=23; P<0.05). Infusion of the vehicle had no effect on LHRH or PGE₂ release. These results suggest that the stimulatory effect of MTX on LHRH release is mediated by PGE₂, since MTX stimulates not only LHRH but also PGE₂ release, and since PGE₃ itself stimulates LHRH release. Moreover, the stimulatory effects of MTX and PGE₂ can be observed in the absence of estrogen in the rhesus monkey, Suffluates Linin release. Moreover, the stimulatory effects of M1λ ample PGE₂ can be observed in the absence of estrogen in the rhesus monkey, unlike in rodents. Therefore, PGE₂ may be an important endogenous mediator of α₁-adrenergic input stimulating pulsatile LHRH release. Our results also demonstrate the usefulness of the push-pull perfusion technique for studies of cellular mechanisms in neuroendocrine research. (NIH HD15433)

PHOTOPERIODIC MODULATION OF N-METHYL-D-ASPARTATE (NMDA) RECEPTOR BINDING IN THE SYRIAN HAMSTER. H.F.Urbanski and M.Pierce*. Division of Neuroscience, Oregon Regional Primate Research Center, Beaverton, OR

ence, Oregon Regional Primate Research Center, Beaverton, OR 97006.

The involvement of excitatory amino acid receptors in the photoperiodic control of seasonal breeding is suggested by the finding that administration of NMDA to Syrian hamsters can block the inhibitory influence of short days on the reproductive axis. To investigate the effect of photoperiod on the binding properties of NMDA receptors adult male hamsters were either maintained under long days (LD) or induced to revert to a juvenile condition by exposure to short days (SD). The procedure of Price et al., (Eur. J. Pharmacol. 158:279, 1988) was then used for the in vivo labeling of NMDA receptors with [HMK-801, a specific noncompetitive antagonist. Under both photoperiods, the specific binding of MK-801 to NMDA receptors was high in the cerebral cortex (ca. 50 dpm/mg wet tissue), significantly lower (P<0.05) in the medial basal hypothalamus (ca. 10 dpm/mg w.t.), and undetectable in the pituitary gland. In contrast, the specific binding of MK-801 in the pre-optic area (POA) was significantly (P<0.05) higher in the sexually active (LD) than in the sexually quiescent (SD) animals (31 vs. 7 dpm/mg w.t., respectively). Since this brain region is particularly rich in neurons that secrete luteinizing hormone-releasing hormone, photoperiodic modulation of POA NMDA receptor binding might play a pivotal role in the neuroendocrine control of seasonal breeding.

DOPAMINE (DA) FIBERS ORIGINATING IN THE ANTERO NTRAL PERIVENTRICULAR NUCLEUS (AVPN) INNERVATE THE RAT MEDIAL PREOPTIC AREA (MPO) GAD AND LHRH NEURONS. C. Leranth¹² and F. Naftolin.¹ Dept. of Obstetrics and Gynecology¹ and Section of Neuroanatomy², Yale Univ. Sch. of Med. New Haven, CT. 06510

Interconnections between the GABA-, DA-, noradrenaline-, and LHRH-systems may play an important role in the episodic release of luteinizing hormone. We previously dem GABAergic innervation of LHRH cells, and that while both MPO GABAergic and LHRH neurons were synaptic targets of tyrosine hydroxylase (TH) immunoreactive axon terminals, following transection of the ascending noradrenergic bundles only the GABA cells contacted degenerated TH positive noradrensline-containing boutons, indicating DA connections on LHRH neurous. Experimental: since DA input to the MPO LHRH and GABAergic neurous may derive from the rostral periventricular DA cell group, including the sexually dimorphic AVPN (Simerly et al. '85), 30 minutes after i.p. desipramine HCL (25mg/Kg) injection to protect noradrenaline fibers, 1mg 6-OH DA (1mg in 1µl saline with 0.2% vitamin C) was stereotaxically injected into the AVPN of adult female rats (B.W. 260g). To increase density staining, 24 hrs later animals were colchicine treated (intracerebroventricular injection of 80ug colchicine in 20ul saline). One day later they had transcardial perfusion of fixative. Consecutive MPO vibratome sections were immunostained for GAD, LHRH, or TIL EM analysis of GAD and LHRH stained material revealed degenerated, auto e-containing boutons establishing synaptic contacts with both GAD and LHRH neurons. Conclusion: since degeneration was observed in TH immunoreactive axon term DA innervation of the MPO's GAD and LHRH neurons is suggested with DA fibers originating in the sexually dimorphic AVPN that has been implicated in the positive feedback control of gonadotrophin release (Simerly et al. '85). Supported by NIH grant HD23830.

CHANGES IN HYPOTHALAMIC-PITUITARY FUNCTION DURING BRIEF PERIODS OF FASTING IN RHESUS MONKEYS (Macaca mulatta) D.L. Helmreich, L. G. Mattern², and J.L. Cameron. Depts. of Behavioral Neuroscience, Physiology and Psychiatry and the Center for Neuroscience, Univ. of Pittsburgh, Pittsburgh PA 15260. States of Chronic undernutrition suppress the activity of hypothalamic-pituitary-gonadal (HPG) axis, frequently leading to complete suppression of reproductive function. We have previously shown that in adult male rhesus monkeys there is already a decrease in the central drive to the reproductive axis, as indicated by a slowing of pulsatile LH secretion, after only one day of fasting. This suggests that the signal(s) that eventually lead to complete inactivity of the HPG axis are already present after one day of fasting. To determine if the activity of other hypothalamic-pituitary systems is modified by brief periods of fasting, we measured levels of AVP, OT, growth hormone (GH), prolactin (PRL), FSH, T3 and cortisol during a day of formal feeding and during a day of fasting. For analysis of AVP, OT, T3 and PRI, samples were collected hourly for 24 hr. For analysis of cortisol, LH, FSH, and GH, samples were collected hourly for 24 hr. For analysis of cortisol, LH, FSH, and GH, samples were collected hourly for 24 hr. For analysis of cortisol, LH, FSH, and GH, samples were collected every 15 or 20 min for 24 hr. (n = 3-6). As previously reported, one day of fasting resulted in a decrease of LH pulse frequency from 8.33 ± 1.2 to 4.33 ± 5.03 pulses/24 hr. Additionally, there was a decrease in mean FSH and T3 levels and an increase in mean GH levels, as illustrated in 4 for the property of the p

decrease in mean GH levels, as illustrated in the figure. Circulating cortisol levels were slightly elevated in the evening of the fasted day. We found no changes the levels of OT, AVP or PRL. These results indicate that one AVP or PRL. These results indicate that one aday of fasting causes a significant metabolic stress that results in changes in hypothalamic-pituitary drive to a number of systems that regulate energy balance. These findings support the hypothesis that "metabolic changes" may provide the signal(s) that lead to the suppression of reproductive function in undernourished states

THE ROLE OF COGNITIVE FLEXIBILITY IN FRONTAL LOBE MEMORY DISORDERS. L.M. GRATTAN AND P.J. ESLINGER, Depts. of Neurology, Univ. of Maryland (Baltimore, MD, 21201) and Penn State (Hershey, PA, 17033) Colleges of Medicine.

The memory disorders associated with frontal lobe damage in humans appear to be different from those after damage in humans appear to be different from those after limbic system damage (particularly in the medial temporal region and diencephalon). In this study we examined the relationship between memory and several frontal lobe mediated cognitive functions, which have been anecdotally implicated in the organizational and encoding aspects of memory. Forty subjects with CT or MR verified lesions to the frontal lobes or connected subcortical and posterior cerebral structures (including limbic system lesions) were extensively studied with standardized measures of cognitive flexibility and Rey's verbal learning and memory paradigm. Results indicated significant associations between certain aspects of cognitive flexibility and memory in the frontal lobe sample, but not in the posterior cerebral or subcortical lesion groups. We conclude that learning and memory performance after frontal lobe lesion may be related to select aspects of cognitive flexibility, including the abilities to initiate, generate, and adopt alternative ways of managing information. (Supported by grant P50 NS26985, Boston University Memory Disorders Research Center).

127.3

A DISSOCIATION BETWEEN VERBAL AND SPATIAL MEMORY FOLLOWING UNILATERAL TEMPORAL LOBECTOMY. A. Chiba. R.P.

Neurosurgery, Univ. of Utah, Salt Lake City, Utah 84112.
Computerized memory tests were administered to assess verbal and spatial memory abilities of patients following unilateral temporal lobe spatial memory abilities of patients following unilateral temporal lobe resection for refractory complex partial epilepsy of temporal lobe origin (CPET). The extent of tissue resected for each patient in the testing population typically included 3-5 cm of the anterior temporal lobe, 1-4 cm of the hippocampus, and surrounding mesio-temporal structures unilaterally. Matched preoperative control subjects with CPET were also tested. Patients were tested on a series of four tests of episodic memory emphasizing explicit information for the recognition of item and order information for words and spatial location. Postoperative test results revealed a dissociation between each patients memory for verbal information as compared to their memory for spatial information. Each patient showed a statistically significant persistent memory deficit for either verbal or spatial information relative to that of preoperative control subjects. These data suggest the existence of interhemispheric parallel memory processes for spatial and verbal information. Neither hemisphere appears to be capable of the sole support of memory function. These data appears to be capable of the sole support of memory function. Neutrer nemisphere appears to be capable of the sole support of memory function. These data also correspond well with animal data collected on analogous tasks of item and order memory for spatial location. Since hippocampal lesioned rats show a significant deficit on such tests, it can be concluded that mesiotemporal structures play an important role in memory for spatial location across species. across species.

127.5

DATA BASED (EPISODIC) MEMORY FOR MOTOR RESPONSES IN HYPOXIC PATIENTS. R.O. Hopkins and R.P. Kesner. Dept

of Psych., University of Utah, Salt Lake City, UT 84112.
Patients with hypoxic or minor brain injury, and normal age matched controls were tested for memory impairments. The Denman memory scale was given to all subjects as a baseline memory assessment. The subtests for digits and paired associates show a decreased performance for the hypoxic subjects, but not for minor brain injury or control All subjects were then tested for item and order ecognition memory for lists of six words, pictures, ab-

stract pictures, spatial locations, and motor responses.
Results indicated that compared to age matched controls and minor brain injury control groups, hypoxic brain injured individuals displayed on item and order recognition tasks, deficits for words, pictures, abstract pictures, and spatial locations with a slight recency effect for words, pictures, and abstract pictures, and a larger recency effect for spatial locations. For motor response item and order recognition, no major deficits compared to controls were obtained.

In conclusion, it appears that subjects with hypoxic brain injuries in the face of severe memory deficits for words, pictures, abstract pictures and spatial locations display residual capacity for remembering motor responses, using episodic, working, declarative, or data-based memory.

127.2

THE ABILITY OF PATIENTS WITH FRONTAL- OR TEMPORAL-LOBE EXCISIONS TO ENCODE AND RECALL VISUAL DISTANCE AND LOCATION. (G. Leonard and B. Milner). Montreal Neurol. Inst., McGill Univ.,

Montreal, Canada H3A 2B4.

Patients with large right frontal-lobe lesions are impaired in their ability to encode and/or reproduce large movements of the arm and/or reproduce large movements of the arm (with vision excluded), and also in recalling the end position of their arm movements (Leonard, 1987). The present experiments examined the ability of 60 patients with focal cerebral excisions and 13 normal control subjects to judge visual distance and location, to determine if the above deficits are specific to kinesthesis. Subjects viewed a dot moving to kinesthesis. Subjects viewed a dot moving across a screen and immediately, or after a 15 or 30 s delay (with or without a distracting task) reproduced the distance through which the dot had moved (Exp. 1), or pinpointed its final

location (Exp. 2).

All groups performed normally on the location task, but patients with large right frontal-lobe lesions were impaired on the distance task. It is concluded that the right frontal lobe not only contributes to the encoding and recalling of kinesthetic information but also to recalling distance information presented visually.

DIFFERENT PROFILES OF HUMAN AMNESIA AND DIFFERENT PROFILES OF HUMAN ANNESIA AND CEREBRAL DAMAGE ASSOCIATED WITH ENCEPHALITIS.

P.J. Eslinger, M.P. Alexander*, L.S. Cermak*,
L.M. Grattan, Memory Disorders Res. Ctr., Penn State (Hershey, PA), Boston Univ. (Boston, MA),
Univ of MD (Baltimore, MD) Colleges of Medicine.
Several remarkable cases of human amnesia after herpes simplex encephalitis have been described. While study of individual cases
continues to advance our understanding of the

continues to advance our understanding of the neural basis of memory, extant data also reveal differences among these patients. To examine this issue, we studied a group of 4 encephalitics who developed amnesia. Neuropsychological, cognitive and neuroimaging studies revealed distinct differences among patients with variation in both memory disorder and cerebral damage. Limbic system structures were most significantly affected. Bilaterality of lesion and its neocortical extension were different in each case and from the encephalitic patient Boswell (Damasio et al. 1985). In correlated fashion, the degree of anterograde and retrograde amnesia was unique to each case. In conclusion while encephalitis consistently produced amnesia and limbic system damage, the extent of memory loss and cerebral damage varied significantly. (Supported by grant P50 NS26985)

A COMPUTATIONAL STUDY INDICATES CROSS-MODAL ASSOCIATION ARISES NATURALLY IN NEOCORTEX VIA FEEDBACK PROJECTIONS

Paul Rhodes, Univ. Of California, San Diego, CA
Anatomical studies (Pandya and coworkers) have revealed that unimodal association Anatomical studies (randya and coworkers) nave revealed that unimodal association cortex may be viewed as a cascade of reciprocally interconnected regions. Further, the unimodal association areas project into polymodal association areas which themselves are similarly organized. The forward-going projections tend to terminate in a columnar fashion in layer IV, and the reciprocal recurrent projections tend to terminate in layer I. To explore the flow of neural activity that might be found in this structure, I have done simulations which include 2 regions of unimodal association cortex and a polymodal structure which they converge the might be described to which they converge the might be described. simulations which include 2 regions of unimodal association cortex and a polymodal region to which they convergently project, and which reciprocally projects back. Each region is comprised of a 10x10 grid of cortical modules. Each module possesses layer III and V pyramidals, a layer II Cajal-Retzius (horizontal) cell, and a layer III basket. Each is modelled as a 2-compartment neuron with active calcium, sodium, and potassium conductances and fairly realistic firing properties. The neurons are laterally interconnected within regions, vertically interconnected within columns, and reciprocally interconnected between regions as described above. Synapses between pyramidals are assumed modifiable by a covariance version of the Hebb rule. Baskets project to pyramidal somata The model includes 1200 model neurons and 50,000 modifiable synapses. The simulated activity suggests a mechanism for cross-modal associative memory. After bimodal sensory input during a plastic period, a fragment of the original activity is then input to one modality. This input projects to the bimodal region, driving firing there which results in pattern completion for the full associated bimodal activity pattern. Recurrent projections to the unimodal regions then produce activity in each that reconstructs their original activity during the plastic period. Attention is called to the vital role of the horizontal fiber system of layer I, which provides the network of large-scale lateral connections giving rise to pattern completion. Note that layer I is primarily activated by the feedback projections. We hypothesize that both pattern completion and cross-modal associative memory are particularly dependent upon feedback projections. articularly dependent upon feedback projections.

THE NEURAL REGIONALIZATION OF KNOWLEDGE ACCESS DEVICES A. R. Damasio, H. Damasio, D. Tranel and J.P. Brandt,
Department of Neurology, University of Iowa College of Medicine, Iowa City, Iowa.

We performed experiments involving visual recognition and naming of numerous entities of varied categories in 40 subjects with damage to different temporal association cortices. Results indicate that the linkage mechanisms that permit access of concepts given the names (or viceversa), are neurally segregated and subcompartmentalized. versa, are neurally segregated and subcompartmentalized. Different lesion probes correlate with different recognition and naming profiles, e.g., damage to left temporal pole disrupts access to proper names of unique entities but not recognition of those entities, nor access to common names; damage to inferior occipito-temporal cortex disrupts recognition of certain classes of natural entities but leaves intact recognition of other natural kinds and man-made kinds. suggest a parcellation of the systems that support neural inscriptions of entities sharing certain characteristics, (e.g., visually ambiguous natural kinds versus manipulable, nonambiguous man-made kinds), and a regionalization of the neural devices that permit access to the reference lexicon, e.g., the devices that access proper nouns is clearly separate from those that access common nouns. which are, in turn, subregionalized relative to different kinds.

IMPLICIT MEMORY: NO EVIDENCE FOR RAPID ACQUISITION OF NEW ASSOCIATIONS IN AMNESIC PATIENTS OR NORMAL SUBJECTS. G. Musen and L. R. Squire VA Med Ctr & UCSD Psychiatry Dept., La Jolla, CA 92093. Amnesic patients perform normally on many nondeclarative (implicit) memory tasks such as skill learning, priming, and classical conditioning. For example, amnesic patients exhibit normal facilitation of reading speed after a single reading of new text. It is unclear whether this phenomenon, or any other intact memory ability in ammesia, depends on the rapid acquistition of new associations. We attempted to replicate the only study known to us to suggest that memory-impaired patients can rapidly acquire new associations (Moscovitch et al., 1986 JEP:G. 115:331-347). Nine amnesic patients and 12 control subjects studied a list of 30 word pairs (5 sec/pair). Then, as quickly as possible, they read three different lists: 10 previously studied word pairs, no new word pairs and 10 recombined word pairs. As expected, both amnesic patients and normal subjects read the old pairs more quickly than the new pairs (ammesic patients: 14.5 sec vs. 16.5 sec; normal subjects: 16.4 sec vs. 17.8 sec). If new associations are acquired during the study phase, then recombined pairs should later be read more slowly than the old pairs. However, we found that amnesic patients and normal subjects read old and recombined pairs equally rapidly (ammesic patients: 14.5 sec vs. 15.0 sec; normal subjects: 16.4 sec vs. 17.8 sec). We also replicated this finding in a second study of normal subjects. Finally, in two experiments, we found that mormal subjects finally, in two experiments, we found that normal subjects and acquire new associations, i.e., they read recombined word pairs more slowly than old pairs, when they were given 10-20 repetitions of the study pairs. Implicit memory may not be adapted for the rapid acquisition of new associations.

127.11

IMPAIRED HABIT LEARNING FOLLOWING CEREBELLAR HEMORRHAGE: A SINGLE-CASE STUDY. J. Fiez, S.E. Petersen, & M.E. Raichle. Dept. A SINGLE-CASE STODY: <u>J. FIEX, S.E. Petersen, a. M.E. Ratchie.</u> Dept. Neurol. & Neurol. Surg., McDonnell Ctr. for Higher Brain Function, Mallinkrodt Inst. of Rad., Wash. Univ. Sch. of Med., St. Louis, MO 63110. Previously, using positron-emission tomography (PET), increased blood flow to a right posterior cerebellar region was found when subjects were

asked to "generate" verbs for presented nouns. A similar change was not found when subjects merely repeated aloud the presented nouns. In an attempt to account for this activation, we have studied a 49-year old

male lawyer (M.M.) who suffered a stroke affecting a large portion of his right posterior cerebellum. Neither MRI nor CT scans revealed any other neurological abnormalities. M.M. has returned to full-time practice and reports no significant motor or cognitive deficits.

However, M.M. was impaired on the generate task in two ways. First, in initial testing, 60% of his responses were errors (compared to 2% in normals). Second, M.M.'s median reaction time decreased by only 8% across trials (compared to a 27% decrease in normals). Consistent with M.M.'s failure to learn the generate task is his performance on concurrent discrimination tasks - tasks used previously to dissociate habit formation from another type of long-term (declarative) memory in monkeys (Phillips, et. al., Exp. Brain Res., 27:99-107). While normals reach criterion on word and pattern discriminations after 4-6 trials, M.M. failed to do so after even 14 trials. On the Tower of Toronto puzzle, a task amnesics learn normally, M.M. scored only a 2, far below the normal 13-16 (Saint-Cyr, et. al., <u>Brain</u>, 111:941-959). In contrast, M.M. scored normally on tests of word fluency, short-term and

declarative memory, language, and frontal function. These dissociations lead us to conclude that M.M.'s deficits are attributable to a specific impairment in habit learning resulting from damage to the right cerebellum.

127.8

MEMORY FOR SPATIAL LOCATION AND OBJECT MEMORY ARE EQUIVALENTLY IMPAIRED IN HUMAN AMNESIA. C. B. Cave¹, J. Janowsky², and L. R. Squire¹, VA Med. Ctr., and Dept. of Psychiatry,

Janowsky²· and L. R. Squire¹· VA Med. Ctr., and Dept. of Psychiatry, UCSD, La Jolla, CA 92093i¹· Univ. of Oregon, Eugene, OR 91403². One hypothesis about the function of the mammalian hippocampus emphasizes its special role in spatial cognition. We tested this idea by asking whether amnesic patients with damage to the hippocampal formation, or other amnesic patients, are especially poor at spatial memory tasks. Sixteen amnesic patients were tested, seven with alcoholic Korsakoff's syndrome, eight with confirmed (N=5) or suspected (N=3) damage to the hippocampal formation, and one with a bilateral thalamic infarction. Patients and control subjects first studied each of 16 toy items randomly arrayed on a 60 cm² surface (Smith & Milner, Neuropsychologia, 19:781-793, 1981). After a delay of 5 min for amnesic patients and 5 min to 5 wks for different groups of control subjects, object recall and recognition were tested. Finally, subjects control subjects, object recall and recognition were tested. Finally, subjects were given a new surface and were asked to place the toys where they had previously appeared. For the amnesic patients, memory for the objects (both recall and recognition) was equivalent to that of the control subjects who were recall and recognition) was equivalent to that of the control subjects who were tested after 3-5 wks, and poorer than control subjects who were tested after 5 min or 1-2 wks. If amnesic patients are #sproportionally impaired in their memory for spatial location, then their spatial memory for the toys should be more impaired than their object memory, relative to the control subjects. However, spatial location memory of the amnesic patients was equivalent to the control subjects who were tested after 1-2 wks and was therefore, if anything, better than their object memory. A second condition showed that the object memory tests were not being influenced by spatial strategies. The results were the same when the amnesic patients were considered as a single group and when patients with diencephalic or hippocampal damage were considered separately. The results show that in human amnesia, even in patients with direct damage to the hippocampal formation, spatial memory is no more affected than memory for objects.

127.10

EXTENSIVE RETROGRADE AMNESIA IN TWO SEVERELY AMNESIC PATIENTS ON TESTS OF FAMILIARITY AND NAME COMPLETION ABILITY. F. Haist¹, L.R. Squire¹, and A.R. Damasio², ¹VA Med. Ctr. and UCSD Dept. of Psychiatry, La Jolla, CA 92161, and ²Dept. of Neurology, Univ. of Iowa, Iowa

City, IA 52242.

In a single-case study, Warrington and McCarthy suggested that retrograde amnesia is not observed when remote memory tests for previously acquired facts are re-designed as semantic memory tests, e.g., when they assess simple racts are te-designed as semantic fine to the second with the second consistency (Brain & Cog. 7:184-200,1988). This result raises the possibility that retrograde amnesia can be mitigated by simple changes in test procedures. However, an impairment may have been difficult to detect due to the high (ceiling) level performance of their patient. We administered remote memory tests like those performance of their patient. We administered remote memory tests like those used by Warrington and McCarthy to 8 control subjects and 2 amnesic patients (Boswell and WI), both of whom have severe and extensive retrograde amnesia as measured by standard recognition tests. In the Familiarity task, subjects attempted to select the famous name when it was presented together with two nonfamous distractor names. In the Name Completion test, subjects attempted to complete a famous name, given the first name and part of the surname (e.g., Marilyn Mon___). The names for both tests were taken from a standard Famous Faces test and spanned the time period 1940 to 1985. Control subjects scored better than 96% correct in all 5 decades on the Familiarity test and better than 80% for all decades on the Completion test. On both tests, the 2 patients scored outside the range of control subjects for every decade and were more than 2 standard deviations below the control mean. In summary, the were more than 2 standard overations below the control meant. In summary, the amnesic patients had severely impaired remote memory, even when the tests were designed to assess simple familiarity or name completion ability. The findings suggest that retrograde amnesia reflects impairment of a single (declarative) memory system. Thus, there seems little basis for fractionating retrograde amnesia into semantic and cognitively-mediated components.

127,12

VISUALIZATION OF THE MODULAR AND LAMINAR ORGANIZATION OF THE HUMAN CEREBRAL CORTEX IN VIVO WITH MAGNETIC RESONANCE. H. Damasio, R.O. Kuljis, W.T.C. Yuh, G.W. Van Hoesen. J.C. Ehrhardt and A.R. Damasio. Departments of Neurology, Radiology and Anatomy, The University of Iowa College of Medicine, Iowa City, Iowa

Several neurologic and psychiatric illnesses result in a disruption of the internal structure of the cerebral cortex, which can only be visualized postmortem by histological examination. Current neuroimaging methods lack sufficient resolution to visualize cortical organization at the microscopic level, imposing limitations on diagnostic studies in vivo. Here we report that a modified protocol for magnetic resonance imaging at 1.5 Tesla may permit the visualization of some features of the internal organization of the cerebral cortex in vivo. The protocol included revisions to pulse sequences, field of view, number of repetitions, and sectioning plane in 14 living human subjects and two fixed brains. The latter were prepared for histological analysis of the cell (Nissl) and myelin (Gallyas) architecture after scanning. In all cases, a periodic pattern of up to 1mm thick low-signal slabs was present in the entorhinal cortex. The slabs were perpendicular to the pial surface, separated by relatively high-signal septa, arranged in a pattern similar to the modules defined histologically by the clusters of neurons in layer II, and traversed at mid-cortical thickness by a low-signal lamina that corresponds to the lamina dissecans. Our observations suggest that the modular and laminar architecture of the cerebral cortex can be visualized *in vivo* by magnetic resonance imaging. Supported by NINDS grants PO1 NS19632 and 14944.

ACUTE NEUROTOXICITY IN CULTURED RAT CEREBELLAR GRANULE CELLS: ENDOGENOUS GLUTAMATE AND THE EFFECTS OF ACIDIC AMINO ACIDS, pH AND Zn⁺⁺. M. Schramm and S. Eimerl^{*}, Dept. Biological Chemistry, Hebrew University, Jerusalem 91904, Israel.

During 14 days in culture cells accumulate 40 mM glutamate; about x 4000 the final medium concentration, and become extremely sensitive to addition of this amino acid. Release from the endogenous store might contribute to the toxicity evoked by addition of 20 µM glutamate. 5 min exposure killed 70% of the cells within 1 hr. Of 6 other acidic amino acids tested cysteine sulfinate was most active. Even with cystein sulfinate, 500 µM were required to produce the high toxicity of 20µM glutamate. The pH dependence of acute toxicity corresponded to the function of the NMDA receptor channel (Tang et. al., Soc. Nerosci. Abstr. 15: 326 (1989). Glutamate, 20µM had a negligible effect at pH7.0 but produced maximal toxicity at pH 8.0.Zn++, 2µM inhibited 66% of the toxicity of 20µM glutamate, but the metal ion, by itself, killed, 40% of the cells at 20µM. It is suggested that endogenous glutamate, pH and low Zn++ concentrations, play an important role in acute toxicity in this system.

128.3

Degeneration of Neurons in Organotypic Hippocampal Culture is Delayed Over 24 Hours After Brief Exposure to Glutamate Agonists I. I. Yornov, R. C. Tasker* and I. T. Coyle Depts. Neurology, Anesthesiology, Neuroscience and Psychiatry, The Johns Hopkins School of Medicine, Baltimore, MD 21205

Glutamate release appears to be responsible for neuronal injury in some animal models of ischemia, with degeneration often delayed by hours or days. We have observed such a delayed time course of morphological degeneration of neurons in organotypic hippocampal cultures after exposure to glutamate agonists. Cultures were prepared using the roller tube method of Gahwiler. After 14 days in vitro, cultures were exposed for 30 minutes to glutamate agonists at 37°C and allowed to survive in fresh growth media for 24 hours or 5 days. There was no LDH released during exposure to glutamate (10mM), NMDA (100µM) or kainate (100µM). However, media from all cultures contained LDH activity 24 hours later, indicating significant injury. Despite the large amounts of LDH released, thionin staining showed many morphologically intact neurons at 24 hours. Neuronal degeneration, denoted by pyknotic neuronal nuclei was most apparent after NMDA exposure. Kainate exposure caused less morphological damage, though shrunken nuclei with surrounding halos were seen (as observed 24 hours after striatal kainate injection in vivo). The effects of glutamate were the least evident. After 5 days of recovery, neuronal degeneration was widespread in all treated cultures, but cultures exposed to glutamate still contained neurons, that while not normal in appearance, were not pyknotic. These results suggest that injury in organotypic hippocampal culture, as in vivo, is a prolonged process.

128.5

THE PROTEIN KINASE C ACONIST 7-OCTYLINDOLACTAM V ATTENUATES SLOW EXCITATORY AMINO ACID-INDUCED NEUROTOXICITY IN CORTICAL CELL CULTURES. D.M. Hartley and D.W. Choi. Dept. of Neurology and Neurosciences Program, Stanford Univ. Med. Sch., Stanford, CA 94305.

Protein kinase C (PKC) has been suggested to play an important role in glutamate receptor-mediated neuronal death (Favaron et al., PNAS 85: 7351, 1988). We attempted to modify slow excitatory amino acid-induced neuronal injury in mixed cortical cell cultures, using the new synthetic indolactam derivative, 7-octylindolactam V (7-OIL). Cultures exposed to 30 - 35 µM kainate for 24 hr developed widespread submaximal neuronal degeneration. Addition of 10 µM 7-OIL, either 24 hr before kainate exposure or upon initiation of kainate exposure, reduced neuronal damage by 30 - 90 %; lower concentrations of 7-OIL were ineffective. 10 µM 7-OIL also partially attenuated the neuronal injury induced by 24 hr exposure to 10 µM AMPA or 15 µM NMDA. Further study will be required to elucidate the mechanism of this protective action of 7-OIL. Patch

Further study will be required to elucidate the mechanism of this protective action of 7-0IL. Patch clamp studies showed no acute attenuation in kainate-induced whole cell currents (voltage-clamped at -60 mV and +30 mV) with application of 10 μ M 7-0IL. Arguing against a simple interaction with neuronal PKC is the high concentrations required for neuronal protection; furthermore, (-) and (+) enantiomers were equivalent in reducing kainate-induced injury.

NMDA ANTAGONISTS PREVENT KAINATE TOXICITY IN RAT RETINAL GANGLION CELLS IN VITRO. Nikolaus J. Sucher, Elias Aizenman† and Stuart A. Lipton. Dept. of Neurology, Children's Hospital & Harvard Medical School, Boston, MA 02115. (†Present address: Univ. of Pittsburgh).

Under defined culture conditions, exogenous glutamate (Glu), *N*-methyl-D-aspartate (NMDA), or an endogenous Glurelated toxin are lethal to rat retinal ganglion cells. These detrimental effects are NMDA receptor-mediated since specific NMDA antagonists can prevent cellular injury. In the presence of the endogenous Glu-like toxin, 125 μ M kainate (KA) further increases the proportion of retinal ganglion cells that die, but the toxicity (due to both KA and the endogenous toxin) is totally prevented by 200 μ M APV, a specific NMDA receptor antagonist. The fraction of toxicity attributed directly to KA can be blocked by the relatively specific non-NMDA antagonist, CNQX (10 μ M), but under these conditions a proportion of neurons still die due to the endogenous Glu-like toxin. In patch-clamp recordings, the response to 125 μ M KA was totally unaffected by 200 μ M APV, even under conditions of [Mg²+]0 = 0 in which nonspecific KA-activation of NMDA receptors would be expected to be maximal were it to occur in this preparation. These findings suggest that (i) KA-induced retinal ganglion cell death is mediated via NMDA receptors, and (ii) KA may possibly lead to the net efflux of additional endogenous Glu-related toxin that acts at the NMDA receptor under these *in vitro* conditions.

128.4

MUSCIMOL ATTENUATES SLOW EXCITATORY AMINO ACID-INDUCED INJURY OF CULTURED CORTICAL NEURONS. H. Monyer, D.M. Hartley, H. Ehsani, P.H. Seeburg, and D.W. Choi². Tontr. for Molecular Biology, Heidelberg, FRG; Dept. of Neurology, Stanford Univ. Med. Sch., Stanford, CA 94305.

Mixed cortical cell cultures containing both neurons and glia were exposed to 25 - 30 μ M kainate for 24 hr in a defined medium. At the end of this exposure, widespread submaximal neuronal degeneration was evident by phase-contrast microscopy or efflux of lactate dehydrogenase to the bathing medium; this injury could be attenuated by 10 μ M CNQX. Addition of 10 μ M to 1 mM concentrations of the GABAA agonist, muscimol, partially attenuated kainate-induced neuronal damage, with IC50 about 100 μ M; maximal injury reduction produced by 300 μ M · 1mM muscimol generally ranged between 40 · 70%. High concentrations of muscimol also produced partial protection against the slow excitotoxic neuronal death induced by 24 hr exposure to 10 μ M AMPA or 15 μ M NMDA. However, 1 mM muscimol had little or no protective effect against the excitotoxic damage induced by 5 min exposure to 500 μ M NMDA.

These observations are consistent with the hypothesis

These observations are consistent with the hypothesis that neuronal depolarization, perhaps leading to activation of voltage-gated calcium channels, may be an important factor in the slow excitotoxic injury of cortical neurons induced either by non-NMDA agonists, or by low concentrations of NMDA agonists.

NORDIHYDROGUAIARETIC ACID (NDGA) ATTENUATES SLOW EXCITATORY AMINO ACID-INDUCED NEURONAL DEGENERATION IN CORTICAL CULTURES. <u>K. ROSE, V.M.G. BRUNO, R. OLIKER</u>, and <u>D.W. CHOI.</u> Dept. of Neurology, Stanford Univ. Med. Sch., Stanford, CA 94305

Recent evidence suggests that free radical formation may be responsible for a portion of the neuronal injury resulting from excess exposure to excitatory amino acids (Monyer et al., Soc. Neurosci. Abstr. 15: 479, 1989; Murphy et al., Neuron 2: 1547, 1989). An important mechanism of glutamate receptor-induced free radical formation may be augmentation of arachidonic acid metabolism. These experiments examined the ability of the lipoxygenase inhibitor NDGA to attenuate excitatory amino acid neurotoxicity in murine cortical cell cultures.

 $30~\mu\text{M}$ NDGA did not protect cortical neurons against the fast excitotoxic injury induced by 5 min exposure to either $100~\mu\text{M}$ NMDA or $150~\mu\text{M}$ glutamate; higher concentrations of NDGA were toxic. However, 3 - 30 μM NDGA attenuated the slow excitotoxic injury induced by 24 hr exposure to 10 μM AMPA, 30 μM kainate, 20 μM NMDA, or 600 μM quinolinate; at 30 μM , neuronal injury in all these paradigms was reduced by about half. 3 - 30 μM NDGA also protected cultures against the neuronal injury induced by glucose deprivation for 12 hr. NDGA may be a useful alternative to receptor

NDGA may be a useful alternative to receptor antagonists for attenuating slow excitotoxic injury.

NMDA-INDUCED CALCIUM TRANSIENTS IN CALBINDIN-CONTAINING STRIATAL NEURONS IN PRIMARY CULTURE. S. Weiss, D. Hochman and B.A. MacVicar. Neuroscience Research Group, University of Calgary, Calgary, AB, Canada T2N 4N1.

It has been suggested that the selective presence of calciumbinding proteins, e.g. calbindin-D_{28K} (CaBP), in neurons may confer resistance to neurodegeneration mediated by excitatory amino acids. In striatal neurons in primary culture, 15-20% of the cells contained CaBP-like immunoreactivity as revealed by indirect immunocytochemistry. We examined the actions of excitatory amino acid agonists on intracellular calcium ([Ca2+]) in CaBPimmunoreactive (IR) striatal neurons by combining imaging of [Ca²⁺], using FURA-2 with post-hoc immunocytochemistry. Increases in [Ca²⁺], were observed in CaBP-IR neurons in response to NMDA (100μM), kainate (100μM) or elevated K⁺ (50mM). With a single administration of NMDA (100µM), neither the peak increase in [Ca2+], nor the rate or extent of recovery in CaBP-IR cells were significantly different from those that did not contain CaBP. In preliminary experiments with repeated agonist application, increases in [Ca²⁺], in neurons that did not contain CaBP were more prolonged than those in CaBP-IR neurons. These findings support the hypothesis that the presence of calcium binding proteins may serve to protect neurons from sustained increases in [Ca2+].

INTRACELLULAR CALCIUM CONCENTRATIONS DURING COMBINED 'CHEMICAL HYPOXIA' AND EXCITOXIC NEURONAL INJURY J.M. Dubinsky and S.M. Rothman Dept. of Anatomy and Neurobiology and Dept. of Pediatrics, Washington University School of Medicine, St. Louis, Mo. 63110.

Since ischemic and hypoxic neuronal damage can be attenuated by

Since ischemic and hypoxic neuronal damage can be attenuated by NMDA antagonists, it is assumed that the initial metabolic insult causes a release of endogenous glutamate that itself is neurotoxic. To test the hypothesis that hypoxic damage might be additive to glutamate neurotoxicity, we have examined neuronal survival and rises in intracellular calcium after exposure to glutamate and/or cyanide, as a model of 'chemical hypoxia'. Experiments were performed on cultures of dissociated postnatal hippocampal neurons after 2 weeks in vitro. Intracellular Ca, levels were measured in fura-2-AM loaded cells with a photometer based system. Dose response curves for rises in Ca, show that glutamate maximally increased Ca, 250-300nM with a K₀ of 30 µM, while 3-10mM NaCN produced Ca, levels approaching 1 µM. 300 µM NaCN, the minimal dose to produce a response, shifted the glutamate dose-response curve left and raised the maximal Ca, level in an additive fashion. The rise in Ca, produced by either glutamate or NaCN was greatly reduced by coapplication with MK801 or 7-chlorokynurenic acid. Simultaneous application of glutamate and NaCN produced a rise in Ca, which was reduced by MK801 plus CNQX. Glutamate killed 80% of neurons after a 5 min exposure while 3 mM NaCN was not toxic for 30 min. We suspect that in NaCN, a small increase in Ca, probably triggered by glutamate accelerates release from intracellular stores, producing a rise in Ca, far above that seen with glutamate alone. Thus, an extremely large increase in Ca, is not toxic when the Ca is liberated from internal sites. Supported by NS19988 and Monsanto.

AIDS VIRUS COAT PROTEIN SENSITIZES NEURONS TO NMDA RECEPTOR-MEDIATED TOXICITY. Stuart A. Lipton, Peter K. Kaiser, Nikolaus J. Sucher, Evan B. Dreyer, and Jeffrey T. Offermann. Dept. of Neurology, Children's Hospital & Progr. in Neurosci., Harvard Medical Sch., Boston, MA 02115.

Recently, we have shown in vitro that picomolar doses of HIV coat protein gp120 produce a dramatic increase in $[Ca^{2+}]_i$ in rodent retinal ganglion cell and hippocampal neurons. Further, in retinal ganglion cells this rise in $[Ca^{2+}]_i$ is associated with neurotoxicity that can be prevented with calcium channel antagonists (Dreyer et al., *Science* 1990;248:364). In other experiments, it was demonstrated that these cultures contain an endogenous glutamate-related toxin that activates NMDA receptors to produce retinal ganglion cell death; however, this form of neurotoxicity is evident only in elevated Ca^{2+} /low Mg^{2+} medium (Levy & Lipton, *Neurology*, in press). In the present experiments, performed under normal ionic conditions ($[Ca^{2+}]_0$ = 1.8 mM; $[Mg^{2+}]_0$ = 0.8 mM), we found that the toxic effect of 20 pM recombinant gp120 on retinal ganglion cells was attenuated by the NMDA antagonists APV (100 μ M) or MK-801 (12 μ M) but was unaffected by CNQX (5-10 μ M) (n = 9 experiments). When glutamate-pyruvate transaminase was added to the culture medium to break down endogenous glutamate, 20 pM gp120 no longer killed retinal ganglion cells. Taken together, these results suggest that low (20 pM) doses of gp120 may enhance NMDA receptor mediated toxicity in this preparation.

GANGLIOSIDES NORMALIZE DISTORTED SINGLE CELL [Ca⁺⁺]₁ DYNAMICS AFTER TOXIC DOSES OF GLUTAMATE IN CEREBELLAR GRANULE CELLS. G. A. de Erausquin, G. Brooker, H. Manev, A. Guidotti and E. Costa. Fidia-Georgetown Institute for the Neurosciences and Dept. of Biochemistry and Molecular Biology, Georgetown University Medical Center, Washington, D.C. 20007.

Glutamate induced delayed neurotoxicity after abusive and paroxismal activation of its receptors has been proposed to depend upon a sustained increase in intracellular free [Ca++]_i. To elucidate the temporal and causal relationship between glutamate induced changes in [Ca⁺⁺]; and neuronal death, we simultaneously studied the dynamics of [Ca⁺⁺]; changes in single neurons with fura-2 and the cell viability by imaging the nuclear penetration of propidium iodide. The main difference between toxic (50 uM) and non-toxic (5 uM) doses of glutamate is the lack of rectification in $[Ca^{++}]_i$ 20 min after glutamate is removed. This protracted rise in [Ca⁺⁺]_i in a single given cell is correlated with (r=0.87, p<0.01, Spearman's test), and consequently predictive of, the time of appearance of neuronal death, as measured by propidium iodide fluorescence. In addition, glutamate receptor antagonists (MK-801 or CPP) reduce the acute increase of $[{\rm Ca}^{++}]_i$ induced by glutamate but fail to revert the protracted increase of $[{\rm Ca}^{++}]_i$, elicited by toxic doses of glutamate. In contrast, ganglioside GM₁ and the semisynthetic analogs LIGA-4 and LIGA-20 (JPET, 1990, 252, 419) failed to change the immediate rise of $[Ca^{++}]_i$ elicited by glutamate but prevented the protracted increase in $[Ca^{++}]_i$ after toxic doses of glutamate. Voltage dependent Ca⁺⁺ channel blockers (nifepedine, etc.) did not change the initial or protracted responses to glutamate. Supported by NIH Grants HL 28940 and NS 28130.

ACTIVATION OF A TRANSLATIONAL DEATH PROGRAM IN CNS NEURONS BY EXCITATORY AMINO ACIDS. S.D. Skaper, A. Morandi*, L. Facci, D. Milani* and A. Leon. Fidia Research Laboratories, Abano Terme 35031, Italy.

Research Laboratories, Abano Terme 35031, Italy.

Excitatory amino acids (EAAs), especially glutamate, appear to play a key role in the delayed neuronal death of CNS insults like hypoxia, hypoglycemia or cerebral ischemia. To explore the molecular mechanisms underlying EAA induced cellular injury, postnatal rat cerebellar granule neuron cultures were used which, when exposed to 100 µM glutamate (15 min, 24°C) in Mg²+-free medium, undergo a massive and delayed degeneration during the next 24 hr. Prior treatment of the cultures with inhibitors of protein synthesis (1 ug/ml cycloheximide, CHK; 2 µg/ml puromycin, PUR) for 18-24 hr eliminated 80-90% of the subsequent neuronal loss induced by glutamate. Actinomycin D (5 µg/ml, AMD), a blocker of RNA synthesis, reduced this neuronal loss by only 50-60%. A pretreatment time of 6 hr was less effective in limiting glutamate neurotoxicity. Similar neuroprotective effects of CHX, PUR and AMD were seen against acute exposure to kainate. EAA receptor-operated Ca²+ influx was not affected by these inhibitors. 2-D PAGE analysis revealed a time-dependent increase by glutamate of several proteins (mainly 54 and 61 KD); gangliosides, which are also neuroprotective, appear to prevent this latter response. Translationally-linked death programs may thus participate in dysfunction of EAA transmission systems.

INCREASED RATIO OF QUINOLINATE:KYNURENATE AND INCREASED CEREBRAL CORTEX AND LUNG INDOLEAMINE-2,3-DIOXYGENASE ACTIVITY IN BOTH SRV-D AND SIV-INFECTED MACAQUES M.P. Heyes. K. Saito*, M. Gravell*, E.K. Jordan*, A. Lackner*, M. Smith* and S. P. Markey* NIMH and NINDS, Bethesda, MD 20892 and California Primate Center, Davis, CA 95616.

Increased quinolinate (QUIN) and kynurenate (KYNA) in CSF occur in patients with AIDS and have been implicated in pathogenesis of the AIDS dementia complex. Sustained increases in CSF and blood QUIN occurred in macaques infected with either simian retrovirus type-D (SRV-D, D/1/California serotype) or simian immunodeficiency virus (SIV). Increases in CSF KYNA also occurred, but to a lesser degree than the increases in CSF QUIN. Highest CSF QUIN concentrations were observed in macaques with neurologic signs and encephalitis (>5,000 nM vs 25 nM in control macaques). The activity of indoleamine-2,3-dioxygenase (IDO), the first enzyme of the kynurenine pathway from L-tryptophan (L-TRP) to QUIN and KYNA, was increased in both cerebral cortex and lungs of viremic macques. Hepatic tryptophan-2,3-dioxygenase was unaltered. Highest IDO activity was found in SIV-infected macaques with encephalitis. Increased lung and cerebral cortex IDO activity likely accelerate the formation of kynurenine pathway metabolites in both systemic and central tissues. However, it remains to be determined which kynurenine pathway metabolites, produced either intracerebrally or systemically or in both tissues, provide substrate for the synthesis of QUIN and KYNA in CSF. Further studies are required to determine whether the depletion of L-TRP and consequential production of QUIN, KYNA have any detrimental neurologic consequences in infection.

MAGNETIC RESONANCE IMAGING OF THE RHESUS MONKEY BRAIN: FUNCTIONAL IMAGING OF CEREBRAL PERFUSION USING DYSPROSIUM-DTPA-BMA. R.C. Saunders, J.A. Frank*, T. Aigner, D. Doudet, S. Rocklage*, & S. Quay*, NIMH and NIH, Bethesda, MD 20892 and Salutar Inc., Sunnyvale, CA 94086.

Sunnyvale, CA 94086.

We used rapid magnetic resonance (MR) scanning in combination with a paramagnetic contrast agent, dysprosium-DTPA-BMA (DYS), to differentiate cerebral perfusion in monkey visual cortex during stimulated and non-stimulated conditions. Monkeys were prepared with either a unilateral optic tract section/forebrain commissurotomy or with a complete commissurotomy of the corpus callosum, anterior commissure, and optic chiasm. Thus, in each animal, one hemisphere was blind and commission of the corpus canonical areas. In contrast to control and the other was not, so that each animal served as its own control. Animals were scanned with visual stimulation and in complete darkness. MR imaging was performed in a GE Signa 1.5 T scanner with a 5" receive-only surface coil. Sixty sequential dynamic GRASS images through striate cortex were collected with TE=11 ms, TR=20 ms, flip angle=10°, FOV=16 cm, NEX=0.75, with 128 views (1.92 s/image) after a bolus injection of DYS. Signal intensity of the DYS was determined in several regions in both visual and nonvisual cortical areas. In contrast to control monkeys, in which no differences were observed between hemispheres under either stimulated or non-stimulated conditions, comparison of the visual cortex in the normal and blind hemispheres of the operated animals revealed a mean signal intensity difference of 9%. These results demonstrate that modest changes in cerebral perfusion resulting from physiological stimulation can be quantified by DYS-enhanced MR imaging.

THE INFLUENCE OF AMPHETAMINE TREATMENT ON SOMATOSENSORY FUNCTION IN THE NORMAL AND INFARCTED RAT BRAIN. Dietrich, O.F. Alonso, R. Busto and M.D. Ginsberg. Cerebral Vascular Disease Research Center, Univ. Miami

School Medicine, Miami, FL 33101.

The consequences of d-amphetamine (d-AMP) on the metabolic responsiveness of the cerebral cortex to physiological activation were studied in normal and barrel field (BF) infarcted rats. Treated rats received 4 mg/kg d-AMP 1 hour prior to unilateral vibrissae stimulation and 2-deoxyglucose study. In nontreated rats, activation led to significiant increases in glucose metabolism (lCMRglu) restricted to the cortical BF. In d-AMP treated rats, stimulation-induced increased lCMRglu was enhanced in layer 4 of the BF compared to nontreated rats (120 vs. 81 umols/100g/min). In addition, ipsilateral and con-81 umois/100g/min). In addition, ipsilateral and contralateral cortical regions <u>outside</u> the BF demonstrated metabolic activation under d-AMP. A 84% increase in lCMRglu above control was seen in cortical areas anterior to the BF. Stimulation-induced increased lCMRglu was severely depressed in nontreated rats which had undergone left BF infarction two weeks previously. In contrast, bilateral increases in lCMRglu were observed within multiple cortical regions of treated infarcted rats. A 50% increase in lCMRglu was detected in areas bordering the BF infarct. Thus, in the normal and infarcted rat, d-AMP promotes alternate circuit activation - a pharmacological property which may be advantageous for post-injury recovery.

DECREASED LOCAL CORTICAL BLOOD FLOW ELICITED BY ELECTRICAL STIMULATION OF THE DORSAL RAPHE NUCLEUS IN RAT. M.D. Underwood, M.J. Bakalian*, V. Arango and J.J. Mann. Labs. of Neuropharmacology, University of Pittsburgh, Pittsburgh PA 15213.

Electrical stimulation of the dorsal raphe nucleus (DRN) elicits a widespread reduction in cerebral blood flow (CBF) as shown by autoradiography (Bonvento et al., JCBFM 9:251-5, 1989). Using a laser-Doppler flowmeter, we sought to determine the time-course and magnitude of change in local cortical blood flow (CrtBF) following electrical stimulation of DRN.

Rats were anesthetized (chloralose: 30-40 mg/kg), paralyzed and artificially ventilated. Arterial pressure (AP), heart rate (HR) and blood gases were continuously monitored and controlled. The effect of stimulus frequency (1-200 Hz) and intensity (10-100 µA) on AP and HR was examined. CrtBF was measured using a laser-Doppler flowmeter with the probe placed extradurally over parietal sensorimotor cortex. Stimulation sites were histologically verified.

Stimulation of DRN (8 sec train; 0.5 msec; n = 6) elicited stimulus-locked frequency and intensity dependent increases in AP, HR and CrtBF. Maximal elevation in AP (34 \pm 4 mmHg) was observed at 100 μA and 200 Hz. In contrast, continuous stimulation of DRN (200 Hz; 1 sec on/1 sec off; 0-70 μA slowly increased then sustained 10 min) elicited a slow onset (approximately 1 min) decrease in CrtBF (p < 0.05) with no change in AP. The greatest decrease in CrtBF was observed 4 min after stimulus onset (88.7% \pm 2.5% of baseline), CrtBF thereafter gradually increased (to 93% of baseline) and was sustained, remaining below pre-stimulation levels (p < 0.05).

Acute activation of the DRN, perhaps via serotonergic pathways, elicits prominent effects on the systemic circulation, while continuous stimulation reveals reduced cerebrocortical blood flow. Partially supported by P50 MH46745.

129.2

CEREBRAL BLOOD FLOW IN THE VISUAL SYSTEM OF THE RHESUS MONKEY BY PET. D.J. Doudet, R.C. Saunders, J. Frank and R.N. Nakamura. Clinical Brain Imaging/LCM, NIMH, Clinical Brain Disorders Branch, NIMH, Dept. of Radiology, NIH, Bethesda

Regional Cerebral Blood Flow (rCBF) using 150 labelled water for PET (Positron Emission Tomography) was used to study the effects on brain activity of deafferentation of the visual system. PET scans were collected in normal rhesus monkeys and animals in which one hemisphere was blinded by unilateral optic tract section together with forebrain commissurotomy, at rest, in a darkened room, and during simple visual stimulation. rCBF was studied in several neocortical areas and in the striatum.

No left/right differences were found in the normals under both conditions. A significant decrease in rCBF existed in the occipital, preoccipital and parietal areas of the deafferented hemisphere compared to rCBF in the intact side. rCBF in striatal and non visual cortical areas in both hemispheres of the lesioned monkeys were not significantly different from rCBF in normal rhesus. Visual stimulation induced increased rCBF (8-12*) at the level of the intact primary occipital cortex only. Magnetic Resonance Imaging scans did not present evidence of pathology in the cortical and striatal areas studied

PET can be used to evidence functional abnormalities in an integrated system after deafferentation of one element. of this system.

SEVERE HYPERTENSION AND SYMPATHETIC STIMULATION: LOCAL HETEROGENEOUS CHANGES IN CEREBRAL BLOOD FLOW. <u>U.I. Tuor</u>. Neonatology, Hospital for Sick Children and University of Toronto, M5G 1X8, Toronto, Canada. This study mapped the <u>local</u> influence of sympathetic

stimulation on the cerebral circulation during extreme Local cerebral blood flow was measured in 11 anesthetized rats with 14C-iodoantipyrine autoradiography after 10 minutes of severe hypertension (MABP approx.190 mmHg, angiotensin II,IV). Animals also underwent: (i) unilateral section of the sympathetic nerve trunk (denervated) or (ii) electrical stimulation of the superior cervical ganglion + contralateral denervation (stimulated).

contralateral denervation (stimulated).

In both groups, severe hypertension resulted in heterogeneous areas of marked hyperemia within the cortex, thalamus, and cerebellum. In the denervated group, local blood flow during hypertension was similar within innervated and denervated hemispheres. In the stimulated group, most foci of hyperemia had similar levels of flow in the stimulated and denervated hemispheres. In contrast, within some regions with homogeneous perfusion, blood flow was reduced 15-25% insilateral to the stimulated side (eq. caudate nucleus and ipsilateral to the stimulated side (eg. caudate nucleus and globus pallidus). Thus, sympathetic stimulation during severe hypertension limits elevations in global cerebral blood flow by a diffuse but selective increase in cerebrovascular resistance. (Supported by the Heart and Stroke Foundation of Ontario).

BLOOD FLOW:METABOLISM COUPLING IN EFFERENT SITES OF ELECTRICALLY STIMULATED AREA POSTREMA K.M. Wall, D.S. Wainman*, and P.M. Gross.

Neurosurgical Research Unit, Departments of Surgery & Physiology, Queen's University, Kingston, Canada K71. 3N6

Neurons of the brainstem circumventricular organ, area postrema (AP), innervate specific nuclei in the medulia oblongata and pons. Some of this innervation may be destined for the microvasculature to control blood flow (F) and capillary function. We tested the hypothesis that electrical stimulation of AP would couple F precisely to the increases in glucose metabolism (GM) found previously in medullary and pontine structures (Am. J. Physiol. 258:R788, 1990). A microelectrode was positioned stereotaxically to stimulate the dorsocentral AP of anesthetized, ventilated albino rats (ES, 150 µA, 15 pps, 1 ms). F and GM were determined in stimulated and shamprepared rats by autoradiographic analysis of iodo[¹¹C]antipyrine and i¹*Cjdeoxyglucose images, respectively. ES caused a 13% decreased in arterial blood pressure. There was little change in F or GM during ES in a medullary structure not receiving prominent AP innervation, the spinal trigeminal nucleus. In nucleus tractus solitarius, nucleus ambiguus, locus coeruleus, and lateral parabrachial nuclei, however, ES increased GM by 28-62%, decreased cerebrovascular resistance (CVR) by 41-46%, and increased F by 108% (increase in F:GM ratio of -9 to 27%). In the C1 adrenergic cell group, ES decreased CVR by 58% and increased F by 108% (increase in F:GM ratio of 198%). The results are evidence for active dilatation of resistance vessels in AP-innervated structures during ES and indicate a particularly strong influence of AP projections on capillary perfusion in the medullary C1 cell group.

STIMULATION OF THE FASTIGIAL NUCLEUS PRODUCES A FOCAL ELEVATION IN CEREBROCORTICAL INTERSTITIAL K⁺ C. <u>ladecola ¹ & R.P. Kraig²</u> Departments of Neurology, Univ

of Minnesota, Minneapolis, MN 55455¹ & Univ of Chicago²
Electrical stimulation of the fastigial nucleus (FN) increases cerebral blood flow (CBF), an action which in cerebral cortex is mediated by local neurons. These neurons might influence local microvessels by the interstitial release of vasoactive ions, such as K+. We studied if FN stimulation produces interstitial K+ (K+0) as K. We studied if FN stimulation produces interstitat $K = (K_{0.0})$ accumulation in cortex and, if so, whether changes are focal or diffuse. Rats were anesthetized (halothane 1-5%), paralyzed and artificially ventilated. FN was stimulated through electrodes stereotaxically implanted. $K^*_{0.0}$ was measured in parietal cortex by ion-sensitive microelectrodes. FN stimulation (5-10V, 50Hz, 8 sec) elicited sustained K⁺₀ increases ranging from 0.1 to 2.9 mM (n=47). Increases were stimulus-locked, stimulus frequency and intensity dependent (n=7) and were not evoked from other cerebellar sites (n=5). K*0 elevations were consistently greater 600-900µ below the pial surface (0.5-2.9 mM; n=9). Smaller or no changes (0.0-0.7 mM) occurred at depths of 250-500µ (n=15) and 1000-2000µ (n=23). Thus the rise in cortical K⁺0 evoked from the FN is highly focal and may reflect activation of a subset of afferent fibers and/or intrinsic neurons. Such restricted K+0 change is unlikely to mediate the widespread increase in cortical CBF evoked from the FN Rather, if a focal K^{\star}_0 rise participates in the vasodilation, a mechanism resulting in a wide dispersal of K+, possibly within syncytial glia, must be involved.

129.9

LOCALIZATION OF NICOTINE-INDUCED INCREASES IN CORTICAL CEREBRAL BLOOD FLOW (CBF). D.G. Linville and S.P. Arneric, Department of Pharmacology, Southern IL University School of Medicine, Springfield, IL 62702 and Neuroscience Research, Abbott Laboratories, Abbott Park, IL 60064-3500

Electrical stimulation of the basal forebrain (BF) elicits increases in parietal cortical CBF (+150%) as measured by laser-doppler flowmetry (LDF), and this increase is selectively attenuated by the nicotinic antagonist, mecanylamine (Neurosci. Abstr. 13:288.12, 1987). We sought to determine: 1) Does nicotine receptor activation in the BF and/or cortex influence cortical CBF? 2) Does the receptor activation in the BF and/or cortex influence cortical CBF? 2) Does the BF-elicited increase in cortical CBF require intrinsic cortical neurons? Sprague-Dawley rats (3-6 months) were anesthetized (chloralose), paralyzed, artificially ventilated and arterial blood gases controlled. Phosphate buffered saline or L-nicotine (0.0, 0.125, 0.25 & 0.5 mod/100nl) were microinjected into the cortex (immediately beneath the LDF probe) or BF. BF-injected nicotine increased cortical CBF by +39, +116, +163, +127%, respectively (N=4-5, p<0.05), whereas no detectable increases were obtained with cortical microinjections (N=3). Corticopascular responsivity was confirmed at each intertion site with whereas no detectable increases were obtained with cortical microinjections (N=3). Corticovascular responsivity was confirmed at each injection site with glutamate, 10 mmol/100nl. Secondly, 5-7 days following selective unilateral destruction of intrinsic cortical neurons with ibotenic acid, BF-elicited increases in cortical CBF were determined within the lesion and compared to the homologous sham-injected side. No significant differences were observed when lesions were restricted to superficial layers of cortex. However, when lesions disrupted all cortical layers, marked attenuation of responses was observed. CONCLUSIONS: 1) Nicotinic receptor activation in BF, but not cortex, enhances cortical CBF. 2) BF-stimulated cortical CBF responses appear to require synaptic mediation through intrinsic cortical neurons, which is similar to the increases in cortical CBF elicited from the fastigial nucleus of the cerebellum (Iadecola, et al., Am. J. Physiol. 252:1082-91, 1987). (Supported by the American Health Assistance Foundation for Alzheimer Disease Research) Health Assistance Foundation for Alzheimer Disease Research)

MITRIC OXIDE (NO): ITS ROLE IN MEDIATING INCREASES IN CORTICAL CEREBRAL BLOOD FLOW (CRF) ELICITED BY ELECTRICAL STIBULATION OF THE BRANL FOREBRAIN (BF)-S.P. Armerić. D.G. Limylle. J.F. KEYMIN. Jr., and F. Murad. Neuroscience Research. Abbott Laboratories, Abbott Park, Il. 60064-3500, and Dept. of Pharmacology, Southern Illinois University School of Medicine, Springfield, Il. 62702.

NO is an EDRF (endothelium-derived relaxing factor) released from endothelial cells in response to transmitters such as acetylcholine (ACh), and may mediate multiple messenger functions in macrophages and brain tissue. It diffuses into smooth muscle where it causes activation of guarylate cycless and relaxation. Recent evidence suggests that neurons arising from the BF participate in a regionally selective regulation of cortical CBF (Armeric, Excerpta Int. Cong. Series 869: 381-384, 1989). The BF-elicited CBF response appears, in large part, to be cholin-ergically mediated since physostigmine potentiates (Lacombe et al., Brain Res. 491:1-14, 1989). and nicotinic cholinergic antagonists attenuate this response (Arneric, 1989). This study sought to determine: Is the release of NO an important physiologic Link required to mediate increases in cyrtical CBF overned by the BF? To do so, an inhibitor of NO synthetase (i.e., N°-nitro-L-arginine, LNNA) was infused iv. and changes in resting and BF-elicited increases in cortical CBF were assessed using laser-doppler flowmetry (LDF). Sprague-Dawley rats (3-5 months) were anesthetized (urethane), paralyzed, artificially ventilated and arterial blood gases controlled. Flow probes were stereotaxically positioned on the dural surface (2.5 mm rostral & 2.6 mm lateral to Bregma). Unilateral electrical stimulation (100 uA; 10 sec.) of BF at 5, 10, 25 and 50 Hz resulted in graded, stimulus-tocked increases in CBF (up to 271% above resting control). Induson of LNNA (60 mg/kg) maximally attenuated the BF-elicited increases from +271 % to +165 % at 25 Hz (i.e. a -44 ± 10 % reduction in the ability to inc

129.8

CEREBRAL VASODILATATION ELICITED BY ELECTRICAL STIMULATION OF THE CENTROMEDIAN-PARAFASICULAR THALAMUS IS MEDIATED IN PART BY NICOTINIC CHOLINERIC NEURONS S. Mraovitch, P.J. Goadsby¹ and J. Seylaz* Laboratoire de Physiologie et Physiopathologie Cérébrovasculaire, Universite Paris VII, Paris France & ¹The National Hospitals for Nervous Diseases, Maida Vale, London England.

The centromedian-parafasicular complex of the intralaminar thalamus (CM-Pf) is a collection of neurons that have been implicated in cortical electrical activity, nociception and more recently in cerebrovascular regulation since the CM-Pf can increase cerebral blood flow in the absence of an associated rise in cerebral metabolism. Using laser Doppler flowmetry (LDF) the pharmacology of the cerebral vasodilator response to CM-Pf stimulation has been studied. Adult Wistar rats were anesthetised with halothane and chloralose (40mg/kg), paralysed and artificially ventilated. Cerebral perfusion (CBF $_{\text{LDF}}$) was measured continuously with a BPM 403a (TSI) LDF monitor. The CM-Pf was electrically 403a (TSI) LDF monitor. The CM-Pf was electrically stimulated with varying frequencies (1-500/s) and intensities (50-250uA). Stimulation produced a frequency and intensity dependent increase in CBF_{LDF} up to a maximum of 114%. At 150uA/200/s the response was tested after intravenous injection of both atropine (300ug/kg; no effect) and monitoring (mg/kg; proposed attentions of the contraction of the contracti intravenous injection or both atropine (3000g/mg; no effect) and mecamylamine (4mg/kg; response attenuated by 80%). We conclude that the marked reduction of the CM-Pf elicited cerebral vasodilator response by mecamylamine implicates a cholinergic nicotinic mechanism.

Horwitz, S.I. Rapoport, Lab. Neurosciences, National
Institute on Aging, NIH, 10/6Cl03, Bethesda, MD 20892.
Unilateral destruction of the nucleus basalis magnocellularis (nbm) in rats reduces cholineraic inputs to the
ipsilateral frontoparietal neocortex and disrupts hehavior. Regional cerebral metaholic rates for nlucose
(rCMRglc) of denervated cortex initially are reduced, but
normalize by 2 wk. To examine brain functional interactions, correlational analysis of rCMRglc was performed on
2 groups of 16 young rats at 2 wk after stereotaxic ablation of the right nbm with ibotenate or sham surgery.
rCMRglc was measured in 117 brain regions of awake rats
with the [14C]deoxyglucose method. For each region pair, rCMRqlc was measured in 117 brain regions of awake rats with the [140]deoxyglucose method. For each region nair, correlation coefficient (to control for effect a partial correlation coefficient (to control for effect of mean CMRqlc) was calculated for rCMRqlc across animals. Most correlations between cholinerqic nuclei (medial septum and diagonal band) and right (66/72, mean increase 0.44) but not left (39/72) frontonarietal cortical regions were larger (P < 0.001) in lesioned rats, as were those between most frontoparietal region pairs (516/630, P < 0.001). These results suggest that functional interactions within frontoparietal region pairs (316/630, P < 0.001). within frontoparietal neocortex, and between denervated cortex and remaining cholinergic nuclei, are altered at 2 wk after unilateral nhm ablation.

AGE-DEPENDENT CEREBRAL METABOLIC EFFECTS OF UNILATERAL LESION OF NUCLEUS BASALIS MAGNOCELLULARIS IN RATS. F. De Micheli, H.W. Holloway*, D.M. Larson*, S.I. Raponort,
T.T. Soncrant. Laboratory of Neurosciences, National
Institute on Aging, NIH, 10/6C103, Bethesda, MD 20892.
Unilateral ablation of the nucleus basalis magnocellularis (nbm) in rat causes degeneration of cholinergic

projections to the ipsilateral frontoparietal neocortex and, in young rats, reduces regional cerebral metabolic rates for glucose (rCMRglc) in denervated cortex at 3 To evaluate the age-dependent cerebral metabolic effects of unilateral nbm destruction, rCMRq1c was determined, using the [14C]deoxyq1ucose method, in 48 brain regions of 3- and 24-month old Fischer-344 rats at 3 days after stereotaxic injection of ibotenate into the right Lesion placement was confirmed in adjacent Nissl-ned sections. Immunohistochemical acetylcholinesstained sections. stained sections. Immunonistochemical acetylcholines-terase staining of coronal tissue slices was markedly reduced in frontoparietal cortex ipsilateral to nhm lesion in all brains. rCMRglc was reduced in fronto-parietal regions ipsilateral to nhm ablation (compared to the contralateral side) to a greater extent (P < 0.05) in 3 month old (-25%) than in 24 month old (-8%) rats. These results suggest that the tonic activity of cally-projecting cholinergic neurons is reduced in aged rats, or that cerebral metabolic changes after nbm lesion follow different time courses in young and old rats.

ORGANIZATION OF RHESUS MONKEY PRIMARY VISUAL CORTEX AS REVEALED BY MAP₂ ANTIBODY STAINING. A. Peters. Dept. of Anatomy, Boston Univ. Sch. of Med., Boston, MA 02118.

Area 17 has been analyzed using an antibody to MAP₂ (Kosik et al., Proc. Natl. Acad. Sci., 81:7941, 1984) which can be used to label the cell bodies and dendrites of neurons. It is found that the cortex contains vertically oriented modules of pyramidal cells. The modules average 30 µm in diameter and are centered around the layer V pyramids. The apical dendrites of these cells ascend through layer IV in narrow clusters or bundles. When these clusters pass through layer II/III the apical dendrites of pyramids in those layers are added to them. The apical dendrites of layer VI pyramids also form bundles, but these appear to be disposed randomly. MAP₂ staining also shows the presence of groups of pyramidal cells in layer IVA. The cell bodies of the neurons in these groups are in cones, from the tops of which emerge bundles of apical dendrites. There are about 120 cones of layer IVA pyramids beneath I mm of cortical surface, and they seem to occupy the spaces within the horizontally oriented honeycomb pattern that is revealed in layer IVA by cytochrome oxidase reactions. Consequently, it is likely that the parvocellular input from lateral geniculate body to layer IVA terminates in relation to these cones of pyramidal neurons. Supported by NIH grant NS 07016.

CYTOCHROME-OXIDASE ACTIVITY IN CAT VISUAL CORTEX: IS IT PERI-ODIC?. K.M. Murphy, R.C. Van Sluyters & D.G. Jones*. Dept of Psychology, McGill University, Montreal PO H3A 1B1, School of Optometry, University of California, Berkeley CA 94720. Computer Science, Stanford University, Stanford CA

The inputs from the two eyes to visual cortex are largely segregated in layer IV, forming the anatomical correlate of physiologically identified ocular dominance. In the cat visual cortex, examination of the 2D anatomical ocular dominance pattern in unfolded and flattened sections reveals an irregularly branching and beaded arrangement¹. Previously, we analyzed the complete tangential arrangement of ocular dominance in normal and monocularly deprived cats². The total number of ocular dominance beads in area 17 was similar for all animals studied, furthermore, the center-to-center spacing of the beads was not perturbed by monocular deprivation. These results indicate that there is some modularity to the arrangement of inputs to visual cortex. In primates the arrangement of ocular dominance has been related to the array of patches of high cytochrome oxidase activity in layers II-III. However, in the cat examinations of cytochrome oxidase staining of radial sections have failed to demonstrate any periodicity, making it unclear as to whether there is an intrinsic cortical periodicity that may relate to the pattern of geniculocortical inputs.

Since the complete pattern of cortical ocular dominance in the cat is most easily recognized in tangential sections from unfolded and flattened cortex we have used this same approach to examine cytochrome oxidase staining in area 17 of the cat. In the tangential plane cytochrome oxidase staining of area 17 reveals marked periodicity in the supragranular layers. This indicates that a periodic pattern of cytochrome oxidase staining is not unique to the primate visual cortex.

NOVEL ASPECTS OF THE FUNCTIONAL ARCHITECTURE OF AREA 18 IN CAT VISUAL CORTEX. T. Bonhoeffer and A. Grinvald. Laboratory of Neurobiology, The Rockefeller University, New York, NY 10021; IBM Research Division & The Weizmann Institute of Science, Rehovot, Israel.

In cat visual cortex, it has been shown that cells with similar ocular dominance or orientation tuning are grouped together, forming columns which run from the pia to the white matter. In vivo optical imaging of intrinsic signals was used to investigate the functional organization of area 18. We measured neuronal activity by recording the changes in light reflectance with a high resolution CCD camera. This technique allowed us to obtain multiple maps of the functional architecture of the same cortical area as a function of various parameters of the visual stimulus. In our maps of orientation preference we observed that orientation was most often organized radially rather than in parallel slabs; orientations from 0 to 180° were arranged in a pinwheel-like fashion around singularities which we Lermed "orientation centers". We found on the average 1.2 orientation centers / mm². Currently we are investigating the receptive field properties of single cells which are located in these optically-imaged singularities.

More recently, direction selectivity has been proposed to be a parameter according to which neurons are clustered in the visual cortex. Direction selectivity maps were also evaluated. In seven hemispheres we found that the cortical areas responding best to gratings moving in one direction exactly coincided with the areas showing the strongest response to the same stimulus moving in the opposite direction. Given the resolution of optical imaging we conclude that cells in area 18 do not form "directional" cortical columns. If cells with similar direction selectivity are clustered at all, then the size of these clusters is below 100 µm (the resolution of our method) or cells with different cortical depth.

130.2

DENDRITIC ARBORIZATIONS OF VISUAL CORTEX NEURONS AND THEIR RELATION TO THE CYTOCHROME OXIDASE (CO) RICH BLOBS IN MONKEY STRIATE CORTEX. R. Malach

Weizmann Inst. Rehovot, Israel 76 100.

The CO dense blob system is intriguing in being dispersed throughout striate cortex while maintaining clear connectional and physiological compartmentalization. Is this organization caused by the developmental superposition of two segregated systems, or does it subserve enhanced cross-talk at blob margins? These alternatives imply different levels of dendritic segregation of blob and interblob neurons. To investigate this issue CO and Golgi staining were combined within the same sections of monkey striate cortex.

Dendritic arbors were either traced relative to CO borders using a computer aided microscope or scanned in 3-D using confocal, laser scanning, microscope. Neurons with cell bodies located at the centers of blobs and interblob regions had dendrites which were mostly confined to the same compartment. However, in the population of neurons located near blob boundaries there were many instances in which dendrites of interblob neurons appeared to penetrate deep into the blobs and vice versa. Quantitative analysis is being conducted to test for more subtle relationships between CO topography and dendritic architecture. Supported by BSF 88-0275 and BRF 527/89.

IN VIVO THREE DIMENSIONAL OPTICAL IMAGING OF FUNCTIONAL ARCHITECTURE IN PRIMATE VISUAL CORTEX. D. Malonek, D. Shoham, E. Razlaff & A. Grinvald. Lab. of Neurobiology, The Rockefeller Univ., New York, NY 10021, IBM Research Division & The Weizmann Institute of Science.

High resolution optical imaging of cortical intrinsic signals has facilitated the visualization of the two-dimensional functional architecture in the living brain. However a central feature of cortical organization is its functional segregation into layers; distinguishing different layers requires discriminating signals originating from different depths. Our previous experiments provided 100-150 µm resolution in two dimensions, but the depth resolution was not examined systematically.

Here we report that the depth resolution of previous measurements was limited by the optics used. The resulting images represented a weighted average of the signals originating from the pial surface to a depth of 600-2000 microns (depending on the illuminating wavelength). To study the functional architecture in three dimensions we have designed a new optical system which offers computer controlled optical sectioning of cortical maps in vivo. A tandem lens arrangement provided the CCD camera with a depth of field resolution of 45 μm (nominal). Images of the macaque primary visual cortex were taken at several depths (using 630nm illumination), interlacing different visual stimuli and different depths in a single experiment. Vascular artifacts seen with previous measurements virtually disappeared when focusing 300μm below the cortical surface. To show that optical sectioning was feasible we imaged the blobs, the orientation and the ocular dominance columns at different depths and obtained very similar maps of all these three functional features between depths of 100 and 600 μm. However, as expected from electrophysiological studies, both the blobs and the orientation columns were not detected at depths of 700-1000 μm, corresponding to layer 4C, while the ocular dominance columns were still visible at those depths. These results suggest that further improvements in the three dimensional resolution should be feasible using deconvolution of serial images and/or confocal microscopy.

COLUMNS BEYOND V1 AND V2 IN MACAQUE VISUAL CORTEX: A DOUBLE-LABEL DEOXYGLUCOSE STUDY. R.B.H. Tootell and R.T. Born. Dept. Neurobiology, Harvard Med. Sch., Boston, MA 02115.

Several lines of evidence suggest that functional columns exist in cortical visual areas beyond V1 and V2, but they have never been directly labeled, nor analyzed with functional anatomical techniques. To do this, we developed a double-label (using ¹⁴C and ³H-DG) deoxyglucose (2-L-DG) protocol which shows, for the first time, cleanly separable regions of high and low brain activity in the original (¹⁴C- vs. ³H-sensitive) films, without subtracting one image from the other. We used this technique in conjunction with specifically chosen stimulus pairs to test whether cells were systematically grouped into columns on the basis of preferred orientation, color, binocular disparity and other stimulus parameters. We examined all of visual cortex in flattened sections from 11 macaque monkeys.

We found many types of columns, especially in areas MT, VP, V3/V3A, V4, and two discrete, previously-undescribed areas which we call V8 (dorsal to MT) and VM (on the ventromedial bank). Drifting square wave gratings, at orientations/directions 90° apart, were used to produce clearly interdigitated orientation/direction columns in areas V1, V2, MT, and what appears to be VP. The same stimulus produced columns of cells which were not discriminable by orientation/direction changes in areas V3/V3A and V4. Area MT also has a columnar patch/interpatch architecture, in which cells highly responsive to texture are segregated from those more responsive to contours (Tootell and Born, ARVO 1990). Spatially-diffuse variations in color consistently produce numerous columns of active cells in areas V8 and VM, and scattered columns in VP. V3A and V4.

We conclude that the 2-L-DG approach has clear value for mapping unknown columnar systems present in visual cortex, and for doing preliminary (2-condition) functional analysis of them. Supported by EY0798 and NIMH 14275.

FUNCTIONAL ARCHITECTURE OF COLOR AND DISPARITY IN VISUAL AREA 2 OF MACAQUE MONKEY. <u>D.Y. Ts'o, C.D. Gilbert, T.N. Wiesel.</u> Laboratory of Neurobiology, The Rockefeller University, NY, NY 10021.

Guided by functional maps of primate area 18 (V2) obtained from in vivo optical imaging, we have used single unit electrophysiology and tracer injections to study the organization and subcompartmentalization of functional properties within the cytochrome oxidase-rich "thick and thin stripes". Within the thick stripes, a high proportion of cells showed sharp disparity tuning. The disparity tuned regions showed separate clusters of tuned excitatory, near and disparity tuned regions showed separate clusters of funed excitatory, near and far cells. On a finer scale, sites along a given electrode penetration represented disparities that showed regular shifts in position in depth relative to the fixation plane. The clusters of the different disparity tuned cell classes lay within regions of relatively uniform orientation preference, whereas penetrations in non-disparity tuned cortex often encountered cells with rapid shifts in orientation preference

The thin stripes of V2 contained color selective cells. Color oriented cells were found primarily at the border of the thin stripe, between the unoriented color cells and neighboring regions of non-color selective oriented cells. In some cases, color selective regions bordered disparity selective regions, and here cells exhibiting both color and disparity selectivity were found.

Retrograde labeling after injections of multiple tracers within disparity and color selective regions of V2 revealed long range horizontal connections between stripes of the same functional type. A further segregation of connections was seen in the distribution of cells labeled after injections at sites containing near cells versus those containing far cells. Taken together, our studies reveal a functional sub-structure within each stripe of area V2. (Supported by grants EY07968, EY05253, and the Whitaker and Rita Allen Foundations)

NEURONS WITH END-STOPPED RECEPTIVE FIELDS DETECT OCCLUSION CUES. E. Peterhans and R. von der Heydt*, Dept. of Neurology, University Hospital, 8091 Zürich,

Figures like the Kanizsa triangle mimic situations of spatial occlusion that induce illusory contours in perception. Based on previous experiments we have proposed a neural mechanism that produces such contours by integrating the signals of end-stopped cells. Under this aspect we have now studied end-stopped cells in areas V1 and V2 of the alert monkey.

We found that cells that responded to short lines or edges nearly always responded also to the ends of long lines or to corners. Lineends and corners often evoked similar, sometimes even stronger responses than the short stimuli. Exclusive responses to corners were also found. Half of the cells (32/61) had asymmetric receptive fields: they preferred the line-ends or corners to cover one endzone, but not the other. Moreover, they also responded to line-ends and corners of illusory-contour figures where these features indicated occlusion. The responses were reduced or abolished when a thin line was added to a corner so as to contradict the assumption of occlusion, or when a T-junction was changed into a cross

We conclude that end-stopped cells, and especially those with asymmetric fields, may serve the detection of occlusion cues and may provide input to the proposed contour mechanism. Supported by Swiss-NF grant 3.939.84.

RECEPTIVE FIELD LENGTHS IN CAT STRIATE CORTEX CAN INCREASE WITH DECREASING STIMULUS CONTRAST. B. Jagadeesh and D. Ferster. Department of Neurobiology and Physiology, Northwestern University, Evanston, IL 60208.

We have found that the lengths of cortical receptive fields measured

with low-contrast stimuli can be far longer than those measured with high-contrast stimuli in the same cells. Length summation curves were made using drifting sine-wave gratings with contrasts of 1% to 64%, and lengths of 0.25° to 24.0°. As previously shown within the classical receptive field, length can compensate for contrast: At low contrasts, longer stimuli are required to evoke the same response evoked by shorter, high-contrast stimuli (Schumer & Movshon, Vision. Res. 24:565). This compensation between length and contrast, can extend beyond the length of the receptive field measured at high contrasts. In other words, the optimal length of the receptive field can increase. For example, cells that showed complete summation at only 2° with highcontrast stimuli, could show length summation to 11° at low contrasts. In end-inhibited cells, summation at low contrasts could extend into the region in which the response had been decreasing at high contrasts.

One possible origin for the increased summation lengths observed one possible origin to the interested summation regions observed at low contrasts may be input from layer 6 cells with long receptive fields, which provide an excitatory projection to layer 4 (Ferster & Lindström, J. Physiol. 367:233). In end-inhibited cells, the mechanism may be more complex, depending on the initial difference in length thresholds of both excitatory and inhibitory mechanisms. We speculate that the increase in summation lengths of individual cells at low contrasts might improve the detection of low-contrast stimuli, but only at the expense of spatial discrimination.

DISTRIBUTION OF NEURONAL RESPONSE PROPERTIES IN MACAQUE V2. J.B. Levitt, D.C. Kiper, and J.A. Movshon. Department of Psychology and Center for Neural Science, New York University, NY, NY, 10003.

Visual area V2 in the macaque contains alternate thick and thin stripes of cytochrome

Visual area V2 in the macaque contains alternate thick and thin stripes of cytochrome oxidase (CO) rich tissue separated by CO-sparse interstripes. It has been reported that the specificity of the anatomical connections of these regions is matched by the physiological properties of neurons within them. We have quantitatively examined the response properties of neurons in V2 and related their properties to the local CO architecture. We recorded the activity of single units representing the central 5 deg in all laminae and CO division of V2 in anesthetized, paralyzed macaque monkeys. After mapping receptive fields with colored and black-and-white bars, slits, or spots, we measured the responses of V2 neurons to drifting sinusoidal gratings that varied in orientation, spatial frequency, drift rate, and contrast.
While there was a tendency for neurons with certain response selectivities to be

orientation, spatial frequency, drift rate, and contrast.

While there was a tendency for neurons with certain response selectivities to be segregated (for example, directional cells in thick stripes and color-selective cells in thin and interstripes), the striking feature of V2 was its uniformity. Unoriented, end-stopped, color-selective, and direction-selective cells could be found in all CO divisions; the majority of cells in all CO compartments of V2 were oriented, nondirectional, and not color-selective. Furthermore, cells in the different CO divisions differed little in their spatial, temporal, or contrast sensitivity. Nor did directional cells differ from color-selective cells in their sensitivity or responsiveness. We did note a difference in the laminar distribution of certain cell types. We found direction-selective cells predominantly in layer 4 and the bottom of layer 3, and color We did note a difference in the laminar distribution of certain cell types. We found direction-selective cells predominantly in layer 4 and the bottom of layer 3, and color cells outside of 4 in the supra- and infragranular layers. We also identified a group of neurons, all within the central 2 deg, having simple receptive fields similar to those seen in V1. These were found mainly in layer 4, had low spontaneous firing rates, and were tuned to lower spatial frequencies than were complex cells. These simple cells were found in all CO regions. Our results suggest that the physiological organization of V2 is substantially more homogeneous than has been suggested by others.

Supported by NIMH grant MH09692 and NIH grants EY02017 and EY05864.

130.10

THE NEURAL BASIS OF STEREOSCOPIC DEPTH DISCRIMINATION: PHASE CODING BY SIMPLE CELLS IN THE VISUAL CORTEX, G.C. DeAngelis*, I. Ohzawa, and R.D. Freeman, Bioengineering and Neurobiology Groups, School of Optometry, Univ. of California, Berkeley, California 94720. Neural processing of stereoscopic depth information is thought to be initiated in the visual cortex, where binocular neurons can encode retinal image disparity. Traditionally, it has been assumed that the neural basis for depth discrimination involves disparity selective neurons whose preferred disparity is determined by the horizontal offset of identical receptive fields in the two eyes. This notion has been supported by the claim (Maske et al. 1984) that receptive field profiles of binocular simple cells are similar for the two eyes.

supported by the claim (maske et al. 1964) that receptive field profiles of bindediar simple cells are similar for the two eyes.

We have proposed an alternative mechanism (Freeman and Ohzawa, 1990) in which binocular simple cells encode disparity by having different receptive field profiles, which are in retinal correspondence, in the two eyes. To test this hypothesis in anesthetized and paralyzed cats, detailed two-dimensional receptive field profiles are constructed for both eyes using a reverse correlation technique (Jones & Palmer, 1987). An optimization method is then used to fit a Gabor function to each receptive field profile. The spatial phase parameter of the best-fitting Gabor function describes the relative positions and strengths of the receptive field subregions, and provides a

the relative positions and strengths of the receptive field subregions, and provides a quantitative measure for comparison of left and right eye profiles.

In contrast to the results of Maske et al., we find that the left and right eye receptive field profiles of simple cells often differ substantially. The difference in spatial phase between the two receptive field profiles ranges from 0 to 180 degrees. Moreover, the data indicate that cells with preferred orientations near horizontal tend to have similar receptive fields (small phase differences) in the two eyes, whereas cells tuned to orientations near vertical exhibit a wide variety of phase differences

between the left and right eye receptive field profiles.

These results provide support for a neural mechanism of stereoscopic depth discrimination in which disparity is encoded among simple cells in terms of phase at multiple size or spatial frequency scales. (EY01175)

130.12

PROCESSING OF FORM IN MONKEY VISUAL AREA VI. K. Purpura and J. Victor. Cornell Univ. Med. College and The Rockefeller Univ., New York, N.Y. 10021.
 Physiological and anatomical evidence indicate that visual

information processing is divided among submodalities in both the striate (V1) and extrastriate cortex. The analysis of visual form must, however, require some unification across these modalities and may not be the function of any one cortical area. We present evidence for the analysis of form in V1 of the monkey.

Visual stimuli consisted of achromatic and chromatic isodipole textures produced on a CRT with specialized computer-driven hardware. Isodipole textures have identical spatial frequency spectra but differ in particular local features. Interchange between textures will produce a differential response only in mechanisms sensitive to the form elements; spatial filtering mechanisms will respond similarly to all such textures. The stimuli were presented to anesthetized and paralyzed cynomolgus monkeys. Visual evoked potential recordings (VEPs) were made with electrodes placed on the VI pia and, in separate experiments, local field potentials and multiunit activity (MUA) were simultaneously monitored with tungsten-in-glass electrodes inserted into the cortex. Both recording arrangements revealed differential responses to the interchange of isodipole textures. The epicortical VEPs were striking in their similarity to human scalp VEPs elicited by isodipole textures. The differential MUAs were characterized by a drop in the population firing rate during the appearance of a structured texture in a structured/random interchange. These responses indicate that analysis of local form is present in V1

STIMULATING PERIPHERAL 5-HT.-LIKE SEROTONERGIC RECEPTORS INCREASES WATER INTAKE BY A VAGALLY-DEPENDENT MECHANISM IN RATS. K. J. Simansky and K. Eberle-Wang, Dept. of Pharmacology, Med. Coll. of Pennsylvania, Philadelphia, PA 19129.

This study analyzed the mechanisms for the dipsogenic action of subcutaneously administered serotonin (5-HT) in rats given free access to dry food and water. 5-HT increased water intake during the 2-h test period in a dose-related manner with an approximate ED_T of 10 µmol/kg, SC. Drinking produced by this dose of 5-HT was antagonized by the 5-HT₁/5-HT₂ antagonists, metergoline, methysergide and 1-(1-naphthyl)-piperazine (1-NP), but not by ketanserin, mianserin, ritanserin or xylamidine. Thus, 5-HT₁ receptors other than the 5-HT₂ subtype probably mediated the dipsogenic action of 5-HT. The 5-HT analog, 5-carboxamidotryptamine (5-CT), a 5-HT agonist, also increased water intake but the peripheral 5-HT, agonist, a-methyl-5-HT, did not. The antagonist profile for blocking drinking produced by 5-CT was identical to that for 5-HT. The 5-HT [M]B and beta-adrenergic antagonist, propranolol, stereoselectively decreased drinking caused by either 5-HT or 5-CT. This effect was probably due to beta-blockade as atenolol also prevented drinking by 5-HT or 5-CT. Total abdominal vagotomy (VGX) prevented drinking caused by 5-HT and 5-CT and the 5-HT₃ antagonist, ICS 205-930 neither restored 5-HT-induced drinking in VGX rats nor blocked it in controls. These data suggest that stimulating peripheral 5-HT₁-like receptors produces drinking by a vagally-dependent mechanism in rats. Supported by MH 41987 (KJS).

131.3

STIMULATION OF FEEDING BY CNS METERGOLINE VARIES WITH INJECTION SITE. <u>D.V. Coscina, J.N. Nobrega and D. Feifel,</u> Sect. of Biopsychology, Clarke Inst. of Psychiatry, and Dept. of Psychology, Univ. Toronto., Toronto, Ont. Canada M5T 1R8.

Past research has shown that systemic administration of the serotonin antagonist, metergoline (MET), elicits feeding in satiated rats as well as a blank of the serotonin antagonist.

Past research has shown that systemic administration of the serotonin antagonist, metergoline (MET), elicits feeding in satiated rats as well as blocks the anorectic action of the serotonergic agonist, d-fenfluramine, in both hungry rats and humans. What remains unclear is whether MET produces these effects by acting in the periphery (e.g., gastrointestinal tract) or in the brain. To begin addressing this question, ad libitum fed adult male rats were implanted unilaterally with CNS cannulae terminating in either the lateral cerebroventricle (LCV) or the paraventricular nucleus of the hypothalamus (PVN), a site at which MET has been shown to block food intake stimulated by local injections of norepinephrine (NE). One hr feeding tests after LCV injection of 0, 50, 100 or 150 nanomoles MET produced reliable enhancements of feeding at the two highest doses. To probe the specificity of this finding, separate 90 min tests of water intake, spontaneous activity, oxygen (O₂) intake and carbon dioxide (CO₂) output were run in the absence of food following 100 nanomoles MET vs. vehicle. The only difference observed was a small (+6.9%) but reliable increase in CO₂ output. Contrasting to this, PVN injections of 0, 5, 10, 20, 40 or 60 nanomoles MET produced no reliable changes in one hr feeding. Separate tests confirmed that NE injected into the PVN produced reliable enhancement of feeding, thereby eliminating the likelihood of negative findings because of improper cannula placements. These results indicate that the stimulation of feeding by systemic MET may be mediated partially or wholly through actions on the CNS, but the PVN is an unlikely site responsible for this effect.

5-Ht, AND 5-Ht, RECEPTOR BINDING SITES IN DISCRETE HYPOTHALAMIC SUCLEI: RELATION TO CIRCADIAN RHYTHM AND GENDER. <u>S.F. Leibowitz and M. Uhanwar-Uniyal.</u> The Rockefeller University, New York, N.Y. 10021, U.S.A.

Hypothalanic serotonin (5-HT) has a suppressive effect on feeding behavior, which is found to be strongest at the onset of the dark (active) cycle and more potent in female as compared to male rats. In this study, 5-HT receptor binding sites, of 1A and 1B subtypes, were biochemically examined in 8 discrete hypothalanic areas, across the light/dark (12:12 hr) cycle and also in female versus male rats.

Hypothalamic nuclei [paraventricular (PVM), ventromedial (VMM), medial preoptic (FOM), dorsomedial (DMM), supraoptic (SOM), suprachiasmatic (SCM), arcuate-median eminence (ARC-MB) and lateral perifornical hypothalamus (PLB) were micropunched and assayed. Employing the radioligand binding technique, we measured the binding of the 5-HT receptor agonist [3B]8-OM-DPAT (2 nM) to 5-HT1A receptors (in presence or absence of 10 µM 5-HT). For 5-HT, receptors, [3H]5-HT (2 nM) was incubated with 8-OM-DPAT (100 nM) and mesulergine (100 nM), in presence or absence 10 µM 5-HT.

The results revealed a significant light/dark rhythm of 5-HT, receptor binding sites in 5 of the 8 hypothalamic nuclei. In the PVB and SCH, a single peak of 5-HT binding to 1B sites was detected in the middle of the light cycle; this peak was followed by a sharp decline in 5-HT binding at dark onset and a subsequent rise starting after midnight. A different temporal pattern was observed in the ARC-HE and PLH; these two nuclei showed greatest binding in the middle of the dark cycle and lowest binding at dark onset. In the YMB, a small but significant rise in 5-HT, receptor sites occurred at dark onset. Analysis of 5-HT receptor binding in female as compared to male rats demonstrated that 5-HT, receptor sites in females were significantly higher in the PVB, ARC-HE, and PLH, while lower in the YMB. Concentration of 5-HT, receptor sites in females was greater in the ARC-HE, PLH and SOH but lower in the POM. These results indicate circadian and gender differences in 5-HT receptors comsistent with pharmacological findings.

131.2

ANORECTIC ACTION OF PERIPHERAL SEROTONIN (5-HT) AFTER ABDOMINAL VAGOTOMY IN RATS. K. Eberle-Wang and K.J. Simansky, Dept. of Pharmacology, Medical College of Pennsylvania, Philadelphia, PA, 19129.

Previous work by Fletcher and Burton (1985) demonstrated an increased responsiveness to 5-HT anorexia after vagotomy (VGX) in rats. We reexamined this issue by determining dose-response curves for 5HT-anorexia in male VGX rats under various testing conditions. Nondeprived VGX rats given a 30-min test meal of sweetened mash during the dark period displayed comparable percentage reductions in mash intake following 5-HT (22-4.0 μmol/kg, i.p.) when compared to laparotomized (LAP) controls. A separate group of food-deprived VGX/LAP rats was tested during the light period. 5-HT (2.0, 4.0, 8.0 μmol/kg, i.p.) produced anorexia in both groups; in contrast, CCK-8 (4.5 and 8.0 nmol/kg, i.p.) reduced food intake only in the LAP rats. In the same animals, 5-HT (4.0-16.0 μmol/kg, s.c.) decreased mash intake in both groups; once again, VGX did not enhance this action. Immunocytochemistry for α-neurofilament protein was used as a novel verification procedure for vagotomy. These results demonstrate that total VGX does not reliably produce supersensitivity to the anorectic action of peripheral 5-HT. Together with similar evidence using liquid diets (Simansky, in preparation), our data establish that 5-HT reduces food intake via an extravagal mechanism. Moreover, these data suggest that separate peripheral neural substrates mediate anorexia after 5-HT and CCK-8. Supported by MH 41987 (KJS).

SEROTONIN PARTICIPATES IN SUPPRESSION OF FOOD INTAKE BY EXOGENOUS CCK BUT NOT BOMBESIN. R.C. Ritter, L.A. Brenner and A. Zetino*. Dept. of VCAPP, Washington State University, Pullman, WA 99164-6520.
Stallone et al. (1987) observed that suppression of food intake by

Stallone et al. (1987) observed that suppression of food intake by CCK is attenuated by metergoline, a relatively nonselective serotonin (SHT) receptor antagonist, suggesting that 5HT-sensitive neurons participate in CCK satiety. To further assess the involvement of 5HT in suppression of food intake by CCK, we examined the effect of several 5HT receptor antagonists on suppression of real feeding by exogenous CCK or bombesin. We also assessed the effects of 5HT antagonists on CCK-induced suppression of sham feeding. Four 5HT receptor antagonists exhibiting some selectivity for 5HT 1, 2 or 3 receptors were examined: metergoline, mianserin, ketanserin and MDL72222. Both metergoline and mianserin attenuate suppression of real feeding and sham feeding by intraperitoneal (IP) CCK. Neither drug affected suppression of real feeding by IP bombesin. Neither ketanserin nor MDL72222 altered suppression of feeding by CCK or bombesin. Metergoline alone increased intake during real feeding and produced an even greater increase during sham feeding. No increases in intake were observed with the other receptor antagonists by themselves. Our results suggest that 5HT₁ receptors participate in suppression of food intake by CCK but not bombesin. While the effect of mianserin appears somewhat selective for attenuation of CCK's effects on feeding, metergoline directly stimulated feeding, especially in the absence of GI feedback signals. Therefore, the actions of mianserin and metergoline may represent interference with more than one neural system. Supported by NIH grant NS20561.

BRAIN D-2 RECEPTOR BLOCKADE REDUCES SUCROSE REWARD. L.H. Schneider, J.D. Davis, E. Rauhofer*, J. Gibbs and G.P. Smith. Dept. Psychiatry, NY Hospital-Cornell Medical Center, White Plains, NY 10605 and Dept. Psychology, University of Illinois, Chicago, IL 60680

Psychology, University of Illinois, Chicago, IL 60680

PURPOSE: To determine and compare the efficacy of the selective D-2 receptor antagonist sultopride administered centrally (icv) or peripherally (ip) to inhibit sucrose sham feeding in the rat.

METHODS: 8 male S-D rats were prepared with chronic gastric and lateral ventricular cannulas. They sham fed a 20% sucrose solution for 30-min tests after 4.75h pellet deprivation and pretreatment at -1h with vehicle-only (saline; 10 ul icv and 0.8 ml ip) or with sultopride (gift of SESIIF, France).

RESULTS: Data are Mean (SE) ml/30 min sham intake of 20% sucrose.

		Later	ai ventr	<u>icie</u>			
Dose	0	0.1	0.15	0.2	0.4		
	29.4	26.5	20.0*	12.7*	11.8*		
	(1.3)	(2.3)	(2.9)	(3.1)	(2.8)		
		Intra	peritone	al			
Dose	0_	_				4.0	10.0
	28.9					29.6	3.0*
	(1.3)					(2.8)	(1.3)
						. ` 'a .	• •

Dose is mg sultopride/rat. *significant inhibition from vehicle icv and ip.

CONCLUSIONS: Since sultopride is about 30 times more potent when infused centrally than injected peripherally, central D-2 receptors are critical to the orosensory positive reinforcing effect of sucrose on sham feeding. [Supported by NIH (NINDS) R29 NS24781 (LHS); NIMH RSA MH00149 (GPS).]

TRANSIENT DECLINES IN BLOOD GLUCOSE PRECEDE MEAL INITIATION IN EXPERIMENTALLY INDUCED DIABETES IN RATS. F.J. Smith, L.A. Campfield and D. Howell*. Neurobiology and Obesity Research, Hoffmann-La Roche Inc. Nutley, NJ 07110

The objective of this study was to determine if transient declines in blood glucose (BG) similar to those previously observed prior to meal initiation in lean and obese rats preceded feeding in experimentally diabetic rats. Female Wistar rats were chronically implanted with cardiac cannulas. Following recovery from surgery, a single subcutaneous injection of streptozotocin (40 mg/kg BW) was administered to induce hyperglycemia. Two to seven days following streptozotocin induced diabetes, continuous monitoring of BG was performed at the light/dark transition of the 12/12 light cycle. All meals (n=8) were preceded by a fall in BG of -9.7 + 1.9% below baseline at 17.4 + 3.2 min. The total duration of the transient decline in BG was 34 + 5 min and the meal occurred at 19 ± 4 min following the beginning of the decline. The parameters of these transient declines were similar to those previously reported for non-diabetic rats. Mean baseline BG was 294 ± 17 and the nadir was 265 ± 13 mg/dl. These data provide additional support for the relationship between transient declines in blood glucose and meal initiation and further emphasize the role of relative changes in systemic blood glucose rather than absolute glucose concentrations These findings directly address one of major challenges to the glucostatic theory of Mayer (1955) and extend the pattern of blood glucose dynamics as a signal for meal initiation to the hyperglycemic, hyperpha-

NEURONS REQUIRED FOR LIPOPRIVIC FEEDING ARE NOT LIMITED TO A SINGLE VAGAL BRANCH. S. Ritter, B.W.

Hutton* and T.T. Dinh*. Department of VCAPP, Washington State
University, Pullman, WA 99164-6520.

Our previous work indicates that feeding responses stimulated by

decreased glucose and fatty acid utilization (glucoprivation and lipoprivation, respectively) rely on different and distinct neural pathways. Lesion of vagal sensory neurons with capsaicin and total subdiaphragmatic vagotomy both abolish lipoprivic, but not glucoprivic, feeding. Thus, lipoprivic feeding requires intact vagal sensory neurons innervating the abdominal viscera. In the present work, we lesioned specific vagal branches in order to trace the pathway for lipoprivic feeding in more detail. After recovery from surgery, rats were adapted to a medium fat (40% of calories) diet for at least two weeks. Subsequently, glucoprivic and lipoprivic feeding were measured in 6 hr tests beginning immediately after drug injection. Fatty acid oxidation was blocked with mercaptoacetate (400 or 600 μmole/kg, i.p.) and glucose utilization with 2-deoxy-D-glucose (100 or 200 mg/kg, s.c.). None of the lesions blocked glucoprivic feeding. In contrast, lipoprivic feeding was abolished by transection of the gastric branches, but not transection of any other single vagal branch or total liver denervation. However, if all vagal branches were transected, leaving only the gastrics intact, the response was also impaired. Thus, sensory neurons required for lipoprivic feeding are not exclusively located in one vagal branch and may be distributed videly in the abdomen. Supported by grant PHS #DK 40498.

COMPARISON OF BRAINSTEM METABOLIC ACTIVITY ASSOCIATED WITH SHAM AND NORMAL FEEDING. C.B. Phifer. Scholars' College, Northwestern State Univ., Natchitoches, LA 71497.

Gastric distension is the only gastrointestinal stimulus for termination of ingestive behavior in very young rat pups. Thus the sham-feeding infant rat offers an excellent model for investigation of neural activity associated with the presence or absence of gastric distension. Chronic gastric fistulas were installed in six-day-old rat pups; pyloric nooses were also installed to prevent any leakage of stomach contents into the intestines. Pups were then allowed to ingest a milk diet with either open or closed fistulas during a 1 hr [14-C] 2-deoxyglucose incorporation period (30 uCi/100g, sc). Autoradiographic images corresponding to several levels in the brainstem were averaged for sham-feeding pups and pups feeding normally. Differences in activity between treatment groups were revealed by subtracting one average image from another.

Preliminary analyses of difference images revealed that sham-feeding animals had decreased metabolic activity relative to animals feeding normally in the nucleus tractus solitarius, particularly in medial regions at the level of area postrema. Further results will be discussed in relation to earlier findings on metabolic changes associated with gastric distension alone. (Supported by NICHD Grant HD-17457.)

INCREASING THE SATURATION OF A FATTY ACID INCREASES ITS SATIATING POTENCY IN RATS. D.R. Lewis, J.M. Philopena*, and D. Greenberg. New York Hospital-Cornell Medical Center, White Plains, NY 10605.

Polyunsaturated fatty acids are essential in mammalian nutrition. In order to evaluate whether the degree of saturation of a fatty acid is important in determining satiating potency, we tested the effects on feeding of duodenal infusions of monounsaturated oleic acid or diunsaturated linoleic acid in sham feeding rats.

Rats (n=14) were fitted with gastric cannulas and duodenal catheters. Rats were given equivolumetric duodenal infusions of several concentrations (total caloric loads from 0.625 kcal to 13 kcal) of either oleic or linoleic acid and of 0.15M NaCl vehicle. Linoleic acid was significantly more potent in reducing sham fed intakes for all concentrations tested. The percent inhibition from intake during vehicle infusion for representative concentrations are:

Concentration:

Oleic Acid Linoleic Acid 6.25 kcal 1.25 kcal

Percent Inhibition: 55 ± 6 88 ± 4 Since the potency for inhibition of intake is at least four times greater for linoleic than for oleic acid these results suggest that degree of saturation is a critical stimulus for fat-induced satiety. Supported by: The Weight Watchers Foundation, and NIH

CAROTID AND SYSTEMIC NUTRIENT INFUSIONS REDUCE FOOD INTAKE. E.K. Walls*, P.H. Reinhardt*, A.E. Willing* and H.S. Koopmans. Med. Physiology, Univ. of Calgary, Calgary, Canada T2N 4N1.

Both the glucostatic and aminostatic theories propose that food intake is regulated by cells in the brain that sense the levels of circulating nutrients and/or their intracellular utilization. To determine whether glucose and amino acid the brain that sense the levels of circulating nutrients and/or their intracellular utilization. To determine whether glucose and amino acid sensitive cells in the brain or in the periphery are more important in the control of food intake, two levels of dextrose (5 and 10 kcal/day) and 10 kcal/day of amino acids were each infused for 24 hr periods into rats with chronic catheters in the common carotid artery (C) or the superior vena cava (VC). Daily food intake was unchanged by 5 kcal dextrose. However, intake decreased from a 3 day baseline by 6.2 + 2.3 kcal for the C rats and by 6.4 + 1.3 kcal for the VC rats during the 10 kcal infusion (p < 0.01). Infusing 10 kcal of amino acids produced compensatory reductions in food intake of 12.1 + 3.0 kcal and 10.8 + 2.2 in the C and VC rats. The similar decreases in food intake for C and VC rats clearly show that nutrients fail to produce greater effects when infused directly into the brain. Instead, these findings suggest that the effect of infused nutrients on daily food intake is predominantly a function of nutrient-specific sensory receptor activation in the periphery.

EXPRESSION OF NERVE GROWTH FACTOR RECEPTOR (NGFrec) AND TYROSINE HYDROXYLASE (TH) mRNAs IN THE IMMATURE RAT OVARY. G.A. Dissen, G. Nilaver, D.F. Hill,* and S.R. Ojeda. OR Reg. Prim. Res. Ctr., Beaverton, OR 97006, and OR Hith. Sci. Univ., Portland, OR 97201.

It has recently been shown that NGF is produced in the ovary and that development of the sympathetic innervation of the gland is NGF-dependent. In development of the sympathetic inhervation of the gland is NGT-dependent. In the present study, NGFrec mRNA was detected in the immature ovary by RNA blot hybridization and the NGFrec protein was detected by ¹²⁵I-NGF cross-linking/immunoprecipitation/PAGE. NGFrec mRNA levels, readily detectable in juvenile rats, became maximally elevated on the day of first proestrus and declined markedly, after ovulation, suggesting that NGFrec synthesis is tightly coupled to the development of preovulatory follicles. No such fluctuations in NGFrec protein were observed, presumably because of active retrograde transport of the receptor by the ovarian nerves. Denervation of the gland reduced NGFrec protein levels during the first 6 days after the transection, but did not change NGFrec mRNA values. This suggests that the extrinsic nerves bear a significant fraction of the ovarian NGFrec and that receptor synthesis is not limited to the innervating neurons, but also occurs in ovarian cells. That some of these NGFrec bearing cells may be catecholamine-producing, is suggested by the hybridization of a rat TH cRNA to multiple ovarian TH mRNAlike transcripts and by the surprising finding that after denervation TH immuno-reactivity, normally present in nerve fibers, becomes expressed in granulosa cells of a subpopulation of small to medium size follicles. The results suggest that the immature ovary is influenced by a dual catecholaminergic control provided by the extrinsic sympathetic nerves and ovarian cells able to synthesize catecholamines. While the relative contribution of the latter remains to be established it is likely that the function of both is under NGF influence. (Supported by NIH Grants HD24870 and RR00163).

TROPHIC ACTIONS OF RECOMBINANT HUMAN NERVE GROWIH FACTOR ON CULTURED RAT EMBRYONIC CNS CELLS. L.E. Burtonl, B. Knuselz, F. Heftiz, F.M. Longoz, W.C. Mobleyz, V.E. Knuselz, F. Heftiz, F.M. Longoz, W.C. Mobleyz, V.E. Koliatsos, and D.L. Pricet. "Genentech, Inc., S. San Francisco, CA 94080; Zandrus Gerontology Cent., USC Los Angeles, Los Angeles, CA 90089; Dept. Neurology, UCSF, San Francisco, CA 94100; Dept. Pathology, Johns Hopkins Univ., Baltimore, MD 21205.

Baltimore, MD 21205.

Recombinant human nerve growth factor (rhNGF) (>95% pure by SDS-PAGE) was tested for actions on fetal rat brain neurons in culture including, in particular, the cholinergic neurons of the basal forebrain. rhNGF was more potent in increasing choline acetyltransferase (ChAT) activity in septal cultures than NGF purified from mouse salivary glands (mNGF). ED50s were 4.9 pM for rhNGF and 13.8 pM for mNGF. The maximal ChAT activity response was achieved at approx. 35 pM with both NGFs and their efficacies were not significantly different. The two NGFs were not additive in approx. 35 pM with both NGFs and their efficacies were not significantly different. The two NGFs were not additive in effect. Identical to the results with mNGF, rhNGF strongly enhanced the intensity of ChAT immunostaining in septal cultures. Neither rhNGF nor mNGF affected the appearance of the cultures under phase contrast illumination. Survival of cells at very low plating density on polyomithine/ laminin coated culture dishes were not affected by either factor. Protein content and the uptake of GABA were also unaffected. At concentrations of up to 10 ug/ml, rhNGF did not significantly increase uptake of dopamine into cultures of ventral mesencephalon. We conclude that rhNGF produces potent and selective actions on cholinergic neurons of the basal forebrain as previously shown for mNGF.

PREVENTION OF CHOLINERGIC NEURON DEGENERATION IN THE RAT AND PRIMATE BRAIN WITH RECOMBINANT HUMAN NERVE GROWTH

FACTOR. M. H. Tuszynski¹, D. G. Amaral^{1,3}, H.-S. U*², J. Barnett*⁴, H. Chen*4, and F. H. Gage 1. Dept. Neurosciences 1 and Neurosurg. 2, Univ. California-San Diego, La Jolla, CA. 92093, Salk Inst. Biol. Stud.³, La Jolla, CA. 92037, Syntex Research⁴, Palo Alto, CA.

Previous studies have shown that infusions of the 2.5S form of mouse β-NGF

Previous studies have shown that infusions of the 2.5S form of mouse 8-NGF prevent the retrograde degeneration of both rat and primate adult basal forebrain cholinergic neurons after axotomy. In the current set of experiments, we assayed the ability of recombinant human NGF (rhNGF) to prevent retrograde cholinergic neuron degeneration in both rats and primates.

The coding sequence of human BNGF was inserted into a baculovirus expression vector and used to infect insect cells. In vitro, the cells secreted microgram quantities of BNGF which was biologically active on PC12 cells and SY5Y human neuroblastoma cells. Equivalent doses of rhNGF and mouse NGF (mNGF) were then tested in two in vivo models. Adult Sprague-Dawley rats underwent unilateral fimbria fornix transections and continuous infusions of either 1) artificial CSF (controls), 2) 50 ug/ml mNGF, 3) 100 ug/ml mNGF, 4) 50 ug/ml rhNGF, or 5) 100 ug/ml rhNGF. After 2 week survival periods, immunocytological markers for ChAT in the medial septum showed persistent ChAT labelling in 43±3% of control animals, 307±6% of low-dose and 101±3% of high-dose mNGF-treated animals, and 79±8% of 97±6% of low-dose and 101±3% of high-dose mNGF-treated animals, and 79±8% of low-dose and 93±5% of high dose rhNGF-treated animals.

Similarly, primates underwent unilateral formix lesions and continuous infusions of either artificial CSF (controls), 180 ug/ml mNGF, or 180 ug/ml rhNGF. Persistent medial septal ChAT labelling 4 weeks later was found in 45% of control animals, 80% of mNGF treated animals, and 86% of rhNGF treated animals. Thus, rhNGF is biologically active in vitro and in vivo, and prevents the retrograde degeneration of cholinergic neurons in both rats and primates

132.2

EFFECT OF DECORTICATION AND TROPHIC FACTOR TREATMENT ON THE ChAT IMMUNOREACTIVE FIBER NETWORK OF THE ADULT RAT CORTEX. L. Garofalo, A. Ribeiro-da-Silva and A.C. Cuello. Dept. Pharmacology & Therapeutics, McGill Univ., Montréal Qué., Canada H3G-1Y6.

Unilaterally decorticated rats treated with both NGF and the monosialoganglioside GMI show large increases, over control values, of cholinergic markers in the remaining cortex adjacent to the lesion site (Cuello at al., PNAS, 86:2056, 1989). In order to determine the nature of these biochemical increases we have measured using an image analysis system changes in cortical ChAT immunoreactive fibers and varicosities. Decorticated rats and GMI (1.5mg/day) via minipump for 7 days beginning immediately post-lesion. A decrease in the number of ChAT positive processes, detected at the light microscopic level, was observed thirty days post-lesion in the remaining cortex adjacent to the lesion site of vehicle treated rats. In contrast, cortical ChAT immunoreactive processes quantified from decorticated rats treated with both NGF and GMI were moderately increased over control values. At the ultrastructural level, quantification of ChAT immunolabelled varicosity area showed that those observed in trophic factor treated lesioned rats were significantly greater than those seen in control or vehicle treated decorticated animals. These results together with previous data suggest that NGF and GMI modulate neuroplasticity in the adult mammalian CNS and may favor functional cortical cholinergic recovery following injury. Supported by MRC (Canada) and the Canadian Center of Excellence Network for Neural Repair and Functional Recovery. L.G. receives a studentship from FRSQ (Québec).

132.4

RECOMBINANT HUMAN NERVE GROWTH FACTOR PREVENTS RETROGRADE DEGENERATION OF AXOTOMIZED BASAL FOREBRAIN CHOLINERGIC NEURONS. V.E. Koliatsos, M.D. Applegate, R.E. Clatterbuck, L.E. Burton, W.C. Mobley, F. Hefti and D.L. Price. Neuropathology Laboratory, The Johns Hopkins University School of Medicine, Baltimore, MD 21205.

University School of Medicine, Baltimore, MD 21205.

The present investigation tested in vivo the efficacy of a recombinant human nerve growth factor (rhNGF) assessed in vitro in an accompanying study. In rats and monkeys, axons of cholinergic neurons of the basal forebrain magnocellular complex were transected in the fimbria-fornix; animals survived for two weeks. One group received intraventricular mouse NGF (mNGF), a received intraventricular mouse war (mwar), a second group was given rhNGF, and a control group received vehicle. Animals in the latter group showed a significant reduction in the number and size of choline acetyltransfer medial septal nucleus ipsilateral to the lesion. Treatment with either mNGF or rhNGF completely prevented these abnormalities in size and transmitter phenotype of basal forebrain neurons. Our results indicate that intraspecies differences in NGF do not influence the responsiveness of neurons to this trophic factor and that a potent rhNGF is now available for use in other settings characterized by degeneration of basal forebrain cholinergic neurons.

132.6

RECEPTOR-MEDIATED TRANSPORT OF RECOMBINANT HUMAN NGF FROM OLFACTORY BULB TO FOREBRAIN CHOLINERGIC NUCLEI. C. A. Altar and C. Bakhit Developmental Biology, Genentech Inc. South San Francisco, CA 94080.

Receptors for nerve growth factor (NGF) are present in the olfactory bulb and the nuclei of its cholinergic afferents. The degeneration of the bulb and its cholinergic afferents in Alzheimer's disease warranted a study of the transport of biologically active [1251] labeled recombinant human NGF (rhNGF) following its injection into the olfactory bulb.

(rhNGF) following its injection into the olfactory bulb. [1251]rhNGF (103 nM; 330,000 cpm, 1.5 ul) was injected into the left olfactory bulb of 6 male Sprague-Dawley rats. Rats were glutaraldehyde-paraformaldehyde perfused 18 h later. Autoradiography revealed [1251] label in the ipsilateral horizontal and vertical limbs of the diagonal band (DB) and in no other brain region except within the injected olfactory bulb. The transport of label to the diagonal band was blocked by a coinjection with 17 uM of unlabeled rhNGF. Cerebellar injections of [1251]rhNGF (652,000 cpm, 2 ul), with or without 19.5 uM unlabeled rhNGF, did not label the diagonal band, nor the lateral vestibular or red nuclei, from which originate the primary cholinergic afferents to cerebellum.

vestibular or red nuclei, from which originate the primary cholinergic afferents to cerebellum.

The receptor-dependent transport of rhNGF from olfactory bulb to forebrain cholinergic nuclei and the ability of exogenous rhNGF to increase in vivo calbindin-28K content in the olfactory bulb (Iacopino et al, this meeting) suggests that the bulb and its innervation from the DB may be responsive to endogenous NGF or exogenously administered rhNGF.

REGULATION OF NGF EXPRESSION DURING DEVELOPMENT AND IN HIPPOCAMPAL CULTURES. W.J. Friedman and H. Persson, Lab. of Molecular Neurobiology, Karolinska Institute, Stockholm, Sweden

NGF is a well-characterized neurotrophic factor which is synthesized in the hippocampus and cortex and supports the function of basal forebrain cholinergic neurons. We have examined expression of NGF and NGF receptor mRNA during development using in situ hybridization. We have further studied regulation of NGF mRNA expression in vitro using a dissociated culture system of embryonic rat hippocampus.

We previously demonstrated that agents which mediate inflammatory responses, such as interleukin-1 (IL-1) and prostaglandin E₂ (PGE₂), enhance levels of NGF mRNA. Immunosuppressing agents such as dexamethasone suppress NGF expression. We have further examined the role of tumor necrosis factor (TNF α), which synergizes with IL-1 in many peripheral systems, on NGF regulation. TNF enhances NGF mRNA expression in the hippocampal cultures and may have a synergistic effect with IL-1.

cultures and may have a synergistic effect with IL-1.

Further work has investigated possible second messenger pathways involved in mediating the II-1 induction of NGF expression. Pretreatment of hippocampal cultures with phorbol ester to exhaust the protein kinase C pathway did not inhibit the ability of IL-1 to induce NGF mRNA, suggesting that either this pathway is not involved, or is not the only pathway necessary to regulate NGF expression. Studies are in progress to examine the possible involvement of cAMP and other second messenger pathways in regulation of NGF mRNA expression.

QUANTITATION OF NGF RECEPTOR mRNA REGULATION IN DISSOCIATED RAT BASAL FOREBRAIN CULTURES. R. C. Elliott. B. Lu. I. B. Black, and C. F. Dreyfus. Cornell U. Med. Coll., N.Y., NY, UMDNJ/Robt. Wood Johnson Med. Sch., Piscataway, NJ.

Although recent study is characterizing the regulation of nerve growth factor receptors (NGF-R), quantitative characterization of NGF-R mRNA in defined populations in rigoterization of NGF-R mRNA in defined populations in rigorously controlled culture systems remains unexplored. We have used a sensitive nuclease protection assay to monitor steady-state levels of NGF-R mRNA in dissociated cultures of embryonic day 17 rat basal forebrain (BF) in serum-free, fully defined medium to reduce support cell number. This approach allows precise quantitation of alteration in NGF-R mRNA levels in a well characterized system. In initial experiments we examined effects of NGF on expression of its own receptor mRNA. Cultures were maintained for 1, 4, or 7 days in the presence or absence of the factor. In control cultures. in the presence or absence of the factor. In control cultures, NGF-R message expression per total mRNA increased 2-fold over 7 days. Exogeneous NGF increased NGF-R message over controls as early as day 4, and elevated receptor mRNA 5-fold by day 7. These data suggest that NGF is capable of selectiveby day 7. These data suggest that NGF is capable of selective-ly elevating receptor message with respect to total cellular mRNA. Furthermore, the effects of NGF appear to be exerted locally, since the increases occurred in dissociates enriched for BF neurons. We are currently investigating mechanisms underlying NGF-R mRNA regulation by NGF, and character-izing potential regulatory effects of other growth and tro-phic factors. (Support: NINDS, NICHD, and McKnight Fdn.)

132.11

NGF REGULATION OF CHOLINE-ACETYLTRANSFERASE (ChAT) mRNA EXPRESSION IN RAT CNS. L. Cavicchioli, R. Dal Toso. M. Fusco, G. Vantini, T. Flanigan^{1*}, G. Dickson^{1*}, F. Walsh¹ and A. Leon. Fidia Research Laboratories, 35031 Abano Terme, Italy and ¹ Dept. Exp. Pathol., Guy's Hospital, London SE1 9RT, UK

Choline-acetyltransferase (ChAT) is a specific cholinergic marker and both enzymatic activity and immunoreactivity have been widely used to monitor the effects of NGF on CNS cholinergic neurons. However, almost no information is available on possible mechanisms of NGF-induced ChAT regulation at transcriptional, translational and post-translational levels. To this end, we have developed a PCR procedure allowing for detection and relative quantification of ChAT mRNA in descrete CNS areas (Carisabila) and a contractive contractions of the contractive contractions of the contraction of the c tive quantification of ChAT mRNA in descrete CNS areas (Cavicchioli et al., Neurosci, Abst., 29.9, 1989). Here we report that; i) detection of ChAT mRNA occurs only in CNS areas featuring cholinergic cell bodies; ii) the amount of ChAT mRNA in the septum is subject to ontogenic development reaching adult levels between postnatal day 14 and 25; iii) levels of ChAT mRNA are increased following i.c.v. NGF administration in the septum of both young and adult rats. These results indicate that NGF effects on ChAT activity are, at least in part associated with increased levels of ChAT mRNA. As such, this parameter is now being utilized in defining mechanisms underlying ganglioside GM_1 induced potentiation of NGF effects in vivo.

132.8

EFFECTS OF PERIPHERAL INJURY ON THE DISTRIBUTION OF NERVE GROWTH FACTOR RECEPTOR (NGFR) AND NGFR mRNA IN THE SPINAL CORD AND BRAIN. C.E. Hulsebosch, W.T. Stamps, T.E. Kruger, and B.A. Urschel. Dept. of Anat. and Neurosci, Marine Biomed, Inst., Univ. Texas Med. Br.,

Affait and Pediosci, Warnie Biolifed, fist, Offiv. Texas Wed. Br., Galveston, TX 77550.

NGFR has been postulated to be involved with neurite guidance and regeneration by providing a "pathway" of NGF which is associated with the low affinity, fast disassociating NGFR on Schwann cells. Since central projections of somatosensory fibers are known to sprout under certain conditions, it is of interest to determine if the distribution of NGFR and mRNA for NGFR correlate with the occurrence of sprouting. The present paradigm employs a forelimb amputation sprouting. The present paradigm employs a forelimb amputation paradigm in which minimal somatosensory sprouting occurs. Five neonates were anesthetized by hypothermia at birth, either right or left forelimbs were amputated and the animals sacrificed 7 days later. The NGFR distribution was determined using the monoclonal 192 and standard immunohistochemical techniques. In situ hybridization was used to determine the presence of the mRNA for NGF using a synthetic oligonucleotide probe corresponding to the membrane-spanning domain of the rat NGFR sequence as determined by Radeke, et. al. The NGFR distribution was particularly sparse in laminae II (inner zone) both ipsi- and contralateral to the amputation. The forelimb region of the motorcortex contralateral to the amputated side demonstrated heavy labeling of neuron like cells. We hypothesize that the presence of NGFR is involved with successful regeneration of somatosensory components of the spinal cord and in the absence of restoration, surviving neurons in the motor pathway upregulate NGFR mRNA.

132.10

MECHANISM OF NGF mRNA REGULATION BY INTERLEUKIN-1 AND BASIC FIBROBLAST GROWTH FACTOR IN RAT ASTROCYTES, X. VIGE and B.C. WISE. FGIN, Georgetown University, Washington, D.C. 20007.

Neonatal rat cortical astrocytes in primary culture synthesize and secrete nerve growth factor (NGF). Interleukin-1 (IL-1) and basic fibroblast growth factor (bFGF) treatment of astrocytes increased NGF mRNA content by about 2-fold. The concentrations of IL-1 and bFGF causing half-maximal stimulation were 4 and 31 pM, respectively. The increase in NGF mRNA elicited by IL-1 and bFGF was maximal at 3 hours of incubation. In the presence of IL-1, this increase persisted for 72 hrs, whereas in the presence of bFGF, the increase was of shorter duration, and after 24 hrs of incubation the NGF mRNA content was below control levels. The combined treatment of astrocytes with maximally effective doses of IL-1 and bFGF produced an additive increase in NGF mRNA content, which suggests that different mechanisms are operative. Astrocyte treatment with cycloheximide increased (about 4.5-fold) NGF mRNA content and this content failed to increase further by IL-1 or bFGF treatment. Experiments using actinomycin D indicated that IL-1 increased by 40% the half-life and reduced by 30% the rate of degradation of the NGF mRNA. bFGF treatment failed to change these parameters. Thus, in astrocytes, IL-1 increases NGF mRNA content, at least in part, by stabilizing mRNA, whereas bFGF does not affect mRNA stability, but may act at the level of NGF gene transcription.

DEVELOPMENTAL EXPRESSION OF NERVE GROWTH FACTOR (NGF) RECEPTOR mRNA IN THE RAT BASAL FOREBRAIN: INFLUENCE OF NGF ADMINISTRATION. W.C. Mobley, T. Barrall. B.J. Gwag, and J.E. Springer.

ADMINISTRATION. W.C. Mobley. T. Barrall.* B.J. Gwag. and J.E. Springer. Department of Neurology, University of California at San Francisco, San Francisco, CA 94143, and Dept. of Neurology, Center for Neurological Research, Hahnemann University, Philadelphia, PA 19102-1192.

The distribution and actions of nerve growth factor (NGF) in the central nervous system (CNS) support is role as a neurotrophic molecule for developing and adult basal forebrain cholinergic neurons. CNS infusions of NGF during development will increase the activity of choliner acetyltransferase, an enzyme responsible for acetylcholine production. Cholinergic axotomy in adult animals will result in neuronal loss and/or dysfunction, which can be ameliorated with exogenous NGF application. While the mechanism(s) of action of this neurotrophic molecule is unclear, recent studies indicate that NGF may regulate the expression of NGF receptors (NGFR). Following release from target structures (i.e. hippocampus and neocortex) NGF binds to specific receptors located on cholinergic neurons and is transported to the cell body. We used in situ hybridization histochemistry to analyze the developmental expression of NGFR mRNA located on cholinergic neurons and is transported to the cell body. We used in situ hybridization histochemistry to analyze the developmental expression of NGFR mRNA in the basal forebrain at postnatal days (PD) 1, 4, 8, 11, 21, and adult. In addition, NGFR mRNA expression was determined in PD4 and PD8 animals following intraventricular infusions of NGF. Radiolabeled sense or antisense NGFR mRNA probes were transcribed from a 3.4kb cDNA and hybridized to 16 µm thick brain sections. Basal forebrain cells expressing NGFR mRNA were first detected at PD4 with a striking increase in mRNA levels per cell observed at PD8 and PD11. In addition, NGFR mRNA levels at these two developmental time periods were greater than levels detected in adult animals. Animals infused with NGF at PD3 and analyzed at PD4 showed a dramatic increase in NGFR mRNA expression. In addition, a similar increase in NGFR mRNA was observed in animals infused every other day starting at PD3 and analyzed at PD8. We suggest that basal forebrain cholinergic neurons are sensitive to the presence of NGF throughout development and into adult. In addition, a similar increase in NGFR on the support of the presence of NGFR mRNA expression in addition, in addition, a similar increase in NGFR on the support of the presence of NGFR mRNA and thus the cells ability to respond to NGF at very early developmental periods. Supported by NIH grant AG-08969.

EVIDENCE FOR GLYCINE-LIKE IMMUNOREACTIVE INPUT ONTO RETROGRADELY LABELED SYMPATHETIC PREGANGLIONIC NEURONS IN THE RAT AND PIGEON. J. Cabot, A. Bushnell and V. Alessi, Dept. of Neurobiology & Behavior, SUNY at Stony Brook, Stony Brook, NY 11794.

Iontophoresis data collected in vivo and in vitro in the cat and rat thoracic spinal cord suggest that glycine may be an inhibitory neurotransmitter released from synapses directly contacting sympathetic preganglionic neurons (SPN's). This study provides light and electron microscopial evidence showing the presence of glycine-like immunoreactive(GLY-IR) processes within the SPN neuropil.

Male rats and pigeons were sacrificed 72 hrs after HRP injections into the superior cervical ganglion or paravertebral ganglion 14, respectively. Following intracardial perfusion, thoracic spinal cord was vibratome sectioned in the longitudinal plane and DAB reacted for HRP. For light microscopy, postembedding protocols using ABC immunohistochemistry were followed. For electron microscopy, preembedding immunohistochemical procedures were used.

Light microscopically, GLY-IR processes and punctate swellings are found in all the SPN subnuclei within rat thoracic spinal cord. Some GLY-IR profiles closely appose HRP-labeled SPN somata and proximal dendrites. GLY-IR cell bodies are observed among intermediolateral cell column (IML) neurons, within medial lamina V and throughout lamina VII. In the pigeon, the SPN neuropil contains a dense network of GLY-IR processes. GLY-IR profiles closely appose and appear to encircle HRP-labeled SPN's in both subnuclei. GLY-IR interneurons are found in the principal SPN cell column and throughout lamina VII.

To date, the ultrastructure of GLY-IR processes has only been examined within the rat IML. GLY-IR terminals have been observed making contact with HRP-labeled SPN somas and proximal dendrites. They form symmetrical contacts and contain spherical vesicles. GLY-IR dendrites and axons are also present in the IML. (Supported by HL24103; JBC is an Established Investigator of AHA.)

RELATIONSHIPS BETWEEN ACTIVITY IN POSTGANGLIONIC SYMPATHETIC NERVE PAIRS IN UNANESTHETIZED DECEREBRATE (UD) CATS. S. M. Barman and G. L. Gebber. Dept. of Pharmacol., Michigan State Univ., E. Lansing, MI 48824.

The coherence function and phase spectrum were used to evaluate the relationships between inferior cardiac nerve (ICN) and renal nerve (RN) activity in eight UD and baroreceptor-denervated cats. Midbrain transection at stero-taxic plane A3 was completed under short-lasting ketamine hydrochloride (20 mg/kg, im) anesthesia. Decerebration was indicated by rigidity in all four limbs and the failure to alter the EEG in response to pinching. Analyses were made between 4 and 8 hr after decerebration. Mean arterial pressure was 126±10 mm Hg. As was the case in barbiturate-or chloralose-anesthetized cats, most of the activity in these sympathetic nerves in UD cats was between 2 and 6 Hz. However, there were important differences among these three groups of animals. First, the peak coherence value (0.48±0.07) relating ICN and RN activity in the 2- to 6-Hz band was significantly lower in UD cats than in barbiturate-(0.63±0.02; n=24) or chloralose-anesthetized (0.74±0.03; n=16) cats. Second, the coherence values and phase differences were considerably more labile in UD cats than in anesthetized cats. In some UD cats the coherence of ICN and RN activity disappeared spontaneously without an apparent change in the general condition of the animal or the shape of the autospectra of nerve activity. Third, mild hypercapnia (5% end-tidal CO2) often was accompanied by a loss of coherence in the 2- to 6-Hz band in UD but not anesthetized cats. Fourth, bimodal autospectra and coherence functions were seen only in UD cats (3 of 8 experiments). ICN and RN activity cohered between 2-6 Hz and 7-11 Hz in these experiments. We conclude that coupling between the components of the central system responsible for the 2- to 6-Hz rhythm in sympathetic nerve activity is weaker and more sensitive to change in UD than in anesthetized cats. (Supported by HL-13187 and HL-33266).

CHEMICAL LESION OF ROSTRAL VENTROLATERAL (RVLM) OR VENTROMEDIAL (RVMM) MEDULLA PREVENTS NEUROGENIC HYPERTENSION.

K.J. Varner, E.C. Vasquez and M.J. Brody. Dept. of Pharmacology & Cardiovascular Ctr., Univ. of Iowa, Iowa City, IA 52242.

Integrity of neurons in RVLM and/or RVMM is required

Integrity of neurons in RVLM and/or RVMM is required for the maintenance of arterial pressure, sympathetic activity and baroreceptor and cardiopulmonary reflex function in anesthetized rats. The purpose of this study was to determine whether chemical destruction of neurons in RVLM or RVMM prevents the increases in mean arterial pressure (MAP) and heart rate (HR) produced by sinoaortic deafferentation (SAD). Male Sprague-Dawley rats were anesthetized with pentobarbital and mechanically ventilated. RVLM or RVMM was lesioned bilaterally by microinjecting N-methyl-D-aspartic acid (NMDA) (200 nl, 30 nMoles) through one barrel of a 3 barrel pipette. Block of pressor responses to NMDA (20-40 ng, 50-100 nl) confirmed the effectiveness of the lesion. SAD significantly increased MAP and HR in sham lesion rats. Lesion of RVLM or RVMM prevented the increases in MAP or HR following SAD. Resting MAP and HR were not significantly reduced by either lesion but MAP was lowered by ganglionic blockade. From these studies we conclude that cells in both RVLM and RVMM are involved in the hypertensive unrelated to maintenance of arterial pressure.

RELATIONSHIPS BETWEEN ACTIVITY OF PREGANGLIONIC SYMPATHETIC NERVES: PHASE AND COHERENCE. B. Kocsis, S.M. Barman and G.L. Gebber. Dept. of Pharmacol., Michigan State Univ., E. Lansing, MI 48824. We (Kocsis *et al.*, Soc. Neurosci. Abstr., Vol. 15, Part 1, p. 335, 1989)

We (Kocsis et al., Soc. Neurosci. Abstr., Vol. 15, Part 1, p. 335, 1989) previously described the frequency-domain relationships between the activity of different cat postganglionic sympathetic nerves. Coherence analysis revealed that the discharges of the inferior cardiac and renal nerves are correlated between 0.2 and 12 Hz. Phase spectral analysis showed that the interval between activity in these nerves is either constant between 0.2 and 12 Hz or frequency-dependent. The current study was designed to test whether the constant and frequency-dependent interval patterns represent different states of the <u>central</u> system responsible for basal sympathetic nerve activity. For this purpose, we studied the relationships between the discharges of preganglionic rather than postganglionic nerves. Recordings were made from the second thoracic preganglionic white ramus (T2WR) and splanchnic preganglionic nerve (Spl.N.) in baroreceptor-denervated cats anesthetized with chloralose. We found that 1) the peak coherence value and coherent frequency band relating T2WR and Spl.N. discharges were 0.77±0.05 and 0.2 to 12 Hz, respectively, 2) the interval between T2WR and Spl.N. discharges was either constant or frequency-dependent under normocapnic conditions and 3) the constant interval pattern was switched to the frequency-dependent pattern when end-tidal CO₂ was raised to hypercapnic levels. These results parallel those obtained in our earlier experiments with postganglionic nerve recordings. We conclude that the constant and frequency-dependent interval patterns of relationship between the discharges of different sympathetic nerves arise in the central nervous system. (Supported by NIH grants HL13187 and HL33266.)

MECHANISMS ACCOUNTING FOR RAPID RHYTHMS IN SYMPATHETIC NERVE DISCHARGE (SND). <u>G.L. Gebber, S.M. Barman and B. Kocsis.</u> Dept. of Pharmacol., Michigan State Univ., E. Lansing, MI 48824.

The cardiac-related rhythm recorded from sympathetic nerves in baroreceptor-innervated cats and its free-running 2- to 6-Hz counterpart in baroreceptordenervated cats might reflect 1) the oscillatory activity of a population of single central neurons or 2) the output of a central network of neurons whose discharges are probabilistically rather than strictly related to the phases of the population rhythm. These models were tested by studying the frequency- and time-domain relationships between the discharges of single medullary neurons and inferior cardiac postganglionic SND in diallylbarbiturate-urethane anesthetized cats. Our findings are as follows. First, although statistically significant, the coherence values relating SND to the activity of neurons in the medullary lateral tegmental field, rostral ventrolateral medulla and raphe were closer to zero than to unity. Second, whereas most of the power in the autospectra of SND was contained between 2 and 6 Hz, that in the autospectra of medullary unit activity was more evenly distributed over a much wider frequency band. Third, the interspike intervals of medullary unit activity were much more variable than the intervals between the cardiac-related bursts of SND in baroreceptorinnervated cats. Thus, the rapid rhythms in SND are not strongly reflected in the spike trains of individual medullary neurons believed to comprise the network responsible for the population rhythms. Rather, it appears that the rapid sympathetic nerve rhythms are emergent properties of a network composed of "non-oscillatory" brain stem neurons. Our data further indicate that each cycle of the population rhythm is generated by a different subset of the network. Regarding this point, individual medullary neurons with sympathetic nerve-related activity did not fire in every cycle of SND. (Supported by NIH grants HL13187

THE NON-NMDA SUBTYPE OF EXCITATORY AMINO ACID RECEPTOR PLAYS THE MAJOR ROLE IN CONTROL OF CARDIOVASCULAR FUNCTION BY THE SUBRETROFACIAL NUCLEUS IN CATS. T.P. Abrahams and R.A. Gillis*, Dep. of Pharmacology Geography University Washington D.C. 20007.

Pharmacology, Georgetown University, Washington, D.C. 20007.

Recent studies (Am. J. Phsiol. 256:R722, 1989) have reported that microinjection of kynumenic acid (KYN; 12.5-25.0mmol), the non-selective Excitatory Amino Acid (EAA) antagonist, into the rostral ventrolateral medulla of the cat decreases arterial blood pressure (BP) and inferior cardiac sympathetic nerve discharge. The purpose of our study was to confirm this finding and determine the subtypes of EAA receptor(s) responsible for mediating this effect. This was done by microinjecting various EAA antagonists bilaterally into the subtretorfacial nucleus (SRFN) of chloralose anesthetized animals while monitoring BP and heart rate (HR). KYN (12.5nmol; N=5) produced a decrease in mean BP (-31±9mmHg, P<0.05) with no significant change in HR. To determine the subtype of EAA receptor responsible for eliciting tonic sympathetic outflow from the SRFN, specific antagonists of NMDA and non-NMDA EAA receptors were tested. The NMDA receptor antagonist 3-((RS)-Carboxypiperazin-4-yl-)-propyl-1-phosphonic acid (CPP; 2.25nmol; n=3) microinjected into the SRFN produced a small but significant decrease in BP (-13±1mmHg; p<0.05). This effect of CPP on BP was significantly lower than that seen with KYN. Two antagonists of the non-NMDA subtype of EAA receptor,6-Cyano-7-nitroquinoxaline-2,3-dione (CNQX; 2.25nmol; n=4) and g-D-Glutamylaminomethyl sulphonic acid (GAMS; 2.5nmol; n=4), were microinjected into the SRFN. Both of these drugs produced decreases in BP (-29±4 and -23±3mmHg, respectively; p<0.05) similar to that observed with KYN. No significant changes in HR were noted with CPP, CNQX or GAMS. These data indicate that a non-NMDA EAA receptor plays the major role in control of cardiovascular function by the SFRN. Supported by USPHS grant 1P01 NS28130.

INTERACTION BETWEEN AS AND BARORECEPTOR AFFERENT INPUTS IN THE NUCLEUS OF THE SOLITARY TRACT. M. B. Hug and J. Ciriello, Dept. of Physiology, Univ. of Western Ontario, London, Canada, N6A 5C1.

The A5 noradrenergic cell group has been shown to alter cardiovascular reflexes. In this study, to investigate if A5 neurons could alter these reflexes by influencing the activity of nucleus of the solitary tract (NTS) neurons. single unit extracellular recordings were made from NTS units during A5 stimulation in alpha-chloralose anesthetized rats. Of 139 spontaneously active NTS units tested, 25 were excited and 4 were inhibited during A5 stimulation. Nine of these 25 units were also excited orthodromically by stimulation of the aortic depressor nerve (ADN). When a conditioning stimulus was applied to the A5 region and the ADN was stimulated at several delay intervals ranging from 0 ms to 300 ms, the ADN response of 6 units was decreased at intervals of 0 to 80 ms. An additional 4 units in NTS were antidromically activated by A5 stimulation. These antidromic units also responded orthodromically with an excitation (n=2) or inhibition (n=2) to A5 stimulation and 2 were further excited by ADN stimulation. These data have demonstrated that A5 and ADN inputs converge on NTS neurons, that A5 inputs to NTS decrease the response of NTS neurons to ADN inputs and that A5 and NTS are reciprocally connected. These data suggest that A5 neurons alter cardiovascular reflexes by inhibiting the activity of NTS neurons to cardiovascular afferent input. (Supported by MRC of Canada).

IDENTIFICATION OF ENKEPHALIN-CONTAINING NEURONS IN THE CENTRAL NUCLEUS OF THE AMYGDALA PROJECTING DIRECTLY TO THE NUCLEUS AMBIGUUS. M.M. Caverson and E.T. Kiriakopoulos, Departments of Anatomy and Physiology, University of Western Ontario, London, Canada N6A 5C1.

The central nucleus of the amygdala (Ce) has been shown to influence the vagal outflow to the heart. However, relatively little is known about the neurochemical specificity of amygdala neurons innervating medullary regions containing preganglionic vagal cardiomotor neurons (VCN). Therefore, the present study was done to investigate the putative neurotransmitter content of amygdala neurons projecting directly to regions of the nucleus Ambiguus (AMB) shown to contain VCN. Iontophoretic injections of the retrograde tracer Fluorogold were made into the region of AMB in adult male Sprague-Dawley rats. After survival periods of up to 24 days, the animals were treated with colchicine, and subsequently perfused transcardially. Transverse sections of the forebrain and brain stem were cut and processed using a streptavidin immunofluorescence technique for the presence of enkephalin (ENK), CRH, CGRP, neurotensin or substance P in Fluorogold retrogradely labelled neurons. Injection sites were centred in AMB and included the compact, semicompact and ventral external formation of the nucleus at levels primarily rostral to obex. Within the amygdala, a dense cluster of Fluorogold retrogradely labelled neurons was observed throughout the rostro-caudal extent of the Ce, bilaterally. Of the substances examined only ENK was observed in a small number of Fluorogold retrogradely labelled neurons in the medial aspect of These data indicate that for the five neuroactive substances investigated in this study there exists a neurochemical specificity in amygdala neurons projecting directly to AMB. The role of these medullary projecting ENK-containing amygdala neurons in the vagal control of the heart has yet to be determined. (Supported by the Medical Research Council of Canada).

CHARACTERISTIC DYNAMICS OF CARDIAC R-R INTERVAL VARIATION IN OBSTRUCTIVE APNEA, NOCTURNAL MYOCLONUS, AND CONGESTIVE HEART FAILURE SYNDROMES DURING SLEEP. R.B. Trelease*. A. Garfinkel and R.M. Harper. Department of Anatomy & Cell Biology, Department of Kinesiology and the Brain Research Institute, UCLA School of Medicine, Los Angeles, CA 90024.

Variation in cardiac R-R intervals (RRIs) characteristically occurs in the fundamental respiratory frequency (respiratory sinus arrhythmia) and vasomotor oscillation frequency (1-3/minute) ranges, with sleep-waking states selectively enhancing or attenuating the expression of these components of variation. We previously reported that additional large oscillations in RRIs occur during sleep in human subjects in association with nocturnal myoclonus and hypoxemic sleep apneas. Conventional procedures for assessing cardiac interval variation such as spectral analysis and other linear statistics mask dynamic aspects of interval change because such procedures average characteristics over time. We employed interval "phase plane diagrams" that plot each RRI against the subsequent RRI for entire nights of sleep-waking data in 6 normal subjects, 6 patients with obstructive sleep apnea, and 6 patients with congestive heart failure. Such plots provide a type of nonlinear "autocorrelation" indicating the range of subsequent RRI for entire nights of sleep-waking data in 6 normal subjects, 6 patients with obstructive sleep apnea, and 6 patients with congestive heart failure. Such plots provide a type of nonlinear "autocorrelation" indicating the range of subsequent RRI for entire nights of sleep-waking data in 6 normal subjects of potents with points scattering less in the lower left quadrant and greater variability at long RRIs. Patients with sleep nanges syndromes showed naterers with few short RRIs and as RRI variation in each RRI. Formal subjects demonstrated RRI pions with points scattering less in the lower left quadrant and greater variability at long RRIs. Patients with sleep apnea syndrome showed patterns with few short RRIs and a larger range of long RRI variation relative to normals. Patients with congestive heart failure showed a reduced range of RRIs with an absence of variation in long RRIs. These results suggest that normal and pathophysiologic characteristics may be differentiated on the basis of the nonlinear dynamics of RRI variation desires accurate along exhibits. during nocturnal sleep studies.

FOREBRAIN PROJECTIONS OF THE VENTROLATERAL MEDULLA. S.Roder and J. Ciriello, Dept. of Physiology, Univ. of Western Ontario, London,

The present study was done to provide a detailed mapping of forebrain structures innervated by ascending fibers from catecholaminergic neurons in the ventrolateral medulla (VLM). Fibers and terminals in the forebrain of the rat from neurons in the caudal (c) VLM, the rostral (r) VLM and the intermediate (int) VLM, were identified using the anterograde tracer Phaseolus vulgaris leucoagglutinin (PHA-L) combined with either tyrosine hydroxylase (TH) or phenylethanolamine-N-methyltransferase (PNMT) immunohistochemistry. PHA-L labelled cells within the injection sites overlapped the catecholaminergic cell groups as indicated by PHA-L and TH double labelled cells. The heaviest projection of PHA-L labelling in the forebrain originated from the intVLM, followed by cVLM and then by rVLM. Labelling from intVLM was observed in medial (MS) and lateral (LS) septum, median preoptic nucleus (MnPO), bed nucleus of the stria terminalis (BST), lateral (LPO) and medial (MPO) preoptic area, paraventricular nucleus of the hypothalamus (PVH), supraoptic nucleus (SON), paraventricular thalamic nucleus (PVA), lateral hypothalamus (LH), substantia inominata (SI), zona incerta, central amygdaloid nucleus, arcuate nucleus (Arc), ventromedial (VMH) and dorsomedial (DM) hypothalamus, posterior hypothalamus and posterior thalamus. PHA-L labelling from a cVLM injection was observed in MnPO, LS, BST, PVH, SON and PVA, whereas PHA-L labelling from a rVLM injection was observed in MnPO, BST, MPO, LPO, LS, MS, PVH, SON, PVA, LH, Arc, DM, VMH and SI. These data demonstrate that the projections from VLM neurons have a wide distribution in the forebrain and may alter the activity of structures previously implicated in the control of the circulation. (Supported by MRC).

EVIDENCE FOR A NOVEL NEUROPHYSIN II HYPOTHALAMO-MEDULLARY PATHWAY. E.T. Kiriakopoulos, M.M. Caverson and J. Ciriello, Depts. of Anatomy and Physiology, Univ. of Western Ontario, London, Canada N6A

We have previously shown that neurons in paraventricular nucleus that project directly to regions of nucleus ambiguus (AMB) contain neurophysin II (NII) or oxytocin (OXY). This study was done in Sprague Dawley rats to identify the location of NII and OXY fiber pathways that innervate AMB. Frozen transverse sections of the brainstem were cut and adjacent sections were processed for either NII or OXY immunoreactivity using the streptavidin immunofluorescence technique. The distribution of NII or OXY immunoreactive fibers was mapped on projection drawings of the brainstem. NII fibers were consistently more dense than OXY, throughout the entire brainstem. The most notable difference in their distribution was observed in the dorsal medulla. A discrete collection of NII fibers was seen running caudally along the dorsal medullary surface. This pattern of labelling was not evident for OXY fibers. The dorsal bundle of NII fibers appeared to course through the ventrolateral aspects of the central grey and continue caudally to innervate the parabrachial nuclei, locus coereleus, vestibular nuclei, nucleus of the solitary tract (NTS) and spinal trigeminal nucleus. An additional pathway coursing along the ventral surface appeared to contribute to the innervation of the A5 region, AMB, ventral and medial reticular formation and raphé nuclei. OXY fiber labelling in the dorsal medulla was observed in the regions of NTS, dorsal motor nucleus of the vagus and AMB and appeared to originate from a pathway coursing along the ventral medullary surface. These results provide evidence for the existence of a specific NII-containing pathway innervating dorsal medullary structures. (Supported by the MRC).

SIMULTANEOUS EFFECTS OF MULTIPLE RECEPTOR POPULATIONS ON A COMMON SECOND MESSENGER SYSTEM, G.A. Paleos and J.J. Mann, Labs. of Neuropharmacology, University of Pittsburgh, Pittsburgh, PA. 15213

Labs. of Neuropharmacology, University of Pittsburgh, Pittsburgh, PA. 15213

The interaction of multiple receptor populations on a common second messenger system in neurons is a critical aspect of nervous system function and may be involved in human neuropsychiatric disorders. We therefore studied the interactions of the 5-HT₂, alpha₃-adrenergic and prostaglandin (PGI₂) receptors on phosphoinositide (PI) turnover in human platelets. Epinephrine (EPI) and serotonin stimulated PI hydrolysis in a dose-dependent manner. Yohimbine (20 μM) completely blocked the PI response to EPI indicating this effect was mediated by alpha₃-adrenergic receptors. The 5-HT₂ and 5-HT₁_C receptors are both coupled to PI turnover. Competition experiments indicated that in the platelet the response to serotonin was mediated by the 5-HT₂ receptor. A weak synergistic response was generated by the combination of 5-HT and EPI. EPI (0.1 mM) and serotonin (0.2 mM) increased PI turnover by 47 ± 8 (S.D.)% and 55 ± 8%, respectively, but these two agonists together elevated PI hydrolysis by 129 ± 9%. The maximal response to EPI (54 ± 2%) and 5-HT (66 ± 5%) was $129 \pm 9\%$. The maximal response to EPI (54 $\pm 2\%$) and 5-HT (66 $\pm 5\%$) was less than the maximal response to the combination. Prostacyclin at $1\mu g/ml$ tess than the maximal response to the combination. Prostacyclin at $|\mu|g/m|$ reduced PI turnover induced by 0.1 mM EPI or 0.2 mM 5-HT by 44 \pm 2% and 77 \pm 3% respectively. In contrast, prostacyclin reduced PI hydrolysis stimulated by a combination of EPI (0.1 mM) and 5-HT (0.2 mM) by only $16 \pm 13\%$. These studies indicate: 1) The pool of phospholipases appears to exceed the maximal capacity of the individual alpha,-adrenergic and 5-HT, receptor populations to activate this second messenger system. 2) Some potentiation occurs when two receptor populations are both activated. 3) Inhibition of PI turnover by prostacyclin can be partly reversed by activation of a combination of these receptor populations. Future studies should examine other neuron and cell systems to assess the generalizability of these findings. This work was partly supported by MH40695.

PET INVESTIGATIONS OF DOPAMINERGIC AND CHOLINERGIC INTERACTIONS IN THE PRIMATE BRAIN. S.L. Dewey, J.D. Brodie, J.S. Fowler, R.R. MacGregor, D.J. Schlyer, P.T. King, D.L. Alexoff, N.D. Volkow, C.-Y. Shiue, A.P. Wolf, and B. Bendriem. Dept. of Chemistry, Brookhaven National Lab, Upton, NY 11973. Dept. of Psychiatry, NYU Medical Center, NY NY 10016 NY 10016.

Central nervous system (CNS) function requires proper neurochemical balances between neurotransmitter systems. Neurotransmitter interactions provide the fundamental basis for homeostatic balance and for appropriate responses by the CNS to changes in the internal and external environment. Interactions between the dopaminergic D_2 and the muscarinic-cholinergic receptor systems in the primate brain (*Papio anubis*) were receptor systems in the primate brain (*Papio anubis*) were examined using positron emission tomography (PET) combined with [¹⁶F]-N-methylspiroperidol (NMSP). Pretreatment with benztropine (Cogentin), a long lasting anticholinergic drug, bilaterally reduced, by an average of 13.0 % (n=4), the incorporation of radioactivity in the corpus striatum but did not alter that observed in the cerebellum or the rate of metabolism of [¹⁶F]-NMSP in plasma. This reduction exceeded the normal variation (1.6 %) in tracer incorporation in repeated studies without any intervention in the same animals. This study. without any intervention in the same animals. This study demonstrates the usefulness of PET for investigating neurotransmitter interactions in vivo and provides insight into the consequences of multiple pharmacologic administration. Supported by USDOE, OHER and NS-15638 from NIH.

ANATOMIC EVIDENCE FOR GABA-ERGIC AFFERENTS TO THE RAT LOCUS COERULEUS IN THE DORSAL MEDIAL MEDULLA: A IMMUNOCYTOCHEMICAL, AND RETROGRADE TRANSPORT STUDY. Vincent A. Pieribone 1. Michael T. Shipley 2 Matthew Ennis 2 and Gary Aston-Jones 3, 1 Dept. Bio. New York Univ., NY, NY, 2 Dept. Anat. Cell Bio., Univ Cinn. Med. Col., Cinncinati., OH and 3Dept. Mental Health Sci., Hahnemann Univ.,

Recent physiologic studies have indicated that the rat locus coeruleus (LC) recieves a potent GABA-ergic input from the dorsal medulla (Ennis and Aston-Jones, 1989). Anatomic studies have shown that the medial suprafascicular nucleus prepositus hypoglossi (PrH) innervates the locus coeruleus. present study uses anatomic methods to investigate this pathway.

present study uses anatomic methods to investigate this pathway.

Immunocytochemistry for GABA or glutamic acid decarboxylase revealed that neurons of the LC recieve a very dense network of GABA-ergic terminal boutons (Shipley et. al. Neurosci. Abs. 1988). There were no GABA-ergic somata found within the LC, however colchicine pretreated was not used.

Only with colchicine pretreatment (75 µg i.c.v. or 5 µg within the medulla) were large numbers of GABA-ergic neurons found in the medulla. With such treatments, a collection of large (20-30µm) GABA-ergic neurons were found clustered beneath the IVth ventricle above the medial longitudinal fasciculus (mlf) and extending alongside the mlf ventrolaterally. These neurons extended rostrally from the hypoglossal nucleus to the level of the VIIth nucleus and were distinct in size (larger) and location (more medial) to GABA-ergic neurons found in the lateral PrH and nucleus of the solitary tract. Injections (150 nl) made into the LC of WGA-apoHRP/colloidal gold particles resulted in retrogradely labeled neurons in the suprafascicular PrH. When these sections were then processed for GABA immunocytochemistry numerous doubly labeled neurons were identified. Over 60 percent of LC afferent neurons in the dorsal medulla contain GABA immunoreactivity following colchicine pretreatment identifing this as a major inhibitory afferent to the LC. This work upported by PHS Grant NS24698.

(+) 3PPP SELECTIVELY DIFFERENTIATES EFFECTS OF SIGMA LIGANDS IN VIVO: EVIDENCE FOR SUBTYPES. S. Iyengar, S.J. Mick, V. Dilworth, P.C. Contreras, N. M. Gray, J.M. Farah, T.S. Rao and P. L. Wood. CNSDR, G. D. Searle, St. Louis, MO 63198. 3PPP SELECTIVELY DIFFERENTIATES EFFECTS OF

P. L. Wood. CNSDR, G. D. Searle, St. Louis, Mo 63198.

The effects of sigma ligands, (+) 3PPP, (-) butaclamol, (+) SKF 10,047 and (+) entazocine were evaluated in vivo on striatal dopamine (DA) turnover, ACTH and prolactin (PRL) release and cerebellar CGMP release. (+) SKF 10,047 and (+) pentazocine increased both PRL and DA turnover. (+) 3PPP and (-) butaclamol decreased PRL release and did not affect DA turnover. All 4 compounds increased ACTH release; however, only the increases caused by (+) SKF 10,047 and (+) pentazocine were reversed by pretreatment with CPP, a NMDA antagonist, while those caused by the other compounds were not. (+) 3PPP and (-) butaclamol potentiated NMDA receptor mediated CGMP increase while the benzomorphans did not.In addition to identifying a functional interaction of sigma receptors with DA receptors as well as NMDA receptors, these studies further divide the observed effects into two groups characterized by benzomorphan compounds and non-benzomorphan compounds suggesting the existence of sigma receptor subtypes in vivo. The effects of sigma ligands ifenprodil, BMY 14802, WY 47384 and SC 48960 will be discussed in light of these data.

RELATIONSHIP OF GABAERGIC TO CHOLINERGIC NEURONS WITHIN THE LATERODORSAL AND PEDUNCULOPONTINE TEGMENTAL NUCLEI. Montreal Neurological Institute, McGill University, Montreal, Quebec, Canada, H3A 2B4.

In assessing the potential contribution of noncholinergic neurons to the activity and role of neurons in the laterodorsal and pedunculopontine tegmental (LDT and PPT) nuclei, the identification, distribution and frequency of neurons synthesizing the inhibitory neurotransmitter GABA were studied. Immunohistochemical staining using the peroxidase-antiperoxidase (PAP) technique was utilized for choline acetyltransferase (ChAT) and glutamic acid decarboxylase (GAD) in the rat brain. ChAT and GAD were stained singly in adjacent sections or doubly in a sequential procedure in the same sections using as respective chromogens: diaminobenzidine (DAB, producing a homogenous brown staining) and benzidine dihydrochloride (BDHC, producing a granular blue staining). The two enzymes were found in separate and different cells. GAD-immunoreactive cells were smaller than ChAT-immunoreactive cells and were either more numerous (in the LDT) or equally as numerous (in the PPT) than the ChAT-immunoreactive neurons in these nuclei. These results suggest that GABAergic neurons in the LDT/PPT may modulate the activity of the intrinsic cholinergic neurons and/or contribute to the efferent projections to the rostral or caudal target structures of these nuclei, as is currently being

NEUROPEPTIDE Y (NPY) REVERSIBLY ABOLISHES ACTIONS OF GLUTAMATE IN NUCLEUS TRACTUS SOLITARII

L. Grundemar, C. Wahlestedt, R. Håkanson*, and D.J. Reis. Pharmacol., Univ. of Lund, Sweden and Div. of Neurobiol., Cornell Univ. Med. Coll. NY, NY 10021 USA.

NPY and its receptors are found in the nucleus tractus solitarii (NTS). Here baroreceptor afferents terminate to initiate reflex hypotension and bradycardia presumably by release of l-glutamate (GLU). We sought to determine whether NPY might modify the actions of GLU upon arterial pressure (AP) and heart rate (HR) in the NTS. Rats were anesthetized (achloralose and urethane), paralyzed and ventilated. NPY microinjected into NTS unilaterally elicited a dose-dependent fall in AP and HR (max at 90 pmol of -42.1 \pm 6.1 mmHg and HR -65 \pm 13.7 bpm; n=8). GLU (0.7 nmol) injected into NTS also evoked transient falls in AP and HR (- 64.6 ± 4.06 mmHg and -95.0 ± 24.0 beats per minute; n=8). Injection of NPY (90 pmol), but not vehicle or galanin, unilaterally into NTS reversibly abolished, for hours, the hypotensive actions of GLU; the contralateral NTS still responded normally to GLU. The effect was not anesthetic, however, since, unlike 2% lidocaine, NPY did not block the hypotension elicited by electrical stimulation at the injection site. NPY injected bilaterally in NTS inhibited, by over 70%, the baroreceptor HR response in response to phenylephrine (10 μg/kg i.v.; n=5). We conclude that in NTS, NPY reversibly inhibits the cardiovascular responses elicited by local application of GLU and inhibits baroreflex responses.

NEOSTRIATAL SUBSTANCE P AND SOMATOSTATIN NEURONS RECEIVE A DIRECT NIGRAL DOPAMINERGIC INPUT: AN ULTRASTRUCTURAL DOUBLE LABELING IMMUNOCYTOCHEMICAL STUDY. I. Mendez, K. Elisevich, C.C.G. Naus and B.A. Flumerfelt. Depts. of Anatomy and Clinical Neurological Sciences, University of Western Ontario, London, Canada, N6A 5C1.

Evidence for substance P (SP) and somatostatin (SS) containing neurons in the neostriatum has been provided by numerous studies. A dopaminergic input from the substantia nigra to the neostriatum is also well documented. However, a direct synaptic interaction between the dopaminergic input and the SP and/or SS containing cells has not yet been demonstrated. In this study, tyrosine hydroxylase (TH) and either SP or SS were simultaneously localized using the PAP method and two chromogens with distinct reaction products. TH-immunoreactive terminals were first demonstrated using 3,3' diaminobenzidine tetrahydrochloride (DAB), then SP or SS immunoreactivity was localized in neurons using benzidine dihydrochloride (BDHC). Ultrastructural examination revealed that TH-positive terminals made synaptic contacts on neostriatal SP and SS immunoreactive dendrites. The present study thus provides evidence of a direct dopaminergic synaptic input on neostriatal SP and SS neurons which suggests the anatomical basis for dopaminergic control of striatal SP and SS activity.

SEROTONIN INCREASES NEOSTRIATAL SUBSTANCE P AND PREPROTACHYKININ mRNA. P. D. Walker, L. A. Riley, R. P. Hart and M. Jonakait. Dept. of Biological Sciences, Rutgers University., Newark, NJ 07102.

The trans-synaptic regulation of substance P (SP) in the neostriatum (NS) has been of considerable interest since it was found that loss of activity in the dopaminergic nigrostriatal pathway decreases SP biosynthesis. Previous studies from our laboratory have shown that the depletion of serotonin (5-HT) similarly lowers striatal levels of the mRNA coding for preprotachykinin (PPT), the prohormone precursor of SP (Walker et al., Soc. Neurosci Abstr. <u>15</u>:581).

The present studies examined the effects of increasing 5-HT neurotransmission on levels of PPT mRNA and SP peptide in the NS. Adult rats received injections of saline or the 5-HT uptake inhibitor zimelidine (10 mg/kg i.p. twice daily for 5 days). Northern blot analysis of individual striata revealed that PPT mRNA levels were increased to 168+10% (p<0.0005) of control in the NS suggesting that raising extracellular 5-HT leads to increases in striatal SP biosynthesis. To begin to identify the receptor subtype mediating the action of serotonin, saline or the 5-HT₂ agonist DOI (7.5 mg/kg s.c. for 9 days) were infused via Alzet minipumps into adult rats. In DOI-treated rats (n=10), PPT mRNA levels in the NS were increased to $208\pm26\%$ (p<0.0005) of control. Similarly, SP peptide levels in the NS were increased to $128\pm5\%$ (p<0.0005, n=10) of control. These results taken together suggest that 5-HT, acting at a 5-HT2 receptor, helps to regulate SP biosynthesis in the NS. (Supported by MH43365 and AHA-NJ).

EFFECTS OF COCAINE ADMINISTRATION ON THE NEUROPEPTIDE CONTENT OF THE BASAL GANGLIA IN THE RODENT. E.L. Lynd, S.N. Haber. Department of Neurobiology and Anatomy, University of Rochester Medical Center, Rochester, NY 14624.

Anatomy, University of Rochester Medical Center, Rochester, NY 14624. Cocaine is a widely abused drug that acts by lowering reinforcement thresholds for brain stimulation reward. The cellular mechanism for cocaine's reinforcing properties is its ability to inhibit dopamine reuptake. The basal ganglia consists of several interconnected subcortical nuclei which are thought to subserve both motor and limbic function. Both the nucleus accumbens and the ventral pallidum, limbic related regions of the basal ganglia, have been implicated as sites for cocaine's actions. Studies have demonstrated that dopamine can regulate the expression of several neuropeptides in the basal ganglia. Most work on cocaine has focused on behavioral studies, and changes in dopamine and other transmitters detectable by assays. We examined the effects of repeated cocaine administration on enkephalin, substance P, and tyrosine hydroxylase staining. Furthermore we studied its effect on the regulation of these transmitters. transmitters.

Subcutaneous injections of cocaine (40mg/kg) were made in adult male Subcutaneous injections of cocaine (40mg/kg) were made in adult male rats once a day for four days. One hour after the last injection animals were sacrificed and perfused with paraformaldehyde. Immunocytochemistry revealed changes in staining patterns of transmitters. In situ hybridization techniques were performed using probes to enkephalin, substance P, and tyrosine hydroxylase to examine changes in regulation.

The results indicate that cocaine administration alters the relationship

between these neurotransmitter systems and their regulation

SEROTONIN UPTAKE INHIBITION DECREASES PREPROTACHYKININ mRNA AND SUBSTANCE P IN MEDULLARY RAPHE NEURONS. L.A. Riley, R.P. Hart

and G.M. Jonakait, Dept. of Biol. Sci., Rutgers Univ., Newark, NJ 07102.

Substance P (SP) is colocalized with serotonin (5-HT) in neurons of the medullary raphe, but its role and regulation there is not well understood. We have sought to determine whether changes in 5-HT levels affect the biosynthesis of colocalized SP. Recently we showed that depletion of 5-HT (by chronic inhibition of 5-HT biosynthesis) increased levels of the mRNA coding for the prohormone precursor of SP, preprotachykinin (PPT; Walker et al., Mol. Brain Res., in press)

In order to determine whether increases in 5-HT cause the opposite effect and whether changes in terminal SP also occur, rats were treated with the specific 5-HT uptake inhibitor zimelidine. Medullary raphe RNA prepared from individual animals was subjected to Northern blot hybridization using a [32P]-labeled probe for rat PPT mRNA (a gift from James Krause, Washington Univ., St. Louis, MO). Zimelidine treatment lowered PPT mRNA levels 35.4+5.3% $(p\!<\!0.001,n\!=\!20).$ The SP content of ventral thoracic spinal cord was determined by radioimmunoassay. Zimelidine treatment also slightly decreased the SP terminal content (16%, p<0.05, n=10). These results suggest that 5-HT uptake inhibition decreases SP biosynthesis in medullary raphe cells. Supported by MH43365.

DETERMINATION OF THE PROSPECTIVE FATE AND POTENCY OF CELLS OF THE EARLY AVIAN EPIBLAST. I.S. Alvarez and G.C. Schoenwolf. University of Utah School of Medicine, Salt Lake City, UT 84132.

We have been generating quail/chick transplantation chimeras and labeling localized regions of chick blastoderms with cell

markers to construct prospective fate maps of the early (H&H stages 3,4) avian epiblast. Additionally, we are testing the fates and behaviors of marked epiblast cells placed in atypical locations to ascertain their state of determination. The locations of three major cell populations have been delineated in the prenodal epiblast: prospective surface epithelial cells, prospective L (lateral) cells of the neural plate, and prospective MHP (median hinge point) cells of the neural plate. The fates of these three types of cells is not yet determined at stage 4. However, their characteristic rearrangement (migratory) behavior has already become established by the mid-primitive streak stage (stage 3c). For example, when prospective L cells are replaced with prospective MHP cells, the graft cells are able to form both L and MHP cells, as well as mesodermal cells, but they cannot intercalate with prospective L cells. Rather, they extend toward adjacent MHP cells and intercalate with them. This suggests that different populations of epiblast cells each contain unique surface properties psychiatoris of epibasis consists and indices a state of protein that allow them to recognize each other. Additional experiments are under way to define the nature of these properties. Supported by NIH grant no. NS 18112 and a Fulbright Fellowship no. FU89-8797464.

THE MICROENVIRONMENT OF THE ROSTRAL HALF-SOMITE ENHANCES GROWTH AND REGULATES SEGMENTATION OF SYMPATHETIC GANGLIA. C. Kalcheim and R.S. Goldstein. Dept. Anat. and Embryol.,
Hebrew Univ., Jerusalem 91010 ISRAEL.
Unilateral creation of a paraxial mesoderm with only
rostral somitic (RS) halves, leads to the development of

non-segmented dorsal root ganglia (DRG) that are larger and contain more cells than the sum of the contralateral, control DRG. Increased cell number is the result of a specific mitogenic effect on neural crest (NC) cells developing into DRG (Goldstein et al, Proc. Natl. Acad. Sci. USA, 1990, in press). We report here that grafts of RS halves also produce unsegmented sympathetic ganglia (SG) of 380 to 809% greater volume than the sum of the volumes of control SG in E6 and E10 quail-chick chimeras. Therefore, the RS mesoderm exerts a general mitogenic effect on NC cells developing into peripheral ganglia. In the same embryos, the increase in DRG volume on the operated side ranged between 28 and 74%, one-tenth the increase in SG volume. Moreover, on ElO, the average volume of the SG is 56% of that of the corresponding DRG on the grafted side, in contrast to only 16% on the control side. These data suggest that: 1) SG precursors may be more sensitive to the mitogenic effect of the RS than DRG precursors, and/or 2) the extended presence of sympathoblasts with mitotic potential is responsible for the 10-fold greater effect on the SG. Funded by the MDA, the Israel Acad. of Sci., and the Isr. Council for R & D.

A MARKER SYSTEM FOR THE DORSAL EMBRYONIC RETINA.

P. McCaffery*, H. Roth* and U.C. Dräger. Department of Neurobiology,
Harvard Medical School, Boston, MA 02115.

In a search for mechanisms underlying retinal polarity formation we generated monoclonal antibodies (mab's) that label strongly the dorsal part of the undifferentiated embryonic retina. These mab's recognize a 44kD protein (p44) that has been named the high-affinity laminin receptor; this term may not, however, describe its function. Immunohistochemically the mab's label a granular cytoplasmic antigen in dorsal retina. In cells grown in vitro the granules labeled by the mab's form a subpopulation of the granules labeled by an antiserum to ribosomes. In subcellular fractionations we find all of p44 associated with very large sedimentable complexes, from which it is quantitatively released by divalent cation chelators. We find no evidence for laminin binding to p44. The divalent-cation dependent binding to part of the ribosomal system is consistent with Brawerman's hypothesis that p44 constitutes an initiation factor.

Despite the pronounced dorso-ventral asymmetry seen immunohisto-chemically, a large range of biochemical tests show an even distribution of p44 throughout the embryonic retina. However, in situ digestions with trypsin reveal a higher susceptibility of p44 in dorsal than ventral retina, which points to a more accessible, open conformation of the protein in dorsal retina. As a possible candidate involved in this conformation difference we identified a 53kD protein whose distribution mimics the immunohisto-chemical labeling pattern by the p44 mab's: it is present only in the dorsal part of the undifferentiated embryonic retina. From these observations we conclude tentatively that the dorso-ventral difference in p44 does not consist in a difference in laminin binding, but possibly in a differential control of the protein translation system. REGULATION OF N-CADHERIN DURING NEURAL DEVELOPMENT: PHOSPHORYLATION, CYTOSKELETAL ASSOCIATION AND MRNA. Laura A. Lagunowich and Gerald B. Grunwald. Department of Anatomy, Thomas Jefferson University, Phila., PA 19107.

We have previously described expression of N-cadherin during retina and brain development including down-regulation of protein expression and posttranslational modifications such as sulfation and phosphorylation. The present studies, directed at elucidating regulatory mechanisms and their possible functional significance, demonstrate that N-cadherin phosphorylation and detergent extractibility change in a coordinated, tissue and age-specific fashion suggesting that cytoskeletal association of N-cadherin may be regulated in part by phosphorylation. During neural development, N-cadherin protein decreases while the degree of phosphorylation increases concomitantly with enhanced apparent cytoskeletal association. In the lens and heart all three parameters remain consistently high at all ages tested. Northern blotting studies indicate that the decrease in N-cadherin protein expression is mediated in part by a reduction in the N-cadherin mRNA level. Supported by NIH grants NRSA-EYO6067 to LAL and ROI-EYO6658 to GBG.

DOES THE MESODERM INDUCE HOX GENE EXPRESSION IN THE ZEBRAFISH NERVOUS SYSTEM? M. Westerfield. Inst. of Neurosci., Univ. of Oregon, Eugene OR 97403.

Axial polarity within the vertebrate embryo may be

Axial polarity within the vertebrate embryo may be determined by the spatially restricted expression of transcriptional regulators. Hox genes are expressed in specific regions of the embryonic nervous system and may serve this function. To learn how Hox gene expression is regulated, we injected 1-cell zebrafish embryos with DNA constructs containing the promoter regions of mammalian Hox 1.1 or Hox 3.3 genes fused to sequences coding for \$\textit{\textit{perpension}}\$ each to sequences coding for \$\textit{\textit{perpension}}\$ each to sequences coding for \$\textit{\textit{perpension}}\$ each to sequences coding for \$\textit{perpension}\$ expression stages in cells entering the posterior embryonic axis. Later, expressing cells were found in the spinal cord and somites of the trunk. Expression was missing in the trunk segments of spt-1 mutants that lack muscle. Instead, ectopic expression appeared in both the spinal cord and somites of the tail, the region where mutant mesodermal cells inappropriately migrate. These results suggest that early interactions between the mesoderm and the neurectoderm, which fail to occur in the trunk of spt-1 mutants, normally induce Hox gene expression in this region.

expression in this region.

THE EXPRESSION OF ASTROTACTIN, A NEURON-GLIA ADHESION LIGAND IN MOUSE CEREBELLUM, IS DEVELOPMENTALLY REGULATED T.N. Stitt, C.A. Mason, M. Berger, P. Joyce and M.E. Hatten, Center for Neurobiology and Behavior and Department of Pathology, College of Physicians and Surgeons, Columbia University, New York, NY 10032

In the developing brain, glial guidance provides a primary mechanism for the positioning of young neurons. We have previously described an immune activity, which we named astrotactin, which blocks neuron-glia binding, the formation of neuron-glia contacts, glial organization of neuronal positioning, and glial-guided neuronal migration of early postnatal mouse cerebellar cells in vitro. By imunoprecipitation and Western blot analysis, blocking antibodies, purified by absorption against adult brain membrane fractions, recognize a neuronal glycoprotein of apparent molecular weight 100Kd. By Western blot analysis, the level of expression of astrotactin varies with the developmental age of the cerebellum, with low levels of expression in the later embryonic period, high levels in the postnatal period and low levels in the adult.

cells, but not by astroglial cells in vitro. In addition, astrotactin is expressed by granule cells, but not by astroglial cells in vitro. In addition, astrotactin is expressed by neurons migrating along glial processes in vitro. Astrotactin is not expressed by PNS neurons, including PC12 or sympathetic neurons. In tissue sections of postnatal cerebellum, astrotactin is expressed by neurons migrating along Bergmann glia in the molecular layer and by granule neurons in the internal granule cell layer. Cells in the EGL are unstained as are axons of the white matter. A similar pattern is seen in the developing cortex. These experiments suggest that astrotactin is expressed in zones, and at developmental periods, where neuronal migration along glial fibers and glial-mediated neuronal assembly into cell layers is occurring. Supported by NS 15429 (MEH).

REGULATION OF N-CADHERIN DURING NEURAL DEVELOPMENT: A POSSIBLE ROLE FOR EXTRACELLULAR PROTEOLYSIS. Gerald B. Grunwald, Nancy E. Paradies and Eileen F. Roark*, Department of Anatomy and Developmental Biology/Teratology Training Program, Thomas Jefferson University, Phila.. PA 19107.

Anatomy and Developmental Biology/Teratology Training Program, Thomas Jefferson University, Phila., PA 19107.

During retinal development N-cadherin expression sharply decreases and a soluble fragment of N-cadherin is released from the cell surface. To relate these observations, we have used an in vitro retinal organ culture system to examine the role of extracellular proteases in regulating N-cadherin expression. The results indicate that 1) N-cadherin turnover is blocked by metalloprotease inhibitors; 2) retinal tissues secrete metalloproteases; 3) the rate of turnover of retinal N-cadherin increases during development; 4) the profile of secreted retinal proteases changes during development; 5) both the soluble fragment of N-cadherin and proteases observed to accumulate during in vitro retinal culture also accumulate in vivo in the vitreous humor. The identity of the secreted proteases and their possible role in directly mediating N-cadherin cleavage are presently being investigated. Supported by NIH grants T32-HD07326 and R01-EY06658 (GBG.)

ALTERNATE NEUROMUSCULAR TARGET SELECTION IN DROSOPHILA LARVAE TRANSFORMED BY HOMEOTIC MUTATIONS. S. Casit's H. Keshishian. Dept. of Biology, Yale Univ., New Haven, CT 06511.

The innervation of the bodywall musculature of *Drosophila* larvae is highly stereotyped, permitting the identification of individual muscle fibers as well as their specific synaptic contacts. In larvae carrying the homeotic mutation *abx pbx bx3/DI(3R)P2*, segment T3 of the CNS is transformed toward T2. In contrast, it is the abdominal segments that are transformed in the musculature. Thus, abdominal muscle fibers have a different segmental identity relative to their innervating motoneurons. We have examined this mismatch between CNS and periphery to determine whether motoneuronal ending anatomy is a feature conferred by the neuron or the target. The transformation also results in the loss of specific muscle fibers. We have examined the behavior of motor endings orphaned by the loss of these fibers. Where muscle fiber 12 in one third of the bodywalls, and at lower frequencies on the adjacent fibers 4, and 21-24. The overall architecture of nerve pathways, however, remains intact. Focal iontophoresis of glutamate shows that active receptors are present on both the native and supernumerary sites. These results show that *Drosophila* synaptic targets can tolerate inappropriate endings, that synapses can be made on membrane domains other than the normal sites, and that ectopic endings may be functional. Where the normal muscle fiber is missing, motoneurons select one of several alternate targets. We are investigating the extent to which ectopic ending morphology recapitulates the normal ending, and are attempting to phenocopy this result by laser ablations of embryonic muscle fibers.

ENHANCER TRAP MUTAGENESIS OF THE EMBRYONIC NEURO-MUSCULAR SYSTEM IN DROSOPHILA MELANOGASTER. E. Harkins, A. Fluet*, E. Farrell*, and H. Keshishian. Dept. of Biology, Yale Univ., New Haven, CT 06511.

The neuromuscular system of Drosophila embryos and larvae consists of a set of highly stereotyped bodywall muscles which receive morphologically characteristic motoneuronal inputs. We are currently conducting a search for embryonically expressed molecules which may play a role in establishing the observed neuromuscular stereotypy.

Enhancer trap mutagenesis is a means of single insert mutagenesis

that allows the screening of regulatory elements by temporally and spatially regulated expression of a marker gene, E. coli lacZ. From approximately 10,000 lines generated in collaboration with Allan Spradling at the Carnegie Institute of Washington, we are looking for staining patterns which reflect the expression of an endogenous gene that may be involved in the specificity of muscle pattern formation, paths taken by motoneuronal growth cones, target recognition, and/or synaptogenesis. In particular, we are looking for patterns with subsets of motoneurons, muscle fibers, muscle precursors, and combinations thereof. We have isolated lines which demonstrate such combinations thereof. We have isolated lines which demonstrate such intriguing patterns, with staining in CNS, muscle, or specific regions of the epidermis where muscle fiber insertion occurs. Selected lines will be used for molecular genetic and functional analyses. Mutant phenotypes, if not obtained by the initial insertion event, will be generated by inducing imprecise excision of the element. Supported by grants from NIH and the March of Dimes.

FURTHER CHARACTERIZATION AND CLONING OF A SURFACE ANTIGEN EXPRESSED IN A STRIPED PATTERN DURING SEGMENTATION AND LATER SPECIFIC TO THE NERVOUS SYSTEM IN GRASSHOPPER EMBRYOS. Rolf O. Karlstrom and Michael L. Bastiani. Dept. of Biology, University of Utah, Salt Lake City, UT 84112.

L Bastiani. Dept. of Biology, University of Utah, Salt Lake City, UT 84112.

Cell-cell interactions play a central role in insect development, guiding such processes as segmentation, cell differentiation, and axonal outgrowth. We are characterizing cell surface molecules which may be involved in intercellular interactions during embryogenesis. The IC10 MAb recognizes a surface antigen (Ag) specific to the nervous system in 40% grasshopper embryos. Before neurogenesis, just prior to segmentation, the Ag is expressed in a pattern of broad stripes consisting of approximately one third of the cells in a future segment. As segmentation proceeds, labelling becomes restricted to the neurogenic ectoderm, then is further

proceeds, labelling becomes restricted to the neurogenic ectoderm, then is further restricted to neuroblasts and their progeny, ganglion mother cells and neurons. Axons express the 1C10 antigen immediately upon axonogenesis. Limb neurons express the 1C10 Ag is expressed on the surfaces of most or all axons, neurons, and some neuroblasts at 40% of embryonic development. After 50% of development axonal expression becomes restricted to a dorsal longitudinal pathway.

A MAb affinity column was used to purify the 40 kD 1C10 antigen and a serum antibody (SAb) was generated against the purified protein. The SAb labels embryos in a pattern identical to that of the MAb and recognizes a 40 kD doublet on an immunoblot of embryonic membrane proteins. This SAb has been used to screen an expression library prepared from 40% embryonic grasshopper mRNA. Three clones have been independently identified which produce epitopes recognized by the SAb. At least one of these clones produces an epitope recognized by both the SAb and MAb. In situ hybridization is being used to determine whether one or all of these clones represents the 1C10 gene. Supported by NS25378, McKnight Foundation, and NSF graduate fellowship to R.K.

135,10

EXPRESSION AND CHARACTERIZATION OF NERVOUS SYSTEM ANTIGENS IN GRASSHOPPER EMBRYOS. Ellen M. Carpenter and Michael <u>I. Bastiani</u>, Dept. of Biology, University of Utah, Salt Lake City, UT 84112

J. Bastiani. Dept. of Biology, University of Utah, Salt Lake City, UT 84112

Using immune suppression, we have generated six monoclonal antibodies which recognize epitopes expressed in the central nervous system (CNS) of developing grasshopper embryos. Three of these antibodies were selected for further characterization based on their recognition of different elements of the developing CNS. The 10H11 antibody recognizes most neuronal cell bodies and axons in the CNS. Labeling using 10H11 is restricted to the CNS; no peripheral nervous system structures are labeled. 10H11 labeling appears early in development associated with the earliest identifiable neurons and antigen expression is maintained on most or all CNS axons and neuronal cell bodies during early embryonic development. The 10E6 antibody recognizes a small population of CNS neuronal cell bodies and a discrete subset of axons comprising one fascicle running through the longitudinal connective and three fascicles crossing the midline in the anterior and posterior commissures. 10E6 also labels peripheral sensory structures. The 1B5 antibody labels glial cells as evidenced by discontinuous labeling overlying the surfaces of the longitudinal connectives corresponding to the location of identified glial cells. 1B5 labeling also surrounds laterally positioned neuronal cell identified glial cells. 1B5 labeling also surrounds laterally positioned neuronal cell bodies, but does not appear to label the cell bodies themselves. All three antibodies recognize epitopes expressed on the surfaces of cells as the labeling patterns obtained after labeling live embryos closely match the patterns seen in fixed tissue.

Preliminary biochemical characterization of the antigens using periodate treatment to remove carbohydrates and chloroform-methanol extraction to remove glycolipids suggests that 1B5 may recognize a carbohydrate epitope expressed on a glycoprotein while 10E6 and 10H11 may recognize epitopes expressed on glycolipids. 10H11 labeling was particularly striking following chloroform-methanol extraction as labeling became restricted to a subset of axon fascicles and to localized regions of the axons in these

EMBRYONIC DEVELOPMENT OF THE LOBSTER HOMARUS AMERICANUS: MORPHOGENESIS AND SEROTONIN APPEARANCE.

AMERICANUS: MORPHOGENESIS AND SEROTONIN APPEARANCE.
S. M. Helluy and B. S. Beltz. Bio. Dept., Wellesley College, MA. C2181.

During the development of Homarus in the egg, three periods of organogenesis are distinguishable: that of the nauplitus, postnauplitus and first larval stage (L1). Behavioral and morphological landmarks have been examined and their times of appearance related to Perkins' eye index based on the size of the lateral eyes. This index has been transformed to a percentage scale of embryonic development.

Serotonin immunoreactivity (5-HT IR), studied as a marker of development express extractives to first even in the protogen house.

Serotonin immunoreactivity (5-HT IR), studied as a marker of developing nervous structures, is first seen in the protocerebrum at approximately 10% development (E10). By E20, 5-HT IR forms a "U"-shaped path from the medial edges of the optic lobes, along the protocerebral tracts, and in the protocerebral bridge. By E30, 5-HT IR is also clear in the central body, and in the circumesophageal and subesophageal ganglia. At that stage, the olfactory lobes emerge. The deutocerebral giant neurons show staming in their cell bodies and axons projecting to the olfactory lobes by E40. Presumptive sensilla are forming then, inverted in each of the uniramous antennulae, and the axons of the sensory neurons are seen at the base of the antennulae. By E50, all the prominent stained structures present in adults in the optic lobes, brain and nerve cord have appeared, except for the accessory lobes of the deutocerebrum which are labeled as soon as they begin to emerge at about E60. These lobes continue to develop during the organogenesis of the L1 and after hatching. Based upon the late development of the accessory lobes in Homarus, and upon neuroanatomical and ontogenetic evidence from different crustacean taxa, we are proposing that delayed hatching and slow maturation may be among the primary factors that enable the growth of a complex deutocerebrum in crustaceans. (Supported by BNS-8718938 complex deutocerebrum in crustaceans. (Supported by BNS-8718938 and 8958169, and NIH NS-25915)

DRUGS OF ABUSE: AMPHETAMINE AND COCAINE

136.1

HIGH-AFFINITY ACTIVE TRANSPORT OF [3H]-d-AMPHETAMINE INTO RAT STRIATAL SYNAPTOSOMES. R. Zaczek, S. Culp* and E.B. De Souza, NIDA

Addiction Research Center, Baltimore, MD 21224.

The incorporation of [⁹H]-d-amphetamine (³H-dAMPH) into rat brain synaptosomes was examined using physiological buffer at 37°C. Saturation curves of ³H-dAMPH incorporation into striatum revealed a high affinity site (K_i = 73 nM) which was ouabain-sensitive, suggesting the presence of active transport. 6-Hydroxydopamine lesion of the striatum caused approximately 50% reductions in both ³H-dAMPH and [³H]-dopamine approximately 30% feducions in John Transport, suggesting that 3H-dAMPH transport, suggesting that 3H-dAMPH transport occured into dopamine terminals. Furthermore, there was an absence of high-affinity 3H-dAMPH transport into brain areas such as cerebral cortex, which have a paucity of dopamine terminals. The high-affinity transport of ³H-dAMPH into striatum was inhibited by the monoamines: dopamine ($IC_{50} = 257 \text{ nM}$), norepinephrine (IC₅₀ = 437 nM) and serotonin (IC₅₀ = 7.9 μ M). The pharmacological profile of high-affinity ³H-dAMPH transport into striatum also showed sterospecificity: d-amphetamine (IC₅₀ = 60 nM) was an 8-fold more potent inhibitor than its I-isomer ($IC_{50} = 466$ nM). High-affinity transport of ³H-dAMPH was potently inhibited by putative dopamine uptake blockers such as methamphetamine (IC50 = 48 nM), methylphenidate (IC50 = 53 nM) and cocaine ($IC_{50} = 172$ nM). Other compounds such as diethylpropion (IC $_{50}$ = 4.2 μ M) and phendimetrazine (IC $_{50}$ = 4.9 μ M) were weak inhibitors. In summary, 3 H-dAMPH is actively transported into dopamine terminals and may lead to release of dopamine through a heteroexchange process. This process may be important in low-dose effects of amphetamines such as increased locomotor activity in rats and stimulant activity in man.

136.2

HETEROGENEITY OF THE METABOLIC RESPONSE OF THE VENTRAL STRIATUM TO PSYCHOSTIMULANT ADMINISTRATION AS ASSESSED BY THE 2[1°C]DEOXYGLUCOSE METHOD. L.J. Porrino and M.L. Garnett. Unit on Brain Imaging, NINDS, Bethesda, MD 20892.

Previous studies have shown that the acute intravenous administration of psychostimulants such as cocaine (COC) and methamphetamine (MA) increases local cerebral metabolic rates in the nucleus accumbens and olfactory tubercle, the major components of the ventral striatum (Porrino et al., 1988; Pontieri et al., 1990). We have conducted a more detailed analysis of the topographical distribution of the metabolic effects in these structures. Rates of glucose utilization (LCMR_{gl}) were measured at three anterior-posterior levels of the ventral striatum (AP+2.7, +1.7 and +1.0; Paxinos and Watson) following administration of COC (0, .5, 1, 5 mg/kg, iv) or MA (0, .05, .5, 2.5 mg/kg, iv). At moderate and high doses of COC, LCMR_{glc} was increased in the olfactory tubercle and nucleus accumbens at all levels. However, at low doses LCMR_{glc} was increased only in the most rostral portions of these ventral striatal structures. Low doses of MA produced similar selective increases in LCMR_{glc} in the rostral accumbens, but only at the highest dose level was metabolism altered in the olfactory tubercle. These data demonstrate that the ventral striatum is heterogenous in its metabolic response to psychostimulants with more rostral regions appearing uniquely sensitive to low doses of these drugs. In additions, they provide evidence that the olfactory tubercle and nucleus accumbens beta that the ventral striatum is heterogenous in its metabolic response to psychostimulants with more rostral regions appearing uniquely sensitive to low doses of these drugs. In additions, they provide evidence that the olfactory tubercle and nucleus accumbens are functionally distinct.

REGULATION OF ACETYLCHOLINE AND TAMINO BUTURIC ACID IN NUCLEUS ACCUMBENS BY AMPHETAMINE. N. Lindefors, Y. Hurd, S. Brenét, U. Ungerstedt and H. Persson. Department of Pharmacology and Department of Medical Chemistry, Karolinska Institute, Stockholm, Sweden. In situ hybridization and in vivo microdialysis were used to study the effect of amphetamine on expression of choline acetyl transferase (ChAT) and glu-

tamic acid decarboxylase (GAD) mRNA and in vivo release of acetylcholine (ACh) and γ-amino buturic acid (GABA), in rat medial nucleus accumbens The effect of repeated systemic amphetamine (1.5 mg/kg; twice daily for 7 days) was compared with the effect of saline injections and/or a single amphetamine injection. The level of ChAT mRNA was not affected by amphetamine while GAD mRNA was decreased (28%) by repeated injections. Extracellular ACh showed a two-fold increase after an acute amphetamine injection and a 60% increase after repeated injections. Extracellular GABA was decreased (45%), but only in rats receiving repeated amphetamine injections. Thus systemic amphetamine stimulate ACh release in medial nucleus accumbens without stimulating expression of ChAT mRNA. GABA release is attenuated by repeated amphetamine injections and a concomitant decrease in GAD mRNA expression is observed. ChAT is the key enzyme in ACh synthesis but probably not rate limiting in the formation of ACh, while changes in GAD activity are more closely correlated to changes in the formation of GABA. This may explain why an association is only seen between GABA release and GAD mRNA expression. Evidence are thus provided showing that amphetamine induce changes in neuronal function postsynaptic to limbic dopamine terminals, in medial nucleus accumbens. GABA release is decreased by a slow mechanism that is associated with decreased expression of GAD mRNA, while ACh release is increased by a fast mechanism not associated with any signs of change in ChAT mRNA levels.

136.5

NEUROTOXIC EFFECTS OF RING-SUBSTITUTED PHENYLETHYLAMINE

NEUROTOXIC EFFECTS OF RING-SUBSTITUTED PHENYLETHYLAMINE ANALOGS. M. S. Kleven. G. M. Farfel. W. L. Woolverton. and L. S. Seiden. Department of Pharmacological and Physiological Sciences, Drug Abuse Research Center, The University of Chicago, Chicago, IL 60637
Amphetamine, methylamphetamine and ring-substituted analogs including MDA (3,4-methylenedioxyamphetamine), MDMA (3,4-methylenedioxymethylamphetamine) and MMDA (3-methyoxy-4,5-methylenedioxy-amphetamine) cause long-lasting depletions of brain dopamine (DA) and/or serotonin (5-HT). To determine whether different ring substitutions of the amphetamine moiety affect neurotoxic activity, long-lasting neurochemical effects were examined in rats treated with a 4 day regimen of a variety of amphetamine analogues. Doses were approximately 0, 5, 10, and 20 times the ED50 for suppression of milk intake in rats allowed to drink sweetened condensed milk during 15 min sessions. Rats (n=6-8/group) were administered mescaline (0, 50, 100, or 200 mg/kg), 2,5-dimethoxy-4-methyl-amphetamine (DMA, 0, 50, 100, or 200 mg/kg), 2,5-dimethoxy-4-ethyl-amphetamine (DOMT, 0, 5, 10, or 20 mg/kg), 2,5-dimethoxy-4-ethyl-amphetamine (DOMT, 0, 5, 10, or 20 mg/kg), 2,5-methyl-amphetamine (MMDA-2; 0, 25, 50, 50 mg/kg) or 2-methoxy-4,5-methylenedioxyamphetamine (MMDA-2; 0, 25, 50, or 100 mg/kg) s.c. twice daily for 4 days and sacrificed 2 or 8 weeks after the last injection. Monoamines and metabolites were assayed in somatosensory cortex, striatum, hippocampus, or hypothalamus. Only the highest dose of PMA (50 mg/kg) significantly depleted striatal and hypothalamic 5-HT and 5-HIAA, an effect which was not observed 8 weeks after the 4 day regimen. None of the other drugs tested had long-lasting effects on DA or norepinephrine. The results suggest that hallucinogenic amphetamine analogs (mescaline, DOM, DMA, MMDA-2, and DOET) do not have neurotoxic activity, whereas drugs which also have amphetamine-leffects (e.g., MDA, MDMA, MMDA, and PMA) are potentially neurotoxic to 5-HT neurons. (Supported

EXPERIENTIAL AND INDIVIDUAL FACTORS IN THE ACQUISITION OF AMPHETAMINE SELF-ADMINISTRATION. G.Mittleman.J.M.Deminiere*.M.Le Moal.H.Simon.P.V. Piazza. I.N.S.E.R.M. U-259, Universite de Bordeaux II, 33077 Bordeaux,

When low drug doses are used, some, but not all, rats develop amphetamine self-administration (SA). Similarly, when food deprived and given intermittent presentations of small amounts of food, some, but not all, rats develop schedule-induced polydipsia (SIP). These individual differences are related to differences in the response to activating or arousing conditions as well as the response to amphetamine (AMPH). These experiments studied the behavior of animals tested in the self-administration and SIP paradigms in order to determine if the previously observed individual differences in behavior were consistent in both conditions. In Experiment I, 29 rats were allowed to acquire AMPH SA (10 ug d-amphetamine sulfate/20 ul saline/injection) AMPH SA (10 ug d-amphetamine sulfate/20 ul saline/injection) during 30 min sessions over 5 days. Rats that acquired SA were designated SA-pos and those that did not were designated as SA-neg. All animals were then given 10 daily SIP tests where a 45 mg food pellet was dispensed every minute of the 30 minute tests. The results indicated that SA-pos rats acquired SIP more rapidly than SA-neg animals. In Experiment II 16 animals were first tested for SIP. Rats that acquired drinking were designated as SIP-pos; those that failed to acquire drinking were classified as SIP-neg. All animals were then tested for AMPH SA using the same procedure as above. It was found that SIP-neg rats acquired SA more rapidly than SIP-pos rats.

PERSISTENT EFFECTS OF 3,4-METHYLENEDIOXYAMPHETAMINE (MDA) ON DOPAMINE AND SEROTONIN NEURONS IN REAGGREGATE TISSUE CULTURE. L.A. Won, P.C. Hoffmann and A. Heller. Dept. of Pharmacological and Physiological Sciences, The University of Chicago, Chicago, IL 60637.

MDA is a synthetic amphetamine analog which is neurotoxic to serotonin (5-HT)-containing, but not dopamine (DA)-containing neurons in adult animals (Ricaurte et al., Science 229, 986-988, 1985). We have examined the effect of MDA on <u>developing</u> murine DA and 5-HT neurons in reaggregate tissue cultures formed from dissociated cells of fetal mesencephalic tegmentum and corpus striatum. Both (+) and (-) isomers of MDA cause reductions in DA and 5-HT (Soc. Neurosci. Abstr. 15, 686, 1989). Moreover, reaggregates treated for 7 days with 10⁻⁴M MDA, showed cellular damage to both DA and 5-HT neurons. The present study examined whether DA and 5-HT neurons would recover from MDA treatment in neurotransmitter levels and cellular morphology. Reaggregates were exposed to (+) or (-) MDA at 10⁻⁴M between 15 and 22 days. At 22 days, half exposed to (+) or (-) MDA at 10⁻⁴M between 15 and 22 days. At 22 days, half of the flasks continued in drug-containing media while the other half grew in drug-free media for an additional 6 days. At the end of the 28 day culture period, all of the reaggregates were analyzed for endogenous DA and 5-HT levels using HPLC. DA and 5-HT cells were visualized using tyrosine hydroxylase (TH)- and 5-HT-immunocytochemistry. Light microscopic examination of TH- and 5-HT-immunoreactive cells revealed no extensive cytoplasmic vacuolization in reaggregates allowed to recover, in contrast to the cellular damage seen after 7 days of drug exposure. Reaggregates treated with either (+) or (-) MDA at 10 days of thing exposure. Reaggregates treated with either (+) or (-) MDA at 10 MM over the 13 day period had significant reductions in DA and 5-HT levels. In the case of (+) MDA, DA levels returned to control values following 6 days of recovery, while 5-HT remained significantly depressed (25%) below control values. For (-) MDA, neither DA (-16%) nor 5-HT (-26%) levels fully recovered following 6 days in drug-free medium as compared to control cultures. Supported by MH42134.

136.6

AMPHETAMINE EXERTS ITS PSYCHOSTIMULANT EFFECTS VIA A WEAK BASE MECHANISM. David Sulzer, Wei-Xing Shi and Stephen Rayport. Depts. Psychiatry, Anatomy & Cell Biology, and Ctr. Neurobiology & Behavior, Columbia Univ.; Dept. Neuropathology, Psychiatric Inst., New York City 10032. Several psychostimulants act in the brain by increasing dopamine (DA) levels

at mesolimbic synapses (Koob & Bloom, 1988). Amphetamine works primarily at the vesicular level, unlike cocaine which is thought to act by binding to the plasma membrane uptake transporter. However, how amphetamine affects vesicular DA levels has been unclear. Acidification by an ATP-dependent proton pump in synaptic vesicles is required for accumulation of monoamine transmitters. We have found that amphetamine and other lipophilic weak base psychostimulants inhibit storage vesicle acidification (Sulzer & Rayport, 1989); we now show that

amphetamine-induced alkalinization is sufficient to explain its action.

We observed the effect of pharmacologically-relevant concentrations of amphetamine in mesolimbic DA cell cultures. We visualized acidic organelles with the weak base vital dye acridine orange under low-light, non-bleaching conditions using a chilled-CCD camera. Areas that contain synaptic vesicles in the cell body perimeter and varicosities were stained, as well as lysosomes distributed primarily in the perinuclear region. 1 µM amphetamine caused alkalinization at both sites; the reduction in staining was dose-dependent up to 100 µM.

To examine the effects of amphetamine on transmitter storage vesicles directly, we used isolated bovine adrenal chromaffin granules. Supporting our findings in cultured DA neurons, similar concentrations of amphetamine inhibited the granule pH gradient. This resulted in a parallel decrease in uptake and increase in release of ³H-serotonin. Amphetamine, several other psychostimulants, native monoamine neurotransmitters and classic weak bases such as ammonium all had first-order dose-response curves. The weak base mechanism may also contribute to the action of other psychostimulants including cocaine, phencyclidine and tyramine.

COCAINE AND AMPHETAMINE AFFECT THE LOCOMOTOR BEHAVIOR OF *DROSOPHILA MELANOGASTER*. R.C. Richmond, T. L. Mench*, M. F. Gerteisen*, M. D. Boyer* and P. E. Mitchell*. Department of Biology, Indiana University, Bloomington, IN. 47405.

The long-term objective of our work is to develop Drosophila as a system for exploring the genetic bases for responses to psychoactive drugs. We tested the hypothesis that cocaine and amphetamine affect the locomotor behavior of *D. melanogaster* larvae and adults. Larvae were allowed to ingest sucrose solutions containing cocaine at concentrations up to 1.0% and their locomotor activity was measured as the length of a track left in a thin suspension of yeast on a petri plate. Cocaine solutions of 0.25% and greater reduced locomotor activity below that of paired controls fed sucrose alone. Adult flies were induced to feed on sucrose solutions containing cocaine and their locomotor activity measured as the distance walked in a glass tube under standard conditions. Cocaine solutions of 0.001% were effective in reducing the locomotor activity of adult flies below that of paired controls. Both larval and adult locomotion were tested after ingesting amphetamine to determine if effects on locomotion were present for a compound which does not act as a local anesthetic. Flies which ingest amphetamine also show a reduction in locomotor which figest ampletamine also show a feducitor in accommodition behavior although the sexes appear to differ in their response to this drug. These results suggest that cocaine and amphetamine act on the CNS of *Drosophila*. *Drosophila* may be a particularly useful system for identifying specific genes which affect responsiveness to cocaine and other psychoactive drugs.

CHARACTERIZATION OF SIGMA BINDING SITES IN HUMAN CHARACTERIZATION OF SIGMA BINDING SITES IN HUMAN PLACENTA: EFFECT OF PERINATAL COCAINE EXPOSURE <u>D.D. Flynn</u>, A.A. Vaishnav, Y. Itzhak, L. Sanchez*, and D. C. Mash. Depts. Pharmacology, Neurology and Biochemistry, University of Miami School of Medicine, Miami, FL 33101 and the Deptartment of Obstetrics and

Gynecology, University of Florida, Jacksonville, FL. 32209
Recent studies suggest that the psychotropic actions of opiate benzomorphans are mediated by sigma receptors. In addition, putative sigma receptors have been characterized in peripheral tissues and cells including the ovary, spleen and lymphocytes (Wolfe et al., 1988; 1989). We report here the characterization of a high affinity sigma binding site in the human placenta. Placental tissue was obtained from patients admitted for delivery at the University of Florida Medical Center at Jacksonville. Cocaine users were identified both by self-reported drug histories and urine screens for cocaine metabolites. Sigma receptors were labeled in placental membranes with R(+)[3H]-3-3-hydroxy[phenyl]-N-(1-propyl)piperidine ([3H]-PPP). Saturation analysis revealed an apparent single class of sites (Kd = 80 nM; Bmax = 20-30 pmol/gram tissue). Haloperidol, pentazocine, 1,3 di (2-tolyl)guanidine, and (+) SKF 10,437 displaced [3H]-PPP binding in placental membranes. The rank order of potency and stereoselectivity demonstrated in competition assays with [3H]-PPP were identical in human cerebellum and placenta. Progesterone competitively displaced [3H]-PPP binding in the placenta (Ki = $0.2 \mu M$). Cocaine was equipotent at sigma binding sites labeled in placental and cerebellar membranes. The density of sigma binding sites in the placentas taken from mothers who tested positive for urinary cocaine metabolites was significantly reduced compared to control values matched for gestational age. These preliminary findings suggest that peripheral sigma receptors may be regulated by cocaine exposure. DA 06227 and NIH BRSG

A PHARMACOGENETIC EVALUATION OF THE COCAINE-KINDLING PROCESS. R. J. Marley, J. M. Witkin & S. R. Goldberg, NIDA-Addiction Res. Ctr., Box 5180, Baltimore, MD 21224.

Repeated administration of cocaine has been shown to result in the development of increased susceptibility to the convulsant properties of cocaine (i.e. kindling). Cocaine's local anesthetic actions have been implicated in the cocaine-kindling process. Genetic differences in susceptibility to cocaine- and lidocaine-kindled seizures were evaluated in 4 inbred mouse strains and compared with susceptibility to seizures induced by the acute administration of the two drugs. The acute administration of cocaine produced convulsions in mice from all 4 genotypes with the following rank order for susceptibility: C57 > BALB = DBA > SJL. The rank order of the 4 strains for sensitivity to the development of cocaine-kindled seizures was opposite to that observed for initial susceptibility to cocaine-induced seizures. In 3 of the genotypes, however, the cocaine-kindled state did not persist upon further exposure to cocaine. Following a period of increased sensitivity to cocaine-induced seizures, a high degree of tolerance to the convulsant properties of cocaine developed among C57 mice. Partial tolerance was also apparent among BALB and DBA mice. Only among the SJL mice did the development of a kindled state persist upon repeated exposure to cocaine. The rank order of the 4 strains for susceptibility to lidocaine-induced seizures and for the development of susceptibility and/or tolerance to lidocaine-induced seizures were not the same as observed for cocaine, suggesting that while the local anesthetic properties of cocaine may underlie, at least in part, its convulsant and epileptogenic actions, the effects of cocaine on these parameters do not completely parallel those of lidocaine.

136.10

BLOCKADE OF THE CONVULSANT EFFECTS OF COCAINE BY MK-801 IN

BLOCKADE OF THE CONVULSANT EFFECTS OF COCAINE BY MK-801 IN A DIAZEPAM-INSENSITIVE MOUSE MODEL. J. M. Witkin and F. C. Tortella. NIDA Addiction Research Ctr., Baltimore, MD 21224 and Walter Reed Army Inst. Res., Washington, DC 20307 Experimental focus on both the convulsive and lethal effects of cocaine and the finding that these toxic manifestations can be dissociated (Witkin et al., Life Sci. 44: 1285, 1989) has led to the use of a model of cocaine toxicity using supramaximal seizure-inducing doses of cocaine. In male Swiss Webster mice where cocaine HCl (ip) produces convulsions with an ED 50 of 57 mg/kg and death with an LD 50 of 73 mg/kg, 75 mg/kg of cocaine was used to evaluate the anticonvulsant and life-protectant effects of potential therapeutic entities. After 75 mg/kg cocaine, convulsions occurred in 100% and death in 50% of the mice tested. Diazepam (1 - 10 mg/kg, sc, 30 min prior) protected against lethality without altering cocaine-induced clonic convulsions. However, diazepam produced induced clonic convulsions. However, diazepam produced dose-dependent protection against convulsions induced by 60 mg/kg cocaine. In contrast, the N-methyl D-aspartate (NMDA) antagonist, MK-801 (0.1 - 0.3 mg/kg, sc, 30 min prior), produced dose-dependent protection against convulsions induced by 75 mg/kg cocaine without completely blocking lethality. Cocaine did not produce convulsions in the presence of 0.3 mg/kg MK-801 even when given at about 2 X ED 50. These results suggest a role for NMDA antagonists in the treatment of severe cocaine convulsions.

DEVELOPMENTAL CORTICAL ANOMALIES AFTER PRENATAL EXPOSURE TO COCAINE. W.E. Kaufmann. Neuropathology Laboratory, The Johns Hopkins University School of Medicine, Baltimore, MD 21205.

Experimental and clinical studies have shown that cocaine exposure *in utero* leads to neurobehavioral sequelae, particularly as regards disorders of attention sequelae, particularly as regards disorders of attention and learning. The biological substrate of these problems is not known but may involve lesions of the cerebral cortex. Therefore, using conventional histological and immunocytochemical techniques, cortical organization was studied in three infants (1-3 months of age) born to cocaine abusers. Cases showed increased numbers of neurons in white matter as compared to controls. In prefrontal and anterior temporal areas, ganglionic and fusiform elements, sometimes in clusters, were located mainly superficially (p = 0.003 and p = 0.002, respectively). Slight astrocytosis and decreased staining of myelin were seen in the two older subjects. respectively). Slight astrocytosis and decreased staining of myelin were seen in the two older subjects. Temporal and occipital regions showed decreased immunoreactivity for nonphosphorylated neurofilaments in layers V and VI , possibly reflecting disturbed cytodifferentiation, whereas findings in white matter suggested abnormal neuronal migration and/or failure of physiological cell death. The involvement of cells in association cortices may play a role in some of the neurobehavioral manifestations reported in cocaine-exposed offspring.

TRANSMITTERS IN INVERTEBRATES I

FMRFamide-like peptides in *C. elegans*: Developmental expression and cloning and sequencing of the gene. <u>C. Li</u>. Dept. of Biology, Boston University, Boston, MA 02215.

About 25 neurons, many of which have been identified, stain with an antibody against the neuropeptide FMRFamide (see Neurosci. Abst. 12:246). The onset of FMRFamide-like expression in these neurons, as determined immunocytochemically, appears to be developmentally regulated. All neurons arise by the first larval stage in *C. elegans*. The first visible staining occurs in the nerve ring of young L1 animals. Shortly thereafter during L1, the cell bodies of about 8 neurons in the nerve ring region and anterior ventral cord processes become visible. As the animal progresses through the four larval stages and into adulthood, more neurons throughout the animal and processes along the entire

more neurons throughout the animal and processes along the entire length of the ventral, lateral, and dorsal nerve cords become visible. All neurons continue to express the peptide into adulthood, and no neuron is stained in larval animals that is not present in adult animals.

Degenerate oligonucleotides against Phe-Met-Arg-Phe-Gly-Lys(Arg) were used to screen a C. elegans cDNA library (from S. Kim). One of the 16 hybridizing clones has been subcloned and sequenced thus far. The deduced amino acid sequence of the translation product reveals 8 potential neuropeptide sequences, each of which is flanked by possible endoproteolytic cleavage sites (1-3 basic residues) and ends with a C-terminal Gly, a potential amide donor. Seven of the peptides terminate with the sequence -Pro-Asn-Phe-Leu-Arg-Phe-Gly. These FLRFamide-like peptides would be recognized by the FMRFamide antiserum, and are likely to account for some, if not all, of the immunoreactivity seen in the animal.

137.2

AF2, A NEMATODE NEUROPEPTIDE. C. Cowden* and A.O.W. Stretton, Dept. of Zoology, University of Wisconsin-Madison, 53706.

We are interested in the role of neuropeptides in the control of locomotion in Ascaris suum. Our strategy is to isolate peptides that cross-react with an antiserum which binds to neural antigens in Ascaris heads. The RIA used to monitor the isolation is specific for C-terminal RFamide (Marder et al, 1987). 1987)

The isolation of AF1 (KNEFIRFamide) from head extracts of <u>Ascaris</u> <u>suum</u> and its physiological effects have been reported (Cowden, Stretton, and Davis, 1989). A second FMRFamide-like peptide has been isolated using 3 HPLC steps: n-butanol in TFA; acetonitrile in HFBA; and acetonitrile in TFA. The natural peptide has the sequence KHEYLRF. Its mass is 991 daltons which is the same as the mass of the synthetic peptide KHEYLRFamide; its elution times in 3 HPLC systems are the same as those of the synthetic peptide. The synthetic peptide is active at 10⁻⁶ M in injected worms and in a muscle strip assay. We conclude that AF2 is a bioactive neuropeptide with the chemical structure KHEYLRFamide.

LOCALIZATION OF GLUTAMATE-LIKE IMMUNOREACTIVITY IN THE LEECH CENTRAL NERVOUS SYSTEM, P.D. Brodfuehrer and A.H. Cohen. Neurobiology and Behavior, Cornell University, Ithaca, NY, 14853

In the medicinal leech, Hirudo medicinalis, pressure ejection of Lglutamate onto a single segmental ganglion or subesophageal ganglion can induce swimming activity along the ventral nerve cord. This suggests that glutamate may play a role as an excitatory neurotransmitter in leech central nervous system. Using a monoclonal antibody for glutamate (IMN) we tested whether the leech central nervous system contains glutamatelike immunoreactivity.

In 20 µm cryostat sections of leech ganglia, we found positive staining for glutamate-like immunoreactivity distributed along the ventral nerve cord. However, to date cell bodies have only been stained in the supraesophageal ganglion (SupraEG), subesophageal ganglion (SubEG) and segmental ganglion (SG) 1. No neuronal cell bodies labeled in any other segmental ganglion (SG). Two hearonal cell bodies labeled in any other ganglia tested (SG 2, 5, 6, 10, 20, 21 and tail ganglion). Neuronal processes, on the other hand, were labeled reliably in all ganglia examined. The distribution of cell body staining consisted of the following: In both the SupraEG and SG 1 up to 5 cell bodies generally labeled, while in the SubEG pair of 30 µm cell bodies on the ventral surface of the most posterior division of the SubEG, with anteriorly projecting axons ipsilateral to their cell bodies, consistently stained. Moreover, up to 3 other cell bodies occasionally stained in the SubEG. Throughout both the SupraEG and SubEG neuronal processes routinely labeled, while only a small group of bilaterally symmetrical processes were clearly labeled in the other SG examined. Preabsorption controls blocked all positive staining in our sections. Supported by NIMH grant# MH44809 to A.H.C.

137.5

REGULATION OF PHARYNGEAL MOTILITY IN THE LEECH HIRUDO MEDICINALIS. B. A. O'Gara. Dept. of Biology, Univ. of Virginia, Charlottesville, VA 22901.

The role of serotonin in the feeding behavior of the leech is well established (Lent et al., Amer. Zool. 29:1241, 1989). Application of serotonin to the pharynx or stimulation of the serotonin-containing LL cells causes repetitive pharyngeal peristalsis with a frequency of about 1 Hz (Lent and Dickinson, J. Comp. Physiol. A 154:457, 1984). In addition, biting behavior is dependent on CNS serotonin levels. However, the roles of other neurotransmitters as well as the neuronal circuitry underlying feeding in the leech are largely unknown. In the present study, FMRFamide immunoreactivity was localized to neural

processes of the pharynx associated with the longitudinal muscles as well as the processes of the posterior sphincter, the accessory ganglia associated with the pharynx and jaws, and the cephalic ganglia. Application of FMRFamide to the isolated pharynx induced phasic contractions of 20-35 s duration superimposed upon a dose-dependent increase in maintained tension (threshold 1 nM). The small cardioactive peptide B (SCP_B) also induced phasic contractions (20-35 s duration) and slightly increased maintained tension.

However, the threshold for these effects was high (10-100 μ M). Several neurons that caused pharyngeal contractions were discovered which have somata in the first neuromere of the subesophageal ganglion. Each of these neurons has a ventral soma with a contralateral axon that enters the circumesophageal connectives and exits the CNS through the stomatogastric nerve of the supraesophageal ganglion. Stimulation of one identified cell caused quite complex effects, longitudinal contractions when depolarized and pharyngeal peristalsis when the depolarization was terminated. Stimulation of other cells caused longitudinal or circular contractions. Supported by NIH grants NS08263 to B.A.O. & NS21778 to W.O. Friesen.

ISOLATION OF A NEUROPEPTIDE THAT MEDIATES PROLONGED INHIBITION OF BAG CELL TARGET NEURONS IN APLYSIA. S.M. Rajpara*, J.C. Eliassen*, M.L. Block and E. Mayeri. Department of Physiology, University of California, San Francisco, CA 94143

The neuroendocrine bag cells of the marine mollusk Aplysia utilize α-bag cell peptide (αBCP), egg laying hormone (ELH) and 2 other neuropeptides as transmitters to produce several types of effects on abdominal ganglion neurons. αBCP mediates inhibition that lasts the duration of the bag cell burst discharge, approx. 30 min., in about 50% of ganglion neurons. In cells L3 and L6, however, inhibition lasts for more than 2 hr and αBCP application mimics only an early component of the response.

To identify the substance mediating the prolonged component of inhibition we purified material from acid extracts of abdominal ganglia using gel filtration HPLC on TSK 250-125 followed by reverse phase HPLC on C4. Elution peaks were assayed for inhibitory activity on L3 and L6 by arterial perfusion application.

We isolated two inhibitory factors whose effects persist after a ways of the second of the capacity.

inhibitory activity on L3 and L6 by arterial perfusion application. We isolated two inhibitory factors whose effects persist after a wash of seawater applied 5-10 min after initial perfusion. Mass spectroscopy and partial amino-acid sequence analysis of one factor indicates that it is ELH[2-36], i.e., ELH that lacks the first amino acid. This peptide appears to be effective at a higher concentration than the other inhibitory factor, which is presently being characterized. This inhibitory activity is the first to be described for an ELH-related peptide. It remains to be determined whether both factors or just one of them is involved in mediating the prolonged inhibition. mediating the prolonged inhibition.

137 A

IDENTIFICATION OF FOUR RFAMIDE PEPTIDES IN LEECH . B.D. Evans, Pohl*1, and R.L. Calabrese. Dept. of Biology, Emory University, Atlanta, GA 30322 1 Microchemical Facility, Emory University, Atlanta, GA 30322

RFamide peptides are potent modulators of neuromuscular interaction in leech (Norris & Calabrese, 1990). Each ganglion of the CNS of the leech Hirudo medicinalis contains neurons which are EMREamide-like immunoreactive as determined with two different antisera (Kuhlman et al., 1985; Evans & Calabrese, 1989).

Using a four step rpHPLC separation, we have purified four FMRFamide-like immunoreactive peptides from leech CNS. Gradients of acetonitrile/H₂O were used for separation, with either 0.1% TFA or HFBA as counterion. Prior to the third separation, samples were incubated in 1.5% $\rm H_2O_2$, which oxidizes methionyl residues, thus changing the retention times of peptides containing methionine. FMRFamide-like immunoreactivity was detected with RIA, using antiserum 671C (Marder et al., 1987). The first peptide we isolated cochromatographed with FMRFamide in all systems tested. Sequence analysis indicated Phe-Met-Arg-Phe. The specificity of the antiserum used in RIA for amidated peptides identifies this peptide as FMRFamide. The second peptide isolated was similarly shown to be FLRFamide. YMRFamide and YLRFamide were also purified and sequenced, but coelution with synthetic peptides remains to be tested.

Our results indicate the presence of at least four RFamide peptides in the central nervous system of the annelid Hirudo. At least three of these four endogenous peptides can modulate neuromuscular interactions in leech (Kuhlman et al., 1985; Norris & Calabrese, 1990). The identification of multiple species of RFamide peptide in leech should lead to further investigation into the nature of the biological actions of these neuropeptides

ION CHANNELS IN SKELETAL MUSCLE MEMBRANE OF LOBSTER. M.K. Worden, N. Cherbuliez, E.A. Kravitz and R. Rahamimoff.
Dept of Neurobiology, Harvard Medical School, Boston, MA
02115 and Dept. of Physiology, Hebrew University Medical School, Jerusalem, Israel.

To examine the cellular and molecular mechanisms responsible for hormonal modulation of muscle activity in the lobster <u>Homarus americanus</u> we began characterizing ion channels in lobster muscle membrane using a modification of the bleb (spherical outpocketing of membrane)-forming technique (Burton, et al. Muscle and Nerve 11:1029 (1988)) and the bleb attached and inside out versions of the patch and the bleb attached and inside out versions of the patch clamp technique. Data were recorded from the accessory flexor muscle in 50 patches with seal resistance > 2 gigaohms. At least three different single channel activities were observed. The first type had a single channel conductance (χ) between 121-153pS (n=6) in symmetrical KCl (460mM). This channel displays bursting activity, and the closed time distribution can be fitted with at least two exponentials. The mean channel open time (moct) is 0.36ms at -40mV; the probability of opening has (mcot) is 0.36ms at -40mV; the probability of opening has a slight voltage dependence between -50 and +50mV. For the second channel type χ is between 33 and 42pS (n=3) and the mcot is 1.8ms over a voltage range between -100 and +50mV. The third channel type has a \$ between 250 and 310ps (n=6), and the mcot is 5.0 ms. These channels may regulate electrical and contractile activity in muscle. (Supported by NIH.)

ULTRASTRUCTURAL LOCALIZATION OF SCP AND BUCCALIN LIKE IMMUNOREACTIVITY IN THE ACCESSORY RADULA CLOSER MUSCLE OF APLYSIA. F.S. Vilim1. I. Kupfermann1. and K.R. Weiss2. 1Cntr. Neurobiol.

IMMUNOREACTIVITY IN THE ACCESSORY RADULA CLOSER MUSCLE OF APLYSIA. E.S. Vilim¹, L. Kupfermann¹, and K.R. Weiss². ¹Cntr. Neurobiol. & Behav., Columbia Univ., NYS Psych Inst., NY, NY, and ²Dept. Physiol. & Biophys., Fishberg Res. Ctr. in Neurobiol., Mt. Sinal School of Med., NY, NY. The accessory radula closer muscle (ARC) and its innervation provide a model system for studying the role of neuromodulation and cotransmission. Motorneuron B15, which innervates the ARC, has been shown to synthesize peptides that modulate ARC contractions when applied exogenously. These peptides fall into two classes which are coded for by different genes, the SCPs and the buccalins. The SCPs potentiate and the buccalins depress motorneuron induced ARC contractions. The ultrastructural localization of buccalin and SCP have important implications for understanding the functioning of this system. We have undertaken immunogold double labeling at the EM level using rabbit primary antibodies against buccalin and rat antibodies against SCP. Double labeling using these antibodies at the light microscope (LM) level indicated distinct patterns of labeling that were consistent with known biochemical data. Post embedding EM double labeling using these antibodies and secondary antibodies conjugated to different sized colloidal gold particles was carried out on ARCs and buccal ganglia. Immunostained ARC sections revealed that a large proportion of dense core vesicles (DCVs) were labeled for both SCP and buccalin. Control experiments indicate that these results are not due to some artifact of antibody cross reactivity. Immunostained sections of buccal ganglion revealed processes in the neuropil whose DCVs stained only for buccalin or only for SCP. Omitting one of the primary antibodies or preabsorption of the primary antisera with SCP or buccalin eliminated the labeling of the appropriate size gold particles. Furthermore, switching the gold particle size of the secondary antibodies did not substantially alter co-labeling. These results suggest tha results suggest that SCP and buccalin are localized in the same vesicles

DIFFERENTIAL EFFECTS OF BUCCALIN ON PEPTIDERGIC AND CHOLINERGIC COMPONENTS OF B15-INDUCED CONTRACTIONS OF THE ARC MUSCLE. E. C. Cropper¹, S. L. Hooper³, I. Kupfermann³, and K. R. Weiss^{1,2}, ¹Dept. Physiol./Biophysics, ²Fishberg Ctr. Neurobio., Mt. Sinai Schl. Med., NY, NY 10029, ³Ctr. Neurobio./Behav., Columbia Univ., NY, NY 10034.

Evidence suggests that B15-induced contractions of the accessory radula closer (ARC) muscle have a cholinergic component produced by release of ACh, and a peptidergic component produced by release of SCP_A and SCP_B. In addition to the SCPs and ACh neuron B15 contains two peptides, buccalin A and buccalin B, that have an inhibitory rather than an excitatory effect on contractile activity

of the ARC. It has been demonstrated that the inhibitory effect on contractile activity of the ARC. It has been demonstrated that the inhibitory effect of the buccalins is exerted on the cholinergic component of muscle contractions: in this study we sought to determine whether it is also exerted on the peptidergic component.

We bilaterally stimulated B15 neurons while we unilaterally

We bilaterally stimulated B15 neurons while we unilaterally exposed ARC muscles to buccalin at a concentration that has an inhibitory effect on the cholinergic component of muscle contractions (10⁻⁶ M). After stimulation, cAMP levels in buccalin-exposed and nonbuccalin-exposed muscles were compared. (cAMP levels are a sensitive measure of peptidergic effects of B15 stimulation.) The presence of buccalin had no significant effect on cAMP levels produced by motor neuron stimulation. In other experiments we measured the cAMP stimulation produced by direct application of SCP to the ARC (10⁻⁷ M) in the presence and absence of buccalin (10⁻⁶ M). Again buccalin had no effect on cAMP levels. Thus, in these experiments buccalin had an inhibitory effect on the cholinergic component of ARC muscle contractions but it did not significantly affect the peptidergic component.

RELEASE OF PEPTIDE COTRANSMITTERS FROM AN IDENTIFIED MOTOR NEURON MODULATE NEUROMUSCULAR EFFICACY IN APLYSIA M. D. Whim and P.E. Lloyd, Dept. Pharm. Physiol. Sci. & Comm. on Neurobiol. Univ. Chicago, Chicago, IL 60637.

Buccal muscle 15 is innervated by two motor neurons (B15 and B16). In addition to the classical transmitter ACh. B15 also contains

Buccal muscle 15 is innervated by two motor neurons (B15 and B16). In addition to the classical transmitter ACh, B15 also contains the two SCPs. We have previously shown that the SCPs are released from the terminals of B15 in the I5 muscle and that peptide release is dependent on the pattern of stimulation (Whim & Lloyd, PNAS 86: 9034, '89). We examined the possibility that the SCPs released from B15 modulate I5 muscle contractions produced by released from 613 modulate 13 muscle contractions produced by stimulation of B16. Application of exogenous SCPs to 15 muscles increased the amplitude and relaxation rate of B16-evoked contractions. Stimulation of B15 using paradigms known to cause release of the SCPs resulted in a long-lasting increase in the amplitude and relaxation rate of muscle contractions evoked by B16. This modulation of B16-evoked contraction amplitude and relaxation rate was still observed when the B15 contractions were blocked by a cholinergic antagonist. Stimulation of B15 at frequencies which produce no measurable release of the SCPs did not elicit significant modulation of B16-evoked contractions. The minimum B15 stimulation frequency required to modulate B16-evoked contractions was found to be within the physiological range at which B15 fires during feeding (Cropper et al., PNAS 87: 933, '90). Thus, the mechanism underlying this modulation involves the release of the SCPs from B15 terminals in the muscle. Supported by NS 23569.

STRUCTURE AND DISTRIBUTION OF MYOMODULIN RELATED NEUROPEPTIDES IN APLYSIA. M.W. Miller, F. S. Vilim. E.C. Cropper. A. Alevizos, R. Tenenbaum*, D. Karagogeos, I. Kupfermann, and K.R. Weiss. Ctr. for Neurobiol. & Behav., Coll. P. & S, and NYS Psychiat. Inst., NY, NY 10032; FRCN Mount Sinai Sch. of Med., 1 Gustave Levy Pl., NY, NY 10029.

The neuropeptide myomodulin, originally purified and sequenced from the accessory radula closer (ARC) muscle of Aplysia, has been shown to be present in one of the cholinergic motor neurons (B16) innervating this muscle, where it has been proposed to act as a modulatory cotransmitter (Cropper et al., 1987). The identification of a related peptide, myomodulin B, also present in B16 (Vilim et al., Neurosci. Abstr., 15:665, 1989), suggested that these peptides may belong to a larger neuropeptide family. Four additional bioactive belong to a larger neuropeptide ramily. Four additional bloactive peptides with sequence homology to myomodulin and myomodulin B have been purified from the ARC muscle: GWSMLRLa, GLSMLRLa, GLQMLRLa, and SLDMLRLa. Antibodies raised against the first of these peptides revealed myomodulin-like immunoreactivity in cell bodies and clusters in each of the central ganglia and in fibers in the major connectives. Identified neurons exhibiting immunoreactivity include the buccal motor neuron B16 and the abdominal cholinergic interneuron L10. In the periphery, immunoreactive varicosities are interneuron L10. In the periphery, immunoreactive varicosities are present on tissues associated with the cardiovascular, digestive, and reproductive systems. Richly innervated tissues include the large hermaphroditic duct, the pericardium, and the esophagus. The widespread distribution and multiple forms of the myomodulin related peptides suggest that they are involved in a number of neural circuits where they may exert a diversity of actions.

137.12

RELEASE OF PEPTIDE COTRANSMITTERS (SCPs) FROM AN IDENTIFIED CHOLINERGIC MOTOR NEURON IN APLYSIA IS HIGHLY TEMPERATURE DEPENDENT P.E. Lloyd and M. D. Whim Dept. Pharm. Physiol. Sci. & Comm. on Neurobiol. Univ. Chicago, Chicago, IL

Cholinergic motor neuron B15 innervates buccal muscle I5 (also termed ARC) and contains and synthesizes the SCPs (A & B). Release of SCPs from terminals of B15 in the I5 muscle has been demonstrated (Whim & Lloyd, PNAS 86: 9034, '89). One of the methods used to demonstrate release was that stimulation of B15 with certain paradigms increased cAMP levels in I5 muscle fibers. Increased cAMP levels were critically dependent on stimulation frequency, burst duration, and interburst interval. At 22°C with 4 s bursts and 3s interburst intervals the lowest frequency that frequency, burst duration, and interburst interval. At 22°C with 4 s bursts and 3s interburst intervals, the lowest frequency that produced significant increases in cAMP was 15 Hz. With the same pattern of stimulation, the minimum frequency needed to elevate cAMP levels was reduced to 10 Hz at 16°C. The effects of 0.1 μM synthetic SCP_D on cAMP levels in muscle fibers were the same at 16°C and 22°C. Thus, it appears that the SCPs were released at significantly lower stimulation frequencies at 16°C. Consistent with significantly lower simulation required as 16 evoked contractions by stimulation of B15 (which appears to be a consequence of release of the SCPs; see Whim & Lloyd, these abstracts) was also more effective at 16°C. Supported by NS 23569.

EPILEPSY: HUMAN STUDIES AND ANIMAL MODELS

138.1

DEVELOPMENT OF KINDLED SEIZURES FOLLOWING ELECTRICAL DEVELOPMENT OF KINDLED SEIZUNES FOLLOWING ELECTRICAL STIMULATION VIA THE CORNEA G. Skeen", J. Woodhead", H. Wolf", E. Swinyard", E. Tietz², S. White¹ ¹Anticonvulsant Drug Development Program, Dept. of Pharmacol. & Toxicol., Univ. of Utah, S.L.C., UT 84108 and 2Dept. of Pharmacol. Medical College of Ohio, Toledo, OH. 43699
The observation that anticonvulsants which are effective in human complex

partial seizures are also effective against amygdala kindled seizures in laboratory animals has led to acceptance of amygdala kindling as a viable model for complex partial seizures in man. The results of the present report laboratory animais has led to acceptance of amygolata kindling as a viole model for complex partial seizures in man. The results of the present report represent an effort to develop a model wherein rats could be effectively kindled to Stage 5 motor seizures (Racine, Electroenceph. Clin. Neurophysiol., 32:281, 1972) by the daily administration of a subconvulsive current (8 ma, 4 sec) delivered through corneal electrodes following topical corneal anesthesia with 1% butacaine sulfate. The developmental curves and the pharmacological profile of this model closely approximate those reported previously for other kindling models. Of the prototype anticonvulsants tested, carbamazepine, valproate and clonazepam were all effective in nontoxic oral doses in preventing the expression of Stage 5 seizures (EDS0's: 28.9, 118 and 1.9 mg/kg, respectively). Phenytoin (100 mg/kg) and ethosuximide (1000 mg/kg) were both ineffective following oral administration. In contrast, phenytoin was effective following i.p. administration (EDS0: 48.3 mg/kg). These observations, coupled with the demonstration that there is transfer between comeal kindling and amygdala kindling, suggest that the comeal-kindled rat may represent a useful animal model for identifying potentially useful compounds for the treatment of partial seizures secondarily generalized in man. One distinct advantage of this model is that it is useful for the large-scale pharmacological screening of potentially useful anticonvulsant substances. KINDLING ENHANCES SENSITIVITY OF CA3 HIPPOCAMPAL PYRAMIDAL CELLS TO NMDA. <u>D. Martin, J.V. Nadler and J.O. McNamara</u>. Depts. Pharmacology, Neurobiology and Medicine (Neurology), Duke Univ. Med. Ctr., Durham, NC 27710. Several reports suggest that increased NMDA receptor density and/or

Several reports suggest that increased NMDA receptor density and/or enhanced NMDA receptor function at least partially explains the hyper-excitability associated with kindling. This idea was investigated with use of a grease-gap preparation for assaying the depolarizing responses of CA3 or CA1 hippocampal pyramidal cells to amino acid excitants. At both 1 day and 1-2 months after the last evoked seizure, CA3 pyramidal cells from kindled rats were significantly more sensitive to NMDA than pyramidal cells from implanted or unimplanted controls. Kindling did not alter the ability of Mg²+ to reduce NMDA potency. In both control groups NMDA potency declined 2.5 to 4-fold over the 1-2 month experimental period, apparently as a result of increasing age. This agerelated loss of sensitivity to NMDA was completely prevented by kindling. Thus 1-2 months after the last evoked seizure, NMDA was 4 to 6-fold more potent on CA3 pyramidal cells from kindled rats than on pyramidal cells from implanted or unimplanted control rats. Neither Mg²+, kindling nor aging significantly altered the potency of AMPA or L-glutamate. In addition, kindling did not affect the sensitivity of CA1 pyramidal cells to NMDA or AMPA.

These findings suggest that kindling prevents a loss of NMDA receptor

These findings suggest that kindling prevents a loss of NMDA receptor function in CA3 pyramidal cells that normally occurs during early adulthood. Such a change could contribute to maintenance of the kindled state. (Supported by NIH grants NS 17771 and NS 16064.)

KINDLING-INDUCED DECREASE IN PARTICULATE PKC LEVELS IN THE HIPPOCAMPUS AND MOTOR CORTEX. <u>T. Saitoh, M. Sundsmo*, K. Uéda*, M. Hsu. Z. Horvath, G. Buzsaki,</u> UCSD, School of Medicine, Department of Neurosciences, M-024, La Jolla, CA 92093

PKC has been suggested to play an important role in the modification of synaptic connection. In the LTP model, high frequency stimulation of hippocampal afferents induces translocation of PKC from the cytosol to the membrane. Here we examined the PKC changes in kindled animals, a possible model for epilepsy. Young female rats were implanted with stimulating electrodes in the angular bundle and recording electrodes in the hippocampus. Hippocampal afterdischarges were evoked by high frequency trains once (control) or daily until the rats displayed class 5 seizures on 3 consecutive days (kindling). Despite daily high frequency activation, evoked responses failed to potentiate during the course of kindling. Rats were decapitated 24 hr after the last kindling trial. PKC was determined by Western blotting using polyclonal antibodies raised against specific peptides for isozymes (a), (BI), (β II) and (γ). The single episode of kindling trial did not alter the levels and distribution of any PKC isozymes in hippocampus or in motor cortex. The kindled animals, however, demonstrated a reduced level of particular $PKC(\alpha)$ and $-(\gamma)$ in hippocampus. In the kindled motor cortex, the level of total PKC isozymes did not change, whereas the fraction associated with particulate fraction was reduced. The results demonstrate the possibily important involvement of PKC in the development of kindling.

SECOND MESSENGERS IN THE HIPPOCAMPUS IN HUMAN TEMPORAL LOBE EPILEPSY. S. Sundaresan, N.C. de Lanerolle, M.L. Brines and D.D. Spencer. Sections of Neurosurgery and Neuroendocrinology, Yale University School of Medicine, New Haven, Connecticut 06510.

The distribution of the second messengers adenylate cyclase and protein kinase C (PKC) in the hippocampus in tumor related (TTLE) and cryptogenic (CTLE) temporal lobe epilepsy was compared. Autoradiographic detection of adenylate cyclase by [3H]-forskolin binding revealed significantly increased levels on a per neuron basis in the molecular layer (ML), CA4, CA3, CA2 and CA1 of CTLE hippocampi compared to TTLE. Autoradiographic detection of PKC by [3H]-phorbol-12,13-dibutyrate binding revealed a similar pattern in that levels on a per neuron basis were increased in CTLE compared to TTLE in all hippocampal fields and in the dentate molecular layer. Most CTLE hippocampi displayed substantial PKC levels within the granule cell bodies. Adenylate cyclase is thought to mediate inhibitory effects in hippocampal cells, whereas PKC is thought to have excitatory effects. Levels of both second messengers were increased by similar percentages in the molecular layer of CTLE, but the overall levels of PKC are comparatively higher than adenylate cyclase in the hippocampus. This, together with the observation that PKC is found in granule cell bodies in CTLE but not TTLE or autopsy controls, suggests that these second messenger mechanisms may result in an overall increased excitation of the granule cells.

138.7

AUTORADIOGRAPHIC QUANTITATION OF CENTRAL AND PERIPHERAL BENZODIAZEPINE RECEPTORS IN HUMAN EPILEPTOGENIC TISSUE. E.W. Johnson, N.C. de Lanerolle, J.H. Kim. S. Sundaresan, D.D. Spencer, and R.B. Innis. Depts. Psychiatry and Neurosurgery, VA Medical Center and Yale University School of Medicine, West Haven, CT 06516.

the distribution and density of benzodiazepine (BZ) binding sites were determined with in vitro receptor autoradiography to hippocampal tissue obtained from patients treated neurosurgically for medication-refractory epilepsy. Tissue was studied from three groups: 1) Patients with complex partial seizures (CPS) (n=6), where pathological examination of the neurosurgical tissue showed mesial temporal sclerosis ("Epilepsy" group). 2) Patients with CPS (n=5), who were found on neurosurgery to have a tumor adjacent to the hippocampus as the cause of their seizures ("Tumor" group). 3) Autopsy samples (n=5) obtained from subjects with no neurologic or neuropathologic disorder ("Autopsy" group). Autoradiography was performed with two radioligands: 1251-Ro16-0154 (selective for the "central" type BZ receptor, thought to be located on neurons); and 3H-PK11195 (selective for the "peripheral" type BZ receptor, thought to be located on glia).

The Epilepsy group showed large and regionally selective losses of ¹²⁵I-Ro16-0154 binding compared to the Tumor and Autopsy groups, with the latter two not being significantly different. Binding of ¹²⁵I-Ro16-0154 in various hippocampal regions of the Epilepsy group were: CA1-14%; CA2-42%; CA3-19%; CA4-28%; molecular layer of dentate-61%; and subiculum-100% (expressed as percentage of regional levels in Tumor and Autopsy groups). The decreases of ¹²⁵I-Ro16-0154 binding closely correlated with neuronal cell losses. The binding of ³H-PK11195 in the Epilepsy group were most increased in those regions which showed decreased ¹²⁵I-Ro16-0154 binding: CA1-286%; CA2-186%; CA3-174%; CA4-260%; molecular layer of dentate-230%; and subiculum-100% (relative to regional levels in tumor and autopsy groups.

138.4

AMYGDALA KINDLING ALTERS HIPPOCAMPAL PROTEIN KINASE ACTIVITY S.J.Chen. M.A.Desai, E.Klann, J.D.Sweatt and P.J.Conn, Division of Neurosciences, Baylor College of Medicine, Houston, TX 77030 and Department of Pharmacology., Emory University, Atlanta, GA 30322.

Kindling is a model of epilepsy and neuronal plasticity in which repeated electrical stimulation of certain CNS structures gradually leads to development of generalized clonic convulsions. To investigate the molecular mechanisms responsible for kindling, we have measured protein kinase activity in several rat brain regions. Rats were kindled in the basolateral nucleus of the amygdala to a criterion of 2-5 stage 5 seizures. Brain tissues from kindled and control animals were dissected 2 hours or 24 hours after the last stage 5 seizure and homogenized in buffer containing 50 mM HEPES, pH 7.4, 10 mM MgCl2, 1 mM EDTA and 1 mM EGTA. Homogenates were added to reaction mixtures containing 5 mM sodium pyrophosphate to nhibit protein phosphatase, 100 µM 32P-ATP and 2 µg of the kinase substrate myosin light chain (MLC). After SDS-PAGE, incorporation of 32P-PO4 into MLC was quantitated using autoradiography and densitometric scanning. All values were normalized to the values obtained from control, shem operated, animals. Elevated kinase activity was observed in kindled hippocampal CA3 region (167±7% of control, N=3) as well as in the dentate gyrus (162% of control, N=1) when tissue was assayed two hours after the last seizure. In contrast, the kinase activity in CA1 region was found to be depressed (72.2% of control, N=1). No significant difference in protein kinase activity between control and kindled samples was observed in amygdala/pyriform cortex or limbic forebrain. Twenty-four hours after the last seizure, however, a different pattern of altered kinase activity was observed. The kinase activity was found to be elevated in CA1 region (150±4% of control, N=2) and depressed in the dentate gyrus (35±2% of control, N=2). No consistant change in CA3 region was observed. These results indicate kindling is associated with a regionally specific and time-dependent alteration of protein kinase activity.

138.6

HIPPOCAMPAL DOPAMINE RECEPTOR CHANGES IN HUMAN TEMPORAL LOBE EPILEPSY. N. C. de Lanerolle, J. R. Tompkins* and D.D. Spencer, Section of Neurosurgery, Yale University School of Medicine, New Haven, CT 06510

The distribution of dopamine D2 receptors in hippocampi surgical-

The distribution of dopamine D2 receptors in hippocampi surgically removed from patients with tumor related temporal lobe epilepsy (CTLE) and cryptogenic temporal lobe epilepsy (CTLE) was compared to that in autopsy specimens obtained from neurologically normal subjects, by autoradiographically localizing the binding of [125] iodosulpride. The mean density of ligand binding was lower in the granule cell layer, areas CA4, CA1 and the subiculum of autopsy specimens compared to both TTLE and CTLE. The density of binding on the granule cell bodies of CTLE was higher than in TTLE, with a marked increase in receptor density in the inner molecular layer of only CTLE. Ligand binding per cell was greater in almost all areas of CTLE than TTLE. There is also a significant inverse correlation between the density of ligand binding in the granule cell layer and dentate molecular layer with the number of granule cells in CTLE. It is suggested that the upregulation of D2 receptors in the CA fields of CTLE and TTLE may be an effect secondary to seizures, whereas the increase in granular layer and molecular layer of CTLE may be a change contributing to epileptogenesis in CTLE. However, these changes must be taken in conjunction with previously reported (Brain Res., 495: 387-395, 1989) in the chemical neuroanatomy of CTLE hippocampi, in evaluating the epileptogenic mechanisms in this disorder.

138.8

GRANULE CELL DISPERSION IN HUMAN TEMPORAL LOBE EPILEPSY. C.R. Houser. Dept. of Anatomy and Cell Biology, and Brain Research Institute, UCLA, and VA Medical Center, Los Angeles CA 90024

Angeles, CA 90024.

The distribution of dentate granule cells has been studied in control autopsy and temporal lobe epilepsy (TLE) specimens. At mid rostro-caudal levels of the dentate gyrus, the granule cell somata in control specimens were closely approximated and formed a distinct, narrow lamina. In a subpopulation of TLE specimens, granule cell somata were dispersed and extended into the molecular layer to varying extents, creating an irregular border between the granule cell and molecular layers. Granule cell dispersion was observed in specimens with and without obvious granule cell loss. However, there appeared to be a relationship between the extent of granule cell dispersion and the amount of cell loss in the polymorph region of the dentate gyrus. The most common feature in the histories of cases with granule cell dispersion was febrile seizures during the first four years of life. The dispersion of granule cells suggests that there has been some alteration in the migration of these neurons, resulting in an extended distribution of the granule cell somata into the molecular layer. Loss of the precise laminar pattern of the dentate gyrus could affect the functional circuitry of this region. Supported by NIH grant NS21908 and VA Medical Research Funds.

PHYSIOLOGIC PROPERTIES OF DENTATE GRANULE CELLS WITH DENDRITIC DEFORMITIES IN HUMAN EPILEPTIC HIPPOCAMPAL SLICES. M. Isokawa. T. Babb and J. Engel, Jr. Brain Research Institute and Dept. of Anatomy and Neurology, University of California Los Angeles, CA 90024.

Neuronal excitability and synaptic responses were studied in 23 human epileptic dentate granule cells which showed varying degrees of morphological deformities, previously reported as characteristic of human temporal lobe epilepsy by the Golgi study (Scheibel et al., 1974). Intracellular recording was obtained through Lucifer Yellow or Biocytin filled electrodes to measure resting membrane potentials, membrane resistances and synaptic responses. Dye injection subsequent to each recording demonstrated pathologic cell morphology in agreement with Golgi studies: 1) loss of spines, 2) nodule formation, 3) dendritic swelling, 4) development of "string-of-beads", and 5) restricted dendritic arborization. The first three features were observed in tight correlation, and the "string-of-beads" dendrites were not necessarily correlated with the degree of restriction in their dendritic domains. Resting membrane potentials of these neurons were -57.4 mV in average (N=22) and typically-observed synaptic responses were EPSPs by perforant path stimulation. In 2 cases, IPSPs were detected upon depolarizing current injection as hyperpolarization following EPSPs. In one neuron, an extreme case of "string-of-beads" morphology was observed, retaining no normal-appearing dendritic branches or identifiable pattern of cell body. Nevertheless, this neuron was capable of maintaining a membrane potential at -30 mV at the time of penetration and generating EPSPs. Intracellular current injection hyperpolarized the cell to -78mV or depolarized it to generate a spike, but no burst firing was elicited. Further studies in 1) synaptic responses in correlation to dendritic arborization patterns are in progress. Supported by NIH Grant NS02808.

138.11

IMMUNOHISTOCHEMICAL STUDY OF QUINOLINIC ACID CATABOLISM IN EPILEPTIC HUMAN HIPPOCAMPUS F. Du. W.O. Whetsell L. B. Abou-Khalil L. B. Blumenkopf L. E. Okuno and R. Schwarcz. Md. Psych. Res. Ctr., Baltimore, MD. 21228 and Landerbilt University School of Medicine, Nashville, TN 37232.

Quinolinic acid phosphoribosyltransferase (QPRT), the specific degradative enzyme of the excitotoxin quinolinic acid, was studied immunohistochemically in human epileptic hippocampi surgically resected from 6 patients with temporal lobe epilepsy. As compared with normal hippocampi (J. Comp. Neurol., 295:71, 1990), a clearly disease-related pattern of QPRT-immunoreactivity (QPRT-i) was consistently noted in all hippocampal specimens showing sclerosis (5 out of 6). Thus, QPRT-i, mainly associated with proliferated glial cells, increased substantially in the severely degenerated CAl region, where QPRT-i is very sparse under normal conditions. In contrast, a pronounced decrease in QPRT-i was observed in the largely degenerated end folium which normally contains the highest density of QPRT-i in the hippocampus. QPRT-positive neurons were preserved in areas of CAl where most other neurons had degenerated. Preliminary double-labeling studies demonstrated that almost all surviving QPRT-i neurons also exhibited glutamic acid decarboxylase-immunoreactivity, which has been reported to be spared in human epileptic hippocampus. The specific pattern of QPRT-i in the pathological specimens may indicate a role of quinolinic acid in temporal lobe epilepsy. (Supported by USPHS grant NS 16102).

INDUCTION OF HEAT SHOCK PROTEINS GENES IN KINDLED BRAINS. M-L Wong, M.A. Smith, S.R.B. Weiss, R.M. Post*, P. W. Gold*. Clinical Neuroendocrinology Branch, National Institute of Mental Health Intramural Research Program, Bethesda, MD 20892.

MD 20892.

Heat shock proteins (HSP) have been implicated in a number of neuronal responses to stress. HSP may play a role in cellular repair/protection mechanisms, and they have been suggested to be markers for neural injury (Gonzalez et al., 1989). HSPs gene expression increases locally during tissue injury, ischemia, adenovirus infection, and hypertermia. More recently, HSP have also been implicated in generalized status epilepticus (Lowenstein et al 1989). We examined the induction of mRNAs for HSPs 70 (HSP of about 70 kilodaltons) and 84 (HSP of about 84 kilodaltons), in rat hippocampi that were subjected to electrical kindling. Male Sprague-Dawley rats were stereotaxically implanted with electrodes in the amygdala and received subconvulsive electrical stimulation (800 µA, 60 Hz, 1ms for 1 sec.), 1-2/days for 2 weeks. Animals were considered kindled after the development of 3 stage-5 seizures and were sacrificed 2 hours, 24 hours, or 3 weeks after their last seizure. Control animals with amygdala electodes never received electrical stimuli. Brain sections were cut through the dorsal hippocampus sections and in situ hybridization was done using 35S-dATP labelled oligodeoxynucleotide probes for HSP70 and HSP84. Section were apposed to films and quantified by densiometry and dipped in NT-2 emulsion (Kodak). Both HSP mRNAs had a transient increase (p<0.05) 2 hours after their last seizures.

STIMULATION EVOKED CHANGES IN INTRINSIC OPTICAL SIGNALS IN THE HUMAN BRAIN. <u>B.A.MacVicar</u>, <u>D.Hochman</u>, <u>F.LeBlanc and T.Watson</u>. Neuroscience Research Group, University of Calgary, Calgary, Alberta T2N4N1.

Neuronal activity in several systems has been shown to be associated with changes in the optical properties of nervous tissue. We have asked whether activity in the human neocortex is also associated with changes in intrinsic optical signals. The cortex of patients was exposed during operations to remove seizure foci for the treatment of intractable epilepsy. Stimulation by silver ball electrodes was normally performed during these operations to map key motor and sensory areas. During electrical stimulation, video imaging of the cortex was performed to ascertain whether there were changes in the reflectance of the tissue during stimulus-Digitized images were averaged during evoked activity. stimulation and were subtracted from averages obtained during control periods. During stimulation there was a progressive decrease in tissue reflectance around the stimulating electrodes. This change was repeatable and was graded with changes in stimulus intensity. These results indicate that non-invasive video imaging of changes in intrinsic optical signals could potentially be used to map areas of cortical neuronal activity during

PROCESS OUTGROWTH, GROWTH CONES AND GUIDANCE MECHANISMS II

139.1

AXONAL PATHFINDING IN THE CORD OF ZEBRAFISH MUTANTS MISSING THE FLOOR PLATE (FP).J.Y. Kuwada & K. Hatta, Dept. Biology, U. of Michigan, Ann Arbor, MI 48109 & Institute of Neurosci., U. of Oregon, Eugene, OR 97403.

In the cord of zebrafish embryos the growth cones of

the ascending commissural (Co) and VeLD neurons exhibit cell-specific behaviors in the immediate vicinity of the FP cells. Both neurons initially project growth cones ventrally towards the FP. The Co growth cone crosses the midline and turns rostral and dorsal while in apparent contact with the FP. The VeLD growth cone does not cross the midline, instead it turns caudal along the FP. These observations suggest that the FP may have multiple, cellspecific effects on spinal growth cones in the zebrafish embryo. We have examined this by analysis of cyc-1 mutants in which FP cells fail to develop. We find that Co and VeLD neurons (n=77) all extend to the ventral midline but that approximately 40% then make errors in pathfinding. Two examples of errors are Co axons fail to cross the midline but turn rostral and dorsal, and VeLD axons ascend. These results 1) suggest that the FP is not necessary for extension of growth cones to the ventral midline, and 2) are consistent with the existence of multiple, partially redundant growth cone guidance mechanisms. The removal of one mechanism may degrade the fidelity of cell-specific pathfinding normally insured by multiple and redundant mechanisms of growth cone guidance in the zebrafish cord. (Supported by NIH, MOD, and NSF .)

139.2

FLOOR PLATE (FP) ABLATIONS INDUCE AIONAL PATHFINDING ERRORS BY SPINAL COMMISSURAL CELLS IN THE ZEBRAFISH EMBRYO. R.R. Bernhardt & J.Y. Kuwada, Dept. Biology, Univ. of Michigan, Ann Arbor, MI 48109.

The growth cones of ascending commissural (Co) cells extend ventrally and cross the ventral midline by inserting between a row of FP cells and the basal lamina surrounding the cord. They then extend rostrally and dorsally along a diagonal pathway to reach and ascend in a dorsal tract (DLF). We have tested the role of FP cells for guidance of Co growth cones by laser ablating the FP. Ablations did not affect ventral outgrowth of Co axons indicating that the FP is not necessary for ventral extension. However, 3 kinds of errors were observed at the midline. Axons crossed the midline and ascended in an abnormal ventral pathway for at least 2 segments before drifting dorsally to reach the DLF. Other axons did not cross the midline and either turned rostrally and dorsally or caudally and dorsally to ascend or descend, respectively, in the ipsilateral DLF. Normal Co axons were also observed in experimental segments. Together with control ablations of ventrolateral cells, this argues against mechanical blockage as a cause of errors. The increase in Co abnormal trajectories suggests that the FP cells are one of a set of pathfinding cues at the midline. Removal of one cue leads to errors but does not eliminate the capacity for directed axonal outgrowth. (Supported by Swiss NSF, NIH, MOD, and UM.)

A MUTATION THAT DELETES THE FLOOR PLATE AND DISTURBS AXONAL PATHFINDING IN ZEBRAFISH. K. Hatta*, R.K. Ho*, C. Walker*, & C. B. Kim

Inst. of Neuroscience, Univ. of Oregon, Eugene, OR 97403. In the early zebrafish embryo, the floor plate (FP) is a single row of immunologically distinctive cells extending through the spinal cord and into the brain. The entire floor of the CNS, including the FP, fails to develop in embryos bearing the "cyclops" mutation *cyc-1(b16)*. The phenotype appears during late gastrulation and is rescued by orthotopic transplantation of wild-type gastrula ectoderm into mutants, suggesting, but not yet establishing, that the mutation acts cell-autonomously to block FP specification.

cyc-1 also causes defasciculation and invasion into the midline of longitudinal axonal pathways that normally neighbor the FP. These pathways include axons derived from identified reticulospinal neurons such as the Mauthner cells. The pathways look normal where they border wild-type FP transplanted into mutants, and ablation of the FP in wild-type embryos by laser-irradiation produces a local phenocopy of the axonal disruption. These findings suggest that the axonal disturbances in *cyc-1* arise because of loss of the FP, that normally provides essential cues for axonal guidance. (Supported by the NIH.)

Interactions of optic fibers with the pre-existing tracts

Interactions of optic fibers with the pre-existing tracts of the embryonic zebrafish. J. D. Burrill and S. S. Easter, Jr., Dept. of Biology, Univ. of Michigan.

The first retinal ganglion cells of the zebrafish extend an axon at 32-36h, and reach the tectum about 46-48h, after crossing three pre-existing tracts.

The optic axons of fixed embryos were labelled by intracular injections of Dil, and in some the tract of the posterior commissure (TPC) and the dorsoventral diencephalic tract (DVDT) were also labelled with DiO. Wholemounts were viewed in a fluorescence microscope, and some were photoconverted and viewed as wholemounts or in sections.

The leading growth cones were visualized at 47-49h in 10 doubly labelled preparations, and in 23 with only the optic fibers labelled. The only deviations from the normal optic projection were at intersections with other tracts. In 8, some optic axons grew parallel to TPC fibers. In 2, some failed to leave the tract of the postoptic commissure with the others, and continued caudally. In no cases did the optic axons join the supraoptic tract (SOT), DVDT, or the contralateral optic nerve. 28 hatchlings, 5-7d, were labelled intraocularly. In 6, a single axon deviated from the normal pretectal projection pattern, and turned rostrally along the SOT into the telencephalon.

These observations suggest that optic axons are led astray by other axons, and raise the question of why such deviations are so infrequent.

139.7

DYNAMICS OF AXONAL GROWTH AND ARBOR FORMATION DURING DEVELOPMENT OF THE RETINOTECTAL PROJECTION IN ZEBRAFISH EMBRYOS. R.J. Kaethner and C.A.O. Stuermer. Friedrich-Miescher-Laboratorium der Max-Planck-Gesellschaft, Tuebingen, FRG.

Individual retinal axons were observed over 3 to 13 hrs during their growth to their target and during the process of terminal arbor formation in the tectum of living zebrafish embryos. Axons were labeled by inserting crystals of DiI or DiO $\,$ into defined regions of the retina in embryos of 50-60 hrs postfertilization (pF) and viewed with low intensity light and a SIT Camera between 70-120 hrs pF.

During their growth through the optic tract and the tectum the axons are lead

by a single growth cone and only occasionally emit transient sidebranches of up to $20\mu m$ in length. The average axonal growth velocity is in the optic tract $18\mu m/hr$ and $10\mu m/hr$ in the tectum. Axons grow directed towards their retinotopic target. Here they cease to elongate and emit sidebranches. Branches extend and retract lamellipodia and filopodia in a rapid sequence. Initially neither one of the branches is stable and primary, secondary and higher order branches are withdrawn and new ones created. With time, one or two branches become stable. The rapid sequence of branch extension and retraction, however, continues on the higher order sidebranches, and is still seen in embryos at

This branch turn-over may last longer and could perhaps be necessary for the process of "shifting" (Easter and Stuermer, 1984). Whether these dynamical changes during arbor formation involve formation and breakage of synapses is currently under investigation.

139 4

Larly Generation of Tracts in the Zebrafish Brain.

L.S. Ross, T.J. Parrett* and S.S. Easter, Jr. Dept. of Biology,
University of Michigan, Ann Arbor, MI 48109.

The zebrafish brain at 24 hours is characterized by a small number of spatially distinct axon tracts that form a simple scaffold (Wilson et al.,

Dev. 108:121, 1990). We have examined the earliest formation of these axon tracts in the forebrain and midbrain of the embryonic zebrafish using acetylcholinesterase (AChE) expression to label differentiated neurons as well as antibodies to HNK-l to label axons.

The first AChE-positive cells in the brain appeared at 16 hours as The first AChE-positive cells in the brain appeared at 16 hours as small clusters in the presumptive telencephalon, diencephalon, ventral tegmental area, and hindbrain. At each stage thereafter, more labeled cells were added to these pre-existing populations. At some stages, new clusters of labeled cells appeared elsewhere in the brain These new clusters were in the anlage of the epiphysis at 18 hours, in the region of the posterior commissure, rostral tectum, and pituitary at 24 hours, and in the caudal hypothalamus at 30 hours. The number of labeled cells in the stage of the labeled cells in the stage of the labeled cells. increased most rapidly in the telencephalon and diencephalon, and cells continued to be added to these two regions after the counts in other regions had reached a plateau.

The first HNK-1 positive cells in the forebrain and midbrain also appeared at 16 hours, as a small (2-3 cells) cluster in the ventral tegmental area. The cells of the ventral tegmental area extended axons caudally toward the hindbrain, pioneering the ventral longitudinal tract. At 18 hours, a second tract was established by the caudal extension of the state of the process in the dispension to form the tract of the protection components. axons in the diencephalon to form the tract of the postoptic commissure. At 20 hours, the supraoptic tract was formed by a large cluster of telencephalic cells. (Supported by NIH EY-00168 and EY-07022).

139.6

APPEARANCE AND DISTRIBUTION OF GFAP IMMUNOREACTIVITY IN THE EMBRYONIC ZEBRAFISH CNS. R.C. Marcus and S.S. Easter, Jr. Department of Biology, Neuroscience Program, University of Michigan, Ann Arbor, MI 48109. The earliest tracts in the brain appear between 16 and 18h of development and enlarge thereafter (unpublished, and Wilson et al., Development 108:121, 1990). To better characterize the cellular environment which axons traverse, an antibody against goldfish GFAP (Nona et al., Glia 2:189, 1989) was used to stain sections and wholemounts of zebrafish at 12, 14, 15, 16, 18, 21, 24, 27, 30, 33, and 48h. and 48h.

GFAP immunoreactivity was first seen at 15h. At 16h it was distributed uniformly along the ventro-lateral pial surface throughout the CNS, but the dorsal surface and the ventral midline were GFAPnegative. The presence of label in regions where tracts are formed suggests GFAP-positive endfeet may contribute to the permissiveness of the superficial lamina for axonal growth. This same distribution is maintained at later times, but modified in three ways: 1) long GFAPmaintained at later times, but modified in three ways: 1) long GFAP-positive radial processes intersperse with the axons in the developing tracts, 2) the GFAP-positive superficial label gradually becomes restricted to the tracts, and 3) GFAP-positive tangentially oriented fibers cross the ventral midline in the mid and hindbrains. The persistence of label in the tracts may reflect a role for glial cells in the maintenance of axonal pathways. The relationship of the GFAP-positive cells to the developing tracts was confirmed by showing that the neuronal marker, the HNK-1 antibody, labeled in the same regions as anti-GFAP. Electron microscopic studies are under way to further investigate this Electron microscopic studies are under way to further investigate this relationship. Supported by EY00168 to SSE

MONOCLONAL ANTIBODY E21 RECOGNIZES NEW AND RE-GENERATING RETINAL AXONS IN GOLDFISH. K.A. Wehner and C.A.O. Stuermer, Friedrich-Miescher-Laboratorium, Max-Planck-Gesellschaft., Tuebingen, FRG.

In adult goldfish growing retinal axons from newly added ganglion cells and axons regenerating after optic nerve section (ONS) express several growth specific cell surface proteins. These were detected by monoclonal antibodies, D3, 6587 and Reggie, and are N-CAM 180 (Bastmeyer et al., 1990), a 200 kD (Vielmetter and Stuermer, 1989) and a 50 kD protein (Wehner and Stuermer, 1989).

By immunizing mice with cell surface membranes of regenerating goldfish optic nerves we obtained a new monoclonal antibody, E21, and detected another cell surface associated protein, that is expressed on newly added and re-expressed on regenerating goldfish retinal axons. Like N-CAM 180, the 200 kD and 50 kD proteins, the re-expression of the E21-antigen on regenerating retinal axons declines with time after ONS and is no longer detectable at 10 months after ONS.

The immunoaffinity-purified antigen has an apparent MW of 84 kD, is glycosylated and carries the HNK-1 sugar moiety. Sequence analysis of 15 amino acids at the N-terminus revealed, to this point, no homology with known neuronal proteins.

SUBPLATE NEURONS "PIONEER" THE OUTPUT PATHWAY OF RAT CORTEX BUT NOT PATHWAYS TO BRAINSTEM OR SPINAL TARGETS.

[J.A. De Carlos and D.D.M. O'Leary Depts of Neurosurgery and of Anatomy & Neurobiology, Washington Univ Sch Med, St Louis, MO 63110

Preplate (PP) cells are the first cortical neurons generated and aggregate below the pial surface. The later generated, cortical plate (CP) neurons accumulate in the PP and split it into a marginal zone and subplate (SP). McConnell et al (1989 Science 245-978) find in cats that SP neurons send the first axons through the internal capsule (IC), the path taken by layer 6 axons to thalamus and by layer 5 axons enroute to brainstem and spinal cord. Layer 5 axons exit cortex via the IC and bypass their brainstem targets (e.g. superior colliculus - SC) as they extend through the cerebral peduncle, pyramidal tract (PT) and into the spinal cord; later collaterals form along the primary axons and take distinct paths to the brainstem targets (O'Leary & Terashima 1988 Neuron 1:901; 1989 Soc NS Abs 15:875). Here we address in rats whether SP neurons "pioneer" the subcortical paths of layer 5 axons by using the tracers Dil and RITC. Dil labeled axons are seen in the developing cortex on E13, and first exit cortex and enter the nascent IC on E14. These axons are from rostral cortex, axons from caudal cortex are growing rostrally in the nascent intermediate zone. Backfilling from rostral cortex on E13 and IC on E14 identifies the cells of origin as PP neurons based on position and morphology (also the first CP neurons are born on E14 and the CP is first identified on E15-E16). No afferent axons are labeled from the IC on E14. Labeled axons reach the cerebral peduncle on E17: at this age both SP and CP cells are backfilled evith Dil from the born on E14 and the CP is first identified on E15-E16). No afferent axons are labeled from the IC on E14. Labeled axons reach the cerebral peduncle on E17; at this age both SP and CP cells are backfilled with Dil from the IC. To determine if SP axons grow down the PT or to the SC, RITC was injected into them in newborn rats. Layer 5 axons reach PT on E21 and SC at P1.5. SP cells are not labeled from either site. We conclude that in rats SP neurons send the first axons into the IC, but SP axons do not "pioneer" the more distal subcortical path of the primary axons of layer 5 neurons, nor the paths taken to their targets by their later forming collaterals.

139.11

IN VIVO EVIDENCE FOR TARGET CONTROL OF COLLATERAL FORMATION AND DIRECTIONAL AXON GROWTH IN MAMMALIAN BRAIN A. Missias, L. Kutka', B.S. Reinoso and D.D.M. O'Leary. Depts of Neurosurgery and Anatomy & Neurobiology, Washington Univ Sch Med, St Louis, MO 63110.

The corticopontine projection develops by a delayed interstitial budding of collaterals from layer 5 corticospinal axons, rather than by a direct

or conserens from layer 3 cornecospinal axons, rather than by a direct ingrowth of primary axons or by bifurcation of the growth cone. Branches form in the axon tract overlying the basilar pons (BP) and extend directly into it (O'Leary & Terashima 1988 Neuron 1:901). In vitro studies suggest that a diffusible tropic substance released by the BP can elicit the formation into it (O'Leary & Terashima 1988 Neuron 1:901). In vitro studies suggest that a diffusible tropic substance released by the BP can elicit the formation and directional growth of collateral branches from layer 5 axons (Heffner, Lumsden & O'Leary '90 Science 247:217; Heffner & O'Leary '90 Sco NS Abs). Here we present in vivo experiments that support this chemotropic mechanism. First, we x-irradiated fetal rats during the generation and migration of BP neurons, resulting in a reduction in the BP and the formation of ectopic islands of BP neurons beneath the path of layer 5 axons. Dil labeling reveals that layer 5 axons form collateral branches directly over the reduced BP, and over the ectopic islands of BP neurons - points where branches normally do not form. No branches form at positions that would normally overlie BP. Thus, the BP, rather than local cues in the axon tract, seems to control the location of cortical axon branching. Second, we prevented cortical axons from invading the right BP. We reasoned that if BP was attracting cortical innervation by a diffusible tropic activity, developing cortical axons on the left side should be lured to the right BP. Indeed, Dil labeling shows that an abnormally large number of layer 5 axons cross the midline at the level of the BP and grow into the denervated side. Finally, we find that late arriving layer 5 axons will grow directly into the BP if early arriving axons are removed. Thus, the growth cone of primary layer 5 axons is receptive to cues that identify the BP. Based on these and our in vitro findings, we conclude that the basilar pons attracts its cortical innervation through the release of a diffusible chemotropic molecule.

139.13

MOTONEURON SPECIFICATION IN THE LUMBOSACRAL SPINAL CORD OF THE CHICK EMBRYO. <u>C. Lance Jones</u>. Dept. of Neurobiology, Anatomy, and Cell Science, Univ. of Pittsburgh, Sch. of Med., Pittsburgh, PA 15261. Studies in the chick embryo indicate that lumbosacral

(LS) motoneurons are specified with respect to muscle target before sending axons into the hindlimb. How and when does this specification occur? LS motoneurons may be specified as they form a motor column, a mode of specification likely to be dependent on interactions with other spinal cord components. To begin to address this hypothesis I have asked if motoneurons within a piece of ventral neural tube, 1/3-1 segment in length, can project appropriately when placed in a foreign motor column site. At stage 15 the neural tube piece with some underlying notochord was removed from axial levels LS1, 2, or 3 in a quail embryo. In a chick embryo, all or most of the LS1-3 neural tube segments were removed and the quail tissue positioned in an incorrect position within the gap (i.e. an LS1 piece in place of LS3 and adjacent to LS4). St 29-30 chimeras were fixed, paraffin adjacent to LS4). St 29-30 chimeras were fixed, paraffin sectioned, and stained with a quail-specific antiserum. Motoneuron axons stained by the antiserum projected to their originally appropriate muscle targets. These observations suggest that motoneuron specification within a 1/3-1 segment neural tube piece is independent of the adjacent dorsal spinal cord and the presence of correct neighboring segments.

AXON TARGETING POTENTIALS OF LAYER 5 PROJECTION NEURONS ACROSS THE DEVELOPING CORTEX. A.R. Bicknese and D.D.M. O'Leary, Depts of Neurology and Neurological Surgery and of Anatomy and Neurobiology, Washington Univ Sch Med, St. Louis, MO 63110

Neurons in layer 5b of the mammalian neocortex are the source of

Neurons in layer 5b of the mammalian neocortex are the source of cortical projections to targets in the brainstem and spinal cord. Dil labeling of developing 5b axons shows that each brainstem target is contacted exclusively by collateral branches extended from spinally-directed primary axons. 5b neurons in motor and visual areas develop a similar set of axon branches from which the area-distinct projections in the adult emerge via the selective loss of axon branches and/or segments of the primary axon (O'Leary & Terashima 1988 Neuron 1:901; O'Leary & Terashima 1989 Soc NS Abtsr 15:875). Here we address whether subcortically projecting 5b neurons are equipotential in axon targeting by focusing on branched projections to two brainstem targets, the superior colliculus (SC) and dorsal column nuclei (DCN). We provide evidence that: (1) as a population 5b neurons in all neocortical areas initially form this set of branches, (2) individual 5b neurons are competent to form each of the branches, (3) individual 5b neurons can form both branches. The retrograde dyes Diamidino Yellow and Fast Blue were injected in the SC and DCN of neonatal rats to label neurons that send branches to them, and into the spinal cord (SpCd) to and Fast Blue were injected in the SC and DCN of neonatal rats to label neurons that send branches to them, and into the spinal cord (SpCd) to label the primary axon. 5b neurons that send branches to the SC or DCN are distributed across the entire, tangential extent of neocortex. Neurons that send branches to the SC or DCN and/or a primary axon to the SpCd are coextensive over the radial extent of layer 5b. Many 5b neurons are double labeled when one dye is injected into the SC or DCN and the other into SpCd, and when the SC and DCN are injected with different dyes. Our findings suggest that subcortically projecting layer 5b neurons throughout the developing neocortex have similar potentials in axon targeting, and belong to the same neuronal class, even though they may ultimately have distinct projections in the adult. SPATIALLY COMPLEX EXPRESSION OF NEURON-SPECIFIC ANTIGENS DURING PERIPHERAL PATHFINDING. Landmesser, L.T., S. Swain*, S. Ou*, and P. Patterson. Dept. Physiol. & Neurobiol., Univ. Connecticut, Storrs, CT 06269, and Div. Biology, Cal Tech, Pasadena, CA 91125.

In the chick limb the axons of sensory and motor neurons exhibit a series of specific pathway choices as they project into the limb between st 23-30. To study the molecular basis of specific pathfinding, monoclonal antibodies were generated to a membrane preparation of st 27-30 peripheral nerve using the cyclophosphamide immune suppression method to reduce the response to common and/or abundant antigens; and the resultant clones screened on frozen sections. Among the neuron-specific clones, the following exhibited staining patterns consistent with a role in pathfinding. 9C11 recognizes a cell surface epitope expressed on cells in the lateral motor column from motoneuron outgrowth (st 22) through muscle nerve formation (st 28). Although 9C11 uniformly stains axons within major nerve trunks and muscle nerves, does not stain the intramuscular portion of the axon. 5E10 recognizes an antigen sequentially expressed on different subsets of sensory and motor axons at precise proximo-distal levels, staining axons only from the point at which they diverge to follow specific pathway choices, until they reach their targets; within muscle staining was weak. Thus this antigen appears to be part of the neuron's mechanism to detect and/or respond to specific target-related cues. Support: NIH NS-19640

METABOLIC ENZYMES FOR QUINOLINIC ACID HAVE DIFFERENT AND FUNCTIONALLY SIGNIFICANT LOCALIZATIONS IN THE RAT MAIN OLFACTORY BULB. M.R. Poston', M.S. Bailey', R. Schwarcz' and M.T. Shipley'. Dept. of Anatomy & Cell Biology, Univ. of Cincinnati, Cincinnati, OH 45267 and Maryland Psychiatric Research Center, Baltimore, MD 21228.

Quinolinic acid (QUIN) is an excitotoxin endogenous to the brain. Previous studies demonstrated that QUIN's synthetic enzyme 3HAO (3 hydroxyanthranilic acid oxygenase) and degradative enzyme QPRT (quinolinic acid phosphoribosyltransferase) are preferentially expressed (quinoillic acid phosphorioosyltransferase) are preferentially expressed in glial cells widely distributed throughout the brain, including the main olfactory bulb (MOB). Since 1) excitatory amino acids can influence growth cone motility, and 2) primary olfactory neurons (PON) are replaced throughout adult life, the existence of QUIN in MOB astrocytes could function to modulate the motility of new PON axons reaching the bulb.

We report that QPRT and 3HAO have a complementary distribution just superficial and just deep, respectively, to the glomerular layer (GL) where PON axons terminate. QPRT antibody staining is heaviest at the nerve layer-glomerular interface where PON axons enter the GL; 3HAO staining is heaviest in the external plexiform layer (EPL) just deep to the GL. This suggests a gradient of QUIN expression high in the EPL, low in the nerve layer. If QUIN stops PON growth cones, a gradient of QUIN might function to restrict the ingrowth of new PON axons to the glomeruli. Supported by NIDCD-DC00347, NS 16102.

THE CORTICOSPINAL TRACT IN THE ABSENCE OF CNS MYELIN. <u>B. B. Stanfield</u>. Lab. of Clinical Science, NIMH, NIHAC, Poolesville, MD 20837.

Since myelination normally occurs relatively late in neural development and, in any given fiber pathway, well after axonal extension is complete, it has generally been assumed that myelin plays no role in the initial formation of axonal projections. Recently however it has been shown that CNS myelin can inhibit neurite extension in vitro, and thus the myelination of early developing pathways oculd influence the formation of later developing projections. One late developing pathway in which such interactions might occur is the corticospinal projection. Corticospinal axons have only begun to enter the cervical cord at a stage when myelination is already well under way in other spinal pathways, including the adjacent gracile and cuneate fasciculi. I therefore examined the disposition of the corticospinal tract in the dysmyelinated mutant mouse, jimpy (jp). Jimpy is an X-linked, juvenile-lethal mutation in which the lack of oligodendrocyte differentiation together with frank oligodendrocyte loss results in the virtual absence of myelin from the CNS.

To label the corticospinal tract I injected WGA-HRP or biocytin into the rostral neocortex of 15 to 19 day old hemizygous jimpy mice (jp/Y) and littermate controls (X/Y O's or ?/X O's). One day later the animals were perfused with fixative and the brains and spinal cords were processed appropriately. In both jimpy and normal mice the corticospinal fibers traverse the medulla along its ventral aspect in a well-defined pyramidal tract, decussate in several fascicles at the spinomedullary junction and extend down the spinal cord in a compact bundle in the ventral part of the dorsal funiculus, just beneath the ascending primary sensory fibers. Even in the virtual absence of central myelin, the trajectory of the corticospinal tract in jimpy appears to be entirely normal. Thus, while the neurite inhibiting properties of central myelin may prevent neurite extension and axonal sprouting and thereby help stabilize existing pathways within the mature CNS, the disposition of the corticospinal tract in jimpy suggests that CNS myelin does not play a critical role in pathway selection during the development of this projection.

139.17

TARGET SPECIFIC OUTGROWTH OF DIFFERENT TYPES OF VASOPRESSIN NEURONS TRANSPLANTED INTO VASOPRESSIN-DEFICIENT BRATTLEBORO RATS. H.A. Al-Shamma, and G.J. De Vries. Program in Neuroscience and Behavior, Univ. of Massachusetts, Amherst, MA

Suprachiasmatic nucleus (SCN) grafts in Brattleboro rats show specific outgrowth of vasopressin (VP) fibers into areas that are innervated by the SCN in non-deficient rats (Wiegand SJ, Gash DM, J. Comp. Neur. 265:562 '88; Boer GJ et al., Neurosci. 15:1087 '85). We compared the outgrowth of VP fibers from grafts of the SCN, bed nucleus of the stria terminalis (BST) and medial amygdaloid nucleus (MA) of fetal long evans rats. These grafts were placed into the lateral ventricle of adult Brattleboro rats. Eight weeks later, these rats were sacrificed, and immunocytochemically stained sections of their brains were studied using computerized image analysis. Grafts of the SCN showed very little outgrowth of VP fibers into the lateral septum (LS), which correlates with the absence of VP innervation from the SCN to the LS in non-deficient rats. In contrast, grafts of the bed nucleus of the stria terminalis (BST) showed significantly denser VP outgrowth into the LS (p<0.05), which correlates with the dense VP projections from the BST to the LS in non-deficient rats. MA grafts showed a similar pattern of outgrowth as did BST grafts. This is remarkable, since in contrast to the BST, the MA does not appear to send dense VP projections to the LS in non-deficient rats. However, the MA and BST supposedly share a common evolutionary lineage (Alheid GF, Heimer L, Neurosci. 27:1 '88) and are similar in many other respects (neurotransmitter content, steroid sensitivity, morphology etc.). Thus, our findings suggest that the VP neurons of these two nuclei may also follow similar cues to reach their target.

139.16

IS THE PITUITARY CHEMOTROPIC TO GNRH AXONAL OUTGROWTH FROM PREOPTIC AREA (POA) GRAFTS IN HYPOGONADAL (HPG) MICE? M.J.Gibson, Y.Saitoh, and A.J.Silverman. Department Medicine, Mount Sinai Sch. of Medicine, New York, NY 10029 and Columbia Coll. Phys.& Surgeons. New York, NY 10032.

and Columbia Coll. Phys.& Surgeons, New York, NY 10032. GnRH fibers consistently grow out of intraventricular (3rdV) POA grafts in hpg mice to the median eminence (ME) of the GnRH-deficient hosts. GnRH axons there terminate on capillaries of the pituitary-portal plexus; resultant stimulation of the hpg gonadotrophs leads to corrected reproductive function. In continuing studies to determine the factor(s) mediating this directed outgrowth, we are evaluating the role of the pituitary (PIT): (1) Hpgs were given 3rdV fetal co-grafts of PIT+POA, muscle+POA, or POA alone. After 1 mo, 2 hpg with POA had increased testes wt (54.9±1.3 mg) and GnRH innervation of the ME. In 3 mice with POA+2PITs testes wts were 15.6±4.5 mg. GnRH neurons in PIT co-grafts were often in large clusters with thick fascicles of axons but with only modest GnRH outgrowth in the ME. GnRH axons entered PIT co-grafts and were often in apposition to growth hormone cells. Muscle in co-grafts degenerated into a fibroblastic mass which the GnRH axons appeared to actively avoid. (2) Hpg mice were hypophysectomized (HYPOX) 1-2 wk before POA graft surgery. GnRH innervation was absent or sparse in the anterior and mid-ME, with some outgrowth in the post-infundibulum in 4 of 5 mice studied 1-4 wk after HYPOX. Together, these studies suggest that the pituitary may exert a chemotropic influence on GnRH axonal development.

PROCESS OUTGROWTH, GROWTH CONES AND GUIDANCE MECHANISMS III

140.1

THROMBOSPONDIN PROMOTES AXONAL GROWTH IN SYMPATHETIC NEURONS. D.J. Osterhout and D. Higgins, Dept. of Pharmacology, State Univ. of New York, Buffalo, N.Y.14214 Thrombospondin (TSP) is an extracellular matrix protein

Thrombospondin (TSP) is an extracellular matrix protein which has been detected in both the central and peripheral nervous systems. We examined its effects on cultures of neurons dissociated from embryonic rat sympathetic (21d) ganglia. Neurons were plated in serum-free medium onto poly-D-lysine coated coverslips with or without adsorbed TSP. After 24 hours, TSP had caused a 6-fold increase in the number of neurons extending processes; it also increased the number of processes/neuron and the total neuritic length. Processes formed in the presence of TSP had the cytochemical characteristics of axons; dendrites were not observed. Maximal effects of TSP were obtained with precoating concentrations of 100 ug/ml; similar concentrations of fibronectin, fibrinogen or albumin failed to elicit significant process extension. The neurite-promoting activity of TSP was blocked by a monoclonal antibody (A4.1) directed to the stalk region of the molecule. These data suggest that TSP could participate in regulating axonal outgrowth in situ. (supported by NSF #8909373 and NIH GMO 7145)

140.

NEURAL CREST CELLS UTILIZE THROMBOSPONDIN AS A MIGRATORY SUBSTRATUM IN SITU. L.J. BOYNE, K.S. O'SHEA, V.M. DIXITT. Univ. of Michigan Medical School, Ann Arbor, MI 48109.

Thrombospondin (TSP) is a trimeric glycoprotein temporally and spatially located along the neural crest cell (NCC) migratory pathway. TSP supports NCC migration in vitro to a greater extent than fibronectin and that addition of anti-TSP antibodies inhibited migration on TSP. To determine if TSP is a substrate for NCC migration in situ, day 9 mouse embryos (plug+=day 1) were injected with 10 ul anti-TSP IgG unilaterally in the thoracolumbar region of the developing spinal cord. Control embryos were injected with 10 ul pre-immune serum or PBS. Embryos were allowed to develop for an additional 8 hours in whole embryo culture and then fixed, sectioned, and progress of NCC migration and morphology examined. Injection of anti-TSP antibodies but not PBS or pre-immune serum into the mesenchyme resulted in cell rounding and inhibition of cell migration. Consistant with their ability to migrate on TSP in vitro, NCC utilize TSP as a migratory substratum in situ. Supported by NIH grant HD-23867.

PROTHROMBIN mRNA IS EXPRESSED IN RAT BRAIN. M. Dihanich*, E. Reinhard and D. Monard. Friedrich Miescher Institute, 4002-Basel, Switzerland.

Glia-derived Nexin (GDN) is a serine protease inhibitor mainly expressed in the brain, but also in the peripheral nervous system during also in the peripheral nervous system during nerve regeneration. Its function in the brain is still largely unknown, but in vitro experiments suggest a role in the proteolytic balance regulating neurite outgrowth. Since thrombin, a serine protease of the blood coagulation system, antagonizes neurite outgrowth and is by far the best target protease for GDN in vitro, a thrombin-like protease might also interact with GDN in the brain. Investigation of rat brain mRNA isolated from various developmental states (E16, E20, P5, P10, P21, adult) by quantitative PCR, Northern analysis and in situ hybridization indicate that thrombin itself is expressed in the brain, especially during early development. A comparison of thrombin sequences development. A comparison of thrombin sequences cloned from both rat liver and rat brain shows that nerve cells produce the same enzyme as liver cells. Both neuronal and glial cell lines are capable of expressing prothrombin mRNA. Future experiments will investigate the regulation of thrombin expression and its possible role in nerve degeneration and regeneration.

GROWTH INHIBITION OF GOLDFISH OPTIC AXONS IN VITRO BY NICOTINE. Ronald L. Meyer and Thomas H. Hogan*. Developmental Biology Center, University of California, Irvine, CA 92717.

The activity rearrangement of optic fibers during the formation of the retinotectal projection implies the existence of retrograde activity mediated signal affecting growing fibers. Since transmitter release is good candidate for this, the capacity of neurotransmitters to regulation axonal growth was tested. Retinal explants were made onto laminin-polylysine coated coverslips and the outgrowing neurites, which filled several criteria for being optic axons, were monitored by timelapse videomicroscopy. A number of neurotransmitters (and agonists) including glutamate, serotonin and dopamine were added to the culture media without notable effect. TTX also had no effect. Nicotine at 50 μm, however, rapidly and were added to the culture media without notable effect. TTX also had no effect. Nicotine at $50~\mu m$, however, rapidly and strongly inhibited filopodial movement and growth. This inhibition could be antagonized by curare and a-bungarotoxin. Nicotine was equally effective when delivered locally to the growth cone with a micropipette. We speculate that nicotinic cholinergic receptors may be a component of a retrograde regulatory signal. This work was supported by EY06746.

EVIDENCE FOR THE DELINEATION OF NEURAL CREST MIGRATION PATHWAYS BY INHIBITORY BOUNDARIES K.W. Tosney. Biol. Dept. and Neurosci. Program, Univ. of Michigan, Ann Arbor, MI 48109 and Zool. Dept., Univ. Cal., Davis, CA 95616. We have demonstrated that tissues known to act as barriers to axon

We have demonstrated that tissues known to act as barriers to axon advance in vivo also express peanut agglutinin (PNA) binding epitopes (Oakley and Tosney NS Abstr. 347.7, 1988). We are characterizing the binding of PNA in relation to neural crest migration in the chick embryo to determine if PNA binding is also typical of tissues that exclude neural crest cells. We determine the distribution of neural crest cells using the HNK-1 antibody with both frozen sections and the whole mount staining method of Loring and Erickson (Dev. Biol. 121:220, 1987). We find a differential binding of PNA within the posterior half of early epithelial somites prior to the invasion of the anterior half sclerotome by the earliest migrating neural crest cells. This suggests that PNA binding epitopes may inhibit migration in the posterior sclerotome and thereby contribute to the preferential migration through the anterior sclerotome. We also find consistent HNK-1 labeling of the neural crest cells that enter the dorsolateral melanocyte pathway between the ectoderm and the dermamyotome using the whole mount method. These crest cells enter

dermamyotome using the whole mount method. These crest cells enter the dorsolateral path approximately 24 hours after the first crest cells have invaded the anterior sclerotome. We find that the delayed entry of the premelanocyte population is correlated with a diminution of PNA binding within the dorsolateral pathway. These results suggest that PNA binding epitopes may restrict neural crest migration in at least some pathways. Supported by NIH grant NS-21308.

140.4

REGENERATING RETINAL AXONS OF GOLDFISH RESPOND TO A REPELLENT GUIDING COMPONENT ON CAUDAL TECTAL MEMBRANES OF ADULT FISH AND EMBRYONIC CHICK

J. Vielmetter, J. Walter* and C.A.O. Stuermer, Friedrich-Miescher-Lab./Max Planck-Gesellschaft and *Max-Planck-Inst. f. Entwicklungsbiologie, Tübingen, FRG

We applied the *in vitro* choice assay developed by F. Bonhoeffer for the retinotectal system of embryonic chick (Walter et al., '87) to the retinotectal system of adult goldfish (Vielmetter and Stuermer, '89). On a substrate of alternating rostral (R-)/caudal (C-) tectal membrane stripes of adult goldfish regenerating fish temporal (T-) axons accumulate on R-membranes

Here we demonstrate that fish T-axons (like embryonic chick T-axons) avoid the C-membranes. C-membranes of adult fish -as those of embryonic chick- have a repellent influence on T-axons. This property is abolished when C-membranes are exposed to phosphatidylinositol-specific phospholipase C (PI-PLC). Then T-axons grow randomly over R-/C-stripes. In a cross species choice assay with R-/C-membranes of E9 chick, fish T-axons respond to the repellent properties of C-membranes. Here fish T-axons accumulate on chick R-membranes but cross freely chick R-/C-stripes after PI-PLC-treatment of C-membranes.

When offered to fish axons as the sole substrate fish and more so chick C-membranes have an outgrowth reducing effect on fish T-axons which is abolished after PI-PLC-treatment of these membranes. E16 chick C-membranes, no longer repellent for embryonic chick T-axons (Walter et al., '87), are less outgrowth reducing for fish axons than E9 chick C-membranes

Thus, fish tecta posses a repellent guiding component for retinal axons that is related to the repellent component in chick tecta. Unlike chick, however, fish appear to express this axon guiding component lifelong.

ADDITIONAL PURIFICATION STEPS OF AN ACTIVITY FROM EMBRYONIC CHICK BRAIN THAT INHIBITS NEURONAL GROWTH CONE MOTILITY. D.W. Raible* and J.A. Raper, Dept. of Anatomy, Univ. of Penn. Sch. of Med., Philadelphia, PA 19104

Local environmental cues that guide growth cones to their appropriate targets may either promote or inhibit neurite outgrowth. We recently reported the development of a growth cone collapse assay that has made possible the search for molecules that inhibit neurite outgrowth. Neuronal growth cone collapsing activity from embryonic chick brain was enriched by column chromatography on embryonic chick brain was enriched by column chromatography on heparin and hydroxylapatite (Raper, J.A., Kapfhammer, J.P., Neuron 2:21-29, 1990). We have now identified two additional purification steps that we hope will allow isolation and identity of the collapsing activity.

collapsing activity.

Heparin-purified collapsing activity is retained by the mannose-binding lectins *Lens culinaris* (lentil) agglutinin, Concanavalin A and *Pisum sativum* (pea) agglutinin. Growth cone collapsing activity elutes from *Lens culinaris* agglutinin upon incubation with methyl α-D-glucopyranoside and methyl α-D-mannopyranoside.

Collapsing activity enriched by heparin and hydroxylapatite chromatography can be further purified on a HPLC cation exchange column. The enriched activity binds to a sulfopropyl matrix in buffer containing 0.2 M NaCl and elutes in buffer containing 0.9 M NaCl. We are now combining these isolation steps in sequence so as to further purify the growth cone collapse activity.

140.8

AN ANTIBODY AGAINST A HELISOMA LAMININ-LIKE PROTEIN INHIBITS AN AN IBOUT AGAINST A HELSOMA LAMININ-LIKE PROTEIN INHIBITS OUTGROWTH FROM IDENTIFIED NEURONS IN VITRO. J. D. Miller* and R. D. Hadley. Dept Anat & Cell Biol, Med U of SC, Charleston, SC 29425. Laminin is a potent stimulator of outgrowth from PNS and some CNS neurons in culture, and the laminin B chains are proposed to function as

neurite outgrowth promoting (NOP) factors in some conditioned media (CM). We have identified, and raised a rabbit antibody against, a \sim 300 kD protein in the extracellular matrix (ECM) of the snail, Helisoma, that is antigenically related to the B chains of vertebrate laminin.

related to the B chains of vertebrate laminin.

NOP activity of CM can be abolished either by immunoprecipitation of CM proteins with the anti-~300 kD antibody, or by addition of the anti-~300 kD antibody to CM (at 170 µg/ml). In 3 experiments, a total of 13 B5 neurons were cultured for 3-4 d in antibody-treated CM. No outgrowth from any B5 neuron was observed (100% inhibition) in these experimental plates, although the cells appeared healthy, as evidenced by the formation of veils surrounding the cell bodies. In control plates which were treated with nonimmune IgG, 16 of 17 B5 neurons (94%) exhibited completely normal outgrowth, with neurites at least twice the soma diameter in length.

Immunoblots of Helisoma brain CM probed with the anti-~300 kD antibody, or an antibody against the B chains of vertebrate laminin, reveal a prominent ~300 kD protein, which comigrates with the ~300 kD protein in Helisoma ECM. Reduction of CM proteins with s-mercaptoethanol causes a decrease in the ~300 kD band, with a concomitant increase of a ~190 kD immunoreactive protein. Reduction of the ~300 kD ECM protein does not result in the appearance of an ~190 kD immunoreactive protein, suggesting that the laminin-related protein may be processed during the production of CM. An important question is whether such processing may be necessary for the NOP activity of the $^{\sim}300~\rm{kD}$ laminin-related protein.

SUBSTRATE ADHESIVENESS DOES NOT CORRELATE WITH NEURITE GROWTH AND FASCICULATION. <u>V. Lemmon. G.J. Elmslie*</u>, and M.L. <u>Hlavin*</u>. Departments of Neurosciences and Neurosurgery, Case Western Reserve University, Cleveland, OH 44106.

The differential adhesion hypothesis has had a major influence on the design and interpretation of axon growth and guidance investigations. A major prediction has been that axons prefer to grow on more adhesive substrates. We have compared the relative adhesiveness of different substrates and their ability to promote growth and fasciculation. Neurites were grown from chick retinal explants. The relative adhesiveness of different substrates was determined by squirting tissue culture media from glass pipettes at the neurite growth cones. The pulse duration required to blast a growth cone from the substrate was used as a measure of substrate adhesivity. Growth rates were measured using time-lapse video microscopy.

substrate	laminin	L1	poly-L-lysine
blast duration ms	74 ± 2	181 <u>+</u> 8	179 ± 12
growth rate μm/hr	110±15	56 ± 5	10 ± 2
fasciculation	+	-	+++

These results indicate substrate adhesivity does not primarily determine neurite growth rate. In addition, fasciculation does not correlate with the relative adhesiveness of a substrate. Implications of these results will be discussed.

LACK OF NEURITE OUTGROWTH IN HYDROCEPHALIC MUTANT RAT EMBRYO NEURONS. C.J.D'Amato, K.S.O'Shea and S.P.Hicks Depts. of Pathology, and of Anatomy and Cell Biology, Univ. of Michigan Medical Center, Ann Arbor, MI 48109.

A recessive mutation that arose in long brother-sister mated Wistar albino rats was expressed in homozygous state principally as stenosis of the aqueduct with resultant prenatal hydrocephalus, many animals living to adulthood. A transient structural defect of formation of the basal lamina (BL) of the neuroepithelium of the midbrain-thalamic junction (MTJ) associated with delayed deposition of type IV collagen in that BL occurred during embryonic days 11-13. Normal collagen deposition and BL formation then resumed, but stenotic overgrowth of MTJ ensued. The current study tested whether neurons from 13th day mutant embryo brains were competent to extend neuritic processes on different extracellular matrix substrates. Neurons isolated from mutant and control embryo brains were plated $(5x10^5)$ cells/ml) on petri dishes coated with laminin (25ug/ml), fibronectin (20ug/ml), type IV collagen (20ug/ml), or tissue culture plastic alone (control), and grown in medium composed of 50% BME, 25% fibronectin-depleted horse serum, and 25% HBSS. Neuron responses were recorded photographically at 4 hr intervals for 24 hrs. The length of neuritic processes was measured from the photomicrographs using a digitizing tablet interfaced with a microcomputer. Mutant embryo neurons were unable to extend neurites on any of the substrates, while controls formed elaborate neurites.

MEROSIN, A LAMININ-LIKE MOLECULE, IS ASSOCIATED WITH NEURONAL PROCESSES IN SELECTED REGIONS OF THE ADULT RABBIT CNS. C. Portera-Cailliau*, T. Hagg, E. Engvall*, S. Varon, J.C. Louis, M. Manthorpe, Dept. Biol., M-001, UCSD, La Jolla, CA 92093

Merosin, like laminin, possesses two 200 kD short "B1" and "B2" chains and one 400 kD long "M"-chain, which has about 40% sequence homology with the corresponding laminin "A"-chain. Like laminin it has potent in vitro neuritethe corresponding laminin A -chain. Like laminin it has potent in vitro neutrino promoting activity (Manthorpe et al., <u>Soc. Neurosci. Abstr.</u>, 16, 1990). We have previously described that anti-laminin polyclonal and anti-B₂ monoclonal antibodies react with a "laminin-like" molecule within rat CNS neurons (Hagg et al., <u>Neuron</u> 3:721, 1989). Here we used monoclonal chainspecific antibodies and a sensitive ABC immunochemical staining technique to compare the cellular distribution of B2, A and M chains in the adult rabbit CNS. With all three antibodies immunoreactivity was detected in blood vessel basement membranes. As in rat, most neuronal cell bodies stained intracellularly with anti-B₂ antibodies. With antibodies to M-chain (merosin) no cell body staining was seen but punctate staining associated with neuronal fibers was observed in certain brain regions., e.g. rostral cingulate, insular, perirhinal, piriform and entorhinal cortices, molecular layer and hilus of the dentate gyrus, amygdala and hypothalamus. In addition, M-chain, but not B_2 - or A-chain, antibodies stained 3^{rd} ventricle-associated tanycytes. These results suggest the existence in the brain of multiple forms of "laminin-like" molecules with different chain compositions and different cellular distributions. Supported by NINCDS grants NS-16349, NS-25011 and NSF grants BNS-88-08285, BNS-86-17034.

NCAM DEPENDENT NEURITE OUTGROWTH IS DOWN REGULATED DURING DEVELOPMENT AND INHIBITED BY REMOVAL OF POLYSIALIC ACID FROM NEURONS. P. Doherty, J. Cohen and F.S. Walsh. Depts. Experimental Pathology and Anatomy, UMDS, Guy's Hospital, London SE1 9RT, England.

Neurite lengths have been measured for chick retinal ganglion cells (RGCs) cultured on confluent monolayers of control 3T3 cells and 3T3 cells expressing transfected human NCAM (see Doherty et al., Nature, 343:464-466). NCAM in the monolayer stimulated neurite outgrowth from E6, but not E11 RGCs. This response could be specifically inhibited by removal of & 2-8-linked polysialic acid (PSA) from retinal neurons, treatment with heparin (250 µg/ml) or treatment with antibodies that react exclusively with chick (neuronal) NCAM. These data suggest that NCAM on the marginal endfeet of neuroepithelial cells in the optic tract may stimulate neurite outgrowth from RGCs in a time dependent manner, with this response controlled in part by a down-regulation of expression of PSA on neuronal NCAM NCAM DEPENDENT NEURITE OUTGROWTH IS DOWN REGUin part by a down-regulation of expression of PSA on neuronal NCAM.

140.12

RETRACTION OF GROWING AXONS: CYTOSKELETAL CORRELATES AND ENHANCEMENT OF RESPONSE MAGNITUDE BY LAMININ. S. Finnegan Sloan.* E. Koenig and V. Lemmon. Dept. of Physiology, SUNY at Buffalo, Buffalo, NY 14214, and Center for Neurosciences, Case Western Reserve Univ., Cleveland, OH 44106

Monoclonal antibody (mAb) 8A2 triggers a global retraction response in ganglion cell (RGC) axons regenerating from goldfish retinal explants in vitro which is arrested by cytochalasin D (Soc. Neurosi. Abstr., vol. 15, p. 1027, 1989). The response is characterized by (i) retrieval of axoplasm from growth cones, (ii) aggregation into a distal mass, and (iii) bulk retrograde translocation of axoplasm, leaving evacuated residual strands distally. Induced global retraction may serve as a model of axon elimination during developmental residual strands distally. Induced global retraction may serve as a model of axon elimination during developmental maturation. The 8A2 retraction response is significantly more robust when axons are grown on laminin substratum as compared to that of polylysine, implicating membrane-cytoskeletal interactions as modulating factors. RGC axons label with antibodies to putative talin. When the column of distal axoplasm is disrupted by nocodazole, the distal aggregate mass becomes isolated and continues to translocate. This suggests that microtubules are probably passive components in the response, and that the force generating mechanism may be of an acto-myosin type intrinsic to the moving mass. Myosin II, putative myosin I, actin, myosin light chain kinase, calmodulin and putative talin are present in the aggregate mass. in the aggregate mass.

140.14

MEROSIN, A LAMININ-LIKE EXTRACELLULAR MATRIX MOLECULE, STIMULATES NEURITE OUTGROWTH. M. Manthorpe, E. Engvall, S. Varon, D. Muir. Dept. Biol., Univ. Calif. San Diego, La Jolla, CA 92093

Merosin is a laminin-like molecule whose location in situ is Merosin is a laminin-like molecule whose location in situ is restricted to peripheral nerve and muscle basement membranes (Lievo, PNAS 85: 1544, 1989) and to basement membranes and neuronal cells within central nervous system (Portera-Cailliau, Soc. Neurosci. Abstr. 16: 1990). In common with laminin, merosin has two 200 kD chains ("B1" and "B2") but has a 400 kD "M" chain which shares only about 40% sequence homology with the corresponding laminin "A" chain. Since the neurite-promoting activity of human laminin aboutleted to exide within the A chain. laminin "A" chain. Since the neurite-promoting activity of numan laminin is postulated to reside within the A chain, we tested whether merosin, in which the "A" chain is replaced by a analogous "M" chain, also possesses neurite promoting activity. Microwells were coated with polyornithine for 1 hr, washed and treated for 2 hrs with serial dilutions of purified human laminin or merosin. Embryonic chick ciliary ganglion neurons were cultured in the wells for 4 hrs, the assay terminated by fixation of the neurons, and the percentage of neurons bearing neurites determined. Merosin expressed a specific neurite promoting activity having an ED₅₀ of 800 ng/ml (50 µl/well) and was comparable to that of laminin in the same assays. The JG22 antichick B1 integrin antibody inhibited the neuritic response of ciliary neurons in response to both laminin and merosin, suggesting that both proteins stimulate ciliary neurite outgrowth using integrin receptors. Supported by NINCDS NS16349, NS25011 and NSF BNS808285, BNS8617034.

ANALYSIS OF AN ASTROCYTIC SURFACE MOLECULE THAT

ANALYSIS OF AN ASTROCYTIC SURFACE MOLECULE THAT PROMOTES NEURITE OUTGROWTH. B.MITTAL and S.DAVID. Centre for Research in Neuroscience, MGH, McGill Univ., Montreal, Canada, H3G 1A4.

Laminin, N-cadherin and N-CAM are known to mediate neurite growth on cultured astrocytes. The present study was undertaken to identify other neurite outgrowth-promoting molecules on astroglia. A monoclonal antibody (mAb) 1A1 was generated using neonatal rat astrocytes.

astroglia. A monoclonal antibody (mAb) 1A1 was generated using neonatal rat astrocytes.

By indirect immunofluorescence, the 1A1 molecule is found on a subpopulation of cultured astrocytes. Flat, type-1 astrocytes express the 1A1 molecule on their surfaces. Less than 5% of process-bearing, type-2 astrocytes are 1A1⁺. 1A1 immunoreactivity is not seen on oligodendrocytes or neurons, even in long term cultures. Fab fragments of mAb 1A1 inhibit neurite outgrowth from cerebellar neurons on astrocytes by 25%. from cerebellar neurons on astrocytes by 25%. Under reducing conditions, the immunoaffinity purified 1A1 molecule migrates as a major band at 60 kDa and a minor one at 30 kDa. Purified 1A1 molecule adsorbed on to nitrocellulose-coated substrata is able to promote neurite outgrowth from cerebellar neurons. This mAb, therefore, recognizes an astrocyte surface molecule that also contributes to prove the molecule that also contributes to nerve fiber growth in culture.

EXTRACELLULAR MATRIX MOLECULES ARE ASSOCIATED WITH PREPLATE CELLS IN EARLY NEOCORTICAL DEVELOPMENT.

A.M. Sheppard and A.L. Pearlman, Depts. of Cell Biology and Neurology, Washington Univ. Sch. of Med., St. Louis, MO 63110.

The first postmitotic cells of embryonic neocortex form the preplate zone; they are divided by cortical plate formation into the marginal zone and subplate. We have previously shown that fibronectin (FN)-like immunolabeling is distributed along radial glia but is restricted to the preplate, marginal zone and subplate and is virtually excluded from the cortical plate. In this study we immunolabeled sections of murine cortex (E11-13) with antisera to laminin (abLAM), J1 and chondroitin sulfate proteoglycan (abCS). Labeling with abLAM resembles abFN but is less intense. Immunoreactivity to abJI does not appear until cortical plate formation; it is sparse and largely restricted to the subplate and marginal zone. Labeling with abCS is very prominent around the cells of the preplate and continues to be associated with them as they are displaced into the marginal zone and subplate. Thus CS and FN are the most prominent of several extracellular matrix (ECM) components in developing neocortex. ECM is distributed in the layers that contain preplate cells; regulation of its components may be important in establishing a framework for cortical plate formation and a pathway for early axons. (Supported by NEI grant EY00621).

140.19

EVIDENCE THAT ACCUMULATION OF GM2 GANGLIOSIDE RE-INITIATES DENDRITE GROWTH ON PYRAMIDAL CELLS IN A NON-GANGLIOSIDE STORAGE DISEASE. L.A. Goodman, P.O. Livingston* and S.U. Walkley. Dept. Neuroscience, Rose F. Kennedy Center, Albert Einstein College of Medicine, Bronx, NY. 10461. Several neuronal storage diseases are characterized by a dramatic clustering in concentration.

alteration in neuronal morphology; renewed dendrite growth occurs on the axon hillock of mature pyramidal cells. Ectopic neurite growth first observed in a case of GM2 gangliosidosis suggested that gangliosides might function as neuritogenic agents (Purpura and Suzuki, Brain Res. might function as neuritogenic agents (Purpura and Suzuki, Brain Res. 116:1). Although ectopic neurites are most abundant in ganglioside storage diseases, they also occur in some non-ganglioside storage disorders. In cortical samples from feline models of non-ganglioside storage diseases in which ectopic dendrites do occur, GM2 ganglioside is elevated (Siegel and Walkley, Neurochem. Abstr. 21:110). In the cortex of cats with the carbohydrate storage disease, \(\alpha\)-mannosidosis, only a small proportion of pyramidal cells bears ectopic dendrites. Using a Golgi-EM technique with PAS staining, we established that neurite-bearing pyramidal cells, as well as certain intrinsic neurons, contain PAS-positive membranous inclusions, consistent with storage of sialic acid-containing glycolipids (e.g., gangliosides). The presence of membranous inclusions in those neurons suggests they contain the excess GM2 ganglioside. In contrast, pyramidal cells lacking ectopic neurites contain PAS-negative in those neurons suggests they contain the excess GM2 ganglioside. In contrast, pyramidal cells lacking ectopic neurites contain PAS-negative flocculent inclusions, consistent with storage of oligosaccharides. Using an anti-GM2 monoclonal antibody, we found that subpopulations of both pyramidal and intrinsic neurons contain GM2-like immunoreactivity. EM analysis of GM2-positive cells showed them to contain membranous inclusions. Thus, it is likely that the GM2-positive pyramidal neurons are the neurite-bearing cells. We propose that the re-initiation of dendrite growth on mature pyramidal cells is brought about by the accumulation of GM2 ganglioside. (NS18804)

140.16

PURIFICATION AND CHARACTERIZATION OF A RECEPTOR FOR NEURITE OUTGROWTH FACTOR (NOF). N.Miki*, H.Taniura*, C-H.Kuo, H.Higuchi* and Y.Hayashi. Dept. of Pharmacol., Osaka Univ. Sch. of Med., Pharmacol., Osaka 530, Japan.

A glycoprotein of about 82kDa solubilized from the gizzard muscles both binds to NOF (ligand blot) and inhibits the neurite promoting activity of NOF, suggesting that an 82kDa protein is a NOF-receptor. An 82kDa protein (NOF-receptor) was purified into a doublet band on an SDS-PAGE from gizzard muscle membranes and prepared an antibody against NOF-receptor. An NOF-receptor in the developing retinas exhibited the same physico-chemical properties as that of the gizzard muscles. The quantitative decrease of NOF-receptor embryonic retinas was observed after 11-day embryos when measured by the inhibition assay, ligand blots and immunoblots, which was paralleled well with the reduction of NOF-induced neurite outgrowth of embryonic retinas. The neurite outgrowth of embryonic retinas. The antibody only stained the ganglion cell and optic fiber layers of the retinas of 8-day embryos, but the staining disappeared in the late developing retinas of 18-day embryos. The results suggest that the loss of response of the retinal neurons to NOF reflects a decrease in the NOF receptor molecules.

The effects of substrate-bound proteins on the cyto-Burmeister, A. Buriani, R.J. Rivas, D.J. Goldberg, Dept. of Pharmacology, Columbia Univ. N. Y., N.Y. 10032.

Aphysia neurons form growth cones and rapidly extend neurites on

poly-lysine (PL) substrates treated with substrate binding factors (SBF) from Aplysia hemolymph or conditioned medium. Growth cones form on PL without SBF, but advance slowly and have larger, more stable veils. Confocal fluorescence microscopy reveals differences in microtubule (MT) distribution on the two substrates. On SBF MTs are aligned along the growth cone axis, rarely cross each other, and remain parallel to the substrate, on PL, MTs curve, cross, run perpendicular to the neurite axis, and have a complex vertical distribution. Growth on PL and SBF occurs through the same sequence: filopodial and veil pro-trusion, engorgement of the actin rich veils with organelles and MTs from the central region, and the consolidation of the growth cone into the neurite. Acute application of SBF to growth cones on PL leads to the acceleration of engorgement before any other visible change. The engorgement effect of SBF is mimicked by application of cytochalasin B and is inhibited by application of colcemid. The growth and engorgement stimulation factor(s) in SBF are proteins found in high molecular weight fractions, and are active only when bound to the substrate. Our experiments demonstrate acute effects of substrate molecules on the growth cone cytoskeleton, and suggest that substrate molecules may exert their growth stimulatory effects by regulating the cytoskeletal changes underlying veil engorgement.

EMBRYONIC HUMAN RETINAL NEURITE GROWTH ON EMBATONIC HOMAN RETINAL NEORTH ON CHILLILAR AND ACELLULAR SUBSTRATA. N. Kleitman and J.M. Hopkins, The Miami Project to Cure Paralysis, University of Miami

School of Medicine, 1600 NW 10 Ave., R48, Miaml, FL 33136.
Rat, chick and goldfish differ in substratum preferences during retinal development (reviewed in Kleitman et al., J. Neurosci. 8:653, 1988). This led us to question whether the requirements for human retinal neurite outgrowth could be adequately predicted by animal models. Therefore, we investigated neurite outgrowth from explants of embryonic human retina. Human embryos, aged 8-12 weeks were obtained from elective abortions following protocols approved by the University of Miami Committee for Protection of Human Subjects. Retinas were dissected, separated from the Protection of Human Subjects. Retinas were dissected, separated from the pigment epithelium, cut into 8-10 explants (each containing an area adjacent to the optic nerve head) and plated on one of the following: type I collagen (either an air-dried collagen gel, ADC, or flatter, ammoniated collagen, AC), polylysine (PL), polylysine and laminin (PL-lam), or rat Schwann cells on AC. Extensive outgrowth was observed on ADC but not PL. Neurite growth on AC and PL-lam mostly occurred on the surfaces of flat cells emanating from the explants, but fascicles appeared to relate directly to the accilular substrata. Human retinal explants also extended neurites extensively on a sublayer of rat Schwann cells; neurites associated with Schwann cells in preference to the flat cells which migrated from explants onto the underlying AC. The neurons survived for several weeks in culture and reextended neurites after secondary explantation to fresh culture substrata. We are presently preparing human Schwann cells to test their influence on neurite growth and neuronal survival (Morrissey et al., this Supported by The Miami Project to Cure Paralysis. volume).

REGENERATION OF AXONS FROM ADULT HUMAN RETINA IN VITRO. J.M. Hopkins and R.P. Bunge, The Miami Project to Cure
Paralysis, University of Miami School of Medicine, 1600 NW 10 Ave., R48, Miami, FL 33136.

In an effort to establish an in vitro model of regenerating adult human CNS neurons, we have investigated the potential for neurite growth from explants prepared from adult human retina. This approach is made possible by the fact that certain eye banks make available, for research, eyes donated for corneal transplantation. Eyes were removed within 2 hrs. post-mortem and stored on ice for 1.5-7.0 days. Retinas were then dissected out and cut into explants (1mm square), which were cultured at 37°C on various cellular and acellular substrata (see below) in an oxygen-rich, humidified atmosphere. Neurite outgrowth onto the culture substratum was observed only in the presence of Schwann cells, after a quiescent period of approximately six days in vitro. Of 52 explants cultured for 7 days or more on substrata containing Schwann cells, 43 were viable (showed evidence of intraretinal neurite growth in vitro) and 28 extended neurites beyond the explant border. Estimated rates of neurite growth on Schwann cell substrata reached a maximum of 0.22mm/day. Neurites did not grow beyond the border of viable explants onto acellular culture substrata composed of either polylysine, laminin, type-I collagen, or monolayers of adult human retinal glia. These results demonstrate that, under selected culture conditions, explants prepared from adult human retina harbor viable neurons and that Schwann cells promote and support regeneration of neurites from these retinal neurons <u>in vitro</u>, allowing systematic study of conditions favorable to axonal regeneration in the adult human CNS. (Supported by EY06073-03 [JMH] and the Miami Project to Cure Paralysis.)

DIFFERENTIATION, MORPHOGENESIS AND DEVELOPMENT: FIBER GUIDANCE AND SYNAPTOGENESIS

141.1

PARTIAL CHARACTERIZATION OF NEURONAL INFLUENCE ON CELLS OF REGENERATING LIMBS. C. Eberhardt Maier and Robert H. Miller. Department of Neuroscience, Case Western Reserve University School of Medicine, Cleveland, OH 44106

The ability of urodele amphibians to regrow amputated limbs is known to be nerve dependent, and we have initiated in vitro studies to begin to characterize the required neuronal factors. Dissociated blastemal cells from regenerating newt limbs were cultured on fibronectin in the presence or absence of homogenized newt brain extract. After three days blastemal cells were treated daily for 3 or 6 days with fresh brain extract, culture media, and BrdU. Cells were fixed, permeabilized, and exposed to antibodies to BrdU to identify proliferating The total number of cells and the percentage of dividing cells was

established.

After both 3 and 6 days treatment with brain extract the percentage of dividing cells was double that seen in control cultures, suggesting that brain extract increases the number, but not the rate, of blastemal cells undergoing mitosis.

However, to provide any neurotrophic factors axons must be present in the blastema. We have begun studies to identify possible molecular mechanisms used for guidance of regenerating axons in regrowing limbs. Frozen sections of used for guidance of regenerating axons in regrowing limbs. Frozen sections of blastemas in predifferentiation and differentiation phases were labeled with antibodies against NCAM, L-1, laminin, and fibronectin then visualized by indirect immunofluorescence. Preliminary results indicate that in predifferentiation blastemas the majority of cells stained for the four antigens. The majority of cells also stained for NCAM and L-1 in the differentiation phase while fibronectin staining was significantly reduced. Interestingly, during the differentiation phase laminin staining was confined to specific cells and produced a linear pattern which was reminiscent of that for axons in silver stained sections of blastemas. This suggests that laminin may be a potential substrate for the regenerating axons of regrowing limbs.

141.3

POLARIZED OUTGROWTH OF CIRCUMFERENTIAL FIBERS FROM EXPLANTS OF AVIAN EMBRYONIC SPINAL CORD. H.O. Nornes, E. Knapik*, and S. Kroger*, Dept. of Anat. and Neurobiol., Colorado State Univ., Ft. Collins, Co 80523, and Max Planck Inst. for Devel. Biol., Tubingen, F.R.G.

The neuroblasts in the alar plate of the neural tube have a stereotypic pattern of axon growth. The axons of the circumferential neuroblasts extend ventrally along the marginal zone to the floor plate where the axons change direction and extend longitudinally. The floor plate has been shown to release a chemotropic factor (Tessier-Lavigne et al., Nature, 336:775-778). The objective of this study was to analyze the growth of circumferential fibers from the alar plate in the absence of

basal and floor plates.

Explants of the dorsal 1/2 of the neural tubes of chick embryos were grown on basal lamina substrate. Embryonic spinal cords of 4-5 D embryos were dissected free of their external limiting membranes (ELM), cut into longitudinal strips (300 um x 2 mm) or squares (300 um) and placed ELM-side down onto basal lamina prepared from retina of 8-9 D chick embryos, and cultured in F-12 media supplemented with 10% fetal bovine serum.

There was a polarized growth of axons from both the longitudinal strips and squares of the alar plate. The majority of the axons grew out from the side of the explant that was originally facing the basal/floor plates. These observations indicate that this polarized growth is inherent to the alar plate. (Supported by NIH grant #NS-21309-04 to HON)

141.2

DIFFERENTIAL DEVELOPMENT OF RAT TRIGEMINAL GANGLION CELLS. I.A. Scarisbrick, P.J. Isackson, D.L. Benson, E.G. Jones. Departm

Anatomy and Neurobiology, University of California, Irvine, CA., 92717.

Trigeminal ganglion (Vg) neurons innervate the rat whisker pad vibrissae and brain stem nuclei in a highly somatotopic manner. Immunocytochemical localization of the cell surface antigens, HNK-1, which recognizes neural crest cell derivatives and neural cell adhesion molecule (NCAM), which recognizes all Vg cells, has been employed in the same or adjacent sections of staged embryos to assess the contributions of neural crest and placodal cells to the Vg cell population. HNK-1 immunoreactive Vg cells are arranged dorsomedially within the mandibular lobe. Placode derived cells are distributed throughout the Vg. By E14,

mandibular lobe. Placode derived cells are distributed throughout the Vg. By E14, all HNK-1 immunoreactive cells become parvalbumin positive.

On E12, NCAM immunoreactive neurites extend further through the maxillary arch mesenchyme than HNK-1 labeled neurites. Thus, placode derived axons may pioneer the pathway to the periphery. Crest and placode derived axons enter the neural tube by E12 and contribute fibers to the trigeminal tract. Mesenchyme of the presumptive whisker pad is intensely NCAM immunoreactive on E13 before contact with infraorbital nerve fibers. By E18, the overlying epithelium becomes NCAM immunoreactive and is contacted by nerve fibers. Crest derived axons remain confined to the connective tissue sheath of developing whisker follicles; placode derived axons are located within this and the external root sheath.

placode derived axons are located within this and the external root sheath.

Neural crest and neuroepithelial components of the Vg are known to respond differentially to nerve growth factor and brain derived neuronotrophic factor in vitro. Therefore, we are examining the expression of mRNAs encoding these substances in vivo and correlating this with gangliogenesis, axon outgrowth and target differentiation

EXPANSION OF SENSORY DERMATOMES FOLLOWING EXPERIMENTAL NEURAL LESIONS AND IN SUBJECTS WITH SPINA BIFIDA: TROPHIC INTERACTIONS OF AFFERENT NERVES AND THEIR CUTANEOUS TARGETS. B.L. Munger¹, T.E. Jones*¹, K. Morohunfola*¹, Feinberg*¹, A. Mauger*², and R. Saxod*². ¹Dept. Anat., Penn St. Univ., Hershey, PA 17033 and ²Lab. Biol. Anim., Univ. Scient. & Med., Grenoble, France.

The present study analyzes effects of neural lesions in chick embryos and opossum pups, and compares the results with human spina bifida. Serial sections of chick embryos (operated at Stage 14, incubated 8 days) and opossum pups (operated day 1, survival day 1-14) were stained with silver, and whole mounts of chick skin stained for cholinesterase. Lesions of spinal cord and dorsal root (DRG) or trigeminal (TG) ganglia produced skin devoid of sensory nerves, feathers, and hairs. Skin near lesions was hyper innervated, epidermis thickened, and precocious hairs formed. Axons invaded aneural skin from residual hyper plastic DRG & TG, and new waves of feathers and hairs formed. Opossum TG lesions resulted in altered patterns of eyelashes and auricles failed to separate from the head. Serial neurological examinations in patients with spina bifida document equivalent expansion of sensory dermatomes in 65% of 77 patients. These changes result from trophic interactions of afferent nerves and their cutaneous targets similar to the role of afferent nerves in development of muscle spindles (Zelena, 1957). Supported in part by USPHS Research Grant NS 19462.

DEVELOPMENT OF THE NASAL INNERVATION IN RAT EMBRYOS. M.-C..Bélanger*, R. Marchand and L. Bertrand*. Lab. Neurobio., Hôp. Enfant-Jésus, 1401, 18e rue, Québec, Qc. Canada, G1J 174.

The olfactory system, though well studied in respect to its morphogenesis, has not been fully explored regarding the development of its connections. The fluorescent tracer Dil can diffuse passively along axonal membranes in fixed tissues (Godement et al., 1987). By implanting crystals of Dil in the olfactory epithelium of rat embryos (ages from E160 to E180), we could follow the development of several nerves. After implantation in the olfactory epithelium, the following results were obtained. The olfactory nerve was always labeled. The olfactory nerve layer, slightly labeled at E160 displayed a bright fluorescence from E168. A few fibers had already penetrated deeper in the brain at E168. At E180, the mitral cell layer and the lateral olfactory tract were also labeled, suggesting a trans-synaptic transport of Dil. The nervus terminalis was never labeled farther than the olfactory bulb (OB) though its cell bodies were seen as soon as E168. The nasociliary nerve was labeled at E178, and a few cell bodies were labeled in the dorsomedial part of the trigeminal ganglion. Dil was also inserted in the dorsomedial part of the trigeminal ganglion. Dil was also inserted in the vomeronasal organ (in E160 to E178 embryo). The vomeronasal nerve was strongly fluorescent. Fibers were seen in the accessory olfactory bulb, which was situated more caudally as the embryos grew older. As early as E160, the was situated more caudally as the embryos grew older. As early as E160, the nervus terminalis was labeled in the telencephalic septum where, at E1618 and E178, fluorescent cell bodies were present. The pterygopalatine ganglion was labeled as soon as E160. From E168, distinct cell bodies were fluorescent in the ventral aspect of the ganglion. A few cell bodies in the ventral portion of the trigeminal ganglion were also labeled in all animals. In the E178 embryo, fibers of the spinal root of the trigeminal nerve were seen from the level of the nucleus principalis to the spinal trigeminal nerves results illustrate the rich innervation of the embryonic nasal epithelia, as soon as E160. (Supported by MRC, FRSQ, FCAR).

141.7

THE SEQUENCE OF MYELIN FORMATION IN THE BRAIN OF THE NORTH AMERICAN OPOSSUM. G. Ghooray and G.F. Martin, Department of Anatomy and Neuroscience Program, The Ohio State University, Columbus, Ohio 43210.

The aim of this study was to observe the sequence of myelin formation in the opossum brain by using myelin basic protein (MBP) immunohistochemistry and the Weigert technique. By postnatal day (PD) 26 the white matter of the spinal cord exhibited some MBP immunoreactive structures. MBP-like immunoreactivity (LI) was also present in the reticular formation, the spinal and mesencephalic tracts of V, the trapezoid body and lateral leminscus, the medial longitudinal fasciculi, the superior cerebellar peduncles, and the posterior commissure. In contrast, the above areas did not stain for myelin by the Weigert technique until PD 47. By PD 33, additional MBP-LI was also found in the brainstem as well as within the optic chiasm and tracts, the supraoptic decussation, the presumptive medial forebrain bundle, and the internal capsule. The Weigert technique showed no evidence for myelin in any of these areas until sometime between PD 54 and 68. MBP immunostaining developed rapidly between PD 26 and 40 during which time most of the tracts in the medulla and pons became immunoreactive. By PD 41, MBP-LI was present in most, if not all, of the appropriate areas in the spinal cord, medulla and pons as well as within many areas of the midbrain and forebrain. In the forebrain, immunostained areas included the fornices, the vertical limbs of the diagonal band of Broca, and the olfactory tracts. These structures were not stained by the Weigert technique until PD 68. By PD 62, MBP-LI was present in the ventral (olfactory) part of the anterior commissure, but the neocortical portion was not immunostained until PD 77. The ventral part of the anterior commissure was not stained with the Weigert technique until about PD 81. Although the sequential appearance of MBP immunostaining and Weigert staining appeared to be comparable, MBP-LI was present well before myelin could be demonstrated by the latter technique. (Supported by NS-25095).

DISTRIBUTION OF TWO HEPARIN-BINDING NEURITE PROMOTING MOLECULES, AMPHOTERIN (p30) AND HB-GAM (p18) IN DEVELOPING

E. Castrén, P. Panula, J. Merenmies* and H. Rauvala*. Departments of Anatomy and Medical Chemistry, University of Helsinki, 00170 Helsinki, Finland.

Amphoterin is a 30 kD heparin-binding protein that promotes neurite outgrowth of newly formed neurons presumably by an adhesive mechanism. This 214 amino acid protein is rich in lysine residues and has a polyanionic carboxy terminus consisting only of glutamic and aspartic acids. HB-GAM (heparin-binding growth-associated molecule) also binds strongly to heparin and promotes neurite growth. This 136 amino acid polypeptide is also rich in lysine residues, but has two polycationic heads rather than one cationic and one polyanionic.

We have studied the distribution of amphoterin and HB-GAM and their respective mRNAs in developing rat brain. Both amphoterin and HB-GAM are unevenly distributed in the developing rat brain. Amphoterin is present in cortical neurons and HB-GAM is widespread Amphoterin is present in cortical neurons and his-dam is widespread in superficial cortical laminae. HB-GAM is also found in distinct laminae of the olfactory bulb. Amphoterin gene is expressed in all areas of developing brain with high concentrations in cortex. The expression of both proteins is developmentally regulated. Amphoterin content is very high just before birth, whereas HB-GAM peaks one week postnatally. mRNA concentrations for both proteins follow the same developmental pattern as the respective protein levels.

These results suggest that amphoterin and HB-GAM may have an important role in brain growth and maturation.

SPECIFICITY OF SYNAPTIC CONNECTIONS

142.1

TRANSIENT EXPRESSION OF CELL-SPECIFIC LABELS ON GROWTH CONES AND DEVELOPING SYNAPSES IN THE GRASSHOPPER EMBRYO. H. Reichert and T. Meier*. Dept. of Zoology, University of Geneva, CH-1211 Geneva, Switzerland. The construction of a functional nervous system requires a high degree of neuronal specificity for establishing the correct pattern of synaptic connections. Neuron-specific molecular labels may be involved in synaptic this procession.

generating this specificity. We are studying such highly specific neuronal labels by using monoclonal antibodies to characterize molecules that are transiently expressed on the growth cones and developing synaptic terminals of identified neurons in the grasshopper embryo during the period of axonal outgrowth and synaptogenesis.

Several cell-specific molecular labels of this type have been found. The molecular label with the highest degree of specificity is expressed in two pairs of identified projection neurons, which have their cell bodies and dendritic arbors in the brain and project to the ganglia of the ventral nerve cord. During axonogenesis, the label becomes concentrated in the axonal growth cones of these neurons. Later during synaptogenesis, the label is predominantly expressed on the membrane of the axon collaterals and synaptic boutons of these neurons. This neuron-specific label is not expressed in any other of the approximately one million neurons in the nervous system, nor in any other cell in the developing embryo.

These findings suggest the existence of a molecular labeling system

that is remarkably specific for individual cells and may be important for establishing precise synaptic connectivity. The isolation and characterization of these molecules are now in progress. (Supported by the Swiss NSF).

142.2

POSITIONAL INFORMATION CONTROLS AXON MORPHOLOGY AND SYNAPTIC CONNECTIVITY VIA INDEPENDENT MECHANISMS.

J.M. Blagburn and J.P. Bacon*. Inst. of Neurobiol., Univ. of Puerto Rico R.C.M., 201 Blvd. del Valle, San Juan, Puerto Rico 00901 and Dept. of Biology, Sussex University, Brighton, U.K.

We are using the insect peripheral nervous system to study the effects of positional information on sensory axon morphology and choice of synaptic partners. Each cercus of the first instar cockroach *Periplaneta* americana has two wind-sensitive filiform hair sensory neurons, one medial (M) and the other lateral (L). The L axon runs in the lateral tract of the cercal nerve, and forms a characteristic arborization within the terminal ganglion, where it forms a strong monosynaptic connection onto giant interneuron 3 (GI3) but does not synapse with Gi2. The M axon follows the medial tract, has a different morphology, and evokes large monosynaptic EPSPs in GI2 and small EPSPs in GI3. We have bred a strain of cockroaches in which supernumerary hairs arise at different positions on the cercus. Supernumerary lateral neurons have the same axonal branching pattern and synaptic connectivity as the normal L neuron, while supernumerary medial neurons are similar to the M neuron, thus supporting the hypothesis that circumferential position controls both axon morphology and synaptic connectivity. Very infrequently, extra sensory neurons arise on the cercal midline (C neurons). In 4 out of 4 cases, the C axon follows the lateral tract of the cercal nerve, and has a arborization similar to that of L. However, the C axon always forms M-type synapses. We conclude that the circumferential position in which the neuron is born may control both its axon morphology and choice of synaptic partners, but via independent mechanisms. (Supported by NIH Grant NS07464 and the SERC, U.K.)

142 3

PERIPHERAL LOCATION OF CUES THAT SPECIFY MUSCLE AFFERENTS.

P. Wenner and E. Frank. Dept. of Neurobiology, Anatomy and Cell Science, Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA 15261
How are neurons specified during development to make their appropriate connections? Motoneurons appear to be committed to supply a particular target muscle at the time their axons exit the spinal cord. In contrast, muscle sensory neurons can innervate a variety of peripheral targets; some aspect of their peripheral projection then appears to specify their central connections with motoneurons. This peripheral influence might arise from the target muscle itself, or the sensory axons might receive cues directly from the motoneurons

with motoneurons. This peripheral influence might anse from the target muscle itself, or the sensory axons might receive cues directly from the motoneurons with which they grow.

To study the location of this peripheral cue, we made dorsoventral rotations of chick hindlimbs at the level of the knee at stages 20 - 22, before sensory or motor neurons have grown into the limb bud. This surgical manipulation forces motoneurons to innervate inappropriate (and often antagonistic) muscles (Whitelaw and Hollyday, 1983). Do muscle afferents supplying these muscles make central connections appropriate for the muscles themselves or for the motoneurons with which they grow?

Muscle sensory input to lumbosacral motoneurons was assessed using intracellular recordings from isolated spinal cords. In normal embryos, muscle afferents project strongly to motoneurons supplying their own muscle (homonymous inputs) but only weakly to functionally unrelated motoneurons. Some antagonistic motoneurons actually receive disynaptic inhibition. Preliminary results suggest that in embryos with rotated hindlimbs, muscle afferents make central connections appropriate for the muscle they supply, not for the motoneurons they grow with. Motoneurons supplying rotated muscles were less likely to receive homonymous monosynaptic input, and we have seen some cases of homonymous disynaptic inhibition. These results provide further evidence that muscle afferents are not specification depends upon some signal in the rotated part of the limb. (Supported by NSF to EF)

DEVELOPMENTAL INTERACTIONS BETWEEN CHEMICAL AND ELECTRICAL SYNAPSES IN IDENTIFIED LEECH MOTOR NEURONS. G.K. Bryan and W.B. Kristan, Jr. Biology Dept., Univ. of Calif. - San Diego, La Jolla, CA 92093.

We are investigating interactions in the development of synapses among identified motor neurons in the leech Hirudo medicinalis. The dorsal excitatory motor neuron, DE-3, excites dorsal longitudinal muscles, and the dorsal inhibitors, DI-1 and DI-102, inhibit the same muscles; they also inhibit DE-3. This neuronal inhibition is known to be important for two different neuronal inhibition is known to be important for two different leech behaviors, swimming and local bending. In addition, DI-1 is electrically coupled to DI-102. We want to know whether this coupling plays a role in the establishment of the inhibitory connection onto DE-3. We have previously investigated the morphological development of DE-3 from embryonic day 10 to the adult (Kristan and Jellies, Soc. Neurosci. Abstr., 1989, 15: 498) and have found an orderly development of the neurites. We characterize the development of electrical coupling between DI-1 and DI-102 by pairwise intracellular recording from them 1 and DI-102 by pairwise intracellular recording from them, then we fill the two cells with different dyes to characterize their morphological development. In a similar way we use pairwise recordings and dye fills of DE-3 with each inhibitor to characterize their chemically mediated inhibition and associated morphological development. These studies will show whether the electrotonic connections of DI-1 and DI-102 are established prior to their chemical inhibition of motor neuron DE-3. Supported by USPHS research grant NS25916.

TOPOGRAPHICALLY SELECTIVE MOTOR REINNERVATION OF THE RAT'S SERRATUS ANTERIOR MUSCLE AFTER A NEONATAL LESION. M. B. Laskowski, M. DeSantis, A. Norton, and P. Berger. Dept. of Biol. Sci. & WAMI Program, Univ. of Idaho, Moscow, ID 83843. The rat's serratus anterior (SA) muscle has seven sectors that are innervated by

motor neurons of spinal segments C6 and C7; their axons form the long thoracion (LT) nerve. Normal development results in a topographic projection such that C6 motor neurons predominate over those of C7 in more rostral sectors of SA and vice versa for the most caudal sectors. We compared the sequence of events that take place in an optimal reinnervation paradigm with those that occur during normal development. Within 48 hrs of birth anesthetized rats had the LT nerve frozen where it passed between SA rostral sectors I and II. After recovery periods from 32 hrs to 70 days, the rats were reanesthetized and the C6 and C7 roots, the LT nerve and the SA muscle were dissected as a unit and superfused with Ringers. Intracellular recordings were made from muscle fibers in each sector of SA while stimulating by turns the C6 and C7 ventral roots. Sectors II through VII were reinnervated sequentially from rostral to caudal between 2 and 8 days after the lesion. For all time periods (6.5 to 70 days), the average target fields of the C6 versus C7 motor neurons were significantly different from each other, but not to as great an extent as in sham-operated and unoperated controls. The average target fields at one week reinnervation time (initial contact) were as precise as at 10 weeks. This means that topographic selectivity is established by motor neurons at an early stage of reinner vation rather than being a gradual reorganization from a random outgrowth to the muscle. Reinnervation of SA after a neonatal lesion resembles embryological development in that a topographically selective pattern is present from the earliest stages so far examined (E-17). They differ in that topographic selectivity is enhanced over a period of several postnatal weeks in normal development but does not improve following reinnervation. (Supported by NIH, NS 27024)

A GENETIC ANALYSIS OF THE GENE UNC-55 AND THE D
MOTONEURONS IN CAENORHABDITIS ELEGANS. W. W. Walthall H. Park* and E. A. Murry* Dept. of Biology, Georgia State University, Atlanta, GA. 30303

Fourteen hours after hatching in the nematode C elegans a class of embryonic motoneurons, the DD cells, respecifies its pattern of synapses At about the same time a related set of postembryonic motoneurons, the VD cells, complete differentiation and assume a pattern of connections equivalent to the initial pattern of the DD cells (White et al. Nature 271.1978). Morphologically and biochemically representative neurons from each class are indistinguishable. Eight genes have been identified by mutation that cause identical changes in both classes suggesting that they have similar genetic programs. However, the two classes of neurons have different patterns of synapses Mutations in a single gene, unc-55 (uncoordinated). suggest that its gene product is responsible for establishing the differences in target specificity that distinguish the two classes. In differences in target specificity that distinguish the two classes. In uac-55 alleles the VD and DD motoneurons have identical patterns of synapses (Nawrocki and White, personal communication). We have expanded the collection of uac-55 alleles from 3 to 10, and have found that placing the most severe allele, jdf, over the corresponding chromosomal deletion does not increase the severity of the uncoordination. Thus the null phenotype is not lethal and this is one criterion for establishing it. Another allele, jd5, is temperature sensitive, animals grown at 250c are uncoordinated, animals grown at 150 are normal. Temperature shift experiments are underway to determine the critical period for the expression of the gene

SEGMENTAL ORGANIZATION OF VIth NERVE RELATED MOTONEURONS IN THE CHICK HINDBRAIN, R. Baker and D. Naden*. Dept. of Physiol. and Biophys., NYU Med. Ctr., New York, NY 10016, Dept. of Anat., New York State Coll. of Vet. Med., Cornell Univ., Ithaca, NY 14853.

Avian embryos have been studied with carbocyanine dyes from H-H Stages 16-35 in order to establish the early temporal and spatial relationship between motoneurons and extraocular muscle anlagen. All mesodermal muscle precursors are reported to originate from the prechordal plate between H-H 8-10 and later become aligned in a paraxial segmental array in the head mesenchyme surrounding the neural tube. Sixth nerve related motoneurons arise medially from neuroblasts in two segments of the hindbrain neuroepithelium - thombomeres 5 and 6. At H-H 16 each rhombomere contains 3-6 cellular clusters that sends axons towards the common mesenchymal muscle precursor. Although the collective rootlets from 15 and 16 fasciculate beneath the hindbrain and travel together, they are distinct, and by H-H 18 each enters an individual muscle condensation. Frequently, 3 distinct terminal arborizations distinguish between muscle primordia of the lateral rectus, pyramidalis and quadratus that can only be recognized later following primary myotube specification. At this time, H-H 32-35, each innervated muscle condensation begins to diverge toward its scleralinsertion site. Also, the accessory abducens motoneurons in 6 migrate to a ventro-lateral position in the medulla. Since the separate populations of abducens and accessory abducens motoneurons are placed in register with appropriate paraxial mesodermal units, these data demonstrate an unexpected early source of axial position signals intrinsic to the hindbrain f5 and r6 neuromeres. Thus, motoneurons from adjacent rhombomeres distinguish between peripheral musculature producing the different somatic motor behaviors of eye rotation and translation. We hypothesize that neuromeric specific phenotypes underlie positioning of the motoneu

LACK OF TOPOGRAPHY IN MOTOR NEURON PROJECTIONS TO MUSCLE FIBERS IN THE NEONATAL RABBIT SOLEUS MUSCLE. K. S. Cramer and D. Van Essen, Division of Biology 216-76, California Institute of Technology, Pasadena, CA 91125

A topographic arrangement of projections from spinal motor neurons to muscle has been found in some, but not all, mammalian skeletal muscle. We have examined the topography of innervation in the neonatal rabbit soleus muscle with respect to the rostrocaudal position of the innervating motor neurons in the spinal cord. The extensive polyinnervation at postnatal days 4-5 allowed us to use the tension overlap method to ess whether neurons which are clustered in the spinal cord are more likely to innervate common muscle fibers than neurons which lie in different regions of the soleus motor pool. Using an in vitro preparation, we stimulated pairs of ventral root filaments together as well as separately, and measured the tetanic tension generated in each case. Tension overlap is defined as the degree to which tetanic tensions of pairs of filaments were not additive. Assuming that stimulation of all inputs to a fiber will not evoke more tension than stimulation of any single suprathreshold input, we used tension overlap to estimate the percentage of muscle fibers in each filament which were shared between the two filaments. We compared overlap for neighboring filaments to that for widely separated filaments along the rostrocaudal axis of the spinal

Our results indicate that for 10 pairs of adjacent multiunit filaments which contributed $29\pm4\%$ of the maximum tension, the mean overlap was $44\pm9\%$; for 10 pairs of distant filaments which contributed $28\pm4\%$ of the maximum tension, the mean overlap was 41 ±8%. Thus, the overlap was not significantly different between these two groups. As expected, these overlap values were significantly higher than those found in singly innervated control muscles from older animals. These results suggest that the projection to the neonatal soleus muscle has little, if any, topographic organiza-

Loss of Regenerative Specificity Coincides With the Development of Myelination in the Builtrog Tadpole. M.L. Meeker and P. B. Farel. Dept. Physiol., Univ. N. Carolina Sch. Med., Chapel Hill, NC 27599

Transected lumbar ventral root axons are able to regenerate to the proper hindlimb region during the first third of larval (tadpole) life in the bullfrog, after which time regenerative specificity is lost (Farel and Bemelmens, 1986). Based on an analysis of reinnervation errors we have hypothesized that regenerating axons in older tadpoles have the capability of responding to guidance cues, but may be prevented from doing so by the development of non-neural structures in the hindlimb (Lee and Farel, 1988). The most likely such structure is the basal lamina secreted by Schwann cells and which surrounds all peripheral axons. The basal lamina forms a continuous tube that persists following axon transection, even though the distal axon and myelin degenerate. Regenerating axons entering the incorrect tube might be constrained from responding to guidance cues and thus forced to innervate the structure at the distal opening of the particular tube they had entered.

To test this hypothesis, we examined the development of myelination at the ultrastructural level. We found that the development of myelination and of the basal lamina around axons coincides with the loss of regenerative specificity. These findings are consistent with previous studies of cross-stage limb transplants which show that motor axons from older animals have the capability of responding to at least some guidance cues. Thus, motor axons may be capable of responding to guidance cues in the hindlimb at developmental stages when specific reinnervation is not typically

142.11

ROSTROCAUDAL POLARITY OF AVIAN OPTIC TECTUM AND ORDERED NERVE CONNECTION.

Hiroyuki Ichijo*, Toru Matsuno* and Harukazu Nakamura. Dept. of Pathol. and Biol. Kyoto Pref. Univ. of Med. Kyoto 603 Japan.

Retinotectal projection is organized precisely in a retinotopic manner. Nasal retinal axons project to the caudal tectum, and temporal axons to the rostral tectum. We carried out rotation of the tectal primordium at an early stage of development to understand the mechanism retinotectal map formation.

used three marking systems. Quail was used as a graft and transplanted into a chick embryo by rotating rostrocaudal axis 180°. Dio was applied to a graft locally to ascertain orientation of the graft. We could make sure of orientation of the graft. DiI was used to examtopographic relationship between the retina and the tectum.

Nasal retinal axons projected to the causal side of the rotated tectum (originally rostral side of the tectal primordium), and temporal axons to the rostral side of the rotated tectum (originally causal side). This pattern was the same as the normal projection. Our results same as the normal projection. Our results showed plasticity of rostrocaudal polarity of the tectum primordium.

EFFECT OF FETAL DEAFFERENTATION UPON THE **ORGANIZATIONOFSOMATOSENSORY REPRESENTATIONS** IN THE GRACILE, CUNEATE AND TRIGEMINAL NUCLEI OF ADULT RATS. H.P. Killackey, J.T. Wall, N.L. Chiaia, and R.W. Rhoades. Dept. of Psychobiology, Univ. of Calif., Irvine, CA 92717 and Dept. of Anatomy, Medical College of Ohio, Toledo OH 43699.

Prenatal forelimb removal in rat increases the portion of primary somatosensory cortex devoted to the representation of the hindlimb. We recorded from 3 adult rats that sustained left forelimb removals on embryonic day 16 to determine the extent to which this reorganization might reflect altered brainstem somatotopy. Receptive fields were mapped for unit clusters in the gracile, cuneate, and trigeminal nuclei at, and up to 2 mm caudal to, the obex. Data from the deafferented side of the brainstem were compared with those from penetrations on the intact side and with recordings from 2 normal adults. In each experimental animal, units with receptive fields restricted to the remaining forelimb stump and/or shoulder were recorded in the part of the brainstem normally containing the cuneate forepaw and forelimb representations. In addition, there were small reductions in the mediolateral extents of the portion of the brainstem devoted to the residual forelimb and shoulder representations and the cuneate nucleus as determined from cytochrome oxidase stained sections. The changes in somatotopy induced by fetal limb removal appear less extensive in brainstem than in cortex. Supported by DE 07734, BNS 85 17537, NS 21105, BNS 87 19311, and DE 08971.

A COMPARISON OF IMMUNOSUPPRESSION TECHNIQUES AND THEIR APPLICATION TO THE PRODUCTION OF MONOCLONAL ANTIBODIES SPECIFIC FOR AXONS ON THE NASAL SIDE OF THE DEVELOPING RETINA. C. Vermeersch. C. Stechmann* and S. McLoon. Univ. of Minnesota, Minneapolis, MN

Monoclonal antibodies produced from immunizations with complex mixtures of antigens have allowed identification of numerous molecules important in developmental processes. A common problem in the application of this technology is the tendency of the immune system to recognize only a few immunodominant antigens. Consequently, it has been difficult to generate antibodies to minor antigens that may play an important role biologically. Several investigators have designed approaches to suppress the immune system to common antigens in order to favor the production of antibodies to the minor antigens. These techniques include injecting uninteresting antigens into newborn mice or killing activated immune cells with cyclophosphamide. The degree of immunosuppression achieved with different techniques and combinations of techniques was compared in this study

The optimal immunosuppression technique was applied to the production of antibodies to axons from the nasal side of the developing chick retina. Hybridomas were produced from mice suppressed with temporal retinal tissue and immunized with nasal retinal tissue. The antibodies generated were screened by ELISA for recognition of protein from nasal but not temporal retina. Three antibodies to nasal retinal axons have been identified.

CELL BIRTH DATE DOES NOT PREDICT THE VIBRISSA FOLLICLE INNERVATED BY A GIVEN TRIGEMINAL PRIMARY AFFERENT NEURON. W.R. Bauer, C.M. Goddard, N.L. Chiaia, G.J. Macdonald, H.L. Enficijan and R.W. Rhoades. Dept. of Anatomy, Medical College of Ohio, Toledo, OH 43699.

The trigeminal (V) primary afferent neurons innervating different rows of mystacial vibrissa follicles in rats are organized in partially overlapping, rostrocaudally oriented bands that generally parallel the long axis of the ganglion. It has been proposed that, during development, vibrissa follicles are innervated in a caudal to rostral order. This, in turn, suggests that ganglion cells born early during gestation may innervate caudal follicles while cells born later might innervate rostral follicles. We tested this possibility directly by combining prenatal injections of [³H]-thymidine with retrograde tracing from the C-1 and C-4 vibrissa follicles in adulthood. The V primary afferent neurons supplying the mystacial vibrissa follicles are born throughout the period of V ganglion neurogenesis (embryonic days 9-14) and those innervating the C-1 and C-4 follicles have essentially the same distribution of birth dates. Furthermore, primary afferent neurons born on a given day and innervating a given follicle are distributed throughout the band of all ganglion cells supplying that vibrissa. Thus, V ganglion cell birth date cannot be readily related to the organization of the sensory innervation of the mystacial vibrissae follicles. Supported by DE 07734, BNS 85 17537, and funds from the State of Ohio Research Challenge.

CHROMOGRANIN A IN THE OLFACTORY SYSTEM OF THE RAT

CHROMOGRANIN A IN THE OLFACTORY SYSTEM OF THE RAI M. Gratzl*, G. Lahr*, C. Heiss*, A. Mayerhofer*, K. Schilling*, R.J. Parmer*, Ch. Pilgrim, and D.T. O'Connor*. Abt. Anatomie und Zellbiologie, University of Ulm, D-7900 Ulm, FRG; Univ. of California, San Diego, CA 92161, USA.

Olfactory bulbs of the rat contain chromogranin' A (CGA) in amounts comparable to those of rat adrenal or hypophysis. In various brain regions including hippocampus CGA could not be detected by immunoblotting, while CGA mRNA was found in all brain regions examined, including the olfactory bulb. In situ hybridization histochemistry and immunocytochemistry revealed CGA synthesis in cell bodies of mitral and tufted cells in the external plexiform layer and in the periglomerular region of the olfactory bulb. Immunocytochemically, CGA was also detected in the axonal terminals of mitral and tufted cells (primary olfactory cortex and amygdaloid nucleus) the axonal terminals of mitral and tufted cells (primary olfactory cortex and amygdaloid nucleus) but not in the olfactory glomeruli, where the incoming olfactory nerve fibers of the primary olfactory neurons establish synaptic contacts. Thus CGA in mitral and tufted cells is specifically transported into their axonal terminals but not into their dendrites. We propose that the rat olfactory system could serve as a model for the study of CGA function in signal transduction.

TRANSMITTER-MEDIATED INTERACTIONS BETWEEN CULTURED SYMPATHETIC AND HIPPOCAMPAL NEURONS OF THE RAT_M.D. Johnson, A.G. Yee and D.D. Potter. Dept. of Neurobiology, Harvard Med. Sch., Boston, MA 02115 When dissociated neurons of the superior cervical ganglion

(SCG: hooded rats, 0-6 d old) were co-microcultured with cells of the hippocampal formation (HF) in the presence of NGF, transmtter-mediated interactions were frequently seen. In 23 transmtter-mediated interactions were frequently seen. In 23 of 52 trials, activity of an HF neuron resulted in a psp-like event in an SCG neuron; 91% of these effects were depolarizations that were usually less than 15 mV in amplitude. Bicuculline (10 µM) partially or completely blocked these events, reversibly, in 10 of 11 trials; this is evidence for GABAergic interaction. The similarity of the time course of these events to conventional nicotinic cholinergic epsp's in the SCG network raises the possibility that the two types of neurons were synaptically linked. In 18 of 51 trials, stimulation of an SCG neuron produced a rapid and/or slow depolarizing of an SCG neuron produced a rapid and/or slow, depolarizing and/or hyperpolarizing effect on a HF neuron. In 9 trials of atropine, 4 cases were completely blocked, 4 cases partially blocked and one case was not affected. The origin of the atropine-resistant interactions and the effects of norepinephrine and other transmitters are being investigated, as is the morphological basis for interaction between the two types of neurons. DEVELOPMENT OF CORTICOSPINAL ARBORS IN THE POSTNATAL HAMSTER R.Z. Kuang and K. Kalil. Dept. of Anatomy, Univ. of Wisconsin, Madison, WI 53706.

A previous study of corticospinal axon arbors showed that when one pyramidal tract is severed early in development contralateral corticospinal axons sprout into the denervated spinal cord, maintaining topographic and functional specificity. We wished to determine whether sprouting was an extension of early bilateral connections or occurred in response to injury, and how cortico-spinal arbors achieved specificity during development. Dil crystals were inserted into the hindlimb sensorimotor cortex of hamsters 3-6 days postnatal. After 2-6 day survival times animals were perfused with 4% paraformaldehyde, and the brains and spinal cord sectioned with a vibratome at 50 µm. Sections were viewed under fluorescence microscopy to visualize Dil labeled corticospinal axon arbors. Results show that (1) axons grow out from the dorsal column with no significant waiting period (2) axons innervate only one side of the spinal cord with no transient bilateral connections (3) functional sensory and motor specificity of corticospinal arbors innervating the dorsal and ventral horn is apparent as soon as axons grow out (4) axons growing into the dorsal or ventral horn begin to branch immediately. These results show that specificity of adult corticospinal axon arbors is apparent from the onset of target innervation and does not occur by the paring away of diffuse or inappropriate branches. Second, injury induced sprouting does not occur by the maintenance of transient bilateral connections but arises de novo from signals similar to those present during development. (Supported by NIH grant NS-14428).

THE DENDRITIC ORGANIZATION OF GABAERGIC PARVALBUMIN-CONTAINING NEURONS IN THE RAT HIPPOCAMPUS IS ALTERED BY PARTIAL DEAFFERENTATION

Inst. Anat., Univ. Freiburg, 7800 Freiburg, FRG
Entorhinal afferents form synapses with dendrites of parvalbumin (PARV)-immunoreactive neurons in the rat fascia dentata. In this study we analyzed the postlesional effects of entorhinal deafferentation on the dendritic morphology of the postsynaptic PARV-positive cells. immunocytochemistry was performed 2,8 and 55 days after a unilateral entorhinal lesion. Two days after the lesion we observed an abnormal swelling of the distal tips of PARVpositive dendrites in the termination zones of the perforant path. The distal dendrites of immunoreactive neurons seemed to retract from these zones. 8 days after the lesion PARV-positive distal dendrites were reduced by 70% in the outer molecular layer and by 40% in the stratum lacunosum-moleculare. This reduction of PARV-positive dendrites in the entorhinal termination zones persisted 55 dendrites in the entorninal termination zones persisted 55 days after the lesion. In the electron microscope, we observed abnormal glial invaginations in the PARV-positive dendrites. Our results suggest a high neuronal specificity of this hippocampal input as sprouting of nearby afferents (e.g. commissural fibers) is not effective in restoring a normal pattern of PARV-positive dendrites. (This study was supported by the DFG: SFB 45 and Fr 620/1)

CHARACTERISTICS OF VISUAL CALLOSAL TRANSFER IN NORMALLY REARED KITTENS. C.Milleret* J.C.Houzel* and P.Buser *(1).(SPON: European Neuroscience Association). Lab de Neurophysiologie, Collège de France ;(1) Dept de Neurophysiologie comparée CNRS & UPMC,75005 Paris France.

While abundant data is available on the characteristics of the callosal transfer of visual information in the adult cat, surprisingly little is known in the kitten. The present study considers this transfer in animals aged from 2 to

Fifteen kittens underwent a midsagittal section of their optic chiasm under Saffan anaesthesia. Two days later, they were again anaesthetized and paralyzed with flaxedil. Unit activities were recorded from the quasi total extent of visual cortical areas 17 and 18 and were tested for their responses to stimulation of the contralateral eye through slits and bars projected into the

From the analysis of 548 cells, it appeared that callosal transfer (observed in 71 cells): 1) was already effective in the youngest animals tested, at an age when the first visual cortical responses are detectable according to classical data; 2) only concerned the central vertical meridian of the visual field; 3) mainly implicated cells at the 17/18 border (identified through Nissl or Cytochrome-Oxidase staining); 4) differed however from the adult through weaker visual responses and larger receptive fields.

Visual callosal transfer in kitten is thus very similar to that in the adult. Transient callosal projecting neurons described by anatomists do not seem to establish detectable functional connections with the contralateral visual cortex at least outside the 17/18 border.

ENDOCRINE CONTROL AND DEVELOPMENT I

NEURONS BORN DURING SONG LEARNING DO NOT CONTRIBUTE TO THE MAJOR EFFERENT PROJECTION OF AREA X. K. W. Nordeen, F. Sohrabii. and E. J. Nordeen. Dept. Psych., U. Rochester, Rochester, NY 14627.

Area X is a large, sexually dimorphic nucleus that has been implicated in avian song learning. During song learning in zebra finches, the number of new neurons added to this region is far greater in males (who sing), than in females. In this study we determined if the Area X neurons added during song learning form part of the efferent projection to the medial nucleus of the dorsolateral thalamus (DLM), and if this projection is sexually dimorphic. Male and female zebra finches received 2.5uCi/gm 3H-thymidine daily between 15 and 34 days posthatch. The birds were killed at 60 days, 5 days after receiving an injection of the tracer Fluorgold (Fig) into DLM. In both sexes the region corresponding to Area X was examined in autoradiograms for thymidine and retrogradely-labeled cells.

The density of cells projecting to DLM (Fig-labelled) was about 50% greater in males than in females. However, in neither sex did this sexually dimorphic pathway include neurons born during adolescence (thymidine-labeled). Hence, the majority of neurons added to Area X during song learning are not recruited into the Area X-DLM pathway and are likely to be interneurons. Furthermore, the sexually dimorphic projection to DLM probably consists of earlier-born neurons incorporated before or during the onset of song acquisition (<20 days). In fact, preliminary studies using the tracer Dil indicate that this pathway is present in males as early as 15 days.

143.2

CHARACTERIZATION OF A TRANSIENT PATHWAY LINKING AN AVIAN SONG NUCLEUS WITH THE VENTRICULAR ZONE DURING SEXUALLY DIMORPHIC NEURON ADDITION. F. Sohrabji. E. J. Nordeen, and K. W. Nordeen. Dept. Psych., U. Rochester, Rochester, NY 14627.

Area X is a sexually dimorphic region critical for avian song learning. Early estrogen (E2) exposure masculinizes this region by stimulating addition of neurons born during adolescence. Identifying putative proliferative zones and migratory paths for these neurons will aid in determining whether E2 stimulates their production or survival. Here we describe a transient pathway linking Area X to the ventricular germinal zone (VZ) during hormone-dependent neuron addition.

Brains of male zebra finches (12d, 25d, and >120d) were perfused and a crystal of dil placed into the lobus parolfactorius (LPO) either inside or outside of Area X. Following a 3 week incubation period, the position of labeled cells and fibers were traced in coronal sections.

At 12 days, injections of dil into Area X labeled fibers leading to cell bodies in the VZ dorsal to the lamina medullaris dorsalis. Dil injections outside of Area X labeled a distinctly different portion of the VZ. The VZ-Area X pathway was sparse at 25 days, and absent in adult birds. The morphology of labeled VZ cells and the orientation of their processes resembled those of avian radial glia (Alvarez-Buylla and Nottebohm, 1989). In support of this hypothesis, we have recently identified vimentin-positive fibers oriented similarly to the dil-labeled pathway. This Area X-VZ projection may reveal the source and migratory route of Area X neurons, thus facilitating identification of cellular processes underlying sex differences in the addition of Area X neurons.

THE RAT VISUAL CORTEX IS SEXUALLY DIMORPHIC BY WEANING AGE. P. Seymoure and J. M. Juraska. Dept. of Psychology, University of Illinois, Champaign, IL 61820.

Recently our laboratory reported sex differences (male > female) in laminar thickness in the binocular (Oc1B) region of the visual cortex of adult socially housed Long-Evans rats (Reid & Juraska, Neuro. Abs. 1989). In the present study cortical depth was measured in the monocular (Oc1M) and Oc1B regions of littermate pairs of 25-day old male and female Long-Evans rats to determine if sex differences in cortical depth were present before puberty. The weaning-age males had thicker layer I, layer II-IV, and total cortical depth than females in Oc1B. No sex differences were found in Oc1M layers. The possibility that sex differences in dendritic field size might account for the differences in layer thickness was explored by quantifying Golgi-Cox stained layer III pyramidal neurons from the visual cortex of 7 littermate pairs of weaning-age Long-Evans rats. Analysis of the dendritic tree revealed that females had a 12% greater length in the basilar tree and a 19% greater length of apical oblique branches than males. We are presently analyzing whether the differences in dendritic size vary between Oc1M and Oc1B. At this time, the relationship between the sex differences in the thickness of the upper layers and dendritic field size is unclear. Supported by NSF BNS 89-

143.5

DO DIFFERENCES IN NEURON NUMBER CONTRIBUTE TO THE SEX DIFFERENCES IN THE SIZE OF THE BINOCULAR AREA OF THE RAT VISUAL CORTEX? S.N.M. Reid and J.M. Juraska. Neuroscience Program & Dept. of Psychology, Univ. of Illinois, Champaign, IL 61820

We have shown that there are sex differences (M>F) in the overall thickness of the binocular area (the 17/18a border) of the hooded rat visual cortex (Reid & Juraska, Neuro. Abst. 1989). In order to investigate whether sex differences in neuron number are the basis for the differences in thickness, we first established the volume of each layer within the binocular area of each sex. The posterior cortex of nine littermate pairs of rats, socially housed to 90 days of age, was frozen sectioned at 40 microns and stained with methylene blue-azure II. The borders of the binocular area (Oc1B according to Zilles, 1985) were delineated and the boundaries of each layer were identified. Serial reconstruction of the area from 5-8 sections (both hemispheres) were made with a Eutectic imaging system. Male rats had a significantly greater volume overall (11.8%) and in each layer (I, II- III, IV, V, VI). No hemispheric differences were found. Currently, neuronal number and size are being estimated through the disector method (Sterio, J.Micro. 1983) on semi-thin sections obtained from the same animals that were used for the volume estimation. Supported by NSF BNS 89-09164 & HD07333.

PUBERTAL-RELATED INFLUENCES ON HYPOTHALAMIC NOREPINEPHRINE PROJECTIONS. S. Choi and C.K. Kellogg. Dept. of Psychology, Univ. of Rochester, Rochester, NY 14627. Earlier studies have indicated that norepinephrine (NE) uitilization (following synthesis inhibition) was undetectable in the diencephalon until after day 14 and that NE turnover in the hypothalamus (HY) at 28 days was only one third adult rates. NE turnover rate in the cortex (CTX) was found to be adult-like at birth. During puberty, organisms undergo dramatic hormonal changes, and the events organisms unucigo trainanc normonal changes, and the events occurring during puberty may influence further development in NE projections to the HY. To test this hypothesis, male Long Evans rats were castrated at 14 days of age. NE and dopamine turnover were estimated in the HY and CTX at 28 (prepuberty), 42 (early puberty) and 70 (late adolescence) days. Catecholamine (CA) turnover was estimated by measuring the decrease in CA levels (using HPLC counted to altertechanical detection) four three of the counted to altertechanical detection. coupled to electrochemical detection) four hrs after administering a tyrosine hydroxylase inhibitor, alpha methyl-p-tyrosine (250 mg/kg). The rate of NE utilization increased in the HY in intact animals over age but changed little in the CTX. Juvenile castration retarded the development of NE utilization in the HY but not in the CTX.

Whereas NE levels in the HY decreased approximately 57% in intact rats at 70 days, there was only a 33% decrease noted at this age in castrated rats, a magnitude of loss observed in both intact and castrated rats at 42 days. DA turnover in the HY was unaffected by castration. Full kinetic analyses are underway. In summary, NE projections to the HY show a delayed onset in function, compared to other NE projection systems, and pubertal events may influence development in this system. Supported by Grant MH31850.

SEX DIFFERENCES IN THE ULTRASTRUCTURAL DEVELOPMENT OF THE RAT CORPUS CALLOSUM. J.H.Y. Kim and J.M. Juraska. Neuroscience Program & Dept. of Psychology, Univ. of Illinois, Champaign, IL 61820

Our previous research has demonstrated that 55 day old female Long-Evans hooded rats have more axons than male rats in the splenium of the corpus callosum (Juraska & Kopcik, Br.Res. 1988). This sex difference could be due to developmental differences in axonal outgrowth and/or withdrawal in the corpus callosum prior to 55 days of age. To investigate this, we examined the development of the corpus callosum at 15 and 25 days of age. First, gross size measurements of the splenium (posterior fifth) were obtained from brains cut midsagittally and Weil stained en block. No sex differences were found, but there was an increased area in 25 day old relative to 15 day old rats. Second, the splenial region was sampled with electron microscopy in a dorsal to ventral fashion. There were no sex differences in the number of axons at 15 days of age. At 25 days, females had significantly more unmyelinated axons than their male littermates, similar to the pattern previously seen in young adults. The number of myelinated axons increased in both sexes between 15 and 25 days. In females, the number of unmyelinated axons increased from 15 to 25 days of age. This latter result is startling enough that we are adding subjects to confirm that the corpus callosum can continue to add axons after 15 days of age. Supported by NSF BNS 89-09164.

143.6

NEONATAL EXPOSURE TO GONADAL HORMONES AFFECTS ATECHOLAMINE SYSTEMS IN THE DEVELOPING CORTEX OF THE RAT. J. Stewart, S. Kühnemann and H. Rajabi. Center for Studies in Behavioral Neurobiology, Department of Psychology, Concordia University, Montreal, Canada, H3G1M8.

The effects of neonatal castration of male, and TP treatment of female

art pups on levels of monoamines and metabolites in the cerebral cortex were assessed using HPLC with electrochemical detection. In a first experiment, pups were killed at 0, 4, 10 and 21 days of age, and the anterior and posterior portions of cortex in each hemisphere were rapidly removed. At 21 days of age the levels of DA in anterior cortex were higher in males and TP-treated females than in females and GX were night in males and 17-treated remaies than in remaies and GX males. However, dopaminergic activity developed earlier in females than in males and the gonadal hormone manipulations shifted the pattern of development to that of the other sex. In a second experiment, the effects of these same gonadal hormone manipulations on the uptake, metabolism and storage capacity of CA neurons in cingulate (CING), agranular insular (AID), parietal (PAR) and occipital (OC) cortex were estimated at 4 and 10 days of age by considering the difference between measured CA in animals pretreated with vehicle or reserpine and then measured CA in animals pretreated with vehicle or reserpine and then given I-dopa (Coyle & Molliver, 1977). Again, the data indicated earlier development of CA neurons in females, especially in AID. DA was found to account for the group differences; when only DA was considered it was found that at 4 days of age females had the highest levels in every area with the exception of OC where GX males had equally high levels. These data suggest a mechanism that might account for sex differences in the development of specific cortical regions

REDUCTION IN THE VOLUME OF THE SEXUALLY DIMORPHIC NUCLEUS OF THE MEDIAL PREOPTIC AREA (SDN-MPOA) RESULTING FROM PRENATAL STRESS IS INDEPENDENT OF DEFICIENT MALE RAT COPULATORY PATTERNS. M. Kerchner, W. Grisham, and I. L. Ward. Psychology Department, Villanova University, Villanova, PA 19085.

Prenatal stress disrupts full masculinization of adult sexual behavior and reduces the number of neurons within the Spinal Nucleus Bulbocavernosus (SNB) and the Dorsolateral Nucleus (DLN) [Grisham, Kerchner, & Ward, unpublished]. However, there is no difference in cell number between

(SNB) and the Dorsolateral Nucleus (DLN) [Grisham, Kerchner, & Ward, unpublished]. However, there is no difference in cell number between subjects that ejaculate and those that fail to ejaculate. We now report the SDN-MPOA volume from the same animals for whom we previously counted SNB and DLN neuron number.

56 control males and 44 male offspring of pregnant female rats exposed to daily stress during the last week of gestation were studied. All males were screened as being either an ejaculator or nonejaculator. Brain sections were stained with thionin. A computer assisted digital image analysis technique was used to obtain morphometric data. In each animal, the average volume of the left and right SDN-MPOA was calculated.

The mean volume (x 10⁻³ mm³) of the SDN-MPOA of stressed males was

or the left and right SDN-MPOA was calculated. The mean volume (x $10^{-3} \, \mathrm{mm}^3$) of the SDN-MPOA of stressed males was significantly smaller than that of control males [13.93 (±0.15) and 18.39 (±0.90) respectively (p < .01)]. There was no difference between ejaculators and nonejaculators, in either the control or stressed groups. We conclude that prenatal stress can lead to an incomplete masculinization of sexually dimorphic structures in the brain and spinal cord, but that these alterations need not be associated with abnormal sexual behaviors. (Supported by 2R01 HD-04688 from NICHHD and 2K05 MH00049 from NIMH.)

Early Experience Affects Spatial Learning Ability. L.A.Wilson and L. Nadel. Dept. of Psychology, Univ. of Arizona, Tucson, AZ 85721. Handling and isolation of infant rats are forms of experience that alter structure and function of the nervous system. Handling of rat pups increases brain and body size, glucocorticoid receptor concentrations in the hippocampus, and produces reduced emotionality and improved learning ability on many tasks. Isolation of young rats from their mothers halts growth in the pups and increases the tendency of the pups to respond to stress with elevation of normally low levels of corticosterone. Emotional and social behavior is impaired in monkeys that have been isolated during infancy, however it is unclear what effect this manipulation may have on learning however it is unclear what effect this manipulation may have on learning ability. Although it is not immediately obvious what these two manipulations have in common, one possibility is that both exert at least some of their effects by interfering with the late developing areas of the hippocampus This brain area is in a dynamic phase of development during the time that handling and isolation produce their effects; it plays a crucial role in learning ability and is also an important link in the adrenocortical stress response system. Thus it was hypothesized that when rat pups were handled and/or system. Thus it was hypomersized that when rat pups were nanoled annow isolated, they would exhibit enhanced hippocampal learning ability, and that they would respond to a novel environment with higher activity levels than controls. Litters of 8 Long-Evans rats were assigned to either handled(HO), isolated(IO), handled/isolated (HI) or control (CO) groups at birth. Activity levels were measured in an open field at 40 days of age and all animals were tested on a spatial and a nonspatial version of the Morris water maze task at 60-70 days. Activity levels did not differ between the groups, and none of the groups had any difficulty learning the nonspatial task. On the spatial task however, the HO animals required significantly longer to acquire the task than IO or CO, and HI animals learned the task more quickly.

143.11

THE DEVELOPMENT OF CUTANEOUS CONTROL OF LORDOSIS. G.S. Benedict and C.L. Williams. Depts. of Psychology, Columbia Univ. and Barnard College, NY, NY 10027.

Psychology, Columbia Univ. and Barnard College, NY, NY 10027. Previous work has demonstrated that male and female 6-day-old rats are capable of performing lordosis to rapid brushing on the sides combined with pressure on the rump. Priming with estradiol benzoate (EB) and progesterone (P) facilitates lordosis frequency, duration, and intensity (Williams, Behav. Neurosci., 101, 1987). Kow and Pfaff (Brain Res., 101, 1976) demonstrated that input from a region around the anterior curve of the hips is the important cutaneous region for the elicitation of lordosis in the adult female rat. The purpose of this study is to examine the effect of EB and P priming on lordosis responding to tactile stimulation and to compare the cutaneous control of lordosis in the neonate and the adult female. To examine the localization of cutaneous input for lordosis, subjects were denervated on the waist (a the neonate and the adult female. To examine the localization of cutaneous input for lordosis, subjects were denervated on the waist (a region which includes the anterior curve of the hips), on the midriff (a larger region including the waist), on the flanks, and on an extensive region containing the midriff and flanks. Denervated and sham-operated adult females received either 5 or $100 \, \mu g$ EB and $0.5 \, mg$ P, $40 \, and 4 \, hrs$ prior to lordosis testing, respectively, while neonates were tested either without hormone-priming or with $100 \, \mu g$ EB and $0.5 \, mg$ P. The results suggest: 1) a high dose of EB increases the size and/or sensitivity of the cutaneous region critical for eliciting lordosis; 2) lordosis in the infant does not appear to be under strong cutaneous control as it is in the adult; 3) there is a sex difference in the cutaneous control of lordosis in infant 3) there is a sex difference in the cutaneous control of lordosis in infant rats -- female rats require more regionally specific input than male rats.

143.13

THYROXINE INDUCED CHANGES IN DISTRIBUTION OF A MULLER CELL ANTIGEN. D. Eastzer. G. Kirchbaumer* and S. Hoskins. Department of Biology, City College of New York, NY, NY 10031.

To study thyroxine regulated developmental changes in the *Xenopus*

visual system, we used immunosuppression techniques to generate monoclonal antibodies to molecules expressed in the retina during metamorphosis. One antibody, IPS30, stains a subset of Müller cells, glial cells which span the thickness of the neural retina. immunoreactivity is both developmentally regulated and spatially localized. Before metamorphosis, staining is seen in the ganglion cell layer and at the inner limiting membrane. During metamorphosis, the portion of the cell which spans the inner plexiform layer (IPL) is also stained.

To test the hypothesis that the apparent redistribution of the IPS30 antigen is caused by thyroxine, we blocked endogenous thyroxine antigen is caused by thyroxine, we blocked endogenous thyroxine synthesis in premetamorphic tadpoles using propylthiouracil. One eye of each tadpole was then injected with 3 ng of thyroxine in oil, the other eye receiving oil alone. At this dose, no systemic effects of thyroxine are seen. In 4 of 5 metamorphically-blocked tadpoles, the thyroxine treated retina showed more IPS30 staining in the inner plexiform layer. On average, 71% (range: 42%-89%) more cells with staining spanning the IPL were found in thyroxine treated eyes. one tadpole showed no staining in the IPL of either eye. Thus, the altered distribution of this Müller cell antigen during metamorphosis appears to be regulated by thyroxine acting at the level of the eye. Supported by NIH R29 NS25042 and NSF BNS 8616730.

EFFECT OF HYPOTHALAMIC LESIONS INDUCING PRECOCIOUS PUBERTY ON THE MORPHOLOGICAL AND FUNCTIONAL MATURATION OF THE LHRH CELL SYSTEM. M.P. Junier, A. Wolff, G. Hoffman, and S.R. Ojeda. Div. Neuroscience, OR Reg. Prim. Res. Ctr., Beaverton, OR 97006, and Dept. Physiology, Univ. Pittsburgh, Pittsburgh, PA.

We recently showed that preoptic area-anterior hypothalamic area (POA-AHA) lesions induce precocious puberty through the enhanced production of transforming growth factor α (TGF α). In the present study we examined the effect of these lesions on the morphological and functional maturation of the luteinizing hormone-releasing hormone (LHRH) neuronal system. Electrolytic lesions of the POA-AHA of 22-day-old female rats advanced the timing of puberty by 6 days. Immunocytochemical studies revealed that the lesion, although compromising the medial preoptic area, spared most LHRH neurons. The morphological characteristics of LHRH neurons at the light microscopy level, evaluated at the time of vaginal opening, were not different in animals undergoing precocious puberty than in the almost 1 week older intact controls. While TGF_{α} mRNA levels increased within 4 days after the lesion, no changes in LHRH mRNA levels were detected by RNA blot hybridization of polyadenylated RNA to a LHRH cRNA probe. During the first four days after the lesion LHRH content in the POA-AHA and median eminence (ME) of lesioned animals was similar to that of age-matched controls. On the day of vaginal opening the LHRH content in the ME of lesioned rats was almost two-fold greater than control animals having vaginal opening at a normal age. Although setting in motion the releasing mechanisms underlying the first preovulatory setting in motion the releasing mechanisms underlying the first preovulatory surge of gonadotropins. (Supported by NIH grants RR09988 and RR00163)

DEVELOPMENTAL EXPRESSION OF VASOPRESSIN HYPOTHALAMUS: DOUBLE LABELING WITH IN SITU HYBRIDIZATION AND IMMUNOCYTOCHEMISTRY.

K Murayama, RB Meeker, S Murayama and RS Greenwood. Depts of Neurology and Pathology, Univ. of North Carolina, Chapel Hill, NC, 27599 Magnocellular neurons in human hypothalamus were studied by double

labeling with in situ hybridization for vasopressin (VP) mRNA and immunocytochemistry for VP peptide. Frozen (20 um) or paraffin (8um) sections were cut from 10% buffered formalin-fixed brains from the files of Department of Pathology. The sections were hybridized by newly synthesized 27-mer (HVP-2) and 30-mer (HVP-1) oligonucleotide antisense probes complementary to sequences in Exon C of the human VP gene coding for glycoprotein (HVP-2) or VP neurophysin (HVP-1), double-stained with an anti-neurophysin II antibody (K.Dierickx, *Cell Tissue Res.* 184:15-27, 1977) using the avidin blotin complex or alkaline phosphatase-avidin method, and processed for autoradiography. Single cell silver grain

densities were analyzed with an image analysis system (Bioquant IV).

Both probes (HVP-1, HVP-2) gave comparable patterns of hybridization.

Positive cells for both in situ hybridization and immunocytochemistry were detected in supraoptic, paraventricular and intersupraoptico-paraventricular nuclei of hypothalamus as early as 19 weeks of gestational age. weeks gestation vasopressinergic neurons were found in the usual adult position in the hypothalamus. Cellular size grew larger as gestational age. increased. No significant decrease in hybridization intensity was apparent in the 22 week fetal brain relative to adult levels. Our study shows that some human fetal supraoptic and paraventricular neurons express vasopressin and have migrated by the second trimester

ALTERED CEREBELIAR PROTEIN SYNTHESIS IN PROPYLTHIOURACIL TREATED RATS. D.M. Jaworski*, N.C. Mills* and J. Hines Dept. of Biology, Texas Woman's Univ., Denton, TX, 76204. Thyroxine alters the developmental expression of a

number of genes. Central nervous system effects include altered cellular morphology, migration and synaptogenesis in addition to gross morphological alterations of cretinism -retarded skeletal growth, retention of infantile skull proportions and awkward motor coordination. The goitrogen propylthiouracil (PTU) (20 mg/kg s.c. to dams and pups) was used to induce hypothyroidism for investigation of altered cerebellar protein synthesis. A significant reduction in body, brain and cerebellum weights, as well as brain:body and cerebellum:brain weight ratios were observed. Histologically, cerebellar cortical stratification is also altered. Total RNA has been isolated from pooled cerebella of 1,10,20,30 and 60 day postnatal male rats and mRNA prepared using oligo (dT) cellulose. Protein profiles were generated by in vitro translation in a micro-coccal nuclease treated reticulocyte lysate system and synthesized proteins were separated by weight using SDS-Synthesized proteins were separated by weight using SDS-PAGE. In addition, the mRNAs are being used for Northern hybridization with cDNAs for apolipoprotein E (apoE) and transferrin (Tf). In control animals both apoE and Tf display time-dependent alterations in synthesis. It is anticipated that synthesis in hypothyroid animals will be both reduced and delayed.

SEXUAL DIMORPHISMS IN VERTEBRATE MOTOR SYSTEMS HORMONAL INFLUENCES ON MOTONEURONS AND THEIR TARGET MUSCULATURE IN A VOCALIZING FISH. A. Bass, M. Marchaterre and R. Brantley, Neurobiology & Behavior, Cornell University, Ithaca, N.Y. 14853.

In a vocalizing fish, the plainfin midshipman (Porichthys notatus), the fundamental frequency of sound communication signals is determined by the contraction rate of striated "sonic" muscles apposed to the lateral walls of their swimbladder; this rate is established in turn by the rhythmic discharge frequency of sonic motoneurons. Only large, nest-guarding (Type I) males are sonic; gravid females and non-reproductive juveniles are not known to generate sounds. Earlier studies have shown that differences in vocal behavior are paralleled by those in the dimensions of sonic motoneurons and sonic muscles. For example, absolute muscle mass is about 2500%, muscle fiber diameter is 200-300%, and moto neuron soma diameter is 100%, greater in vocalizing males. The muscle fibers of vocalizing males are also characterized by expanded peripheral and central zones of sarcoplasm filled with mitochondria, a highly branched sarcoplasmic reticulum, and myofibrils with widened Z-lines. Juvenile males and juvenile females were implanted with pellets of 11-ketotestosterone or testosterone (androgens). The muscle fibers of androgen-treated juveniles resembled those of vocalizing namely they had an expanded peripheral and central sarcoplasm filled with mitochondria. Their peripheral sarcoplasm was also characterized by dense whorls" of endoplasmic reticulum, clusters of glycogen, and islets of myofribrils. There was also an average increase of 40-50% in motoneuron soma diameter.

Together with data on androgen-binding in sonic muscle but not motoneurons, the results support the hypothesis that the development of sexual dimorphisms in the sonic pathway are ultimately dependent upon a cascade-like series of trophic events initiated by an expanded periphery. Support by NIH, NSF and NIMH.

MATERNAL STIMULATION AFFECTS THE NUMBER OF MOTONEURONS IN THE SPINAL NUCLEUS OF THE BULBOCAVERNOSUS (SNB).

C.L. Moore, H. Dou and J.M. Juraska. Dept of Psychology,

Univ. of Illinois, Champaign, IL 61820

During early postnatal development, male rats receive extensive stimulation from maternal anogenital licking (AGL). Previous work has shown that reduction of AGL by producing anosmia in the dam results in deficits in masculine sexual behavior of offspring, thus raising the question of how the stimulation affects the development of underlying neural mechanisms. In the present study, we examined the spinal cord of adult male rats that had either been raised normally or been raised by dams made anosmic through intranasal applications of zinc sulfate. The lumbar spinal cord was celloidin embedded, sectioned at 50 microns and stained with methylene blue. Motoneurons having visible nucleoli were counted in each section of the SNB motor column. In our preliminary data, we have found a significant (t=2.9, df=13, p<.02) 12% reduction in the number of motoneurons in the SNB of males raised by anosmic dams (n=6) compared to control males (n=9). SNB motoneurons innervate penile muscles that control sexual reflexes, and inadequate development of this neuromuscular system may underlie some reported deficits in sexual behavior. Supported by NSF RII 89-05498.

NORMAL DISTRIBUTION OF SEROTONIN AND SUBSTANCE P IN THE SEXUALLY DIMORPHIC CREMASTER NUCLEUS OF ANDROGEN-INSENSITIVE TESTICULAR FEMINIZED (Tfm) RATS. B.W. Newton & K.W. Chung* Depts. of Anatomy, U. of Arkansas for Medical Science, Little Rock, AR 72205 & U. of Oklahoma Health Sciences Center, Oklahoma City, OK 73190 King-Holtzman (K-H) Tfm male rats produce androgens, but they

lack at least 85% of their androgen receptors. Consequently, two of their sexually dimorphic lumbar nuclei (male motoneuron number > female) and their muscle targets are distinctly feminized (spinal nucleus of the bulbocavernosus and dorsolateral nucleus; J. Neurobiol., 17:157,'86). In Sprague-Dawley rats the male cremaster nucleus (CN) has a larger number of motoneurons and a much greater serotonin (5HT) and substance P (SP) innervation than females. Previous data suggests that the SP and 5HT innervation of the male CN is predominately under muscle target vs. androgen control (Brain Res. 485:149,'89). However, no one has examined the Tfm CN and its 5HT and SP innervation. Normal male, female, and male Tfm K-H rats were perfused for the PAP technique and their CN immunostained for either 5HT- or SP-immunoreactivity (IR). Results reveal that despite the >85% reduction in androgen receptors, the 5HT- and SP-IR within the CN of male Tfm rats appears the same as normal male K-H rats, and is much greater than in normal K-H females. These data suggest that either androgens are not the principle factor which maintains the 5HT and SP innervation of the CN in male Tfm K-H rats or, that <15% of androgen receptors can maintain the 5HT and SP afferent input in male K-H rats. Supported by BRSG RR05350, Arkansas Caduceus Club (BWN), and Presbyterian Health Foundation (KWC).

SEXUAL POLYMORPHISMS AND ANDROGEN SENSITIVITY OF SOUND-GENERATING MUSCLE IN A VOCALIZING FISH. R. Brantley and A. Bass. Section of Neurobiology and Behavior, Cornell University, Ithaca NY 14853 and UC Bodega Marine Lab, Bodega Bay CA 94923

Two sexually mature male morphs exist in *Porichthys notatus*: "Type I" males which produce a "humming" vocalization believed to function as a mate call, and sneak-spawning "Type II" males which, like females, are not known to vocalize. Sounds are generated by the contraction of "sonic" muscles apposed to each wall of the swimbladder. Differences in vocal behavior are paralleled by those in muscle mass: Type I males possess larger muscles than paralleted by Inose in music is mass: Type I makes possess larger muscles man either females or Type II males in both absolute mass (25-fold and 53-fold, respectively) and relative to body weight (11-fold and 7-fold). To test for a role of gonadal steroids in the development of these dimorphisms, both intact and gonadectomized juvenile males, juvenile females, and Type II males received subcutaneous pellet implants for 9 weeks of testosterone (T), 11-ketotestosterone (KT), 17B-estradiol (E2), or cholesterol (C). Relative sonic muscle mass was then determined. Responses by intact and gonadectomized groups did not differ, so the data were pooled. KT stimulated increases of 68-99% in all three classes of fish (PLSD p<0.05); T results were similar (p<0.05; Type II males not implanted with T). Neither E2 nor C showed any

(p<0.05; Type II males not implanted with T). Neither E2 nor C showed any effect. We conclude that the dramatic increase in sonic muscle mass in Type I males at reproductive maturity is induced by androgens.

Natural sex dimorphisms in sonic muscle mass are paralleled by those in fiber number: Type I males have more sonic muscle fibers than either females or Type II males (means of approx. 41,648 fibers per side (n=11) vs. 8130 (n=4) and 14,056 (n=5) respectively; Scheffe p<0.01). Given this, one hypothesis is that androgens stimulate sonic muscle enlargement in Type I males at least in part through their influences on muscle fiber number. Supported by NIMH, NSF, and NIH grants.

FIELD POTENTIAL ANALYSIS OF DESCENDING PROJECTIONS TO THE LUMBAR SPINAL CORD AND OF PROPERTIES OF ANDROGEN-SENSITIVE MOTONEURONS IN MALE RATS. J. Tanaka & A.P. Arnold, Department of Psychology, UCLA, Los Angeles CA 90024-1563.

Recent anatomical evidence suggests that projections from the lateral vestibular nucleus (LVe) and gigantocellular reticular nucleus (Gi) innervate areas of the lumbar spinal cord near the spinal nucleus of the bulbocavernosus (SNB). To confirm this result electrophysiologically, we recorded and mapped averaged field potentials within the lumbar spinal recorded and mapped averaged field potentials within the lumbar spinal cord of urethane-anesthetized male rats in response to electrical stimulation of the LVe or Gi, and compared this with the location of somatic action potentials elicited at the same levels by stimulation of SNB axons. In all the rats (n=7) tested, LVe stimulation elicited a negative field potential (latency 2.7 ± 0.4 ms; threshold $46 \pm 7 \mu A$). Gi stimulation also produced a negative potential (latency 2.4 ± 0.1 ms; threshold $32 \pm 12 \mu A$). LVe- and Gi-evoked responses were largest at the 200 450 and descriptions that SNB captages and the spinal strateges of the spinal strateges and the spinal strateges and the spinal strateges and the spinal strateges are strateged to the SNB captage in the spinal strateges and the spinal strateges are spinal strategies. sites 200-450 μ m dorsolateral to the SNB somata, indicating that afferent input to the lumbar spinal cord from LVe and Gi occurs most strongly some distance away from the SNB somata, perhaps onto a population of interneurons

Since SNB motoneurons are regulated by androgen, we compared antidromic somatic field potentials of SNB motoneurons in intact (n=14) and castrated (n=8) rats, but found no group differences in the latency or refractory period. When the SNB motoneurons were antidromically activated with double axonal pulses, long-latency inhibitory effects were observed suggesting the presence of recurrent or other inhibition evoked by stimulation of the motor nerve. Supported by NIH grant HD15021.

ONTOGENY OF STEROID ACCUMULATION IN RAT LUMBAR MOTONEURONS. <u>C.L. Jordan, S.M.Breedlove & A.P.Arnold¹,</u> Psych. Dept., UC Berkeley and ¹UCLA, CA.

Androgens influence postnatal development of motoneurons in the spinal nucleus of the bulbocavernosus (SNB), for example by regulating neuromuscular synapse elimination and growth and retraction of dendrites. We used steroid autoradiography to measure the ontogeny of steroid accumulation in these motoneurons as part of an attempt to determine where steroids act during the postnatal period. Male rat pups were castrated 2 days prior to s.c. injection of ³H-testosterone (300uCi/100g BW) on postnatal days (P)7, 14, and 21, and sacrificed 1.5 hi later. At least 40 SNB cells were examined from each animal (n=3/grp). Based on the Poisson criterion, virtually all SNB motoneurons accumulated testosterone at both P14 ($83\pm3.2\%$ mean \pm SEM) and P21 (84 \pm 8.9%) whereas very few SNB motoneurons accumulated androgen at P7 (9 \pm 7.8%). There was also an overall increase in the density of labelling between P14 and P21. At P14, 46% of SNB motoneurons had 3 or more times the number of background silver grains whereas 75% of the SNB motoneurons exceeded this criterion at P21. Since SNB motoneurons begin to accumulate androgen during the second week of life, androgen may act directly on SNB motoneurons to regulate synapse elimination and dendritic development. Supported by HD15021, NS08686, and the Sloan foundation.

GLIAL FIBRILLARY ACIDIC PROTEIN (GFAP) IMMUNOREACTIVITY IS INCREASED IN THE HYPOTHALAMUS OF ANDROGEN-INSENSITIVE (Tfm) MICE. K.L. Olsen, J.C. Speh and R.Y. Moore. Dept. Microbiology, George Washington Univ., Washington, DC 20037; Dept. Neurology, SUNY-Stony Brook, NY 11794.

Mice with the testicular feminization mutation (Tfm) have analysis of and approximately approximately and the story of and approximately approximately for the story of and approximately for the story of the s

Are with the testicular remining that in mutation (//m/) have a reduced number of androgen receptors. As a result of this X-linked recessive gene defect, these XY males are insensitive to their testicular androgens and develop a female external phenotype.

Hemale external phenotype.

Using the *Tfm* mouse, GFAP was identified as a protein that may be important in hormone-regulated functions (Olsen et.al., *Neuroendocri., 50:392,1989). Silver-stained 2D gels showed that GFAP concentration was higher in the hypothalamus of *Tfm* mice compared to wild-type males. In this study, we used immunohistochemistry to localize this increase in GFAP.

Nineteen mice (*Tfm-9; wild-type-10) were perfused and coronal sections through the hypothalamus were cut and stained for the presence of GFAP immunoreactivity. The increased staining in the *Tfm* extends from the caudal medial preoptic area through the anterior hypothalamic area into the retrochiasmatic area. This is predominantly periventricular in location. There are no consistent differences in other regions, including regions such as the hippocampus with heavy GFAP staining. The difference between the *Tfm* and wild-type mice appear to be an increase in astrocytic GFAP rather than mice appear to be an increase in astrocytic GFAP rather than in the number of astrocytes but this remains to be established.

143.23

ESSENTIAL ROLE OF THYROID HORMONES IN MATURATION OF OLFACTORY RECEPTOR NEURONS IN POSTSUCKLING RATS: A KNOB COUNT AND OMP STUDY. M. Paternostro and E. Meisami, Physiol. Dept., Univ. Illinois, Urbana, IL 61801.

We have shown that growing hypothyroid rats show a 40% reduction in the normal increase in olfactory epithelial (OE) surface area and olfactory neuron (ORN) number during the suckling period and no growth post-weaning. waithdrawal of PTU, show, by 90 d, complete compensation of OE surface area and total ORN number. To examine the maturation of ORNs, we determined the surface density of ORN dendritic knobs in (1 µ) sections of nasal septum in normal and hypothyroid rats. Dendritic knobs are characteristic for the contraction of the acteristic of mature ORNs (1 knob/ORN). The surface density of knobs increases postnatally, reaching 60x10³ (knobs/sq mm) in 90 d rats; the density was 45% and 70% of this value in newborn and 25 d normal rats. By 25 d, hypothyroid pups had 25% reduction in this parameter, compared to controls. After weaning, no more increase in knob density occurred in the hypothyroid rats, resulting in a 45% deficit by 90 d. The recovering rats, however, showed marked growth in density, nearly catching up with normal rats by 90 d. Immuno-histochemical localization of olfactory marker protein (OMP) in sections of septal OE confirmed the results obtained by knob count. Supp.: NIH Training Grant to M.P. & UICU Res. Board.

IMMUNOCHEMICAL AND MORPHOMETRIC CHARACTERIZATION OF NEUROPHYSIN NEURONS IN PARAVENTRICULAR CULTURES. M. Morris, B.A. Bennett and H. Xu*. Physiology and Pharmacology, Bowman Gray Sch. of Med., Wake Forest University, Winston-Salem, N.C. 27103. Immunochemical and neurophysiolgical studies show that hypothalamic

neurophysin (NP) cells are viable in culture. Experiments were performed to further characterize these peptidergic cells. Dissociated cultures of the paraventricular (PVN) region from neonatal rats were fixed and stained immunochemically with NP, vasopressin (VP) and oxytocin (OT) antisera. The NP antisera recognizes both VP and OT-NP while the peptide antisera are specific for the amidated peptides or the C-terminal extended forms. A morphometric analysis was performed to determine the size distribution of the MP cells and the density of the specific cell types. The NP positive cells showed a herterogeneity in size and shape. 38% of the NP cells were between 100 and 150 μ m², 48% were larger than 150 μ m² and the remainder were less than 100 μ m² (n = 50 cells). The cell diameter and process length were 14.8 \pm 1.4, 16.5 \pm 0.7 and 20.3 \pm 0.8 μ m (diameter) and 84 \pm 26.3, 243 \pm 40.6, and 261.2 \pm 43.2 μm (process length) for the small, medium and large cells, respectively. The immunochemical data showed that there was little or no staining when the specific VP and OT antisera were used. The majority of the peptide cells were immunopositive for the extended peptide forms. There were 34.8 \pm 2.8 VP cells and 102 \pm 17.1 OT cells/culture well (n = 4). This represented 14 and 41% of the total NP positive cells which averaged 248 cells/culture. These results demonstrate that PVN cultures contain a heterogenous population of neurophysin cells, reminiscent of the in vivo organization. There are differences, however, in the nature of the peptide cells since there is evidence for incomplete processing of the vasopressin and oxytocin precursor in the cultured cells.

MATERNAL SEPARATION EVOKES CRF RELEASE AND HPA AXIS ACTIVATION IN NEONATAL RAT PUPS. C. Pihoker, M.J. Owens, C.M. Kuhn and C.B. Nemeroff. Depts. of Psychiatry and Pediatrics, Duke Univ. Med. Center, Durham, NC 27710

Stress activates the hypothalamo-pituitary-adrenocortical (HPA) axis, with release of the hypothalamic neuropeptide corticotropin-releasing factor (CRF) stimulating pituitary ACTH secretion, which in turn promotes adrenal glucocorticoid release. The neonatal rat has been shown to be relatively stress hyporesponsive, during which time the hormonal response to certain stressors is diminished or absent. We have investigated the response of 10 day rat pups to a major stressor, maternal separation. Pups were removed from their dams for 2-24 hr, then sacrificed by decapitation. Trunk blood was collected and plasma assayed for corticosterone. Brains were rapidly removed and frozen; the median eminence was dissected and assayed for CRF concentration by RIA. Pups subjected to maternal separation exhibited a significant reduction in median eminence CRF concentration, accompanied by a dramatic rise in serum corticosterone. These results are similar to those observed in adult rats subjected to stress, with the decrease in CRF content reflecting its release from median eminence nerve terminals. Thus, release of CRF and subsequent activa tion of the HPA axis occurs in neonatal rats subjected to maternal separation. Supported by: The MacArthur Foundation, NIMH MH-19109, MH-42088, NIH DK-41777.

INSULIN-LIKE GROWTH FACTOR 1 (IGF-1) STIMULATES LHRH RELEASE FROM THE PREPUBERTAL FEMALE MEDIAN EMINENCE IN VITRO. J.K. Hiney*, S.R. Ojeda', and W.L. Dees. Dept. of Veterinary Anatomy, Texas A&M University, College Station, Texas 77843 and 'Division of Neuroscience, OR Regional Primate Res. Ctr., Beaverton, OR 97006.

Insulin-like growth factor 1 (IGF-1), is a polypeptide that functions in growth and development. Studies using the chimpanzee (Copeland, K.C. et al., J Clin Endo Met 55:1198, 1982), and the rat (Handelsman D., Endo, 120:491, 1987) revealed serum IGF-1 increases prior to and during puberty. In the present study we have examined the ability of IGF-1 to affect the release of LHRH from the median eminence (ME) of 30 day old female rats in vitro. The ME's were incubated in Krebs Ringer Bicarbonate Glucose Buffer (KREBS) then followed by KREBS containing doses of IGF-1 ranging from 1-200ng/ml. Results indicate that IGF-1 significantly induced LHRH release in a dose dependent manner, with a minimal effective dose of 10 ng/ml and a maximal effective dose of 100 ng/ml. Experiments to verify the specificity of this effect indicated that IGF-1 is ten times more potent at stimulating LHRH release than IGF-2 or Insuling Three vestiles indicate that IGF-1 is ten times more potent at stimulating LHRH release than IGF-2 or Insuling Three vestiles indicate that IGF-1 times more potent at stimulating LHRH release than IGF-2 or Insulin. These results indicate that IGF-1 can induce LHRH release in the prepubertal female rat and suggest that IGF-1 may play a role in the onset of female puberty.

"Regulation of the homeotic gene <u>Ultrabithorax</u> by ecdysone in the <u>Drosophila</u> larval central nervous system" M. A. Glicksman and J. W. Truman, Zoology, Univ. of Washington.

The adult CNS of <u>Drosophila</u> is made up of remodeled larval neurons as well as adult-specific cells that are

born during larval and early pupal stages. After the adult-specific cells are born, they are then arrested in their development until metamorphosis when they mature into functional neurons. We are interested in the role of homeotic genes in regulating the changes that occur in the CNS at metamorphosis. Using antibodies against the Ultrabithorax (Ubx) proteins, we have examined the time course of expression of Ubx in the post-embryonic nervous system. <u>Ubx</u> shows two levels of protein expression, high levels in neurons of embryonic origin and low levels in post-embryonic neurons. At the start of metamorphosis, the post-embryonic neurons shift to the high level of expression. Studies with ecdysoneless mutants and hormone treatment of larval nervous systems in tissue culture show that ecdysteroids control this change in level of protein expression.

(Supported by NIH F32HD07079)

CO-LOCALIZATION OF ECDYSTEROID RECEPTORS (ER) AND 29 K-PROTHORACICOTROPIC HORMONE (PTTH) IN THE NEURO-ENDOCRINE COMPLEX OF MANDUCA SEXTA. H.-J BIDMON*, W.E. STUMPF, W.E. BOLLENBACHER*, and N.A. GRANGER, DEPT. OF CELL BIOLOGY & ANATOMY, *DEPT. OF BIOLOGY, UNIV. of NC, CHAPEL HILL, NC 27599.

Ecdysteroids regulate insect development and metamorphosis and their production is controlled by the neuropeptide, PTTH. In vitro incubation of brains (BR), subesophageal ganglia (SEG), corpora allata (CA) and prothoracic glands (PG) in the 20-hydroxyecdysone agonist H-ponasterone A (4 nM, spec. act. 178 Ci/mmol), followed by thaw mount autoradiography was used to study the distribution and expression of ER during larval-pupal developopment. ER are found in neurons of the pars intercerebralis, pars lateralis and certain other regions in the BR and SEG on day 0, 3.5 and 4-6 of the last larval stadium, while ER in the PG are present on day 0, days 3-9 and after pupation. Between days 3 and 5 the number of neurons having ER increases as well as the number of ER per cell. Certain neurons like the ventral unpaired motoneuron in the SEG exhibit ER only at distinct times during development, e.g. days 5-6. The identification of the PTTH neurons in the BR with a PTTH monoclonal antibody revealed that the PTTH neurons contain nuclear ER. The presence of ER in PTTH neurons suggests that these cells respond to specific intercerebral ecdysteroid concentrations as part of the feedback regulation of ecdysteroid synthesis.

ENDOCRINE CONTROL AND DEVELOPMENT II

CO-LOCALIZATION OF TACHYKININ AND ENKEPHALIN IMMUNOREACTIVITY IN CELLS OF THE RAT HYPOTHALAMUS.

C. A. Priest, P. Popper and P. E Micewych. Department of Anatomy and Cell Biology and the Laboratory of Neuroendocrinology, Brain Research Institute, UCLA School of Medicine, Los Angeles, CA 90024-1763.

Regulation of lordosis behavior by the ventromedial hypothalamus (VMH) involves the interaction of estrogen with several steroid-sensitive, reproductively relevant neuropeptide circuits, including those which contain enkephalin (M-ENK) and the tachykinin, substance P (sP). Recently, cells in the VMH which contain sP or M-ENK have been shown to concentrate estrogen (Akesson and Micevych, J. Neurosci. Res., 19:412, '88; Akesson and Micevych, Submitted), and estrogen induces expression of M-ENK, but not of sP. Because distributions of M-ENK immunoreactive and sP immunoreactive cells overlap, we hypothesized that the Because distributions of M-ENK differential regulation of M-ENK in sP cells would represent an important component of the mechanism by which estrogen modulates lordosis. To test this hypothesis, we determined whether M-ENK and sP immunoreactivity were colocalized in cells of the VMH. Adult Long-Evans rats received 100 µg colchicine i.c.v., were perfused 48 h later with 4% paraformaldehyde and brains were processed for histochemistry. Immunoreactivity was localized using a rat monoclonal antiserum to sP (Sera Labs) labeled by a biotin-avidin conjugated Texas Red reaction combined with use of a rabbit polyclonal antiserum to M-ENK (Inestar) which was visualized using an antirabbit IgG conjugated to fluorescein isothiocyanate. M-ENK and sP immunoreactivity were co-localized in cells of the ventrolateral part of the ventromedial nucleus. Additionally, doubly-labeled cells were found in the medial preoptic area, dorsomedial hypothalamus, lateral hypothalamus, and in a band extending from the ventrolateral part of the ventromedial nucleus toward the fornix. The co-localization of M-ENK and sP immunoreactivity provide evidence for a common neuroanatomical substrate for the regulation of lordosis behavior by cells of the VMH. Supported by NS 21220.

ANDROGENS REGULATE EXPRESSION OF CALCTIONIN GENE-RELATED PEPTIDE IN THE SNB MOTONEURONS THROUGH THEIR TARGET MUSCLES. P.Popper, C.Ulibari and P.E Micevych, Dept. of Anatomy and Cell Biology, Laboratory of Neuroendocrinology, Brain Research Institute, UCLA School of Medicine, Los Angeles, CA 90024.

Previous work showed that castration of adult male rats increases the steady state levels of calcitonin gene-related peptide (CGRP) and «CGRP mRNA in the motoneurons of the spinal nucleus of the bulbocavernosus (SNB). In the present experiments we tested the hypothesis that castration-induced up-regulation of CGRP expression is the result of feed-back of the bulbocavernosus (BC) and levator ani (LA) muscles on the SNB. We hypothesized that lack of androgens induce a soluble, CGRP-inducing factor by reducing BC activity. Muscle extracts were prepared from the BC of gonadally intact and castrated male Long Evans rats. Extract or buffer (50 µl/treatment) was injected in the BC of intact rats every 12 hours for 10 days. A group of rats whose pudendial nerves were cut (PDNX) 10 days prior to their killing was also included in the experiments to account for the effect of nerve damage. Alternate section through the SNB were processed for CGRP immunoreactivity and in situ hybridization with a probe complementary to the 3'-end of the «CGRP mRNA, respectively. The effects of different treatments were compared to buffer and sham treated rats. Anesthesia significantly increased the number of SNB motoneurons containing acGRP mRNA and CGRP and increased the steady state levels of «CGRP mRNA. Treatment with extract prepared from the BC of castrated rats increased the number of SNB motoneurons containing acGRP mRNA and the level of acGRP mRNA. PDNX did not increase the number of SNB motoneurons expressing acGRP mRNA but slightly increased the steady state levels of acGRP mRNA. These results suggest that the increase of CGRP and acGRP mRNA at least in part, by the effect of castration-induced decreased muscle activity on the SNB motoneurons. Supported by NS 21220.

TACHYKININ IMMUNOREACTIVE NEURONS ACCUMULATE ESTROGEN IN SEXUALLY DIMORPHIC NUCLEI OF THE RAT LIMBIC SYSTEM. T.R. Akesson and P. E Micevych. Dept of VCAPP, Washington State University, Pullman, WA 99164 and Dept of Anatomy and Cell Biology and the Laboratory of Neuroendocrinology, Brain Research Institute, UCLA School of Medicine, Los Angeles, CA 90024-1763.

Gonadal steroid induction of mechanisms regulating reproductive function have been proposed to involve activation of a network of intercommunicating neurons in the hypothalamus and limbic system. In addition to their ability to concentrate extragen, subjects of neurons which form parts of this network have been further.

Gonadal steroid induction of mechanisms regulating reproductive function have been proposed to involve activation of a network of intercommunicating neurons in the hypothalamus and limbic system. In addition to their ability to concentrate estrogen, subsets of neurons which form parts of this network have been further characterized by identification of neuropeptide content. In an earlier study we combined the techniques of steroid autoradiography with immunohistochemistry to demonstrate a population of estrogen-concentrating, substance P-immunoreactive (8Pir) neurons in the ventromedial nucleus of the hypothalamus (VMH). Present results extend the localization of doubly labeled neurons to include the encapsulated part of the bed nucleus of the stria terminalis (BSTenc) and the posterodorsal division of the medial nucleus of the amygdala (MeApd). The results further indicate that while numbers of estrogen-concentrating sPir cells were similar between sexes in the VMH, males were found to have numbers of doubly-labeled neurons in both the BSTenc and MeApd that greatly exceeded female numbers. These findings are consistent with the possibility that estrogen-concentrating sPir cells convey steroid sensitive olfactory information to the hypothalamus and thus represent a component of the network which regulates reproductive function.

cells convey steroid sensitive olfactory information to the hypothalamus and thus represent a component of the network which regulates reproductive function. To address the question of whether or not gonadal steroids modulate tachykinin levels, intact males (n=6) and ovariectomized females receiving 4 mm silastic implants of estradiol benzoate (n=6) rats were compared to orchidectomized (n=6) or ovariectomized (n=6) rats. Gonadectomized rats were found to have greatly reduced immunodectable levels of sP in cells of the BSTenc and MeApd but not the VMH. In contrast, expression of mRNA coding for preprotachykinin has been shown to be unaffected by ovariectomy. This raises the possibility that estrogen may affect sP levels postranscriptionally. Supported by HD 22869 and NS 21220.

PREPROCHOLECYSTOKININ mRNA IN SPINAL CORD AND BRAINSTEM MOTONEURONS OF THE RAT. <u>L.A. Abelson and P.E Miceyych</u>. Dept. of Anatomy and Cell Biology, Laboratory of Neuroendocrinology, Brain Research Institute, UCLA School of Medicine, Los Angeles, CA 90024.

Preprocholecystokinin (pCCK) mRNA was localized to the motoneurons of the rat brainstem and lumbar spinal cord with in situ hybridization. A ³⁵S-labelled single-stranded cRNA probe complementary to the entire coding sequence of the prepro-CCK mRNA was used. The probe was transcribed from a 535 bp prepro-CCK cDNA inserted into a pGEM riboprobe vector (gift from Dr. J. Dixon, Purdue University, IN). Adult male Long Evans rats were perfused with 4% paraformaldehyde in 0.1M Sorensen's phosphate buffer. Tissue was removed and cryoprotected in 15% sucrose. 30 µm sections were cut through the lumbar cord and brainstem on a sliding microtome and collected onto silanated slides. Tissue pretreated with RNase A as well as tissue hybridized with a ³⁵S-labelled sense-strand CCK probe were used as controls. pCCK mRNA was localized to motoneurons with the antisense probe, but no specific labelling was noted on sections pretreated with RNase A or after hybridization with the sense-strand. Motoneurons of each motor column in the caudal lumbar spinal cord contained pCCK mRNA; the ventral motor pool, the ortorosolateral nucleus the spinal nucleus of the bulbocavernosus, the retrodorsolateral nucleus and the lateral motor nucleus. In the brainstem pCCK mRNA was localized in motoneurons of the facial nucleus, abducens nucleus and the motor trigeminal nucleus. Motoneurons, however, do not appear to be labelled when antibodies directed against CCK-8 are used, thus only speculative considerations about this discrepancy are possible. Currently, we feel that the greater sensitivity of in situ hybridization methods may account for this discrepancy.

DEVELOPMENT OF THE INHIBITORY EFFECT OF CHOLECYSTOKININ ON LORDOSIS IN RATS IS CONTROLLED BY PERINATAL ESTROGENS. C. Ulibarri and P.E. Micevych. Department of Anatomy and Cell Biology and the Laboratory of Neuroendocrinology, Brain Research Institute, UCLA School of Medicine, Los Angeles, CA 90024-1763. Female rats are more sensitive than males to the inhibitory effects of infusions of cholecystokinin (CCK) into the ventromedial nucleus of the hypothalamus (VMN). Neonatal castration of male rats prevents the defeminization of this effect of CCK on lordosis behavior. Androgenization of females with 100 gg of testosterone propionate (TP) on postnatal day 5 reduces the response to CCK. The present research investigated the role of estrogenic component of the defeminization of the response to CCK.

On the day of birth male rats were either given sham surgeries, castrated, implanted with either a 4 mm Silastic capsule of aromatase inhibitor 1,4,6 androstatrien-3,17-dione (ATD), or a 1 mm capsule of the antiestrogen tamoxifen. Females received either sham surgeries, or were implanted with a 4 mm capsule of TP. Capsules were removed 10 days later. As adults the rats were castrated and implanted unilaterally with a cannulae directed at the VMN.

mini capsure of 17. Capsures were reinvect to days later. As adults the table were castrated and implanted unilaterally with a cannulae directed at the VMN. Forty-eight hours after injections of 5 kg estradiol benzoate the animals were tested in a counterbalanced design for their response to infusions of 0, 5, 50, or 100 ng CCK/0.3 kl artificial CSF.

ATD-treated males, neonatally eastrated males and control females showed similar high levels of lordosis behavior and inhibition of that behavior by CCK. Terreated females and control males showed low levels of lordosis and therefore no response to CCK. Tamoxifen-treated males showed virtually no lordosis behavior. The high dose of tamoxifen may have been estrogenic and thereby increased the level of defeminization.

These results suggest that estrogens are involved in the defeminization of the response to CCK. Specifically, perinatal estrogens may reduce adult sensitivity to the inhibitory effects of CCK on lordosis behavior.

CHROMATOGRAPHIC CHARACTERIZATION OF RADIOACTIVITY IN CELL NUCLEI FROM THE BRAINS OF NEONATAL MACAQUES AFTER ADMINISTERING ³H-TESTOSTERONE. R.W. Bonsall and R.P. Michael, Department of Psychiatry, Emory University School of Medicine, Atlanta, Georgia 30322 and the Georgia Mental Health Institute, Atlanta, Georgia 30306.

During the neonatal period in male macaques, the testes produce adult-like plasma levels of testosterone. To investigate the mechanism of testosterone's uptake by the brain during this stage of development, 2 male and 2 female uptake by the brain during this stage of development, 2 male and 2 temate neonatal cynomolgus monkeys, gonadectomized 2-4 days after birth, were injected s.c. 3 days later with 500 μ Ci [³H]testosterone ([³H]T). After 60 min, brains were removed and dissected into blocks containing the hypothalamus and preoptic area (HYP), amygdala (AMG), hippocampus (HIP) and midbrain (MB). Samples of cerebral and cerebellar cortex and the entire pituitary gland were also taken. Purified nuclear pellets were prepared by centrifugation through 2 M sucrose, extracted into ether and analyzed by high performance liquid chromatography. Concentrations of radioactivity in nuclei from HYP were 10-20 times higher than those in cerebral cortex (P<0.001). In HYP, 49.9 \pm 6.5% of the extracted radioactivity was in the form of [3 H]estradiol, 16.5 \pm 2.1% was in the form of unchanged [3H]T and 10.1 ± 1.6% was in the form of [3H]dihydrotestosterone. Nuclear levels of radioactivity were also significantly higher than those in cerebral cortex in midbrain and amygdala (P<0.05). In pituitary gland, concentrations of radioactivity were similar to those in HYP, but 77.7 ± 13.3% was in the form of [HT]T and less than 4% was in the form of all-plestradiol. No significant differences were observed between male and female neonates. Results suggested that testosterone in the neonatal male primate may interact with cell nuclei in the brain and pituitary gland and that aromatization is active at this stage of development. ONTOGENY OF THE SEXUALLY DIMORPHIC MALE NUCLEUS IN THE PREOPTIC/ANTERIOR HYPOTHALAMUS (POA/AH) OF FERRETS AND ITS MANIPULATION BY GONADAL STEROIDS .A. Cherry, M.E. Basham*, C.E. Weaver*, R.W. Krohmer and M.J. Baum, Biology Department, Boston University, Boston, MA 02215

A sexually dimorphic nucleus exists in the dorsal region of the ferret POA/AH, called the male nucleus of the POA/AH (MN-POA/AH) because it is found only in males. The MN-POA/AH is present in males as early as embryonic day 37 (E37) of a 41-day gestation, and its volume increases until postnatal day 56 (P56). No nucleus is present in the dorsal POA/AH of females at any age. Densities and average somal areas of cells in the dorsal POA/AH are similar in both sexes at E33, before the MN-POA/AH can be visualized. However, at E37 and E41 dorsal cells are greater in density and/or somal area in males than in females. Previously, it was shown that the dorsal POA/AH nucleus could be created in adult females whose mothers were implanted sc with testosterone (T), and prevented from forming in adult males whose mothers were ovariectomized and implanted sc with the aromatase inhibitor, ATD, on day 30 of gestation. These treatments also sex-reverse dorsal POA/AH morphology in animals sacrificed on E41, confirming that the dorsal POA/AH nucleus seen in males at E37 and E41 is the same structure present in adult males. Thus, the MN-POA/AH is potentially functional during much of the period between E28 and P20 when behavioral sexual differentiation occurs in the male ferret. DEVELOPMENT OF RAT PITUITARY AND HYPOTHALAMIC ANDROGEN RECEPTOR (AR) AND AR mRNA. <u>E.W. Rodriguez, L.H.Burgess,</u> D.B. Lubahn, F.S. French, E.M. Wilson, R.J. Handa. Dept. of Cell Bio., Neurobio. and Anat., Loyola Univ., Stritch Sch. of Med., Maywood, IL 60153 and Lab. Reprod. Biol., Univ. of North Carolina, Chapel Hill, N.C. 27599 Androgens play an important role in the neonatal

organization and adult function of the hypothalamo-pituitary-gonadal (HPG) axis. To investigate how androgens affect HPG development, we examined the ontogeny of AR and AR mRNA in Sprague/Dawley rats of various ages. AR were measured by the in vitro binding of $^3\mathrm{H-dihydrotestosterone}$ to cytosol preparations of hypothalamus (HT), preoptic area (POA), hippocampus (HIP), and anterior pituitary (AP). AR was detected in HT, POA, and AP as early as postnatal day (PND) 1. Significant increases were detected on PND 12 and adult levels were reached by PND 20 on PND 12 and adult levels were reached by PND 20 (9.3±0.6, 6.8±0.3, 25.8±2.8 fmol/mg prot.; respectively). We examined AR mRNA from AP, hypothalamus-preoptic area (HPOA), and HIP using two ³²P-labelled fragments of rat cDNA (rAR-1 and rAR-2) and a ³²P-labelled cRNA transcribed from a Thal fragment of rAR-1. Northern blot analysis revealed a single 10 kb hybridization band in adult AP, HPOA, and HIP. A similar band was seen in neonatal HPOA and AP and was first detected on embryonic day 20-21 in HPOA and on PND 7 in AP. These data show that AR and AR HPOA and on PND 7 in AP. These data show that AR and AR mRNA are present in the neonatal HPOA and AP and thus may be involved in the organization of the HPG axis.

An Organ Culture System for the Study of CNS Metamorphosis in Drosophila melanogaster

Tim A. Awad*, John Palka, and James W. Truman, Department of Zoology, University of Washington, Seattle, WA 98195

The central nervous system (CNS) of holometabolous insects

becomes extensively remodelled during metamorphosis by the addition of adult-specific neurons, and the modification or elimination of larval neurons. Previous studies in the tobacco hornworm moth, <u>Manduca</u> sexta, have shown that the molting hormone, 20-OH-ecdysone is intimately involved in regulating the cellular and molecular events that take place in the CNS during metamorphosis, including the differentiation of adult-specific neurons. We have designed a tissue culture system in order to study the role of 20-OH-ecdysone in Drosophila CNS metamorphosis. Isolated larval nervous systems can <u>Drosophila</u> CNS metamorphosis. Isolated larval nervous systems can be grown in <u>vitro</u>, with or without 20-OH-ecdysone, for periods up to several days. Using this system, we have found that many of the changes that occur in the CNS during the first 24 hours of normal metamorphosis are regulated (directly or indirectly) by 20-OH-ecdysone, and can be reproduced within 48 hours of growth in <u>vitro</u>. Larval nervous systems cultured in the presence of 20-OH-ecdysone show an increase in cell proliferation, partial disintegration of the perineural sheath, and neuropilar expansion (in particular in the leg neuropiles and the optic lobes) due to the outgrowth of adult specific neuronal processes. In addition, we are using this system to analyze the hormonal regulation of changes in the morphology of some of the existing larval neurons that express SCP-like immunoreactivity which normally become modified during metamorphosis. (Supported by NIH Training Grant HD07183 (TAA) and NIH Grant NS13079 (JWT)).

INDEPENDENT EFFECTS OF AN AROMATASE INHIBITOR ON ESTRADIOL LEVELS AND THE DEGREE OF MASCULINIZATION OF THE ZEBRA FINCH SONG SYSTEM.

G.A.Mathews & A.P.Arnold.

Department of Psychology, UCLA, Los Angeles, CA 90024-1563.

In an attempt to block the masculine ontogeny of the zebra finch song system hypothesized to be caused by early estrogenic action, 100ug of the aromatase inhibitor 4-hydroxyandrostenedione (4-OHA) or vehicle were administered daily to zebra finch chicks for the first 20 days after hatching (Experiment 1). Males in both experimental and control groups were castrated at Day 20. At 60 days the animals were killed and their brains were sectioned at 50um and stained with thionin for light microscopic analysis. In males 4-OHA increased neuronal soma area

microscopic analysis. In males 4-OHA increased neuronal soma area in MAN (p<.001) and HVc (p<.001), and HVc volume (p=.002). In females 4-OHA increased neuronal soma area in HVc (p<.001) and the volume of nucleus rotundus (p=.04).

In Experiment 2 we measured plasma estradiol (E_2) and testosterone (T) levels in six day old zebra finch chicks that had received daily injections of 100ug 4-OHA or vehicle for the first five days after hatching. 4-OHA did not alter levels of T or E_2 in males. 4-OHA-treated females had E_2 levels that were equivalent to those found in males (2.3X that of control females n=006) and T levels that were no males (2.3X that of control females, p=.006), and T levels that were no

different from those in control females

These results show (1) that 4-OHA hypermasculinized males
without affecting E₂ levels early in development, and (2) that females are
only modestly masculinized by 4-OHA that raised E₂ levels early in
development to the levels seen in males. Supported by NIH grant DC00217.

AROMATASE ACTIVITY IN DISCRETE FOREBRAIN NUCLEI OF EMBRYONIC MALE AND FEMALE FERRETS: DISTRIBUTION AND REGULATION BY ANDROGEN. <u>C.E.</u> Weaver* and M.J. Baum, Department of Biology, Boston University, Boston, MA 02215.

Previous studies have failed to demonstrate consistent sex differences or androgenic regulation of aromatase activity (AA) in the developing ferret brain. These negative results may reflect the use of large blocks of neural tissue in those studies. In the present study AA was measured in punches of discrete forebrain regions from male and female ferrets taken on embryonic day 35 (E35) from mothers which had been treated over days E28-E35 with the androgen receptor antagonist, Flutamide, or vehicle. This is a period when the biosynthesis of estrogen promotes the development of a sexually dimorphic nucleus in the dorsal preoptic/anterior hypothalamic area (POA/AH), and controls aspects of behavioral differentiation in males. In both sexes AA was significantly higher in the medial POA/AH and medial amygdala than in the lateral POA/AH and lateral amygdala, respectively. AA in the bed nucleus of the stria terminalis (BNST) and ventromedial nucleus of the hypothalamus was significantly higher in males than in females. Flutamide significantly reduced AA only in the male BNST. Very low levels of AA were measured in parietal cortex. These results show that sexually dimorphic, androgenic regulation of AA does occur selectively in fetal ferret brain, though not in the POA/AH which is the site of a structural dimorphism. (Supported by: HD21094 and MH00392)

EXPRESSION AND REGULATION OF ESTROGEN RECEPTOR mRNA IN THE DEVELOPING RAT FOREBRAIN. R.C.Miranda, & C.D.Toran-Allerand Dept. Anat. & Cell Biol., Columbia Univ. P&S, New York, N.Y., 10032.

The estrogen receptor (ER) is an important ligand-modulated regulator of xpression. The expression and developmental regulation of ER mRNA was studied by non-isotopic (digoxigenin) in situ hybridization histochemistry, using a 48 base oligonucleotide probe, complementary to a sequence in the region of the estrogen-binding domain of rat uterine ER cDNA. Hybridization signal was limited to cytoplasm and proximal processes; nucleus and background were stained. Controls demonstrated probe specificity. During development, in intact brain and in organotypic cultures, mRNA was observed in all regions previously reported to be ER containing, such as the medial and periventricular preoptic area, bed nucleus of the stria terminalis, septum, nuclei of the diagonal band, and cerebral cortex. ER mRNA was also observed in regions not traditionally considered targets of estrogen (striatum & thalamus). The spatial distribution of ER mRNA in the cerebral cortex showed age-related changes. ER mRNA was observed in primitive cerebral cortex as early as E16. By E20, there was inten staining in the emerging cortical plate, with lower levels of staining in the plexiform layer and ventricular zone. With maturation of the cortical plate staining appeared to be restricted to the upper third of the cortex and to the large neurons of its deepest layer. In all ER-containing regions, mRNA expression persisted through P21, declining to low or undetectable levels from P28 onwards. Ovariectomy of adult female rats dramatically increased ER mRNA expression in all ER containing regions, including the cerebral cortex. The results demonstrate developmental regulation of ER mRNA expression and provide further evidence that in the adult, estrogen down-regulates ER mRNA expression. (Suppor NIH grants HD08364 and AG08099 and NSF BNS8700400 and AHAF.)

ESTROGEN RECEPTORS IN HIPPOCAMPAL AND NEOCORTICAL, TRANSPLANTS DURING DEVELOPMENT. J.A. O'Keefe, E.B. Pedersen, A.J. Castro, R.J. Handa. Dept. of Cell Biology, Neurobiology, and Anatomy, Loyola Univ. Stritch School of Medicine, Maywood, IL 60153.

Previous investigations have demonstrated a transient rise in estrogen

receptor (ER) levels in the rodent hippocampus and neocortex during the first postnatal week. The function of these receptors is largely unknown as is the mechanism by which they are regulated. To further study ER development, we grafted fetal (E14-15) hippocampal or frontal cortical tissue into frontal cortical lesion cavities made in postnatal day (PND) 0 rats. Accordingly, the grafted tissue was one week younger than the host. At two and four we post transplantation surgery (corresponding to theoretical donor age PND 7 and 21), the grafts, a region of the adjacent cortex and the endogenous hippocampus or opposite homotypic cortex of the host were assayed for ER content. ER levels were measured by the *in vitro* binding of [3H]-estradiol to cytosolic preparations. Radioinert moxestrol was used to determine nonspecific binding. ER levels in hippocampal grafts at theoretical age PND 7 found in the adjacent host (PND 14) cortex (1.3 \pm 0.29) and the endogenous hippocampus (1.58 \pm 0.19) [ANOVA; Dunnett T3 post hoc comparison test; p<0.05]. At theoretical donor age PND 21 (host age PND 28), ER concentration in hippocampal transplants had decreased to levels that comparable to host levels. A similar transient elevation in ER levels which corresponded to the donor developmental timetable was observed in neocortical grafts. These data suggest that developmental alterations in hippocampal and neocortical ER levels are intrinsically determined by the genetic age of the tissue. (Supported by AA 06487, NS 13230 and a Potts Foundation Award.)

AROMATASE ACTIVITY IN THE BRAINS OF NEONATAL GRAY SHORT-TAILED OPOSSUMS (MONODELPHIS DOMESTICA). Barbara H. Fadem, Neil J. MacLusky and Michael J. Walters. Department of Psychiatry, UMDNJ-New Jersey Medical School, Newark 07103 and Division of Reproductive Science, Toronto General Hospital, Toronto, Ontario, Canada.

In developing eutherian mammals, presence of neural aromatase activity is correlated with critical periods for brain sexual differentiation. Marsupials are useful for studying hormonal organization of the brain since they are born neurally and reproductively undeveloped. For the present report, aromatase activity in brain tissue homogenates obtained from 1, 4, 8, 16 (approximately equivalent to postnatal day 1 in rats) and 60 day old gray shorttailed opossums was assayed by the tritiated water release method (Roselli et al., Endocrinology 114:192, 1984). Con-trol samples contained either no tissue, or the same quantities of tissue homogenate in the presence of the specific aromatase inhibitor, 4-hydroxyandrostenedione (4-OHA).

Aromatase activity was low but detectable on postnatal

day 1 (8.4 + 2.7 fmol/mg protein/hr) and increased to levels similar to those seen in adult male gray opossums by postnatal day 16 (77.77 ± 3.5 fmol/mg protein/hr). This finding suggests that the aromatization of testosterone to estradiol may, as in eutherian mammals, be involved in sexual differentiation of the marsupial brain. Supported by NSF grant BNS 8616514 to B.H.F.

CO-LOCALIZATION OF ESTROGEN RECEPTOR MRNA AND PROTEIN IN DEVELOPING RAT BRAIN. <u>C.D. Toran-Allerand¹, N.J. MacLusky², R.C. Miranda¹, and R.B. Hochberg¹. Dept. Anat. & Cell Biol. 1, Columbia Univ. P&S, New York, NY 10032, Div. Reprod. Sci. 2, Univ. Toronto, Toronto,</u> Canada, M5G 1L4, and Dept. Ob. & Gyn.3, Yale Univ. Sch. of Med., New Haven, CT 06510.

Neurons expressing estrogen receptor mRNA have been reported in h extragen receptor and non-receptor CNS regions. 1251-estrogen both estrogen receptor and non-receptor CNS regions. 1251-estrogen autoradiography (2200 Ci/mmol) of P12 forebrain was followed by nonisotopic (digoxigenin) in situ hybridization histochemistry with a 48 base oligonucleotide complementary to a sequence of rat uterine estrogen receptor cDNA to study if the mRNA is translated into the encoded protein. Many neurons of the hypothalamus/POA, septum/diagonal band and cerebral cortex and in presumed non-estrogen targets (thalamus, striatum) co-expressed nuclear silver grains (receptors) and blue/purple cytoplasmic hybridization signal. All neurons showing receptors co-localized mRNA, confirming probe specificity. mRNA expression while very extensive did not always co-localize with ligand binding, perhaps reflecting regional, intercellular or temporal differences in receptor content. Strong hybridization signal with few or no nuclear silver grains during development may also herald initiation of receptor synthesis or its decline, particularly in regions (cerebral cortex) with transiently high receptor levels. Co-expression of estrogen receptor mRNA and protein during development in a distribution transcending neuroendocrine boundaries, as identified by ³H, documents the greater sensitivity of ¹²⁵I and suggests that these neurons may comprise an extensive, interacting neural system with broader functional significance. Supported by NIH grants HD08364 and AG08099 (DT-A) and CA3799 (RBH); and AHAF and NSF BNS 8700400 (DT-A)

EARLY POSTNATAL MATERNAL DEPRIVATION AND CORTICOSTERONE ADMINISTRATION INCREASE BEHAVIORAL REACTIVITY TO NOVELTY AND AFFFECT GLUCOCORTICOID RECEPTORS IN THE HIPPOCAMPUS OF RATS STUDIED AS ADULT. E. Merlo Pich.*, G. Biagini*, M. Zoli*, F. Benfenati, L.F. Agnati* and K. Fuxe. Inst. of Human Physiology, University of Modena, Modena, Italy and Dept. of Histology, Karolinska Institutet, Stockholm, Sweden.

The effect of neonatal administration of corticosterone and of repeated episodes of maternal deprivation on the levels of glucocorticoid receptor (GR) immunoreactivity (IR) in the hippocampus have been studied in male rats. Pups were repeatedly injected with corticosterone (10 mg/kg/1 ml sesame oil every 48 h., s.c.) or segregated from the mother for 5 h/day from day P2 to day P6. On day P45 the effects of novelty were assessed in the rats using an exploratory two-compartment test (Merlo Pich & Samanin, Pharmachol Res 21:295 1989). Rats were then killed and brain sections (40 µm) were processed for indirect immunoperoxidase method using a mouse monoclonal antibody against rat liver GR. Microdensitometric and morphometric analyses were carried out by IBAS II image analyzer. A high significant reduction of GR specific immunoreactivity was found in the CA1 area of hippocampus of rats treated with corticosterone, whereas significant increase of GR-IR was found in maternal deprived rats. Both groups showed an increase reactivity to novelty when compared with control animals. These results suggest that early maternal deprivation induces behavioral changes which are similar to those obtained in rats administered with corticosterone in the same period of life, but with different effects on GR levels in hippocampus, an area involved in mediating the negative feedback regulation of plasma glucocorticoids.

THE STRESS NON-RESPONSIVE PERIOD PERMITS NATURALLY OCCURRING CELL DEATH IN THE DEVELOPING DENTATE GYRUS. E. Gould, C.S. Woolley, D.L. Miller*, G.M. Begany*, R.E. Brinton and B.S. McEwen The Rockefeller Univ. N.Y., N.Y. 10021, Univ. Southern California, L.A., CA., 90033

The granule cells of the dentate gyrus appear to be a unique population of neurons in that they display both birth and death in adulthood. Sloviter and coworkers (1989) have demonstrated that, in the adult, dentate gyrus granule cells are dependent on glucocorticoids for their survival. Our laboratory has demonstrated that short term adrenalectomy (ADX) results in massive cell death in the granule cell layer of the adult dentate gyrus. In order to determine whether cell death occurs naturally during the developmental period during which glucocorticoid levels are very low, i.e. the stress non-responsive period (SNRP), we examined Nissl stained brain sections from rats at ages E18,E19,P2,P4,P6,P8,P15 and P40. Quantitative analysis revealed degenerating cells in the dentate gyrus at all ages examined with the peak in the density of pyknotic cells, accompanied by a decrease in the density of healthy cells, at P6, the midpoint of the SNRP. phenomenon is sensitive to glucocorticoids as administration of corticosterone to neonatal rats significantly attenuated cell death at P6 and removal of circulating glucocorticoids by ADX at P15, toward the end of the SNRP, extended the period of cell death. These results suggest that low levels of glucocorticoids which occur during the SNRP permit naturally occurring cell death in the developing dentate gyrus.

144.19

ESTRADIOL REGULATES SYNAPSE DENSITY IN THE CA1 REGION OF THE HIPPOCAMPUS IN THE ADULT FEMALE RAT. C.S. Woolley and B.S. McEwen, Rockefeller Univ., NY, NY 10021

Recently, our laboratory has demonstrated a positive correlation between circulating levels of estradiol (E) and progesterone (P) and the density of dendritic spines on hippocampal CA1 pyramidal cells both with administration of E and P to ovariectomized (OVX) animals and as E and P levels fluctuate naturally during the estrous cycle. As dendritic spines have been shown to be postsynaptic sites, which very often, if not always, contain synapses, these results imply often, if not always, contain synapses, these results imply that the density of synapses may also be regulated by ovarian steroids. In order to determine whether synapse density in the hippocampus is sensitive to estradiol, we compared the density of synapses in the stratum lacunosum-moleculare of the CA1 region of the hippocampus, estimated according to Beaulieu and Colonnier (<u>J. Comp. Neurol.</u>, 289:178, 1989), in 3 OVY adult female, rate which received estradiol (OVYA-E) to that OVX adult female rats which received estradiol (OVX+E) to that in 3 OVX rats which received oil vehicle (OVX+O). Synapse density on postsynaptic elements identified as dendritic spines was significantly higher in OVX+E animals compared to OVX+O. In contrast, synapse density on postsynaptic to OVX+O. In contrast, synapse density on postsynaptic elements identified as dendrites was unchanged by estradiol treatment. These results demonstrate that the density of synapses on hippocampal dendritic spines is sensitive to estradiol and imply that synapse density on spines may fluctuate naturally as ovarian steroid levels vary during the estrous cycle.

TIMING AND DURATION OF DHT TREATMENT ALTERS MOTONEURON NUMBER MORPHOLOGY, AND SPECIFICITY IN A SEXUALLY DIMORPHIC RAT SPINAL NUCLEUS. L.A. Goldstein and D.R. Sengelaub. Program in Neural Science,

Dept. of Psychology, Indiana University, Bloomington, IN 47405.

The development of the sexually dimorphic spinal nucleus of the bulbocavernosus (SNB) is regulated by androgens. Females treated with (E+D females) from embryonic (E) day 16 through postnatal (P) day 5 have masculine numbers of SNB motoneurons. Treatment with E alone does not masculinize the SNB; treatment with DHT alone from E17-22 (ST-D) results in a feminine SNB and significantly altered motoneuron morphology and connectivity. To determine if masculinization of the SNB involves the interaction of E and DHT or results from a longer exposure to DHT alone, the number, morphology, and connectivity of SNB motoneurons in females treated with DHT from E16-P5 (LT-D) were examined.

At E22, LT-D females have SNB motoneuron numbers identical to E+D and

normal females, but far fewer than normal males, indicating that T is essential for masculine prenatal development. After E22, motoneuron number declines precipitously in normal females but remains stable in LT-D and E+D females, who do not differ from normal males at P10. In adulthood, HRP histochemistry reveals that the connectivity, dendritic length, and some size of SNB motoneurons in LT-D females are identical to normal males but differ significantly from ST-D females. These data suggest that the aftered connectivity in ST-D females is not simply a hormone-specific effect, but the result of a truncated hormone exposure. Thus, DHT can fully masculinize SNB morphology and connectivity if given during the appropriate period of development. Therefore, while T may be required prenatally, DHT may be involved postnatally in the masculinization of the SNB. (Supported by NIH NS24877)

A TESTOSTERONE RELATED SEXUAL DIMORPHISM IN THE DENTATE GYRUS OF THE RAT. R.L. Roof and M.D. Havens. Dept. of Psych. and Neuroscience Program, Univ. of Wyoming, Laramie, WY 82071.

The hippocampus is thought to be involved in spatial processing, a skill for which sex differences have been found. To determine whether these sex differences might be related to hippocampal structure, a morphometric analysis was conducted.

Male and female rats (n=24) were treated with either testosterone (150)

make and relinate rats (11-24) were treated with either testserone (130 ug) or the oil vehicle on postnatal days 4 and 6. Nissl stained sections, 300 um apart, (6 per animal), containing the dorsal hippocampus were included. Medial-lateral (width) and dorsal-ventral (thickness) measures of the right and left pyramidal and granule cell layers were made with the aid of a microprojector and a digitizing pad interfaced with a computer. Mean granule cell area was also determined by tracing the somata with camera heids at 1000-2 lucida at 1000x.

The granule cell layer was wider and thicker in control males than in control females. This sex difference was of greater magnitude in the right hemisphere than in the left. The size of this cell layer in testosterone treated females was intermediate between control males and females. In treated females was intermediate between control males and females. In control males, treated males and treated females, the right granule cell layer was wider than the left. Since mean granule cell area did not differ between the groups, the sex and hormone effects were likely due to increased numbers of cells. No sex or hormone effects were seen on the measures taken in the pyramidal cell layer.

Width of the right granule cell layer was found to correlate (r=.86) with

Morris water maze scores obtained from the same animals in an earlier study (Roof, 1989).

These data suggest a testosterone related sexual dimorphism in the number of granule cells in the dentate gyrus of the rat, which may be related to sex differences in spatial performance.

GLUCOCORTICOID RECEPTOR IN THE DEVELOPING ANIMAL: EFFECT OF ADRENALECTOMY ON HIPPOCAMPAL BINDING CAPACITY AND mRNA LEVELS. D.M. Vázquez, I.F. López, M.I. Morano and H. Akil. Mental Health Research Institute and Department of Pediatrics, University of Michigan, Ann Arbor, MI 48109-0720.

An important component of the adrenocortical response is the glucocorticoid negative feedback which "turns of?" the hypothalamic and pituitary secretion. The hippocampus glucocorticoid (GR) and mineralocorticoid (MR) receptors have been implicated in the modulation of this particular mechanism. The developing animal exhibits a stress hyporesponsive period during the first two weeks of life and a gradual adrenocortical response appears after postnatal day 14. In order to investigate the emergence of the glucocorticoid negative feedback mechanism; we have studied the GR binding capacity (Bmax) and the GR and MR mRNA levels in response to 12 hour and 48 hour adrenalectomy (ADX) in adult (A), 14 (D14) and 18 day old (D18) male rats. Analysis of the the Bmax was carried out using saturating amounts of 3HDexamethasone, RU26938 and Corticosterone. mRNA levels were quantitated by solution hybridization using a 456bp GR cRNA and a non-homologous 54bp MR cRNA. An increase in Bmax was seen on the 12 hr. D14 ADX group when compared to SHAM controls (D14 SHAM-52.225.45 (±SE); D14 ADX=227.4±16, p≤0.05). Increases in Bmax of the 48 hr. ADX and D18 animals was also seen (A SHAM =132.3±8.8; A ADX=379.10t6.2; D18 SHAM=115.75t4.9; D18 ADX=64.47t5.0, p<0.05). In addition, it appears that up-regulation of the GR and MR mRNA levels occurs on the D18 48 hr ADX animal. This implicates an enhanced gene response in the D18 animals which is not present in the adult. Supported by NIMH MH09720 and MH422251.

ANDROGENIC REGULATION OF CONTRACTILE PROPERTIES IN SEXUALLY DIMORPHIC MUSCLES OF FROGS (Xenopus). A.A. Herrera and M. Regnier. Biological Sciences, University of Southern California, Los Angeles, CA 90089.

During mating male frogs use forearm flexion to maintain a prolonged loose grip on females for several hours. They are also able to tighten their grip briefly but rapidly in response to sudden movements by female (Hutchison & Poynton, Behavior 22:41,1964). Flexor muscles of the male forearm are sexually dimorphic and androgen sensitive. To test the effects of androgens on muscle contraction we compared male frogs that were either castrated or castrated and given testosterone implants. Tension measurements were made from the androgen sensitive flexor carpi radialis. At 8 weeks, time to peak twitch tension was not different but twitch relaxation times were significantly longer in muscles of androgen treated frogs (P<0.01). These results suggest that androgens enhance the maintainence of tension without compromising the ability to develop tension rapidly. An interesting finding was that tension per unit cross sectional area of fiber was greater in castrates than in androgen treated frogs. are testing whether this involves androgenic regulation of particular fiber types, conversion of fiber types, or differences in synaptic efficacy. We are also investigating the time course of androgen effects. Supported by NIH grant NS27209.

DIFFERENTIAL SENSITIVITY TO ANDROGENS WITHIN SEXUALLY DIMORPHIC MUSCLES OF MALE FROGS (Xenopus). M. Regnier and A.A. Herrera. Biological Sciences, University of Southern California, Los Angeles, CA 90089.

Forearm flexor muscles in male frogs vary in size and contractility in response to seasonal changes in levels of circulating androgens. To understand the androgenic regulation of muscle properties, males were either castrated or castrated and given testosterone implants. Cryostat cross sections of the androgen sensitive flexor carpi radialis muscle (FCR) were used to measure myosin ATPase activity (pH=10). Adjacent sections were used to measure fiber cross sectional area and for quantitative measurements of succinate dehydrogenase (SDH) activity. Preliminary analysis showed that the pattern of myosin ATPase staining was not affected by androgen levels. At Arrase staining was not arrected by antrogen levels. At 8 weeks, average fiber size was 45% smaller in castrates without androgen implants. Fibers that stained darkly for myosin ATPase atrophied twice as much as lighter fibers (56% vs. 24%) regardless of location within the muscle. Total SDH activity decreased dramatically but activity per unit cross sectional area of muscle fiber was unchanged. We are currently investigating whether some motor units in the FCR are more sensitive to androgens than others and also determining the time course of androgen effects. Supported by NIH grant NS27209.

EFFECT OF CASTRATION AND TESTOSTERONE REPLACEMENT ON THE GNRH NEURON SYSTEM IN PUBERTAL DJUNGARIAN HAMSTERS. S.M. Yellon and C.P. Haase*. Div. Perinatal Biology, Depts. Physiology, Pediatrics and Anatomy, Loma Linda Univ. Sch. of Med., Loma Linda, CA, 92350.

At puberty (25 days after birth), testes growth and peak gonadotropin secretion in Djungarian hamsters are correlated with increased numbers of GnRH-stained cells in the medial preoptic area (MPOA) and diagonal band of Broca (DBB) regions of the brain compared to cell numbers in prepubertal males (age 15 days). The developmental increase in number of GnRH cells was hypothesized to depend upon gonadal steroid feedback. Males were castrated at 12 days and implanted with a blank or testosterone-filled silastic capsule (5 mm, s.c.). At age 15 and 25 days, five hamsters from each castrate group and from testes-intact controls were anesthetized and killed by intracardiac perfusion. Brain sections (60 μ m) were processed for GnRH immunocytochemistry (LR1 courtesy of Dr. R. Benoit). GnRH-stained somata had smooth contours and were predominantly unipolar or bipolar, irregular-shaped or multipolar somata were rare. In testes-intact controls, the total number of unipolar GnRH cells in the MPOA and DBB was increased at 25 days (75 \pm 7) compared to 15 day males (39 \pm 2, p<0.05). At 15 or 25 days, the number of unipolar GnRH somata was not different among castrates (blank or testosterone-treated) and controls (p>0.05). However, as in testes-intact males, more GnRH cells were found in 25 day castrates whether implanted with a blank or testosterone capsule compared to similarly treated males at 15 days. Bipolar GnRH cell numbers in the MPOA and DBB were the same irrespective of age or treatment (about 55 perikarya). The data do not support the hypothesis that gonadal steroid feedback affects the pubertal increase in numbers of unipolar GnRH cell bodies, rather development of the GnRH neuron system in the male Djungarian hamster at puberty is independent of the testes or testosterone feedback. PROGESTIN RECEPTOR CELLS IN ESTROGEN PRIMED POST-NATAL MALE AND FEMALE MOUSE CORTEX: EVIDENCE FOR A SEXUAL DIMORPHISM. P.J. SHUGHRUE, W.E. STUMPF and M. SAR*. Cell Bio. and Anat., Univ. of NC, Chapel Hill, NC 27599.

Autoradiographic studies were performed to determine whether and, if so, where progestin (P) receptor (R) cells are located in cortex, and whether there is evidence for a sexual dimorphism during early postnatal brain development. Eight during early postnatal brain development. Eight (4 male/4 female) 8-day postnatal mice, treated with 100 μ g/100g bw estradiol for 72 hr, were sc injected with 0.32 μ g/100g bw of (2)-17 β -hydroxy-17 α -(2-[¹²⁵I]iodovinyl 4-estren-3-one (¹²⁵I-P) 2200ci/mM. Two hr after injection brains were frozen and 4 μ m cryostat sections processed for frozen and 4µm cryostat sections processed for thaw-mount autoradiography. After 8-60 days of exposure, cells with a nuclear retention of ¹²⁵I-P were concentrated in lamina VI of the male and female lateral cortical regions, while additional cells were scattered throughout the remaining regions and laminae. Competition studies with unlabeled R5020 prevented nuclear concentration of ¹²⁵I-P. A sex comparison revealed that the number of PR cells was significantly greater in female of PR cells was significantly greater in female cortex at several brain levels evaluated. The results demonstrate that the developing cortex contains PR cells and that a sexual dimorphism in labeled cell number is present in cortical cells.

HYPOTHALAMIC SOMATOSTATIN mRNA EXPRESSION IN DWARF MICE: DEVELOPMENTAL TIME COURSE OF RESPONSE TO GROWTH HORMONE DEFICIT. D. L. Hurley* and C. J. Phelps. Department of Neurobiology & Anatomy, University of Rochester Medical Center, Rochester, NY 14642. (Present address: Department of Anatomy, Tulane University Medical Center, New Orleans, LA 70112)

Immunocytochemical expression of somatostatin (SS) neuropeptide shows

severe reduction in growth hormone (GH)-deficient adult dwarf mice, isolated to pituitary-regulatory neurons in anterior periventricular hypothalamus (PeN) severe reduction in growth hormone (GH)-deficient adult dwarf mice, isolated to pituitary-regulatory neurons in anterior periventricular hypothalamus (PeN) (Phelps and Hoffman, 1987), and likely in response to absent GH stimulatory feedback. In order to examine the possible developmental onset of the SS deficit at a transcriptional level, brains of Ames dwarf (df/df) and normal littermate (Df/?) mice were examined for SS mRNA using in situ hybridization histochemistry at intervals from 1 day to 6 months of age. Heterozygous Ames dwarf (DF/df) breeders were a gift from Dr. Andrzej Bartke. 35S-labeled SS antisense RNA probe was synthesized with SP6 RNA polymerase from a rat SS cDNA provided by Dr. Richard Goodman, and hybridized to 20-30 µm coronal brain sections using standard conditions and stringent washes. Autoradiography revealed strong hybridization signals by 7 postnatal days in regions of the PeN, thalamus, hippocampus, and cortex, as previously described (Bendotti et al.; 1989). Strong signal was also noted in neurons of the medial basal hypothalamus. Through 21 days of age, signals in all SS-expressing areas were comparable for df/df and Df/? mice. By 6 months of age, dwarfs showed markedly fewer SS mRNA-positive neurons in PeN alone, particularly in dorsal regions of the nucleus. Signal in non-GH controlling regions, such as cortex, remained comparable between dwarf and normal. The results indicate that SS deficit in GH deficiency in Ames dwarfs occurs at the transcriptional level, as in adult Snell dwarfs (O'Hara et al., 1989) and following hypophysectomy (Rogers et al., 1988). Further, the results suggest that the adult SS deficit is the result of a regressive developmental sequence in response to critical periods of GH deficiency. Supported by NIH grant NS25987 (CJP)

MOTOR SYSTEMS: DEVELOPMENT AND PLASTICITY I

145.1

METABOLIC VARIABILITY OF MUSCLE FIBERS IN SELF-REINNERVATED MOTOR UNITS IN THE CAT TIBIALIS ANTERIOR MUSCLE. G.A. Unquez. S.

MOTOR UNITS IN THE CAT TIBIALIS ANTERIOR MUSCLE. G.A. Unquez. S. Bodine-Fowler. D.J. Pierotti. R.R. Roy and V.R. Edgerton. Dept. Kinesiology and Brain Research Inst., UCLA, LA., CA 90024 and Div. Orthopaedics & Rehab., UCSD, SD, CA 92039.

The succinate dehydrogenase (SDH) activity of muscle fibers belonging to a motor unit (MU) following 6 months of self-reinnervation (SR) was studied. Nerve branches innervating the anterior compartment of the tibialis anterior in both limbs were cut near the muscle and resutured in 7 adult cats. MUs were functionally isolated via ventral root teasing, physiologically characterized and glycogen depleted. Two of the four MUs analyzed were classified as fast fatigue-intermediate and two as fast fatigue-resistant (Burke et al. J. Physiol. 234:723, 1973). SDH activity was determined histochemically (Martin et al. Am. J. Physiol. 255:C43. 1988) in a sample of MU fibers from the cross-section. Physiol 255:C43, 1988) in a sample of MU fibers from the cross-section containing the largest number of MU fibers. All sampled MU fibers stained dark for myosin ATPase (pH=8.75). The fatigue index (FI), sample size (n), mean (X) and range in SDH activity, and coefficient of variation (CV) for the 4 MUs were:

MU	El	(U)	X (OD/min)	Bance	CV(%)
1	0.99	13	0.008	.006009	12
2	0.91	36	0.017	.009029	30
3	0.74	37	0.014	.005032	51
4	0.48	37	0.010	.005018	40

4 0.48 37 0.010 ...005-.018 40

The mean CV for SDH of non-depleted fibers was 40% with a range of 32-45%. The interliber variability within MUs 1 and 2 was less than that observed in non-depleted fibers, whereas a similar or greater variability was seen in fibers from MUs 3 and 4, MU fibers taken from two distinct regions showed different SDH activities, i.e., fibers with high and low oxidative capacity. These data indicate that after 6-months of SR, SDH variability among MU fibers is the same or greater than that found in normal MUs suggesting that SDH activity of fibers of a MU can be influenced but is not under complete control by the motoneuron. (SUPPORTED BY NIH GRANT NS16333). 0.010

145.2

HISTOCHEMICAL PROFILES OF MOTOR UNITS OF THE CAT TIBIALIS ANTERIOR AFTER 6 MONTHS OF ELECTRICAL INACTIVITY. D.J. Pierotti.

AN LEHIOH AFTEH 6 MONTHS OF ELECTHICAL INACTIVITY. <u>D.J. Pierotti.</u>
<u>R.R. Roy. J.A. Hodgson*, and V.R. Edgerton.</u> Brain Research Institute and Kinesiology Department, UCLA, LA, CA, 90024-1568.

The effects of electrical inactivity on the succinic dehydrogenase (SDH) and myosin ATPase activity of fibers in tibialis anterior (TA) motor units (MU) of adult cats were studied. Electrical inactivity was produced in 10 cats by spinal isolation (SI), i.e., spinal cord transection at T12-T13 and L7-S1 and bilateral dorsal rhizotomy between the two transection sites. Two 24-hr EMG recording sessions were used to verify that the muscles in the lower limb were electrically silent. One motor unit from each hindlimb was isolated using ventral root isolation techniques, physiologically typed, and glycogen depleted as described by Bodine et al. (J. Neurophysio) 57:1730, 1987). Optical density measurements from glycogen-stained frozen sections were used to classify fibers as depleted (unit) or non-depleted (non-unit). Myosin ATPase was determined using a modification of the technique of Weisberg et al. (Circ Res 51:802, 1982). SDH activities were determined using quantitative histochemical technique of by Martin et al. (*J. Histochem Cytochem.* 33:1053, 1985). The coefficient of variation (CV) of cross-sectional area (CSA) ranged from 29 to 68% for unit fibers and from 31 to sectional area (CSA) ranged from 29 to 68% for unit fibers and from 31 to 58% for non-unit fibers. In all MUs analyzed, the ranges in CV in SDH and ATPase activities were 12 to 28% and 4 to 17% respectively. These ranges were 25 to 69% and 8 to 27% in non-unit fibers. Compared to fibers in control MUs (Martin et al. Am J Physiol. 255:C43, 1988), SI MU fibers showed a larger degree of variability in fiber CSA and a similar degree of variability in SDH activity. The variability in ATPase activity was lower than either SDH or CSA in SI MUs. These data suggest that the variability in mean SDH and CSA observed among fibers within normal units persists in units after 6 months of electrical silence. Therefore, electrical activity cannot be the sole determinant of these MU properties. (SUPPORTED BY NIH GRANT NS16333). NS16333).

SPATIAL DISTRIBUTION OF MOTOR UNITS: A GENERAL PATTERN ? A. J. Dekhuijzen, R. R. Roy, and V. R. Edgerton,
Brain Research Institute and Department of Kinesiology, UCLA, Los Angeles, CA 90024-1568.

The spatial distribution of the muscle fibers of motor units from published papers including Bodine, S.C. et al, (L Neurophysiol., 57:1730, 1987) was analyzed. The power (C) was calculated from the number of muscle fibers (N) as a function of radius (r): $N-r^{C}$. A power of 2 reflects an even distribution of fibers within the territory of a unit, while a value >2 suggests a higher density of fibers toward the periphery of a unit and C<2 reflects a reduction in density toward the periphery. The mean (\pm SD) power for 14 normal motor units from rats and cats was 1.8 \pm 0.2. After denervation-reinnervation in the neonatal rat, units had a recover of 2.2 \pm 0.8 (n=7). The mean power for reinnervated 57:1730, 1987) was analyzed. The power (C) power of 2.2 ± 0.8 (n=7). The mean power for reinnervated units was not significantly different (p>0.05) from normal. units was not significantly different (p>0.05) from normal. However, the variance of normal units was significantly less then reinnervated units (p≤0.05). In addition, the spatial distribution of fibers of units modelled by Monte Carlo methods reflecting a random pattern were studied. Of 14 normal and 7 reinnervated units, 13 and 4 respectively, were not significantly different (p>0.05) from Monte Carlo generated units. SUPPORTED BY NIH GRANT NS16333.

POSITION AND FIBRE TYPE DEPENDENT SELECTIVITY IN NEUROMUSCULAR SYNAPSE FORMATION. A. W. Everett*, D. R. Brown* and M. R. Bennett. Neurobiology Research Centre, The University of Sydney, Sydney, Australia, 2006.

Using glycogen depletion procedures we have shown that motor axons to the glutaeus muscle of the toad (Bufo marinus) distribute their terminals according to the position of the average along the neural axis.

terminals according to the origins of the axons along the neural axis. Those glutaeus axons arising most rostrally innervate muscle fibres located in the ventral portion of the muscle, near nerve entry, while caudal axons innervate fibres mostly towards the opposing dorsal surface. The terminals of 'intermediate' axons are found mostly in the middle regions of the muscle. We found the same projection was re-established in adult muscle following two experimental procedures: firstly, when the muscle nerve was cut and regenerating axons were forced to reinnervate the muscle via entirely novel pathways through the dorsal surface; and secondly, when the muscle was reinnervated by a greater than normal number of axons that were mostly foreign but segmentally appropriate. The distribution of terminals, at least of rostral and intermediate axons, was clearly unrelated to the arrangement of fibre types: the majority of the muscle, excluding the very dorsal surface layers, consisted of a mosaic of type 1 and 2 amphibian fibre types both before and after nerve cut. In addition, the regenerated axons did not synapse randomly with the available selection of muscle fibres in their particular territory, but instead displayed the same fibre type bias seen normally, with rostral units consisting of mostly type 1 fibres and caudal units mostly type 2. The findings provide evidence for a clear distinction between at least two determinants that influence the innervation of muscle - positional cues and fibre types, with the former taking precedence over the latter.

ADAPTATIONS OF DIAPHRAGM TO PROLONGED COMPENSATORY LOADING. G.C.Sieck and W.Z.Zhan. Dept. Biomed. Engineering, USC, Los Angeles, CA 90089. Compensatory loading (CL) of the left hemidiaphragm (DIA) in hamsters was induced by paralysis of the opposite side for 2 or 6 weeks. paralysis of the opposite side for 2 or 6 weeks. CL doubled the transdiaphragmatic pressures generated during eupnea and increased integrated DIA EMG activity by 60%. Proportions of type I or II fibers were unaffected by CL. The cross-sectional areas of type I fibers were unchanged whereas the size of type II fibers increased throughout the 6 weeks of CL. Succinate dehydrogenase (SDH) activity (quantified microdensitometrically) of both type I and II fibers increased after 2 weeks and remained higher. Isometric twitch contraction time (direct muscle stimulation) decreased after 2 weeks and then increased by 6 weeks. Half relaxation time decreased throughout the 6 weeks of CL. Maximum tetanic tension increased after 2 weeks and then decreased by 6 weeks. The DIA also became more fatigable, but only after 6 weeks. In conclusion, the effect of CL on DIA mechanical properties are time-dependent but do not correlate with morphological adaptations. Changes in fatigability do not correlate with adaptations in fiber SDH activity.

CHRONIC CHANGES IN VENTRAL CORD FIELD POTENTIALS EVOKED BY STIMULATION OF RETICULOSPINAL NEURONS AFTER PARTIAL SPINAL CORD LESIONS IN THE RAT. J.H. KIM, Y.-G. PARK, and D.M. Shim, The Miami Project to Cure Paralysis, University of Miami School of Medicine, Miami, FL 33136.

Reticulospinal neurons (RtN) project to all levels of spinal cord and terminate mainly ipsilateral in the ventral horn (VH). Some of these RtN send collaterals across the midline at the level of termination and make synaptic contacts with contralateral VH neurons. Stimulation of RtN produces mono- and di-synaptic EPSPs in motoneurons. The goal of this study was to investigate chronic changes in RtN evoked field potentials in the spinal cord after controlled spinal cord lesions (SCLs). A total of 20 female rats were used. Under sterile conditions, SCLs were made at the T5 level using a #11 blade sparing only one ventral quadrant (VQ). The electrophysiological study was made from 1 day to 4 weeks after the lesion. RtN evoked field potentials were recorded bilaterally in the VH at L2/3 level using a glass microelectrode filled with 2 M NaCl (1.5-1.7 M Ohm). The gigantocellular reticular nucleus ipsilateral to the spared VQ was stimulated using a microelectrode. In some animals field potentials were monitored just before and right after the SCL. In an intact spinal cord, RtN stimulation produced very consistent field potentials bilaterally. The amplitude of the fields generated in the VH contralateral to RtN stimulation, however, was about one third of those recorded ipsilaterally. Following the lesions sparing the left VQ, field potentials evoked by left RtN were completely abolished in the right side VH whereas the field potentials remained intact in the left VH. The RtN evoked field potentials in the <u>right</u> VH gradually returned within 7 to 10 days after SCL. The time course of the returning evoked potentials coincided with the restoration of right hindlimb locomotion. Supported by The Miami Project.

Determining the Postnatal Growth Period of Corticospinal Axons in Cats Using MAP-1B Immunoreactivity. J.M. Alisky and D.L. Tolbert. Dept. of Anat. & Neurobiol. and Surgery (Neurosurg.) St. Louis Univ. Sch. of Med., St. Louis, MO 63104.

Growing and mature axons have different microtubule associated proteins (MAPs). Growing corticospinal (CS) axons in rats have been demonstrated immunocytochemically using monclonal antibodies to MAP-1B (J. Neurosci. 9:1712-1730). We used MAP-1B immunoreactivity to determine the growth period for CS projections in cats. From 1-21 postnatal day (PND), CS axons were strongly immunoreactive for MAP-1B in the pyramidal tract and spinal cord. The lateral corticospinal tracts (LCSTs) at all levels were immunoreactive. There was strong immunoreactivity in the anterior corticospinal tracts (ACSTs) only in the cervical levels but some ACST axons were labeled in lower levels.

Immunoreactive axons were present in the dorsomedial portion of dorsal columns in cervical spinal cord levels. At 28 PND, immunoreactivity of CS axons was markedly decreased in the pyramidal tract and spinal cord. Within the context of this overall decrease, immunostaining of the LCSTs in thoracic and lumbar levels was slightly greater compared to cervical levels. At 38 and 46 PND, CS axons were not immunoreactive in the cervical levels and only lightly reactive in thoracic and lumbar levels. We conclude that most of the postnatal growth of CS axons occurs in the first 3-4 weeks after birth. By 6 weeks after birth, the growth period is virtually complete, ending rostrally before caudally.

We wish to thank Richard Vallee and George Bloom for their gift of anti-MAP-1B monoclonal antibody (PNAS 82:5404-5408). We also thank Thomas Schoenfeld and James Hammarbach for their helpful suggestions. Supported by NIH Grant N5-20227.

145.8

ADAPTATIONS OF THE MEDIAL GASTROCNEMIUS MUSCLE TO INACTIVATION. W.Z.Zhan and G.C.Sieck. Dept. Biomed. Engineering, USC, Los Angeles, CA 90089. The effects of 2 weeks of inactivity on the physiological, morphological, and histochemical properties of the medial gastrocnemius (MG) muscle were studied in hamsters by blockade of the sciatic nerve with tetrodotoxin. The proportions of type I and II muscle fibers (classified based on ATPase activity) were unaffected by inactivity. The cross-sectional area (CSA) of type I fibers increased while the CSA of type II fibers decreased. Fiber succinate dehydrogenase (SDH) activities (quantified microdensitometrically) of both type I and II fibers decreased with inactivity. Isometric contractile properties of the MG were studied using direct muscle stimulation. Twitch contraction and half relaxation times increased after 2 weeks of inactivity. Muscle tensions decreased at all frequencies of stimulation. Fatigue resistance to repetitive activation improved. decreased at all frequencies of stimulation. Fatigue resistance to repetitive activation improved. We conclude that the mechanical changes induced by inactivity are most likely due to the increased relative contribution of type I muscle fibers to the total area of the MG. The improvement of fatigue resistance is not correlated with changes in fiber SDH activity.

MOTOR-UNIT ACTIVITY PATTERN IN THE DEVELOPING RAT SOLEUS MUSCLE. T. Eken*, G. Elder* and T. Lørno* (SPON: European Brain and Be haviour Society). Institute of Neurophysiology, University of Oslo, 0162 Oslo 1,

The fibre-type composition of the rat soleus muscle undergoes marked changes during postnatal development, from 57% slow-twitch Type I fibres at day 18 to 90% at day 224 (Elder & McComas, J Appl Physiol 62:1917–1923, 1987). Can these changes in fibre type be explained by changes in motor-unit

We implanted electrodes for single-unit (Hennig & Lømo, Nature 314:164–166, 1985) and gross EMG registrations chronically in soleus muscles of 1–5 week old rats. The rats were allowed to move freely in a cage, and the recordings were made during spontaneous movements. In selected cases the movements were also recorded on video tape.

ments were also recorded on video tape. The modal firing frequency of single motor units did not change appreciably from 10 days to adult, ranging from approximately 20 to 30 Hz in all groups. The distribution of interspike intervals was broader in the younger rats compared to adult rats, and the bistable firing behaviour characteristic of adult soleus motor units (Eken & Kiehn, *Acta Physiol Scand* 136:383–394, 1989) was not observed. Gross EMG recordings indicated a two-stage development of the adult activity pattern: During the second week, the activity changed from phasic to irregular tonic. This tonic activity gradually changed into the adult type, which is characterised by single units often firing with a stable frequency for periods lasting up to several minutes. ing up to several minutes.

is concluded that changes in firing frequencies are not likely to be responsible for the observed changes in fibre-type composition. However, during the first weeks the animal steadily increases the amount of muscle activity, which is an important parameter for the induction or maintenance of slow contractile properties in the adult (Eerbeek, Kernell & Verhey, *J Physiol* 352:73–90, 1984; Eken & Gundersen, *J Physiol* 402:651–669, 1988; Westgaard & Lømo, *J Neurosci* 8:4415–4426, 1988).

145.11

THE NUMBER OF FAST AND SLOW MOTOR UNITS DURING POSTNATAL DEVELOPMENT IN THE RAT SOLEUS MUSCLE W. J. Thompson and S. H. Astrow. Dept. of Zoology, Univ. of Texas, Austin, TX 78712.

During the first 2 weeks of postnatal life the rat soleus contains about During the first 2 weeks of postnatal fire the fat soleus contains about 1200 fast and 1500 slow fibers. Glycogen depletion experiments indicate that the fibers are organized into fast and slow motor units as early as postnatal day 8; however, this technique cannot be used to determine the number of such fast and slow motor units in individual muscles. Twitch number of such fast and slow motor units in individual muscles. Twitch unit size (given by the fraction: unit twitch force/muscle twitch force) and the twitch rise time provide no unambiguous way to identify slow and fast motor units at 17-18 days; these parameters form a continuous distribution extending from units with fast rise times and large unit sizes to units with slow rise time and small unit sizes. However, the ratio of the twitch force to the tetanic force generated by a unit, a value which can be determined for each single unit isolated in a muscle, can be used to predict a unit's fiber type identity in the 17-18 day rat soleus. In such muscles, motor units can be divided into two groups which differ significantly in their twitch/tetanus ratios (Mann Whitney U test). Units with high twitch/tetanus ratios have more rapid rise times, sugressing with high twitch/tetanus ratios have more rapid rise times, suggesting they contain fast fibers. This prediction has been verified using glycogen depletion. Nine units have been depleted, and all units with ratios ≥ 0.38 have been found to be fast and all units with ratios ≤ 0.35 have been found to be slow, even though some of the units have similar twitch rise times. Based on the fraction of units which have ratios characteristic of fast units $\frac{38\%}{100}$ of the units in calculated $\frac{1.7}{100}$ days are fast. fast units, 38% of the units in soleus at 17-18 days are fast. Since the total number of motor units in the muscle is roughly 24, these results suggest an estimate of 9 fast and 15 slow units in soleus at 17-18 days.

THE EFFECTS OF SPINAL TRANSECTION ON THE MOTOR CYCLICITY IN NEONATAL RATS. M. Dyer. E. A. Strauss. and C. R. Almli. Devel. Neuropsychobiol. Lab., Dept. of Psychol., Wash. Univ., St. Louis, MO, 63130.

Cyclic, spontaneous movement (CSM) patterns have

been demonstrated in newborn rat pups. This study determined if fore- and hindlimb CSM were decoupled after midthoracic spinal cord transection.

Under cryoanaesthesia, a midthoracic spinal transection was performed (aspiration) in neonatal rats.

After surgery, pups were placed in an incubator $(37\pm1^{\circ}C)$ until recovery from anaesthesia and then returned to the until recovery from anaesthesia and then returned to the dam for 24 hours. At 24 hours post-surgery the pups were video-taped for 10 minutes while in the incubator. Tapes were computer-analyzed for counts of movements of fore- and hindlimbs. Cyclicity patterns were measured with spectral analyses (FFT).

The present data indicate that spinal transection in rat pups may alter the cyclicity and phase of the hindlimbs. (Conducted under NIH Guide for Care and Use of Laboratory Animals)

of Laboratory Animals).

SEGMENTAL ORGANIZATION OF THORACIC PREGANGLIONIC NEURONS IN CHICK AND RAT EMBRYOS. E.B. Ezerman', J.C. Glover' and C.J. Forehand'. 'Dept. of Anatomy and Neurobiology, Univ. Vermont Coll. Med., Burlington, VT 05405 and *Inst. Physiology, Univ. Oslo, Oslo, Norway.

In the adult rat, an individual midthoracic spinal segment

Physiology, Univ. Oslo, Oslo, Norway.

In the adult rat, an individual midhoracic spinal segment provides sympathetic preganglionic innervation to paravertebral ganglia at levels both rostral and caudal to the segment; however, individual preganglionic neurons send their axons either rostrally or caudally in the sympathetic chain (Forehand & Rubin, Soc. Neurosci. Abstr. 12:1056, 1986). We have explored preganglionic projections in the embryonic rat and chick to determine whether directional specificity is a property of the early outgrowth of these fibers.

Preganglionic projections were labeled with fluorescein and rhodamine conjugated dextran amines (FDA, RDA) in isolated spinal cord/sympathetic chain preparations of 9-10 day chicken and 17-19 day rat embryos. Rostrally and/or caudally projecting preganglionic neurons within a single segment were labeled by placing RDA and FDA on the sympathetic chain, one on either side of a single ganglion. The sympathetic chain rostral and caudal to the labeling site was avulsed prior to labeling. The preparations were maintained alive for 10-16 hours prior to fixation and vibratome sectioning. In some cases, Dil was used to label adjacent segmental sympathetic chain ganglia on either side of the spinal cord in fixed preparations.

In both chick and rat embryos, as in the adult rat, spinal segments provided innervation to both rostral and caudal ganglia, while individual preganglionic neurons projected only in the rostral or caudal direction. Moreover, preganglionic neurons with rostral projections occupied the rostral 2/3 of the spinal segment, while those with caudal projections occupied the caudal 2/3 of the segment. Supported by NIH and a NATO Grant for international collaboration.

MOTOR UNIT TRANSFORMATION IN A MOUSE FAST-TWITCH MUSCLE K. Condon and W. J. Thompson. Dept. Zoology, Univ. of Texas, Austin, TX 78712.

The mouse extensor digitorum longus (EDL) muscle undergoes a progressive loss of slow fibers during early adult life, from ca. 160 fibers at 18 days of age to 0-9 fibers at 3-6 months. Immunocytochemistry using antibodies to myosin isoforms shows many fibers which express slow myosin also co-express fast 2a myosin during the transition, suggesting that slow fibers are being transformed to fast type 2a. Based on the response to denervation, this transformation is innervation dependent. Two explanations can be offered for this transformation: 1) this muscle possesses no slow motor neurons and the slow fibers, innervated by fast motor neurons, are converted to fast; 2) the slow fibers are selectively innervated by slow motor neurons but these slow motor neurons transform to fast and in turn convert the fibers these slow motor neurons transform to tast and in turn convert then they innervate. The first explanation predicts mixed motor units, the slow fibers being distributed among the fast units based upon their relative frequency (approximately 5-6 fibers per unit). The second explanation predicts slow motor units in varying stages of reasformation to a fast 2a type. Individual motor units in C57BL/6J mice between the ages of 20-30 days were isolated from teased ventral roots and identified using the glycogen depletion technique. Biasing our sample to units of slow twitch rise time, we found 3 units where greater than 90% of the fibers stained for slow myosin. Each of these units contained fibers transforming to 2a. Thus, slow fibers in mouse EDL appear to be selectively innervated and their loss results from the transformation of slow units to type 2a, analogous to the reverse transformation known to occur in rat soleus.

ONTOGENIC DEVELOPMENT OF SENSORIMOTOR REFLEXES IN THE OPOSSUM, MONODELPHIS DOMESTICA. G. Cassidy *, D. Boudrias* and T. Cabana, Dép. de Sciences biologiques, Université de Montréal, C.P. 6128, Succ. "A", Montréal, Qc. Canada H3C 3J7.

The ontogenesis of sensorimotor reflexes can be studied in Monodelphis domestica, a marsupial born very immature. At birth, the forelimbs perform a rhythmic, alternate movement resembling swimming, which enables the newborn to climb on the mother's belly and reach a nipple; the hind-limbs are merely more developed than buds and do not move independent of the trunk. A number of reflexes were tested in the adult animal and, daily, in newborn opossums up to 55 days postnatal (PND), when the expression of the reflexes studied resembled the adult pattern. The following sequence in the appearance and maturation of reflexes could be described: forelimb grasp, body righting, forelimb hopping, hindlimb grasp, chin placing, dorsal then lateral forelimb tactile placing, hindlimb hopping, air righting, dorsal then lateral hindlimb tactile placing and, finally, visual placing. Rooting which is present in neonatal opossums, disappears around 32 PND. This behavioral sequence generally matches the sequence of limb and neural (spinal cord and brain structures involved in the control of these behaviors) development and maturation, as judged from histological sections and preliminary tracing studies.

146.3

AFFORDANCES IN GAP CROSSING: DEVELOPMENTAL CONSIDERATIONS K.G. Holt*, L.Fetters, I.Chazan*, J.Meehan* and B. Nelson*. Dept Physical Therapy, Boston University

Adults have been shown to body-scale to leg length in their perception of climbable stairs and in freely adopted cadence of walking . The purpose of this study was to determine the accuracy with which adults and children perceive and act when faced with the task of crossing gaps, as might be experienced in crossing a stream. Leg lengths of nine year-olds change more rapidly than at any other age, and they might be expected to be less sensitive to the action capabilities their bodies afford. Subjects were asked whether various gaps between two platforms were crossable and then to attempt the crossing. Two setups of the gaps were presented for the actual crossing: as discrete widths (DIS) and as a continuous V-shape (CON). Pi (π) values defined as the ratio of perceived $(\pi P E R)$ or actual crossability $(\pi D I S)$ and $\pi C O N$) to leg length were calculated. Results indicated that nine year-olds and adults have the same body-scaling relationships for perception $(\pi P E R) = 1.4$, and continuous action $(\pi C O N) = 1.5$) and are significantly different for discrete action $(\pi C O N) = 1.5$) and are significantly different for discrete action $(\pi C O N) = 1.5$) and are significantly different for discrete action underestimate. Both groups increased the actual size of the gap they could cross on successive trials. CON setup was more ecologically valid than DIS setup. These results suggest that despite rapid increases in growth children are able to quickly adapt to their new dimensions and new tasks. It is suggested that the paradigm may be used to diagnose children whose motor development may be delayed.

PRE-TREATMENT WITH DSP-4 SLOWS BEAM-WALKING RECOVERY IN THE RAT. L.B. Goldstein, A. Coviello, G.D. Miller and J.N. Davis, V.A. & Duke Medical Centers, Durham, N.C. 27705

Treatment with amphetamine hastens the recovery of beam-walking in rats after a unilateral lesion of the sensory-motor cortex. We have hypothesized that the amphetamine effect is mediated through central noradrenergic neurons since selective a2adrenergic receptor antagonists facilitate recovery while a2adrenergic receptor agonists are detrimental. To further test this hypothesis, we carried out an experiment in which one group of rats were pre-treated with DSP-4 and a second group with saline. Two weeks after pre-treatment, rats were trained at the beamwalking task and then randomly assigned to undergo a unilateral sensory-motor cortex suction ablation or sham operation: 1. DSP-4/Lesion (n=14), 2. Saline/Lesion (n=19), 3. DSP-4/Sham (n=6),4. Saline/Sham (n=8). DSP-4 pre-treatment slowed recovery in lesioned rats (ANOVA (3,43) p<.0001; Fisher LSD, p<.05) but did not interfere with beam-walking in sham operates (Fisher LSD, P>.05). DSP-4 pre-treatment resulted in similar decreases in cerebral cortical norepinephrine in both sham-operated and cortical lesioned rats. These data are consistent with the hypothesis that norepinephrine influences motor recovery after unilateral cortex lesions

MORPHOLOGY, DISTRIBUTION AND QUANTITATIVE DEVELOPMENT OF NEURONS IN THE WHITE MATTER OF THE HUMAN MOTOR CORTEX. G.Meyer* and P.Wahle. Dept.Anatomy, Fac. Medicine, La Laguna /Tenerife, Spain, and MPI Biophys.Chemie, Dept.Neurobiology, Göttingen, FRG.

In the adult human brain, neurons in the white matter (interstitial neurons) are especially numerous under the motor cortex. They are mostaburdant in the vicinity of layer VI, where they show a columnar alignment, but they are also present in the white matter several cms below the gray matter. The Golgi method and MAP 2-immunohistochemistry, carried out on autopsy brains, reveal that most neurons in the white matter have a pyramidal morphology, displaying apical and basal dendrites and dendritic spines. The multipolar, nonpyramidal NADPH diaphorase-positive neurons form only a small fraction of the white-matter population. Cell counts in 30 Nissl-stained brains from pre-and perinatal ages until old age show a sharp decrease of cell density due to both cell death and dilution in the expanding white matter, until the first postnatal months. This decrease is more significant in the superficial than in the deep white matter. After the age of 10 years cell density remains stable throughout life.

146.4

MODIFICATION OF THE HUMAN BICEPS SPINAL STRETCH REFLEX: PRELIMINARY STUDIES ON PROLONGED CONTROL AND FOLLOW-UP PERIODS. R.L. Segal, P.A. Catlin*, C. Barker*, P. Broadbent*, A. Cockerham*, L. Reaver* and S.L. Wolf. Div. of Phys. Ther., Emory Univ. Sch. of Med., Atlanta, GA 30322 This study examined the effect on biceps EMG of a prolonged control period before training (subject = 5)

This study examined the effect on biceps EMG of a prolonged control period before training (subject = 5) and prolonged follow-up period after training (subject = 5) and prolonged follow-up period after training (subjects = 4) of the biceps spinal stretch reflex (SSR) in normal humans. Each subject had 4 baseline sessions without feedback of biceps SSR magnitude. Then, subjects were randomly assigned to one of two sequences: 1) control (8 sessions as in baseline)-Training (8 sessions with feedback of SSR magnitude and operant conditioning) or; 2) Training-Follow-up (Follow-up = 8 sessions same as baseline). For subjects in sequence 1, the biceps SSR decreased during the first two control sessions, then remained relatively stable with a mean decrease of 22.7%. For subjects in sequence 2 (at present all uptrainers), the SSR was uptrained a mean of 25% with an average decrease of only 7% during the 8 follow-up sessions. These results suggest that a more prolonged baseline period than previously used is necessary before initiation of training. In addition, there appears to be some persistence of the training effect during follow-up for uptrainers in this study. Interestingly, we also monitored a similar (but more variable) increase in EMG for the synergist brachioradialis during biceps uptraining, but the decrease in follow-up was more substantial (-39%).

L-DOPA INDUCED LOCOMOTION IN NEONATAL DECEREBRATE RATS. T. Iwahara*. C. Van Hartesveldt, E. Garcia-Rill and R. D. Skinner. Dept. of Anatomy, University of Arkansas for Medical Sciences, Little Rock, AR and Dept. of Psychology, University of Florida, Gainesville, FL. Neonatal rats were anesthetized with penthrane and a precollicular brainstem transection performed. At 0-3 days, L-DOPA (100mg/kg s.c.)

Neonatai rats were anestnetized with pentinane and a precollicular brainstem transection performed. At 0-3 days, L-DOPA (100mg/kg s.c.) induced continuous, long-lasting air stepping consisting of four-limb walking with stronger alternation in the forelimbs compared to the hindlimbs. At 6-8 days, continuous air stepping was characterized by better agreement between forelimb and hindlimb step cycles. By 14-16 days, the hindlimbs showed faster stepping than the forelimbs. The first evidence of consistent galloping was observed in this age group. In some cases, the forelimbs were held extended and only the hindlimbs walked or galloped. At 20-22 days, walking (forelimbs) and galloping (hindlimbs) became episodic. Each age group was tested for overground locomotion. Only in the 20-22 day group was weight-bearing overground stepping observed. In general, the duration of the effect of the same dose of L-DOPA decreased with age. Animals in each group which received a mid-thoracic spinal cord transection showed forelimb alternation but no hindlimb stepping. These results suggest that L-DOPA induces stepping by activating brainstem and/or cervical spinal centers via an as yet unknown mechanism. The pattern of the development of gait (forelimb to hindlimb gradient) at various ages was similar to that observed in intact neonatal rats (Sickles et al, ISDP, 1989).

THE FUNCTIONAL SIGNIFICANCE OF NEURONAL AND GLIAL CHANGES OCCURRING IN THE ADULT RAT PRRENIC NUCLEUS DURING AGING. H.G. Goshgarian and X.-J. Yu*. Dept. of Anatomy, Wayne State Univ. Sch. of Med., Detroit, MI 48201.

Morphometric analysis of the ultrastructure of the

Morphometric analysis of the ultrastructure of the phrenic nucleus in young adult rats (9-10 weeks) and older adult rats (9-10 months) showed that there is a significant increase in the number of double synapses in the phrenic nucleus of older rats (27.5 \pm 2.4) as compared to younger animals (20.25 \pm 1.2). Moreover, astroglial process retraction from in between adjacent dendrites during aging results in a significant increase in the length (1.73 \pm 0.1µm) and percentage (6.56 \pm 0.4) of dendrodendritic membrane appositions in the older animals as compared to the length (1.42 \pm 0.1 µm) and percentage (5.05 \pm 0.4) of appositions in the younger rats. Quantitative electrophysiological analysis of phrenic nerve activity during a respiratory reflex known as the "crossed phrenic phenomenon" (CPP) in both young and older adult rats revealed that there was a significant increase in the mean integrated area of the phrenic nerve compound action potential in older rats (45.3 \pm 15.3 mm) as compared to measurements taken from younger rats (11.8 \pm 1.6 mm). Moreover, the duration of the reflex was significantly longer in older rats (36.4 \pm 3.7 sec) as compared to the duration in younger animals (15.81 \pm 3.1 sec). These results suggest that there is a correlation between the morphological changes and the enhanced expression of the CPP.

DIFFUSE NERVOUS SYSTEM INJURY ALTERS CYCLIC. SPONTANEOUS MOVEMENTS OF NEWBORN, FULLTERM AND PRETERM RATS. C.R. Almli and M. Dyer. Developmental Neuropsychobiology Laboratory, Washington University Medical School, St. Louis, MO 63110.

Cyclic, spontaneous movement (CSM) patterns are displayed by fullterm, preterm and fetal rats. The present study determined the effects of diffuse nervous system injury on CSM patterns of neonatal rats born vaginally (fullterm) or delivered by cassarian section at preterm destational ages (Perterm)

patterns of neonatal rats born vaginally (fullterm) or delivered by caesarian section at preterm gestational ages (Preterm). Following delivery at 21-22 days (fullterm), 21 days (preterm), or 20 days (preterm) gestational age, the "neonates" were housed in an incubator (37 ±10°C) for 24 hours. Diffuse nervous system damage was produced by oxygen deficiency. Neonates were videotaped for 10 minutes pre-treatment, at 1-hour post-treatment, and at 19-hours after treatment. Movements were analyzed with computers for counts and durations of body segment movements (mouth, head, limbs, and trunk) and complex movements (ambulation, body position change, and face brushing). Segment and whole body movements were analyzed for cyclicity with spectral analysis (PET)

Diffuse nervous system injury alters movements and movement patters of fullterm and preterm rats. The treatment severely disrupted CSM patters for all age groups. (Conducted under NIH Guide for Care and Use of Laboratory Animals).

TRANSCRANIAL MAPPING OF THE CORTICAL HOMUNCULUS. W.J. Levy. V. Amassian. J. Cadwell. M. Kitagawa*. U. Schmid*. M. Traad*. Dept. of Neurological Surgery, Univ. of Pittsburgh, Pittsburgh, PA 15261.

The motor homunculus is a well-described and well-characterized organizational feature. However, its

The motor homunculus is a well-described and well-characterized organizational feature. However, its representation varies substantially between individuals, and more significantly in the presence of disease. In this sense, the traditional description is oversimplified. These variations are of scientific interest, and can aid or hinder surgery for lesions in the vicinity. We have developed a method for the use of a magnetic coil (Cadwell figure of eight using an MES-10 stimulator) to stimulate designated scalp sites. The contralateral EMG is recorded from surface electrodes over the biceps, triceps, APB, and ADM muscles. Maps are then constructed of EMG amplitude versus stimulation site. These maps are superimposed on an MRI scan of the subject, done with marking stereotaxic coordinates and cortical stimulation. This method is encouraging for the development of a transcranial cortical mapping system. Such a system would improve the knowledge of plasticity in the motor cortex with injury, and the management of patients with lesions in the area.

DEVELOPMENT AND PLASTICITY-VISUAL SYSTEM: RETINA AND OPTIC NERVE

147.1

THE CHARACTERIZATION OF THE RIBBON SYNAPTIC STRUCTURE IN MICE WITH RETINAL DEGENERATION. <u>Grant W. Balkema</u> and <u>Katherine Bachman</u>, Department of Biology, Boston College, MA 02167.

A monoclonal antibody, B16, has been produced that recognizes a protein determinant associated with the ribbon synaptic structure in the photoreceptor terminal. We have found this antigen in every species that we have examined (fish, frog, lizard, mouse, rat, rabbit, cat, and monkey).

We examined the emergence of this synaptic protein in developing mouse retina from birth (P₀=postnatal day zero) through P₂₁. Mouse retinas were lightly fixed with PLP (2% paraformaldehyde/lysine/periodate), frozen, sectioned at 8μM and placed on glass slides. Sections were incubated with the B16 primary antibody and visualized with a fluorochrome conjugated secondary antibody. Using the light microscope we first detected peri-nuclear labeling on days P₃-P₄. By days P₄-P₅ a thin, faint line in the outer plexitorm layer (OPL) could be detected. At day P₇ the OPL was well developed and formed a sharp line. These results are in agreement with previous ultrastructural studies.

The early postnatal development in the rd/rd mouse was similar to its wild-type control through P₂. The rd/rd mouse failed to develop well defined ribons. In the normal mouse (and all other species) the ribbon structure has a characteristic arch shape with the top of the arc pointing towards the outer nuclear and the open end pointing towards the inner nuclear layer; the ribbon in the rd/rd mouse was punctate. We also observed labeled debris at the retina/pigment epithelium border in sections from rd mice days P₄-P₇. The ribbons in the rd/rd mouse persist as the photoreceptor outer segments degenerate, although they are drastically reduced in number. (Supported by the NSF and the NEL)

147.2

EMERGENCE OF THE PHOTORECEPTOR MOSAIC FROM A PROTOMAP OF EARLY-DIFFERENTIATING CONES IN THE PRIMATE RETINA Kenneth C. Wikler and Pasko Rakic. Section of Neuroanatomy, Yale University School of Medicine, New Haven, CT 06510

In the adult rhesus monkey retina about 90% of all cones are red/green-sensitive as revealed by opsin-specific antisera (Wikler and Rakic, J. Neurosci., 1990). Although the general gradient of neurogenesis proceeds from the center to periphery in the monkey retina, a subset of peripheral cones are generated in advance of neighboring photoreceptors (LaVail et al., J. Comp. Neurol., 1990). We have used the red and green opsin-specific polyclonal antibody, 4942A (Lerea et al., Neuron, 1989), to assess whether precociously-generated cones in the periphery express their photograment in advance of later, separated adjacent cones.

green opsin-specific polycional antibody, 4942A (Lerea et al., Neuron, 1989), to assess whether precociously-generated cones in the periphery express their photopigment in advance of later-generated adjacent cones.

Eight monkey retinae from embryonic [B] day 64 to term were flat-mounted and processed for immunocytochemistry. Between E80 and E121, the distribution of 4942A- immunoreactive cells revealed two distinct patterns of ret/green-sensitive cones. As in the adult, more centrally located retinal areas contained about 90% red/green-sensitive cones. In contrast, in peripheral regions of the same retinae, only about 10% of morphologically-identified cones were immunoreactive. These early-maturing, red/green-sensitive peripheral cones were stationed evenly throughout the embryonic retinal surface among still undifferentiated, but already postmitotic cones. The distribution of a sub-population of early immunoreactive cones paralleled that of peripherally located cones labeled by early fetal injections of 3-H thymidine. By E140, the proportion of 4942A- labeled cones reached the mature level of 90% across the entire retina. We suggest that precocious red/green cones may induce the differentiation of about ten surrounding, later-generated immature cones. The emergence of cell phenotypes in the photoreceptor mosaic, prior to the establishment of their synaptic connectivity in the outer plexiform layer (Nishimura and Rakic, J. Comp. Neurol., 1985), supports the concept of a protomap proposed in other regions of the central nervous system (Rakic, Science, 1989) and appears similar to the mode and sequence of development of pioneer cells described in the photoreceptor mosaic in drosophila (Ready, TINS, 1989).

GENESIS OF RETINAL GANGLION CELL SUBTYPES IN THE MONKEY <u>D.H. Rapaport¹, J.T. Fletcher¹, M.M. LaVail² and P. Rakic³ ¹Dept. Anatomy, Univ. of Sydney, ²Dept. Anatomy, U.C.S.F., ³Sect. Neuroanatomy Yale Univ.</u>

The retinal ganglion cell layer (GCL) contains several types of cell which can differ on soma size. Displaced amacrine cells are generally smaller than ganglion cells and P(primate)α, Pβ and Pγ tend to be large, medium and small respectively. Determination of the birthdates of different types and subtypes of cell could suggest the influences which operate in shaping their fate. Retinas from monkeys injected with ³H-thymidine in utero and allowed to survive to maturity were analyzed. Analysis was performed in peripheral retina since central cells are largely of homogeneous size.

The mean diameter of somas in the GCL born on E38 was 10.5µm, and increased monotonically to 14.5µm at E56 before dropping to 9.2µm at E70. The initial increase is due partly to an expansion of the range of diameters. All neurons in the GCL born on E38 or E40 are between 6-14µm dia., the maximum increases to 19µm at E50 and 22µm at E56. The increasing frequency of labeled cells ≥20µm is accompanied by a decrease of labeled cells in the 15-19µm dia. range (from 46% of population at E50 to 30% at E56). By E70 the density of labeled GCL cells dropped considerably and all labeled cells were ≤10µm.

Although distinct size groups of ganglion cells are not readily apparent in the primate the data suggest that different types of ganglion cells are born at different times. Specifically, that Py cells are generated early, P\$ cells somewhat later, and $P\alpha$ cells are last to be born. The absence of labeled cells >10µm at the last stage of generation of cells in the GCL suggests that those small cells which are labeled may be amacrine cells. If this is the case then displaced amacrine cells would be born last among the GCL population, but before cells of the same phenotype in the INL (LaVail et al., submitted). supported by: EY01919 (M.M.L.), EY02593 (P.R.) & NH&MRC (D.H.R.)

147.5

VARIATIONS IN RETINAL LAMINAR THICKNESS MAY PREDISPOSE DIFFERENTIAL STRETCH DURING RETINAL GROWTH. A.D. Springer and B. Lia. Dept. of Cell Biol. and Anat., New York Med. Coll., Valhalla, NY 10595 and Dept. of Psych., Univ. Calif., Davis, CA 95616.

Thickness of the neuroblast (NBL), ganglion cell (GGL), inner nuclear, (INL) and outer nuclear layers (ONL) was determined from plastic sections in developing goldfish retina. At stage 23, prior to any retinal differentiation, the neuroblast layer was 1.5 times thicker at the temporal edge of the embryonic fissure than it was at the temporal periphery or nasal to the fissure. Differentiated layers were observed at stage 25. The GGL, INL, and ONL were 1.5, 1.4, and 1.3 times thicker, respectively, temporally than nasally. By 56 days posthatch these values were 2.2, 1.7, and 1.7 respectively.

E35 cat retina has a GCL 2.5 times thicker temporal to the optic disc than elsewhere. Combined with the NBL, overall retinal thickness is also greatest in this zone at a time when cell size and packing density is relatively uniform throughout the retina. Differential retinal expansion after this stage has been documented (Mastronarde et al., JCN, '84; Lia et al., Sci., '87).

If the retina is thought of as an elastic sheet (Kelling et al., Vis. Nsci., '89), the thickened region would be subject to disproportionately less stretch than the surrounding area as the retina is stretched by growth of the eye. Thus, the thickened cell layers on the temporal side of the early retinal anlage may predispose the vertebrate retina to differential retinal stretch and contribute to the generation of cell density gradients.

147.7

DEVELOPMENT OF A SPECIFIC GANGLION CELL TYPE IN EMBRYONIC CHICK RETINA. S.M. Fraley. Dept. Ophthalmology, New York Medical College, Valhalla N.Y., 10595.

The dendritic development of displaced

ganglion cells was studied using an in vitro method for labeling the optic nerve stump retrogradely with horseradish peroxidase (HRP). The cells were identified in flatmounts and

sections of flatmounts by some position within the retinal laminae. Displaced ganglion cells were observed at the earliest developmental stage studied (E9) and were characterized by a round or elliptical soma containing 3-5 proximal dendrites. The developmental sequence from E9 to the time of hatching (E21) consisted of soma enlargement, considerable dendritic elongation and branching, as well as elimination of short side branches and processes from the dendrites and soma, respectively. At all assessed stages the dendritic field of the displaced ganglion measured as one of the largest compared to other labeled ganglion cells. Thus, it appears that the major morphological features of displaced ganglion cells are evident early in retinal de-velopment. Supported by NIH EY0720603.

THE DENSITY OF BETA CELLS AFFECTS THE SIZES OF ALPHA CELLS IN CAT RETINA. S.J. Ault, K.G. Thompson, Y. Zhou, and A.G. Leventhal, Anat. Dept., Univ. of Utah Sch. of Med., Salt Lake City, UT 84132

and A.G. Leventhal, Anat. Dept., Univ. of Utah Sch. of Med., Salt Lake City, UT 84132

In recent years, the retinal distributions, morphologies, and development of alpha and beta cells have been studied in detail. Experiments have been carried out in normal retinae and in retinae depleted of retinal ganglion cells in the neonate. Indirect evidence from these studies has led to the idea that class specific interactions mediate retinal ganglion cell development. We have now tested this hypothesis directly by examining the morphologies of alpha cells in regions of mature cat retina selectively depleted of beta cells as a result of lesions of visual cortex at birth.

We find that, in beta cell poor regions, alpha cells are present in normal numbers and are distributed normally in a 'mosaic-like' pattern. However, they are clearly larger than normal. Alpha cell size was observed to vary as a function of beta cell density, alpha cells in regions of central retina depleted of beta cells were nearly the same size as their normal peripheral counterparts. Thus, the 'coverage' of central retina by alpha cells appeared to be abnormally high. These results suggest that the sizes of cat retinal ganglion cells depend upon overall cell density, the extrinsic determinants of retinal ganglion cell size appear not to be class specific. On the other hand, the nonrandom, territorial distribution of alpha cells mechanisms. Supported by EY04951.

CALCIUM HOMEOSTASIS IN GROWTH CONES OF GOLDFISH

RETINAL GANGLION CELL NEURITES. V.P. Bindokas and A.T. Ishida.

Dept. Animal Physiology, University of California, Davis CA 95616.

We have found that single retinal ganglion cells of goldfish (Carassius auratus) grow extensive neuritic processes in primary cell culture (Ishida and Cheng, submitted). Since cytoplasmic calcium levels appear to affect neurite outgrowth in a wide variety of cells, we have (Ishida and Cheng, submitted). Since cytoplasmic calcium levels appear to affect neurite outgrowth in a wide variety of cells, we have studied [Ca], (free intracellular calcium concentration) in growth cones of single goldfish retinal ganglion cells by ratio imaging analysis of fura-2 spectra. In saline containing 5 mM K*, [Ca], averaged over growing tips is greater than in the somata. Between the distal and proximal regions of growth cones, [Ca], ranges from ca. 40 nM to several µM; these gradients persist for tens of seconds, even though positions of high [Ca], shift over time. In high-K* salines, growth cone [Ca], increases, and appears to be regulated largely by 3 mechanisms: (1) The increase results largely from influx of external Ca** through L-type Ca-channels: this influx is blocked by Co**, enhanced by BAY K 8644, and antagonized by nifedipine. (2) [Ca], appears to be buffered in a Na*-dependent manner: in salines containing 120 mM Na* and 23 mM K*, plus 0.3 µM TTX, [Ca], initially rises ca. 5-fold over basal [Ca], and thereafter declines by 30% (i.e. to ca. 3-fold over basal) within 5 min. After replacing Na* by n-methylglucamine, the [Ca], increase elicited by 40 mM K* declines by ≤ 3% over 7 min. (3) [Ca], also appears to be buffered in a Na*-independent manner: [Ca], decreases upon return to control Na*-free saline, consistent with the possibility that retinal ganglion cells also possess an ATP-driven Ca** pump. Supported by NIH grant EY08120.

DENDRITIC DEVELOPMENT OF ABNORMALLY PROJECTING RAT RETINAL GANGLION CELLS (RGCs). E.N. Yamasaki & A.S. Ramoa. Lab. Mol. Pharmacol. II, IBCCF, UFRJ, Rio de Janeiro, 21944 RJ, Brazil and Dept. Pharmacol. Exp. Ther., Univ. Maryland Sch. of Med., Baltimore, MD USA 21201.

Interaction with a target is critical for survival of mammalian RGCs, but it is less clear whether this interaction plays a role in maturation of their dendritic trees. To make inferences about the role of target nuclei in regulation of dendritic development we have compared the morphology of three populations of RGCs with distinct patterns of axonal projection: topographically correct projection to caudal superior colliculus (CSC), topographically incorrect projection to CSC or transient projection to inferior colliculus (IC). To identify RGCs, rhodamine-labeled latex microspheres were injected in IC or CSC. Retinae were dissected and the detailed morphology of RGCs was then revealed by intracellular injections of Lucifer Yellow. Different classes of revealed by intracellular injections of Luciler Yellow. Different classes of neurons projected to IC and CSC: topographic targeting errors were most frequent for class III (50% of 70 cells at P3-P30) while class II cells projected to IC (100% of 23 cells at P3-P12). They were morphologically indistinguishable from correctly projecting cells. Dendrite and soma diameters as well as dendritic complexity of aberrant cells were within the normal range for each class. Moreover, as occurred in correctly projecting cells, their dendritic trees displayed a large number of transient filaments which increased in number during the first postnatal days. These results support the notion that dendritic development of RGCs is independent of the pattern of axonal projections but regulated by intraretinal cues. (CNPq & FINEP/Brazil; FINEP/Maryland)

LOCALIZATION OF SPECIFIC mRNAs IN DIFFERENTIATING RETINAL CELL TYPES. P.S Jones and A.J. Aquayo. Center for Research in Neurosciences, Montreal General Hospital and McGill University, Montreal,

Quebec, H3G 1A4.
In situ hybridization was used on developing rat retina to examine the localization and time course of expression of specific mRNAs. At E14 GAP-43 message was localized primarily in the inner layer of the posterior retina, near the optic disc. By E20 reactivity had spread throughout the inner surface of the retina. After birth this reactivity decreased, reaching the adult signal intensity by P25. This pattern of reactivity is consistent with GAP-43 being expressed mainly in retinal ganglion cells undergoing active axonal growth.

Opsin message was first observed postnataly, and was restricted to cells in the outer retina. The opsin hybridization signal increased after P3 and attained adult intensity and distribution by P25. These observations closely follow the development of photoreceptor cells in the rat.

These observations indicate that GAP-43 and opsin mRNA levels reflect the differentiation and

maturation of two distinct cell types in the developing rat retina.

EXPRESSION OF THE COLLAGEN IV GENE DURING DEVELOPMENT OF THE MOUSE RETINA. P.V. Sarthy. M. Fu* and J. Huang*. Department of Ophthalmology, University of Washington, Seattle, WA 98195.

In a recent study we showed that laminin B1 mRNA was expressed by both non-neural cells and retinal ganglion cells (RGC) during development of the mouse retina. Since collagen IV is usually associated with larging in the based language and the state of the collagen IV is usually associated with laminin in the basal lamina, we examined collagen expression in the dev-

laminin in the basal lamina, we examined collagen expression in the developing mouse eye by immunostaining and *in situ* hybridization.

Collagen immunostaining was detected as early as embryonic day 12 (E-12). At E-12 and E-15, collagen was found in the lens, the hyaloid vessels which lie between the lens and the retina, and the internal limiting membrane (ILM) of the retina. At E-17 and subsequent stages, immunostaining was no longer detected in the retina except at the far periphery. The lens and optic vessels were, however, stained. The *in situ* hybridization experiments showed that at E-12, labeled cells were present only in the lens and the HV. By E-17, the density of labeling in these structures decreased dramatically and only faint labeling was observed at later stages in development. No labeled cells were observed in the retina at stages in development. No labeled cells were observed in the retina at stages in development. No labeled cells were observed in the retina at any stage during development. Northern blot analysis showed that a 6 Kb collagen IV transcript was present in the eye. These findings establish that collagen IV is present at the ILM only at early developmental stages (E-12 to E-17) when most axonal growth occurs in the retina. Furthermore, retinal collagen is derived from either the lens or, more likely, the HV. Hence, during development of RGC axons, it appears that both collagen and laminin are present in the ILM when there is maximal axonal growth. At these dwalestments to got the contractions are the stages however lawing lands. axonal growth. At later developmental stages, however, laminin alone remains in the matrix. FASCICULATION, DEFASCICULATION AND DISTRIBUTION OF PIONEERING AXONS IN THE RETINOFUGAL PATHWAY OF EMBRYONIC HAMSTERS. S.Jhaveri, R.S.Erzurumlu and G.E. Schneider. Dept. Brain & Cognitive Sciences, M.I.T., Cambridge, MA 02139.

The lipophilic tracer DiI was placed on the optic nerve head of fixed hamster embryos, aged Ell through El6. Labeled axons were examined in flat-mount preparations of the brainstem.

Tightly bundled optic nerve fibers defasciculate and undergo a spatial reorganization prior to reaching the chiasm. Upon crossing the midline, a group of fibers emerges to form the leading edge of the developing optic tract. These pioneer axons, tipped by large growth cones, course distinctly separate from each other. Successive waves of "follower" axons, each tipped by a large growth cone, are interdigitated between pioneers, but do not necessarily contact them. Axon fasciculation occurs in regions where fiber density is high.

A smaller contingent of ipsilateral axons emerges from the chiasm at about the same time as the contralateral fibers. Leading axons on the ipsilateral side keep pace with the growth of their contralateral fibers. Leading axons may slow their growth rate: by El3.5, the separation between pioneers and followers is not as distinct as at earlier times. Support:NIH grants EY05504, EY00126, EY02621.

DEVELOPMENT OF RETINAL CELL NUMBER, DISTRIBUTION, AND TYPE DURING THE PROTRACTED DEVELOPMENT OF THE CALIFORNIA MOUSE. A.A. Dos Santos, D.A. Schaefer*, and D.B. Sengelaub. Program in Neural Science, Dept. of Psychology, Indiana University, Bloomington, IN 47405.

The California mouse (Peromyscus californicus) and the Syrian hamster (<u>Mesocricetus auratus</u>) are closely related cricetid rodents with virtually identical eye size, retinal cell number, type, and distribution. This similarity is interesting in that developmental duration and rate, two factors hypothesized to be important in producing species differences in retinal organization, are strikingly different between these rodents. Gestation, closed eye period, and attainment of sexual maturity and adult body size are significantly longer or delayed in the mouse. We are studying the protracted development of the California mouse to determine how formative events in retinogenesis are orchestrated in the production of its hamster-like eye.

Neurogenesis of the mouse retinal ganglion cell layer (RGCL) is twice that of the hamster (12 vs. 6 days), but peak cell numbers in the RGCL do not differ.

The morphology of 3H-thymidine labeled cells at adulthood indicates that, like the hamster, ganglion cell generation precedes that of displaced amacrine cells. Perinatal cell death accounts for a decline of at least 40% in the RGCL and is complete by postnatal day 14. Like the hamster, this death is greatest in peripheral retina, and center/periphery differences in cell density begin to emerge during this period of differential death. Significant and symmetrical eye growth occurs postnatally, and this growth likely also contributes to the production of the adult cell distribution. At adulthood however, differences in center/periphery cell densities are apparent for only the early-generated cohorts suggesting that retinal growth alone cannot account for the creation of the retinal topography. Thus, despite its protraction, the events and consequences of retinal development in the California mouse are similar to those seen in the hamster, resulting in a similar retinal morphology.

RETINAL PROJECTIONS AND AXONAL MORPHOLOGY IN THE DEVELOPING VISUAL SYSTEM OF THE QUOKKA, SETONIX BRACHYURUS. SA Dunlop. WM Ross & LD Beazley. Dept. Psychology, University of Western Australia, Nedlands 6009.

During development in the marsupial quokka, there is an excess of optic axons compared to retinal ganglion cells (RGCs) labelled by injecting HRP into the visual centres (Brackevelt et al., Dev Brain Res 25:117-125, 1986). To investigate the source of additional axons, we examined animals during the peak of axon numbers (P40-50). First, we looked for projecting cells from the opposite retina and from the brain by injecting one eye with HRP or by placing HRP-gels into the optic disk. Uninjected retinae were wholemounted or cut as wax sections; brains were cut as vibratome sections. Very few or cut as wax sections, totalis were cut as vinations exections. Very few retino-retinal or efferent projecting cells were observed. Second, we examined axonal morphology in the optic nerve by labelling small groups of axons in the retina with HRP either in vitro (Dunlop, J Comp Neurol 293:425-447) or in vivo. Nerves were cut as longitudinal vibratome sections. Optic nerves from additional animals were prepared for EM and individual axons reconstructed from serial sections. HRP-labelled axons often bore short sidebranches both behind the eye and at the chiasm; such side-branches were also seen in our EM reconstructions and would have been included in optic axon counts. Some HRP-labelled axons executed loops before rejoining the main fascicle while others took sinuous trajectories across the nerve. We assume that axons with unusual pathways would have been counted more than once during quantitative analysis of EM sections. A considerable number of growth cones were also seen in both the HRP and EM sectioned nerves suggesting that some RGC's had not reached the brain. We conclude that there are several sources of excess axons over RGCs in the developing visual system of the quokka.

OLIGODENDROCYTES IN THE MATURING OPTIC TRACT OF POSTNATAL HAMSTERS STUDIED WITH THE RIP ANTIBODY. G.E. Schneider, R.S. Erzurumlu, S. Jhaveri, & B. Friedman. Dept. Brain & Cogn. Sci., M.I.T., Cambridge, MA 02139; Regeneron, Tarrytown, NY. The monoclonal antibody "Rip", specific for rat oligodendrocytes (Friedman et al., G/ma, '89), was used to study the developing optic pathway of postnatal hamsters. At P3 a sparse distribution of pre-ensheathing oligos is seen in the tract (OT) between chiasm and LGB, and also along the tectal midline. Two days later, such cells are present in the OT as far as the pretectum, whereas in the chiasm, axon ensheathment by Rip-positive cells has begun. By P7 pre-ensheathing oligos can be detected in the stratum opticum of SC and within the LGB. OT axon ensheathment is evident to the level of the ventral LGB. From P14-21, increasing fiber ensheathment is found throughout the OT, but Rip-positive elements remain sparse in the upper part of the superficial gray of the SC. Our findings are consistent with a possible role of oligo-derived proteins in inhibiting axon growth (Caroni & Schwab '89): Appearance of pre-ensheathing oligos corresponds to the time (after P3) when OT regrowth after transection of the brachium of SC fails; sprouting within the SC can occur at the ages studied, but it is restricted to the upper part of the superficial gray. Support: NIH grants EY05504, EY00126, EY02621.

RETINOTECTAL AXONS CROSS TO THE WRONG SIDE FOLLOWING DISRUPTION OF TECTAL MIDLINE CELLS IN THE HAMSTER. D.-Y. Wu, G.E. Schneider and S. Jhaveri, Dept. Brain & Cognitive Sci., M.I.T., Cambridge, MA 02139.

A group of radial cells in the tectal midline of developing hamsters expresses GFAP and vimentin. To investigate the possibility that these cells serve as a barrier to retinal axon growth (Wu et al. SN Abst. '89) we undercut the midline in 1-day-old hamsters using a hooked tungsten wire inserted from a point off the midline in the left SC (disrupting midline cells without damaging the overlying pial surface) and the right eye was also removed. Animals were sacrificed on P3-P14, 18 hr. after an injection of HRP into the left eye. Adjacent series of brain sections were processed for visualizing the HRP or for immunolocalization of vimentin or GFAP.

In the region of damage, midline cell processes had lost their pial attachments, although the pia itself remained intact, and retinotectal axons from the left eye crossed the dorsal midline abnormally from the right to the left side. This crossing was not detected in areas where midline cells were intact from their ventricular attachment to the pia.

We conclude that during development, midline cells may serve to preserve the laterality of the retinotectal projection. Support: NIH grants EY00126, EY05504, EY02621, MH15761.

FIBER ARRANGEMENTS IN THE OPTIC STALK OF NORMAL AND ALBINO

S.O. Chan* and R.W. Guillery. Department of Human Anatomy, University of Oxford, South Parks Road, Oxford OX1 3QX, U.K.

The rat optic stalk was studied by the anterograde Di! labelling technique in order to answer, first whether a retinotopy exists in the optic stalk, and second, whether the ventral temporal fibers in albinos take an abnormal course causing them to enter the wrong tract.

In rats aged E16.5 and E18.5 (plugged date= E0), a small Dil granule was put onto one retinal quadrant and the position of labelled fibers was traced with confocal laser microscopy in serial transverse sections. By E18.5 fibers from the ventrotemporal crescent have already reached the tract (Chan et al., 1990 ENA Meeting Abstracts). Just behind the eye, at both ages, fibers from each retinal quadrant cluster together and occupy distinct parts of the stalk. Across the stalk from anterior to posterior, fibers from lower nasal, upper nasal, upper temporal and lower temporal retina lie sequentially. As the fibers are traced towards the optic chiasm, fibers from one retinal quadrant begin to mingle extensively with those of neighbouring ones. The lower temporal fibers spread gradually from the posterior to the anterior parts of the stalk. At the optic chiasm, there is virtually no recognizable map at all. In albino rats, no discernable difference in the fiber arrangement in the stalk can be observed at either age.

We conclude that fibers in the post-optic stalk are retinotopically arranged, but that this order is lost gradually as the fibers pass centrally. Retinotopic maps in the targets are not simply formed by an orderly arrangement of fibers in the stalk. Second, the albino abnormality is not simply due to a misrouting of lower temporal fibers. fibers as they leave the eve.

DEVELOPMENT OF PERMANENT RETINAL PROJECTIONS TO SOMATOSENSORY AND AUDITORY THALAMIC NUCLEI IN HAMSTERS: A DII STUDY. P.G. Bhide, W.C.

AND AUDITORY THALAMIC NUCLEI IN HAMSTERS: A Dil STUDY. P.G. Bhde, W.C. West & D.O. Frost. Neurology, Mass. General Hospital East, Charlestown, MA 02129. In normal adult hamsters, the optic tract divides into superficial and internal tracts (SOT and IOT, respectively) at the level of the ventral lateral geniculate nucleus. Only SOT axons have collaterals that arborize in the visual thalamic (dorsal lateral geniculate, LGd) nucleus (Schneider & Jhaveri, Neurosci. Abstr., 9809, 1983). During development, refinal ganglion cell (GC) axons in the IOT emit transient collaterals to LGd and to the thalamic somatosensory (ventrobasal, VB) nucleus (Langdon et al., Neurosci. Abstr., 13:1023, 1987). Permanent retinal projections to VB and the thalamic auditory (medial geniculate, MG) nuclei were induced in newborn Syrian hamsters by ablation of the superior colliculus and transection of the somatosensory and auditory lemniscal pathways (Frost, J. Comp. Neurol., 203-227, 1991).

transection of the somatosensory and auditory lemniscal pathways (Frost, <u>J. Comp. Neurol.</u>, 203227, 1991).

It is not known if the permanent retino-VB projection arises exclusively by the stabilization of the normally restricted to LGd) also extend to VB following surgery. It is also not known which GC axons project to MG. We examined these issues by labeling individual GC axons with Dil in paraformaldehyde-fixed brains from 6. 8, 1, 15, and 21 day-old hamsters operated at birth to produce retino-VB and retino-MG projections. Dil was placed in the optic disc or the optic nerve contralateral to the novel projections and allowed to diffuse for 3 mo. The Dil label in the thalamus was photoconverted to a DAB reaction product. Labeled retino-VB and retino-MG axons were reconstructed from serial sections. In operated hamsters, by the end of the first postnatal week, both SOT and 10T axon collaterals have entered the VB. Some of these collaterals have "simple" growth cones while others have developing strons in both the LGd and VB. By the end of the 2nd postnatal week developing arbors in both the LGd and VB. By the end of the 2nd postnatal week all collaterals elaborate adult-like terminal arbors. A single SOT or IOT projection, which is not present in normal hamsters at any age, also arises from both SOT and IOT axons and has a similar developmental history. Therefore, it appears that the permanent retino-VB projection is formed both by the stabilization of normally transient (IOT) axon collaterals and by the sprouting of new ones (from SOT); the retino-MB projection arises by the sprouting of new ones (from SOT); the retino-MB projection arises by the sprouting of new ones (from SOT); the retino-MB projection arises by the sprouting of new ones (from SOT); the retino-MB projection arises by the sprouting of new ones (from SOT); the

THE PATTERN OF GANGLION CELL FASCICLES IN THE PIGMENTED AND ALBINO RAT. W.L. Holcomb*, D.M. Murakami, I.S. Westenberg¹, and C.A. Fuller, Dept. of Animal Physiology, University of California, Davis, CA, 95616; ¹Dept. of Psychology, Glendale College, Glendale, AZ 85302.

This study compares the organization of ganglion cell fascicles in the retinal nerve fiber layer of the pigmented and albino rat. In order to control for variation due to different genetic backgrounds, we examined a specific strain (Westenberg Long-Evans) which is congenic except at the albino locus (albino c/c; pigmented c/+). In a previous study we described the fascicle organization in the normally pigmented rat. Light microscopy was used to examine the HRP labeled fascicles in the wholemounted retina. The distribution of fascicles reflects the distribution of ganglion cell bodies in that there is a region of high fascicle density in superior temporal retina located 0.6 mm from the optic disc. In addition, the mean diameter of fascicles in superior temporal retina was smaller when compared to fascicles in other retinal regions. Fascicle density was similar in the pigmented and albino strains; however, isodensity lines failed to exhibit the high density region of specialization in the albino retina. Mean fascicle diameter was smaller in superior temporal retina for both the pigmented and albino rat. Samples of fascicles from the entire retina did not reveal any difference in the distribution of fascicle diameter between the two groups; however, the mean diameter of fascicles in superior temporal retina appears to be reduced in the albino. This study supports others which conclude that the region of central specialization is underdeveloped in the retina of hypopigmented mammals. (Supported in part by NIH MH41477.)

DO LATE-ARRIVING OPTIC AXONS ALL TAKE A CROSSED CHIASMATIC COURSE? B.E. Reese', R.W. Guillery', C.A. Marzi², and G. Tassinari² Dept. Human Anatomy, Univ. Oxford, OX1 3QX, U.K.¹ and Ist. Fisiologia Umana, Univ. Verona, 37134 ITALY² We have examined the relative positions in the optic tract of the crossed and uncrossed optic axons arising from the temporal retina. Since position within the optic tract reflects time of axonal arrival during development (Walsh and Guillery, I. Neurosci. 5: 3061, 1985), we have used axonal position as an indicator of age and have related this to the chiasmatic pathway choice of the axons. Some adult cats were monocularly enucleated, to reveal the position of surviving crossed and uncrossed axon classes within the tract, while others had HRP injected or implanted to label axons in either the deep or the superficial parts of the tract selectively. The retrograde transport of the HRP then showed the distribution and the morphology of the ganglion cells giving rise to early (deep) or late (superficial) arriving axons.

The deep parts of the optic tract contain fine and medium, crossed

axons.

The deep parts of the optic tract contain fine and medium, crossed and uncrossed axons arising from mainly medium-sized cells in the contralateral nasal and the ipsilateral temporal retina; there is a clear line of decussation. In contrast, the superficial parts of the tract contain mainly fine diameter axons arising from small cells in the whole contralateral retina, and a small proportion of large diameter axons arising from large, alpha cells in the whole contralateral retina and also in the ipsilateral temporal retina.

The likelihood that axons from the temporal retina will project contralaterally, therefore increases as development proceeds. However, the presence of a few large uncrossed axons near the surface of the tract complicates the picture of a simple time-dependent signal that guides temporal axons into an uncrossed path and that weakens with age.

147.20

RETINAL GANGLION CELLS IN HAMSTERS WITH RETINAL PROJECTIONS TO THE VENTROBASAL AND MEDIAL GENICULATE NUCLEI. A. Irons, C Métin* and D. Frost. Univ. P & M Curie, Paris, France & Mass. General Hospital,

Boston, MA
Retinal projections to the ventrobasal (VB) and medial geniculate (MG) nuclei were induced in newborn Syrian harmsters by ablation of the dorsal lateral geniculate nucleus (LGd) and superior colliculus and transection of the somatosensory and auditory lemniscal pathways. When the hamsters were ≥12 wk old, a polyacrylamide gel containing 35% HRP was placed in the optic tract on the side of the brain containing the retino-VB and retino-MG projections. After 48-72 h, whole mounted retinae were processed with the Hanker-Yates technique to reveal labeled retinal ganglion cells (GCs). Contralaterally, GCs were found throughout the retina. Their density was 10-950 GC/mm² compared with 300-4,000 GC/mm² in normal hamsters. The total number of labeled GCs was ca 10,000, 15-20% of normal. GC soma diameters were normal: 7-23 µm with a peak in the distribution at ca 13-14 µm. As in normal hamsters, maximum GC densities occured in an elongated inferotemporal to superonasal zone located just above the optic disk, whereas inferotemporal to superonasal zone located just above the optic disk, whereas minimal densities were observed in the inferior periphery; GC diameter tended to increase with decreasing density. The best filled GCs could be classified as belonging to one of the 3 types distinguished in normal hamsters (Métin, C.M. & Frost, D.O., Neurosci. Abs., 15:1207, 1989). Ipsilaterally, GCs were α rrost, U.O., NeUrosci. Aps., 15:1207, 1989). Ipsilaterally, GCs were normally distributed in the temporal crescent and soma diameters were normal: 9-23 μm with a peak in the distribution at ca 15-18 μm. These data show a dramatic decrease in the number and density of GCs in neonatally operated hamsters with retino-VB and retino-MG projections, but no obvious changes in GC soma size or morphological type. Therefore it is possible that the mix of GC types projecting to VB or MG in operated hamsters is similar to the mix projecting to LGd in normal hamsters. SOMATIC AND SYMPATHETIC INNERVATION OF THE RAT CORNEAL LIMBUS. R. E. Kingsley and C. F. Marfurt. SBCME & NWCME, Indiana University School of Medicine, Notre Dame IN 46556.

This study is part of a larger comparative study which is directed at examining the normal innervation of the cornea in various species. Based upon retrograde HRP methods, we previously reported that in the rat there is a normal sympathetic innervation of the cornea by axons whose cell bodies reside in the superior sympathetic ganglion. The results reported here are based upon electron microscopic observations of the rat cornea in both normal and lesioned tissue.

We used adult Sprague-Dawley male rats in this study. In all of our experiments, we anesthetized the animals with 50mg/kg pentobarbital. In some animals, we removed the trigeminal ganglion while in others we performed a superior cervical sympathectomy. After a degeneration period of three to six days, we removed the corneal tissue under pentobarbital anesthesia and immediately placed it in a cacodylate buffered (pH 7.4) solution of 2% glutaraldehyde and 2% formaldehyde. After one hour of aldehyde fixation, we processed the tissue conventionally for transmission electron microscopy.

In the corneal limbus, we saw a number of large nerve bundles

In the corneal limbus, we saw a number of large nerve bundles which contain both myelinated and unmyelinated axons. These bundles are collected together by Schwann cells which express a well defined extracellular matrix. We only observed these well defined bundles in or near the limbus. Axons in the corneal stroma are isolated and always unmyelinated.

Within the axon bundles we saw synaptic-like profiles which contain densely packed clear core vesicles. These profiles did not disappear with trigeminalectomy. With sympathectomy we also saw synaptic-like profiles which contain dense osmiophilic granules.

AXOTOMY INDUCED CHANGES IN CGRP IMMUNONREACTIVITY IN TROCHLEAR MOTOR NEURONS. X.H. Wang, P.G. Iannuzzelli, R.G. Baker and E.H. Murphy. Department of Anatomy, Medical Coll. of PA, Phila, PA 19129 and Dept. Physiol. & Biophysics, NYU Med. Ctr., New York, NY 10016.

In many neurons the level of transmitter\peptide production following axotomy decreases. Some trochlear nucleus motoneurons (TMNs) contain the peptide Calcitonin Gene-Related Peptide (CGRP). We examined the distribution of CGRP immunocytochemically in trochlear motoneurons (TMNs) in the adult cat. CGRP+ cells were counted and the number compared with counts of TMNs in adjacent Nissl stained sections. The trochlear nucleus of the cat contains no interneurons and approximately 1000 TMNs, of which approximately 30% CGRP+. We used quantitative densitometry to classify the intensity of the CGRP in each neuron as light (L), intermediate (I) or dark (D). The distribution was D = 1%; 1=25% and L=75%.

One week following axotomy of the IVth nerve, the number of CGRP+ cells increased dramatically: almost all cells were CGRP+. The distribution of intensity of staining also differed from normal: D = 60%; I = 20% and L = 20%. In animals 1 to 6 weeks postoperative, the number of CGRP+ cells and the percentage of these cells which were classified D decreased with increasing survival time, but remained above normal at 6 weeks (percent of neurons CGRP+ = 40%, percent of CGRP+ cells classified as D = 40%). The changes in the percent cells classified as D,I or L indicate that axotomy increases CGRP expression. The increased number of CGRP+ cells following axotomy presumable reflects an increased production of CGRP or may indicate that axotomy induces CGRP expression in some neurons which do not normally express CGRP. Thus, the behaviour of CGRP in axotomized neurons differs from that found for most peptides and may indicate a role for CGRP in regeneration. Supported by NS24707 to EHM and EY20007 to RGB.

IS C-FOS PROTO-ONCOGENE INDUCED IN FACIAL MOTONEURONS FOLLOWING PERIPHERAL AXOTOMY?
C. Evinger¹, G.A. New² and K.J. Jones². ¹Dept. of Neurobiology & Behavior, SUNY-Stony Brook, NY 11794 and ²Dept. of Cell

Be Benavior, 20N1-Story Brook, N1 11794 and "Dept. of Cell Biology & Anatomy, Chicago Med. Sch., North Chicago, IL 60064. Many different stimuli have been shown to induce the expression of c-fos mRNA and protein in brain. The general time course of the effect is rapid, with maximal mRNA levels reached by 30' and protein levels at 3 h. In this study, we tested the hypothesis that peripheral axotomy will induce the expression of c-fos in motoneurons. Adult hamsters were anesthetized and subjected to axotomy of the right facial nerve at its exit from the stylomastoid foramen, with the left side serving as internal control. As a positive control in separate animals, bicuculline was used to chemically induce seizure activity. At 3 h post axotomy or seizure, the animals were sacrificed by intracardiac perfusion with 4% paraformaldehyde in PBS. Standard immunocytochemistry procedures were accomplished using a panel of commercially available polyclonal antibodies to c-fos. In the positive seizure control animals, the nuclei of neocortical neurons exhibited intense c-fos staining. In contrast, in neither normal nor axotomized facial motoneurons was c-fos detectable with immunocytochemistry. We are currently examining this question at the mRNA level, and in other species, as well as extending the time course for possible c-fos induction.

AXOTOMY INDUCED CHANGES IN CYTOCHROME OXIDASE ACTIVITY IN TROCHLEAR MOTOR NEURONS. P.G.lannuzzelli, X.H. Wang, B. Ju*, R.G. Baker and E.H. Murphy, Department of Anatomy, Medical Coll. of PA, Phila, PA 19129 and Dept. Physiol. & Biophysics, NYU Med Ctr., New York, NY 10016.

When the IVth nerve is cut just distal to the anterior medullary velum, approximately 50% of trochlear motor neurons (TMNs) die. The surviving neurons regenerate and re-innervate their target, the superior oblique (SO) muscle. Regeneration may result in a change in the neurons' oxidative metabolic machinery. Cytochrome oxidase (CO) activity is an indicator of oxidative energy metabolism. In this study, we determined CO levels in control and axotomized TMNs. Density of CO staining in the trochlear nucleus, revealed histochemically, was measured by quantitative image analysis at intervals from 3 days to 6 weeks following unilateral IVth nerve axotomy. At 3 days, no difference was detectable between the control and experimental sides. CO levels in the axotomized nucleus were slightly decreased at 1 week and this decrease was more marked at 3 weeks. By 6 weeks, (2 weeks after regenerating axons reach their target), CO levels in the axotomized nucleus were still lower than normal, but the difference was less marked than at 3 weeks, suggesting some restoration following re-innervation of the target. This decrease in CO levels following axotomy cannot be attributed to decrease excitatory input to TMNs since axotomy-induced synaptic stripping is restricted to inhibitory synapses on TMN somas. The data indicate that oxidative energy metabolism decreases during regeneration and that restoration of normal levels may be delayed for several weeks after the regenerating axons reach their target. Thus, regenerative growth either requires less oxidative energy than normal neuronal function or a different form of energy. Supported by NS24707 to EHM and EY20007 to RGB.

IMPAIRMENT OF NERVE REGENERATION BY ACRYLAMIDE (AC) INHIBITS THE AXOTOMY-INDUCED EXPRESSION OF PHOSPHORYLATED NEUROFILAMENT EPITOPES IN NEURONAL PERIKARYA. B.G. Gold. D. Austin*. N. Sternberger and L. Sternberger*. Center Res. Occ. Environ. Toxicology, Oregon Health Sci. Univ., Portland, OR 97201 and Dept. of Anatomy, Univ. Maryland Sch. Med., Baltimore, MD 21201.

Toxicology, Oregon Health Sci. Univ., Portland, OR 97201 and Dept. of Anatomy, Univ. Maryland Sch. Med., Baltimore, MD 21201.

Abnormal expression of heavily phosphorylated neurofilament (pNF) epitopes in neuronal perikarya is observed in a variety of disorders (e.g., Alzheimer's disease). Little is known about how this response is regulated. However, the appearance of pNF epitopes in sensory neurons following axotomy suggests that expression of at least some of these epitopes represents a neuronal perikaryal response to injury. Moreover, continued expression of pNF epitopes appears to depend upon sustained neuritic outgrowth following axotomy. In the present study, we asked whether inhibition of neuritic outgrowth by AC prevents the induction of pNF epitopes in sensory neurons. Seven-week old rats underwent a bilateral sciatic nerve crush and 10 ml of 0.1M AC (a concentration previously found to inhibit nerve outgrowth following crush) was injected subperineurially just proximal to the crush site via a glass micropipette; the right nerve was injected with saline. Animals were perfused with 4% paraformaldehyde at 7 days. Sections (10 mm) of L4 and L5 dorsal root ganglia (DRG) were stained with antibody 2-135 (directed against a nonphosphorylated NF epitope) or 7-05 (directed against a pNF epitope) using the peroxidase-antiperoxidase method. Antibody 7-05 demonstrated modest to intense staining in 31-36% of neuronal perikarya in DRG from saline-injected crushed nerves. Fewer (9-12%) cell bodies showed staining and only a rare perikarya was strongly stained in DRG from AC-injected crushed nerves; axons were intensely stained. Antibody 2-135 demonstrated intense staining in all perikarya and axons from both AC- and saline-injected nerves. These findings suggest that expression of pNF epitopes in neuronal perikarya is regulated by growth processes in the axon and/or interactions between elongating neurites and supporting elements in the distal stump. Supported by NS 26265.

LOCALIZATION OF THROMBOSPONDIN IN MOUSE SCIATIC NERVE FOLLOWING NERVE CRUSH OR TRANSECTION.

J.R. Hoffman, K.S. O'Shea, and V.M. Dixit*
Univ. of Michigan, Ann Arbor, MI 48109.

Thrombospondin (TSP) is a 420 kDa component of the extracellular matrix associated with outgrowing nerve processes in the embryo, but its role in the adult nervous system is unknown. This study examines the pattern of TSP locali-This study examines the pattern of TSP localization during nerve regeneration. Female CD-1 mice were anesthetized, the sciatic nerve was crushed or transected at the mid-thigh level. After 1-90 d, frozen sections were cut and processed to localize TSP. In the adult sciatic nerve, TSP was present in the connective tissue sheaths, the Schwann cells and axoplasm. With sheaths, the Schwann cells and axoplasm. With nerve injury, Wallerian degeneration proceeds to form empty Schwann cell tubes as the axon degenerates. TSP levels in the endoneurium remained at higher than normal levels in excess of 14 d, but gradually declined. There was also an increase in TSP in association with nerve outgrowth in the axoplasm and endoneurium.

During nerve regeneration, TSP was present in higher than normal levels, but disappeared from

higher than normal levels, but disappeared from the endoneurium if regeneration was prevented. Supported by NIH grant HD-23867.

IMMUNOCYTOCHEMICAL LOCALIZATION OF THY-1.2 ON ADULT AND EMBRYONIC MOUSE RETINAL GANGLION CELL NEURITES IN VITRO. C. A. Bates and R. L. Meyer. Developmental Biology Center; UCI; Irvine, CA 92717 Thy-l is a cell surface glycoprotein which is a

member of the Ig superfamily and thus may be involved in intercellular adhesion. It has been suggested that Thylinteracts with astrocytes to inhibit neurite outgrowth (R. Morris, 1989). In culture, embryonic day 15 (E15) mouse retinal explants extend many long neurites on astrocyte monolayers while adult retinal explant neurites are less numerous and shorter. We have looked at the presence of Thy-1 on neurites of retinal ganglion cells in adult and E15 retinal explants grown on laminin using a Mab to Thy-1.2. Retinal segments were explanted one week after optic nerve crush in adults or at E15. one week after optic nerve crush in adults or at £15. In adult explants, outgrowth was first observed at 24 hours., at which time all neurites extending from the explant were Thy-1.2 positive. £15 explants showed no Thy-1.2 staining 24 hours after explantation. Nor did £15 explants show any Thy-1.2 staining up to 7 days post explantation. We are currently extending our investigations to adult explants grown on astrocyte monolayers. Supported by NS26750 (RLM) and HD07029 (CAB).

THE EXPRESSION OF GAP-43 mRNA IS REGULATED BY AN AXONALLY-TRANSPORTED FACTOR L. I. Benowitz, C. O'Brien, N. I. Perrone-Bizzozero, N. Irwin and C. J. Woolf. Harvard Medical School, McLean Hospital (Belmont, MA, 02178), and University College Lorder (IW). College London (UK).

In view of the likelihood that GAP-43 (B-50, F1, neuromodulin) is causally involved in the formation of neuronal connections, we are investigating ly involved in the formation of neuronal connections, we are investigating the mechanisms that control its expression. Axonal regeneration in the peripheral nervous system (or in the CNS of lower vertebrates) is accompanied by a marked increase in the synthesis of this membrane phosphoprotein^{1,2}. We previously found that either crushing the sciatic nerve or treating it with vinblastine (100 µM, 20 min, to disrupt axonal transport) greatly increased GAP-43 immunostaining in the dorsal hom of the spinal cord³. To verify that these changes were due to an enhanced expression of GAP-43 in the primary sensory neurons, dorsal root ganglia were dissected 1-30 days after sciatic nerves were crushed or treated with vinblastine, and the RNA was probed on Northern blots with a labeled GAP-43 cDNA4. Both treatments caused a several-fold induction of GAP-43 cDNA⁴. Both treatments caused a several-fold induction of GAP-43 mRNA within the first week. Measurements of nerve conduction verified that vinblastine treatment did not physically injure the axons. We conclude that the expression of GAP-43 is normally inhibited by a retrogradely-transported factor that arises from the periphery (or from the glial environment), and that removal of this factor induces the expression of GAP-43 cand perhaps other growth associated proteins in motive nearest. (and perhaps other growth-associated proteins) in mature neurons. Support: NIH NS 25830, the MRC (UK), Wellcome Trust and International Spinal Res. Trust.

DIFFERENTIAL REGULATION OF CALCITONIN GENE-RELATED PEPTIDE (CGRP) IN REGENERATING MOTOR AND SENSORY SYSTEMS. F.L.Dumoulin*, G.Raivich, W.J.Streit, G.W.Kreutzberg. Department of Neuromorphology, Max-Planck-Institute for Psychiatry, D-8033 Martinsried,

Axotomy of the rat facial nerve has previously been shown to increase CGRPimmunoreactivity in parent motoneurons¹. To further characterise the regulation of CGRP in regenerating neurons we have studied the levels of both CGRP-peptide and CGRP-mRNA in regenerating motor and sensory systems.

Axotomy of the rat facial nerve leads to a biphasic increase in CGRP in the

facial motor nucleus with a first rapid, 3-fold increase around day 3, a decrease to normal levels at day 9 and a second, late peak during the time of reinnervation (day 21). The CGRP-mRNA levels reveal a similar time course with the 2 peaks appearing approximately one day earlier. Quite in contrast to that, axotomy of the sciatic nerve slowly decreases CGRP-levels in the sensory, L5 dorsal root ganglia reaching basal levels of approximately 30-50% by day 9. Once again CGRP-mRNA levels decrease 1-2 days earlier.

These data show that changes in CGRP content following axotomy and during regeneration reflect altered levels of CGRP-mRNA expression. The strikingly different patterns of CGRP expression in the DRG and facial nucleus suggest the presense of distinct and opposing regulating signals in the regenerating motor and sensory systems. This differential regulation of CGRP in motor versus sensory systems may reflect different yet unknown functions during nerve regeneration

GAP-43 UPREGULATION IN REGENERATING RETINAL GAN-GLION CELLS IN THE RAT. B. C. Wouters and J. J. Norden. Department of Cell Biology, Vanderbilt University, Nashville, TN

Several reports have shown that retinal ganglion cells (RGC) in rats may be induced to regrow axons through peripheral nerve shunts following injury (eg, Richardson et al., Nature 1980 284, 264-65). We have used this paradigm to investigate the role which the growth-associated protein GAP-43 may play in this regrowth.

Sciatic nerve shunts were grafted onto optic nerves of adult rats following complete transection. Using electron microscopy and the retrograde transport of horseradish peroxidase, we have demonstrated the viability of our preparation and confirmed that rat RGCs axons regrow through the peripheral shunts. At 4-5 weeks post grafting, we show using ³⁵S-methionine that the regrowing RGCs increase their synthesis and transport of GAP-43 by 130%-192% above levels observed in normal control adult rat RGCs or in RGCs whose axons have been transected but not grafted. Immunohistochemistry of retinas using our polyclonal antibody to GAP-43 reveals that this response is localized to a subpopulation of the retinal ganglion cells. We conclude that GAP-43 is upregulated during axon growth through peripheral nerve grafts. We are currently determining whether this upregulation is mediated by translational or transcriptional mechanisms. (Supported by NIH grant NS25150 to J. J. Norden.)

RUBROSPINAL NEURONS INCREASE GAP43 AND TUBULIN mRNA AFTER CERVICAL BUT NOT AFTER THORACIC AXOTOMY

W. Tetzlaff, B.J. Tsui* and J.K. Balfour*. Depts. of Anatomy and Pathology, University of Calgary, Calgary, Alberta, T2N 4N1

We have shown previously that axotomized rubrospinal neurons increase the expression of mRNAs for tubulins, actin and GAP43. These studies were performed with hemi-sections of the spinal cord at cervical level C3/4. Rubrospinal neurons have been reported to regenerate into peripheral nerve transplants implanted at cervical level but not into those implanted at lower thoracic level. We have therefore investigated whether a lesion at lower thoracic level (T10/12) fails to induce the regeneration associated changes in gene expression. Axotomized rubrospinal neurons were retrogradely filled with Fast Blue in order to restrict the analysis to axotomized i.e. labelled neurons. This technique was combined with in situ hybridization for the study of mRNA expression in individual neurons. Neither at 7 days nor at 14 days post thoracic lesion was there an increase in GAP43 or tubulin mRNA expression. Thus, thoracic lesions do not seem to induce the regeneration associated genes. These data support the view that the failure to regenerate into the permissive environment of a PNS transplant is related to the failure to express these genes. Supported by MRC of Canada MT 10689 to W.T.

AXOTOMIZED CORTICOSPINAL NEURONS DO NOT INCREASE TUBULIN AND GAP43 mRNA EXPRESSION. M.A. Bisby, W. Tetzlaff and .S. Alexander*. Dept. of Physiology, Queen's University, Kingston, Ontario K7L 3N6 and Depts. of Anatomy and Pathology, University of Calgary, Calgary, Alberta, T2N 4N1.

Mammalian CNS neurons generally have a limited capacity for regeneration, perhaps due to inhibitory molecules in the CNS environment, and/or defects in the response to injury. When provided with the permissive environment of a nerve transplant, some CNS neurons can regenerate into the transplant, but corticospinal neurons do not. This difference may be associated with differences in the response to injury, and so we have studied the expression of regenerationassociated genes for GAP43 and embryonic tubulin isotypes in rat corticospinal neurons following pyramidal lesions.

Axotomized cortical neurons were identified by retrograde labelling with fluorogold applied to the lesion site, and combined with in situ hybridization using specific probes for GAP43 and tubulin mRNAs. There was no increase in mRNA levels, and in some animals total tubulin mRNA levels decreased by 30%. This contrasts with our findings for rubrospinal neurons lesioned at C3, where both GAP43 and tubulin mRNAs increased. The inadequate response to injury may account for the failure of corticospinal axons to regenerate, even if offered a permissive environment.

REGENERATION OF TRANSECTED SPINAL CORD OF TADPOLE STUDIED BY 2-D GEL ANALYSIS AND IMMUNOCYTOCHEMISTRY. H.S. Yin and M.M. Chiu*, Dept. of Anatomy, Col. of Med. National Taiwan Uni., Taipei, Taiwan, R.O.C. The spinal cords of bullfrog tadpoles at stage IV were transected at the ninth spinal segment. The cords within 4 mm of the scar were dissected at various times following surgery and prepared for two-dimensional gel electrophoresis(2-D) and immunocytochemical staining. The analysis of 2-D gels revealed that the expression of at least 30 proteins was decreased initially and then gradually returned towards control levels by 28 day post-operation except that 3 proteins persisted at the lower expression levels. Among the former β -tubulin was identified by immunoblotting of 2-D gels. Six proteins of the cord increased amounts of their expression until 28 days. Immunostaining of paraffin sections of the scar area by the anti-200K neurofilament antibodies showed that the normal configuration of the neurofilament in the cord atrophied after transection and then was restored by 40 days. This was also supported by a quantitative assay of ELISA using the same antibodies. These results indicate that the morphological regeneration is accompanied by the biochemical regeneration in lesioned spinal cords of tadpoles.

INCREASE IN ACETYLCHOLINE RECEPTOR ALPHA-SUBUNIT MESSENGER RNA LEVELS IN HINDLIMB MUSCLES OF SPINAL CORD INJURED CATS. S. Sayers*, T. Khan, M. Dauvyardis, R. Hauser* and K. Burket*. Neuro-Regeneration Lab., RR&D Center, VA Hospital, Hines, IL 60141.

Peripheral nerves contain neurotrophic substances which may influence gene expression in the muscles which they innervate. Transection of the sciatic nerve was found to cause an increase in acetylcholine receptor (AChR) alpha-subunit messenger RNA (mRNA) levels in rat hindlimb muscles (Goldman, D., et al., Ann, NY Acad. Sci., 505:286, 1987). We conducted a study to determine whether upper motor neuron damage would produce an increase in mRNA levels in hindlimb muscles similar to that observed after transection of the sciatic nerve.

Following a 20-week survival period, total RNA was prepared from the soleus and extensor digitorum longus (EDL) muscles obtained from 8 cats; 2 cats received complete transection of the spinal cord at the T8-T9 level, 2 cats sustained a contusion injury, and 4 normal cats served as controls. Total RNA was slot-blotted onto membranes which were subsequently hybridized with ³²P-labeled riboprobe transcribed from the cDNA clone BMA 407-12 (provided by Dr. James Boulter, The Salk Institute) which codes for the alpha-subunit of the AChR. The membranes were subjected to autoradiography, the autoradiographs were scanned, linear regression lines were plotted, and the slopes of the lines were compared.

The level of alpha-subunit AChR mRNA in the soleus muscle was found to be increased by 40% in cats which received spinal cord transections and by 10% in cats

which sustained contusion injuries as compared to normal cats. In contrast, alpha-subunit AChR mRNA levels in EDL muscle was increased by 14% in spinal cord transected cats and by 30% in spinal cord contused cats as compared to normal cats. Our preliminary data suggests that spinal cord injury causes AChR alpha-subunit mRNA levels to increase in both the soleus and EDL muscles of the cat, a condition similar to that observed after sciatic nerve transection. Funding: VA, Rehab. R&D Service, Rehab, R&D Grant #B423R.

DIFFERENTIAL REGULATION OF \$100\$ AND mRNAs CODING FOR S100-LIKE PROTEINS (42A AND 42C) AFTER LESION OF RAT SCIATIC NERVE AND DURING DEVELOPMENT. M. De Leon 1, L. J. Van Eldik², and E. M. Shooter¹. ¹Dept. of Neurobiology, Stanford University School of Medicine, Stanford CA 94305, and ²Depts. of Pharmacology and Cell Biology, Vanderbilt University, Nashville TN 37232.

The present study analyzes changes in \$1008 (a protein that stimulates neurite extension and neuronal survival) and 42A and 42C (\$100-like proteins whose mRNAs are induced in PC12 cells by NGF) during nerve regeneration and development. Distal segments of rat sciatic nerve were examined by Northern blots at various times after a cut or crush injury, and it was found that \$1008, 42A, and 42C mRNA showed a differential regulation during regeneration. As reported before, 42A and 42C mRNA levels increased in the distal segment of axotomized nerves. In contrast, \$100B mRNA levels significantly decreased during the first week after injury and returned to normal levels during the second week. The decrease in \$100B mRNA levels was reflected by a corresponding decrease in \$100B protein levels. \$100B mRNA was present both in sciatic nerve and brain. However, 42A and 42C mRNAs were more restricted to sciatic nerve, with little found in either embryonic or adult brain. These three and 42C (S100-like proteins whose mRNAs are induced in PC12 found in either embryonic or adult brain. These three proteins, with a high degree of sequence similarity, are differentially regulated during both sciatic nerve regeneration and development, and thus may play distinct roles in these processes.

148.14

A25, A NERVE DAMAGE ASSOCIATED PROTEIN(S) IS PRODUCED AT A COLD-BLOCK. G-S. Perng", D.L. Wilson^{1,2}, and G.W. Perry³, Departments of Physiology and Biophysics¹, and Biology², University of Miami, Miami, and Center for Complex Systems³, Florida Atlantic University, Boca Raton, FL.

Previously, we have seen the appearance of a specific polypeptide(s) in crushed optic and sciatic nerves of frogs. The polypeptide, designated A25, appears within a few hours after crush specifically at the crush site, and is not produced normally in A25 is most likely produced from post-translational processing of a normally fast-transported protein.

To begin to address the mechanism of production of A25, especially whether physical damage to axons is necessary for its production, we have investigated whether A25 is produced at the site of a cold-block placed on a frog sciatic nerve in vitro. Labelled fast-transported proteins, including presumably the precursor to A25, accumulate proximally to a cold-block. Analysis of segments of nerve proximal to the cold-block by 2D-gels, shows that A25 is present in the proximal nerve segment. However, if distal nerve segments containing labelled, fast-transported proteins are kept cold in the in vitro paradigm, A25 does not appear. This indicates that cold alone does not produce A25. Little, if any, physical damage to axons occurs at a cold-block site since rewarming the nerve allows passage of the accumulated fast-transported proteins. Furthermore, A25 does not appear at a crush site which is maintained in the cold. Preliminary evidence also suggests that when the cold-block is released, that is the nerve is allowed to warm-up to room temperature, then A25, which was produced at the cold block is carried orthogradely with other labelled fast-transported proteins.

We conclude from these data that physical damage to axon is not necessary to produce A25. Possibly then, the accumulation of fast-transport vectors proximal to the cold block results in production of A25, perhaps through mixing or fusion of different vectors which are normally kept separate.

REGULATION OF uPA mRNA IN MOUSE SCIATIC INNERVATED MUSCLE. Daniel Hantaï, Riichiro Suzuki, Bokka R. Reddy, Jasti S. Rao and Barry W. Festoff, Department of Neurology, University of Kansas Medical Center, Kansas City, KS 66103, and Neurobiology (151), DVA Medical Center, Kansas City, MO. Plasminogen activators (PAs) play important roles in fibrinolysis as well as in modifying the extracellular environment during embryogenesis, inflammation, and neoplasia. Previous studies (J. Cell Biol. 103: 1415–1421, 1986 and PNAS 87: 2926–2930, 1990) showed eight to ten fold increase in the activation of urokinase (uPA) in muscle after denervation. Present studies further explore neural regulation of PA activities in muscle at the transcriptional level. The nerve crush paradigm was used and both muscle contraction and nerve simulation, and the return of choline acetyltransferase (CAT) activity was used to monitor reinnervation. Total RNA was extracted from contralateral and sciatic nerve innervated muscles from 1–43 days after crush. Total RNA was hybridized with 32 random prime labeled cDNA mouse uPA probe by slot blot and Northern hybridization. uPA mRNA increased from day 5 to 12 in the crushed samples. No increase of the uPA mRNA in the contralateral muscle was seen during these time points. These results suggest that uPA is tightly regulated by nerve at transcriptional level and may play an important role during muscle reinnervation. REGULATION OF upa mrna in mouse sciatic innervated muscle.

RELATIONSHIP OF INSULIN-LIKE GROWTH FACTOR I mRNA MUSCLE TO REGENERATION

CONTENT IN MUSCLE TO REGENERATION OF NEUROMUSCULAR SYNAPSES. G.W. Glazner*, D.M. Niedzwiecki and D.N. Ishii Physiology Dept., Colorado State Univ., Ft. Collins, CO 80523.

Insulin-like growth factor I (IGF-I) mRNA content in muscle is developmentally correlated with synaptogenesis at the NMJ, and increases after denervation. We tested the hypothesis that IGF-I mRNA content in gastrochemius muscle (GM) correlates with regeneration and reestablishment correlates with regeneration and reestablishment of synapses. Sciatic nerves in adult rats were of synapses. or synapses. Stratic nerves in adult rats were crushed on the left but not right sides. IGF-I mRNA content increased specifically in the left GM, correlating with its renewed capacity to accept innervation. IGF-I mRNA content peaked with the arrival of regenerating sciatic axons at the muscle. Thereafter, gene expression slowly returned to baseline, consistent with our previously published hypothesis for neuromuscular feedback inhibition of IGF mRNA content. These feedback inhibition of IGF mRNA content. These data support the hypothesis in which (i) elevated IGF-I levels support regeneration of synapses, (ii) innervation provokes an inhibitory signal on IGF-I mRNA levels which is relieved upon nerve crush, and (iii) reinnervation reestablishes the inhibitory signal which down-regulates IGF-I mRNA. (Supported by NINDS grant PO1 NS 28323)

ONTOGRNY OF DOPAMINERGIC SYSTEMS

ROLE OF NIGROSTRIATAL DOPAMINE SYSTEMS IN THE EXPRESSION OF CALMODULIN-DEPENDENT ENZYMES IN DEVELOPING RAT STRIATUM. J. W. Polli* R.L. Kincaid and M.L. Billingsley. Department of Pharmacology and Center for Cell and Molecular Biology, Penn State University College of Medicine, Hershey, PA 17033 and Section on Immunology, NIAAA, Rockville, MD 20852.

The possible role of nigrostriatal dopamine (DA) systems in the transsynaptic regulation of calmodulin-dependent enzymes (CaM-BPs) was studied in developing rat striatum. High levels of CaM-BPs are found in striatum, and develop in parallel with innervation by DA. Unilateral hemitransections of nigrostriatal DA neurons were performed on postnatal day 7 (PND7). On PND21, striata were removed and CaM-BPs determined using immunoblots, CaM overlays and enzyme assays. Absence of immunoreactive tyrosine hydroxylase (TH) confirmed successful lesions. Dennervated striata expressed levels and activity of calcineurin, CaM kinase II and CaM-phosphodiesterase similar to paired control striata. Chemical ablation of developing DA neurons was performed on PND 8 and 15 using 6-hydroxydopamine. Although TH immunoreactivity was absent in lesioned animals on PND 28, there were no significant changes in CaM-BPs. Developing rats (PND3-24) were chronically treated with haloperidol (1.0 mg/kg/day). Again, no significant changes were seen in CaM-BPs on PND24. These results suggest that CaM-BP expression in developing striatum is not under transsynaptic regulation by DA High levels of CaM-BPs are found in striatum, and develop in striatum is not under transsynaptic regulation by DA

149.3

DOPAMINE D-2 RECEPTOR AUTORADIOGRAPHY WITH 3H-YM-09151-2 REFLECTS BRAIN AND BEHAVIORAL ONTOGENY. A.S. Unis. J.G. Vincent* and B. Dillon*. Dept. of Psychiatry, Univ. of Washington, Seattle, WA 98195.

Using the technique of in witro receptor autoradiography to slide-mounted tissue sections, we studied the suitability of ³H-YM-09151-2 as a ligand for labeling D-2 receptors in day 21 and adult F344 rat brains. Assay conditions were modified from Terai et al. (1989) for tissue slice binding. Alternate sections were incubated with 1 µM haloperidol to determine non-specific binding. Autoradiographs were analyzed using computer-assisted microdensitometry.

Specific ³H-YM-09151-2 binding accounted for 70-80% of the total bound ligand and reached equilibrium after a hour incubation. Scatchard analysis revealed a Kd of 870 pM for adult and day 21 animals. The apparent B_{max} was lower in 21 day-old F344 rats than in adult animals (16.9 fmol/tissue section versus 6.8 fmol/tissue section) and was 66% of the expected value after correcting for differences in brain weight. Autoradiographs for adult and day 21 sections demonstrated high grain densities in the striatum and olfactory tubercle. Diffuse specific binding was also observed in the cortex. These autoradiographic data reflect the expected marked increase in D-2 receptors during ontogeny and are in agreement with our previous work demonstrating an absence of locomotor "hyperactivity" in 21 day-old F344 rats.

149.2

STATHMIN IS A MAJOR NEURONAL PHOSPHORYLATION SUBSTRATE

STATHMIN IS A MAJOR NEURONAL PHOSPHORYLATION SUBSTRATE ASSOCIATED WITH DEVELOPMENTAL AND FUNCTIONAL REGULATIONS. H. Chneiweiss°, J. Cordier°, V. Doye, J. Koppel, L. Beretta and A. Sobel. INSERM U133 and 'INSERM U114, 75005 PARIS, FRANCE Stathmin is an ubiquitous cytoplasmic phosphoprotein (M_r≈19kDa pl≈6.2-5.6) most likely acting as a relay integrating the various intracellular regulatory pathways triggered by diverse extracellular signals. Among all tissues examined, stathmin is most abundant in brain where its expression peaks carvad the people legical bath signals. Among all tissues examined, statimin is most abundant in brain, where its expression peaks around the neonatal period, both at the protein and mRNA levels. It is mostly concentrated in neurons where, at least in primary cultures of mouse embryonic neurons, it is located mainly in the cell body and in one neurite, also labeled for proteins known as axonal markers.

In PC12 cells, phosphorylation of stathmin is stimulated by NGF, in a way probably associated to the early steps of its neuronal differentiating activity.

differentiating activity.

In a way probably associated to the early steps of its heurohal differentiating activity.

In mouse embryonic neurons in culture, phosphorylation of stathmin was stimulated both by forskolin and by the tumor promoter TPA, as well as by vasoactive intestinal peptide (VIP), whose receptors were previously characterized on the same neuronal cultures. Furthermore, the VIP-induced protein phosphorylation pattern indicates that this physiological peptide may act both through cAMP-dependent and independent mechanisms. Finally, the effects of VIP and the combined effects of forskolin and TPA on the various phosphoforms of stathmin and of other related proteins indicate an interdependence of their phosphorylation sites, in a way substantiating the proposed integrating role of stathmin Altogether, our observations indicate that regulations of stathmin phosphorylation and expression are related to both "developmental" and "functional" regulations of neurons.

THE EFFECT OF ASCORBIC ACID ON THE DEVELOPMENT OF DOPAMINE NEURONS IN CULTURE. H. H. Kalir and C. Mytilineou, Dept. of Neurology, Mt. Sinai Sch. of Med., New York, NY 10029

Rat embryonic brain contains high levels of ascorbic acid (AA), a major water soluble antioxidant. We have investigated the effect of AA on the development of dopamine (DA) neurons. Dissociated midbrain cells from embryonic day 14 rats were plated in serum-containing medium in the presence or absence of $2x10^{-4}$ M AA and maintained for 2 weeks in vitro. The initial AA level was 1.74ug/mg protein, and dropped sharply in the untreated cultures to below our detection level of lng by 7 days in vitro (DIV). In AA treated cultures, there was an initial drop of AA levels followed by a rise on days 7 through 14 to the initial embryonic cells' level. The development of DA neurons was monitored by measuring the DA and DOPAC levels with HPLC, [3H]DA uptake and staining for tyrosine hydroxylase (TH). DA and DOPAC levels increased in both groups, but AA treated cultures had higher levels of both DA and DOPAC on DIV 7 and 14. [3H]DA uptake was not affected by AA treatment. TH staining on DIV 8 showed 20% more TH+ cells in AA treated cultures. These results demonstrate that (1) AA levels are depleted in cultured cells but can be restored by addition of AA in the medium, and (2) DA neurons can survive and grow in the absence of detectable levels of AA. We then examined whether the presence of cellular AA would affect 6-OHDA neurotoxicity. On DIV 12, when AA levels are undetectable in untreated and high in treated cultures, 6-OHDA exposure produced circular damage to DA neurons in both groups. Supported by NIII. similar damage to DA neurons in both groups. Supported by NIH grant NS-23017.

DOPAMINE D1 AND D2 AGONISTS HAVE OPPOSITE EFFECTS ON STRI-ATAL DOPAMINE RELEASE IN DEVELOPING RATS. D.E. Walters and S.G. Howard. MRRC, Dept. Pharmacology and BRI, Univ. California, Los Angeles, CA 90024-1759.

To determine the role of dopamine (DA) D1 and D2 receptor subtypes in mediating striatal DA release during development, a dialysis probe was implanted into the striatum of rats at 4 ages and perfused with a Ringer's solution. The DA contained in the perfusates was then measured by high pressure liquid chromatography with electroured by high pressure liquid chromatography with electro-chemical detection following subcutaneous injection of DA agonists and antagonists selective for D1 and D2 receptor subtypes, respectively. The D1 agonist SKF 38393, lOmg/kg, significantly increased DA in perfusates from 35-36-day-old and adult rats. Pretreatment with the Dl antagonist, SCH 23390, 0.5mg/kg, completely blocked the SKF 38393-induced increase in DA levels in the perfusates. SCH 23390 alone did not significantly alter the DA levels at any age studdid not significantly after the DA levels at any age studied. The D2 agonist LY 171555, 0.05mg/kg, and the D2 antagonist sulpiride, l0mg/kg, significantly decreased and increased, respectively, the DA content of the perfusates at each age. Pretreatment with sulpiride blocked the effect observed when each drug was given alone. The results suggest that Dl-mediated DA release develops between 21 and 35 days of age and that D2-mediated inhibition of DA release is functional by 10 days of age. Supported by USPHS grant HD29512.

ONTOGENY OF RAT STRIATAL D2 DOPAMINE RECEPTOR mRNA LEVELS. <u>S. X. Xu and Ian Creese</u>. Center for Molecular and Behavioral Neuroscience, Rutgers, The State University of New Jersey, Newark, NJ 07102

We present here the developmental characteristics of D2 dopamine (DA) receptor mRNA levels in the striata of male Fischer 344 rats during ontogenesis. Three [32P]-labelled oligonucleotides, derived from the coding region of the rat D2 DA receptor cDNA, were used together as a probe to measure the levels of mRNA for the D2 DA receptors in rat striatum by Northern hybridization. These probes do not differentiate between the short and long isoforms of the rat D₂ DA receptor mRNA. The lowest and highest mRNA levels were found in the striata at one day and one month post partum, respectively. The ratios of the optical density of the D₂ DA receptor mRNA to total 28S mRNA in striatum were 0.23, 0.26, 0.39, 0.52, 0.71 and 0.33 at days 1, 7, 14, 21, one month, and 4 months (adult), respectively. There were significant differences in D2 DA receptor mRNA ratio between days 1, 7, 14 or 4 months vs. one month of age (p < 0.05, Dunnett t test). This decrease in mRNA levels in adulthood is similar to the results that were found previously measuring the development of D2 DA receptors using radioligand binding (Pardo et al, 1977). However, mRNA levels increased only 3 fold over the first month of life vs. an eight fold increase in receptor binding. We also observed that the expression of β-actin mRNA decreased gradually as the rats developed.

SELF-MUTILATION INDUCED BY COMBINED D1 and D2 RECEPTOR STIMULATION FOLLOWING SUBSTANTIAL ACUTE DEPLETION OF DOPAMINE IN WEANLING (BUT NOT INFANT) RAT PUPS C.A. Moody and L.P. Spear, Dept. of Psychology and Center for Developmental Psychobiology, SUNY-Binghamton, NY 13901. The behavioral responses to single or combined

administration of the D1 agonist SKF38393 and the D2 agonist quinpirole were examined in infant, postnatal day 10 (P10) and weanling (P21) Sprague-Dawley rat pups depleted of dopamine (DA) via pretreatment with alphamethyl-tyrosine (AMT) (80% DA depletion) or AMT plus reserpine (approx. 99% DA depletion). AMT pretreatment had little impact on D2 agonist-induced behaviors (locomotion, sniffing, wall climbing) at either age. More extensive DA depletion induced by AMT/reserpine attenuated D2 responses at P10, while inducing a different pattern of D2 responses (coprophagia and oral stereotypies) at P21. D1 agonistinduced grooming was not blocked by DA depletion at either age. Combined D1 and D2 receptor stimulation induced marked synergism at P21 which varied with depletion state, inducing licking in non-depleted weanlings, licking and probing in AMT-treated pups, and self-mutilatory behavior in weanlings pre-treated with AMT/reserpine. Selective stimulation of each receptor subtype also elicited atypical responses (coprophagia: D1, D2: oral stereotypies: D2) in depleted weanlings, thus this self-mutilatory response may be related to a rapid depletion-induced increase in D1/D2 receptor responsivity.

EFFECT OF IRREVERSIBLE DOPAMINE RECEPTOR INACTIVATION ON LOCOMOTOR ACTIVITY IN THE RAT

INACTIVATION ON LOCOMOTOR ACTIVITY IN THE RAT PUP. C. A. Crawford*, S. A. McDougall*, and A. J. Nonneman. Dept. of Psychology, Univ. of Kentucky, Lexington, KY 40506.

The role of dopamine (DA) receptors in the ontogeny of locomotor activity was assessed using the irreversible DA antagonist, EEDQ. In two experiments, 16-day-old rat pups received a single i.p. injection of EEDQ (7.5 or 15 mg/kg) after DA receptors were left either unprotected or protected by a combinatin of sulpiride (100 mg/kg) and/or SCH 23390 (1 mg/kg). Quinpirole (0.1 mg/kg), SKF 38393 (15 mg/kg), NPA (1 mg/kg) or vehicle were then administered (i.p.) to these rat pups at 24, 48, 96, and 192 hrs after EEDQ treatment. Locomotor activity was then assessed, treatment. Locomotor activity was then assessed, with activity quantified as the mean number of photobeam interruptions during a 20-min testing period. Results indicated that EEDQ given to non-protected pups produced an increase in locomotor activity at both 24 and 48 hrs after treatment. NPA and quinpirole increased the activity of non-protected and SCH 23390pretreated rat pups, but these agonists did not increase the activity of pups with intact D-2 receptor systems (sulpiride pre-treated pups). SKF 38393 did not affect locomotor activity.

LONG-TERM INTRAVENTRICULAR ADMINISTRATION OF NGF TO RATS

150.1

LONG-TERM INTRAVENTRICULAR ADMINISTRATION OF NGF TO RATS WITH PARTIAL FIMBRIAL TRANSECTIONS. E. O. Junard, P.A. Lapchak, C. N. Montero* and F.F. Hefti Andrus Gerontology Center, U.S.C., Los Angeles, CA, 90089.

Adult rats with unilateral partial fimbrial transections (Montero and Hefti J. Neurosci. 8: 2986-2999, 1988) were injected intraventricularly twice weekly (during 5 months) with 1 µg of mouse beta-NGF through chronically implanted cannulas. These lesions resulted in a topographically gradual loss of Achs-positive and NGF receptor-positive fibers in the hippocampus. Fiber density was strongly reduced in the temporal portion, whereas only slight reductions were observed in the septal portion. Long-term, but not short-term (1 month), NGF treatment increased the fiber density in the septal part of the hippocampus on the side of the lesion. The increase was most pronounced in the dentate gyrus. In some animals, stained fibers appeared to invade areas of the dentate gyrus not normally receiving a large amount of cholinergic innervation. As evidenced by Nissl and thioflavin histochemistry, long-term NGF treatment did not produce pathological changes in the brain. Immuno-blot experiments failed to reveal the presence of antibodies against mouse beta-NGF in the serum of rats given chronic intraventricular NGF injections. These results indicate that long-term NGF treatment affects fiber outgrowth in the hippocampal formation, but does not initiate pathological changes within hippocampal neurons.

150.2

MITOGENIC STIMULATION OF AGED PRIMATE SCHWANN CELLS IN VITRO. M.F.D. Notier. J.T. Hansen and D.M. Gash. Dept.

of Neurobiology and Anatomy, University of Rochester, Rochester, NY 14642. We have previously shown that primate peripheral nerve induces neuronal differentiation and maintains the neuronal phenotype of primate adrenal medullary cells in coculture in vitro as well as in cograft in vivo. Schwann cells from peripheral nerves are thought to be the source of the neurite promoting factor(s); however, studies with these cells are hampered by the poor yields and low mitotic rate of Schwann cells from aged animals. Therefore the present study was undertaken to define an appropriate mitogen to obtain cultures enriched for Schwann cells for transplantation.

Explants of sural nerve from aged Rhesus monkeys were established on

Explants of sural nerve from aged Rhesus monkeys were established on collagen coated coverslips in F14 medium. After Schwann cell outgrowth was intitiated, the medium was supplemented with one of the following substances: acidic fibroblast growth factor (aFGF) 100 ng/ml; basic FGF 100 ng/ml; interleukin (IL-1) 1 ng/ml; platelet derived growth factor (PDGF) 10 ng/ml; transforming growth factor B1 (TGFB1) 10 ng/ml; Schwannoma conditioned medium (SCM) 1:1; or rat Schwann cell conditioned medium (rSCCM) 1:1. Cultures were scored for DNA synthesis by autoradiography for 3H thymidine incorporation or by immunofluorescence for bromodeoxyuridine incorporation. A three to fourfold increase in DNA synthesis in Schwann cells was induced by IL-1, acidic and basic FGF, PDGF and Schwannoma conditioned medium. However, a more dramatic response was seen with rSCCM which enhanced DNA synthesis sixfold over control cultures while TGFB1 induced an eightfold increase in the mitotic rate of these cells. increase in the mitotic rate of these cells.

These data indicate that rat Schwann cells release a factor that stimulates

growth in Schwann cells from other species and that TGFB1 may be an important mitogen for obtaining enriched cultures from aging animals. Supported in part by NIH NS 25778.

AXONAL ATTEMPTS AT REGENERATION IN EXCITOTOXICALLY LESIONED ADULT CNS, ROI NEUROGLIAL INTERACTIONS. I. Dusart, S. Marty*
Peschanski, INSERM U 161, 2 rue d'Alésia, 75014 Paris France. THE ROLE and

Many afferent fibers deprived of target-neurons by an excitotoxic lesion exhibit during several months morphological alteration resembling regenerative growth cones (Peschanski and Besson, JCN, '87). These attempts at regeneration can be successful if new target-cells are provided via neurotransplantation (Peschanski and Isacson, JCN, '88). The present study analyzes the evolution of the cellular content of a neurodegenerative lesion (induced by kainic acid-KA) of the somatosensory thalamus, in the search for mechanisms at work to

support long-term axonal survival and regenerative attempts.

Three periods can be defined: (i) During three weeks after KA, there is a profuse leakage of the blood-brain barrier, a disruption of the glia limitans and a proliferation of macrophages/microglia. Few, if any, reactive astrocytes are present. There are conspicuous signs of a demyelinating process. (ii) Between three weeks and three months, numerous reactive astrocytes and some oligodendrocytes appear. In the same time, many Schwann cells -migrating along blood vessels- invade the parenchyma. Peripheral glia ensheath and myelinate central axons. (iii) Later, reactive astrocytes rebuild a glia limitans, containing Schwann cells and other elements, apparently tending to eliminate them.

The present results support the hypothesis that Schwann cells are called into a neurodegenerative area of the brain parenchyma and replace oligodendrocytes injured by toxic agents either blood-borne or released by macrophages. It is our contention that Schwann cells may transitorily support axonal survival and regenerative attempts in the CNS. (supported by MRT 106728)

LOCAL INJECTION OF INTERLEUKIN-1, TNF OR LPS INCREASES ω_{α} (PERIPHERAL TYPE BENZODIAZEPINE) BINDING SITE DENSITIES IN THE RAT BRAIN. F. Bourdiol*, S. Toulmond*, A. Serrano*, J. Benavides and B. Scatton. Synthélabo Recherche (L.E.R.S.), 31, av. Paul-Vaillant Couturier, 92200 Bagneux (France).

The presence of high densities of ω_2 (peripheral type benzodiazepine) binding sites on astrocytes has provided the basis for the use of ω_2 sites to index the glial reaction to brain injury (Benavides et al, Ann. Neurol. 24, 708, 1988). Previous studies have suggested a role for interleukin-1 (IL-1) in the astroglial reaction to injury (Giulan et al., J. Neurosci. 8, 2485, 1988). In the present study, we have examined the effects of local injection of ${\rm IL}\text{--}1$ and other immune mediators in the rat cerebral cortex and striatum on the density of ω_3 sites in these regions. Intracortical or intrastriatal infusion of IL-1 ($\frac{5}{2}$,10 and 20 units) caused a marked increase (+80 % at 20 units) in the density of ω_3 sites around the injection site at 7 days post-infusion. Significant increases in ω_3 site densities were also observed in striatal homogenates one week after the local injection of TNF- α (+ 80 % at 3 units). The local injection of E. Coli LPS, a bacterial endotoxin known to stimulate IL-1 and TNF production by microglial cells in culture, also resulted in significant increases (+ 170 % at 200 ng) in ω_{γ} site densities in striatal homogenates. In contrast, the intrastriatal injection of IL-2 or of the chemotactic peptide FMLP failed to alter ω_0 site densities. No change in the density of two binding sites associated with neurons ("H-TCP and "H-Ro15-1788) was observed after instrastriatal injection of IL-1, TNF- α or LPS. These results suggest that the increase in ω_3 site densities observed after brain injury may involve the activation of microglia or monocytes, release of IL-1 or TNF and the promotion, by these cytokines, of the astroglial reac-

PROGRESSIVE CHANGES IN THE PATTERN AND INTENSITY OF ASTROCYTE HYPERTROPHY IN THE BRAINS OF KINDLED RATS. M. Khurgel, N.W. Milgram, R.J. Racine and G. O. Ivy. Life Sci. Div., Univ. of Toronto at Scarborough, Ont. MIC 144 & Psychology Dept., McMaster Univ., Hamilton, Ont. L8S 1B9.

We have previously shown that repeated seizure activity causes both neural damage and astrocyte hypertrophy (AH).

We now report the development of AH following kindling in the absence of neuronal death. Rats with electrodes in the amygdaloid complex (AC) underwent a) a standard kindling procedure (SK), b) a rapid kindling procedure (RK), c) stimulation which was subthreshold (ST) for afterdischarges or d) no stimulation. Rats were sacrificed at ld, lwk, lmo or 2mo and the brains processed for AH using immunoreactvity for anti-GFA. Control rats display AH only at the site of electrode implantation regardless of survival time. In contrast, by 1 wk both ipsi- and contralateral pyriform-AC areas display AH in the stimulated groups, although the AC areas display AH in the stimulated groups, although the precise pattern of AH varies. By 1 mo, the AH pattern was unchanged in the ST group but had spread to include the entire AC and pyriform regions in the SK and RK groups and had increased in intensity; this effect was especially dramatic in the basolateral nucleus. Thus, subthreshold stimulation of AC triggers an AH response by 1wk which does not appear to increase over time, whereas kindling causes a progressive increase in AH in anatomically related brain regions. These results suggest that progressive functional regions. These results suggest that progressive functional changes occur after the termination of kindling.

BENZODIAZEPINE EFFECTS ON RECOVERY OF FUNCTION LINKED TO TRANS-NEURONAL MORPHOLOGICAL EVENTS. J.S.Sims, T.A.Jones, R.L.Fulton*, L.E.Shapiro*, M.D.Lindner, and T.Schallert, Inst.for Neuroscience, Univ. Texas, Austin, TX 78713.

Diazepam chronically disrupts recovery from the otherwise transient behavioral effects of unilateral damage to the anterior medial cortex if it is administered continuously during a sensitive 12-96 hour postoperative period. Sensorimotor asymmetries caused by the cortical lesion failed to recover within a 100 day postdrug period. Sedative and motor effects were ruled out. A benzodiazepine (BZ) receptor antagonist (RO 15-1788) enhanced recovery. Recovery was not affected by the non-BZ anxiolytic gepirone, a SHT_{1A} receptor ligand.

Diazepam increased atrophy of subcortical brain areas in the ipsilateral hemisphere, including the striatum, substantia nigra pars reticulata and VM/VL thalamus, without affecting the size of the lesion or atrophy in primary thalamic afferent nuclei. A time course analysis of these morphological changes was carried out. The data suggest that multi-level degenerative events may contribute to the detrimental effects of BZ/GABAergic agents on recovery. Funded by NS-23964, AA-07471, MH-18837 & Bristol-Myers.

CONTEMPORANEOUS OBSERVATION OF SYNAPTIC AND GLIAL POSITION IN LIVING MICE. S.L. Pomeroy, Departments of Anatomy and Neurobiology and of Pediatrics, Washington University School of Medicine, St. Louis, MO 63110.

The relationship between synapse remodelling and glial cell movement on the surface of parasympathetic ganglion neurons has been evaluated directly in living mice. When viewed independently in vivo, synapses and glia change their position over the course of weeks to months (Purves the tolling of the colline of weeks to minima (rational et al., 1987, Science, 238:1122-26; Pomeroy and Purves, 1988, J. Cell Biol. 107:1167-75). EM observation shows that synaptic boutons on ganglion cells tend to cluster near glial cell nuclei (op. cit.). To test whether glia and synapses move together, the positions of glial nuclei and synaptic boutons on the same cell were monitored over

Salivary duct ganglion neurons in anesthetized adult male mice were viewed by low-light-level video microscopy after staining synaptic boutons with a styryl pyridinium dye. Video images of focal planes through the entire depth of the cell were digitized and stored, and the animals were allowed to recover. This procedure was repeated after 1 month, and the images obtained over this interval compared.

When synaptic boutons moved to occupy a different part of the neuronal surface, glial nuclei were found to move to the same region. The persistence of this association supports the idea that glia may have a role in synaptic maintenance and remodeling. (Supported by USPHS NS27773.)

INTRAMMYGDALOID INFUSIONS OF CLONIDINE RETARD LOW-FREQUENCY KINDLING. M. R. Pelletier and M. E. Corcoran. Department of Psychology, University of Victoria, Victoria, BC, Canada. Considerable evidence indicates that noradrenaline (NA) delays the kindling of seizures provoked by stimulation at limbic and neocortical sites, Recently several laboratories have reported that systemic injections of the \$\alpha = 2\$ agonist clonidine slow the rate of amygdaloid kindling by delaying emergence out of the early stages of partial seizure. To begin to localize the critical \$\alpha 2\$ receptors that delay epileptogenesis, we examined the effects on kindling of intraamygdaloid infusions of clonidine.

Male rats were prepared with chemitrodes implanted bilaterally in the amygdala. To reduce the number of infusions administered, we rapidly kindled seizures with 60-sec trains of unilateral square-wave stimulation at 3/sec and delivered at a high intensity at 48-hr intervals. Ten min before each stimulation the rats received ipsilateral infusions of 0.5 ll of saline or of clonidine in concentrations of 1 mM, 100 mM, or 1 mM.

Rats receiving infusions of saline developed generalized seizures in a mean of 2.7 stimulations, comparable to previous results (Corcoran & Cain, Brain Res., 1980). Kindling proceeded in clonidine-treated rats at the following rates: 1 mM, 4.4 stimulations; 100 uM, 5.0; 1 uM 4.2 (each p<0.05). Clonidine's prophylactic effects were produced by delaying the progression out of partial seizure during the early stimulations. A significant shortening of durations of afterdischarges and generalized behavioral seizures was observed only in the rats receiving 100 µM of clonidine. Administration of clonidine to already kindled control rats had no effect on seizure duration or intensity. Intraamygaloid clonidine thus produces a small but significant retardation of kindling, and it is a genuine prophylaxis. Systemically administered clonidine may be acting in the pyriform lobe to delay limbic kindling.

DIFFERENTIAL EFFECT OF D-AMPHETAMINE ON SEIZURES INDUCED BY PICKOTOXIN AND BICUCULINE. R.D. Kirkby and L. Kokkinidis. Dept of Psychology, University of Saskatchewan, Saskatoon, Saskatchewan, S7N OWO.

We have demonstrated that amphetamine (amph), administered twice daily, facilitates ongoing amygdaloid kindling (short-term effect). Under this condition, rats with prior amph experience (14 days, twice daily) show a further kindling acceleration (long-term effect). Moreover, several researchers have reported bidirectional transfer between electrical kindling and PIX- or PIZ- induced convulsions or "chemical" Kindling. In addition, amph withdrawal has transiently exacerbated PIZ-induced seizure expression. Collectively, these findings indicate that electrical kindling and "GABAergic" seizures share common mechanisms, which are subject to the influence of amph. In the present investigation, a single intraperitoneal (i.p.) administration of d-amph sulphate (7,5mg/kg) shortened latencies to generalized motor seizures induced 12 hours later by PIX (i.p., 10mg/kg) in adult, male Swiss mice. Chronic (14-day) amph pretreatment (2 i.p., injections per day, 7.5mg/kg) failed to alter either the PIX-elicited convulsions or the seizure-facilitating effects of the single amph administration. By contrast, neither the chronic nor the single amph treatment affected (+) bicuculline-induced (BIC; i.p., 5mg/kg) seizures.

BIC does not readily kindle convulsions, and differs from PIX and PIZ with respect to mechanism of GABAergic antagonism and subsequent generation of behavioral and electrographic seizure activity. Whereas BIC block Subsaterial and subsequent generation of behavioral and electrographic seizure activity. Whereas BIC block GABA-related chloride ionophores. It is therefore possible that withdrawal from amphetamine enhances both electrical kindling of the amygdala and seizures induced by PIX or PIZ via transient and subtle changes to GABA-mediated chloride ionic currents.

TYROSINE HYDROXYLASE AND CHOLINE ACETYLTRANSFERASE ENZYMES EXHIBIT SIMILAR DOWN REGULATION IN RESPONSE TO AXOTOMY M. Weiser, T. Wessel, H. Baker, U.J. Kang and T.H. Joh Lab. Molec. Neurobiol. Cornell Univ. Med. Coll., Burke Rehab. Center, White Plains, NY 10605.

Axons of dopaminergic neurons in the substantia nigra travel rostrally in the medial forebrain bundle to synapse within the striatum. Cholinergic neurons in the horizontal limb of the diagonal band send axons rostrally which terminate within the olfactory bulb. To determine whether neurons expressing different neurotransmitter synthesizing enzymes have comparable responses to axotomy, the presence and distribution of tyrosine hydroxylase (TH) immunoreactivity in the substantia nigra and choline acetyltransferase (ChAT) immunoreactivity in the horizontal limb of the diagonal band were examined in Sprague-Dawley rats. One week following unilateral axotomy there was a prominent decrease ipsilaterally in both TH and ChAT immunoreactivities in comparison to the control side. Cell bodies of the neurons on the lesioned side were more rounded, more lightly stained and appeared fewer in number. In addition, a marked decrease was observed in the immunoreactivity of the ramifying dendritic processes of neurons of both phenotypes. *In situ* hybridization using a specific [35S]labelled cDNA for TH demonstrated a corresponding down regulation in the mRNA for this protein. Thus, we hypothesize that neurons of two different transmitter phenotypes exhibit similar responses to axotomy. Supported by MH44043 and AG08702.

TIME-DEPENDENT EFFECTS OF TRIGEMINAL MANIPULATION IN BASAL GANGLIA: ANATOMICAL CHANGES AND NEUROCHEMICAL EFFECTS GANGLIA: ANATOMICAL CHANGES AND NEUROCHEMICAL EFFECTS
ASSESSED BY IN VIVO DIALYSIS. H. Steiner, F. Adams*, R.K.W.
Schwarting, F. Boix*, H.-T. Weiler*, S. Morgan* and J.P.
Huston. Inst. of Physiol. Psychol. I, Univ. of Düsseldorf,
Universitätsstr. 1, D-4000 Düsseldorf, F.R.Germany.
Unilateral removal of vibrissae (URV) induces neuronal

changes in nigrostriatal (NS) and tuberomammillary-striatal projections in relation to recovery from asymmetries in facial scanning induced by URV. New data indicate that NS projections to the striosomes and to the striatal matrix are differentially influenced by URV. During the time when rats express behavioral asymmetries (1-3 days after URV), an asymmetry was found in the nigro-matrixal subset of crossed NS projections (more HRP labeling in the projection to the CPU ipsilateral to URV). In contrast, during a period after behavioral recovery, an opposite asymmetry was found (more HRP labeling in the crossed projection to the CPU contralateral to URV); this asymmetry was restricted to the nigro-striosomal subset. These results are indicative of a functional dissociation of nigrostriatal projections to striosomes and matrix.

Trigeminal stimulation also affected the striatal dopamine (DA) transmission (assessed by in vivo dialysis) and behavior: After unilateral mechanical stimulation of the vibrissal area of the snout, asymmetries in extracellular DA and metabolites (increased levels in CPU ipsilateral to stimulation) were found, concomitant with contraversive asymmetries in facial scanning.

SHORT AND LONG TERM EFFECTS OF KINDLING AND CHRONIC IMIPRAMINE ON TYROSINE HYDROXYLASE REGULATION IN THE TEGMENTO AMYGDALOID PATHWAY. V.Leviel*, N.Emma*, B.Guibert*, N.Faucon Biguet*, C.Pasqualini*, G.Machek* and B.Naquet, Lab. Physiol. Nerveuse CNRS 91198 Gif sur Yvette,

We observed previously that repeated electroconvulsive shocks (ECS) produced an initial activation of tyrosine hydroxylase (TH) activity in the tegmento amygdaloid pathway, followed by a long term inhibition (1 month). Moreover, the long term decrease occurred likely through modifications of TH gene expression. In order to determine if the antidepressive effect of ECS could be related with these particular biochemical modifications, chronic treatments with imipramine (5 and 20 mg/Kg/day, 20 days) were realized on the rat. The same modifications, i.e. an initial increase and a long term decrease were obtained in the same central structures. In addition, a similar analysis of TH regulation was conducted on another model of experimental epilepsy, the kindling phenomenon, which is not considered as an animal model of depression but is known to be antagonized by imipramine. In opposite with the results obtained after BCS treatment, TH activity was decreased the day after the last of a series of ten kindled seizure and increased 30 days later both in ventral tegmental area (VTA) and amygdala (AC). Thus, kindling induces opposite effects on TH regulation than do seipramine and repeated ECS. These results suggest first, that the monoaminergic control of AC by neurons originating from VTA could be implicated in the antidepressive mechanism initiated by ECS and imipramine. Second, that some particular biochemical modifications consecutive to kindling could participate to the development of the depressive syndrome.

150.12

CHANGES IN CORTICAL DOPAMINE CONCENTRATION AFTER EARLY OR LATE LESIONS F FRONTAL CORTEX IN RAT. Deborah Christie and M. Bloomfield, (SPON: European Brain and Behaviour Society). Dept. of Experimental Psychology and University Laboratory of Physiology, University of Oxford, (U.K.) It is commonly assumed that early brain damage causes fewer deficits

than equivalent damage experienced as an adult. The greater plasticity shown to exist in the infant brain may make it more vulnerable to brain damage than the adult. Prefrontal cortex in all mammals receives a convergent input from Mediodorsal thalamus and the ventral tegmentum. Unilateral lesions of this area produce a transient polymodal contralateral neglect where animals fail to attend to stimuli presented in the contralateral field. After a 3 month recovery period animals with early (postnatal day 1) or late (3 months) lesions were tested on spatial alternation, non-visual search and visual search task. Compared to a group of age matched non-operated controls the degree of recovery measured by of age matched non-operated controls are degree of recovery measured by turning behaviour, was shown to be dependant upon both the age of lesion and the task used (Christie, D., & Cowey, A. <u>Neurosci. Abs.</u>1988). The initial contralateral neglect can be reduced by treatment with the DA agonist Apomorphine or increased with the DA antagonist Spiroperidol. Following the completion of behavioural testing the concentration of dopamine in the unlesioned and lesioned cortex was measured. The cortical DA concentration in adult lesioned animals was identical to the controls. In the neonatally lesioned animals there was a significant increase in DA concentration in the cortex surrounding the lesion. This was correlated with the individual animals' turning behaviour. It is suggested that there are different mechanisms underlying the recovery and subsequent control of animals behaviour depending on the age at which frontal cortex

TIME COURSE OF RECOVERY FROM COPULATORY BEHAVIOR DEFICITS FOLLOWING MPOA INJECTIONS OF 6-OHDA T.Bazzett, L.A. Lumley, V.P. Markowski, D. Bitran, R. W. Warner E. M. Hull. Dept of Psychology, SUNY at Buffalo, Buffalo, NY 14260

We have shown that dopaminergic influence at the medial preoptic area (MPOA) is important for the regulation of male rat sexual behavior. A previous study using 6-OHDA to destroy DA terminals in the MPOA produced no copulatory deficits in male rats tested as soon as 3 days following 6-OHDA injection. The current experiments were undertaken to determine: 1) Whether earlier testing would reveal behavioral deficits 2) If so, when recovery occurred 3) What mechanisms could account for the recovery.

Using 20 male Long Evans rats we tested the effects of 6-OHDA injections into the MPOA on male copulatory behavior. Tests were conducted at 30 min and again at 24 hours after injections. A separate group of 20 males was tested at 4 hours and again at 28 hours after 6-OHDA injection.

6-OHDA animals at 30 min exhibited fewer ejaculations compared with their own scores and controls at 24 hours. However, they were not significantly different from controls at 30 min post lesion. Behavioral deficits 4 hours after injection were statistically significant when compared with vehicle injected animals at 4 hours and with 6-OHDA injected animals at 28 hours. Furthermore, a CA challenge by AMPT that had no effect on intact male rats, produced copulatory behavior deficits in rats that showed no deficits several

weeks after 6-OHDA injections.
The results of these studies show that MPOA injections of 6-OHDA impair copulatory behavior. However, these deficits are rapidly reversed within 24 hours. One mechanism underlying behavioral recovery appears to be increased DA metabolism at remaining DA terminals. Supported by NIMH grant MH-40826 to EMH.

CHANGES IN THERMAL PLASTICITY OF RAPHE NEURONES AFTER MICROCUT LESIONS AND NEUROTRANSMITTER APPLICATIONS. P. Hinckel, M. Rüsing*, K. Schröder-Rosenstock*. Physiologisches Institut, Universität Giessen, Aulweg 129, and Zentrum für Neurologie und Neurochirurgie, Abt. Klinische Neurophysiologie, Am Steg 28, D-6300 Giessen 1, Federal Republic of Germany.

Neurones in the nucleus raphe magnus (NRM) have been shown to belong to the thermoafferent system. In coldacclimated guinea-pigs average maximum activity and average basic spike rate of warm-responsive NRM units were significantly larger than in normal-acclimated animals.

After interruption of the dorsal and rostral afferents and efferents of the NRM by microcuts in cold-acclimated

After interruption of the dorsal and rostral afferents and efferents of the NRM by microcuts in cold-acclimated guinea-pigs basic spike rate was significantly reduced (to the basal level in normal-acclimated intact animals), whereas the maximum spike rate was not changed.

whereas the maximum spike rate was not changed.

Microiontophoretic application of serotonin on warmresponsive NRM neurons caused a similar increase of peak
activity and basic rate, whereas substance P caused an
increase of peak activity but not of basic rate. Application of both substance P and serotonin together induced a
prolonged peak activity increase in all tested warm-responsive NRM units.

It is possible that the observed cold-adapted peak activity increase in NRM neurons is generated by neuronal interactions at the lower brain-stem level in which this transmitter complex is involved.

mRNA REGULATION: GENERAL

151.1

INDUCTION OF A HEAT SHOCK GENE (hsp70) IN THE RABBIT SPINAL CORD AFTER HYPERTHERMIA: AN IN SITU HYBRIDIZATION STUDY. I.R. Brown and S.J. Rush*. Department of Zoology, University of Toronto, Scarborough Campus, West Hill, Ontario, Canada, MIC 1A4.

We have previously reported that hyperthermia induces the expression of a heat shock gene in the rabbit brain (Sprang and Brown, Molec Brain Res, 3, 89-93, 1987). Striking regional and cell type differences in the pattern of induction of hsp70 mRNA were noted. Tissue injury also induces a rapid induction of hsp70 mRNA in the mammalian brain (Brown et al., Neuron, 2, 1559-1564, 1989). In the present study in situ hybridization with 35S-labeled antisense or sense riboprobe was employed to investigate the effect of fever-like temperatures on hsp70 gene expression in the rabbit spinal cord where delineation of white and gray matter is distinct. Constitutive expression of hsp70 mRNA was detected in large motor neurons. Within 1 hr after hyperthermia a massive induction of hsp70 mRNA was noted in fibre tracts in the spinal cord, a pattern consistent with a strong glial response to heat shock. Little induction was noted in the large motor neurons which exhibited constitutive expression. Supported by grants from MRC (Canada).

151.3

ANALYSIS OF mRNA SHOWING REGION - SPECIFIC EXPRESSION IN NONHUMAN PRIMATE CORTEX.

M.F. Matocha. J. Stoll. S.P. Wise and S.I. Rapoport.

Lab. of Neurosci., NIA, Bethesda, MD 20892 and Lab. of Neurophysiology, NIMH, PO Box 289, Poolesville, MD 20837. Alzheimer's disease preferentially afflicts the phylogenetically recently elaborated association neocortices and their connections to phylogenetically older brain regions (Rapoport, S.I. Rev. Neurol, Paris, 144: 79,1988). To understand the molecular basis of this selective vulnerability, we have begun to identify mRNAs that show specific expression in association neocortical regions of the Rhesus monkey. A cDNA library was made using mRNA prepared from the frontal pole. 10,000 plaques in the frontal pole cDNA library were screened by differential hybridization. 10 cDNA clones were identified that hybridized with the total cDNA probe prepared from the primary visual cortex. These cDNA clones, in Northern blot analyses, showed higher expression of mRNA in frontal and di prefrontal regions as compared to the primary visual cortex. Sequencing and homology search with the GenBank were done on two of the clones. One clone showed homology to the mitochondrial cyt.oxidase subunit I gene, while the second clone did not show a homology with the sequences in the GenBank. Other clones are being sequenced and compared to identify the nature of the one products.

151.2

IDENTIFICATION OF LOCUS COERULEUS-ENRICHED PROTEINS BY SUBTRACTION HYBRIDIZATION. P. Tinsley III. K. Saijoh. R.S. Duman. and E.J. Nestler. Lab. of Molecular Psychiatry, Depts. of Psychiatry and Pharmacology, Yale School of Medicine, New Haven, CT 06508.

We have used subtraction hybridization and cloning procedures to identify proteins enriched in the locus coeruleus (LC) that could contribute to the distinct anatomical, electrophysiological, and pharmacological characteristics exhibited by these neurons.

"Subtracted" bovine LC cDNA was generated by hybridization with excess biotinylated mRNA from bovine cerebellum and then used to probe an LC cDNA library containing >10⁶ recombinants. 150 positive clones were identified initially, of which the first 50 have been studied further. About half of these show enrichment in the LC compared to cerebellum by differential hybridization; the regional distribution of 15 of these clones have been studied to date by northern blotting.

cerebellum by differential hybridization; the regional distribution of 15 of these clones have been studied to date by northern blotting.

Clone 21 (mRNA 3.9 kb, insert 1 kb) is present in the LC at 10-fold greater levels than any other brain region or peripheral tissue analyzed. Clone 38 (mRNA 3.2, insert 2.3 kb) is also enriched (by >3-fold) in the LC compared to all other brain regions and tissues analyzed. These two clones do not correspond to known proteins enriched in the LC. A number of other clones show interesting distributions in brain, although they are not enriched uniquely in the LC. For example, clone 9 appears to be a thalamus-enriched protein.

LC. For example, clone 9 appears to be a thalamus-enriched protein.

Current studies are aimed at sequencing these various clones and studying the regulation of their expression by psychotropic drug treatments known to influence the functional state of LC neurons. Characterization of proteins highly enriched in the LC will provide important information concerning the molecular basis of some of the unique functional properties of these neurons.

151.4

SUBCELLULAR LOCALIZATION OF MRNA: ISOLATION AND CHARACTERIZATION OF MRNA FROM AN ENRICHED PREPARATION OF HIPPOCAMPAL DENDRITIC SPINES. M. E. Chicure¹, D. M. Terrian², and H. Potter¹. ¹ Program in Neuroscience, Dept. Neurobiology, Harvard Medical School, Boston, MA 02115. ² Dept. Anatomy and Cell Biology, East Carolina Univ. School of Medicine, Greenville, NC 27858-4354.

Differential targetting of cellular components underlies the establishment and maintenance of cell polarity. The intracellular targetting of proteins is well established. More recently, evidence for mRNA targetting in several cell types has also been obtained. We are interested in analyzing the mRNA population within a specific neuronal cell compartment: the CA3 dendritic spine. Poly-A plus RNA was isolated from a preparation of rat hippocampal mossy fiber synaptosomes which includes the postsynaptic CA3 spines and their endogenous ribosomes. Electrophoresis and transfer of this putative spine RNA and of total hippocampal poly-A plus RNA to nitrocellulose filters was followed by hybridization to radiolabelled cDNA obtained from each mRNA preparation. The results revealed significant differences in labelling patterns. Some species were more abundant in the spine mRNA; some were more abundant in the spine mRNA; some were more abundant in the spine mRNA; we have also used probes for known genes to assess the presence of specific RNAs in this subcellular compartment. Once again, comparisons of these signals to those obtained with total hippocampal mRNA indicate interesting differences, consistent with the conclusion that our spine mRNA preparation contains a specific subset of hippocampal mRNA species. Supported by NIH grant GM35967, AFOSR 89-0531; MEC is a Howard Hughes fellow.

PANCREATIC RIBONUCLEASE mRNA IN RAT BRAIN C.Cosi, A.Carsana^{*} A.Furia^{*} M.Palmieri^{*} G.Grassi Zucconi^{*}
Inst.Biochemistry Univ.VERONA, Inst.Cell.Biol.Univ.PERUGIA

Pancreatic ribonucleases form a group of homologous proteins which are secreted in some organs of mammals. In past years, a ribonuclease strictly homologous to bovine pancreatic RNase has been purified from ox brain. On the other hand a ribonuclease activity, not yet characterized, has been detected in rat brain by histochemical and biochemical methods chemistry, 88:587, 1988).

We have performed in situ hybridization experiments using -as a probe- a 35 cDNA specific for the pancreatic ribonuclease mRNA, in order to study the presence and cellular localization of the secretory enzyme in the rat brain.

Emulsion autoradiography of brain sections reveals the gene of the pancreatic RNase is highly expressed in neurons. The expression pattern appears higher in stratified regions such as the hyppocampus, the olfactory bulb, the cerebral and cerebellar cortices. In comparison the density of labeling in the glial cells of the white matter -corpus callosum- is very low. Experiments are in progress in laboratory to try to understand the functional significance of the presence of a secretory ribonuclease in the brain.

151.7

IMMUNOREACTIVE POU-PROTEINS OF RAT SENSORY NEURONS AND CELL LINES. J.N.Wood and P.R.Coote* Neuroimmunology Department, Sandoz Institute for Medical Research, 5 Gower place, London WC1E 6BN POU-proteins are a class of homeobox-containing proteins that play a role in tissue-specific transcriptional regulation. The distribution of transcriptional regulation. The distribution of

transcripts for one such protein, Brn-3, is similar to the pattern of transcripts for one such protein, Brn-3, is similar to the pattern of susceptibility to the toxic effects of the plant neurotoxin capsaicin [He et al.(1989) Nature 340, 35-42, Ritter and Dinh (1988) J. Comp. Neurol. 271, 79-90]. In order to compare the expression of capsaicin-sensitivity with that of Brn-3 protein at the single cell level, we raised specific rabbit antisera to a POU-domain peptide, and to a unique peptide present in Brn-3. Immunocytochemical analysis demonstrated that all DRG neurons in culture exhibit punctate nuclear staining associated with chromatin, the nucleolus and the nuclear membrane, using either POU or Brn-3 specific antisera. Western blots using POU-domain antisera define a number of immunorreactive using POU-domain antisera define a number of immunoreactive proteins with molecular weights corresponding to the known POU proteins Oct-1, OTF2A and 2B. In addition, several other immunoreactive putative POU proteins, including a ubiquitous band of immunoreactive putative POU proteins, including a ubiquitous band of molecular weight 145 Kd are present in dorsal root ganglia, and neuronal (N18, ND7, ND8) endothelial (CPAE) and fibroblast (NIH-3T3) cell lines. Anti-Bm-3 peptide antisera define 3 candidate Bm-3 proteins on western blots of DRG extracts that also exhibit immunoreactivity towards POU-domain antisera, of molecular weights 67,60 and 58 Kd. It is concluded that both capsaicin-sensitive and insensitive sensory neurons express Bm-3-like immunoreactivity, and that novel putative POU proteins may be identified with these sera.

151.9

REGULATION OF mRNAS ENCODING GAP JUNCTION PROTEINS IN ASTROCYTES AND C6 GLIOMA CELLS. C.C.G. Naus¹, S. Caveney*², J. Bechberger*¹, D. Belliveau¹, D. Zhu*² and G.M. Kidder*². Depts. of Anatomyl and Zoology², University of

Western Ontario, London, Canada, N6A 5C1.
Although gap junctions are present in the mammalian central nervous system, the cellular specificity and function of these junctions remains unclear. To begin to understand the significance of these junctions in neural systems, the expression of the gene coding for the gap junction protein, connexin43, has been investigated in astrocytes and C6 glioma cells, using a combination of Northern blotting, dye-coupling, and immunocytochemistry. While both connexin43 and connexin32 gap junction mRNAs are present in brain, only connexin43 mRNA is detectable in astrocytes. In contrast, the level of expression of connexin43 is dramatically reduced in C6 glioma cells. In cultures of primary astrocytes, the injection of carboxyfluorescein into a single cell resulted in the rapid spread of dye into surrounding astrocytes. In contrast, similar spread of dye was rarely noted in cultures of C6 glioma cells. To examine the role of gap junctions in these cells, C6 cell cultures were transfected with a full-length connexin43 cDNA. The level of connexin43 mRNA in these cells increased. We are presently monitoring the effect of increased connexin43 expression on the phenotype of these glioma cells.

151.6

A SPECIFIC INCREASE IN APP-695 mRNA LEVELS IS CORRELATED WITH AMYLOID PLAQUE PATHOLOGY IN THE CEREBRAL CORTEX OF ALZHEIMER'S DISEASE. J.S. Jacobsen, B. Beer, A.J. Blume and M.P. Vitek, Molecular Neurobiology Group, CNS Research, Lederle Laboratories, American Cyanamid Company, Pearl River, NY, 10965.

We have measured the expression of several similar but non-identical amyloid precursor protein (APP) mRNA forms associated with Alzheimer's disease (AD) in order to determine whether the expression of either one or all of the transcripts correlate with the observed amyloid plaque pathology. An S1 nuclease protection strategy employing an antisense probe derived from APP-770 cDNA was used to qualitatively detect mRNA forms including APP-770, APP-751 and APP-695, as well as our recently described 365 amino acid amyloid precursor related protein mRNA variant (APRP-365). Cyclophilin mRNA also was measured in order to permit one to quantitatively compare the relative abundance of APP mRNA forms between samples.

A comparison of frontal, temporal, parietal and occipital cortex (listed in

relative abundance of APP mRNA forms between samples.

A comparison of frontal, temporal, parietal and occipital cortex (listed in order of decreasing plaque pathology) from AD and age-matched normal brain reveal the following observations on the relative abundance of APP mRNA forms: (1) some but not all APP forms increase in AD, (2) not all brain regions display the same uniform increase in APP levels, (3) APP-770 accounts for the largest "fold-increase" while APP-695 the largest molar increase, (4) an increase in APP-895 correlates with plaque densities, but APP-770 does not, and (5), total APP levels roughly parallel plaques densities. When analyzed as a percent of total APP mRNA, the data reveal that plaque pathology is best correlated with (1) an increase in APP-895, rather than APP-770, and (2), a decrease in APP-731 and APRP-365 forms.

These observations suggest an imbalance in the APP mRNA forms containing or lacking the Kuintz protease inhibitor (KPI) insert is potentially significant in the etiology of AD. Here we show a specific increase in the KPlacking APP mRNA form in AD. This pattern of expression coincides with those brain regions most involved with amyloid plaque formation.

151.8

IN SITU HYBRIDIZATION OF GAP JUNCTION mRNA IN THE NEO-NATAL RAT BRAIN. A. Matsumoto (1), Y. Arai* (1), A. Urano (2) and S. Hyodo* (2). (1) Dept. Anat., Juntendo Univ. Sch. Med., Hongo, Tokyo, (2) Ocean Res. Inst., Univ. Tokyo, Nakano, Tokyo, Japan.

Gap junctions are considered to play an important

role in intercellular communication. Possible participation of gap junctions is presumed in the neuronal organization of developing brain. We studied the cellular distribution of the mRNA for gap junction protein in the brain of rats at postnatal day 2 by using in situ hybridization. A complementary DNA specific for the mRNA for rat liver gap junction protein (connexin 32) (gift from Dr. D.A. Goodenough) was applied to in situ hybridization on cryostat and paraffin sections of the middle level of the brain. Autoradiographic signals for connexin 32 mRNA were found to distribute in various regions of brain such as parietal cortex hippocampus regions of brain such as parietal cortex, hippocampus, thalamus/striatum and hypothalamus. These signals were localized on neurons, glial cells and ependymal cells. The level of expression of connexin 32 mRNA on cryostat sections was much higher than that on paraffin sections. These results indicate that connexin 32 mRNA may be expressed in neural substrates in the neonatal rat brain and that the process of paraffin embedding may result in degradation of connexin 32 mRNA in tissues. (Supported by grant of Ministry of Education, Culture and Science of Japan).

AFFERENT ACTIVITY REGULATES GLIAL GENE EXPRESSION IN THE RAT HIPPOCAMPUS. E.R.Torre, R.A.Tomasulo, and O.Steward, Dept. of Neuroscience, Univ. of VA, Charlottesville, VA 22908

Message RNA for glial fibrillary acidic protein (GFAP) increases dramatically in the rat hippocampus within 48 hours after a unilateral electrolytic lesion of the entorhinal cortex (EC) (Steward et al, J.Neurosci. in press). The initial increase in message is not limited to the denervated area, but occurs throughout the hippocampus bilaterally. At longer postlesion intervals the increases in GFAP mRNA are restricted to zones containing degeneration debris. The increases in GFAP mRNA in zones not containing degeneration debris could occur in response to changes in neuronal activity, due either to the burst of afferent activity which accompanies the lesioning procedure, or to the reduction of activity which follows the lesion. Using 35S-labelled riboprobes for GFAP mRNA for dot blot hybridization we measured GFAP message in each hippocampus 24 hours after manipulations designed to increase or decrease activity in the perforant path. 25 Hz stimulation of the angular bundle (AB) increased GFAP message to 349% of control values in the ipsilateral hippocampus and 171% in the contralateral. This compares to 440% ipsilaterally and 144% contralaterally following electrolytic lesions. 0.1 Hz stimulation led to modest increases (208% ipsilaterally and 120% contralaterally). A knife lesion of the AB, which we assume to produce a smaller burst of afferent activity than an electrolytic lesion, led to large increases ipsilaterally (366%), but no change contralaterally (107%). Injections of tetrodotoxin into the EC led to small decreases in GFAP mRNA. We conclude that bursts of afferent activity can trigger transcription of the GFAP gene, and that the stimulation which accompanied electrolytic destruction of the EC contributed to increasing the mRNA. Supported by NSF BNS8818766 to OS. RT received postdoctoral training grant NS07199

CHARACTERIZATION OF PLASMINOGEN ACTIVATOR AND PLASMINOGEN ACTIVATOR INHIBITOR RELEASE FROM SCHWANN CELLS TRANSFECTED WITH THE SV-40 LARGE T ANTIGEN GENE. T.K. White, R.S.

Compton and M.B. Clark, Univ. of Maryland, Baltimore.
We have assessed plasminogen activator (PA) and
plasminogen activator inhibitor (PAI) release and regulation in a permanent Schwann cell (SC) line prepared regulation in a permanent Schwann Cell (SC) line prepared by transfecting primary SCs with the SV-40 large T antigen gene (Tennekoon et al., 1987, J.C.B., 105:2315). Using SDS PAGE and zymography, we have demonstrated that the transfected cell line (tSCs) and primary SCs show identical profiles for PAI activity and very similar PA profiles. Using anti-tPA IgGs, we have demonstrated that the tSCs, like primary SCs, release tissue type PA. Furthermore, Northern analysis indicates that both cell types contain identical levels of tPA mRNA. The changes that occur in the tPA activity profile in tSC cells following denervation of SC + NC cell cultures are similar to those previously reported for primary SCs under similar conditions. Most notably, we observed the appearance of a 92 kDa species with 1 day post-denervation, as well as the gradual disappearance of a 25 kDa species. Thus, transfected SCs and primary SCs exhibit virtually identical PA/PAI responses to denervation, and the tSC line will be an appropriate model for future studies in which we will further characterize neuronal regulation of SC PA and PAI at the protein and mRNA levels. (Su by PVA-SCRF grant NBR 645 and NIH NS24252 to MBC). (Supported

TRANSCRIPTIONAL REGULATION OF NERVE GROWTH FACTOR INDUCED GENE A (NGFI-A) IN SCHWANNOMA CELLS. C. Matheny and J. Milbrandt. Department of Pathology, Washington University School of Medicine, St. Louis, MO 63108.

MGFI-A, an early response gene, encodes a zinc-finger protein that was identified by virtue of its induction by NGF in PC12 cells. In contrast, in JS1 cells, a rat Schwannoma cell line that expresses low affinity NGF receptors, NGFI-A is expressed constitutively. To determine the enhancer elements important for transcription in Schwann cells, a series of 5'nested deletions of the 5' flanking region of NGFI-A (ranging from -532 to -52 nucleotides(nts)) were cloned in front of a promoter-less CAT (chloroamphenicol acetyl transferase) gene and trans-CAT (chloroamphenicol acetyl transferase) gene and transfected into JS1 cells. Experiments with these deletion constructs indicated that an enhancer element must be contained within the 194 nucleotides between -532 and contained within the 194 nucleotides between -532 and -339. Interestingly, the NGFI-A gene is rapidly induced, more than twenty fold, in both JS1 Schwannoma cells and primary Schwann cell cultures treated with cycloheximide (CHX). This suggests that NGFI-A is under stringent transcriptional control by repressor proteins. Nuclear run-off experiments indicated that the effect of CHX occurs at the transcriptional level. Currently stable transfectants of JS1 cells containing the NGFI-A/CAT deletion constructs are being analyzed for CAT gene expersion to localize the sequence elements involved in pression to localize the sequence elements involved in the CHX induction (or derepression) of NGFI-A.

DIFFERENTIAL CONTROL OF LAMININ B1 AND B2 CHAIN GENE TRANSCRIPTION IN PRIMARY ASTROCYTES. Y. P. Kedar. H. Haleem-Smith*. J. R. Wujek and Y. Yamada* Lab. of Molecular Biology, NINDS, NIH, and Lab. of Dev. Biol. and Anomalies, NIDR, NIH., Bethesda, MD 20892.

Laminin, a large extracellular matrix protein, consists of three individual subunits: A chain, B1 chain and B2 chain. The whole

molecule stimulates extensive neurite outgrowth from many neuronal molecule stimulates extensive neurite outgrowth from many neuronal cell types in vitro. Embryonic glial cells transiently express laminin during the development of the midbrain and optic nerve in rodents (Letourneau et al., Dev. Biol., 1988, 125: 135; McLoon et al., J. Neurosci., 1988, §: 1981). Astrocytes, which stimulate neurite outgrowth in vitro, synthesize and secrete only the B2 chain of laminin (Wujek et al., Dev. Brain Res., 1990, in press). We have investigated the molecular mechanisms that regulate expression of laminin B1 and B2 chain gene transcription in primary astrocytes and in a hepatoma cell line (HepG2). We made plasmid constructs containing the 5' flanking region of both the B1 (-1900 to +1) and B2 (-830 to +106) laminin chain genes fused to a structural part of the chloramphenicol acetyltransferase (CAT) gene. We examined the promoter activity by transfecting the constructs into primary rat astrocytes and HepG2 hepatoma cells. Both the astrocytes and the HepG2 cells exhibited significant CAT activity when transfected with the B2 construct. In contrast, the astrocytes did not exhibit any CAT activity after transfection with the B1 construct whereas the HepG2 cells exhibited significant activity. These results suggest that astrocytes regulate B1 and B2 laminin chain gene expression by differential recognition of gene promoters.

NOVEL MODIFICATIONS OF ACETYLCHOLINESTERASE (AChE) PHARMACOHISTOCHEMISTRY. <u>C. Mathes. P. L. Di Patre and L. L. Butcher</u>. Lab. of Chemical Neuroanatomy, Dept. of Psychology, UCLA, Los Angeles, CA 90024-1563, U.S.A.

Available methods for AChE histochemistry do not allow visualization of both somata and processes in striatum (Str), forebrain nuclei (FN) and their

Available methods for ACIE histocentristry or lot allow Nisalization both somata and processes in striatum (Str), forebrain nuclei (FN) and their terminal fields in the same brain. To obtain good staining of AChE-positive neuronal bodies, pretreatment with diisopropyltluorophosphate (DFP) is commonly used. In order to demonstrate neuronal somata and fibers, we combined DFP-pretreatment with a new and highly sensitive technique (Tago et al., J. Histochem. Cytochem., 34: 1431, 1986), which affords clear visualization of axons in the rat brain. Sprague-Dawley rats were treated with DFP, 1.8 mg/kg i.m. and sacrificed 6, 12, 24 or 48 h after treatment. Brain sections were incubated in iso-OMPA 30 uM for 30 min, then for 15 min in diluted Karnovski-Roots (K-R) medium prepared according to Butcher et al. (Naunyn-Schmied. Arch. Pharmacol., 285: 31; 1974); the stain was enhanced with diaminobenzidine-nickel ammonium sultate (DAB-NAS) (Tago et al., 1986). Intense staining of somata in Str and cholinergic FN was obtained with K-R medium diluted 1:1, enhanced with DAB-NAS. By diluting K-R medium 1:10 and increasing the concentration of DAB-NAS by two, it was possible to see fibers in the cortex, hippocampus and fimbria. Visualization of AChE-reactive fibers was previously unattainable after DFP-treatment; with this method it becomes feasible to use the same brain for AChE-histochemical analyses of somata and fibers on adjacent sections. AChE-histochemical analyses of somata and fibers on adjacent sections. [Support: NS 10928].

152.2

FLUORESCENT MITOCHONDRIAL STAINS AS VITAL PROBES OF METABOLIC ACTIVITY IN THE RAT HIPPOCAMPAL SLICE PREPARATION. S. R. Quartz², R. J. Adams and T. J. Sejnowski², Salk Institute, La Jolla, CA 92037 and ²UC, San Diego, La Jolla, CA 92039

Distribution of the cationic mitochondrial fluorescent dyes rhodamine 123 and 2-(4-dimethylaminostyryl)-N-methylpyridinium iodide is governed primarily by the Nernst equation. Since mitochondrial membrane potentials have been reported to be -150mV in situ (Farkas et al., Biophys. J. 56, 1989), these dyes serve as vital stains of mitochondria. We have utilized these properties of the dyes as probes of metabolic mitochondria. We have utilized these properties of the dyes as probes of metabolic activity in conjunction with confocal microscopy. In agreement with the histochemical localization of cytochrome oxidase (CO) (Kageyama & Wong-Riley, Neuroscience 7, 1982), we observe the following: 1) low to moderate staining in principal cell layers; 2) low staining of proximal apical dendrites of CA1 pyramidal cells; 3) intense staining of outer molecular layer, dentate gyrus; 4) intense staining of stratum oriens, CA3; 5) low average staining of stratum lucidum, CA3, under low magnification. However, under higher magnification we observe intensely stained mossy fibers and their synaptic extensions, suggesting that average intensity under low magnification may not be an accurate indication of activity. In contrast to CO localization, we have not found general intense staining in stratum moleculare (SM) of CA1, although, in agreement with those studies, we have observed highly reactive (CAI, although, in agreement with those studies, we have observed highly reactive dendritic processes, presumably of interneurons, extending throughout the region. The lack of general staining in SM may be due to the finding that synaptic mitochondria are less active than nonsynaptic mitochondria (Leong et al. J. Neurochem. 42, 1984).

tess active man nonsynaptic mitochondria (Leong et al., <u>I. Neurochem.</u> 42, 1984).

Recent studies report a 50% higher ATP content in cultured astrocytes than in cortical neurons (Hertz et al., <u>Neurochem.</u> Res. 13, 1988). In agreement with this finding, we observe intense staining in both protoplasmic and fibrous astrocytes. We have determined that these cells are astrocytes according to general morphological characteristics, distribution patterns, and by double-labelling with immunofluroescent markers for GFAP. These results suggests that these dyes may provide a simple in vitro assay for the study of astrocyte function.

CYTOCHROME OXIDASE HISTOCHEMISTRY LABELS DISPLACED GANGLION CELLS THAT PROJECT TO THE ACCESSORY OPTIC SYSTEM (AOS) IN THE CHICK. Debora L. Nickla*, Michael D. Gottlieb, Gonzalo Marin*, Ximena Rojas* & Josh Wallman. Biology Department, City College, City University of New York, New York, NY 10031.

In birds, cells of the isthmo-optic nucleus (and ectopic neurons) send axons to the retina. We have previously reported that cytochrome oxidase (COx) histochemistry labels these axons and three types of cells in the inner nuclear layer (INL) of the chick retina (ARVO, 1990). One type, an amacrine cell, is clearly contacted by centrifugal terminals. Another type is the classical large oval displaced ganglion

reminals. Another type is the classical large oval displaced ganglion cell (DGC) that is known to project to the nucleus of the basal optic root (nBOR) of the AOS. The third type (round) could be large amacrine cells, or alternatively, the smaller DGCs reported to project

amacrine cells, or alternatively, the smaller DGCs reported to project to other targets. We here report that both types of COx positive cells (oval and round) are indeed DGCs that project to the AOS.

Rhodamine beads were bilaterally injected into the nBOR of the AOS of 3 week old chicks. After 8 days, the retinas were fixed, sectioned and reacted for COx (Wong-Riley protocol).

We observe two types of double labeled cells in the inner INL that correspond to those described above: (1) large (30 um) and oval (2) small (approximately 15 um) and round. This supports the notion that two types of DGCs project to the AOS. Furthermore, COx staining, of DGCs, as well as that of centrifugal axons and their amacrine cell targets, provides additional support for a functional connection targets, provides additional support for a functional connection between the centrifugal system and the AOS. (Supported by EY 02727).

HIGH RESOLUTION IMMUNOHISTOCHEMISTRY OF TYROSINE HYDROXYLASE AND GLIAL FIBRILLARY ACIDIC PROTEIN IN SEMITHIN PLASTIC SECTIONS. S. Chen and D.E. Hillman. Dept. Physiol. & Biophys., New York Univ. Med. Ctr., New York, NY 10016.

We have successfully demonstrated immuno-labeling of tyrosine hydroxylase (TH) and glial fibrillary acidic protein (GFAP) on one micron plastic sections revealing the fine structure of Bergmann glia and dopamine cells of the substantia nigra. Rats were perfused with 4% paraformaldehyde and 0.1% glutaraldehyde for 10 minutes. Five-hundred micron, vibratome sections were collected in 0.1M phosphate buffer, slowly dehydrated with ethanol and embedded in Durcupan. The curing temperatures were kept below 8°C. One micron sections were mounted on glass slides and dried overnight at 55°C. Etching with a 1:1 alcohol dilution of saturated ethoxide for 20-30 minutes exposed the tissue surface from the soft plastic sections. Following a thorough rinsing in absolute alcohol, the sections were rehydrated to a phosphate absolute alcohol, the sections were rehydrated to a phosphate buffered saline. Immuno-histochemical staining was performed for either GFAP or TH using the Vector ABC kit. Labeling was intense highlighting of glial and neuronal projections on a relatively clear background. Because the sections are thin, different antibodies can be applied to adjacent serial sections for labeling the same cell (Stensaas et al., Soc. Neurosci. Abst. 1989). Supported by USPHS NS-13742 from NINCDS.

IMMUNOCYTOCHEMICAL DIFFERENTIATION OF GLUCOSEPHOSPHATE ISOMERASE ALLOTYPES. H.J. Li*, M.Chen*, T.G.Goodwin* and P.K.Law. Depts. of Neurol. and Physiol./Biophys., Univ. of Tennessee, Memphis, TN 38163. The genetic polymorphs of glucosephosphate isomerase (GPI) differentiated electrophoretically have been used as markers to identify cell genotypes in chimeric mice and myoblast transplantation. However, such approach does not allow histological localization of the isozymes. The histochemical method for GPI staining does not differentiate between the allotypes. Antisera against GPI-1CC and GPI-1BB raised in rabbit lack specificity in tissue section staining. We have developed a method to produce specific antibodies that could differentiate between the two GPI allotypes. We first purified the GPIs from mouse muscles with cellulose phosphate ion exchange chromatography. About 50 g of mouse skeletal muscle was anotypes. We first puttied the OFIs from mouse muscles with centurise phosphate ion exchange chromatography. About 50 g of mouse skeletal muscle was homogenized in 250 ml of 10 mM Tris buffer, pH 7. After centrifugation, the supermatant was concentrated with Amicoon ultrafilter (XM 50) to about 20 ml final volume. It was then loaded into a column (2.5 X 60 cm) of activated cellulose phosphate, and 7 mM F-6-P buffer solution was used as a specific GPI elution. The enzyme isolated with this procedure was found to be homogenous in agarose gel and a CPS and the state of the enzyme isolated with this procedure was found to be nomogenous in agarose get and in SDS polyacrylamide get electrophoresis. About 100 µg of purified GPI-1CC emulsified with Freund's complete adjuvant was injected intraperitoneally to a C57BL/61-gpi-1b/b female mouse. A boost with the same dose of the antigen in Freund's incomplete adjuvant was given after three weeks. Another boost with the same dose of the antigen without adjuvant was given two weeks thereafter. Two weeks after the last injection, the samples of immunized mouse sera were tested with ELISA. Some of them showed high tier and specificity against GPI-1CD but not against GPI-1BB. These sera had been used successfully for mouse muscle section against OFI-1BB. These seri and been used successfully for mouse musicle section staining. The goat anti-mouse immunoglobulins peroxidase conjugated was used as second antibody in the section staining. We found that muscle sections from C57BL/6J-gpi-1b/b mouse were stained negatively, but muscle sections from C57BL/6J-gpi-1b/c mouse were stained positively. There were a lot of negative staining central nuclei in muscle sections of the C57BL/6J-gpi-1b/b dystrophic mice. (Supported by USPHS NS 20251 and NS 26185)

INCREASED GFAP EXPRESSION IN AGED RAT BRAIN REVEALED BY QUANTITATIVE IMMUNOHISTOCHEMISTRY.

MN Gordon, DG Berg*, CM Flores* and DG Morgan. Andrus Gerontology Center, U Southern Cal, LA, CA 90089-0191.

Two methods of immunohistochemical staining were compared as quantitative techniques to assess antigen levels in vibratome tissue sections. The <u>amplified</u> method used the avidin-biotin complex technique, horseradish peroxidase (HRP) and diaminobenzidine (DAB) as the chromogen, while the <u>nonamplified</u> method used a secondary antibody directly coupled to HRP. Brain sections from young (5-6 mo) and old (24-28 mo) Wistar rats were stained for glial fibrillary acidic protein (GFAP) using a monoclonal primary antibody. DAB-reacted sections were quantified using a computer-assisted densitometry system (Technology Resources) and a CCD camera with gain and blacklevel settings fixed by the user. Using the amplified technique, no differences in the area of the section occupied by reaction product were observed in three brain regions as a function of age. Using the nonamplified technique, significant increases of 90%, 80% and 40% in the section area occupied by reaction product were obtained in cerebral cortex, striatum, and hippocampus, respectively; no differences in the average density value were observed. These findings are in complete accord with the age-related increases in GFAP detected by immunoassay and solution hybridization measurements of GFAP RNA, both regionally and in terms of the fold increase. Supported by NIA AG07892, the Greenwall Award from AFAR and an Est. Invest. Award from the Am Heart Assn to DGM.

INTRACELLULAR SEGREGATION OF PARVALBUMIN. *, Plogmann D.*, Celio M.R., Institute of Histology and general Embryology, University of Fribourg, Pérolles, CH-

and general Embryology, University of Fribourg, Pérolles, CH1700 Fribourg and Institute of Anatomy, University of Kiel,
Olshausenstr. 40, D-2300 Kiel.

The Ca²⁺ binding protein Parvalbumin (PV) occurs in a
subpopulation of neurons in the brain (Celio M.R. (1990)
Neuroscience 35/2:375-475). In general the whole cell is
stained by PV-antibodies, and this phenomenon is at the
origin of it's excellent reputation as a marker. Sometimes,
however, PV is restricted in occurrence to certain domains of
a given neuron. In this study, using a combination of
techniques to examine two different regions of the brain, we
uphold the concept of intracellular segregation. In the deep
cerebellar nuclei (DCN) PV occurs only in the axons, whereas
the cell bodies are devoid of immunoreactivity. Colchicine
application increases the concentration of PV in the
perikaryon to a detectable level. As a further proof that DCNneurons synthetize PV we can localize in them PV- mRNA by
in-situ hybridisation. In the hippocampus PV is normally
seen only in interneurons. However, using strong fixatives seen only in interneurons. However, using strong fixatives (2.5 % glutaraldehyde) and semithin cryo-sections (0.5 um thick), PV is revealed in the apical dendrite of pyramidal cells and in-situ hybridisation shows the presence of PV- mRNA in

their cell bodies.

In conclusion PV, particularly in long-axon neurons, seems to be concentrated in those domains in which important movements of Ca2+ take place.

152.8

A SIMPLE TECHNIQUE FOR THE LOCALIZATION OF NEURONAL SURFACE ANTIGENS IN FORMALIN-FIXED HUMAN BRAIN

P.T. Stephenson and P.D. Kushner, ALS Research Center,
Pacific Presbyterian Medical Center, San Francisco, CA 94115.
Immunocytochemical analyses of human CNS tissue are
limited by processing techniques considered necessary to
optimize both tissue preservation and antigenicity. We have devised a simple technique that employs routine, formalindevised a simple technique that employs routine, formalinfixed postmortem tissue. Blocks (1 x 1 x 1/2 cm³) of formalinfixed brains are first extensively washed in cold, buffered saline (up to 6 hours) and equilibrated through cold, graded sucrose solutions: 12% aqueous sucrose, 1 day; 15%, 1 day; 18%, 1-3 days. Blocks are then mounted, flash-frozen (in isopentane cooled with liquid nitrogen), cryosectioned, and immunostained with standard techniques. Gradual alcohol dehydrations (15 to 100% in 10% increments) are essential for the detection of surface antigens in plastic-mounted sections. The monoclonal antibody (MAb) Tor 23, which recognizes an epitope present at the surface of rare mammalian CNS neurons, was primarily utilized in the development of this technique, although all other MAbs tested thus far appear to work equally was primarily utilized in the development of this technique, although all other MAbs tested thus far appear to work equally well. Significantly, *Tor* 23 staining is similar in all tissues, stored 3 days, 6 months or 3 years in formalin, although tissue frankly oxidized is not suitable for any marker. This protocol expands tremendously the number of cases available for any immunocytological investigation, a fact important in the study of neurological disorders, where tissues are frequently hard to come by. Supported by the State of California.

IMMUNOCYTOCHEMICAL DETECTION OF MONOAMINE OXIDASE A AND B IN CLONAL CELL LINES OF NEURONAL ORIGIN. M-C. Holst, M.S. Sutphin* and T.D. Buckman*. Nutritional Sciences, UCLA School of Public Health, Los Angeles, CA 90024.

Both forms of the enzyme monoamine oxidase (MAO A and B) appear to play a central role in the metabolism of monoamine neurotransmitters in the mammalian central role in the metabolism of monoamine neurotransmitters in the mammalian CNS. In primary brain cultures and clonal cell lines of neuronal origin only the A form, which appears first in development, is generally expressed. An exception to this is the report by Nagatsu et al. in 1981 (Neurochem. Internat. 3:137) of appreciable levels of activity identified as B type MAO on the basis of the effects on enzyme activity of the specific MAO A and B inhibitors, clorgyline and deprenyl in two neuroblastoma cell lines (NCB20, mouse neuroblastoma x fetal hamster brain hybrid, 80% MAO B, 20% MAO A; NCB140-3, x glioma, 75% MAO B). We have prepared polyclonal antibodies to MAO A and B which show a high degree of specificity on the basis of Western Blot analysis. Immunocytochemistry with these confirms the presence of both MAO A and B in these two neuroblastoma hybrids where staining was found both in the cell soma and neuritic processes. The PC12 pheochromacytoma cell line which, on the basis of biochemical evidence appears to have only MAO A, does not give any staining with our antibody to MAO B. Supported by NIH grant NS-25797.

rab3Ap DISTRIBUTION IN RAT BRAIN. B. Tavitian

rab3Ap DISTRIBUTION IN RAT BRAIN. B. Tavitian, K.L. Moya, A. Zahraoui* and A. Tavitian*. INSERM U334, S.H.F.J., C.E.A., 91406 Orsay, and INSERM U248, 75010 Paris, France.

Some members of the ras superfamily are associated with secretory vesicles, and some have been shown to mimic the effects of neuronotrophic factors. rab3Ap is a ras-like GTP binding protein found predominantly in the nervous system. Using a monorecific immune serum we examined the monospecific immune serum we examined the

distribution of rab3Ap in the adult rat brain.

Cell bodies and major fiber bundles such as
the corpus callosum, anterior commissure and optic tract were devoid of staining, while certain areas of neuropil were darkly stained such as the striatum, lateral geniculate, superior colliculus and regions of the cortex. The hippocampus exhibited a striking pattern with dark staining in the stratum oriens, stratum radiatum and the dentate gyrus molecular layer. The pyramidal cell layer was not stained in CA1 and CA3, while in CA2, this layer contained dense immunoreactivity surrounding blank profiles of cell bodies.

This pattern is consistent with a synaptic localization of rab3Ap and suggests that the protein may serve a specialized function in particular pathways.

152.13

ESTABLISHMENT OF OPTIMAL PARAMETERS FOR IN SITU TUHSC. Alkaline Phosphatase conjugated probes have recently been used to identify mRNA of neurotransmitters and enzymes (Denaro, JF, The Histo.Chem. Soc., Orlando, FL, 1989). In the present study a series of hybridization experi ments were conducted to establish the optimal ments were conducted to establish the optimal parameters for maximum signal to noise. The major points to be investigated and which will be discussed are: 1. Tissue fixation, 2. Hybrization temp. & time, 3. Probe concentration, 4. Wash buffer, and 5. Digestion of unhybridized probe. These experiments reveal that excellent can be obtained by using any one of results can be obtained by using any one of a number of protocols. This makes the technique of in situ hybridization with Alk Phos conjugated probes adaptable to a number of experimental situations. For example, one may combine it with immunocytochemistry and one can choose between frozen or paraffin sections. The combination of a radio labeled probe with a colorimetric one is also possible. While standardization is desired to make such techniques readily available to the laboratory, one should not lose sight of the varied research application inherent in the different approaches different approaches.

152.10

DISTRIBUTION OF FOS IMMUNOREACTIVITY FOLLOWING
STIMULATION OF THE PERFORANT PATH IN RATS. C. L.
Mitchell, L. M. Grimes¹ and M. I. Barnes*. LMIN,
NIEHS/NIH, Research Triangle Park, NC 27709 and
¹Curriculum in Toxicology, Univ. of North Carolii.,
Chapel Hill, NC 27514.

Depending on the stimulation parameters, unilateral stimulation of the perforant path (PPS) elicits wet dog shakes (WDS) only or WDS followed by behavioral snakes (wbs.) only of wbs forlowed by behavioral seizures. We compared the distribution of fos immuno-reactivity in rats exhibiting only WDS vs. those exhibiting profound behavioral seizures. Fischer-344 rats were anesthetized with pentobarbital 1 or 2 hrs following the initiation of stimulation, perfused with 4% paraformaldehyde and 0.2% glutaraldehyde for subsequent analysis of reactivity to antibody to fos protein. Areas stained in both the WDS and S groups were: dentate granule cells, CA1 and CA3 pyramidal cells, subjiculum, amyodalphipocampal area, and layers II and subiculum, amygdalohippocampal area, and layers II and VI of the cerebral cortex. Areas stained in the S group but not the WDS group were: all layers of the cingulate cortex, layer IV of the cerebral cortex, zona incerta, central and cortical nuclei of the amygdala, piriform cortex, subthalamic nucleus, caudate-putamen, medial geniculate nucleus of the thalamus and ventromedial nucleus of the hypothalamus. We conclude that analysis of fos immunoreactivity following PPS can aid in determining pathways activated by such stimulation.

152.12

ON THE USE OF C-FOS AS A CELLULAR ACTIVITY MARKER IN THE STUDY OF VISUAL PATHWAYS.

Y.H. Yücel, C. Beaulieu, R.M. Douglas, M.S. Cynader. Dept Ophthalmology, UBC, 2550 Willow St, Vancouver, B.C., CANADA

C-fos, a proto-oncogene protein, is rapidly and transiently induced in response to a variety of stimuli. To test whether c-fos can be used as a high resolution activity marker for visual pathways tracing, c-fos immunoreactivity has been studied in rat visual cortex after unilateral pharmacological stimulation (intravitreal injection of picrotoxin), electrical stimulation of the LGN, and physiological (optokinetic)

Picrotoxin induced moderate number of c-fos immunoreactive cells in layers II-III-IV and VI of the hemisphere contralateral to the stimulated eye and only a few in layer VI in the ipsilateral cortex. Electrical stimulation of the LGN induced c-fos in a large number of cells located in all layers except layer V of the ipsilateral visual cortex while very few immunoreactive cells were found in the contralateral hemisphere, located mostly in layers II and VI. Optokinetic stimulation did not increase c-fos immunoreactivity in the visual cortex but it induced c-fos immunoreactivity in several midbrain structures (superior colliculus, accessory optic system, and nucleus of the optic tract). We conclude that c-fos can be used as a high resolution activity marker in polysynaptic tracing of visual pathways.

152.14

CYTOARCHITECTURAL RELATIONSHIPS BETWEEN OUABAIN BINDING AND mRNA FOR ISOFORMS OF THE SODIUM PUMP CATLYTIC SUBUNIT IN

Michael L. Brines, Barbara I. Gulanski, Maureen Gilmore-Hebert*, Adam L. Greene*, Edward J. Benz, Jr.*, and Richard J. Robbins. Neuroendocrine Program, Yale

University School of Medicine, 333 Cedar Street, New Haven, CT 06510
We compared the cell-type expression of the α-subunits of the sodium pump in rat brain using in situ hybridization and ³H-ouabain autoradiography. These techniques allowed us to compare adjacent sections for localization of mRNA and active $\alpha 2/\alpha 3$ pumps. The perikarya of many neurons possessed high levels of $\alpha 1$ and $\alpha 3$ transcripts, compared to glial-enriched areas which appeared virtually unlabelled. In contrast, $\alpha 2$ putilish. The peritarya of many neutrons possessed ingin evers of the anal GS dashear, ps. compared to glial-enriched areas which appeared virtually unlabelled. In contrast, αZ probe was observed to hybridize strongly only over large pyramidal neurons and meningeal cells, and was diffuse elsewhere. A complex and varied regional pattern of $\alpha 1$ and $\alpha 3$ transcripts was noted. Large neurons of the olfactory bulb and piriform cortex possessed high levels of $\alpha 3$ transcripts, but low levels of $\alpha 1$ mRNA. In frontal cortex, pyramidal neurons of layers 2-3 were enriched in $\alpha 1$ mRNA while those in layer 5 exhibited high levels of $\alpha 3$ transcripts. In the hippocampus, all three mRNAs were present in the principal neurons. Dentate granule cells had a high $\alpha 1/\alpha 3$ mRNA ratio, which was reversed for CA1 pyramidal neurons. In the cerebellum, Purkinje and Golgi cells contained high levels of $\alpha 3$ message, while the granule cells appeared to express only $\alpha 1$ mRNA. Ouabain binding correlated most closely with the regional distribution of $\alpha 3$. It was highest in the olfactory cortex, hippocampus, and cerebral cortex, and lowest over perikarya, white matter and choroid plexus. In the cerebellum, ouabain bound at highest density in the granule cell layer, the inner third of the molecular layer in the basket region, and the deep cerebellar nuclei, but was low in the outer 2/3 of the molecular layer. Thus, mature $\alpha 3$ sodium pump appears localized to the axons of Purkinje, Golgi and basket cells, and not to their apical dendrites. These results suggest that in some cells translated $\alpha 3$ protein is predominantly inserted into axon terminals. Many neurons observed with dense $\alpha 3$ message are characterized by long axons. The $\alpha 3$ isoform may be specialized for vectorial transport along these long axons. The $\alpha 3$ isoform may be specialized for vectorial transport along these axons into distant synaptic membrane.

QUANTITATIVE, NON-RADIOACTIVE DETECTION OF PREPROENKEPHALIN mRNA WITH DIGOXIGENIN-UTP LABELED cRNA PROBES. M.E. Lewis, E. Robbins, S.L. Meyer and D.S. Grega¹. Cephalon, Inc., West Chester, PA 19380 and ¹Boehringer Mannheim Corp., Indianapolis, IN 46250.

Non-radioactive detection of mRNA with in situ hybridization histochemistry has emerged as an important new technology for the study of gene expression in brain and other tissues. Quantitative in situ hybridization studies have generally relied upon counting of autoradiographic grains in the emulsion overlying cells containing hybridized, radioactively-labeled probe. However, such studies have been plagued by the nonlinear relationship between grain density and radioactivity, and, in addition, weeks of exposure to the emulsion are radioactivity, and, in adultion, weeks of exposure to the enhalson are necessary. To begin to explore the quantitative potential of non-radioactive *in situ* hybridization histochemistry, we have carried out studies using a digoxigenin-labeled cRNA probe prepared using the linearized plasmid pYSEA1, which terminates at the end of a 935 bp preproenkephalin cDNA insert. Detection of probe hybridized to striatal tissue sections was carried out enzymatically following complex formation with an antidigoxigenin-alkaline phosphatase conjugate. Striatal neurons were intensely labeled (mean OD = 0.308 ± 0.006 ; S/N ratio = 7:1), while neocortical neurons exhibited less signal (mean OD = 0.179 ± 0.003 ; S/N ratio = 4:1), as expected. We are presently exploring the use of the digoxigenin-labeled probe for solution hybridization assays for the quantitation of preproenkephalin mRNA.

We gratefully acknowledge Drs. S. Sabol and K. Yoshikawa as the source of the pYSEA1 plasmid, and Dr. F. Baldino, Jr. for comments.

ASTROCYTES - A HETEROGENEOUS FAMILY Lars Rönnbäck and Elisabeth Hansson, Dep. of Neurology and Inst. of Neurobiology, Univ. of Göteborg, Göteborg, Sweden.

Data are accumulating that astrocytes are a heterogeneous class of cells both in terms of morphology, surface properties and in their distribution within the central nervous system. Using primary astroglial cell cultures from various brain regions it has been shown that these cells are heterogeneous with differences in surface receptors. The number of \betaadrenoceptors per astrocyte and/or their sensitivity vary from one brain region to another. High-affinity uptake of amino acids also vary in different brain regions. The uptake of glutamate was found to be highest in striatum compared to cortex, brain stem and cerebellum. The GABA uptake showed the greatest intensity in brain stem astrocytes compared to cortical astrocytes. Taking such a heterogeneity into account, especially with respect to the expression of membrane receptors astroglia may be able to respond selectively to changes in their humoral environment which may provide new therapeutic approaches.

153.3

DISTRIBUTION OF mRNA'S CODING FOR LIVER AND HEART GAP JUNCTION PROTEINS IN THE RAT CENTRAL NERVOUS SYSTEM. P.E. Micevych and L.A. Abelson. Department of Anatomy and Cell Biology and the Laboratory of Neuroendocrinology, Brain Research Institute, UCLA School of Medicine, Los Angeles, CA 90024-1763.

The present study examined the distributions of connexin43 mRNA and connexin32 mRNA in the central nervous system (CNS) of the rat using in situ hybridization histochemistry. Connexin32 forms direct cell-cell channels in the liver, and connexin43 does in the heart. Generally, the distribution of cells labelled with connexin32 mRNA did not overlap with the population labelled by connexin33 mRNA, thus implying a regional or cellular specificity in the expression of connexins in the CNS. Cells containing connexin43 mRNA were uniformly distributed throughout the gray matter of the neuraxis. Several areas had a higher concentration of cells that express connexin43, such as the supraoptic and paraventricular nuclei of the hypothalamus, anterior cortical amygdaloid nucleus, the reticular part of the substantia nigra, lateral habenula, mesencephalic trigeminal nucleus, Purkinje cell layer of the cerebellum, facial nucleus, prepositus hypoglossal nucleus, and dorsal cochlear nucleus. Connexin32 mRNA was detected in discrete cell groups of the gray matter, including cells in layer 2 of the neocortex, piriform cortex, pyramidal and granule cell layers of the hippocampus, granule cell layer of the dentate gyrus, islands of Calleja, olfactory tubercle, lateral thalamic nuclei, lateral habenula and Purkinje cells of the cerebellar cortex. A significant population of cells in white matter tracts which were labelled with the connexin32 riboprobe were determined to be oligodendrocytes. These results indicate that neurons and glial cells may express mRNA's that code for liver and heart connexins. Many of the areas in which connexin mRNA's were demonstrated have electrically coupled cells, morphologically distinct gap junction plaques, and/or have immunologically identifiable connexin proteins. These results indicate that cell-cell coupling may be a widespread phenomenon in the mammalian CNS. Supported by NS 21220.

ISOLATION OF NEURONS, ASTROCYTES AND OLIGODENDROCYTES FROM BRAIN TO DETERMINE CELL SPECIFICITY OF GAP JUNCTION GENE EXPRESSION. D.J. Belliveau, J.F. Bechberger* and C.C.G. Naus. Dept. of Anatomy, University of Western Ontario, London, Canada, N6A 5C1.

The expression of gap junction genes for connexin32 and connexin43 have been described in the mammalian central nervous system. Cell specificity of gap junction expression has been demonstrated to some extent by the use of antibodies (Dermietzel et al. PNAS 86: 10148-52, 1989). Using previously described cell isolation techniques, we have separated neurons, astrocytes, and oligodendrocytes from adult Spraque Dawley rats (Farooq and Norton, J. Neurochem. 31: 887-95, 1978; Snyder et al., J. Neurochem. 34: 1614-21, 1980). Total RNA extracted from the cell isolation was analyzed using Northern blot analysis and cDNA probes specific for connexin32 and connexin43. Neurons and astrocytes expressed connexin32 and connexin43 mRNA respectively. Connexin32 was the major gap junction mRNA expressed in oligodendrocytes but a low level of connexin43 mRNA was detected and this was thought to be from an endothelial cell contaminant. RNA extracted from cultured endothelial cells confirmed the presence of connexin43 in these cells. The presence of connexin32 in neurons and oligodendrocytes and connexin43 in astrocytes was supported by the use of cell cultures. Similar cell isolation experiments during early postnatal development are underway to examine the developmental expression of gap junction genes in these various cell types.

153.4

PRIMARY CULTURES OF GUINEA PIG ASTROCYTES: HIGH YIELD FOLLOWING DISPASE DISSOCIATION. P.THAKRAN. M.P.LEUSCHEN. A.CHATTERJEE. R.M. NELSON Jr. Joint Division of Newborn Medicine, University of Nebraska Medical Center, Omaha, NE 68198

Primary monolayer cultures of neonatal guinea pig astrocytes were analyzed for yield and purity using a neutral protease Dispase (Collaborative Res. Inc., Bedford, MA.) dissociation and 3 different substrates. The method involved dissociation of cortices from 1-3 neonatal (0-48 hr) guinea pigs per experiment employing 5-6 extractions with Dispase(Frangakis, M. V., Neurochem, Res. 9:1689, 1984) during a maximum total dissociation time of 120 min. The cell suspension was passed through total dissociation time of 120 min. The cell suspension was passed through a 105 μ nylon mesh to remove meningeal remnants. Average cell yield was 15 to 20 X 107 cells/brain with initial viability of 97.7% cells excluding trypan blue. The cells were cultured in Dulbecco's Modified Eagle's Medium containing D-Glucose 4.5 g/L, sodium pyruvate 110 mg/L, Insulin 100 U/L, 100 X Vitamins 5ml/L (Gibco), penicillin 100,000 U/L, streptomycin 100 mg/L, amphotericin B 250 ug/l, supplemented with 20% fetal calf serum (FCS) for the first 48 hrs and 10% FCS subsequently. Three substrates were tested, collagen, poly-L-lysine and MatrigelTM (Collaborative Res, Inc). No significant difference in astrocyte yield was seen between collagen and poly-L-lysine (with an initial seeding density of 2.8 X 105 cells/cm² in 24-well plates, a saturation density in the third week of 3.7 X 105 cells/cm² and 2.9 X 105 cells/cm² was obtained on collagen and poly-L-lysine respectively). Contamination with collagen and poly-L-lysine respectively). Contamination with oligodendrocytes was high on MatrigelTM. Astrocytic purity was characterized by morphological response to 1 mM dbCAMP and immunohistochemistry (Vectastain ABC system, Vector Labs) with the astroglial marker, glial fibrillary acidic protein. This highly reproducible method produces high cell yield and viability for the primary culture of guinea pig astrocytes.

THE EFFECTS OF AXOLEMMA-ENRICHED FRACTIONS ON PO GENE EXPRESSION IN PRIMARY AND TRANSFORMED SCHWANN CELL CULTURES. R.M. Knight, B.L. Attema*, and G.H. De Vries. Dept. of Biochem. and Mol. Biophys., Med. Coll. of Va. Richmond VA 23298.

Primary Schwann cells (PSC) and transformed Schwann cells (TSC) were treated with axolemma-enriched fraction (AEF) and changes in Po gene expression were determined by changes in mRNA levels. AEF (40 ug/ml) caused a two fold increase in Po mRNA levels in the PSC and TSC cultures. Alkaline phosphatase treatment of AEF had no effect on the increase in Po mRNA induced by AEF, while trypsin treatment of AEF abolished the AEF induction of TSC Po mRNA. A myelin-enriched fraction did not increase Po mRNA levels in TSC. AEF isolated from nonmyelinated splenic nerve was as potent as AEF isolated from myelinated axons in increasing Po mRNA in PSC and TSC. Inhibition of transcription via α-amanitin caused a 36 fold decrease in Po mRNA levels, while PSC treated simultaneously with α-amanitin and AEF had Po mRNA levels which were increased 11 fold over cultures treated with α-aminitin alone. This data indicates that the signal for the induction of Po mRNA is not restricted to myelinated axons and that AEF induced increases in Po mRNA may be due to increased Po mRNA stability. (Supported by NIH NS10821 and NIH NS15408).

AN INTERMEDIATE FILAMENT-ASSOCIATED PROTEIN, IFAP-300kD, AS A MARKER FOR HUMAN ASTROCYTOMAS. G.D. Pappas, R.P. Glick*+, D. Shao*, D. Johnson-Seaton*, and H.-Y. Yang. Depts. of Anatomy and Cell Biology, and Neurosurgery+, Univ. of Illinois at Chicago, IL 60612. Intermediate filament (IF) proteins represent a group of cytoskeletal cell markers that can be used for immunotyping of human astrocytomas. For example, gliaf librillary acidic protein (GFAP), an IF structural protein specifically expressed in astrocytes, has been widely used as a marker for astrocytic tumors. In addition, vimentin, another IF structural protein that has been found tumors. In addition, vimentin, another IF structural protein that has been found in immature astrocytes and in some mature astrocytes, has been shown to be present in astrocytomas. However, the diagnostic usefulness of these two proteins is limited since they are normal IF constituents both in mature and reactive astrocytes. A 300kD intermediate filament-associated protein (IFAP) has been identified in baby hamster kidney (BHK) cells. (Yang, et al., J Cell Biol., 100:620, 1985) This IFAP is vimentin-associated, and has been found in many cell lines, including the C6 rat glioma cells. In the present study, the immunoreactivity of IFAP-300kD has been revealed by immunofluorescence in all human astrocytomas examined (including well-differentiated astrocytoma, anaplastic astrocytoma and glioblastoma multiforme) as well as in all primary cultures of stone of these tumors, but not in normal human brain tissue. The cultures of some of these tumors, but not in normal human brain tissue. The ontogeny of IFAP-300kD has also been studied in the CNS of rats. The results ontogeny of IFAP-300KD has also been studied in the CNS of rats. The results show that this IFAP normally is only expressed in radial glia. It was not detected in reactive astrocytes induced by stab wound, nor in neonatal rat astrocytes, either in <u>situ</u> or in primary culture, although all these astrocytes are vimentin/GFAP-containing. These results suggest that IFAP-300kD can be a marker for human astrocytomas. It is also important to note that, since this IFAP is not present in reactive astrocytes, it may be used clinically to define the boundary of the human astrocytomas. (Supported by NILL grant NSSSSOB). NIH grant NS26395)

153.9

GENERATION AND RELEASE OF 1-METHYL-4-PHENYLPYRIDINIUM ION (MPP+) BY PRIMARY CULTURES OF ASTROCYTES. E.Y. Wu*, B.M. Borgeson*, I. Irwin*, L.E. DeLanney, J.W. Langston, and D.A. Di Monte California Parkinson's Foundation and California Institute for Medical Research, San Jose, CA 95128.

The neurotoxic effect of MPTP is due to its conversion to the fully oxidized pyridinium metabolite, MPP+. This metabolic activation occurs via the MAO B-dependent generation of a dihydropyridinium intermediate, MPDP+. Because MAO B is found in astrocytes, it has been proposed that MPP+ is generated within these cells, released, and then taken up by dopaminergic neurons. To test this hypothesis, the mechanism of generation and release of MPP+ was studied in primary cultures of glia cells. Addition of MPTP (250 µM) to these cultures resulted in the production of three metabolites, MPP+, MPDP+ and MPTP N-oxide. MPP+ and MPDP+ together accounted for approximately 90% of the overall biotransformation of MPTP after incubation for 24 hours. Although presumably generated within the cells, MPDP+ was found predominately in the incubation medium. Interestingly, the concentration of MPDP+ in the medium did not increase over time, being 4.2 μM and 4.7 μM at 8 and 24 hours, respectively. In contrast, the extracellular level of MPP+ increased from 2.0 μ M at 4 hours to 5.6 μ M and 14.6 μ M at 8 and 24 hours, respectively. No evidence of cytotoxicity was found in astrocyte cultures exposed to MPTP for 24 hours. These results are consistent with the conclusion that MPP+ may be generated directly in the extracellular space via the autoxidation of MPDP+.

5-BROMODEOXYURIDINE REDUCES THE EXPRESSION OF Po IN SCHWANN CELLS. S.S. Scherer* L.G. Wrabetz, and J. Kamholz. Dept. Neurol., Univ. Penn. Sch. Med., Phila., PA 19104
The thymidine analogue 5-bromodeoxyuridine (BUdR) is incorporated

The thymidine analogue 5-bromodeoxyuridine (BUdK) is incorporated into DNA and reversibly delays cellular differentiation in a variety of cell types. We added 0.5 to 50 µM BUdR to secondary Schwann cells (SC) that had been previously expanded with glial growth factor and forskolin until they were able to proliferate without these mitogens. After one week in BUdR, almost all of the SC nuclei could be stained with a monoclonal antibody against BUdR, and this staining was markedly diminished by the addition of a 5-fold molar excess of thymidine to the medium

antibody against BUdR, and this staining was markedly diminished by the addition of a 5-fold molar excess of thymidine to the medium.

Untreated SC expressed nerve growth factor receptor (NGFR), as shown by staining with a monoclonal antibody, and contained the mRNA for both NGFR and the major myelin protein, Po, as shown by Northern blotting. After one week in BUdR, SC no longer expressed NGFR or Po, unless thymidine had been present in the medium. Futhermore, no Po mRNA was detected in BUdR-treated SC even after the addition of $4 \mu M$ forskolin, in marked contrast to the robust increase in untreated SC.

in untreated SC.

To determine whether BUdR has a cis- or a trans-acting effect on Po gene expression, SC were transiently transfected with a construct containing the Po promoter coupled to the chloramphenicol acetyl transferase (CAT) gene that had been previously shown to promote Po expression in a cell-specific manner (Lenke et al., Neuron 1: 73, 1988, construct pPCAT HA16). The BUdR-treated SC had as much CAT activity as the untreated SC, implying that BUdR had a cis-acting effect, probably as a consequence of its substitution for thymidine in crucial portions of the Po regulatory region. GLUTAMATE-INDUCED CHANGES IN INTRACELLULAR Ca ARE OSCILLATORY IN TYPE-I BUT NON-OSCILLATORY IN TYPE-II CORTICAL ASTROCYTES. A. Jensen* and S.Y.Chiu. Neuroscience Training Program & Dept. of Neurophysiology, University of Wisconsin, Madison, WI 53706.

A mixture of type-I and type-II cortical astrocytes was obtained from neonatal rat cortices following dissociation and plating for 1-4 months. Image analysis of glutamate-induced responses in intracellular Ca was performed on cells loaded with the Ca indicator fluo-3. Following each experiment, the same cells were double labeled with antibodies for correlating Ca repsonse with astrocyte phenotype (type-I is GFAP+ and A2B5-, type-II is GFAP+ and A2B5+). In response to bath application of 30, 100 and 500 µm glutamate, all type-I cells which responded (75-85%) did so in an oscillatory manner. In contrast, all type-II cells which responded (85-100%) exhibited a slow and maintained increase in [Ca]i; this kind of response was seen both in cell soma and the fine processes. Interestingly, in type-II cells, the glutamate-induced increase in [Ca]i was markedly reduced in 13 out of 16 cells by $100~\mu m$ nifedipine, a blocker of L-type calcium channels. In Ca-free bath, the % of cells responding to glutamate is reduced to 76% and 9% for type-I and -II respectively, relative to control with Ca present. Depolarization with 70 mM K+ increased [Ca]i in all type-II cells, but no increase was seen in type-I cells. These findings are consistent with the hypothesis that the [Ca]i increase observed in type-II cells is via voltage-gated calcium channels activated by glutamate-induced depolarization through ionotropic glutamate receptors and that the type-I response is mediated

via the second messenger-linked metabotropic glutamate receptor. Supported by NS-23375 (NIH) and RG-1839 (National MS Society)

PREFERENTIAL GLIAL UPTAKE OF RUBIDIUM IN LEECH CNS AS DETERMINED BY X-RAY MICROPROBE ANALYSIS. A. J. Saubermann, C. Castiglia*, and M. F Foster. Dept. of Anesthesiology,

SUNY at Stony Brook, Stony Brook NY 11794-8480.

Glial cells are thought to play an important role in K homeostasis by clearing, and transiently holding, K from extracellular space (ECS) during neuronal activity and then returning K to adjacent neurons. We have used Rb as a K tracer to determine if glial Rb uptake occurs before adjacent neuron uptake. Determination of such a lag is critically important for confirming the K cycle hypothesis and for obtaining a means to study mechanisms of neuronal K repletion. Ganglia dissected from Macrobdella decora were perfused in either 4 or 20 mmol Rb substituted leech Ringer's solution (LRS) following an equilibration period of 20 min in normal LRS (4 mmol K). Ganglia were perfused for measured time periods ranging from 15 sec to 10 min, rapidly frozen in Freon 22, cryosectioned and subjected to x-ray microanalysis in the frozen hydrated and dried state. Rb, K, Na, and Cl mass fractions were determined (mmol/kg wet wt and dry wt). Following 30 sec of perfusion with 4 mmol Rb LRS, glial cells had exchanged 7% of their K for Rb and <1% in adjacent neurons. Whereas, glial cells in ganglia stimulated with increased ECS Rb (20 mmol LRS) for 32 sec exchanged 44% of their K for Rb, and neurons 13%. After 10 min of 4 mmol Rb LRS, 61% of glial K was exchanged with Rb and only 48% of neuronal K was exchanged. However, after 10 min of 20 mmol Rb LRS, 85% of the glial cells' K was exchanged for Rb compared to 88% of the neurons' K. The faster and, hence, preferential glial Rb uptake rate compared to adjacent neurons supports the K cycle hypothesis and offers a means to study mechanisms of K repletion. RECURRENT SPREADING DEPRESSION INCREASES GFAP STAINING. R.P. Kraig' & C.B. Jaeger². 'Dept. of Neurol. Univ. of Chicago, Chicago, IL & 'Ctr. for Paralysis Res., Purdue Univ., Lafayette, IN.

Reactive gliosis (RG) that is seen after virtually every type of brain injury, may modulate the ultimate severity of associated tissue damage, and yet the molecular mechanisms of the process remain undefined. In other eukarytoic cells a rise in Kto or pH are proposed as signals capable of triggering proliferation and anabolism. Spreading depression (SD) is a stereotypic perturbation of brain with K', and astrocytic pH, changes which we have begun to use in order to define the ionic concomitants which may be necessary for RG.

SD was induced in halothane anesthetized rats (n=20) by application of KCl to parietal cortex for 3 hrs; equimolar NaCl was applied to the contralateral side. SD was confirmed by DC recording of SD made in frontal cortex. Animals were allowed to recover for 48 hrs and then their brains were processed for quantitative immunohistochemical analysis of GFAP staining because this is one, important defining characteristic of RG. SD (13-37 SDs; n=14) correlated with a significant (p<0.01; student's t test corrected with Bonferroni correction) increase in GFAP staining compared to controls (n=3). If SD was prevented (n=3), no significant increase in GFAP occurred.

These results show that SD can be used to study RG and that RG can be prevented. If this is also true for conditions associated with irreversible neuronal injury, it may be possible to prevent or mitigate any inhibition of regeneration or worsening of ultimate neural deficit dependent on RG.

153.13

SODIUM CHANNEL EXPRESSION IN ASTROCYTES FROM RAT OPTIC NERVE IN VITRO J.E. Minturn, J.A. Black, K.J. Angelides^{1*} H. Sontheimer, B.R. Ransom, and S.G. Waxman. Dept. Neurology, Yale Univ. Sch. Med., New Haven, CT, 06510 and ¹Dept. Physiol. and Molec. Biophys., Baylor Coll. Med., Houston, TX 77030.

Astrocytes cultured from neonatal rat optic nerve can be classified into two subtypes, based on morphology and ability to bind antibody A2B5. The presence of sodium channels in astrocytes cultured from rat optic nerve was demonstrated by indirect immunofluorescence with polyclonal antibody 7493. Astrocytes cultured from postnatal day 7 (P7) optic nerves exhibited sodium channel immunostaining on both cell subtypes (A2B5+ and A2B5-) up to 6 days in vitro (DIV). In addition, both cell types showed Na* currents when examined by whole-cell voltage-clamp. Interestingly, the cell subtypes differed with respect to Na+-current inactivation. After 6 DIV, the A2B5/GFAP+ cells exhibited a loss of sodium channel immunostaining, while the A2B5* astrocytes continued to react to 7493. This staining pattern persisted up to 28 DIV continued to react to 1493. Inis staining pattern persisted up to 20 DIV (latest time point examined). Astrocytes cultured from P0 rat optic nerves, in which the vast majority are A2B5/GFAP*, exhibited sodium channel staining in a pattern similar to the P7 astrocytes. After 6 DIV, the A2B5 astrocytes showed loss of 7493 immunoreactivity, while the rare (<1%) A2B5* astrocytes continued to express sodium channels reactive to 7493. The reduction of sodium channel immunoreactivity in A2B5 but not A2B5* astrocytes from both P0 and P7 optic nerves after a similar latency (~6 DIV) suggests that the loss of immunostaining may result from the absence of neuronal associations in the culture environment, rather than an intrinsic biologically-timed loss of sodium channel expression. An analysis of the time-course of Na+-current expression and its correlation to immunostaining is in progress.

REACTIVE ASTROCYTES AND DIBCAMP-TREATED ASTROCYTES HAVE DIFFERENT SURFACE MARKERS <u>F.</u> Wandosell*, P. Bovolenta and M. Nieto-Sampedro. Neural Plasticity Lab., Cajal Institute, 28002 Madrid, Spain.

Epithelioid astroblasts can easily be maintained in culture, but it would also be desirable to have in vitro models of mature protoplasmic and reactive astrocytes. An essential step to develop such models is the description of differential markers for these astrocytes. Antibodies to a dodecapeptide of the extracellular domain of the human EGF receptor (EGFR) bind to rat astrocyte plasma membranes, and discriminate between newborn rat astroblasts and resting and reactive astrocytes from adult animals. Anti-peptide A (residues 513-524 of EGFR) intensely stained cultured astrocytes. In Western blots of membranes from cultured polygonal astrocytes (astroblasts) and C6 glioma cells, the antibody recognized bands of apparent molecular weigth 115, 87 and 68 and much more weakly with a 170 kD band. A similar reaction pattern with an additional 50 kD band was observed with membranes from the same cells after assuming star-shaped morphology brought about by 48 hours treatment with di-butyryl-cAMP. Parallel blots with membranes from adult rat brain showed basically a 87 kD band and, in membranes prepared from tissue 15 days after an open injury, an additional band of 91 kD. These results suggest that the surface of diBcAPM-treated astroblasts is very similar to that of the untreated cells and that both are inaccurate models of mature protoplasmic and reactive astrocytes. (Supported by a grant from the Spanish Science Research Council).

IMMUNO-ULTRASTRUCTURAL LOCALIZATION OF SODIUM CHANNELS IMMUNO-ULIKAS INUCTURAL LOCALIZATION OF SODIUM CHARREST IN DEMYELINATED RAT SPINAL CORD J.A. Black¹², P.A. Felts, B. McKay¹², K.J. Smith¹⁴, S.G. Waxman¹² and K.J. Angelides³. Dept. of Neurology¹, Yale Univ. Sch. Sch., Norfolk, VA 23501, Dept. of Neurology', Guy's Hospital Med. Sch., London SE1 9RT, U.K., and Dept. of

Physiology and Molecular Biophysics⁵, Baylor Col. Med., Houston, TX 77030.

Myelinated fibers exhibit spatial heterogeneity of the macromolecular organization of the axon membrane, with voltage-sensitive sodium channels present in much higher density within the axolemma at nodes of Ranvier than within internodal axon membrane. Demyelination of myelinated fibers leads to conduction block, which may result, in part, from the dispersion of sodium channels along the axon membrane from the nodal axolemma.

The dorsal columns of adult rat spinal cords were experimentally demyelinated by injection of ethidium bromide, and then irradiated to retard remyelination. The lesioned areas were processed for sodium channel localization utilizing antibody 7493 and HRP immunocytochemistry, which has been previously shown to densely immunostain nodal axon membrane.

Most regions of demyelinated axon membrane did not exhibit sodium channel immunoreactivity; however, occasional focal sites of sodium channel immunostaining were observed. Usually, these discrete regions were associated with glial processes. When the demyelinated axons became ensheathed by oligodendrocytes or Schwann cells, the axon membrane displayed moderately intense 7493 immunostaining. These data suggest that, following demyelination, there is a reorganization of sodium channels along the axon membrane.

SODIUM CHANNELS IN THE CYTOPLASM OF SCHWANN CELLS J.M. Ritchie¹, J.A. Black²³, S.G. Waxman^{1,23} and K.J. Angelides^e. Depts. of Pharmacology¹ and Neurology², Yale University School of Medicine, New Haven, CT 06510, PVA/EPVA Neuroscience Center³, VAMC, West Haven, CT 06516, and Dept. of Physiology and Molecular Biophysics, Baylor College of

Medicine, Houston, TX 77030.

It has become clear that Schwann cells in culture express voltage-gated sodium channels. However the physiological and pharmacological studies carried out to date provide little data about localization, within Schwann cells, of sodium channels. In the present study, immunoblotting, ultrastructural immunocytochemistry and saxitoxin (STX) binding experiments were used to

study the distribution of sodium channels in Schwann cells.

Polyclonal antibody 7493, which is directed against purified sodium channels from rat brain, specifically recognizes a 260 kDa protein, corresponding to the alpha subunit of the sodium channel in immunoblots of crude glycoproteins from rat sciatic nerve. Electron microscopic localization of sodium channel immunoreactivity within adult rat sciatic nerves reveals heavy staining of the axon membrane at the node of Ranvier, while internodal axolemma displayed a lack of immunoreactivity. Perinodal Schwann cell processes also exhibit immunoreactivity, localized both within the Schwann cell cytoplasm and the plasmalemma. STX binding was studied both in intact rabbit cultured Schwann passinatemia. 31 A billing was studied out in Intelligence and after homogeneization. Saturable binding of STX was significantly higher in homogenized Schwann cells (410±37 fmole/mg protein) than in intact Schwann cells (214±21 fmole/mg protein). Moreover, the equilibrium dissociation constant was higher for homogenized preparations (1.77±0.37 nM) than for intact Schwann cells (1.06±0.29 nM). These data suggest the presence of an intracellular pool of sodium channels in Schwann cells.

A NOVEL ANTIGEN DEVELOPMENTALLY REGULATED IN OLIGODENDROCYTES. M.M. Daston and N. Ratner. Dept. of Anatomy and Cell Biology., Univ. of Cincinnati-College of Medicine, Cincinnati, OH 45267.

We have examined the cellular localization within the CNS of a novel protein, p30, in order to gain insight into its possible function(s) in the development of the nervous system. P30 was initially described as a protein present in the CNS of young rats, isolated based on its ability to promote adhesion and neurite outgrowth of embryonic brain cells in culture (Rauvala and Pihlaskari, 1987, J. Biol. Chem., 262:16625-16635).

Immunostaining of tissue sections from rats at various ages and of cultured optic nerve cells was performed using polyclonal antibodies generated against a synthetic peptide (p30 N-terminal 1-13, Rauvala et al., 1988, J. Cell Biol. 107:2293-2305) and against intact p30.

P30 is expressed in the developing CNS in cells that extend processes which end in myelin sheaths, suggesting that they are oligodendrocytes. Galactocerebroside-positive oligodendrocytes in cultures of rat optic nerve are also labelled by anti-p30. Oligodendrocytes labelled by anti-p30 are first apparent in the spinal cord at P1 and are most numerous at P8. In the adult spinal cord anti-p30 labelled oligodendrocytes are infrequent. P30 staining is also present, at much lower levels, in most or all developing CNS neurons. Neuronal staining persists into adulthood. The expression of p30 in numerous oligodendrocytes in early postnatal development and a sub-population of oligodendrocytes in the adult is consistent with the hypothesis that p30 expression is limited to actively myelinating oligodendrocytes. Supported by the National MS Society and NIH-NS27227.

ADULT AND FETAL ASTROCYTES IN CULTURE DIFFER IN MORPHOLOGY AND GFAP EXPRESSION. M.S. Bull, J. Qian, A. Tessler and P.Levitt, Dept. Anatomy, Medical College of Pa., Phila., PA 19129.

Astrocyte differentiation and growth in the developing brain are regulated by a complex array of environmental factors. The regulation of

growth of adult astroglia, however, is still poorly understood. We have begun culturing astrocytes from the spinal cord of one year old rats and comparing their growth, morphological and immunohistochemical properties with those of embryonic day (E) 18 spinal cord astrocytes in order to study the cellular processes regulating adult astrocyte growth. The results of these comparisons show marked differences in the complexity of astroglial morphologies and level of GFAP immunoreactivity between adult and fetal astrocytes prepared and cultured under similar conditions, even when the astrocytes prepared and cultures distinate similar conditions, even which interest effects glila are maintained for several months. Whereas adult astrocytes grow slowly, tend to be of similar morphology (Type I) and have low overall GFAP expression, fetal astrocytes grow quickly and are separable into different morphological types (both I and II) with high GFAP expression. In addition, pronounced cytoplasmic tangles, which are GFAP-immunoreactive, are often visible in the somas of adult astrocytes but never in embryonic astrocytes. These findings indicate that in culture, the capacity for morphological differentiation of adult astrocytes is different from fetal-derived astroglia. In addition, the results raise the possibility of substantial age-related changes in adult astrocytes that are never expressed by fetal astroglia, even when maintained for long periods of time *in vitro*. Supported by VA Medical Research Service, USAMRDC grant 5193002, and NIH-NS24707.

BRAIN GANGLIO-N-TETRAOSYLCERAMIDE (GA1): PRESENCE IN ADULT BOVINE AND HUMAN MYELIN. E.L. Hogan and S. Dasgupta*. Dept Neurology, Med Univ of SC, 171 Ashley Avenue, Charleston, SC 29425-2232.

Ganglio-N-tetraosylceramide (GgOse4Cer) is also designated GAl or asialo-GMl. Its presence in mouse CNS wyelin has been indicated by immunchiated and control of the co

myelin has been indicated by immunohistology (Kusonoki et al., Brain Res. 334, 117, 1985). We have purified a neutral glycosphingolipid (GSL) from bovine brain by column chromatography. The purified homogenous compound column chromatography. The purified homogenous compound has an Rf near pentaglycosylceramide of bovine RBC. The gal:galNAc:glc molar ratio is 2:1:1. Permethylation analysis and stepwise hydrolysis with β -galactosidase and β -hexosaminidase indicated its structure as $\operatorname{Gal}\beta(1-->3)$ $\operatorname{GalNac}\beta(1-->4)$ $\operatorname{Gal}\beta(1-->4)$ GlcCer (GAl). The ceramide contains sphingosine and C18:0, C18:1 and C16:0 fatty acids. GAl has been detected in bovine and in human myelin by tlc. Another neutral GSL has also been purified and tentatively characterized as $\operatorname{IV}^3\operatorname{Gal}$ $\operatorname{III}^3\operatorname{GalNAc}$ GbOse₃Cer (Gal GbOse₄Cer) by GC. This GSL has been reported in a human teratocarcinoma cell line (Kannagi et al. The EMBO J. 2, 2355, 1983). This is, to our knowledge its first identification in the nervous system. Purification for complete characterization and NMR characterization of the purified GAl and determination in brain cellular and subcellular compartments is presently being done. presently being done.

PHOSPHORYLATION OF GFAP AND VIMENTIN BY A CYTOSKELETAL-ASSOCIATED INTERMEDIATE FILAMENT PROTEIN KINASE ACTIVITY IN CULTURED ASTROCYTES. B.C. Harrison and P.L. Mobley. Univ. Texas Health Science Center, San Antonio, TX, 78284.

A cytoskeletal-associated protein kinase is present in cultured astrocytes which is capable of phosphorylating the cytoskeletal proteins glial fibrillary acidic protein (GFAP) and vimentin. Studies were conducted to determine if the intermediate filament protein kinase (IFPK) activity was distinct from that of protein kinase C (PK-C) and the cyclic AMP-dependent protein kinase (PK-A). All three kinases phosphorylated GFAP and vimentin, and the sites of phosphorylation of these proteins were compared by 2-dimensional tryptic peptide mapping. Although there were sites of phosphorylation common to all the kinases, the IFPK produced unique phosphopeptide maps of both GFAP and vimentin. Phosphoamino acid analysis was also conducted GFAP and vimentin. Phosphoamino acid analysis was also conducted to determine which amino acids were phosphorylated by the IFPK, PK. C and PK-A. The IFPK increased the ³²P-incorporation into both serine and threonine residues of GFAP and vimentin. PK-A increased the ³²P-incorporation into only serine residues of the proteins, while PK-C increased the ³²P-incorporation into serine and threonine residues of GFAP, and serine residues of vimentin. Vimentin and GFAP have been shown to be phosphorylated by PK-C and PK-A in the aminoterminal domain. The IFPK also phosphorylated GFAP in the aminoterminal domain; however, the IFPK was capable of phosphorylating both the amino- and carboxy-terminal domains of vimentin. Therefore, these studies suggest that the IFPK activity observed in cultured astrocytes is distinct from that of PK-C and PK-A, and is capable of phosphorylating unique sites on GFAP and vimentin.

EXPRESSION OF AN INTERMEDIATE FILAMENT-ASSOCIATED PROTEIN, IFAP-70/280kD, IN RADIAL GLIA AND IN REACTIVE ASTROCYTES OF RATS. H.-Y. Yang, V. Kriho*, D. Johnson-Seaton*, and G. D. Pappas. Dept. of

H.-Y. Yang, V. Kriho*, D. Johnson-Seaton*, and G. D. Pappas. Dept. of Anatomy & Cell Biology, University of Illinois at Chicago, IL 60612. Injury to CNS results in gliosis. The reactive astrocytes are characterized by their augmented intermediate filament (IF) cytoskeleton, in which two IF structural proteins, glial fibriliary acidic protein (GFAP) and vimentin, have been found. Because vimentin is a major IF constituent of immature astrocytes, the expression of this protein may suggest an immature cell state. However, vimentin is found to be present in many mature astrocytes in the white matter. Our research is currently concentrated on expression of intermediate filament-associated proteins (IFAP) in cells of astrocytic lineage. Recently, we have identified an IFAP, IFAP-70/280KD, in a subgroup of non-stellate (type-1, based on morphology) reportal astrocytes in primary cultures. The ontoceny of this identified an IFAP, IFAP-70/280kD, in a subgroup of non-stellate (type-1, based on morphology) neonatal astrocytes in primary cultures. The ontogeny of this IFAP has also been studied by immunofluorescence in rat spinal cord from E12 through postnatal day 28, as well as in adult rats. The IFAP-70/280kD immunoreactivity was detected in the radial gial cells from the earliest day examined, diminished following the expression of GFAP in these cells, and disappeared totally in spinal cord astrocytes after postnatal day 5. The immunoreactivity of this IFAP was not found in mature astrocytes in reactive astrocytes. However, the immunoreactivity of this IFAP was detected in reactive astrocytes of rat brain induced by stab injury with a needle. We have used double-labeling immunofluorescence microscopy with antibodies to GFAP and IFAP-70/280kD (or vimentin) to study the gliotic reaction as it occurred from 4 hrs to at least 20 days post-lesion in the area of the wound. The results show that the vimentin/GFAP-containing astrocytes appear first in the wound area at 8 hrs post-lesion, and the IFAP-70/280kD/GFAP-containing astrocytes appear at 2 days post-lesion. The results indicate that the reactive astrocytes are different from the mature astrocytes by their expression of IFAP-70/280kD which is expressed in radial glia-related cells, and that these astrocytes may be derived from type-1 astrocytes. (Supported by NiH grant NS26395)

ISOLATION AND CHARACTERIZATION OF SCHWANN CELLS DERIVED FROM ADULT NERVE. T.K. Morrissey, N.Kleitman and R.P. Bunge, The Miami Project to Cure Paralysis, University of Miami School of Medicine, 1600 NW 10 Ave., R48, Miami, F1 33136.

Should implants of Schwann cells (ScCs), or prosthetic devices containing ScCs, prove to be a practical approach to treating spinal cord injury it would

be advantageous to be able to harvest and grow a patient's own ScCs for autologous grafting. Toward this end we have been studying methods of purifying and amplifying ScCs obtained from adult peripheral nerve. Adult rat sciatic nerves were removed and enzymatically dissociated either immediately or following a period of 'in vitro Wallerian degeneration' as 1x1mm explants in tissue culture. Immediate dissociation yielded populations of cells containing less than 20% ScCs. Contaminating cells were mostly endoneurial fibroblasts. Conversely, serial explantation of explants over 4-5 weeks decreased fibroblast contamination as these grow out from the explants. After these explantations, dissociation yielded up to 98% pure ScCs. ScCs from this source retained functional capacity in that they associated with sensory neurons in culture and form myelin under appropriate conditions These cells proliferated in response to axonal mitogens as well as in the presence of GGF and forskolin. Studies are underway to determine the most efficient way to acquire large numbers of these cells. Concurrently we are applying these techniques to adult human peripheral nerve. Preliminary results indicate that serial explantation yields a purer population of ScCs than primary dissociation. It thus appears to be possible to obtain quite pure populations of Schwann cells by simple culture methods; it remains to be determined, however, how extensively this population can be expanded while retaining growth control and full functional capacity.

Supported by NS09923 and the Miami Project to Cure Paralysis.

OXYGEN RADICAL INDUCED CELL DEATH OF OLIGODENDROCYTES IN CULTURE. Y.S. Kim* and S.U. Kim. Division of Neurology, Univ. British Columbia, Vancouver, B.C. V6T lW5. Canada.

Previous studies have suggested that oxygen radicals and lipid peroxidation may be implicated in the irreversible loss of neurons and glial cells following brain or spinal cord injury, degenerative neurological diseases such as Parkinson disease and Huntington disease and in multiple sclerosis. The cytotoxic effects of oxygen radicals have been studied in enriched population of mature bovine oligodendrocytes in culture. Oxygen radicals were generated enzymatically by glucos and glucose oxidase, and hypoxanthine and xanthine oxidase. Cytotoxicity was assessed by trypan blue exclusion and percent lactate dehydrogenase release into the media. Incubation of oligodendrocytes with these oxygen radical generating systems for 4 h resulted in significant cell death, especially in the glucose oxidase system. The cytotoxic effects were completely protected by catalase in both oxygen radical generating systems. However, superoxide dismutase, dimethylsulfoxide and antioxidants such as vitamin E and glututhione did not protect the oxidant-mediated cytotoxicity of oligodendrocytes. It appears that hydrogen peroxide is a major toxic oxidant in these oxygen radical generating systems to induce the cell death of oligodendrocytes.

IMMUNOCYTOCHEMICAL LOCALIZATION OF CHLORAMPHENICOL ACETYL TRANSFERASE (CAT) IN BERGMANN CLIA OF THE CEREBELLUM IN TRANSGENIC MICE EXPRESSING HUMAN IMMUNODEFICIENCY VIRUS-LONG TERMINAL REPEAT-CAT (HIV-LTR-CAT) CONSTRUCTS. RICHARD E. HARLAN AND OM PRAKASH.* Department of Anatomy, Tulane Medical School (REH) and Dept. Mol. Oncology, Alton Ochsner Medical Foundation (OP), New Orleans, LA 70112 and 70121. Involvement of the nervous system in HIV infection

Involvement of the nervous system in HIV infection has been demonstrated in 70-80% of AIDS cases at autopsy. The nature of this neurotropism is not well understood. Glial cells are a primary target for HIV infection and replication.

Transgenic mice bearing the LTR of HIV fused to the bacterial reporter gene CAT were constructed. One line of mice showed high, constitutive levels of CAT activity in the cerebellum, compared to other brain regions. Immunocytochemical analysis using a polyclonal antibody to CAT (5-Prime-3-Prime, Inc.) revealed intense immunostaining of Bergmann glia. Immunostaining was found in the cell body and throughout the processes extending through the molecular layer. Subpopulations of glia (presumably astrocytes) in the cerebral cortex, caudate-putamen and olfactory bulb were also immunostained. No staining was seen in non-transgenic mice. It is likely that certain glial cells express proteins that transactivate the HIV-

STRUCTURE AND EXPRESSION OF THE HUMAN GENE FOR GLIAL FIBRILLARY ACIDIC PROTEIN (GFAP). F. Besnard*, E. T. Browning, M. Brenner*, R. Chao*, Y. Nakatani* and E.Freese, Lab. of Molec. Biol., NINDS-NIH, Bethesda, MD 20892, and Dept. Pharmacol., Robt. Wood Johnson Med. School, Piscataway, NJ 08854.

GFAP is an intermediate filament protein expressed almost exclusively in astrocytes. We have sequenced a 12 kb segment of a human genomic GFA clone; the sequence obtained contains the entire GFA coding region, 2 kb of the 5'-flanking region, and 0.5 kb of the 3'-flanking region. Comparison of this sequence to that of the mouse shows strong conservation of the size and sequence of the nine exons, but not of the introns. In particular, many of the sequence repeats present in the mouse introns were absent in the human sequence. For example, the (TG)₈(TC)₁₈(AC)₈ repeats in mouse intron 3 and the (TC)₂₈, 28 bp (R1) and 34 bp (R2) repeats in mouse intron 7 were not conserved in the human sequence. These results suggest that these repeats are not important for expression of the GFA gene.

To identify cis-acting sequence elements responsible for glial-specific GFA transcription, transient transfections were conducted with chloramphenicol acetyl transferase reporter gene constructs. A 2 kb 5'-flanking segment was active in the glial cell lines C6 and U251, but not in the non-glial cell lines HepG2 and HeLa, indicating that it contains cell-specific regulatory sites. Deletion analysis of this fragment identified two regions required for efficient expression; one located close to the RIAA start point, the other about 1.7 kb upstream. These two regions apparently act synergistically, as removal of either one drastically reduced expression. Interestingly, both regions contain similar sequences which display strong DNA footprints. (Supported in part by NSF Grant BNS-8708539).

NEURONAL SPECIFIC EXPRESSION OF THE HUMAN NEUROFILAMENT L PROMOTER IN A HSV-1 VECTOR. H.J. Federoff, A. Geller, and B. Lu. The Departments of Medicine and Neuroscience, The Albert Einstein Coll. of Med., Bronx, N.Y. 10461, The Dana Farber Cancer Institute, Boston, MA 02115.

10461, The Dana Farber Cancer Institute, Boston, MA 02115. The study of gene function and regulation in neurons has been hampered because of the difficulty of introducing genes into neurons. Recently, a Herpes Simplex Virus (HSV-1) vector has been developed that can efficiently transfer genes into cultured peripheral and central neurons (A. I. Geller and Breakefield, X.O. Science 241:1667, 1988, A.I. Geller and A. Freese, PNAS 87: 1149,1990). The prototype vector, pHSVlac, places the E. coll lac Z. gene, under the control of the HSV immediate early (IE) 4/5 promoter. The IE 4/5 promoter and therefore pHSVlac virus, expresses beta-galactosidase in many cell types including fibroblasts, glia and neurons. To determine if a neuronal specific promoter could function properly in a HSV-1 vector we replaced the IE 4/5 promoter with the human neurofilament L promoter (pNFLlac). Initial experiments performed by lipofection into three neuronal cell lines (PC12, NB2a, SKN-SH) and three non-neuronal cell lines (COS 7, NIH 3T3, and a glioblastoma) demonstrated marked neuronal specificity. The neurofilament promoter was 25-75 fold more active in neuronal than in non-neuronal cell lines. Neuronal specificity of expression of beta-galactosidase form pNFLlac virus is currently under study. The packaging of pNFLlac into viral particles will be performed using new HSV-1 deletion mutant packaging system.

ISOLATION AND CHARACTERIZATION OF cDNA CLONES ENCODING β -TUBULIN AND β -ACTIN FROM SQUID GIANT FIBRE LOBE. A.E. Gioio. L. Barbieri*. L.M. Turzai*. J.S. Stiffler*. C. Perrone*. A. Giuditta and B.B. Kaplan. Dept. of Psychiatry, Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA 15213. A cDNA library from squid giant fibre lobe total RNA was

constructed in a λ -zap vector using a modification of the Gubler-Hoffman method. The library contained approx. 6.0 X 10^7 pfu with insert sizes ranging from 600-4000 nucleotides in length. Library screening with rodent cDNA probes for β -tubulin and β -actin mRNAs yielded multiple positive plaques. One β -tubulin clone (pGFL-6) was 1874 bp in length and contained 118 and 424 bp of 5^7 and 3^7 untranslated sequence, respectively. Northern analysis using pGFL-6 and rat β -tubulin cDNAs as probes yielded a single major RNA species approx. 1.9 kb in length. Remarkably, squid β -tubulin manifests approx. 818 and 948 sequence similarity to the mammalian homologues at the nucleic acid and amino acid levels, respectively. Most of the variance represented conservative amino acid substitutions at the N- and C-terminal regions of the molecule. The β -actin clone isolated is approx. 2.0 kb in length

The β -actin clone isolated is approx. 2.0 kb in length and contains the entire coding region of the protein (1.1 kb) and 128 bp of 5' noncoding sequence. Sequence comparison to the murine form of the protein revealed >95% sequence identity at the amino acid level. Taken together, these findings demonstrate the marked evolutionary conservation of sequence manifest by these cytoskeletal proteins.

PROMOTERS OF RAT BRAIN TYPE I AND II SODIUM CHANNEL GENES SHARE A COMMON MECHANISM OF REGULATION. <u>S.D.Kraner, K.M.Dains, M.Azoulay, and G.Mandel</u>, Dept. of Neurobiology & Behavior, SUNY at Stony Brook, Stony Brook, N.Y. 11794.

The sodium channel is encoded by a multi-gene family whose members are expressed in a tissue-specific manner. The excitable rat pheochromocytoma cell line, PC12, expresses the type II sodium channel gene, but not the type I gene. We have previously reported that multiple negatively-acting elements within the 5'flanking region of the type II sodium channel gene confer cell-specificity in vitro. Reporter fusion genes containing this region are expressed to high levels in PC12 cells, but are silent in the skeletal muscle cell line, L6. Using a transient expression assay we have further characterized the strongest of these negatively-acting elements. Removal of sequences between -1051 and -938 nucleotides upstream of the type II promoter results in a ten-fold increase in fusion gene activity in L6 cells, and no change in expression in PC12 cells. We have now isolated a 4 kb piece of the 5'flanking region of the type I gene. Fusion genes containing this entire region, or 5' deletion mutants of this region, have been analyzed in a variety of cell types including PC12, L6, epithelial cells, and a human neuroblastoma cell line, SY5Y. The 4kb type I fusion gene is active in the SY5Y cells but inactive in PC12 cells. Sequential 5' deletions of the type I 5'flanking region result in inappropriate expression of the reporter gene in PC12 and L6 cells. Further analysis of the sequences and promoter activities of these two neuronal ion channel genes will facilitate identification of the elements involved in cell-specific regulation.

Analysis of Molecular and Cellular Variation in NCAM Expression Aoshuang Chen*, Brian Key*, Sue Haines*, Antonio Reyes*, Stephen Small*, and Richard Akeson Childrens Hospital Research Foundation, Cincinnati. Ohio 45229

Expression the the neural cell adhesion molecule (NCAM) is regulated at several levels. NCAM expression is restricted to discrete tissues and times of development. NCAM transcripts are initiated from identical genomic positions is several tissues and cell types. Initial studies suggest that function promoter elements are found within 800 bp of DNA immediately 5' to the start of transcription. This DNA segment contains additional putative regulatory elements which are being evaluated by transient transfection assays into neuronal and non-neuronal cells. Alternative splicing of the single NCAM gene generates a number of different transcripts. We have analyzed regulation of expression of an alternative exon, VASE, found in the fourth immunogluobulin-like domain. VASE appears primarily postnatally in rat brain and somewhat earlier in heart. Within the nervous system, PCR analysis of VASE levels indicates significant variation among brain regions with very low levels observed in the olfactory bulb and also in the olfactory epithelium. The cellular basis of the regulation of alternative splicing of NCAM regulation is differential glycosylation. An additional level of NCAM regulation is differential glycosylation of the NCAM polypeptides within distinct brain regions. Unique N-linked carbohydrate groups are found on NCAM from olfactory tissues but not other brain regions. These multiple levels of regulation of NCAM expression and NCAM form suggest that distinct NCAM forms may have varying biologic roles during nervous system development and function. Supported by grants HD21065 and DS00347.

CONSTRUCTION OF A HUMAN SPINAL CORD cDNA LIBRARY AND SUBTRACTIVE CLONING OF SPINAL CORD SPECIFIC cDNAs.

H. Kobayashi 1, H. Takahashi 2, K. Oyanagi 2, 1) Dept. of Neurology, 2) Dept. of Pathology Brain Res. Inst. Niigata University., Niigata 951, Japan. Neurodegenerative diseases are characterized by neuronal degeneration of specific neurons, e.g. degeneration of motoneurons in amyotrophic

Neurodegenerative diseases are characterized by neuronal degeneration of specific neurons, e.g. degeneration of motoneurons in amyotrophic lateral sclerosis. As the first step to understand molecular mechanisms of neuronal degeneration of spinal cord motoneurons, we have constructed a human spinal cord cDNA library and developed a strategy for isolating spinal cord specific genes by subtractive cloning. To isolate human spinal cord specific CDNAs, spinal cord specific [32P]-cDNA probes were generated by phenol emulsion-enhanced reaction (G. H. Travis and J. G. Sutcliffe., 1988). Approximately 0.5% of ten thousand colonies gave strong signals with the subtracted probe and individual spinal cord specific cDNAs were isolated. The results demonstrate that the subtractive cDNA cloning strategy is quite feasible for isolating genes which are differentially expressed in specific neurons.

GENERATION OF NCAM-TRANSCRIPT DIVERSITY. D.Barthels¹, G.Vopper¹*, C.Goridis²*, and W.Wille¹.¹)Inst. f. Genetik, University of Cologne, Köln, FRG, ²)Centre d'Immunologie, INSERM-CNRS, Marseille, France.
Neural call adhesics

Neural cell adhesion molecules (NCAMs) are cell surface glycoproteins known to be involved in several important events during vertebrate nervous system development. There exist three classes of NCAM-polypeptides (120, 140 and 180 kD) which differ mainly in size of their C-terminal extensions.

Alternative processing of primary RNA-transcripts has been shown as a major strategy to create diversity of the gene products. In the case of murine NCAM the various mRNAs are generated by alternative splicing and differential polyadenylation of transcripts of a single gene which contains at least 24 exons. Since exons 0-14 are common to all NCAM-mRNAs, the utilization of exons 15-19 determines whether the resulting protein is membrane-associated or has transmembrane and cytoplasmic domains.

With PCR and SI nuclease protection analyses we identi-

With PCR and S1 nuclease protection analyses we identified three additional alternative splice sites. The most complex pattern was detected at splice site a (exon borders 12/13), where at least five different combinations of sequences can be observed. The shortest extra segment consisted only of the trinucleotide AAG which was found to be inserted between exons 12 and 13 or 13 and 14 in several independent cDNA-clones, suggesting the existence of an unusual splicing mechanism in this region of the NCAM gene or a novel RNA editing system.

NK-10, A ZINC-FINGER ENCODING GENE DEVELOPMENTAL-LY EXPRESSED IN THE MOUSE BRAIN. R. Lange-Sablitzky*, D. Barthels, and W. Wille. Institute of Genetics, University of Cologne, Zülpicher Str. 47, D-5000 Köln 1, Fed. Rep. Germany

NK-10 has been cloned as cDNA from neonatal mouse cerebellar poly(A)*RNA in $\lambda gt11$. The NK-10 transcript is 1.85 kb in length containing a 0.4 kb 5'-non-coding region, an open reading frame of 1296 nt (coding for 432 AA), and a 3'-non-translated region of 0.16 kb carrying a noncanonic polyadeny-lation signal ATTAAA. The encoded NK-10 protein is composed of repetitive zinc-finger motifs exclusively, some of which are cryptic and non-functional (written below in square brackets). The overall organization of the fingers and pseudo-fingers is A-[B1]-[B2]-C1-C2-C3-C4-C5-[D]-E-[F]-G1-G2-G3-G4-G5.

The upstream region of the NK-10 gene contains a fairly good TATA-box consensus sequence followed by several major and minor cap-sites. An unusual feature of the genomic organization of NK-10 (the locus is unique and <u>not</u> a pseudogene) is the total lack of introns. NK-10 is expressed during the entire late embryonic and postnatal development of the brain with a peak relative level at approx. 3-7 days after birth. No expression was found in the liver as determined by SI nuclease protection assay. Financed through DFG-SFB 243 grant to WW.

154.10

MOLECULAR HOMOLOGY OF A NEUROGLIAL GENE EXPRESSED IN DROSOPHILA AND HUMAN NERVOUS SYSTEMS. J. Martin*, M. Rudnicka*, J. Thomas*, and C. Miller. Department of Pathology, University of Southern California, School of Medicine, Los Angeles, CA 90033.

Monoclonal antibodies have identified immunocytochemical cross-reactions among cells in the human and Drosophila nervous systems (Miller and Benzer, PNAS 80:7641-7648, 1983). We are now exploring which of these represent homologies at the primary sequence level. MAb 23E9 identifies cells in Drosophila retina and optic lobes as well as human oligodendroglia and neurons (Rudnicka et al., J. Neuropath. Exp. Neurol. 48:363, 1989). Using the MAb, cDNA clones have now been isolated from both Drosophila and human brain cDNA \(\text{ gtll expression libraries.} \) A Drosophila cDNA clone has a 1600bp insert, including 1500bp of open reading frame. The nucleotide sequence and deduced amino acid sequence show no identity with any protein in the NBRF Protein Sequence Data Base. In situ hybridization with this clone shows localization to the Drosophila retina in a pattern closely similar to the immunocytochemical staining. Western blots with MAb 23E9 show immunoreactivity with a 220kDa protein on fly head homogenates and two bands of 130 and 80kDa on human brain homogenates. The human cDNA clone of 1600bp cross-hybridizes strongly with the Drosophila cDNA clone on Southern blots. These results suggest possible evolutionary conservation of this gene.

ORGANIZATION OF THE RAT AND THE HUMAN B-50 (GAP-43) GENE. L.H. Schrama, H.B. Nielander*, A.J. van Rozen*, P. Schotman*, and W.H. Gispen* Div. Mol. Neurobiol., Rudolf Magnus Inst., Lab. Physiol. Chem., Inst. Molec. Biol. & Med. Biotechnol., Univ. of Utrecht, Padualaan 8, 3584 CH Utrecht, NL.

The neuron-specific phosphoprotein B-50 (GAP-43) has been shown to be associated with axon development and regeneration. How B-50 transcription is regulated is currently not understood. B-50 is encoded by a single copy gene. The increase in B-50 protein expression during regeneration of the n. ischiadicus is preceded by an increase of B-50 mRNA (Van der Zee et al., *J. Neurosci.*, 9:3505, 1989).

In order to elucidate the regulation of B-50 transcription, we have isolated coding and non-coding portions of the human and the rat B-50 gene, and determined the exon/intron structure of the human B-50 gene. The human exon 2 encodes for amino acids 11-209 and contains the first nucleotide of amino acid 210, and exon 3 encodes for the remainder of the protein. The 10 amino acid insert present in the human B-50 protein as compared to the rat B-50 protein is encoded by exon 2. Currently we are subcloning the human exon 1 using inversed PCR of a 1.8 kb genomic fragment containing exon 1. We have sequenced a 0.8 kb HindIII - NheI fragment upstream of the translation start of the rat B-50 gene. This presumed promoter region of the rat B-50 gene contains repetitive sequences capable of forming H-DNA and Z-DNA. In contrast to recent results published by others (Grabczyk et al., <u>Soc. Neurosci.</u> Abstr., 15:381.3, 1989, Nedivi et al., Soc. Neurosci. Abstr., 15:503.15, 1989), we found that the 0.8 kb fragment also contains consensus sequences for binding of regulatory and transcription factors, including those for AP-1 and the TATA box. Currently the promoter activity of the elements upstream of the proposed various transcription starts is tested in embryonal carcinoma (EC) and PC12 cells after neuronal differentiation using luciferase as the reporter gene.

CHROMOSOME MAPPING AND MUTATIONAL ANALYSIS OF THE NEURON-SPECIFIC PROTEIN, SNAP-25. M.C. Wilson, C.A. Kozak*, T.N. Sato and E.J. Hess, Dept. of Neuropharmacology, Research Institute of Scripps Clinic, La Jolla, CA 92037 and NIH, Bethesda, MD 20892. SNAP-25 is a neuron-specific synaptosomal associated protein which appears to

contribute to synapse formation. In order to better characterize SNAP-25 expression and function, we have mapped the SNAP-25 gene. The SNAP-25 restriction fragment length polymorphisms (RFLPs) observed in the southern blot analysis of a panel consisting of 24 hamster-mouse somatic cell hybrids demonstrated that SNAP-25 is located on mouse chromosome 2. Further analysis of 72 recombinant inbred mouse strains using a Sca I RFLP situated the SNAP-25 locus approximately equidistant between marker genes *Hdc* and *Psp* in the medial region of mouse chromosome 2, 49 to 57 centimorgans from the centromere. Several mouse mutants map in this region of chromosome 2, including the recessive mutants blind sterile (bs), undulated (un), lethal milk (lm) and the semi-dominant mutation coloboma (Cm). Brain RNA and protein was prepared from each mouse mutant and a control littermate; no difference in the mobility of SNAP-25 mRNA or protein was observed among the mutants. However, a ~50% reduction in SNAP-25 mRNA expression and a ~50% reduction in SNAP-25 protein expression was observed on Northern and Western blots, respectively, of the heterozygous mouse mutant, coloboma (Cm/+); the coloboma mouse mutant is a neurological mutant whose phenotype includes opthalmic deformation and stereotypic head shaking, a phenotype which may be consistent with a reduction in SNAP-25 expression. Further experiments are underway including extensive Southern blot analyses of coloboma genomic DNA to determine if the coloboma phenotype is a result of a mutation in the SNAP-25 gene. Supported by PHS CA33730, NS23038 and an American Epilepsy Society Research Fellowship.

154 12

ISOLATION AND CHARACTERIZATION OF THE CHICKEN GENE FOR SNAP-25. Christina Bark. Dan Larhammar#. and Michael C. Wilson##. Department of Developmental Biology, #Department of Medical Genetics, Uppsala University, S-751 23 Uppsala, Sweden. ##Scripps Clinic and Research Foundation, La Jolla, CA 92037, USA

SNAP-25 (synaptosome-associated protein-25) has been shown to localize to presynaptic terminals in certain subpopulations of neurons in mouse and chicken (Oyler et al., 1989; Catsicas et al., submitted). The exact biological role of the SNAP-25 protein has yet to be resolved. Potential functional protein domains include a cluster of four cysteine residues that could mediate binding of metal ions as well as an amphipathic alpha helix that may interact with the synaptosomal membrane. The SNAP-25 protein shows a remarkable degree of evolutionary conservation in that the chick and mouse proteins are identical throughout the 206 amino acids and show 60% sequence identity to the *Drosophila* protein.

The precise onset of gene expression at the time of synaptogenesis and also the localization of SNAP-25 to only a subset

of neurons suggests a stringent regulatory control of the gene at the molecular level. In order to analyze in more detail the *cis-* and *trans-*acting elements influencing gene activation, the chicken gene for SNAP-25 has been isolated. Preliminary characterization indicates that the gene contains at least eight exons that may span as much as 50 kilobasepairs. Exon organization as well as promoter structure will be discussed. (Supported by the Swedish Natural Science Research Council, B-BU9714-300, C.B.)

154.14

STRONG EVOLUTIONARY CONSERVATION OF SNAP-25 BETWEEN DROSOPHILA, GOLDFISH, CHICKEN, AND MOUSE. C. Risinger*, A. G. Blomgvist*, I. Lundell*, S. Catsicas#, M. C. Wilson##, and D. Larhammar. Dept of Medical Genetics, Uppsala University, Box 589, S-751 23 Uppsala, Sweden. #Institute de Biologie Animale, Lausanne, Switzerland. ##Scripps Clinic, La Jolla, CA, U.S.A. SNAP-25 is a 25-kDa protein which is expressed exclusively by

some neuronal subpopulations. It is localized to presynaptic nerve terminals and is associated with synaptosomal membranes (Oyler et al., 1989). Its onset of expression correlates precisely with the time of synaptogenesis and indicates a role in this process (Catsicas et al., submitted)

We have previously shown that the chick and mouse SNAP proteins are identical throughout the 206 amino acids (S. Catsicas et al., submitted). To investigate further the evolutionary conservation of SNAP we have isolated clones from goldfish (Carassius auratus) and Drosphila melanogaster libraries. Drosophila SNAP displays 60% sequence identity to the mouse protein. A segment of 60 amino acids

sequence identity to the mouse protein. A segment of or animo acids shows 85% sequence identity.

Several SNAP clones were isolated from a goldfish retina cDNA library. Six of these have been partially sequenced. Surprisingly, all six clones are distinct. Overall, they show approximately 90% amino acid sequence identity to the mouse protein and somewhat higher identities to each other. Thus, the strong evolutionary conservation of SNAP contrasts with the polymorphism in goldfish. However, goldfish may have been artificially inbred by man for 2,000 years.

The sequences of SNAP-25 from Drosophila, goldfish, chicken, and

mouse reveal an extremely well-conserved protein.

ION CHANNELS: MODULATION AND REGULATION II

155.1

ANOMALOUS EFFECTS OF INTRACELLULAR Ca^{2+} CHELATION IN CAT NEOCORTICAL NEURONS. P.C. Schwindt, W.J. Spain & W.E. Crill. Dept. of Physiology & Biophysics, Univ. Washington Sch. of Med., Seattle, WA 98195.

Excitability and ionic currents were examined in layer V neurons from cat sensorimotor cortex after impalement with microelectrodes containing KCl plus 200mM or 2mM of the Ca²⁺ chelator BAPTA. Cells impaled with microelectrodes containing KCl alone served as controls. Impalement with electrodes containing 200mM BAPTA resulted in rapid abolition of Ca²⁺-mediated afterhyperpolarizations (AHPs). Spike duration was normal, but rheobase was greatly elevated and subthreshold rectification was absent. Both the persistent Na⁺ current and the anomalous rectifier current were absent during voltage clamp of these calls, whereas both currents were appropriately in controls. Calls involved cells, whereas both currents were prominent in controls. Cells impaled with 2mM BAPTA displayed a different abnormality. The Ca²⁺-mediated AHP following a spike train was markedly enhanced in both duration and amplitude. Injection of 1 second current pulses evoked an initial burst of spikes followed by a prolonged cessation of firing instead of the tonic firing seen in controls. Ca²⁺-mediated K⁺ currents were evoked by smaller depolarizations than in control cells, and they were markedly larger and slower than seen in controls when evoked at equivalent potenlarger and slower than seen in controls when evoked at equivalent potentials. These currents were unaffected by apamin or 1mM TEA, but were abolished by muscarinic and adrenergic agonists. We conclude that small changes of $[Ca^{2+}]_i$ can markedly alter both neuronal firing properties and the apparent voltage dependence and kinetics of Ca^{2+} -mediated K^+ currents. A large reduction of $[Ca^{2+}]_i$ results in the disappearance of voltage-gated currents that are normally present. Supported by NINCDS grants NS001166, NS620322 & NS620486.

155.2

MODULATORY EFFECTS OF SEROTONIN ON CAT NEOCORTICAL NEURONS. W.J. Spain, P.C. Schwindt & W.E. Crill. Depts. of Medicine and Physiology & Biophysics, Univ. Washington Sch. of Med., Seattle, WA 98195.

We are interested in the mechanisms for the transduction of synaptic currents into spike trains by neocortical neurons that project to lower brain centers. These layer V pyramidal neurons respond to steady injected current with an initial period of phasic firing followed by adaptation to steady tonic firing rates. The largest neurons of area 4y (termed PHE cells) are recognized by short duration action potentials (mean=0.4 ms). Deactivation of a large inwardly rectifying cation current (I_h) increases their initial firing rate to steady injected current following a period of hyperpolarization. The smaller neurons (termed PHI cells) have wider action potentials (mean=0.8ms), decreased initial firing rate following a period of hyperpolarization and a smaller I_h. The effect of serotonin (5-HT) 10-100µM on these cells in slices was investigated in current and voltage clamp. In PHE cells, 5-HT caused a depolarization of resting potential (RP) and an increase in initial phasic firing rate with a decrease in the tonic firing rate to steady depolarizing current pulses. In addition, the increase in initial firing rate following a period of hyperpolarization was enhanced by 5-HT. In PHI cells, 5-HT caused either a small depolarization, hyperpolarization or no change in RP. 5-HT increased the tonic firing rate and reduced slow adaptation during steady depolarizing current pulses. In both types of pyramidal cells, action potential duration did not change, however, the medium duration afterhyperpolarization was reduced. Following repetitive firing, a slow duration afterhyperpolarization (sAHP), caused predominantly by a Na+ dependent K+ conductance, was markedly reduced in all neurons. In voltage clamp experiments on both cell types 5-HT caused and an increase in Ih. The increase in Ih was accompanied by a positive shift of its voltage-dependent activation, decrease of activation time constants and increase of deactivation time constants. It is concluded that in PHE cells, the dominant role of Ih contributes to the depolarization, and increase in phasic firing in the presence of 5-HT; and in PHI cells, the mechanism underlying the reduction of the sAHP by 5-HT results in the increase in tonic firing. Supported by grants NS001166, NS620322 & NS620486.

A PATCH-CLAMP ANALYSIS OF THE EFFECTS OF MUSCARINE ON DOPAMINERGIC NEURONS OF THE SUBSTANTIA NIGRA. S.V.P. Jones. N.L. Silva and M.R. Brann. Laboratories of Neurophysiology and Molecular Biology, NINDS, National Institutes of Health, Bethesda MD 20892.

Of the 5 muscarinic receptors that have been cloned, in situ hybridization experiments have revealed that the dopamine (DA) neurons within the substantia nigra zona compacta (SNZC) contain only m5 muscarinic receptor mRNA (Weiner et al. 1990). Therefore, electrophysiological analysis of the effects of muscarinic agonists on DA neurons should reveal the actions of the m5 muscarinic receptor subtype. The striatum of 6 day old rats were injected with fluorescent beads. These beads retrogradely label the DA neurons of the SNZC (Silva et al. J. Neurophysiol in press 1990). The cells of the SNZC were acutely dissociated from 9-12 day old rats. Cells containing the fluorescent beads were recorded from using the whole-cell patchclamp technique. Application of 50 μM muscarine resulted in several different responses. These included an outward current response in cells voltage-clamped at -60 mV and inhibition of a tail current observed on return to -60 mV from positive potentials. A reduction in outward current was also noted on application of muscarine in cells held at positive (0 to +40mV) potentials. The identity of the conductances underlying these responses is being further characterized.

155.5

LACK OF EFFECT OF T-CHANNEL BLOCKERS ON PACEMAKER-LIKE FIRING OF DORSAL RAPHE NEURONS RECORDED IN VITRO. A. L. Mueller. Natural

Product Sciences, Salt Lake City, UT 84108.

Dorsal raphe neurons fire action potentials in a rhythmic, pacemaker-like fashion. It has been hypothesized that T-type calcium channels may underlie the generation of such activity in these and other central neurons (Synapse 1:582, 1987; TINS 11:431, 1988; Science 242:1654, 1988). The aim of the present study was to determine the effect of known T-channel blockers on the spontaneous pacemaker-like activity of 5HT-containing dorsal raphe neurons in an in vitro brain slice preparation. Coronal slices (400 µm) of rat neurons in an *in vitro* brain slice preparation. Coronal slices (400 μ m) of rat brainstem containing dorsal raphe were submerged in and superfused with warm (35 $^{\circ}$ C), oxygenated artificial CSF (aCSF) containing (in mM) 125 NaCl, 2.5 KCl, 1.25 NaH₂PO₄, 1.3 MgSO₄, 2 CaCl₂, 25 NaHCO₃, 11 glucose. Methoxamine (10 μ M) was included to increase spontaneous neuronal activity (Brain Res. 289:109, 1983). In experiments involving Cd⁺² or Co⁺², 1.25 mM HEPES replaced the NaH₂PO₄. Putative 5HT-containing neurons, identified on the basis of spontaneous firing rate, action potential duration and waveform, and sensitivity to 5HT, were recorded with standard extracellular recording techniques. Cd⁺² (10-100 µM) or Co⁺² (1-3 mM) totally suppressed the spontaneous firing of all neurons tested; with Cd⁺², a transient excitation preceded the inhibition. Ni⁺² had no effect at concentrations up to 300 µM; at 1 mM, Ni⁺² elicited a slow biphasic increasedecroses in firing rate. Neither respectively (200 µM), per 1 extend (200 µM), per 1 extend (200 µM). concentrations up to 300 μ M; at 1 mM, Ni⁺² elicited a slow biphasic increased decrease in firing rate. Neither amiloride (300 μ M) nor 1-octanol (300 μ M) produced a marked suppression of spontaneous firing. Taken together, these findings, and especially the rank order of potency of Cd⁺² > Ni⁺², do not support the hypothesis that conventional T-type calcium channels (where Ni⁺² > Cd⁺²) are involved in the generation of pacemaker-like neuronal activity in 5HT-containing neurons in the dorsal raphe

MODULATION OF THE GLYCINE RECEPTOR BY CHLORMETHIAZOLE (CLM) AND 2,6-DIISOPROPYLPHENOL (PROPOFOL). T.G.Hales*, J.A.Peters**, J.J.Lambert** & R.L.Katz**, Dept. Anesthesiology, UCLA, Sch. of Med. L.A., CA. 90024.

rmac. & Clin. Pharmac. Dundee Univ. Sch. of Med. Ninewells Hosp. Dundee DD19SY, Scotland.

A number of compounds with anticonvulsant and anesthetic properties

A number of compounds with anticonvulsant and anesthetic properties potentiate the actions of GABA on the GABAA receptor. These compounds include pentobarbitone, alphaxalone, CLM (Simmonds & Turner, Neuropharmac. 26:923, 1987) and propofol (Hales & Lambert, Br.J.Pharmac. 94: 393P, 1988). CLM has also been reported to modulate the glycine receptor and this property of the drug may underlie its use in the treatment of status epilepticus in patients failing to respond to benzodiazepines and anticonvulsant barbiturates (Harrison & Simmonds, Br.J.Pharmac, 80:387, 1983).

The whole-cell configuration of the patch-clamp technique was used to record, from tissue cultured murine spinal neurones and bovine chromaffin cells, currents evoked by the local application of glycine (100 µM) and GABA (100 µM), respectively. Glycine activated currents were blocked by the bath application of strychnine (100 nM), but were unaffected by bicuculline (1 µM). Bath application of alphaxalone (1 & 10 µM) and pentobarbitone (10 & 100 µM), at doses found to cause marked potentiation of GABA-evoked currents, had no effect on currents activated by glycine. In contrast, CLM (10 - 100 µM) and propofol (0.84 - 16.8 activated by glycine. In contrast, CLM (10 - 100 µM) and propofol (0.84 - 16.8 µM) potentiated currents activated by glycine in a dose dependent manner. Within this range of concentrations CLM and propofol were found to cause a much greater potentiation of GABA-evoked currents.

Unlike the other modulators of the GABAA receptor investigated, CLM and propofol potentiated strychnine sensitive currents, evoked by glycine.

ANTIBODIES AGAINST THE G-PROTEIN Gi ATTENUATE COUPLING OF OPIATE (µ) RECEPTOR-EFFECTOR MECHANISMS - A WHOLE-CELL PATCH CLAMP STUDY IN RAT LOCUS COERULEUS (LC) SLICES. M.Alreja*. E.J. Nestler and G.K. Aghajanian. Depts. of Psychiatry and Pharmacology, Yale University School of Medicine, New Haven, CT 06508.

Previous intracellular studies have demonstrated that the opiate-induced outward K⁺ current in noradrenergic LC neurons is mediated by a pertussis toxin (PTX)-sensitive G-protein. We used the whole-cell mode of patch clamping in LC slices (400 μ m) to study the effect of loading these neurons with antibodies to $G_{i\alpha}$ and $G_{o\alpha}$ (the principal PTX substrates in LC) on the opiate-induced outward K⁺ current We also tested the effect of pretreatment of LC membranes with the antibodies on opiate-induced inhibition of adenylate cyclase activity. The antibodies used (Spiegel/NEN, USA) had been raised against C-terminal decapeptides of the α -subunits of G_1 (recognizing $G_{1\alpha-1}$ and $G_{1\alpha-2}$) or G_0 (recognizing

 $G_{0\alpha}$ and $G_{1\alpha-3}$). To test the specificity of the antisera, immunoblots were performed on SDS-PAGE separated G-proteins from rat LC homogenates. Gi and Go antisera did not cross-react up to the tested dilutions (G₀, 1:10; or G_i, 1:50); the G₀ antiserum had a lower titer than the Gi antiserum.

Whole-cell patch clamp recordings from identified LC neurons were made using low resistance (=3 M Ω) electrodes filled with typical "intracellular" solution containing GTP with or without antiserum. D-ala²,D-leu⁵ enkephalin (DADLE) was used to evoke the outward K^+ current. At 1:50 dilution, antibodies against G_i but not G_0 caused over 50% attenuation of the DADLE-evoked response. In preliminary experiments, G_i antiserum also attenuated DADLE-induced inhibition of forskolinexperiments, of anisserum associated and the property of the section of a denylate cyclase activity in LC membranes. Thus the G-protein G_i ($G_{i\alpha-1}$ and/or $G_{i\alpha-2}$) appears to mediate, at least in part, the

opiate-induced opening of K+ channels in rat LC neurons; however, because of the relatively low Go antibody titer, Go involvement could not be ruled out.

MODULATION OF GLYCINE RECEPTOR C1- CHANNELS BY PROTEIN KINASE A (PKA) IN SPINAL TRIGEMINAL NEURONS. Y. Song and L.-Y.M. Huang, Marine Biomedical Institute, Univ. TX Med. Br., Galveston, TX 77550.

Glycine is an important inhibitory transmitter in the brainstem and spinal cord. The electrophysiological and molecular properties of glycine receptor C1- channels have been studied extensively. But very little is known about the modulation of this channel. We have examined the regulation of strychnine-sensitive glycine receptor channels in isolated neurons acutely dissociated from spinal trigeminal nucleus of rat using the patch clamp and intracellular perfusion technique. Under whole cell recording conditions, internally perfused 3'5'-monophosphate (cAMP)-dependent protein kinase (PKA) or cAMP or GTP-y-s dramatically increased the glycine-induced Cl- currents in these cells. To determine which G protein was involved in the modulation, we studied the effects of cholera toxin (CTX) and pertussis toxin (PTX) on the glycine-activated Cl current. PTX had no effect on glycine response. CTX, on the other hand, increased the glycine response substantially. This increase was blocked when protein kinase inhibitor and CTX were simultaneously introduced into the cells. This result suggested that G_s protein in the cAMP pathway is involved in the modulation of glycine responses. Supported by NS01050 and NS23061.

Extracellular ATP Modulates Currents in Chromaffin Cells Through a G-protein Mediated Pathway. Diverse-Pierluissi, M., Dunlap, K.*, and Westhead, E.W. Molecular and Cellular Biology Program, Univ. of Massachusetts, Amherst, MA 01003 and *Dept. of Physiology, Tufts Med. Sch., Boston, MA 02111.

Chromaffin cells cosecrete 150mM ATP with other nucleotides, catecholamines and neuropeptides. We have shown that extracellular ATP can both enhance and inhibit catecholamine secretion, suggesting that it plays a transmitter role. Enhancement is blocked by pretreatment with cholera toxin (CTX) and inhibition by pretreatment with pertussis toxin (PTX). We are employing patch clamp techniques to determine whether ATP exerts this action on chromaffin cells via alterations in calcium entry mechanisms. Both low threshold,transient(T)and high threshold,long-lasting(L) voltage-dependent calcium currents can be recorded.ATP(10-100 mM) has complex effects: in virtually all cells it inhibits the L current(but not T)by an average of 30%. This action is mimicked by ADP and blocked by PTX pretreatment.In 20% of these cells,ATP-induced inhibition is eclipsed by a rapid enhancement of inward holding current and a concomitant increase in the L component. These two enhancing effects desensitize during steady ATP application, uncovering the non-desensitizing inhibition of L current. Neither the increase in holding current nor the potentiation of calcium current is blocked by CTX pretreatment. Thus, the actions of ATP on secretion can, only in part, can be explained by a G-protein mediated modulation of calcium influx. (Work supported by PHS grants NS26606(EW) and NS16483(KD).

MODULATION OF Ca⁺⁺ CHANNELS IN BOVINE ADRENAL CHROMAFFIN CELLS (BCCs). Y. Ohya and R.Y.K. Pun. Dept. of Physiology and Biophysics, University of Cincinnati, Cincinnati, OH

45267, and Department Internal Medicine, Kyushu University, Japan.

Biochemical and electrophysiological evidence indicate that L-type Ca⁺⁺ channels are phosphorylated and modulated by protein kinases. We have studied the effects of the phorbol ester, 12-O-tetradecanoly phorbol-13-acetate (TPA), which activates protein kinase C, on the Ca⁺⁺ channels in BCCs using both whole cell voltage clamp recording and single channel measurement. TPA (80-160 nM) increased the peak amplitude of whole cell Ca⁺⁺ current and revealed a fast decaying component. Tail-current measurements with short voltage pulses showed that the conductance was enhanced. The inactive phorbol ester $4-\alpha$ phorbol (1 μ M) did not enhance the amplitude nor alter the decay. TPA had similar effects on Ba⁺⁺ currents. Single channel measurements were performed with 100 mM Ba⁺⁺ inside the recording pipette under cell attached mode. Inward currents with slope conductances of about 22 pS and 8 pS were recorded. Both channels had similar voltage dependency in activation and inactivation, and open time. Channel opening was prolonged by the agonist BAY K-8644 (1 μ M) and was reduced by the antagonist nitrendipine (1 μ M). TPA increased the probability of channel opening, prolonged the open time, and prolonged the channel burst duration. TPA also shifted the steady-state inactivation relationship to a more negative potential. The shift in inactivation relationship was similar to that observed for whole cell Ca⁺⁺ current. Our results indicate that protein kinase C has a profound effect on Ca⁺⁺ channels in BCCs. (This work is supported by NSF Grant DCB-8812562)

ADENOSINE ANTAGONISTS FAIL TO BLOCK THE ADENOSINE-INDUCED REDUCTION OF CALCIUM CURRENT IN CHICK SENSORY NEURONS. S.C. Nam. L. Yousif and P. E. Hockberger. Dept. of Physiclogy, Northwestern University Medical School, Chicago, IL 60611.

Adenosine analogues reduce calcium and potassium currents in several types of neurons presumably by acting through adenosine receptors (cf. Fredholm & Dunwiddie, <u>Trends in Pharm. Sci.</u>, 9:130, 1988). We have investigated this possibility by testing the effects of several adenosine agonists and antagonists on the calcium currents several adenosine agonists and antagonists on the calcium currents recorded from acutely isolated chick DRG cells, as described elsewhere (Hockberger et al. Nature 338: 340, 1989). High-threshold (HT) currents were monitored during local application of agents via micropipet. The following agonists decreased the HT current in a dose-dependent and reversible manner: 2-chloro-adenosine (CA; 0.1µM reduced the current by 68% on average, n=8); N⁶-cyclohexyl-adenosine (CHA; 0.1μM a 35% reduction, n=3); and SC-32796 (1 nM a 29% reduction, n=3). Likewise local application of adenosine antagonists also decreased the HT current in application of adenosine antagonists also decreased the H1 current in a dose-dependent and reversible manner: 8-phenyl-theophylline (PT; 1 μ M a 44% reduction, n=12); 8-cyclopentyl-theophylline (CPT; 0.5 μ M a 43% reduction n=4), and 1,3-dipropyl-8-p-sulfophenyl-xanthine (DSPX; 1 μ M a 20% reduction, n=3). However, bath application of the antagonists, even at 10 μ M, did not affect the responses to the micropipet-applied agonists. These results suggest that the inhibitory effect of adenosine on calcium current in chick DRG cells is not mediated by adenosine (A1 or A2) receptors. This research was supported by NIH grant #NS-26915.

TROPHIC EFFECTS OF NERVE GROWTH FACTOR (NGF) ON TETRODOTOXIN (TTX) AND CAPSAICIN SENSITIVITY IN ADULT SENSORY NEURONS. Luis G. Aguayo. Geoffrey White and Forrest F. Weight. Section of Electrophysiology, LPPS, NIAAA, Rockville, Md 20852.

Although NGF is critical for the survival of developing dorsal root

ganglion (DRG) neurons, adult neurons can survive in the absence of NGF. We have investigated the effects of NGF (2.5 ng/ml for 1-2 weeks) on adult rat DRG neurons maintained in cell culture in defined-media without background cells. Whole-cell recordings revealed no significant difference in resting membrane potential and input resistance between cells cultured in the absence (NGF⁺) and presence (NGF⁺) of NGF. The sensitivity of the Na⁺ spike to TTX (1 μ M) was different in cells cultured in the absence or presence of NGF. Spikes were abolished by TTX in 100% of NGF⁻ cells (n=15), while in NGF⁺ cells the spike was abolished in only 41% of the neurons (n=29) (p<0.001, chi-square, was aboustised in only 47% of the health's (1-25) (p-0.001, chi-square, x²). The threshold for spike generation was significantly lower in NGF-cells than in NGF+ cells, -25 ± 1.1 mV vs -18.9± 2.2 mV (p<0.05, ANOVA), respectively. Voltage clamp experiments revealed that the action potentials were predominantly carried by TTX-sensitive and TTXaction potentials were predominantly carried by 11x-sensitive and 11x-resistant Na⁺ currents in the absence and presence of NGF, respectively. Chemosensitivity of DRG neurons was also different in the absence and presence of NGF. For example, the percent of neurons in which capsaicin (500 μ M) current was detected increased from 19% (n=16) in NGF- cells to 55% (n=29) in NGF+ cells (p<0.05, x²). The results suggest that NGF has trophic effects on voltage-dependent and chemosensitive properties in adult mammalian neurons.

CALCIUM FLUXES IN ISOLATED BOVINE RETINAL CELLS. T.G.Ma., M.Zhou., R.D.Radtke and M.T.Tseng. Departments of Anatomical Sciences and Neurobiology and of Ophthalmology and Vision Sciences, School of Medicine, University of Louisville, Louisville, KY 40292

Transmembrane movement of calcium is tightly regulated and failure of this regulation contributes to the calcium overload phenomenon observed in the ischemic tissues. We have previously examined the calcium flux in retinal P2 membrane fractions (Ma et al., J Cell Biol 109:334a, 1989) and now report investigations of whole cell preparations. Bovine retinas were digested with papain for 40 min at 37°C to yield >90% viable cells. Cells were incubated with calcium uptake modulators at cells. Cells were incubated with calcium uptake modulators at 37°C for 20 min in the presence of ["5Ca"*]. Results demonstrated that Ca"* uptake was ATP dependent and inhibited by Ca"* channel blockers. Without exogenous ATP, Ca"* uptake was directly proportional to [Ca"*]. In the presence of 1 mM ATP, Ca" uptake was affected by the varying [Ca"*], in the following manner; a gradual decline between 0-1.25 mM [Ca]. and a mirrored increase at higher [Ca⁺⁺]_o (2.5- 5.0 mM). Also, sodium orthovanadate inhibited and ouabain enhanced calcium influx. Verapamil and ketamine inhibited Ca⁺⁺ uptake in a dose dependent manner. The result indicate that Ca⁺⁺-ATPase and calcium channels are functional and that isolated bovine retinal cells are useful for examining calcium flux in excitable tissues.

DOPAMINE INHIBITS VOLTAGE-ACTIVATED CALCIUM CURRENTS IN RAT NEUROINTERMEDIATE PITUITARY CELLS. I. Nussinovitch & A.L. Kleinhaug. Dept. of Anat. Heb. U. Hadassah Med. Sch., Jerusalem, Israel. Dopamine, a potent inhibitor of MSH-secretion and of spontaneous action potentials in neurointermediate pituitary cells (melanotrophs), is thought to act in a way similar to that of calcium channel blockers (Douglas & Taraskevich 1982 J.Physiol.326). Therefore, we examined the effects of dopamine on voltage-gated calcium currents in dissociated rat melanotrophs. Calcium currents in dissociated rat melanotrophs. Calcium currents were recorded using the whole-cell mode of the patch-clamp technique with TTX in the bath solution and with N-methylglucamine as the main intracellular cation. We observed two types of calcium currents similar to the T and L types described elsewhere. The T-type current activated at membrane potentials between -50 to -40 mV and the L-type activated at membrane potentials between -30mV to -20mV. Dopamine (1-20µM), applied from a pipette, reversibly reduced the size of both T and L types of calcium currents by 20%-100%. These findings suggest that dopamine receptors are coupled to calcium channels in the melanotroph and that dopamine inhibits secretion in melanotrophs by decreasing calcium currents. UNSATURATED FATTY ACIDS MODULATE SODIUM CURRENT IN CULTURED SKELETAL MUSCLE.

CURRENT IN CULTURED SKELETAL MUSCLE.
S.J.Wieland, J.E.Fletcher, O.H.Gong*
and H.Rosenberg*,
Hahnemann Univ., Philadelphia, PA 19102
Fatty acids may act as second messengers in signalling pathways, or may interact directly with membrane-associated structures, including with membrane-associated structures, including ion channels, altering their functional properties. Using the tight-seal whole-cell recording method, we monitored the differential effects of intracellular and extracellular application of 1-20 $\mu\rm M$ free fatty acids on cultured human skeletal muscle myocytes. Internal exposure to 5-15 $\mu\rm M$ arachidonic acid caused an increase (16-72%, mean= 41%, n=7, p<.03) in peak inward sodium current during voltage clamp steps from a holding potential of -100 mV. Intracellular oleic acid at 15 $\mu\rm M$ also increased the magnitude of inward also increased the magnitude of inward currents. In contrast, external arachidonic acid (5-15 µM) reversibly inhibited inward currents 40-80%, while internally or externally applied stearic acid had no effect at up to 20 µM. Preliminary data indicates that cells from malignant-hyperthermia susceptible individuals show weaker sensitivity to internally applied arachidonic acid. Supported in part by MDA.

Ca²⁺ CHANNEL ANTAGONISTS REDUCE THE MAGNITUDE AND ALTER THE KINETICS OF M-CURRENT IN BULLFROG SYMPATHETIC B NEURONS. Y.-Y. Peng and J. P. Horn Department of Physiology, University of Pittsburgh, School of Medicine, Pittsburgh, PA 15261. In bullfrog sympathetic B neurons Ach and LIRHH each produces a slow epsp that is mediated primarily through suppression of M-current (I_M), a voltage- and the strength of the produce of the strength of the

time-dependent K⁺ current. In preliminary experiments, we observed that nifedipine and ω -Conotoxin GVIA (ω -CgTx GVIA), antagonists of high-threshold Ca²⁺ channels, partially inhibited both the muscarinic and LHRH epsps, and also the responses to exogenous teleost and chicken II LHRH. We then investigated the effects of Ca²⁺ channel blockers by measuring I_M in B cells

then investigated the effects of Ca^{2*} channel blockers by measuring I_M in B cells of isolated sympathetic ganglia using a single-electrode voltage clamp. I_M was measured with 750 ms voltage steps to potentials between -30 and -90 mV from holding potentials of -30 to -50 mV. The slow current relaxations characteristic of I_M were reduced in amplitude, but never fully blocked, by bath application of nifedipine (1-10 μ M) and ω -CgTx GVIA (3, 10 μ M), and by switching to Ringer containing 0 Ca^{2*} , 10 mM Mg²* and 0.1 mM EGTA. The effects of nifedipine were more pronounced at depolarized potentials whereas those of ω -CgTx GVIA and 0 Ca^{2*} were larger at hyperpolarized potentials. The effects of nifedipine and 0 Ca^{2*} were rapidly reversible while those of ω -CgTx GVIA were only partially reversed by several hours of washing. In addition to reducing its magnitude, Ringer containing either ω -CgTx GVIA or 0 Ca^{2*} altered the kinetics of I_M . Normally the time constant for deactivation of I_M decreases at hyperpolarized potentials. ω -CgTx GVIA and 0 Ca^{2*} reduced the voltage dependence of the time constant such that it resembled that seen at depolarized potentials.

These results demonstrate an interaction between voltage gated Ca²⁺ channels and the gating of M-current. Supported by NIMH training grant MH18273 (YYP) and NIH grants NS21065 and NS01427 (JPH).

COMPARISON OF GALANIN AND BETHANECHOL ACTIVATED POTASSIUM CURRENTS IN DISSOCIATED ATRIAL MYOCYTES OF THE MUDPUPPY. L.A. Merriam and R.L. Parsons. Dept. of Anatomy and Neurobiology, University of Vermont, Burlington, VT 05405.

Previously we demonstrated that a galanin-like neuropeptide is colocalized with acetylcholine in cardiac parasympathetic postganglionic neurons of the mudpuppy, Necturus maculosus (Parsons, et al., Neuroscience 29:749, 1989). Galanin and muscarinic agonists both initiate hyperpolarization of atrial myocytes (Merriam et al., Neurosci. Abstr. 15:219, 1989). The present studies utilized the whole cell patch clamp recording technique to analyze the currents underlying these hyperpolarizations. In myocytes clamped to -50 mV, galanin and the muscarinic agonists bethanechol produced outward currents that differed markedly in their time course characteristics. Bethanechol currents rose to peak more quickly and decayed much faster than galanin-induced currents. The responses to both agonists exhibited voltage-dependence and reversed at the same membrane potential, which was dependent upon external [K+] in accordance with the Nernst equation for a K+ conductance. Both currents exhibited rectification at membrane potentials more positive than the reversal potential. The bethanechol-induced current could be typically reproduced throughout recordings with little or no decrement, while the amplitude and duration of the galanin response often decayed with repetitive agonist application. of the galanin response often decayed with repetitive agonist application. This decay may suggest sensitivity to dialysis of some intracellular component. Results of initial experiments with the GTP binding protein activator GTP-4S and the inhibitor GDP-4S suggest a G protein is involved

in the mediation of both responses.

CYCLIC AMP MODULATES A SLOWLY ACTIVATING K+ CURRENT EXPRESSED IN XENOPUS OOCYTES. E. M. Blumenthal and L. K. Kaczmarek Dept. of Pharmacology, Yale University School of Medicine, New Haven CT 06510.

A cDNA cloned from rat kidney and uterus, termed I,, encodes a 15kDa protein with one transmembrane segment and induces a very slowly activating K+ current when expressed in Xenopus laevis oocytes (Takumi et al, Science, 1988; Pragnell et al, Neuron, 1990). Incubation of I, expressing oocytes in 1 μM progesterone, which lowers intracellular cAMP, caused a 37% decrease in the slow K+ current along with a 7% decrease in membrane capacitance (Cm). Conversely, 1 mM 8-Bromo-cAMP increased both the current and Cm. The current increased up to 300% within 60 minutes of and cm. The current increased up to 300% within 60 minutes of drug treatment while Cm increased up to 15%. Similar experiments were carried out with oocytes expressing both I and Kv1, a delayed rectifier type K+ channel cloned from rat brain (Swanson et al, Neuron, 1990). The Kv1 current was unaffected by both drugs while I, and Cm responded as described above. Additional studies are being conducted to determine if these effects are the result of 1) a change in the number of I, channels present in the plasma membrane through selective endocytosis and exocytosis, or 2) modification of existing channels.

TRH INHIBITS AN INWARD-RECTIFYING POTASSIUM CURRENT IN GH3 CELLS. J.R. Schwarz* and C.K. Bauer* (SPON: European Neuroscience Association), Physiologisches Institut, Universitätskrankenhaus Eppendorf, D-2000 Hamburg 20, F.R.G.

Thyrotropin-releasing hormone (TRH) induces a biphasic prolactin secretion in clonal rat anterior pituitary cells (GH3). The hyperpolarization accompanying the first phase of secretion is induced by an opening of Ca++- dependent K+ channels, whereas the depolarization and increase in repetitive firing during the second phase are assumed to be caused by a closing of K+ channels. We now describe a K+ current which is a likely candidate for mediating the second phase of secretion.

Whole-cell inward K+ currents were elicited by hyperpolarizing pulses from a holding potential of -40 mV in isotonic KCl using the patch clamp technique. These K+ currents showed time- and voltage-dependent inactivation at potentials more negative than -60 mV. Inactivation was faster and more complete at larger hyperpolarizations. The amplitude of inward K+ current increased by 10-20% after depolarizing pre-pulses of 5 s indicating the presence of a steady inward K+ current amplitude of inward K+ current increased by 10-20% after depolarizing pre-pulses of 5 s indicating the presence of a steady inward K+ current at -40 mV. The inward K+ current was drastically reduced by Cs+, Ba2+, quinidine, 4-aminopyridine and TEA. TRH consistently reduced the inward K+ current in the presence of internal Ca2+. This reduction was abolished if the pipette solution contained GDPBS (400 µM), confirming the involvement of G-proteins in the signal transduction path-

way.

In intact cells, closing of K+ channels would result in a depolarization which could readily explain the TRH-induced increase in action potential firing underlying the sustained second phase of secretion.

DUAL REGULATION OF A POTASSIUM CHANNEL BY G PROTEIN AND INOSITOL POLYPHOSPHATES. IT. WU* S.J. Wieland, O.H. Gong* and R.H. Chou*. Department of Anatomy, Hahnemann University, Philadelphia, PA.

Second messenger systems may modulate ionic channels through GTP-binding proteins, polyphosphoinositide metabolites and protein phosphorylation. The effects of various second messengers on the voltage-activated inwardrectifying K+ current (Iki) were examined in macrophages differentiated from the HL-60 promyelocytic leukemia cell line. The amplitude of $I_{\mathbf{k}i}$ in untreated cells remained stable line. The amplitude of \mathbf{i}_{ki} in untreated cens remained state during whole-cell voltage-clamp recording for up to 20 minutes. The presence of 100 uM guanosine 5'-[γ -thio] triphosphate (GTP[γ S]) in the patch pipette solution inhibited \mathbf{l}_{ki} beginning within 3 minutes and lasting as long as 20 minutes post-intracellular application. The effect of GTP[γ S] on pertussis toxin-treated cells suggests that a pertussis toxin substrate is not involved in the suppression of \mathbf{l}_{ki} in HL-60 macrophages. In contrast, 1uM of inositol-1,4,5-trisphosphate or inositol-1,3,4,5-tetrakisphosphate caused an increase in the same voltage-dependent K+ conductance which same voltage-dependent K+ conductance which was independent of a rise in intracellular Ca+2. Hence the present findings demonstrate for the first time a dual modulation of a K+ conductance by G protein and inositol polyphosphates.

PHYSIOLOGICALLY LOW LEVELS OF ADP REVERSE THE INHIBITION OF ATP-SENSITIVE K CHANNELS BY ATP.

INHIBITION OF ATP-SENSITIVE K CHANNELS BY ATP.

S. Fatherazi, D.L. Cook*, K. Tornheim*^ and B.E. Corkey*^ Seattle,

VA Med Ctr and Dept of Physiol/Biophys, U. of Washington, Seattle,

WA 98108 and ^Diabetes/Metab. Div., Boston U., Boston MA 02118.

Both ATP (Kd≈15 μM) and ten-fold higher doses of ADP (Kd≈150 μM) block ATP-sensitive K channels (KATP) in pancreatic B-cells.

Paradoxically, a high level (2 mM) of ADP shifts the ATP-dose response to the right suggesting ATP-ADP competition and implicating ADP in the regulation of KATP activity (and electrical activity) in B-cells. The physiological interpretation of this ADP effect is complicated because physiological interpretation of this ADP effect is complicated because steady-state <u>free</u> cytosolic ADP levels are generally only 20-50 μM and thus may not compete effectively with the mM ATP levels in cells. To thus may not compete effectively with the mM ATP levels in cells. To test this, we exposed KATP channels in inside/out patches from cultured mouse B-cells to a control (0 ATP, 0 ADP) buffer and to ≈ 3.7 mM ATP with ADP levels fixed using creatine phosphokinase with different ratios of creatine/creatine phosphate (total = 12 mM). KATP activity in control buffer was maximal (NPo = 100%). Low ADP ($\approx 18~\mu$ M; ATP/ADP ≈ 220) completely suppressed channel activity (NPo = 0%), as expected with ATP alone. In high ADP ($\approx 500~\mu$ M; ATP/ADP ≈ 7) the ATP block was significantly relieved (NPo = 15% and 25% in 5 trials in 2 patches). Quantitatively, this increase of KATP activity is significant because KATP channels completely determine the resting membrane potential of B-cells and, in physiological conditions, are only 1-2% active. Changes of intracellular free ADP may contribute to the regulation of B-cell electrical activity. The mechanism of interaction of ATP and ADP

electrical activity. The mechanism of interaction of ATP and ADP remains to be determined.

156.3

EFFECTS OF POTASSIUM CHANNEL OPENERS ON TRANSMISSION AT THE FROG MUSCLE ENDPLATE. Eugene W. Shek, Lian-Ming Tian and Karim A. Alkadhi, Department of Pharmacology, College of Pharmacy, University of Houston, Houston, TX 77204-5515.

The ATP-regulated K+ channels are known to exist in high density in skeletal muscle fibers. These channels which also exist in cardiac and smooth muscles as well as in β -cells of islets of Langerhans, are shut under normal circumstances but open when ATP in the cell falls below the normal level. However, the function of these ATP-regulated below the normal level. However, the function of these ATP-regulated K⁺ channels is not clear especially in skeletal muscle where the ATP level is high and well maintained. In this preliminary study we investigated the effects of a new class of "K⁺ channel openers" on the parameters of release at the frog endplate. Conventional intracellular recording was used to study the effects of cromakalim (CKM) and RP52891 on evoked and spontaneous transmitter release. Neither cromakalim (0.1 - 0.5 mM) nor RP 52891 (0.1 mM) caused any significant change in the resting membrane potential when superfused for 1 hr (control: -92±2; CKM 0.3 mM; 1 hr: -91± 6, n=6). No significant effect on MEPP frequency was observed. However, the drugs caused a marked decrease in EPP amplitude (control 7.6±1 mV; CKM 0.3 mM, 1 hr: 3.3±1 mV, n=6). The MEPP amplitude was also decreased but to a lesser extent (control quantal content, m=13±3; after CKM, m=8±3). Pretreatment with the ATP-regulated K+ channel blocker glibenclamide (0.3 mM) did not antagonize these effects. It is concluded that these agents have postjunctional effects at the endplate unrelated to K+ channel opening.

156.5

IS THE ENHANCEMENT OF HIPPOCAMPAL EPSPS BY DIAZOXIDE CAUSED BY DISINHIBITION? <u>V. Crépel, K. Krnjevic, Y. Ben-Ari and A.T. Tan.</u> INSERM U29, Hopital Port-Royal, 750l4, Parls, France and Anaesthesia Research Dept., McGill University,

Paris, France and Anaesthesia Hesearch Dept., McGill University, Montréal, 143G 176, Canada.

Selectiveactivation of ATP-sensitiveK-channels suppresses glutamate release in the CA3 region of hippocampal slices (Ben-Ari, 1990, Eur. J. Neurosci. 2: 62). However, as described in another abstract (Ben-Ari et al.), diazoxide potentiates EPSPs in both CA1 and CA3; in the latter, it can generate seizure activity. A simple explanation is that diazoxide blocks synaptic inhibition.

A simple explanation is that diazoxide blocks synaptic inhibition. To test this possibility, we examined the effects of diaxozide after blocking GABA receptors. EPSP fields were recorded simultaneously from the apical dendritic regions of CA1 and CA3 - separated by cutting the slice. In ACSF with 6 mM Mg²* and 4 mM Ca²* (to avoid seizure activity), diazoxide (0.65 mM) prolonged EPSPs equally in CA1 and CA3 (\sim 30%) and increased their height by 9-12%. After treatment with bicuculline (10 μM , n=7), the increase in height was abolished in CA3, but unchanged in CA1. Conversely, the change in EPSP duration was reduced in CA1, but not CA3. The addition of phaclofen (0.5 mM, n=3) caused no further suppression of diazoxide effects. We conclude that disinhibition can only partly explain the effects of diazoxide, and that EPSPs are facilitated by another mechanism, perhaps as a result of depression of on-going glutamate release or a block of K channels (cf. Kozlowski et al. 1989, Br. J. Pharmacol. 97, 1039).

ATP SENSITIVE K+ CHANNELS MODULATE SYNAPTIC TRANS-MISSION IN THE HIPPOCAMPAL SLICE, Y, Ben-Ari, V, Crépel, S. Zini and D. Hazboun. INSERM U29, 123 Bd Port-Royal. 75014

We have recently shown that peripheral activators of ATP sensitive K+ channels (K+ATP) such as the vasodilator drug diazoxide (Ben-Ari et al. 1990. Neurosci, in press) reduce the enhanced glutamate release observed in the CA3 region during anoxic episodes. The selective K+ ATP blocker glibenclamide has an opposite effect (Ben-Ari 1990, Eur. J. Neurosci. 2.62), We have now examined the effects of these drugs on synaptic responses.

In normoxic conditions bath applications of diazoxide (650 uM) increased the amplitude and duration of the field EPSP in CA1. In CA3 the EPSPs were increased in duration and associated with interictal bursts similar to those evoked by convulsive agents. Glibenclamide (10 uM) usually had no effect on synaptic responses in CA1 and CA3; it did however occasionally generate paroxysmal activity, in particular in slices subjected to repeated brief hypoxic episodes. K+ ATP activators or antagonists had little effect on resting membrane potential or input resistance of CA1 and CA3 neurons, particularly in presence of TTX or the broad spectrum excitatory amino acid antagonist kynurenate (1 mM). In preliminary experiments using hippocampal synaptosomal preparations, gliben clamide enhanced the ongoing release of endogenous glutamate. We propose that transmitter release is modulated by K+ ATP channels, with consequences that depend on the metabolic status of the circuit. The enhanced synaptic responses caused by diazoxide may be in part due to a reduction of GABA release (Abst. Crépel).

CHARACTERIZATION OF POTASSIUM CURRENTS ACTIVATED BY CROMAKALIM IN CULTURED RAT HIPPOCAMPAL NEURONS. Dora M. Politi, Susan M. Jones and Michael A. Rogawski. Neuronal Excitability Section, Medical Neurology Branch, NINDS, NIH, Bethesda, MD 20892.

Previous studies in our laboratory have shown that cromakalim activates a tetraethylammonium (TEA)-sensitive, voltage-dependent K^{\star} current in cultured embryonic rat hippocampal neurons (*Eur. J. Pharmacol.* **168**: 7, 1989). This phenomenon was further characterized using whole-cell voltage-clamp and singlechannel recording techniques. Glyburide (1-25 µM), an antagonist of ATPdependent K^{*} channels, produced a slow concentration-dependent depression of the cromakalim-activated current, whereas charybdotoxin (100 nM; CTX), a blocker of some Ca²⁺-dependent and Ca²⁺-independent K^{*} channels was inactive. Neither glyburide nor CTX affected resting or voltage-activated K⁺ currents in the absence of cromakalim. Single channel recordings in the cell attached configuration showed that cromakalim (100 μ M) activated flickery channels that have a single channel conductance of 15-30 pS. In the presence of cromakalim, the open state probability of the channels was typically >0.8-0.9 at depolarized potentials; channel openings were not observed in the absence of cromakalim. These data are compatible with an interaction of cromakalim with ATP-dependent K+ channels.

BLOCKING POTASSIUM CURRENTS IN CHICK DORSAL ROOT GANGLION (DRG) NEURONS. J. L. Kenyon, C. D. Westbrook, and M. L. Hall*. Department of Physiology, Univ. of Nevada Sch. of Med., Reno, NV 89557.

We are investigating the development of neurons with differing K currents in

chick DRGs and we tested low concentrations of K channel blockers in order to classify voltage-gated K currents. Neurons were isolated from 10 day old chick embryos and voltage-clamped within 12 hours. They were bathed in Ca-free physiological saline with TTX to inhibit inward and Ca-activated currents. K channel blockers were applied via a puffer pipette. K currents were activated by 100 ms depolarizations positive to -40 mV. Control currents were dominated by sustained current components. TEA (20 mM) rapidly and reversibly reduced K current amplitude by $\approx 80\%$. 3,4-diaminopyridine (50 μ M) reversibly reduced K current amplitude by $\approx 50\%$ over several minutes. For both agents, the insensitive current looked like a small version of control. β -Bungarotoxin (100 μ M) did not reduce K currents. Capsaicin (CAP, 50 μ M) reduced late K current by 20 - 50%. α -Dendrotoxin (DTX, 10 and 100 nM) rapidly and reversibly reduced late K current by ≈80%. The current remaining in CAP and DTX increased then

decreased during the step (figure) while the toxin-sensitive current was sustained. The figure shows currents elicited by steps from -95 to +30 mV in control (larger current) and in 10 nM DTX. Thus, all effective blockers reduced sustained currents while only CAP and DTX revealed transient current components. Supported by AHA 87-648.

Effects of various potassium channel blockers on inositol phosphate accumulation in rat striatal slices. R.Levent Buyukuysal and Richard J. Wurtman . Massachusetts Institute of Technology, Department of Brain and Cognitive Sciences, Cambridge MA, USA.

The effects of various potassium channel blockers on inositol phosphate (IP) turnover were tested using cross-chopped striatal slices. The following blockers were tested: 3,4-diaminopyridine (DAP), phalloidine (Ph1), dendrodotoxin (Ddx), charybdotoxin (Chx), apamin (Apm), tetrahydroaminoacridine (THA), quinine (Quin) and tetraethylammonium (TEA). All blockers except Phl, Apm and TEA increased IP accumulation in a dose dependent manner. DAP. Chx and Ddx were effective in a Ca+2-free medium. In contrast, THA and Quin decreased IP accumulation in Ca*2-free medium. The DAP and Chxinduced increases were sensitive to the sodium channel blocker tetrodotoxin, while the THA, Quin and Ddx-induced increases were not. The effects of DAP and of low concentrations of THA were partially blocked, and that of Ddx abolished, by atropine. In eserine-containing medium, DAP and Chx further increased IP accumulation, but THA, Quin, Ddx and TEA decreased it. Moreover THA, Quin and Ddx (but not DAP and Chx) decreased carbachol-induced IP accumulation. These results indicate that although blockade of certain potassium channels can enhance the production of second messengers and potentiate postsynaptic events, most of the above blockers appear to have additional effects (e.g., on muscarinic receptors or on calcium channels).

Supported in part by a grant from NIMH.

REGULATION OF THE CA⁺⁺ SENSITIVITY OF K(CA) CHANNELS BY PROTEIN PHOSPHORYLATION IN A DRG NEURONAL CELL LINE. K. Naruse and G.S. Oxford. Department of Physiology, University of North Carolina, Chapel Hill, NC 27599.

F-11 cells, a dorsal root ganglion × neuroblastoma hybrid cell line can be cultured under conditions that promote expression of neuronal morphology. Single Ca⁺⁺-activated K(Ca) channels (~300pS) in inside-out membrane patches excised from such "differentiated" cells exhibit a higher Ca⁺⁺ packets exceed from some different different care cannot be a light of a sensitivity than in excised patches from cells grown in normal growth media or from cultured rat embryonic DRG neurons (Naruse et al., 1990). As the differentiation of F-11 cells is, in part, triggered by agents that promote intracellular cAMP levels (e.g. dibutryl cAMP, IBMX), we examined the possibility that Ca⁺⁺ sensitivity of K(Ca) channels is regulated by the activity

of cAMP-dependent protein kinase (PK-A).

To test this hypothesis, we (1) acutely incubated undifferentiated F-11 cells with forskolin or dibutyrl cAMP to increase the activity of endogenous PK-A. or (2) exposed excised inside-out membrane patches to the purified catalytic subunit of PK-A from bovine heart. Using only patches with single K(Ca) channels, open probabilities were computed at several membrane voltages and buffered [Ca++]. Both endogenous and exogenous PK-A increased the activity of K(Ca) channels from the undifferentiated cells. The effects were most pronounced at $[Ca^{++}]$ of 0.5 - 1.0 μ M.

Our results suggest that the Ca⁺⁺ sensitivity of neuronal K(Ca) channels is

regulated by PK-A activity with possible consequences for excitability during transmitter induced changes of cellular cAMP levels. Supported by NIH grant

OPEN CHANNEL NOISE OF SUBCONDUCTANCE STATES. M.I. Glavinovic, Dept. Anaesthesia Research, Physiology and Biomedical Engineering, McGill University, Montreal, Quebec, Canada.

Blomedical Engineering, McGill University, Montreal, Quebec, Canada.

Subconductance states within the main open state have been reported for a variety of channels (Barrett et al., J. Physiol., 331, 211-230, 1982). They are usually explained by the partial occlusion of the open channel. Alternatively they may represent a presence of parallel conductive subunits (Hunter and Giebisch, Nature, 327, 522-524,1987). Resolution of this problem is of considerable importance for understanding of the molecular structure and permeation of ion channels. To resolve it the open channel current noise of different current sublevels was examined.

In Ca⁺⁺ activated K⁺ 'maxi' channels of bovine chromaffin cells the variances of current fluctuations through the subconductance states were as a rule greater and more variable than the variances of the main open state. No simple relationship between the variances and the current amplitudes of sublevels was obvious. In contrast, when several channels were simultaneously open the variances of the current fluctuations increased in an apparently linear manner as more channels were open. This argues against the idea that the main open state is a result of simultaneous opening of several conductive subunits, although it does not eliminate it completely. Opening of all subunits may somehow 'stabilize' the channel segments that are the noise sources of the current sublevels. Supported by MRC (Canada).

INHIBITION OF OUTWARD CURRENTS IN DORSAL ROOT INHIBITION OF OUTWARD CURRENTS IN DORSAL ROOT
GANGLION CELLS BY DENDROTOXIN HOMOLOGUES. ^ΩD. G. Owen,
^ΘA. Hall*, *R. G. Sorensen & ^ΩJ. Stow*. ^ΩWyeth Research (UK),
Taplow, UK; *Dept. Biochemistry, Imperial College London, UK; *Dept.
Medicine, Jefferson Medical College, Philadelphia, USA.

α-dendrotoxin (α-dtx), a polypeptide fraction of Green Mamba venom,

and Toxin I, a structurally very similar toxin obtained from Black Mamba venom, are known to facilitate transmitter release, most likely through inhibition of a voltage-activated transient outward (potassium) current (TOC) (see Harvey & Anderson, 1986). We have compared the effects of the peptide homologues (ex green mamba), β_1 -dtx (1 μ M), γ -dtx (1 μ M) and δ -dtx (1 μ M), with α -dtx (100nM) and Toxin I (100nM) on outward currents in rat dorsal root ganglion (DRG) neurones.

DRGs were obtained from rat pups (neonates to ca. 4 days) and cultured together with glia and glial conditioned medium (ex C_6 glioma cells). Voltage clamp recordings were made 4-8 days post-plating using a switching voltage clamp amplifier and patch electrodes (5-7M Ω) filled with (mM): 140 KGluconate; 1 MgCl₂; 1.1 EGTA/KOH; 5 HEPES; pH 7.2. Bathing solution consisted of 140 TrisCl; 4MgCl₂; 5 HEPES; 10 glucose; 20 sucrose; pH 7.4. All the homologues reduced voltage-activated outward current in a sub-population of DRG neurones. Inhibition by Toxin I, β_1 -dtx and y-dtx was indistinguishable in a given neurone, blocking both sustained outward current (I_K) and slowly-inactivating TOC. δ -dtx blocked IK preferentially, in contrast to a dtx which was more selective for TOC whereas, in the same cells, Toxin I blocked TOC and IK with little discrimination.

156.10

SUBCONDUCTANCE BEHAVIOR IN LARGE CONDUCTANCE CA2+-ACTIVATED K+ CHANNELS INDUCED BY BOVINE PANCREATIC TRYPSIN INHIBITOR, BPTI. K. J. Lucchesi* and E. G. Moczydlowski, Dept. Pharmacology, Yale Univ. Sch. Med., New Haven, CT, 06510. Kunitz protease inhibitors are = 60-residue peptides homologous to mamba snake dendrotoxins (DTX) that block certain voltage-dependent K⁺ channels. We previously observed that DTX-I induces long-lived subconductance events in maxi-K(Ca) channels (Neuron, 2: 141-148, 1990). To study structure-activity relationships for this inhibition, we tested BPTI, a well known trypsin inhibitor and model peptide for investigations of protein folding. Like DTX-I, BPTI produced subconductance events by a one-site binding reaction at the inside surface of single K(Ca) channels from rat skeletal muscle incorporated into planar lipid bilayers (Kd = 4.9 μM in 50 mM symmetrical KCl). Several differences between the action of BPTI and DTX-I are noteworthy. The current amplitude of the BPTI-induced substate is 1.2 ± 0.1 pA at + 20 mV, significantly below the 2.8 pA substate seen in the presence of DTX-I. BPTI substates also undergo stronger inward rectification at positive voltages than those induced by DTX-I. Substate lifetimes in the presence of BPTI are much shorter than those produced by DTX-I, yielding respective koffs of 3.7 sec-1 and 0.027 sec-1. Apparent association rate constants of both BPTI and DTX-I are increased by depolarizing voltage and are dramatically reduced at high ionic strength. To probe the mechanism of peptide induced substates, we tested the possibility of binding competition with TEA and Ba²⁺, two internal K(Ca) channel blockers. We found that internal TEA blocks substates and open states with equal affinity (Kd = 37 mM); blocking/unblocking rates of internal Ba²⁺ are virtually unaffected by the presence of up to $100 \, \mu M$ BPTI. These results suggest that the site of peptide-inhibitor binding does not lie within the internal channel vestibule. BPTI may affect K+ permeation by an allosteric mechanism. Supported by NIH AR38796 and HL38156.

NOVEL CONDUCTANCE OF MOTONEURONES IS BLOCKED BY TRH. A. Nistri, N.D. Fisher and M. Gurnell Pharmacology Dept., St. Bartholomew's Hospital Medical College, London EC1M 6BQ, U.K.

The excitatory action of the neuropeptide TRH was studied on motoneurones of the neonatal rat spinal cord in vitro. Cells were voltage clamped with a single KCl or CsCl electrode in the presence of TTX at room temperature. Fast superfusion with TRH (1 μ M) elicited, with a 2-4 min latency, an inward current (I_{TRH}) with a slow offset (> 10 min). At -70 mV I_{TRH} was -0.59 \pm 0.06 nA with a 28 \pm 5% fall in slope conductance (n=12). I_{TRH} reversed near -100 mV and peaked at -55 mV. In 13.5 mM K⁺ I_{TRH} reversal and peak underwent a positive shift. In the presence of TRH the threshold for voltage sensitive Ca²⁺ currents was reduced and slow oscillatory currents appeared, while -10 to -30 mV hyperpolarizing steps induced an instantaneous current (smaller than control) which relaxed outwardly to steady state level within 150 ms (no such relaxation was found in control solution). I_{TRH} was not blocked by TEA (20 mM), 4AP (1 mM), Cs^+ (2 mM or injected intracellulary) or Cd^{2+} (0.2 mM) but was depressed by Ba^{2+} (0.2 - 1.5 mM). It is suggested that TRH blocks (perhaps via internal messengers) a Ba^{2+} sensitive K^+ conductance active at resting potential and apparently distinct from previously reported K⁺ currents of mammalian central neurones. Supported by Cyanamid-Takeda, NATO and an Alliance grant.

EFFECTS OF INTRACELLULAR GDPBS ON THE RESPONSES TO LHRH, MUSCARINE AND SUBSTANCE P IN BULLFROG SYMPATHETIC NEURONS Mark A. Simmons & Robert J. Mather* Neuropharmacology Lab Dept. Pharmacol., Marshall Univ., Huntington, WV 25755

Dept. Pharmacol., Marshall Univ., Huntington, WV 25755
In sympathetic neurons, LIRRH, muscarine, and substance P (SP) all inhibit the M current ($I_{\rm M}$). GDPAS was applied intracellularly to determine the interactions between the three types of receptors, G proteins and $I_{\rm M}$. Whole cell recordings were made from enzymatically dissociated neurons. The inhibition of $I_{\rm M}$ by agonists was dependent upon the ratio of GDPAS:GTP in the pipette solution. At 10:1 GDPAS:GTP, agonist inhibition of $I_{\rm M}$ was either small or absent. At 2:1 GDPAS:GTP the responses to agonists appeared normal. When the GDPAS:GTP ratio was 4:1, the responses to agonists decreased with consecutive agonist applications. The response to SP was almost completely blocked after three SP applications, but LHRH or muscarine was still capable of inhibiting $I_{\rm M}$. When LHRH was applied first, successive responses diminished; however, SP or muscarine was still effective in inhibiting $I_{\rm M}$. Successive responses to muscarine were less sensitive than the peptide responses to inhibition by GDPAS.

These results suggest that each type of receptor is associated with a distinct population of G proteins. It is not clear whether this represents a diversity in the molecular structure of the separate G proteins or reflects a physical compartmentation of the G protein populations activated by the different receptors.

SPONTANEOUS FIRING IN SQUID AXONS INDUCED BY CHANGES IN INTRACELLULAR ph. John R. Clay*, Vijay Kowtha*, and Keith E. Krebs, Lab of Biophysics, NINDS, NIH, Bethesda, MD 20892, and Marine Biology Lab, Woods Hole, MA 02543.

We have observed automaticity (firing frequency ~ 20 Hz) from squid giant axons internally perfused with solutions having a pH > 8.5. $T = 12^{\circ}$ C. The effect is robust and reproducible, lasting in some preparations for as long as 45 min. It is associated with a hyperpolarizing influence on the membrane potential, inasmuch as the recovery of the membrane potential from the foot of the action potential (AP) is slower during automaticity compared to the recovery of the membrane potential toward rest in control (pH_i = 7) following an elicited AP. Moreover, the resting potential is hyperpolarized by ~ 5 mV with a change of pH_i from 7 to 9 with TTX seawater. Voltage clamp measurements revealed a lack of effect of a change in pH $_{i}$ (7<pH $_{i}\!<$ 9) on I $_{Na}\!$. The delayed rectifier is modified in this pH range by a shift of its inactivation curve along the voltage axis in the positive direction as the pH is made basic. This effect produces a hyperpolarizing influence, theoretically, but it is insufficient to explain the excitability and resting potential results. A change in pH_i from 7 to 9 appears to reduce the leak conductance, an effect which may be sufficient to explain these observations. The proposed mechanism underlying automaticity is a reduction of INa inactivation by this hyperpolarization, thereby increasing the amount of inward current available to take the membrane potential beyond threshold following recovery from the foot of the previous AP.

SOMATOSTATIN, OPIOIDS AND α_2 RECEPTOR AGONISTS INCREASE ACTIVITY OF POTASSIUM CHANNELS AND DECREASE ACTIVITY OF CALCIUM CHANNELS IN EXCISED MEMBRANE PATCHES. <u>K-Z. Shen. A. Surprenant and R.A. North.</u> Vollum Institute, Oregon Hlth. Sci. Uni., Portland, OR 97201.

Outside-out recordings were made from neurons enzymatically dissociated from guinea pig submucous plexus. Several potassium channels of different conductances were active, and the unitary currents reversed polarity at potentials appropriate to the Nernst equation when external potassium was 10, 25, 55, 105 and 160 mM. Noradrenaline (0.1-10 μ M), the selective α_2 -adrenoceptor agonist UKl4304 (60-400 nM), somatostatin (40-200 nM) and [Met 5]enkephalin (2-10 μ M) increased potassium channel activities, and these effects were blocked by appropriate antagonists (idazoxan and naloxone). All agonists were effective when applied sequentially to the same patch. Quantitative analysis was difficult in patches with channels of several conductances; however, for the largest conductance channel (about 200 pS in equal 160 mM potassium) agonists prolonged burst duration. Agonist actions were mimicked by including GTP- γ -S (500 uM) in the electrode, and prevented by GDP- β -S (500 uM). With external BaCl2 (110 mM) depolarization of the patch opened unitary N-like calcium channels: openings were much reduced by cadmium (100 μ M) and significantly decreased by the three agonists. The same receptors couple to several potassium channels as well as a calcium channel in isolated membrane patches.

PEPTIDES: ANATOMICAL LOCALIZATION I

157.1

DISTRIBUTION OF PREPRO-MELANIN-CONCENTRATING HORMONE-DERIVED PEPTIDES AND MRNA IN THE RAT BRAIN. J.C. Bittencourt, F. Presse*, J.L., Nahon*, C.A. Peto*, W. Vale and P.E. Sawchenko. The Salk Institute, La Jolla, CA 92037.

In addition to a nonadecapeptide homologous to the teleost melanin-concentrating hormone (MCH), the amino acid sequence predicted from a rat prepro-MCH cDNA (Endocrinology 125:2056, 1989) suggested that at least one (neuropeptide EI, or NEI), and possibly a second (NGE), neuropeptide may be encoded by this precursor. Cross-reactivity with epitopes of NEI or NGE can account for reported localization of a-MSH, rat CRF and human GRF in rat dorsolateral hypothalamic neurons. We have used antisera raised against rat MCH and NEI in immunohistochemical studies at the light and EM levels, along with hybridization histochemical localization of prepro-MCH mRNA, to define the organization of this system. As expected, prepro-MCH mRNA is prominently expressed in cells in the lateral hypothalamic area and zona incerta. In addition, smaller cell groups in the olfactory tubercle and pontine tegmentum were also positively hybridized using cRNA probes. The MCH and NEI peptides were extensively colocalized in neurons in each of these areas. Fibers stained for MCH and NEI were similarly and broadly distributed throughout the CNS in patterns that generally conformed with known projection fields of the lateral hypothalamic area and zona incerta. A differential distribution was seen in at least one region, the interanterodorsal nucleus of the thalamus, which contained a prominent terminal field stained for MCH but not NEI. At the EM level, a subset of MCH stained perikarya displayed prominent staining associated with the Golgi apparatus; this was not encountered in NEI stained cells. Both peptides were localized in terminals in the septal nuclei, lateral hypothalamic area and median eminence, with staining associated principally with dense-cored vesicles.

157.2

LOCALIZATION OF ATRIAL NATRIURETIC FACTOR-LIKE mRNA IN THE RAT BRAIN BY IN SITU HYBRIDIZATION. F. Riftina and B.S. McEwen. Lab of Neuroendocrinology, The Rockefeller University, New York, NY 10021

Atrial natriuretic factor (ANF) is a 28 amino acid

Attial natriuretic factor (ANY) is a 20 amino acid peptide that is proteolytically released from the carbo-xy-terminal end of a larger (126 aa) precursor. ANF released from the atrium of the heart exerts effects on the regulation of water and salt balance. ANF-like immunoreactivity has been shown to be present in the brain where it is implicated in the central regulation of blood-pressure homeostasis, and control of salt appetite. In our experiments, a synthetic oligonucleotide probe complementary to the part of the carboxy-terminal region of the rat ANF (amino acids 107-116) was used to study the distribution of ANF-like mRNA in the rat brain. Perikarya containing ANF-like mRNA were detected in the cortex, septum, hippocampus, preoptic area, thalamus and hypothalamus.

This work was supported by the NIH Grant 5T32 DK 07313-12 and NIMH Grant MH 43787.

FLFOPORF-AMIDE-LIKE PEPTIDES IN RAT CNS: ONTOGENY, ORGANIZATION OF NEURONAL SYSTEMS, AND RELATIONS TO OTHER NEUROPEPTIDES. L. Kivipelto and P. Panula. Dept. Anatomy, Univ. of Helsinki, 50170 Helsinki, Finland.

FLFOPORFamide (F8Fa), isolated from bovine brain, shares the carboxy terminus with the molluscan cardioexcitatory peptide FMRFamide. We used immunohistochemistry and retrograde tract tracing method to study the neuroanatomy of the F8Fa-immunoreactive (ir) system in rat CNS.

system in rat CNS.
Intraventricular and intraspinal colchicine treatment was applied to visualize F8Fa-ir perikarya. To trace F8Fa-ir fiber connections retrograde tracer True Blue® was injected into F8Fa-ir terminal areas. Rats of different ages were studied to establish the ontogeny of F8Fa-like immunoreactivity (LI) containing system. Light microscopic mirror method was applied in a comparative study with other peptides. Tissues were fixed with 4% paraformaldehyde.

F8Fa-ir cells of periventricular hypothalamus projected to the nucleus of the solitary tract (Sol). Neurons of Sol projected within the same nucleus, to periambigual area and lateral parabrachial nucleus. The spinal F8Fa-ir was mainly of intrinsic origin. The spinal F8Fa-ir cells were located in laminae 1, II, X and in the dorsal gray commissure of sacral cord. Fibers and terminals were found in laminae I, II, X, intermediolateral cell column and sacral parasympathetic nucleus. No F8Fa-LI was detected before embryonal day 20 when terminals were detected in median eminence. After that the EFEa-ir system developed very rapidly and reached its adultifixe form by the end of fourth postnatal week. FEFa-ir system appeared to be anatomically distinct from enkephalin and neuropeptide Y-ir systems, although some overlapping of terminal fields was observed, and coexistence of FBFa and NPY-LI was

overlapping of terminal fields was observed, and coexistence of rora and introduced detected in a small group of hypothalamic neurons.

The F8Fa-ir system appears to be distinct from any previously described peptide system. Our results show a perinatal development of the F8Fa-ir structures in rat CNS suggesting a neurotransmitter role of these peptides. These anatomical studies further support the concept that F8Fa-like peptides are involved in the regulation of nociception and autonomic and

DISTRIBUTION OF SOMATOSTATIN-IMMUNOREACTIVE CELL BODIES AND PROCESSES IN THE TELENCEPHALON OF MACACA FUSCATA. S. Iritani* and K. Satoh. Department of Psychiatry, Shiga University of Medical Sciences, Otsu 520-21, Japan. Distribution of somatostatin-immunoreactive cell bodies and pro-

cesses was studied in the telencephalon of the macaque monkey (Macaca fuscata), by applying an immunohistochemical technique using a monoclonal antibody raised against somatostatin tetradecapeptide. Many somatostatin-immunoreactive cell bodies and processes were observed in all regions of the cerebral cortex. The cell bodies were distributed in layers II to VI of the neocortex, and also in the underlying white matter. Three types of somatostatin-containing cell bodies were distributed in the cerebral cortex. A large number of somatostain-containing cell bodies and processes were observed throughout the hippocampal formation, including the subiculum. The regional distribution of somatostatin-immunoreactive puncta was most dense in the molecular layer of the dentate gyrus. Many somatostatincontaining cell bodies were observed in the stratum oriens of CA1 and CA2 and in the field of CA4. In the entorhinal cortex, the distribution pattern of somatostatin-containing cell bodies and fibers was similar to that of the neocortex. Within the amygdaloid nuclei, a dense distribution of immunoreactive cell bodies and fibers were observed in the central nucleus. The present observations demonstrate that somatostatin-containing neuronal systems are highly developed in the forebrain limbic structures of the primate.

157.7

CAJAL-RETZIUS CELLS IN LAMINA I OF THE FELINE CEREBRAL CORTEX EXHIBIT CORTICOTROPIN RELEASING HORMONE-LIKE (CRH) IMMUNOREACTIVITY. V. John Massari, Y. Tizabi, and P.J. Gatti. Howard Univ. Coll. Med., Wash., D.C. 20059.

We have examined the distribution of immuno-reactivity for CRH, Neuropeptide Y (NPY), and choline acetyltransferase (ChAT) in lamina I of the cerebral cortex of colchicine treated cats utilizing an avidinbiotin immunoperoxidase method. In all cortical areas examined, CRH immunoreactive perikarya were found in lamina I. Some of these cells were large and had long horizontal processes, which are the characteristics of Cajal-Retzius cells. CRH immunoreactive perikarya were also found in lamina II. No NPY-like immunoreactive cells were found in lamina I. NPY cells however, were cells were found in lamina I. NPY cells however, were numerous in the deepest layers of the cerebral cortex and particularly in the subcortical white matter. ChAT-like immunoreactive perikarya were not detected in lamina I or in any other lamina of the cerebral cortex examined, despite colchicine pretreatment. However, numerous well stained ChAT cells were seen in other nuclei throughout the brain. Since Cajal-Retzius cells receive input from noradrenergic terminals from the locus ceruleus and synapse upon dendritic bouquets of all cortical pyramidal cells, it appears that CRH-neurons in lamina I are ideally situated to modulate cortical neuronal functions. Supported by A.H.A./N.C.A.

157.4

LOCALIZATION OF DIAZEPAM BINDING INHIBITOR (DBI) IN THE LOCALIZATION OF DIAZEPAM BINDING INHIBITOR (DBI) IN THE RAT BRAIN AND PITUITARY BY HIGH RESOLUTION IN SITU HYBRI-DIZATION, Y. Tong*, E. Rhéaume*, J. Simard*, A. Dupont and G. Pelletier. MRC Group in Molecular Endocrinology, CHUL Research Centre, Quebec, Canada.

An endogenous polypeptide which exhibits high affinity

for brain benzodiazepine (BDZ) receptors has been recently been isolated and characterized. It has been named diazepam binding inhibitor (DBI). Using antibodies against an octadecaneuropeptide (ODN) derived from DBI, we have very recently localized this peptide in glial cells of the rat brain and pituicytes of the rat posterior pituitary. In order to determine whether or not these non-neuronal cells are involved in DBI biosynthesis, high resolution in situ hybridization was performed using [35S]labeled antisense RNA as well as control sense RNA (plasmid supplied by Dr. H. Tiedge). Hybridization signal was observed in both semithin (1 $\mu m)$ and ultrathin sections (0.1 $\mu M)$ in the hypothalamus, cerebral cortex, cerebellum and posterior pituitary. In the different brain areas, specific pituitary. In the different brain areas, specific labeling was exclusively observed in astrocytes and epenlabeling was exclusively observed in astrocytes and epen-dymal cells. In the posterior pituitary, only pituicytes were labeled. These results clearly indicate that DBI is synthesized in non-neuronal cells in the rat brain and posterior pituitary. The present findings together with previous results indicating the presence of BZD receptors in glial cells suggest that DBI may play an important role in glial cell function.

SOMATOSTATIN IN PRIMATE DIENCEPHALON. C. Desjardins* and A. Parent. Lab. of Neurobiol., Laval Univ., Québec, Canada.

As part of a research program designed to investigate the anatomical and functional organization of somatostatin (SS) neuronal systems in primate forebrain, we studied the distribution of SS immunoreactivity in by the diencephalon of squirrel monkeys (Saimiri sciureus) with antibodies SS 309 and SS 320 (R. Benoit). In **thalamus** dense plexuses of SS fibers were noted in medial pulvinar, medial habenula, and causal portions of mediodorsal nucleus. Other fibers and terminals were portions of mediodorsal nucleus. Other fibers and terminals were scattered in midline nuclei, centralis medialis, subparafascicularis, centralis superior lateralis and lateral habenular nuclei. Weakly stained cells occurred in rostral and caudal poles of reticular nucleus and in centralis medialis, mediodorsal, centralis superior lateralis and laterodorsal nuclei. In subthalamic region a dense fiber plexus capped the dorsolateral pole of subthalamic nucleus (STH), whereas few fibers occurred in ventral part of zona incerta and in ventromedial portion of STH. In hypothalamus very dense fiber plexuses were noted in medial preoptic area, suprachiasmatic nucleus, around central core of ventromedial nucleus, in arcuate nucleus and median eminence. Other fibers were scattered in lateral area, periventricular gray, and supramammillary area. Multipolar SS cells were noted in median supramammillary area. Multipolar SS cells were noted in median anterior area, paraventricular nucleus, at the periphery of ventromedial nucleus and in lateral area. Large SS fibers of the "wooly" type coursed along the dorsal surface of the optic tract in lateral hypothalamus. These fibers were morphologically similar to and continuous with the abundant wooly fibers in substantia innominata and amygdala. These results suggest that SS mediates some of the complex interactions that occur between hypothalamus and amygdala.

CRF IMMUNOSTAINING IN THE SYRIAN HAMSTER FOREBRAIN.

CRF IMMUNOSTAINING IN THE SYRIAN HAMSTER FOREBRAIN.
R. L. Meisel and S. N. Del Paine. Dept. of Psychological Sciences,
Purdue University, West Lafayette, IN 47907.
Syrian hamsters differ from many species in the regulation of
adrenocortical secretions. For example, following unilateral
adrenalectomy, Syrian hamsters do not show compensatory adrenal
growth characteristic of other species. This lack of compensation for
diminished adrenal output indicates that there may be differences in
negative feedback sensitivity to adrenal corticoids. In this study we
examined the distribution of CRF immunoreactivity in the forebrain of
the hamster as part of our investigations into the regulation of adrenal examined the distribution of CRF immunoreactivity in the forebrain of the hamster as part of our investigations into the regulation of adrenal function in this species. Immunocytochemistry for CRF was conducted using a primary antibody to oCRF and a peroxidase-based Vector ABC kit. A consistent pattern of neuronal labelling was observed among hamsters treated with colchicine. Large numbers of labelled cells were located in the bed nucleus of the stria terminalis, the preoptic area, the supraoptic nucleus, and the paraventricular nucleus of the hypothalamus. A prominent cell group was also found in the caudal retrochiasmatic area. Fewer cells were seen in several thalamic nuclei, with a sparse distribution of neurons in the lateral septum, and the medial and central amygdaloid nuclei. Some labelled cells were also found in the caudal arcuate nucleus. In the cerebral cortex, labelled cells were evident in the arcuate nucleus. In the cerebral cortex, labelled cells were evident in the superficial layers of the parietal cortex. None of these cellular groups were labelled in noncolchicine-treated hamsters, even after unilateral adrenalectomy. The pattern of CRF staining reported here for the Syrian hamster is very similar to that reported for the rat, though the central nucleus of the amygdala was only weakly stained in the hamster. These results suggest that CRF in the hamster, as in the rat, may regulate extracortocotrophic functions.

DISTRIBUTION OF PRODYNORPHIN PEPTIDES IN PRIMATE CORTEX D.J. Healy, J.H. Meador-Woodruff, and H. Akil. Mental Health Research Institute and Department of Psychiatry, University of Michigan, Ann Arbor, MI 48109.
Prodynorphin (prodyn) is one of the three endogenous opioid peptide precursors, and can be processed into several functional domains with affinities for the opiate receptors. Prodyn is of particular interest, as it is the only opioid peptide precursor that produces peptides with significant affinities for the kappa opiate receptor. Prodyn peptides have been previously studied in various brain regions such as the hippocampus and the basal ganglia; in primates, these peptides also exist in fairly high concentrations in the cortex, but a detailed investigation of the distribution of these peptides in cortex has not yet been performed. In an attempt to understand the nature of cortical prodyn-derived peptides, we studied the distributions of Dyn A (1-17), Dyn A (1-8), Dyn B, and α -neoendorphin in twelve cortical areas in six monkeys (macaca nemestrina) using specific radioimmunoassays. There were between-region differences in amount of each peptide in the twelve cortical areas studied, suggesting regional heterogeneity in the distribution of prodyn in primate cortex. DISTRIBUTION OF VASOACTIVE INTESTINAL FOLYPEPTIDE IMMANOREACTIVE(VIP-IR) NEURONS IN CANIME PORCERAINS

D.S.Lee and C.I.Cha, Department of Anatomy, College of Medicine, Secul National University

To compare the morphological differences in the distribution of the vasoactive intestinal polypeptide immunoreactive (VIP-IR) neurons in the brains of higher animals with those of rodents, an immunohistochemical study of canine forebrains was conducted using the ABC method. Unlike the previous report on rats and mice, we found some interesting characteristics of canine VIP-IR neurons in the cerebral cortex and hypothalamus.

the previous report on rats and mice, we found some interesting characteristics of canine VIP-IR neurons in the cerebral cortex and hymothalamus.

In the cerebral cortex, VIP-IR neurons were present in all layers of the cortex and very control of multipolar neurons was much higher, 2) the staining density of multipolar neurons was much higher, 2) the staining density of multipolar neurons was higher than that of bipolar cells, 3) two band-like distributions of cells were observed one in layers II and III and another in layers V and VI, and 4) among bipolar cells, obliquely lying cells were frequently found even in the middle layers of the cortex.

In the hypothalamus, densely stained cell bodies and fibers were found in the suprachiasmetic nucleus largely in accordance with the previous descriptions in rodents. In addition, there were strong VIP-IR cells doing and fibers in the magnocellular portion of the supraoptic and paraventricular nucleus and also many immunoreactive fibers in the internal layer of the median eminence. Some scattered fibers were seen in the external layer of the median eminence and a few fibers around the blood vessels. VIP-IR cells were also seen in the magnocellular portion of the medial preoptic area.

The above findings in the hypothalamus were largely consistent with previous biochemical studies and presented morphological evidence that VIP had some neuroendocrinological functions, especially in the hypothalamo-neurohypophysial system.

IMMUNOCYTOCHEMISTRY OF THE GNRH SYSTEM IN DEVELOPING XENOPUS. J.W. Wilkin. Dept. Anatomy and Cell Biology, Columbia Univ., Coll. of P&S, New York, NY 10032
The anatomy of the gonadotrophic releasing hormone (GnRH) system has been described in the adult African clawed toad (Xenopus laevis) (Doerr-Schott, J. and M.P. Dubois, Cell Tiss. Res., 172:477, 1976); however it is not known when the system differentiates or whether it is fully (or differently) developed in premetamorphic stages.

Embryonic, larval and young metamorphic toads (Nieuwkoop and Faber stages 23 through 66) were anesthetized with MS222 and fixed by Immersion in 4% paraformatidehyde, 7% sat. picric acid in 0.1M phos. buffer, pH 7.3 for 1/2 hr. to 24 hr., depending upon the age of the animal. Tissues were either: 1) embedded in OCT and cut at 12 um on the cryostat, 2) embedded in 12% gelatin and cut at 40 um on the recazing microtome. Sections (either on slides or free floating) were incubated in an antibody to GnRH (LR1 of Benoit or Rb4468 of our laboratory) followed by the standard Vectastain avidin biotin HRP (ABC) procedure with DAB as the chromogen. Controls in which the primary antibody was omitted or preabsorbed with GnRH peptide had no specific staining.

DAB as the chromogen. Controls in which the primary antibody was omitted or preabsorbed with GnRH peptide had no specific staining.

By larval stage 47, there were GnRH fibers in the anterior telencephalon and the lateral aceilular region of the diencephalon. In addition, there was a dense fiber projection in basolateral region of the entire spinal cord. In young metamorphic toads, there were GnRH neurons in the following locations: the septat/preoptic area, continuing ventrally and posteriorly, with projections towards the infundibulum; ventrolaterally in the diencephalon with projections to the lateral geniculate, habenula and optic tectum; along the pia at the medial surface of the telencephalon, probably in association with the nervus terminalis. Some Inetial strate of the relative phalon, protestly in association with the relative terminants. Single from the previous dentification of the entrance of the optic nerves. There were traceries of fibers in the amyodala, olfactory bulb and in the region bulb, pallial regions, midbrain and hindbrain. Innervation of the spinal cord was notably reduced after metamorphosis, with only an occasional fiber visible in the mid ventral region. USPHS HD10665

NEUROPEPTIDE-Y IMMUNOREACTIVITY IN THE HUMAN STRIATE

NEUROPEPTIDE-Y IMMUNOREACTIVITY IN THE HUMAN STRIATE CORTEX. Nancy E.J. Berman. Dept. of Anatomy and Cell Biology, Univ. of Kansas Med. Ctr., Kansas City, KS 66103

Neuropeptide-Y (NPY) is a potent vasoconstrictive agent found in perivascular axons of peripheral vessels. Little is known about its function in the cerebral cortex. We examined the morphology and distribution of NPY-immunoreactive (NPY-ir) neuronal cell bodies and axon plexuses in human striate cortex using a polyclonal antibody (Cambridge Biochemicals). The stability of NPY in postmortem tissue (Norvell and Macbride, '90), makes this expressed feasible.

approach feasible.

A dense plexus of NPY-ir axons was seen in the upper part of layer I, just A dense piexus of NPY-ir axons was seen in the upper part of layer 1, just beneath the pia. This piexus was especially pronounced in regions where the pia is penetrated by small capillaries, and NPY-ir beaded axons often surrounded these capillaries. In the lower half of layer I, small multipolar NPY-ir neurons were seen. Many of these had beaded axons with tortuous trajectories, including "hairpin" loops. These axons may contribute to the plexus in the upper part of layer I. In layers II-IIII neurons with a variety of

plexus in the upper part of layer I. In layers II-IIIb neurons with a variety of multipolar, nonpyramidal morphologies including neurons with axon loops were found. In layers IVb.c, V, and VI, NPY-ir neurons were relatively less numerous than in the supragranular layers. NPY-ir neurons were relatively more numerous in the white matter. Many of these cells had perikarya elongated in the dimension parallel to the axon bundles.

In addition to the NPY-ir axons surrounding pial capillaries, NPY-ir neurons were found in close approximation to small blood vessels throughout the cortex. Control of cerebral blood flow is thought to be achieved primarily by autoregulation. These results suggest an additional mechanism. As in some peripheral vascular beds, cortical blood flow may be influenced by neuropeptide-Y innervation of arteries. This innervation may originate from intrinsic cortical NPY containing neurons. VASOACTIVE INTESTINAL PEPTIDE mRNA EXPRESSION IN PRIMARY SOMATIC SENSORY AND VISUAL CORTEX OF MONKEY AND RAT

D.L.Benson, P.J.Isackson and E.G.Jones. Department of Anatomy and Neurobiology, Univ. of California, Irvine, CA

Previous immunocytochemical studies have failed to localize vasoactive intestinal peptide (VIP) containing neurons in monkey neocortex. In this study, using in situ hybridization techniques, the areal and laminar distribution of VIP cRNA was examined in primary somatic sensory and visual cortex in rats and monkeys. The cDNA corresponding to the mRNA which encodes VIP and PHM, a related peptide, in monkey neocortex was isolated using polymerase chain reaction amplification. The monkey VIP cDNA was 488 base pairs long and had a 98% sequence identity with the published human cDNA in the comparable region (Itoh, et al, Nature 304:547,1983). Using the monkey VIP clone, we synthesized 35-S labeled antisense RNA probes for in situ hybridization studies. In primary somatic sensory cortex and primary visual cortex, the distribution of VIP cRNA hybridization was very similar. In both rat and monkey, labeled cells were evident in all layers, including layer I. Occasional, labeled cells were also found in the underlying white matter. The greatest density of antisense VIP cRNA labeled cells was in layers II and III. The present results indicate that both rat and monkey III. The present results indicate that both rat and monkey neocortex express VIP mRNA. Supported by N.I.H. grant number NS 21377.

LOCALIZATION OF A NEUROKININ B PRECURSOR PROTEIN FRAGMENT IN GUSTATORY AND OLFACTORY PATHWAYS IN RAT BRAIN BY IMMUNOCYTOCHEMISTRY. L.R. Lucas, J.E. Krause and R.E. Harlan. Neuroscience Training Program and Dept. of Anatomy, Tulane Univ. Sch. Med., New Orleans, IA 70112 and Dept. of Anatomy and Neurobiology, Washington Univ. Sch. Med., St. Louis, MO 63110.

Neurokinin B (NKB), a bioactive tachykinin, derived from the preprotachykinin (PPT) B protein. Raising antisera that do not cross react among the tachykinins has proven difficult in the past given the homology in sequence of the C-terminus region of these peptides. We have raised antisera in rabbit specific for a 30-amino acid fragment (Peptide 2) found in PPT B protein, upstream of the NKB peptide. Immunohistochemical protein, upstream of the NRS peptide. Immunohistochemical localization of the peptide in rats perfused with Zamboni's fixative revealed a widespread distribution in gustatory and olfactory pathways in the brain. Our initial mapping studies have shown immunoreactive fibers and cell bodies in non-colchicine treated animals at dilutions of 1:1000 to 1:10,000. The parabrachial nucleus, central nucleus of the amygdala, and the olfactory tubercle showed very dense immunoreactivity. More moderate staining was observed in immunoreactivity. More moderate staining was observed in the nucleus of the stria terminalis, anterior olfactory nucleus, and olfactory bulb. Immunoreactivity was completely abolished by preabsorption of the antiserum with a 10 μmolar concentration of the 30-residue peptide. Our results agree favorably with previously published reports of NKB mRNA distribution.

ACTH AND ENKEPHALIN (ENK) AXONAL INPUT TO C-FOS CONTAINING PARAVENTRICULAR (PVN) NEURONS. S. Pretel and D.T. Piekut, Neuroendocrine Unit, University of Rochester, Rochester, N.Y. 14642

Recent immunocytochemical studies suggest that the appearance of c-fos in neuronal nuclei of adult rats is dependent on neuronal activity and occurs in particular following stressful stimulation. It is of interest to determine which neurotransmitters modulate specifically those neurons, activated by a certain stress stimulus. We have focused on the afferent input of two peptides, known to be involved in processing of stress information, to c-fos containing neurons in the PVN.

Under ether anesthesia, mustard oil (MO) was gently applied to the left hindfeet of experimental rats, control rats received applications of saline. One to three hours later, the animals were transcardially perfused with phosphate buffer followed by 4% paraformaldehyde. Hypothalamic tissue sections were processed for c-fos (gift of Dr. D. Slamon) immunocytochemistry followed by ACTH or ENK immunocytochemistry using the ABC Vectastain Kit. The c-fos antibodies were visualized with the 3,3'- diaminobenzidine (DAB) procedure, the ACTH or ENK antibodies with the DAB/Nickel procedure. Some sections were plastic embedded for semi-thin sectioning.

semi-thin sectioning.

The c-fos antiserum labeled only neuronal nuclei; the ACTH and ENK antiseral labeled peptide fibers. Mustard oil is known to activate small diameter, nociceptive nerve fibers. Unilateral application of MO increased the number of PVN neurons with c-fos labeled nuclei bilaterally. These c-fos labeled neurons were present in the parvocellular components of the PVN. The data showed that following a stressful, e.g. noxious stimulus, subpopulations of PVN neurons were activated. Double-labled tissue sections demonstrated ACTH and ENK immunoreactive axons in close proximity to these c-fos containing neurons. Two micron sections substantiated that ACTH and ENK varicosities were positioned such, as to be able to modulate the activity of neurons and thus the stress induced expression of c-fos in these neurons. (Supported by NS 18626.)

INTRAVESICULAR ORGANIZATION OF THE NEUROPHYSINS AND THE C-TERMINAL GLYCOPEPTIDE OF PROPRESSOPHYSIN (CPP) IN RAT NEURAL LOBE. M. Tian and W.E. Armstrong. Dept. of Anat. Neurobiol., Univ. Tenn., Memphis, The Health Science Center, Memphis, TN 38163.

Prior to characterization of the vasopressin precursor as a glycopeptide, Tasso et al (Cell Tiss. Res. 180: 11, 1977) reported a probable glycopeptide in the perimeter of vasopressin-containing dense core vesicles of the neural lobe using silver protein stains. By quantifying the distribution of gold particles over dense core vesicles from highly magnified electron micrographs, we find that CPP indeed occupies a distinctly more peripheral part of vasopressin vesicles than does vasopressin-associated neurophysin (VP-NP)

Oxytocin and vasopressin granules were immuno-labeled on thin sections from rapidly frozen, freeze substituted rat neural lobes. In vasopressin vesicles, an antibody to CPP preferentially labels the perimeter of the dense core (~70% of gold particles), compared to a circular core region of equal area (~30%), whereas an antibody cross reacting with both VP-NP and OT-NP (PS45) labels the central region preferentially (~65% central, ~35% perimeter). Thus, in vasopressin vesicles, NP and CPP distributions are complementary. In oxytocin vesicles, an antibody specific to OT-NP (PS38) and PS45 both preferentially label the central region (~60%) of the vesicle compared with the perimeter (~40%).

Thus, within neurohypophysial dense core vesicles, the different products derived from the vasopressin and oxytocin precursor are not homogeneously distributed. Supported by NIH grant #NS23941.

ULTRASTRUCTURAL CHARACTERIZATION OF GALANIN SYNTHESIZING NEURONS IN HYPOPHYSIOTROPHIC REGIONS OF THE RAT DIENCEPHALON. Z. LIPOSITS^{1,2} I. MERCHENTHALER² and A. NEGRO-VILAR³. Dept. of Anatomy, Univ. Med. School, Pecs 7643, Hungary and Funct. Morphol. and Reprod. Neuroendocrinol. Sections, LMIN, NIEHS, NIH, Research Triangle Park, NC

Sections, LMIN, NIEHS, NIH, Research Triangle Park, NC 27709, USA.

Galanin has been shown to be synthesized in the brain (Skofitsch and Jacobowitz, Peptides, 6: 509-546, 1985) and to act upon the pituitary gland (Ottlecz et al., Proc. Natl. Acad. Sci. USA, 85: 9861-9865, 1988). In order to characterize the hypophysiotrophic galanin immunoreactive (IR) system morphologically, parvocellular neurons expressing the peptide were studied, by means of ultrastructural immunocytochemistry, in the medial preoptic area, the paraventricular and arcuate nuclei of colchicine treated (30 $\mu g/100$ g b.w.), adult male rats. The neurons contained immunolabeled ribosomes, neurosecretory granules of 80-120 nm and received synapsing axon terminals on their cell bodies and dendrites. Galanin-containing axons established neuro-hemal junctions with portal vessels in the median eminence and also formed synaptic connections with neurons residing in the preoptic, paraventricular and arcuate regions. Light microscopic double labelling performed in the paraventricular nucleus revealed that the parvocellular galanin-IR cells were densely innervated by adrenergic and neuropeptide-Y-IR axons and received a modest serotonergic input. Galanin-IR axons were in juxtaposition to somatostatin-IR neurons. These data indicate, that both hypophysiotrophic and neuromodulatory functions can be attributed to galanin synthesizing neurons.

INTERACTIONS OF PROPIOMELANOCORTIN (POMC)-RELATED PEPTI-INTERACTIONS OF PROFIOMELANOCORTIN (POMC)-RELATED PETIDES, NEUROPEPTIDE Y (NPY) AND DOPAMINE B-HYDROXYLASE (DBH) FIBERS AND THYROTROPIN-RELEASING HORMONE (TRH) NEURONS IN THE PARAVENTRICULAR NUCLEUS OF RAT HYPOTHALAMUS. N. Liao¹*, M. Bulant²*, P. Nicolas²*, H. Vaudry²* and G. Pelletier¹. ¹MRC Group in Molecular Endocrinology, CHUL Reserach Centre, Quebec, Canada and ²GREM, Faculté des Sciences, Université de Rouen, France.

In order to determine the nature of afferent fibers contacting TPH payroral cells hodies in the rat proporbales.

contacting TRH neuronal cells bodies in the rat hypothalamic paraventricular nucleus, we used dual immunostaining procedures which employed antibodies to ACTH (to label POMC neurons), NPY and DBH and peroxidase-labeled goat anti-rabbit lgG as a first sequence and antibodies to a cryptic fragment (Ps5) of pro-TRH (to label TRH neurons) and alkaline phosphatase-labeled goat anti-rabbit IgG as the second sequence. A rich innervation of the paraventricular nucleus by immunoreactive POMC, NPY and DßH fibers was observed. Numerous NPY and POMC fibers were in intimate anatomic proximity and often appeared to surround in mate anatomic proximity and often appeared to surround in remarkable density TRH-containing cell bodies. Less frequent oppositions between DBH fiber and TRH cell bodies were detected. These results strongly suggest that TRH neurons might be regulated by POMC, NPY as well as adrenergic and/or noradrenergic systems. These interactions might be the neuroanatomical basis for the already observed effects of onests pentides. NPY and catabolism. observed effects of opiate peptides, NPY and catecholamines on TSH secretion.

THE PATTERN OF HYPOTHALAMIC VASOPRESSIN MAGNOCELLULAR NEURONS DIFFERS ACROSS HAMSTER SPECIES. T.P. Goodness and G.J. DeVries. Prog. in Neurosci. and Behav., Univ. of Mass., Amherst, MA. 01003.

Magnocellular vasopressin (VP) neurons respond to osmotic challenge and temperature changes. Several differences in these responses have been observed across hamster species. We compared the pattern of VP-immunoreactive (VP-IR) cells in Cricetellus migratorius (CM) and griseus (CG), Phodopus campbelli (PC) and sungorus (PS), and Mesocricetus auratus (MA) to generate hypotheses about the role of these neurons. In addition to the paraventricular and supraoptic nucleus, MA had all the accessory VP-IR cell groups previously reported in rats, i.e., nucleus circularis, perifornical nucleus and nucleus of the medial forebrain bundle and scattered VP-IR cells in the anterior and lateral hypothalamic area. CM and CG lacked VP-IR neurons in the nucleus circularis and had few in the anterior hypothalamic nucleus. PS also lacked a nucleus circularis, but had more cells scattered rostrally in the anterior hypothalamic nucleus. PC had fewer VP-IR cells in the anterior hypothalamic nucleus, but had a prominent nucleus circularis. CM, CG, and MA had a discrete group of perifornical VP-IR cells, while PC and PS had VP-IR cells spread out throughout the lateral hypothalamus. Finally, CM lacked cells in the nucleus of the medial forebrain bundle. Since some of these accessory nuclei have been linked to temperature and osmoregulation, the species differences may be related to the different environmental demands.

157.20

THE HYPOPHYSIOTROPIC GALANIN SYSTEM OF THE RAT BRAIN AS REVEALED BY COMBINATION OF RETROGRADE TRACING AND IMMUNOCYTOCHEMISTRY. 1. Merchenthaler and A. Negro-Vilar. Functional Morphol. and Reprod. Neuroendoc. Sections, NIEHS, NIH, Res. Triang. Park, NC 27709

Fluoro-Gold is a retrograde tracer which does not penetrate the blood-brain-barrier (BBB) but is taken up by nerve terminals from areas which are outside of the BBB. The median eminence (ME) is a circumventricular organ lacking a BBB and it contains large number of galanin-immunoreactive (GALI) nerve terminals. In order to identify those GALI neurons which have access to capillaries of the ME (the hypophysiotropic GALI neurons), Fluoro-Gold was injected peripherally (15 mg/kg). Five days later colchicine was injected into the lateral ventricle. The animals were perfused with fixative one day later. Thin paraffin sections were immunostained for GAL by the indirect immunofluorescence technique. The retrogradely transported Fluoro-Gold and the endogenous GAL immunoreactivity were examined with an Axiophot photomicroscope equipped with the necessary filter combination. Our studies indicate that the majority (approx. 70%) of the hypophysiotropic GALi neurons are located in the arcuate nucleus. The paraventricular nucleus, and to a lesser extent, the preoptic area also contribute to this system. Since the organum vasculosum of the lamina terminalis, another circumventricular organ, also contains GALI nerve terminals, the proper number of GALI neurons projecting to the median eminence from the preoptic region cannot be determined by this retrograde technique. The hypophysiotropic GALI neurons are intermixed with other non-hypophysiotropic GALI neurons are intermixed wit

CONNECTIVITY BETWEEN AV3V AND BRAINSTEM NUCLEI. S.A. Joseph. C. Bulson*, W.H. Pilcher and L.J. Sim. Neuroendocrine Unit, University of Rochester, Rochester, N.Y. 14642.

The AV3V nuclei encompassing the rostral part of the third ventricle have been shown to exert a significant influence in the regulation of cardiovascular function. Numerous electrophysiological studies have documented the reciprocity and potential interactions between brainstem and forebrain cardiovascular centers. These neuroanatomical studies demonstrate the intrinsic organization of the AV3V region and its afferent and efferent connections with brainstem nuclei.

Horseradish peroxidase conjugated wheat germ agglutinin (HRP-WGA) was injected into central sites of the AV3V region in the rat to elucidate cells of origin projecting to this region. Retrograde transport was identified most densely in the dorsal raphe, lateral parabrachial nucleus, locus coeruleus and the arcuate hypothalamic nucleus. Immunohistochemical analysis of these cell groups demonstrates that noradrenergic and serotonergic neurons contribute to these afferent projections.

Phaseolus vulgaris leucoagglutinin (PHA-L) anterograde marker was iontophoretically instilled into central sites of the AV3V region to determine projections to brainstem nuclei. Efferent projections in the form of terminals and fibers were found in the arcuate nucleus of the hypothalamus, dorsomedial nucleus, locus coeruleus, dorsal raphe and periaqueductal grey. These studies demonstrate neuroanatomical connectivity between forebrain and brainstem cardiovascular centers. (Supported by American Heart Association #871011 and NIH NS21323 grants.)

OPIOIDS: RECEPTORS I

150 1

MOLECULAR CHARACTERIZATION OF OPIOID RECEPTORS IN SUBCELLULAR FRACTIONS OF RAT BRAIN.

M. SZŰGS*, H.A. ÖKLEM* I. Lengyel*, V. SZŰLS*, G. TÓTH,* N. Halász and C.J. Coscia*. Biol. Res. Center Hung. Acad. Sci., 6701 Szeged, Hungary, * St. Louis Univ. Sch. Med., St. Louis MO 63104, USA.

Previously we have reported the binding characteristics of opioid receptors in synaptic plasma (CDM)

Previously we have reported the binding characteristics of opioid receptors in synaptic plasma (SPM) and light (LM) membrane fractions of rat brain. In the present work the subunit structure of opioid binding sites in these fractions was investigated with the mu receptor specific affinity reagent ("H)Tyr-D-Ala-Gly-N(Me)Phe-CH_Cl, ("H)DAMCK spec. activity 56.8 Ci/mmol, prepared by Varga et al. (Neuropeptides 12, 135, 1988). Labelled proteins were separated by SDS-PAGE and evaluated by gel slicing and fluorography. Predominant labelling was seen at about 58 kDa in SPMs as well as LMs. This polypeptide was also detected in subcellular fractions of 1-day-old rats (P-1), but additionally a heavily labelled band at Mr 48 kDa was apparent. This protein might be characteristic for the neonates, since only very weak incorporation into the 48 kDa protein was seen in adults. Incubation of rat brain SPMs under phosphorylating cygditions resulted in specific incorporation of "P from (T-"P)ATP into the 58 kDa protein. Results suggest that the 58 kDa protein might be the integral binding site of the opioid receptors.

MONOCLONAL ANTIBODIES TO MORPHINE AND HALOPERIDOL AS MODELS OF RECEPTOR-LIGAND INTERACTIONS J. M. Anchin. P. H. Kussie, C. Mandal, D. S. Linthicum, Dept. Vet. Microbiol., College of Vet Medicine, Teyas, A&M University, College Station, TY 77843

Vet. Medicine, Texas A&M University, College Station, TX 77843
Knowledge-based computer-assisted molecular modelling of monoclonal antibodies is now feasible using a modelling protocol involving "canonical structures" from known crystallographic coordinates of emperically solved myeloma proteins and monoclonal antibodies. In our study we examined the binding sites of monoclonal antibodies directed against morphine and haloperidol. Both of these drugs have piperidinyl nitrogens with similar pKa's and the protonated form of this molety is thought to be important in drug-receptor interactions for both drugs. Molecular modelling of the antibody binding sites reveals structural features and chemical interactions which may be similar to those found in the neurogenic receptor. For the anti-morphine antibody we have discovered that a hydrophobic pocket is formed by key residues in the hypervariable loops and H:50 glutamate forms a salt-bridge with the piperidinyl nitrogen of morphine. In the anti-haloperidol antibody, the flurophenyl ring of haloperidol "stacks" with an isolated tryptophan (H:50) thereby quenching it's natural fluorescence and also forms a salt-bridge with H:107 aspartate. The use of antibody binding sites as a paradigm for neurogenic receptor binding sites can be an important concept in our understanding of drug-receptor interactions. Detailed structure-activity relationships and molecular modelling studies are important tools if valid comparisons are to be made. (Supported by Am. Heart Assoc. Grant-in-Aid 89-1066)

158.2

AFFINITY LABELING OF THE p OPIOID RECEPTOR IN BRAIN, J.M. Bidlack, R.A. Kaplan, A. Seyed-Mozaffari, and S. Archer, 1Dept. of Pharmacology, University of Rochester, School of Medicine and Dentistry, Rochester, NY 14642 and Dept. of Chemistry, Cogswell Laboratory, Rensselaer Polytechnic Institute, Troy, NY 12181.

Previously, we have shown that after reduction of a disulfide bond at or near the ν opioid binding site in rat brain membranes, 14β -(bromoacetamido)-7,8-dihydromorphine (H₂BAM) alkylated this site, resulting in the irreversible inhibition of ν opioid binding, without altering binding to δ and κ opioid sites. [H]H₂BAM was synthesized and tested for its ability to bind reversibly and irreversibly to the ν opioid receptor. In the absence of a reducing reagent, [H]H₂BAM bound reversibly to rat brain membranes with a K_d value of 0.51 $^{\pm}$ 0.08 nM and a $R_{\rm max}$ value of 185 fmol/mg membrane protein. The ν -selective peptide DAGQ had a 700-fold lower IC $_{50}$ value for the inhibition of 0.4 nM [H]H₂BAM binding than either the δ -selective peptide DPDPE or the κ -selective alkaloid US0,488H. When membranes were treated with dithiothreitol (DTT), followed by the addition of [H]H₂BAM, the ν -opioid binding site was alkylated with the affinity ligand. The alkylation was dependent on pH, temperature, time, and on the concentrations of DTT and [H]H₂BAM. Only opioids known to bind to the ν -opioid binding site were able to block the affinity labeling. When membranes were separated on SDS polyacrylamide gels, proteins with molecular weights of 54,000 and 31,000 were specifically alkylated with [H]H₂BAM. (Supported by grants DA03742 and DA01674).

NALOXONAZINE AND &-FUNALTREXAMINE ANTAGONISM OF μ ACTIONS: FURTHER EVIDENCE FOR DISTINCT μ_1 AND μ_2 RECEPTORS. C.G. Pick, D. Paul and G.W. Pasternak. The Cotzias Lab. of Neuro-Oncology, Memorial Sloan-Kettering Cancer Center and Depts. of Neurology and Neuroscience and Pharmacology Cornell Univ. Medical College, New York NY 10021.

In binding studies, naloxonazine (NAZ) blocks μ_1 receptors whereas ß-funaltrexamine (ß-FNA) alkylates both μ_1 and μ_2 receptors. Because NAZ antagonized analgesia produced by i.c.v. DAMGO but not i.t. DAMGO, we proposed that μ_1 receptors mediate analgesia supraspinally whereas μ_2 receptors are active spinally. However, these results may reflect differing efficacies and levels of spare receptors with a single μ receptor type. If the differences between i.c.v. and i.t. analgesic sensitivity of DAMGO to NAZ were due to spare receptors, the μ -selective antagonist, ß-FNA should show similar results. NAZ antagonized i.c.v. DAMGO analgesia (ID_50-61 mg/kg), 6-fold more potently than i.t. DAMGO analgesia (ID_50-38.8 mg/kg). In contrast, ß-FNA blocked both i.c.v. (ID_50-6.1 mg/kg), and i.t. (ID_50-7.7 mg/kg) DAMGO analgesia equally well. ß-FNA also blocked morphine's inhibition of gastrointestinal transit, a NAZ-insensitive (μ_2) action, as effectively as i.c.v. and i.t. DAMGO analgesia. These differences between NAZ and ß-FNA strongly argue against the efficacy/spare receptor hypothesis and support the concept of distinct μ_1 and μ_2 receptors.

POSSIBLE CONTRIBUTION OF A GLUTATHIONE CONJUGATE TO THE

POSSIBLE CONTRIBUTION OF A GLUTATHIONE CONJUGATE TO THE LONG DURATION OF OPIOID ANTAGONISM BY B-FUNALIREXAMINE (\$B-FNA). D. L. Larson, † A. E. Takemori, † and P. S. Portoghese, † Departments of Medicinal Chemistry † and Pharmacology, † Univ. of Minnesota, Minneapolis, MN 55455. The nonequilibrium opioid antagonist, B-FNA, is an important pharmacological tool in opioid research. In addition to being highly μ -selective in smooth muscle preparations, it possesses an ultra-long duration blockage of μ -opioid receptor sites in vivo. As it is known that \$B-FNA readily reacts with sulfhydryl groups, and the fact that glutathione is found in abundant levels in the brain, the possibility exists that a \$B-FNA-glutathione adduct (\$B-FNAC) may contribute to its long duration of action in FNAC) may contribute to its long duration of action in vivo. Here we report on the activity of this adduct and related conjugates. In guinea-pig ileum and mouse vas deferens preparations, B-FNAG showed no irreversible antagonism of opioid agonists. Administration i.c.v. (4.8 amagerism of option agonism. Administration field, (4.6 monole/mouse) elevated the ED₅₀ of morphine by sixfold after 24 hours. A threefold increase occurred 24 hours following 5 mg/kg s.c. This action in vivo closely paralleled that of B-FNA itself. The B-FNA-cysteine adduct (B-FNAC) also showed reversible activity on the GPI, but in vivo (4.8 nmole/mouse i.c.v.) it exhibited greater (46-In Vivo (4.8 nmole/mouse 1.c.v.) It exhibited greater (46-fold) antagonism of morphine at the 24 hour interval. The possibility exists that both β -FNAG and β -FNAC are either trapped in the brain due to their polarity, or they are enzymatically reconverted to their precursor, β -FNA.

EVIDENCE FOR A ROLE OF KAPPA OPIOIDS IN THE TONIC REGULA-

EVIDENCE FOR A ROLE OF KAPPA OPIOIDS IN THE TONIC REGULATION OF TUBEROHYPOPHYSIAL DOPAMINE (THDA) NEURONS IN THE MALE RAT J. Manzanares, K.J.Lookingland, S.D. LaVigne and K.E. Moore. Department of Pharmacology and Toxicology. Michigan State University. East Lansing, MI 48824.

The purpose of the present study was to characterize the effects of the kappa agonist U-50488 and the antagonist nor-binaltorphimine (NOR-BNI) on the activity of THDA neurons in the male rat. The activity of THDA neurons was estimated by measuring the concentration of 3.4-dibydroxyestimated by measuring the concentration of 3,4-dihydroxy-phenylacetic acid and the accumulation of 3,4-dihydroxy-phenylalanine following administration of a decarboxylase inhibitor (NSD 1015) in the intermediate lobe (IL) and neural lobe (NL) of the pituitary. U-50488 (2.5-20 mg/kg; sc; 60 min) caused a dose-related decrease in the activity sc; 60 min) caused a dose-related decrease in the activity of THDA neurons projecting to both the IL and NL. NOR-BNI (25-50 µg/rat; icv; 120 min) increased THDA activity and this effect was reversed by U-50488. These neuronal results suggest that endogenous kappa opioids regulate the basal activity of THDA neurons projecting to the IL and NL of the male rat. (Supported by NIH grant NS 15911.)

THE PROLACTIN SECRETORY RESPONSE TO 8-ENDORPHIN DOES NOT INVOLVE THE μ_1 OPIATE RECEPTOR SUBTYPE IN THE DIESTROUS FEMALE RAT. \underline{J} Janik, P. Callahan and J. Rabii. Dept. of

DIESTROUS FEMALE RAT. L. Janik, P. Callahan and J. Rabii. Dept. of Biological Sciences, Rutgers University, Piscataway, NJ 08854. It has been proposed that morphine elicits a prolactin secretory response through its activity at the μ opiate receptor subtype. Pasternak and colleagues have reported that the μ 1, site is the key receptor subtype involved in the prolactin release response to morphine. However, the role of this subtype in the action of the endogenous opioid peptides is not firmly established. The purpose of this study was to determine whether or not the μ 1 receptor subtype is involved in the

study was to determine whether of not the μ_1 receptor subtype is involved in the θ -endorphin induced increase in circulating levels of prolactin. Female Sprague-Dawley rats in diestrus were chronically implanted with intraventricular (IVT, lateral ventricle) cannulae and allowed a minimum of 5 days to recover. They were implanted with jugular cannulae 24 hours prior to their use in an experiment. One group of animals received saline or WIN 44.41-3 (WIN, 4 mg/kg, ip), an antagonist of the μ , θ and κ sites. A second group received saline or Naloxonazine (NAZ, 20 mg/kg, iv) at the time of the jugular implantation. All animals received saline or θ -endorphin (0.5, 2.5 or 5 mg) in a 5 til volume.

All doses of β -endorphin produced a large, significant increase in circulating levels of prolactin which was significantly attenuated by WIN. In order to determine the involvement of the μ_1 site, animals were pretreated with NAZ. In contrast to NAZ's ability to antagonize a morphine induced prolactin increase, NAZ had no effect on the increased circulating levels of prolactin produced by β -endorphin administration, indicating that the μ_1 site is not involved in this response.

COMPARATIVE ACTIVITIES OF OPIOIDS AT µ-RECEPTORS IN GUINEA PIG ILEUM AND IN A NEUROBLASTOMA CELL LINE L. Toll and I. Berzetei-Gurske. Neuroscience Department, SRI International, Menlo Park, CA 93025. The μ-opioid receptor is the site mediating the anal-

gesic activity of morphine and most fused ring and peptide opiates. In order to better understand the µ-activities of opioid ligands, experiments were designed to determine the activities of various families of opioid compounds at µ-opioid receptors without interference other receptor subtypes. Experiments were conducted in guinea pig ileum in the presence of the selective κ -antagonist nor-BNI. The IC50 values obtained for the inhibition of contractions were compared with activities found for the inhibition of cAMP accumulation in the μ containing neuroblastoma cell line SH-SY5Y. In the guinea pig ileum, nor-BNI caused about a 2-fold shift in the IC50 value of μ -selective ligands normorphine and DAGO, and a 360-fold shift in the IC50 value of the κ -selective ligand U-69593. For the κ -agonist EKC, the shift was about 60-fold, resulting in an IC50 of approxisnirt was about 60-rold, resulting in an IC50 of approximately 12 nM at $\mu\text{-receptors}$, compared to 8 nM for DAGO. In SY5Y cells, the $\kappa\text{-agonist}$ EKC appears to be 10 times more effective than DAGO, with IC50 values for inhibition of cAMP accumulation of 3 nM and 30 nM, respectively. The results indicate that EKC is an effective $\mu\text{-}$ as well as $\kappa\text{-agonist}$. Differences between guinea pig ileum and SY5Y cells are being investigated.

THE β-ENDORPHIN INDUCED PROLACTIN INCREASE INVOLVES THE KAPPA OPIATE RECEPTOR SUBTYPE IN FEMALE RATS. L. Kehoe and P. Callahan, Dept. of Zoology, Miami University, Oxford, OH 45056.

The Prolactin (PRL) secretory response to β -endorphin (β -end) was determined in female Sprague Dawley rats following pretreatment with the specific κ opiate receptor antagonist, nor-Binaltorphimine Hydrochloride (norBNI).

Intraventricular (IVT) cannulae were chronically implanted in the lateral

Intraventricular (IVT) cannulae were chronically implanted in the lateral ventricle of cycling and lactating rats (day 2 post partum). Following a 5-7 day recovery period, and one day prior to the experiment, animals received chronic jugular cannulae. On the day of the experiment, pups were removed from the post partum females for two hours prior to blood sampling. β -end was injected alone (0.025, 0.05, 0.1 μg in 5 μL saline, IVT), or 45 min after pretreatment with norBNI (10 nm, IVT). All doses of β -end produced a large, significant increase in circulating levels of PRL. PRL concentrations exceeded 200 ng/ml after 15 min. The 0.1 μg dose produced significant elevations in circulating PRL levels during the entire 60 min sampling period, while the other doses produced significant increases which persisted for 45 min. Cycling females also exhibited a significant and dramatic increase in circulating levels of PRL following the administration of β -end. However, the levels were less than those observed in lactating females. NorBNI completely blocked the increase in PRL levels at all doses of β -end tested. Furthermore, PRL levels were significantly lower than basal levels by 15 min, Furthermore, PRL levels were significantly lower than basal levels by 15 min, and remained depressed throughout the 60 min period. These results indicate that β -end elicits an increase in PRL secretion in both lactating and cycling female rats through its action at the k opiate receptor subtype.

MULTIPHASIC EFFECTS OF MORPHINE ON SUBSTANCE P RELEASE FROM TRIGEMINAL NUCLEUS CAUDALIS SLICES. W. Maixner. H. Suarez-Roca, J.R. Zuniga*, and S. Madison*. Dental Research Center and Dept. of Pharmacology, Univ. of North Carolina, Chapel Hill, N.C. 27514.

North Carolina, Chapel Hill, N.C. 27514.

It is generally accepted that morphine acts presynaptically to inhibit substance P (SP) release from afferent terminals in the trigeminal nucleus caudalis (TNC; Nature 268:549, 1977). Recent studies, however, provide evidence that opicids produce both inhibitory and excitatory effects on SP release which are concentration and receptor subtype dependent (J. Neurochem. 48:529, 1987). In the present study, we have examined a wide range of morphine concentrations on K*-evoked SP release from rat TNC slices. Immunoreactive SP was measured in perfusates. Immunoreactive SP was measured in perfusates Morphine produced multiphasic effects on K⁺-evoked SP release without affecting basal release. Very low concentrations (1.0 and 3.0 nM) suppressed release, intermediate concentrations (100-300 nM) facilitated release, high concentrations (1-3 uM) suppressed release, and a very high concentration (30 uM) facilitated release. These effects were abolished by opiate-receptor blockade with naloxone (30 nM). Thus. morphine produces complex effects on SP release from TNC which are concentration and possibly receptor subtype dependent. Supported by DE08013 & RR05333.

MORPHINE PRODUCES MULTIPHASIC EFFECTS ON SUBSTANCE P RELEASE FROM TRIGEMINAL NUCLEUS CAUDALIS SLICES BY STIMULATING DIFFERENT OPIOID RECEPTOR SUBTYPES. H. Suarez-Roca, J.R. Zuniga*, S. Madison* and W. Maixner. Dept. of Pharmacology, University of North Carolina, Chapel Hill, N.C. 27514.

Chapel Hill, N.C. 27514.

Morphine (MOR) produces concentration dependent multiphasic effects on K*-evoked substance P (SP) release from rat trigeminal n. caudalis (TNC; Maixner et al., this volume). In this study, we tested the action of selective opioid receptor antagonists on these multiphasic effects of MOR. The mu opiod receptor antagonist, \$\textit{\textit{B}}\$-funaltrexamine (FNA; 20nM), selectively abolished the increase in SP release elicited by 100 nM MOR, whereas n-binaltorphimine, a kappa opioid receptor antagonist (3nM), selectively reversed the facilitation produced by 30uM MOR. The delta opioid receptor antagonist, ICI173,864 (0.3uM), reversed the inhibition of SP release induced by 3uM MOR and attenuated the facilitation with 100 nM MOR. The initial inhibition of SP release with 1nM MOR was not affected by the antagonists. In conclusion, the increase in SP release produced by 100 nM and 30uM Mor may be mediated by FNA-sensitive mu and kappa opioid receptors respectively, whereas 1nM and 3uM MOR may inhibit release by stimulating FNA-insensitive mu and <u>delta opioid receptors respectively</u>. CHARACTERIZATION OF [D-SER2,LEU5,THR6]ENKEPHALIN (DSLET) ANTINOCICEPTION: DIRECT AND MODULATORY ACTIONS. Qi Jiang and Frank Porreca, Department of Pharmacology, University of Arizona Health Sciences Center, Tucson, AZ 85724

It has been suggested that some supraspinal opioid δ receptors may be functionally associated with opioid μ receptors. Agonists at these $\delta_{complexed}$ (δ_{cx}) sites produce modulation of μ -mediated effects such as antinociception, while compounds acting at the $\delta_{\text{non-completed}}$ (δ_{nea}) receptor do not. Our previous studies have shown that the δ agonist, [D-Pen²,D-Pen⁵] enkephalin (DPDPE), and the δ antagonist, ICI 174,864, act on both δ sites; while [D-Ala²,Leu⁵,Cys⁶]enkephalin (DALCE) has agonist and antagonist actions only at the $\delta_{\rm hat}$ site. The present study investigated the direct agonist and modulatory actions of the synthetic opioid peptide, DSLET in the mouse. Antinociceptive effects of DSLET, DPDPE and morphine were evaluated in the 55° C warm-water tail-flick test following intracerebroventricular (i.c.v.) administration. I.c.v. DSLET (0.044-1.46 nmol) produced dose- and time-related antinociception (10-60 min) with a maximal effect at + 10 min; the A₅₀ value (and 95% C.L.) was 0.22 (0.15 - 0.31) nmol. Similarly, i.e.v. DPDPE and morphine also produced dose-related antinociception, but were approximately 130 and 4-fold less potent than DSLET. The effects of DSLET and DPDPE, but not morphine, were antagonized by co-administration of ICI 174,864 (4.4 nmol). Administration of DALCE (4.57 nmol at -24 hr) blocked only the antinociception produced by DPDPE, but not that of DSLET or morphine. Sub-antinociceptive doses of DPDPE (1.55 nmol) and DSLET (0.0015 nmol) displaced the morphine dose-response line to the left by approximately 4.5 and 10.6 fold, respectively. The modulation of morphine antinociception by DPDPE and DSLET, but not the direct morphine effect, was blocked by ICI 174,864 (4.4 nmol), but not by DALCE pretreatment. These results suggest that both the direct antinociception and µ-modulatory actions of DSLET may occur at the δ_{ex} receptor and support the hypothesis of δ sites which can be differentiated on the basis of interactions with u receptors.

PRESYNAPTIC INHIBITION OF HIPPOCAMPAL MOSSY FIBER SYNAPTIC TRANSMISSION BY KAPPA OPIOIDS. R.L.

Gannon and D.M. Terrian. Dept. of Anatomy, East Carolina Univ. Sch. Med., Greenville, NC 27858. Recently, this laboratory demonstrated the concomitant release of L-glutamate (Glu) and prodynorphin-derived peptides from hippocampal prodynorphin-derived peptides from hippocampal mossy fiber (MF) synaptosomes. Dynorphins are believed to be endogenous ligands for the kappa opiate receptor subtype. However, presynaptic opioid autoregulation at the MF-CA3 synapse has not been reported. In this study, we describe the effects of the kappa agonist U50488H on calcium availability and transmitter release from guinea pig hippocampal MF synaptosomes. MF synaptosomes were loaded with the calcium indicator FURA-2. Application (30 s) of U50488H dose dependently inhibited KC1-evoked increases dose dependently inhibited KC1-evoked increases in MF cytosolic calcium availability. The inhibitory effect of U50488H was reversed by the selective kappa antagonist Nor-Binaltorphimine. In other experiments, superfused MF synaptosomes were depolarized and the superfusates assayed for Glu and dynorphin B. U50488H significantly inhibited transmitter release with an approximate Third telephone transmitter release with an approximate IC₅₀ of 30 uM U50488H. These results suggest the existence of a kappa opioid autoreceptor capable of modulating MF synaptic transmission. Supported by AFOSR 89-0531, NC United Way

EFFECTS OF OPIATE RECEPTOR ANTAGONISTS ON 8 CASOMORPHIN-INDUCED ANALGESIA IN NEONATAL RATS. J. Giordano, Coll. Pharm. Health Sci., Drake Univ., Des Moines, IA 50311

IA 50311 β -casein, and derived peptides, produce analgesia in neonatal rats. While the opioid activity of these ligands has been linked to the μ -receptor, developmental, and pharmacologic patterns of analgesia were inconsistent with the putative profile of μ mediation. The present study directly investigated whether β -casomorphin (BC)-induced analgesia is mediated by casomorphin (BC)-induced analgesia is mediated by multiple opioid receptors during ontogeny. Rat pups, at post-natal day (PND) 7 or 14 were pretreated with the μ -antagonist β -funaltrexamine (β -FNA: 10-50 nmol; 5ul, icv), δ -antagonist naltrindole (NTI: 25-100 nmol; 5ul, icv) Fig. 3-antagonist nor-binaltorphimine (BNI: 25-100 nmol; 5ul, icv) and patterns of analgesia in forepaw (FP) and tail (T) produced by BC (20 mg/kg,ip) were examined. At PND 7, reduction of BC-analgesia by β -FNA was greater in FP than T. At PND 14, β -FNA equipotently decreased BC effects in both FP and T. At PND 7, NTI most effectively reduced BC-analgesia in T. By PND 14, NTI effects in FP and T were less potent. BNI did not affect BC-analgesia at either age. These data suggest that BC-analgesia may be differentially subserved by μ and δ , but not κ receptor systems during post-natal ontogeny.

REGULATION OF 3H-THYMIDINE INCORPORATION BY OPIOIDS IN RAT BRAIN AGGREGATING CULTURES J. BARG*, M. BELCHEVA*, AND C. J. COSCIA. Dept. of Biochem. and Mol. Biol., St. Louis Univ. Sch. Med., St.Louis, MO 63104.

Studies performed to date have not demonstrated

definitively whether opioids directly affect DNA synthesis during brain ontogeny. Herein we present evidence of an opioid receptor-mediated effect of D-ala²,mephe⁴,gly-ol⁵ enkephalin (DAMGE) on ³H-thymidine incorporation that depends on the developmental state of the culture. brain aggregates (embryonal day 15) were grown for various time intervals and exposed to different concentrations of opioids 48 h prior to harvesting and to ³H-thymidine for the final 23 h. A decrease of ³H-thymidine incorporation was observed, with the greatest effect in 7-day cultures whereas DAMGE had no influence in 20-day cultures. dependency studies demonstrated that at levels $\geq 0.5~\mu\text{M}$ DAMGE a substantial proportion (40%) of the cell's DNA synthesis is inhibited and the decrease was naltrexone-reversible but not influenced by (+)naloxone or (+)morphine. Both κ -selctive agonists, U50488 and U69593, (+)morphine. Both k-selective agonists, USU466 and USPSYS, also decreased H-thymidine incorporation, whereas DADL did not alter the incorporation as compared to control. Although the normal developmental role of opioids remains to be determined, these findings may have immediate clinical relevance to fetuses at risk as a result of maternal drug abuse.

158.16

OPIOID RECEPTOR MEDIATED POTASSIUM CONDUCTANCES RECORDED FROM ACUTELY DISSOCIATED HIPPOCAMPAL NEURONS T.L.Wimpey and C. Chavkin. Dept. of Pharmacology, University of Washington, Seattle, WA 98195
The potassium channels controlled by opioids in neurons from the hippocampal CA1 region or the presubiculum/subiculum have different voltage dependencies. Hippocampal neurons acutely dissociated from

adult rats were voltage-clamped using the whole cell patch clamp technique. The neurons were continuously superfused with oxygenated buffer (extracellular [K+] = 5 mM, pipette [K+] = 140 mM) containing TTX; drug responses were determined by pressure application through drug pipettes. CA1 neurons were found that responded to application of the mu pipetics. CAI neurons were found that responded to application of the mu selective opioid agonist PL017 with an outward current averaging 500 pA at -50 mV holding potential (n=4). The properties of this ligand-gated potassium current were similar to those described previously by Williams and coworkers. In recordings from neurons dissociated from the presubiculum/subiculum (a region rich in mu opioid receptor binding) a population of cells was found that responded to application of PL017 or DAMGO. However, unlike the responses seen in the CA1 little or no current resulted from application of the opioid to the cell at a holding potential of 50 mV; rather, the opioid effect was only seen when the cells were step depolarized. The opioids significantly increased the step depolarized (-40 to 0 mV) outward current (n=8) and this effect was blocked by simultaneous application of the antagonist naloxone. The outward currents elicited by step depolarization and the opioid effect were abolished by cesium but unaltered by cadmium indicating that these currents were primarily carried by potassium. The heterogeneity of responses seen suggests that opioid receptors can control more than one type of potassium current. Supported by DA 04123.

CELLULAR LOCALIZATION OF ∂ -OPIOID RECEPTORS USING FLUORESCENT DERIVATIVES OF NALTRINDOLE. R. ELDE. M. SULTANA*†, V. BOYAPATI*†, J. ELLS*, J. WANG AND P.S. PORTOGHESE*†, Departments of Cell Biology and Neuroanatomy and Medicinal Chemistry†, University of Minnesota, Minneapolis, MN 55455

The present understanding of the expression and distribution of opioid binding sites has been established using radiolabeled ligands selective for the three subtypes of opioid

has been established using radiolabeled ligands selective for the three subtypes of opioid receptors. Although much is known concerning the regional occurrence of these binding sites, little is known about their cellular and subcellular localization.

As a step toward understanding the cellular mechanisms that regulate the expression of functional opioid receptors, we have initiated the development of subtype-selective fluorescent ligands which can be visualized using high resolution imaging methods. Naltrindole is a recently described, selective antagonist of the 3-opioid receptor (Portoghese et al., J. Med. Chem. 31:281, 1988). Syntheses and purifications of three fluorescent derivatives of this compound were achieved, each of which retained a significant degree of potency and selectivity as determined in the mouse vas deferens bioassay. NG108-15 cells, a clonal line known to synthesize 3-opioid receptors, were cultured on cover slins using standard conditions, and differentiated by withdrawal of cultured on cover slips using standard conditions, and differentiated by withdrawal of serum from the media. Three days after serum withdrawal, each of the ligands was serum from the media. Three days after serum withdrawal, each of the ligands was incubated with the cells at concentrations ranging from 1 - 100 nM with or without DADL (5 mM) and observed using laser scanning confocal microscopy. In the absence of DADL, patches of fluorescence were observed associated with the membranes of cells and their processes. The intensity of the fluorescent patches was concentration dependent. Patches were frequently associated with varicosities found along the processes. These results suggest that the mechanisms regulating the expression of ∂ -opioid receptors and their association with other membrane proteins can be visualized at the cellular level. Supported by DA 02148 and DA 07234.

UP-REGULATION OF δ-OPIOID BINDING IN SUBCELLULAR FRACTIONS FROM NEURONAL CELL CULTURES. M. M. Belcheva*, J. Barg*, R. J. McHale*, X-M. Gao. D-M. Chuang and C. J. Coscia. St. Louis Univ. Sch. Med., St.Louis, MO 63104, Biological Psychiatry Branch, NINH, Bethesda, MD 20892
In contrast to butyrate-induced up-regulation of receptors, antagonists elicit an increase in opioid receptors.

tors, antagonists elicit an increase in opioid receptors which may not be inhibited by cycloheximide. This was interpreted as possibly due to changes in G protein coupling. To assess this hypothesis, the modulation of agonist δ -binding by Gpp(NH)p and receptor distribution in light (LMs) and heavy (HMs) membrane fractions were examined after either naltrexone (antagonist) or butyrate induced up-regulation. Treatment of NG108-15 cells with naltrexone (1 μ M, 48 h) and NCB-20 cells with Na butyrate (1 mM, 3 days) increased Bmax values of ³H-DADLE and ³H-diprenorphine in LMs and HMs 2-3 fold, without changing Kd. Insign nificant differences were observed in HM and LM Bmax values for the agonist and antagonist under both up-regulation conditions. Upon cycloheximide treatment (1 μ g/ml, 48 h) of NG108-15 cells Bmax values of DADLE and diprenorphine binding in HMs were comparable and increased upon up-regulbinding in his were comparable and increased upon up-regulation in agreement with previous findings. Although IM Bmax values for the agonist were elevated 2-fold in the presence of cycloheximide, no change occurred for antagonist Bmax which was twice that of DADLE. Since up-regulation also increases LM Gpp(NH)p sensitivity, the results indicate that antagonist-induced up-regulation involves Gprotein coupling alterations.

OPIOIDS: RECEPTORS II

AGE-RELATED CHANGES IN THE EXPRESSION OF BRAIN OPIOID RECEPTORS. <u>E.M. Unterwald and M.J. Kreek*</u>, The Rockefeller

University, New York, N.Y. 10021
Possible alterations in the endogenous opioid system have been suggested for the mediation of age-related differences in basal pain threshold, response to morphine administrain basal pain threshold, response to morphine administration, and temperature control. The present study investigates the expression of opioid receptors in the brains of adolescent, young adult, and naturally aged guinea pigs using quantitative in vitro receptor autoradiography with highly selective radioligands. Mu receptors were labelled with [3H]D-ala² N-me-phe⁴,gly-ol⁵-enkephalin, delta receptors with [3H]D-pen³,D-pen⁵-enkephalin, and kappa receptors with [3H]U-69,593. Results demonstrate that throughout most of the brain the density of mu opioid receptors was lower in the aged animals than in either the adolescent or young aged animals than in either the adolescent or young adult groups. The largest reductions in mu receptor number were found in the posterior region of the nucleus accumbens, frontal cortex, hypothalamus, anterior portion of the caudate putamen, septum, and substantia nigra reticular. The density of delta opioid receptors was reduced in some brain regions of the old animals and was increased in others. Areas that showed the largest reductions in delta receptor number were the caudate putamen, hippocampus, and nucleus accumbens whereas the largest increases were found in the amygdala and hypothalamus. These alterations in the expression of opioid receptors may in part underlie the agerelated changes in nociceptive thresholds observed in elderly animals and humans.

159.3

CHANGES IN MU, DELTA, AND KAPPA OPIOID BINDING SITES IN RAT SPINAL CORD AFTER DORSAL RHIZOTOMY. C.W. Stevens and V. S. Seybold, Department of Cell Biology and Neuroanatomy, University of Minne

Minneapolis, MN 55455.

The aim of this study was to determine the binding of highly-specific mu, delta, and opioid radioligands in rat spinal cord following unilateral dorsal rhizotomy. Using computerized grain counting, we quantified changes in mu, delta, and kappa opioid receptor binding in discrete areas of the rat spinal cord associated with the terminations of nociceptive primary afferent fibers.

Spinal segment L4 was obtained from control rats and from surgically prepared animals at 1, 2, 4 and 8 days after unilateral dorsal rhizotomy (N=8 rats/group). Autoradiographic studies of opioid binding sites were performed on spinal cord sections using tritiated sufentanil (0.3 nM), DPDPE (5 nM), and U-69593 (3 nM) to label mu, delta, and kappa sites, respectively. Specific binding was defined as total binding minus the non-specific binding obtained in the presence of unlabeled ligands. Preliminary data suggest a significant decrease for all three ligands in laminae I-II, lamina V, and lamina X after unilateral rhizotomy, with the greatest decreases observed at 4 days after the rhizotomy. Mu and kappa binding sites in laminae V and X returned to control values at 8 days after rhizotomy. In contrast, delta sites in all three regions of analysis remained significantly decreased throughout the 8 day time course of these experiments. The greatest percent decrease (>50%) was observed for kappa sites in laminae I-II, V, and X, at 4 days after dorsal rhizotomy. These results confirm previous studies demonstrating a significant decrease in spinal cord opioid receptors following unilateral dorsal rhizotomy. The decreases suggest the location of mu, delta, and kappa opioid ceptors on the central processes of nociceptive primary afferent fibers Additionally, these studies suggest that opioid receptors located on intrinsic spinal neurons or processes are altered in response to unilateral dorsal rhizotomy.

THE PRENATAL DEVELOPMENTAL PROFILE OF OPIOID PEPTIDES AND RECEPTORS OF THE MOUSE BRAIN. R.A. Rius*+, J. Barg*++, C.J. Coscia++, and Y.P. Loh+. Laboratory of Developmental Neurobiology, NICHD, Bethesda, MD 20892+ and Department of Biochemistry, St. Louis University, School of Medicine, St. Louis, MO 431041.

63104++. Although the opioid system of mouse brain has been studied postnatally, little is known about the development and relationship between embryonic opioid peptides and their receptors. The ontogeny of opioid peptides and receptors was studied during the embryonic period (E) 11.5 to postnatal day 1 (P1). Met-enkephalin, dynorphin and β -endorphin were detected as early as E1.5 and significantly increased from E14.5 to E18.5. μ and κ receptors were first detected at E12.5 and at E14.5 respectively. Differences in immunoreactivity levels of the three peptides occurs with dynorphin being much lower than metenkephalin and β -endorphin. Expression of opioid peptides and receptors from E14.5 to E18.5 reveals an apparent association between the increasing amount of the three peptides and the rise in their receptors from E14.5 to E18.5 reveals an apparent association between the increasing amount of the three peptides and the rise in their corresponding opioid receptors. Interestingly, levels of β -endorphin but not met-enkephalin or dynorphin diminish by P1, the stage at which a sharp increase of μ receptors occur. In a comparative study of the binding of β -endorphin, its truncated form (1-27) and their N-acetyl derivatives, to E14.5 brain membranes, β -endorphin exhibited the highest affinity.

QUANTITATIVE AUTORADIOGRAPHIC MAPPING OF OPIATE (δ , μ and κ) BINDING SITES IN THE AUDITORY CORTEX OF THE MALE FERRET. M.I.

BINDING STIES IN THE AUDITORY CORTEA OF THE MALE FERRET. BLL.
Davila-Garcia R. Lu and F. M. Leslie. Dept. of Pharmacology University of
California, Irvine, Irvine, CA 92717.

The distribution of opiate binding sites in the auditory cortex of the ferret was
analyzed using quantitative autoradiography. Adult male ferrets weighing between
900 and 1.2 Kg were anesthetized with membutal (30mg/Kg) and perfused with 30%
sucrose in 0.85% NaCl. Brains were removed and immediately frozen in dry ice for sucrose in 0.85% NaCl. Brains were removed and immediately frozen in dry ice for 30sec and placed at -70°F until used. The brains were cut in 15µm sections in a cryostat and processed for binding. Opiate binding sites were defined as follows: $[^3H]DADLE$ in the presence of D-pro⁴Morphiceptin for δ receptors, $[^3H]DADLE$ in the presence of D-pro⁴Morphiceptin for δ receptors. Non-specific binding was defined with 1µM levallorphan and specific binding was calculated as the difference between total and non-specific binding. Delta binding sites were identified in the upper layers of auditory cortex, being highest in layers III and IV, and lowest in layers V and VI. In contrast, μ binding sites were restricted to the lower cortical layers, layer V being most significantly labeled, followed by layers VI and IV. Kappa sites were distributed mainly in the border between layers II and III and in layer V, with layers III and IV having moderate and layers I and VI having negligible amounts. These results demonstrate a differential distribution of opiate binding sites in the auditory cortex of the ferret. This distinct pattern of opiate binding sites may correspond to a functional distribution as yet undescribed.

EXERCISE-INDUCED CHANGES IN BETA-ENDORPHIN BINDING PARAMETERS TO EQUINE LYMPHOCYTES. J.G. Hamra*, S.G. Kamerling and J.D. Harkins.* Dept. Vet. Phys. Pharm. and Tox., Louisiana State Univ. Baton Rouge, LA 70803.

Recent studies from our laboratory have shown that racehorses release BE after strenuous exercise and that this opioid binds in a specific and saturable manner to equine lymphocytes (LYMs). In the present study 15 thoroughbred horses were exercised on an inclined treadmill at progressively increasing speeds for 20 minutes. Near maximal exertion heart rates (200 beats/min) were attained post-exercise. Blood samples were obtained prior to and immediately after exercise. LYMs were isolated using density gradient centrifugation and suspended in medium 199 supplemented with 0.1% BSA. LYMs,(7.5 x $10^6 \ \mbox{cells/ml})$ were incubated with $(3-[125I] \mbox{iodotrosyl}^{12}$ BE (human) and increasing concentrations of equine BE $(10^{-12}\mbox{M} - 10^{-6}\mbox{M})$ for 4 hours at $25^{\circ}\mbox{C}$. Scatchard analysis of the binding data revealed a significant decrease in the dissociation constant (K_4) following exercise with a mean decrease of 0.68 pM which suggests a higher affinity for the receptor following exercise. There was also a significant decrease in the Bmax suggesting a decrease in receptor number following exercise. There was also a significant decrease in the Bmax suggesting a decrease in receptor number following exercise. These results suggest that increased BE levels following exercise modulate equine LYM receptor binding and therefore equine LYM function. (Supported by the Grayson Foundation).

INTERLEUKIN-2 SUPPRESSED 3H-OHMEFENTANYL AND 3H-DADLE BINDING TO RAT BRAIN OPIOID RECEPTORS. Z.Y.Li. Shanghai Institute of Materia medica, Academia Sinica, Shanghai 200031, P.R.China.

Interleukin-2 is a lymphokine, an important immune regulator and has been shown to act sommogenic and alagesic via opioid receptors. 3H-Ohmefentanyl and 3H-DADLE are the selectively specific mu and delta opioid receptor agonist respectively. By using the radioligand receptor binding assay and in vitro organ assays, I investigated the mechanism of the Alal251-2 (HrIL-2) acting on opioid receptors. In rat brain membranes, HrIL-2 (10 pM to luM) competitively binds to receptor binding site with the 3H-Ohmefentanyl and 3H-DADLE. The inhibition of the two ligands binding is up to 90%, it is dose-response effect and partially reversed by Naloxone. The depressant effect of HrIL-2 on the electrically evoked contractions of mouse vas deference had EC50 37 nM, Ke 62 nM (Naloxone) and Ke 119 nM (Mr2266) respectively. In contrast with guinea pig ileum assays, the action on the mouse vas deference was slowly reversed by naloxone and Mr2266, indicating that it was mediated by delta receptor not mu opioid receptor.

Alterations in Opioid Receptor Binding Following Continuous ICV Administration of Butorphanol and Morphine. M. Makimura*. P.J. Horan*. B. Hoskins. and I.K. Ho, Dept. Pharmacol. and Toxicol., Univ. MS Medical Center, Jackson, MS 39216

Male Sprague-Dawley rats received continuous ICV

Male Sprague-Dawley rats received continuous IGV infusions of saline (1 μ l/hr), butorphanol or morphine (52.3 nmol/hr) for 3 days via s.c.-implanted osmotic minipumps (Alzet 2001). Withdrawal was precipitated in the butorphanol- and morphine-infused rats by administration of naloxone (5 mg/kg, s.c) or by terminating the infusions (abrupt withdrawal). Binding characteristics of opioid receptors were determined in membranes prepared from whole brains minus cerebella and frontal cortices using the μ receptor ligand, DAGO, the δ receptor ligand, DPDPE, the κ receptor ligand, U-69593, and the non specific ligand, naloxone. Abrupt withdrawal from butorphanol or morphine resulted in 107% and 51% increases, respectively, in naloxone binding. Binding of the other receptor ligands was not altered by abrupt withdrawal. Naloxone-precipitated withdrawal increased the dissociation constants (decreased affinities) of mu and kappa receptors in butorphanol-and morphine-infused animals. These results suggest that the properties of opioid receptors are altered by continuous presence of butorphanol or morphine and receptor sensitivity to antagonists appears to increase. (Supported by DA 05828).

DESIGN OF A POTENT DYNORPHIN-RELATED PEPTIDE WITH A HIGH SPECIFITY FOR THE κ -OPIOID RECEPTOR. <u>G.P. Martinka*. K. Jhamandas. L. Sabourin*. C. Lapierre* and S. Lemaire.</u> Department of Pharmacology, Faculty of Health Sciences, University of OTTAWA, Canada KlH 8M5.

An adrenomedullary dynorphin-related peptide (Dyn-A-(1-13), Tyr*, Leu¹s, Phe¹e, Asn¹?, Gly¹e, Pro¹e: Dyn I-(1-19)), was synthesized by the solid phase procedure. The synthetic peptide was tested for its ability to inhibit electrically-evoked contractions of the guinea pig ileum (GPI), to compete with the binding of prototype liqands selective for κ -, μ - or δ -opioid receptors in membrane preparations of guinea pig cerebellum and rat brain and to produce antinociception in the rat. In the GPI, Dyn I-(1-19) possessed a relative potency (IC_w:0.5nM) that was comparable to that of [D-Pro¹o]-Dyn A-(1-11) (IC_{50}:0.5nM) and Dyn A-(1-13) (IC_{50}:0.7nM). The affinity of Dyn I-(1-19) for the κ site in the membrane preparation of the guinea pig cerebellum (IC_{50}:0.2nM) was also comparable to those of Dyn A-(1-13) (IC_{50}:0.11nM) and [D-Pro¹o]-Dyn A-(1-11) (IC_{50}:0.10nM). Its relative affinities for μ (IC_{50}:7nM) and δ (IC_{50}:71nM) receptors were much lower than those of [D-Pro¹o]-Dyn A-(1-11) and Dyn A-(1-13), rendering the peptide the most selective for the κ opioid receptor. Low doses intrathecal Dyn I-(1-19) produced profound antinociceptive effects in the rat paw pressure assay but not in the tail flick test without affecting blood pressure and motor activity. Supported by MRC (PC-20).

STRUCTURE-ACTIVITY RELATIONS OF NALOXONE BENZOYLHYDRAZONE (NalbzoH): EFFECTS ON SUBTYPE SELECTIVITY AND DISSOCIATION KINETICS. K.M.Standifer, L.Liu, R.Parameswaran, J.Z.Ginos, and G.W.Pasternak. Dept. of Neurology, Memorial Sloan-Kettering Cancer Center, New York, NY 10021.

We have recently reported on the synthesis and activity of a novel opiate derivative, NalbzoH which has several interesting characteristics. Among these are its prolonged duration of my recentor appropriate (T. Le. 2 / h.) and the

We have recently reported on the synthesis and activity of a novel opiate derivative, NalbzoH which has several interesting characteristics. Among these are its prolonged duration of mu receptor antagonism ($\tau_{1/2}=24~\rm hr$) and its potent kappa analgesic activity at doses above those necessary to antagonize mu actions. We have shown that the analgesic actions of NalbzoH are mediated through a novel kappa3 receptor, which was identified using $^{3}\rm H-NalbzoH$. As this compound is structurally similar to naloxone,

As this compound is structurally similar to naloxone, its mu antagonism was expected; the analgesia at the kappag site and the pseudoirreversible binding was not. Consequently, we are very interested in determining the structural entity responsible for each of these properties. While the 3-iodo,4-hydroxybenzoyl hydrazone derivative of $^{\rm 3H-naloxone}$ showed NalbzoH-like binding with similar $\rm K_D,\,B_{max},$ and slow dissociation, the 4-hydroxybenzoyl hydrazone compound exhibited binding properties more similar to naloxone. The lack of correlation between affinity from competition studies and dissociation rates suggests an unusual binding model. Other unlabeled NalbzoH derivatives display interesting differences in the kappa₁/kappa₃ selectivity as well as $\rm mu_1/kappa_3$. These and other structure-activity determinations will be shown.

OPIOID BINDING POTENCY AND INHIBITION OF NEUROTRANSMITTER UPTAKE BY THE ANALGESIC TRAMADOL. E.E. Codd, R.P. Shank, R.B. Raffa and J.L. Vaught. R.W.J. Pharmaceutical Research Institute at McNeil Pharmaceutical, Spring House, PA 19477.

The synthetic opioid analgesic tramadol is the most widely used opioid analgesic in Germany and is in Phase III clinical trials in the U.S. In addition to opioid activity, it appears to have a non-opioid component to its mechanism of action. In the mouse 48°C hot plate, for example, tramadol antinociception was only partially reversed by naloxone. In an attempt to enhance the understanding of the neurochemistry underlying tramadol's analgesic activity, tramadol's interaction with mu, delta and kappa opioid binding sites as well as it's inhibition of the synaptosomal uptake of several neurotransmitters was studied. Tramadol exhibited a 10-20 fold receptor selectivity for inhibition of mu (3H-DAGO) vs. delta (3H-DPDPE) or kappa (3H-U-69,593) binding, with a K₁ for inhibited norepinephrine and serotonin uptake in rat brain inhibition of $^{3}\text{H-DAGO}$ binding of about $2\mu\text{M}$. Tramadol inhibited norepinephrine and serotonin uptake in rat brain synaptosomes, with K_i values of $0.64\mu\text{M}$ and $1.01\mu\text{M}$ respectively. Tramadol, at a concentration of $10\mu\text{M}$, did not inhibit the uptake of dopamine, adenosine, 5'-AMP or GABA. Tramadol's activities in inhibiting both opioid binding and monoamine uptake may be a partial explanation for its unique combination of analgesic efficacy and lack of clinically significant constipation, respiratory depression and abuse liability.

HIGH-AFFINITY BINDING OF [3H]ADAMANTYL-TOLYL GUANIDINE TO THE SIGMA RECEPTOR. J.B. Fischer, N.L. Reddy*, K.J. Burke-Howie*, E. Weber*]J.F.W. Keana* and A.C. Server. Cambridge Na 02139, Dept. of Pharmacology, U.C. Irvine, Irvine CA 92717, and Dept. Chemistry, U. of Oregon, Eugene OR 97403. N-Adamantan-1-yl-N'-o-tolyl guanidine (ADTG) is a higher affinity analog of Di-o-tolyl guanidine (DTG), a well-characterized sigma receptor ligand. We have prepared [3H]ADTG by catalytic tritiation of a brominated precursor and purification by HPLC, giving a product with a specific activity of about 26 Ci/mmol. Used as a radioligand with guinea pig brain membranes [3H]ADTG exhibited a large saturable binding signal that was blocked by low concentrations of haloperidol, (+)pentazocine, (+)3-PPP, DTG and several other sigma ligands, showing a similar pharmacological profile to [3H]DTG. The saturable binding signal defined by 10 µM haloperidol or ADTG was 90-95% of the total binding. Receptor saturation experiments binding. Receptor saturation experiments indicated a single binding site with a Kd value of 4.0 nM and a Bmax of 2.3 pmol/mg protein (n=3). These results indicate that this compound primarily binds to the sigma receptor in guinea pig brain membranes.

159.15
CHARACTERIZATION OF "SIGMA-LIKE" SITES IN RAT LIVER MEMBRANES: FURTHER EVIDENCE FOR SIGMA-1 AND SIGMA-2 SITES. A.E. Bruce, S.B. Hellewell*, and W.D. Bowen. Sect. Biochem., Div. Biol. and Med., Brown Univ., Providence, RI 02912.
Hepatic membranes were prepared by homogenization of rat liver in 10 mM Tris-HCl, pH 7.4, containing 0.32 M sucrose at 4°C. Scatchard analysis of binding of the prototypic sigma ligands [3H]DTG and [3H](+)-3-PPP, revealed the presence of a high density of high affinity binding sites. Parameter values were: [3H]DTG, Kd = 17.9±2.1 nM, Bmax = 11,895±1033 fmol/mg protein; [3H](+)-3-PPP, Kd = 51.9±3.4 nM Bmax = 11,070±1117 fmol/mg protein. Competition studies gave the following rank order of potency: DTG = (-)-pentazocine > fluphenazine > (+)-3-PPP > haloperidol > (-)-3-PPP > (-)-SKF 10,047 > (+)-SKF 10,047 = (+)-pentazocine | All (+)-Pentazocine bound with Kd = 7.5±1 nM and Bmax = 2,929±548 fmol/mg protein, whereas competition with [3H]DTG revealed a Ki = 1,058±123 nM. In addition, displacement of sigma sites of guinea pig brain.

[3H](+)-pentazocine revealed a pharmacological profile similar to that of sigma sites of guinea pig brain.

The majority of [3H]DTG and [3H](+)-3-PPP binding sites in liver resemble sites we have characterized in PC12 cells and designated "sigma-2" (Hellewell and Bowen, Brain Res., in press). While sigma-1 sites are synonymous with the well-characterized sigma sites of guinea pig brain, putative sigma-2 sites are characterized by: 1) high affinity for haloperidol, DTG, and (+)-3-PPP, 2) low affinity for (+)-benzomorphans. 3) reversed stereoselectivity for opiates ((-) > (+)), and 4) lower molecular weight (18-21 kDa). The high affinity of [3H](+)-pentazocine and its profile suggests that liver contains both sigma-1 and sigma-2 sites. This was confirmed by photolabeling with [3H]azido-DTG, revealing labeled polypeptides of 25 and 21.5 kDa. (Supported by PHS Grant NS-26746. We thank Dr. Eckard Weber for his gift of [3H]azido-DTG.)

159.12

COMPETITIVE INTERACTIONS AT [3H]DTG-DEFINED SIGMA RECOGNITION SITES IN GUINEA PIG BRAIN. D.L. DeHaven-Hudkins and L.C. Fleissner*. Dept. of Enzymology and Receptor Biochemistry, Sterling Research Group, Malvern, PA 19355. The interactions of prototypic sigma compounds with the

sigma recognition site in guinea pig brain were,investigated in saturation binding experiments using [3H]DTG as the ligand and haloperidol to define non-specific binding. (+)Pentazocine, (+)3-PPP, haloperidol and rincazole were evaluated at the $\rm IC_{50}$ and two times the $\rm IC_{50}$ determined from competitive inhibition experiments. Although each compound demonstrated a competitive interaction at the compound demonstrated a competitive interaction at the sigma binding site when tested at its respective ${\rm IC}_{50}$ value, as expressed by a two-fold shift in the ${\rm K}_{\rm D}$, the decrease in affinity at higher concentrations of cold competing drug was much less than predicted. The compounds were not interacting with the binding site in a noncompetitive fashion since there were no significant alterations in B values. These data suggest one of the following possibilities: (1) interactions at the sigma recognition site may represent a case of hyperbolic competitive inhibition, or (2) the affinities of these compounds for other bition, or (2) the affinities of these compounds for other receptors are contributing to non-specific effects in the Scatchard analysis of binding to sigma recognition sites. Furthermore, caution is warranted when making conclusions based on Scatchard analysis about competitive vs noncompetitive interactions at binding sites when only one concentration of cold competing drug is evaluated.

A DTG-BINDING PROTEIN SOLUBILIZED FROM LIVER IS SIMILAR TO THAT FOUND IN BRAIN. M.S. Sonders.* J.A. Lee.* J.F.W. Keana.#* and E. Weber. Dept. of Pharmacology, UC Irvine, Irvine CA 92717 and #Dept. of Chemistry, Univ. of Oregon, Eugene, OR 97403

The sigma binding site is a putative receptor which has been

characterized most extensively in brain though its presence has also been recognized in several peripheral tissues. Recent work in our laboratory has been directed towards purifying the protein comprising the sigma binding site from guinea pig liver since it appears to be 15 to 20-fold enriched as compared to brain. Here we detail the initial characterization of a solubilizable sigma binding site from liver.

Washed particulate liver fractions were solubilized and assayed

with [³H]-DTG according to the procedure of Kavanaugh et al. [J. Neurochem. (1989) 53: 1575]. Typically 20 mM cholate solubilized 70% of the protein and 20-30% of the sigma binding sites. Saturation analysis indicated the existence of two sites whose K_Ds were approximately 25 and 500 nM; their densities were 10 pmol/mg and 25 pmol/mg protein, respectively. An array of sigma ligands displayed a rank order of inhibitor potency identical to that seen in solubilized brain tissue [ibid.].

Photoaffinity labeling of the soluble liver sigma binding site with [3H]-azido-DTG using the protocol of Kavanaugh et al. [PNAS (1988) 85: 2844] revealed specific incorporation of tritium into a single protein band of Mr. 28,000 (compare 29 kDa from brain [ibid.]). Taken together, these data suggest the probable identity of soluble DTG-binding proteins from guinea pig brain and liver, and the feasibility of purifying the sigma binding site from liver.

This work was supported by a grant from NIDA.

PHARMACOLOGICAL CHARACTERIZATION OF SIGMA-LIKE RECEPTOR/BINDING SITE IN RAT LIVER. D.I. Schuster,

RECEPTOR/BINDING SITE IN RAT LIVER. D.I. Schuster,
G. Singh, G. Ehrlich, and R.B. Murphy. Dept.
Chemistry, New York University, New York NY 10003.
Previous workers have described a sigma binding site in peripheral tissues. We report the pharmacology of this site in rat liver membranes using [3H]-haloperidol. The binding site is saturable and unitary. K, values found were (nM): haloperidol 1.3, DTG 63, (+)-cyclazocine 296, buspirone 301, (-)-butaclamol 322, (+)-SKF10,047 536, (-)-cyclazocine 1863, (+)-butaclamol 3500, (-)-SKF10,047 5279. Saturation studies in the presence of carbon monoxide gave statistically unchanged values of K_d (0.8 nM) and B_{max} (23,000 fMol/mg), indicating that the binding site is not a liver cytochrome P-450. Values of B_{max} are highest in neonatal rats and rapidly decline with age. These data suggest that the liver sigma-like binding site is similar to but not identical with the CNS site. Supported by NIDA ROI DA 05728 the CNS site. Supported by NIDA RO1 DA 05728 (RBM).

A CORRELATION BETWEEN SIGMA RECEPTOR BINDING PARAMETERS AND BEHAVIORAL RESPONSIVENESS TO A SELECTIVE SIGMA LIGAND IN RATS OF VARIOUS AGES. MK Hemstreet, RR Matsumoto, WD Bowen, and JM Walker. Brown University, Providence, RI

The functional significance of sigma binding sites in motor function was examined with both behavioral and biochemical assays. The behavioral paradigm involved unilateral microinjections of DTG into the red nucleus of male rats of various ages. This technique was previously shown to reliably produce an acute deviation of head angle (torticollis) in rats. For <u>in vitro</u> experiments, rat brain membranes were prepared from age-matched subjects and ligand-binding assays were conducted on these membranes using [3H]-DTG as the radioligand; sigma receptor binding parameters were then determined from the binding data using Scatchard analysis.

In agreement with previous studies, intrarubral DTG induced significantly greater cervical dystonia than did control injections. The degree of torticollis varied with age, although no clear age-dependent pattern emerged. The amount of head deviation following intrarubral DTG was highly correlated with the amount of bound ligand in the brain membranes of the age-matched in vitro subjects (r=0.87). This correlation suggests a functional relationship between sigma receptor binding in the mammalian brain and normal maintenance of head posture.

159.18

CLORGYLINE AND SKF-525A INTERACT POTENTLY WITH SIGMA

CLOHGYLINE AND SKR-525A INTERACT POTERILY WITH SIGMA BINDING SITES G. Battaglia Dept. of Pharmacol, Loyola University of Chicago, School of Medicine, Maywood, IL 60153

The high density of sigma sites labeled by 3H-HAL (3H-Haloperidol) in cerebellum and liver suggests that some "sigma" sites may be on enzymes such as MAO (monoamine oxidase) or cytochrome P450. A pharmacologic profile of 12 MAO inhibitors (MAOI's) at 3H-HAL labeled sigma sites in cerebellar homogenates demonstrated that only clorgyline exhibited high affinity (Ki=3.4nM). Most other MAOI's had affinities greater than 10uM with the isomers of deprenyl being somewhat more potent but exhibiting a stereospecificity opposite that for MAO inhibition. Clorgyline administration (3mg/kg, s.c. 1x/day for 7 days) caused a 15% decrease in 3H-HAL labeled sigma sites in cerebral cortex but no change in liver. Tranylcypromine, an MAOI with markedly lower affinity for sigma sites, was without effect. The microsomal enzyme inhibitor, SKF-525A (Proadifen), also had high affinity (Ki=6nM) for 3H-HAL labeled sigma sites in liver and brain. Subcellular fractionation studies in liver revealed the presence of sigma sites in fractions P1 and P3, but not P2, as indicated by the affinities of pentazocine and (-)BTC. SKF-525A, exhibited high affinity for 3H-HAL labeled sites in the nuclear (P1) and other non-microsomal (P2 and P3) fractions. These data indicate that clorgyline and SKF-525A interact potently with sigma sites. These sigma sites are unlikely to be on mitochondrial MAO since most MAOI's had low affinity. In addition, it is unlikely that these sites are on cytochrome P450 since SKF-525A had high affinity for sigma sites in all non-microsomal fractions. These data do suggest that 3H-HAL labeled sigma sites may be present on mitochondrial components other than MAO, since mitochondria were present in all subcellular fractions investigated.

SECOND MESSENGERS I

ACTIVATION OF MUSCARINIC RECEPTORS IN HUMAN-SK-N-SH NEUROBLASTOMA CELLS ELICITS A SUSTAINED HYDROLYSIS OF POLYPHOSPHOINOSITIDES. S.K. Fisher. A.M. Heacock, E.B. Seguin and B.W. Agranoff. Neurosci. Lab., Univ. of Mich., Ann Arbor, MI 48104
The contribution of polyphosphoinositides to muscarinic receptor

(mAChR)-stimulated phosphoinositide turnover has been evaluated for both intact and digitonin-permeabilized cells. Addition of carbachol (CCh) to [³H]inositol-prelabeled intact cells resulted in a rapid and sustained loss of [3H]phosphatidylinositol 4,5-bisphosphate with the concomitant appearance of labeled I(1,4,5)P₃, I(1,3,4)P₃ and IP₄. Inositol mono- and bisphosphates steadily accumulated in response to mAChR activation and comprised > 95% of inositol phosphate formation at incubation times > 5 min. The major IP $_2$ isomer formed at all times was the (1.4) species.Of the two IP $_1$ isomers produced, [3 H]I(4)P increased continuously whereas label in [3 H]I(1)P/[3 H]I(3)P was delayed in appearance but thereafter progressively accumulated. Whole homogenates of SK-N-SH cells metabolized sively accumulated. Whole homogenates of SK-N-SH cells metabolized added [(1,4,5)P₃ to [(1,4)P₂ and [(4)P, whereas [(1,3,4,5)P₄ was degraded to [(1)P)/(3)P. We conclude that mAChR occupancy elicits the continuous breakdown of polyphosphoinositides, and that much of the label present in [(1)P)/(3)P fraction is derived from operation of the IP3 kinase pathway. Although addition of CCh to digitonin-permeabilized cells also resulted in a sustained release of [3H]inositol phosphates, the ratio of [3H]i(4)P;[3H]i(1)P/i(3)P produced was greater than that observed for intact cells. Measurement of IP3 kinase and IP3 5'-phosphatase activities revealed that digitonin permeabilization enhanced the phosphatase and diminished the kinase activity. Thus, the routes of degradation of I(1,4,5)P3 differ between the intact and permeabilized preparations. Supported by NIH NS 23831, NS 15413 and NIMH MH 42652.

THE na^+/Ca^{2+} EXCHANGER AND PHOSPHOINOSITIDE METABOLISM IN SYNAPTONEUROSOMES. M. Benuck, M.E.A. Reith and A. Lajtha. Center for Neurochemistry, N.S. Kline Institute, Ward's Island, NY, 10035.

We find evidence supporting the participation of the $\mathrm{Na^+/ca^{2+}}$ exchanger in the inositol response to depolarization (30 mM KCl) or sodium channel activation (10 uM veratridine). In these studies, the release of (10 um veratridine). In these studies, the release of [3H] inositol phosphates ($^{1}P_{1}$, $^{1}P_{2}$ and $^{1}P_{3}$) is compared with the increase in $[0a^{2}]_{1}$ measured with fura-2-AM in mouse cerebral cortical synaptoneurosomes. The ratio in the inositol response to veratridine over that to KCl in time is different for IP, and IP,; this may be related to the more rapid rise of $\left[\text{Ca}^{2^+}\right]_1$ upon addition of KCl as compared to veratridine.

The participation of voltage-sensitive calcium channels appears to be minor, since the presence of ω -conotoxin did not significantly affect the inositol response or [Ca2+]_i levels upon addition of KCl or veratridine. Benzamil and 5-(N,N dimethyl) amiloride, blockers of the Na⁺/Ca²⁺ exchanger, inhibited the inositol response to KCl and veratridine. Omission of Na⁺ from the external medium and veratriaine. Umission of Na from the external medium reduced the effect of KCl and veratridine on the inositol response and on $\left[\text{Ca}^{2+}\right]_1$ levels. These results give further indication of the participation of the Na $^+$ /Ca $^{2+}$ exchanger in the regulation of phosphoinositide metabolism.

CELL-SURFACE RATHER THAN SEQUESTERED MUSCARINIC RECEPTORS ARE LINKED TO PHOSPHOINOSITIDE HYDROLYSIS.

A.K. Thompson and S.K. Fisher. Neuroscience Laboratory and Department of Pharmacology, The University of Michigan, Ann Arbor, MI 48104

Addition of carbachol (Cch) to intact human SK-N-SH neuroblastoma cells results in a rapid sequestration of 50% of the cell-surface muscarinic acetylcholine receptors (mAChRs) into a lipophilic domain without a loss of stimulated phosphoinositide (PPI) turnover (Thompson and Fisher, 1990, JPET 252:744). One explanation that may reconcile these inconsistencies is that the sequestered receptor is both recognized by the agonist and can couple to PPI hydrolysis. To address this issue, PPI hydrolysis was monitored at 10°C, a temperature at which the cycling of mAChRs between cell-surface and sequestered domains is prevented intact [4H]inositol prelabeled cells were first exposed to Cch for 1 h at 37°C to induce mAChR sequestration, the agonist removed by washing at 0°C and agonist-stimulated PPI hydrolysis measured at 10°C for 2 h. When compared to controls, pretreatment of cells with CCh resulted in a subsequent 40-50% loss of [4H]inositol phosphate formation when stimulated with either hydrophilic or lipophilic agonists in the presence of Li*. In contrast, when CCh-pretreated cells were incubated at 37°C, a temperature at which receptor cycling occurs, only a 5-15% loss of activity was detected. Pretreatment of intact SK-N-SH cells with carbachol also resulted in the appearance of a population of mAChRs which exhibited a very low affinity for the hydrophilic full agonist, CCh, whereas lipophilic agonists detected the mAChR population in control and CCh-pretreated cells with equal affinities. Thus, whereas the lipophilic agonist conclude that cell-surface mAChRs are preferentially coupled to PPI hydrolysis in SK-N-SH cells. For a sustained PPI hydrolysis to occur, it appears that the sequestered mAChRs must return to the cell surface. (Supported by NIMH Grant 42652 and NIH Training

THE RELATIONSHIP OF AGONIST- AND CAFFEINE-SENSITIVE CALCIUM POOLS IN SINGLE BOVINE ADRENAL CHROMAFFIN CELLS.
K.A. Stauderman and M.M. Muravsky. Merrell Dow Research
Institute, 2110 E. Galbraith Road, Cincinnati, OH 45215.

K.A. Stauderman and M.M. Murawsky. Merrell Dow Research Institute, 2110 E. Galbraith Road, Cincinnati, OH 45215. Stimulation of single bovine adrenal chromaffin cells with histamine or angiotensin II (A_{II}) leads, initially, to at least one large "spike" of elevated intracellular free Ca²⁺ ([Ca²⁺]₁). While IP₃-induced Ca²⁺ release is almost certainly involved in these spikes, the potential contribution of Ca²⁺-induced Ca²⁺-release (CICR) has not been addressed. To examine the role of CICR, we monitored [Ca²⁺]₁ changes in single fura-2 loaded chromaffin cells treated with or without 10 mM caffeine, an agent that will discharge internal Ca²⁺ present, cells not treated with caffeine displayed an initial large spike of [Ca²⁺]₁ after stimulation with either 10 µM histamine or 0.1 µM A_{II} (peaks 720 ± 103 and 746 ± 81 nM, respectively). Caffeine alone produced a large transient elevation of [Ca²⁺]₁ (peak 796 ± 84 nM). In caffeine pretreated cells, the amplitudes of histamine- and A_{II}-induced increases of [Ca²⁺]₁ were both decreased by 94%. Conversely, caffeine responses were inhibited 100% and 92% after pretreatment with histamine or A_{II}, respectively. Thus, over 90% of the Ca²⁺ released by either histamine or A_{II} arises from caffeine-sensitive stores, and are consistent with CICR playing a major role in the development of the initial Ca²⁺ spikes. The role of CICR in the later stages of agonist responses is under investigation.

INHIBITION OF CARBACHOL-STIMULATED PHOSPHOINOSITIDE TURNOVER BY KAPPA OPIOID AGONISTS IN RAT HIPPOCAMPUS. S. Periyasamy and W. Hoss. Dept. of Medicinal and Biological Chemistry, Univ. of Toledo, Toledo, OH 43606.

Periyasamy and W. Hoss. Dept. of Medicinal and Biological Chemistry, Univ. of Toledo, Toledo, OH 43606.

The effects of various subtype-selective opioid agonists on carbachol-stimulated phosphoinositide (PI) turnover response in rat hippocampal slices were examined. U-50,488H, a kappa-selective agonist that stimulates PI turnover in this preparation (Periyasamy and Hoss, Life Sci., in press, 1990), inhibited carbachol stimulated PI turnover in a concentration-dependent manner with an IC50 yalue of 33 ± 9.0 μM. Other kappa-agonists, including ketocyclazocine and D[Ala]²-dynorphin-A (1-13) amide also produced concentration-dependent inhibition of carbachol-stimulated PI turnover but with lower potency. On the other hand, the mu-selective agonist [D-Pent-V-3] enkephalin caused only a small decrease in carbachol-stimulated PI turnover. The inhibitiory effect of U-50,488H was not blocked by either kappa-selective antagonists nor-binaltorphinnine and MR2266 (10 μM) or tetradotoxin (1 μM) suggesting that the U-50,488H effect is neither mediated through kappa-receptors nor through the release of endogenous neurotransmitters. A Lineweaver-Burke plot of the stimulation of PI turnover by carbachol in the presence and absence of U-50,488H showed that the K_m was not changed (11.4 ± 3.4 and 11.5 ± 2.6 μM) whereas V max was reduced (1534 ± 31 and 3849 ± 460 cpm) indicating that the inhibition was non-competitive. U-50,488H also inhibited guanosine 5-[β, γ-imido]triphosphate (Gpp NHP)-stimulated PI turnover in rat hippocampal membranes in a concentration-dependent manner with an IC50 value of 33 ± 12 μM. However, U-50,488H had no effect on phospholipase-C-stimulated PI turnover pinding studies U-50,488H displaced the non-selective muscarinic antagonist [³H]-1-quinuclidinyl benzilate ([³H]-1-QNB) binding in a concentration dependent manner with an IC50 value of 3.5 ± 1.8 μM. A Scatchard plot of [³H]-1-QNB binding in the presence and absence of U-50,488H showed that the K_d was changed (883 ± 250 and 364 ± 147 pM) wh

THE BRADYKININ ACTIVATION OF PHOSPHOLIPASE D IN PC12

THE BRADYKININ ACTIVATION OF PHOSPHOLIPASE D IN PC12 CELLS IS NOT MEDIATED BY PROTEIN KINASE C. J. Horwitz and S. Ricanati*. Dept. of Pediatrics and Kennedy Mental Retardation Res. Ctr., The University of Chicago, Chicago, IL 60637.

Bradykinin activates phospholipase D in PC12 pheochromocytoma cells. Since bradykinin also activates protein kinase C in these cells, the possible role of this kinase in mediating the action of bradykinin was investigated. Phospholipase D activity was assayed by measuring the formation of [3H]Pbosphatidylethanol ([3H]PE) in cells prelabeled with [3H]palmitic acid and incubated in the presence of ethanol. The phorbol ester phorbol dibutyrate (PdBu) mimicked the effect of bradykinin on [3H]PEt. The enzyme activated by PdBu was similar to the enzyme activated by bradykinin in terms of its Ca²⁺ dependence and specificity for phosphatidylcholine. Other data suggested that protein kinase C was not involved in mediating the effect of bradykinin. The protein kinase C inhibitor staurosporine (10 µM) significantly attenuated the effect of PdBu (-70%) but it did not block bradykinin stimulated (3H]PEt. In addition, the effect of PdBu was partially additive with that of bradykinin. Prolonged treatment of PC12 cells with PdBu is known to deplete cells of protein kinase C. PdBu pretreatment completely blocked bradykinin stimulated (3H]PEt in intact cells. This treatment, however, also caused a down regulation of phospholipase D (-55%) as assessed by an in vitro assay. Thus, the effect PdBu pretreatment on bradykinin stimulated (3H]PEt could not be attributed to the depletion of protein kinase C. In conclusion, although the activation of protein kinase C leads to an increase in phospholipase D activity, this pathway does not play a role in mediating the effect of bradykinin. CHRONIC HALOPERIDOL TREATMENT ATTENUATES RECEPTOR-MEDIATED PHOSPHOINOSITIDE TURNOVER IN RAT BRAIN SLICES.
R. Li*, L.LWing, Y. Shen, R.J. Wyatt, D.G. Kirch and D.M. Chuang. Neuropsychiatry Branch, NIMH Neuroscience Center at St. Elizabeths, Washington, D.C. 20032 and Biological Psychiatry Branch, NIMH, Bethesda, MD 20892.
To examine intracellular molecular mechanisms of haloperidol, we studied neurotransmitter receptor—mediated phosphoinositide (PI) turnover in rats treated

haloperidol, we studied neurotransmitter receptor-mediated phosphoinositide (PI) turnover in rats treated with biweekly saline or IM haloperidol decanoate (HAL-D; 1.5 mg/kg/day) for 6 weeks. Basal and receptor agonist-stimulated PI hydrolysis were assayed by lithium-dependent accumulation of ³H-inositol monophosphate (IP,) in brain slices pre-labeled with ³H-myo-inositol. Basal PI turnover was unchanged after HAL-D, preliminary data indicate HAL-D significantly decreased carbachol-induced ³H-IP, accumulation in striatum and hippocamous with a Similar trend in frontal cortex. Norepinephrine sensitive ³H-IP, accumulation was also significantly decreased in frontal cortex and hippocampus. Chronic haloperidol attenuated muscarinic and al-adrenergic receptor-mediated PI hydrolysis, a result similar to previously reported effects of chronic lithium treatment on the PI system.

P2 PURINERGIC AND BRADYKININ RECEPTOR-INDUCED CALCIUM RESPONSE AND INOSITOL PHOSPHATE RELEASE IN NG108-15 CELLS. T.A. Lin, G.A. Weisman* and G.Y. Sun. Dept. Biochem., Univ. Missouri, Columbia, MO 65212.

Both ATP and bradykinin (BK) are known to transduce their signals through stimulation of poly-PI breakdown and release of inositol trisphosphate. In turn, this second messenger can cause an increase in intracellular $[{\sf Ca}^{2^+}]$ i. The present study addresses effects of these two receptor types on $[{\sf Ca}^{2^+}]$ i response and inositol phosphate release in the neuroblastoma-glioma hybrid cells (NG108-15). In the presence of extracellular Ca²⁺ (1 mM), both ATP (1-100 μ M) and BK (1 nM-1 μ M) could induce transient increases in [Ca $^{2+}$]i, reaching a peak within 10 seconds and subsequently declining to near basal level within 1 min. When cells were pretreated with ATP (100 μ M), they failed to repond to cells were pretreated with ATP (100 μ M), they failed to repond to a second challenge of ATP although a small response could be regained on removal of ATP by washing. Cells that were pretreated with ATP (1-2000 μ M) responded well to BK (1 μ M). On the other hand, cells that were pretreated with 1 μ M BK failed to respond to a second challenge of BK (1 μ M) or ATP (100 μ M). Inositol monophosphate isomers in these cells were analyzed by ion chromatography. Cells stimulated by either ATP or BK (5 min in the presence of lithium) indicated a 4-5 fold increase in Ins(4)P and, to a smaller extent, an increase in Ins(1)P also. Information on inositol phosphate isomers will be used to decide whether these receptors use the same or different [Ca²⁺]i pools in the cell.

POLARIZED ACTIVATION OF INTRACELLULAR CALCIUM RELEASE AND CALCIUM-DEPENDENT ION CHANNELS BY ACETYLCHOLINE AND CHOLECYSTOKININ. H. Kasai and G.J. Augustine. Max Planck Inst. for Biophysical Chemistry, Goettingen, FRG.

We have examined the spatial distribution of agonist-induced Ca release and activation of Ca-dependent ion channels in isolated cells from rat pancreatic acini, using digital Ca-imaging and whole-cell patch clamp methods. Acetylcholine (ACh) and cholecystokinin (CCK), which generate IP3, initially triggered Ca release at the luminal pole of these cells even though the receptors for these agonists are thought to be localized in the other (basolateral) side of the cell. The Ca rise then spread toward the basolateral side and eventually made Ca levels highest at this pole. In contrast, CCK-JMV, an analog of CCK that releases Ca without generating IP3, did not produce the initial, spatially-restricted rise in Ca at the luminal pole. The ACh-induced Ca signal initially caused a sharp and transient activation of Cl current, which was followed by a simultaneous activation of both Cl and cation currents. In CCK-JMV the relative magnitude of the early, transient Cl current was small. These data (1) demonstrate that different agonists can regulate Ca release and ion channel activation in spatially and temporally distinctive patterns, (2) are consistent with two agonist-sensitive Ca release mechanisms, one of which is independent of IP3, and (3) suggest a novel push-pull mechanism for Cl secretion in exocrine gland cells.

ENHANCED VASOPRESSIN (AVP)-INDUCED PHOSPHOINOSITIDE (PI) HYDROLYSIS IN RATS PRETREATED WITH I.C.V. OXYTOCIN (OT). Poulin, S. search Group, Weiss and O.J. Pittman, Neuroscience
Univ. of Calgary, Calgary, Alberta, Canada T2N 4N1

Activation of V1 type of AVP receptors in the ventral septal area (VSA) causes motor disturbances in rats. These receptors can be "sensitized" by previous exposure to AVP or OT. This "sensitization" phenomenon is not due to an increase in the number or affinity of the VSA VI receptors. In the present study, we further investigated possible mechanism(s) of the VSA VI receptor sensitization by studying the regulation of postreceptor events (PI hydrolysis). Male Sprague Dawley rats were either sensitized with 10 pmole OT i.c.v. or given saline. 24 hlater we compared the dose-response curves for AVP-stimulation of [3H]inositol-1-phosphate (IP₁) accumulation in VSA slices from sensitized or control animals. In in VSA siles from sensitized of control animals. In sensitized rats, AVP-stimulated accumulation of [³H]IP, was 35% greater than in controls, at AVP concentrations of 10⁻⁸ to 10⁻⁵M. Carbachol (1.0 mM) stimulation of [³H]IP, accumulation was not different between the two groups. These results indicate that the PI response of VSA AVP receptors is functionally increased in sensitized animals when compared to controls. Research Council of Canada. Supported by the Medical

REGULATION OF PHOSPHOINOSITIDE HYDROLYSIS VIA AN M3 MUSCARINIC RECEPTOR IN NEURONS IN PRIMARY CULTURE. J. Ellis. J.H. Huyler*. J. Hovious* and R.H. Lenox. Neuroscience Research Unit, Dept. of Psychiatry, UVM College of Medicine, Burlington VT 05405.

We have previously shown that the muscarinic phosphoinositide (PI) response of striatal neurons in primary culture is mediated by an \mathtt{M}_1 receptor. The same study found that neurons obtained from the brainstem did not possess \mathtt{M}_1 receptors, but were more efficiently coupled to a muscarinic PI response, leading us to suggest the involvement of an \mathtt{M}_3 receptor. Further pharmacological analysis has found that carbachol is more potent in stimulating the PI response in brainstem neurons (EC $_{50}$ 21 μM) than in striatal neurons (61 μM). Pirenzepine is considerably less potent in antagonizing the response of brainstem neurons (apparent K_1 210 nM, compared to 23 nM at striatal neurons), but 4-DAMP is equipotent in the two populations of neurons (apparent K_1 1 nM). This M3 muscarinic receptor is regulated by protein kinase C (PKC) activation in much the same way as we have previously found for the \texttt{M}_1 receptor of striatal neurons. That is, brief exposure of brainstem neurons to phorbol dibutyrate (PDBu) leads to translocation of PKC from the cytosol to the membrane fraction and also attenuates the \texttt{M}_3 -mediated PI response. Washout of PDBu reverses the translocation of PKC, but the attenuation of the PI response persists for at least several hours. (Supported by RO1 AGO5214).

Effect of the Benzodiazepine Midazolam on Calcium Signalling in Astrocytes. William E. Code, J. Steven White, Leif Hertz. Depts. of Anaesthesia and Pharmacology, Univ. of Sask., Saskatoon S7N OWO Canada and College of Pharmacy Linky of Utah Salt Jake City Utah

Pharmacy, Univ. of Utah, Salt Lake City, Utah A potassium induced entry of labelled calcium has been demonstrated in primary cultures of astrocytes (Hertz et al., 1) Neurosci Res, 22, 209, 1989). This calcium uptake is inhibited by a low concentration of the calcium channel antagonist nimodipine, indicating that it occurs through a voltage dependent L-channel. The astrocytic benzodiazepine receptor may interact with calcium channels. Many clinically used benzodiazepines, e.g., diazepam and midazolam, a water soluble benzodiazepine frequently used in anaesthesia, have equal affinity for the neuronal and strocytic benzodiazepine receptor and may thus exert at least part of their action on astrocytes. We have measured free intracellular calcium (Ca²⁺₁) in primary cultures of astrocytes with the fluorescent drug Indo-1. When extracellular K+ (K_O) was raised from 3.6 to 20 mM, Ca²⁺₁ increased by 4.0±1.1 arbitrary units (AU). Exposure to the same K+_O in the presence of midazolam (10 nM) caused a considerably higher increase (18.4±4.1 AU). In the presence of the astrocyte specific benzodiazepine antagonist PK11195 (1 μM) the effect by 20 K+ alone was unaltered (an increase of 4.5±0.90 AU). When PK11195 was added in the joint presence of 20 mM K+ and 10 nM midazolam most of the stimulatory effect by midazolam was abolished (7.9±1.1 AU). Since astrocytes possess calcium dependent K+ channels, these effects may be important in the regulation of channel mediated transport of K+ in astrocytes, a process which is of importance for regulation of K_O+ in brain and thus of neuronal excitability. These effects are more potent than the effects of benzodiazepines on neuronal chloride permeability.

COUPLING OF MUSCARINIC RECEPTORS IN RESPONSIVE AND NONRESPONSIVE RAT SWEAT GLANDS. M. P. Grant and S. C. Landis Depts. of Pharmacology and Neurosciences. Case Western Reserve University, Cleveland, OH 44106.

Previous studies have demonstrated that acutely denervated rat sweat glands, or glands sympathectomized at birth with 6-hydroxydopamine do not secrete in response to muscarinic stimulation; however, they express control levels of muscarinic ligand binding sites. This observation raises the possibility that the receptor is uncoupled from its appropriate intracellular effector. Studies of secretory mechanisms in other exocrine gland tissues have shown that secretion is stimulated *via* the PI pathway through the generation of IP3 promoting the release of intracellular Ca²⁺; however, it is not known if this mechanism is responsible for secretion in rat sweat glands.

We have investigated the coupling of muscarinic receptors to PI turnover in rat sweat glands. Preliminary results from SDS-PAGE analysis of membranes ³²P-ADP-ribosylated with pertussis toxin (PTx) demonstrated the existence of a 40-41 kD pertussis toxin sensitive protein in both control and 6-OHDA membranes. Immunocytochemical and western blot analysis is in progress to determine if this protein is responsible for coupling the receptor to phospholipase C. Stimulation with carbachol (1 mM) of slices of gland-rich tissue isolated from control animals produced approximately a four-fold increase in the amount of total inositol phosphates, and the effect was inhibited by atropine (1 µM); this response was identical to that of a parotid gland control. Further, stimulation of slices isolated from 6-OHDA treated animals also produced a four-fold increase in the amount of total inositol phosphates. Thus, it appears that muscarinic cholinergic receptors present on sweat glands of both responsive and nonresponsive glands are coupled to PI turnover. Supported by NS 23678.

IDENTIFICATION OF HISTAMINE RECEPTORS ON HUMAN ASTROCYTOMA-DERIVED CELLS (UC-11MG) AND THEIR ROLE IN THE REGULATION OF INTRACELLULAR FREE CALCIUM. M. J. Lucherini and E. Gruenstein. Dep't of Molecular Genetics, Biochemistry and Microbiology, University of Cincinnati College of Modicine. Cincinnati OH 45267-0524

University of Cincinnati College of Medicine, Cincinnati, OH 45267-0524.

Astrocytes comprise 20% - 25% of the cellular volume of the human brain. Their function in the central nervous system (CNS) involves the uptake and metabolism of neurotransmitters and the maintenance of low levels of extracellular K*. We have found that these cells are capable of generating repetitive action potentials (unpublished data). This observation suggests the possibility that neurotransmitters might be involved in mediating astrocytic responses. We have tested this hypothesis by examining the ability of a variety of neurotransmitters to elevate levels of the important intracellular second messenger cytoplasmic free Ca²⁺ (Ca²⁺).

Experiments were carried out on UC-11MG human astrocytoma cells, a continuous cell line that expresses a broad range of biochemical and electrophysiological properties of well-differentiated astrocytes (Lomneth et al, Brain Research, 1989;486:95-107). Ca²⁺1 was monitored in substrate-attached cells with the fluorescent indicators fura-2 and indo-1 using digital imaging analysis and dual wavelength photometry, respectively. Of the eleven neurotransmitters tested, only histamine caused a significant elevation in Ca²⁺1. The Ca²⁺1 transient in response to histamine occurred within seconds and was maximal at 300 μM histamine. The response is mediated through H₁ receptors and involves production of IP₃. Although cAMP is not elevated following histamine stimulation administration of dBcAMP 24 hours prior to histamine stimulation caused a 60% increase in the peak Ca²⁺1 response. We conclude that histamine causes a significant Ca²⁺1 response in human astrocytes and that this neurotransmitter may play a role in astrocytic function in the human CNS. Supported in part by grants NIH NS27814 and National AHA ref. #890513.

LITHIUM-INDUCED LETHALITY AND CHANGES IN CEREBRAL INOSITOL, INOSITOL MONOPHOSPHATES AND CALCIUM. M.-R. Hirvonen and K.M. Savolainen. Natl. Publ. Hlth Inst., Dept. Env. Hyg. & Toxicol., P.O.B. 95, SF-70701 Kuopio, FINLAND.
Lithium inhibits the hydrolysis of inositol-1-phosphate

Lithium inhibits the hydrolysis of inositol-1-phosphate (Ins1P), an intermediate in neuronal phosphoinositide (PI) cycle. Ins1P reflects the activity of receptor-coupled PI-signaling. Effects of 2.5, 5, 10, 12, 14, 16 or 18 meq/kg of LiCl on lethality, and brain regignal inositol, Ins1P, inositol-4-phosphate (Ins4P), and Ca⁺ levels were studied in male rats 24 h after a single dose of LiCl. Inositol and inositol monophosphates were measured by gas chromatography and mass spectrometry, and metals with AAS. LiCl at doses exceeding 10 meq/kg increased lethality with a LD50 dose of 14 meq/kg. LiCl decreased brain inositol, and brain Li increased in response to LiCl dose. Low doses of LiCl increased Ins1P but doses exceeding 10 meq/kg decreased Ins1P; LiCl did, not affect Ins4P. Lethal doses of LiCl decreased brain Ca⁺ by 40-60%. Effects of LiCl on Ins1P were significant in all brain regions except cerebellum. Dual effects of LiCl on brain Ins1P provide evidence that several enzymes in PI cycle with different sensitivities to Li may be inhibited by the ion. Thus, Ins1P and Ins4P accumulation does not explain LiCl-induced decreases in brain inositol, and Ins4P even seems to be insensitive to Li . Effects of LiCl on brain total Ca⁺ are likely to be nonspecific because they only occurred at lethal LiCl doses. Supported by The Academy of Finland.

EFFECTS OF CLIMBING FIBRE DESTRUCTION ON INOSITOL 1,4,5-TRISPHOSPHATE RECEPTOR IN THE RAT CEREBELLUM. P.P. Li, M.A. Green, J.J. Warsh. Clarke Institute of Psychiatry, University of Toronto, Toronto, M5T 1R8, Canada.

Inositol 1,4,5-trisphosphate (InsP₃) regulates an array of cellular function through binding to its receptor. While modulations of InsP₃ receptors in vitro have been reported, little is known of the regulation of these receptors in vivo. To investigate whether InsP₃ receptors could be trans-synaptically regulated in vivo, we examined the effect of eliminating the olivocerebellar projection, on cerebellar InsP₃ receptors in rat. Twenty-one days after an injection of 3-acetylpyridine [3-AP] (60 mg/kg, i.p.), which caused a degeneration of the inferior olivary climbing fibres, the density of InsP₃ receptor was significantly reduced by 20% with no apparent changes in the binding affinity. A significant reduction in the binding density was evident as early as at 7 days after 3-AP treatment. No further reduction in binding density was found in rats given a second dose at 7 days. The in vivo effect of 3-AP was not related to a direct action on the InsP₃ receptors as 3-AP (0.5 mM) failed to inhibit ³H-InsP₃ binding in vitro. The above data suggest that some of the InsP₃ receptors in cerebellum may be localized on the climbing fibre terminals. Alternatively, the reduction in InsP₃ receptors may reflect an adaptive response to the heightened parallel fibre-Purkinje cell synaptic transmission which is known to occur following climbing fibre degeneration.

SUBSECOND KINETICS OF INOSITOL 1,4,5-TRISPHOSPHATE-INDUCED CALCIUM RELEASE REVEAL BIPHASIC REGULATION BY EXTRAVESICULAR CALCIUM. E.A. Finch¹³, T.J. Turner², and S.M. Goldin²³. ¹Program in Neuroscience and ²Biol. Chem. Dept., Harvard Med. Sch., Boston, MA 02115, ³Cambridge NeuroScience Research, Inc., Cambridge, MA 02139.

The kinetics and modulation by extravesicular Ca²⁺ (Ca₀) of IP³-induced release (IICR) from synaptosome-derived microsomes were studied using a superfusion system affording 50ms time resolution and the precise control of agonist and ionic concentrations. IP³ evoked a transient release of actively accumulated ⁴⁵Ca²⁺ (EC₀ =250nM, n_H=0.9). Maximal rate of ⁴⁵Ca²⁺ release occurred within 100ms and decayed exponentially (r≤160ms). An invariant τ over a range of [IP³] (30nM-10µM) indicates that rapid decay of release is not simply due to depletion of releaseable ⁴⁵Ca²⁺, but results from attenuation of the release mechanism. Ca modulated the simply due to depletion of releaseable ⁴⁵Ca²⁺, but results from attenuation of the release mechanism. Ca modulated the kinetics and magnitude of IICR. Elevation of [Ca₂] from 100nM to micromolar levels initially potentiated (EC₃₀=650nM) and subsequently inhibited ⁴⁵Ca²⁺ release. Potentiation of IICR by Ca₂ developed within 100ms whereas inhibition by Ca₂ required several hundred msec of exposure to elevated [Ca₂]. The kinetics and biphasic nature of the modulation by Ca₂ suggest a mechanism for sequential positive and negative feedback regulation of IICR that may contribute to transients and/or oscillations of cytosolic free Ca²⁺ in vivo. (Supported by NIH grant GM35423.)

NO EVIDENCE FOR INSP3 MEDIATED CALCIUM MOBILIZATION IN THE ASTROCYTE POPULATION OF THE ADULT RAT HIPPOCAMPAL SLICE.

D. M. Leifer* and S. N. Murphy. Dept. of Radiology, University of Chicago,

Chicago IL 00051.

Recent evidence has supported the presence of InsP3 coupled receptors upon cultured astrocytes from various regions of the CNS including hippocampus. These receptors appear to have many of the properties of neuronal G-protein linked receptors including those for norepinephrine (NE), quisqualate (QUIS), and endothelin (ED), apparently resulting in Ca²⁺ mobilization from intracellular stores. We wished to apparently resulting in car incommutation to include the role of these receptors in the adult rat brain. We therefore performed fura-2 microspectrofluorimetry upon thin hippocampal slices from adult rats. Slices were incubated in fura-2 ester under conditions which rarely resulted in neuronal uptake of the dye. Slices were perfused with glycine rich HCO₃⁻ buffered modified EARLES solution. Lack of neuronal dye loading was confirmed by negative responses to 100 µM veratridine (0/8). Basal [Ca²⁺]_i was 217±9 nM in 222 astrocyte fields. Each field contained approximately 45 astrocytes. Of these fields, 70% responded to a 50 mM K⁺ depolarization with a Δ [Ca²⁺]_i of 113±12 nM, 50 mM K⁺ depolarization following the removal of Ca^{2+} and the addition 500 μ M EGTA to the medium resulted in responses that were reduced by only 12±15%. Under these conditions Ca^{2+} influx induced by ionomycin was abolished. Therefore, the possibility that the release of Ca^{2+} stores mediates part of the depolarization induced [Ca²⁺]; increase seems likely. We proceeded to test the responses of this preparation to ED (0/6), NE (0/6), QUIS (0/7), kainate (0/4), NMDA (1/34), glutamate (3/35), and carbachol (6/83), obtaining responses only in <10% of the astrocyte fields only to the last three agonists which we could not preclude to be due to neuronal contamination in the field. Therefore, although our evidence supports the to neuronal contamination in the field. Interesting, almough our evidence supports the existence of Ca²⁺ stores in adult rat astrocytes, the stores appear either not to be linked to InsP₃ receptors or the InsP₃ linked receptors for NE, QUIS, and ED are absent from the astrocyte fields. (DOE grant DE-FG02-86ER60438.)

HIGH AND LOW AFFINITY RECEPTOR SITES FOR INOSITOL-1,4,5-TRISPHOSPHATE DETERGENT EXTRACTS OF MAMMALIAN CEREBELLUM

W.S. Agnew and S.R. Hingorani, Dept. of Cellular and Molecular Physiology, Yale University School of Medicine, New Haven, CT 06510

A rapid ion exchange binding assay was developed to measure IP₃ binding to sites in detergent extracts of mammalian cerebellum. Separation of bound from unbound ligand occurs within ~1 second resulting in detection of 3-4 fold higher receptor abundance than observed with spun column assays. Scatchard replots of complete saturation isotherms performed with extracts of rat or bovine cerebellar membranes were consistently non-linear, suggesting the presence of multiple classes of receptor sites. In both cases curves were well fit by assuming two classes of sites. In rat preparations one class displayed $K_d = 5$ nM, $B_{max} = 8{\text -}10$ pmol/mg protein, while the second had $K_d \sim 120$ nM and $B_{max} = 22{\text -}30$ pmol/mg protein; somewhat lower abundance was observed in bovine extracts. These sites exhibited differential inhibition by free Ca24, thermal stability and dissociation rate constants, and may represent distinct receptor molecules or different affinity states of the same molecule. The combined population of receptor sites are more than 25 times as abundant as the saxitoxin-binding sodium channel and, assuming subunit molecular weights of 243,000 Da, may constitute up to 1% of the total protein in unfanciated or abundance of the constitution of the c in unfractionated cerebellar membranes.

INTRACELLULAR PERFUSION TECHNIQUE SHOWS THAT Ca²⁺, SUPPRESSED I, IN ISOLATED HIPPOCAMPAL PYRAMIDAL CELLS. Qiang X. Chen. Robert K.S. Wong. College of Physicians and Surgeons, Columbia University, N.Y. N.Y., 10032.

We have continued to examine intracellular calcium (Ca²⁺), effects on hippocampal pyramidal cells by an intracellular perfusion technique (see Chen et al., J. Physiol., 420: 207). Experiments were carried out on acutely dissociated adult guinea-pig neurons. Intracellular and extracellular solutions were prepared to allow isolated activation of K* currents. Whole cell currents were recorded while intracellular solutions with low (>10⁻⁸ M) or high (4.5 x 10⁻⁴ M) Ca²⁺ contents were introduced. Step depolarizations to above -45 mV from -95 mV activated outward currents consisting of a transient component (I_A) followed by delayed sustained currents. Perfusion with the low Ca²⁺ solution caused a gradual increase of I, and decrease of sustained currents. In a second series of experiments stable recordings were obtained in low Ca²⁺ intracellular solution. Introduction of high Ga²⁺ potentiated the sustained K* currents, and suppressed A current. We attempted to confirm the latter observation by isolating A current using kinetic and pharmacological means. Firstly, A current, with a lower threshold, was activated in isolation by low voltage depolarization (-40 mV). Secondly, addition of Cs (10 mM) and TEA (10 mM) to the perfusate blocked delayed currents at all depolarizations but still allowed activation of A current. Suppression and blockade of A current by high intracellular Ca²⁺ were confirmed under both conditions. The results suggest that under different conditions, intracellular Ca²⁺ can either enhance or depress neuronal excitability via its modulatory actions on K* channels.

IDENTIFICATION OF INOSITOL TETRAKISPHOSPHATE AND KISPHOSPHATE BINDING PROTEINS FROM RAT

CEREBELLUM. A. Theibert, C. Ferris, S. Danoff, S. Supattagone, R. Barrow*, and S. Snyder. Dept. Neuroscience, Johns Hopkins School of Medicine, Baltimore, MD 21205. Recently, the InsP3 receptor from cerebellum was purified and reconstituted by researchers in our laboratory. It has been proposed that in addition to InsP3, other inositol polyphosphates such as InsP4, InsP5, and InsP6 may also have signalling functions. Using a similar expectation investigate the function of these vectorial. similar approach to investigate the function of these potential messengers, we have employed ligand binding techniques to characterize and identify their cellular receptors. Both [3H]InsP4 and [3H]InsP6 bind with high affinity to cerebellar membranes. These binding sites can be solubilized using the detergent CHAPS and can be partially purified and separated using heparin-agarose affinity partially purified and separated using heparin-agarose affinity chromatography followed by ion-exchange chromatography. The InsP4 binding protein has an affinity of approximately 10 nm and is very selective for InsP4 over InsP3, InsP5 and InsP6. The binding correlates with a protein of approximately 180 kd. The InsP6 site has an affinity of approximately 20 nm but is less selective than the InsP4 site. InsP5 and InsP6 are 4-fold less potent at this site. The purified InsP6 binding protein migrates as a complex comprised of a doublet protein at 105-110 kd and a singlet at 50 kd. We are currently reconstituting these binding proteins into linid vesicles to examine their reconstituting these binding proteins into lipid vesicles to examine their physiologic function.

CARBACHOL STIMULATES PHOSPHOINOSITIDE (PI) TURNOVER IN CHICK BRAIN SLICES: EFFECT OF MELATONIN. J.M. Fang. K.N. McMasters* and M.L. Dubocovich, Dept. Pharmacol.,

Northwestern Univ., Med. School, Chicago, IL 60611

Melatonin exerts its potent biological effects
through activation of specific receptors, however the cellular mechanism of its action is not well known. The aim of this study was to investigate the second messenger system linked to the melatonin receptor in the chick brain, where 2 [125]-iodomelatonin binding sites are widely distributed. Activation of melatonin receptors by melatonin (10⁻¹⁴-10⁻⁴M) did not modify the forskolin-stimulated adenylate cyclase (AC) activity in norskolin-stimulated adenylate cyclase (AC) activity in homogenates of chick hypothalamus, neo/ectostriatum and nucleus basalis. Activation of the muscarinic receptor with carbachol increased the formation of ${}^{3}H$ -inositol phosphates (lithium, 10 mM) in slices of chick telencephalon in a concentration-dependent manner with EC_{50} -8.5 μ M. The carbachol-induced increase in PI EC50-8.5µM. The carbachol-induced increase in PI turnover was higher in 1 day old (497 ± 43% of control) than in 1 week old (231 ± 11% of control) chick brain slices with no changes in EC50. Melatonin (10⁻⁴ M) did not modify the carbacol-induced increase in PI turnover. We suggest that the melatonin receptor in chick brain may be linked to the second messenger system other than AC and phospholipase C. Supported by USPHS grant MH

EXTRACELLULAR GDPBS INHIBITS WHOLE-CELL CURRENT RESPONSES TO EXCITATORY AMINO ACIDS IN RAT RETINAL GANGLION CELLS. Paul S. Jackson.

IN RAT RETINAL GANGLION CELLS. Paul S. Jackson. Andrew E. Budson*, and Stuart A. Lipton. Dept. of Neurology, Children's Hospital & Harvard Medical School, Boston, MA 02115.

In tissue binding studies, analogs of guanine nucleotides act extracellularly as competitive antagonists at the NMDA receptor (Butcher et al., Biochem. Pharm. 1986;35:991; Monahan et al., Molec. Pharm. 1988;34:111; Baron et al., J. Pharm & Exp. Ther. 1989;250:162). We used the patch-clamp technique to investigate the effects of the most potent of these, the GDP analogue GDP\$\(\beta \), on NMDA-activated currents. In addition, we studied the specificity of this effect, i.e., possible antagonism of other subtypes of glutamate receptors by GDP\$\(\beta \). Postnatal rat retinal ganglion cells were isolated, identified, and recorded from with patch electrodes, as previously described (Lipton and Tauck, J. Physiol. 1987;385:361). GDP\$\(\beta \) (SD0 \(\mu \)) (completely and reversibly blocked the response to NMDA (200 \(\mu \)), whereas 100 \(\mu \) MGDP\$\(\beta \) produced 30% inhibition, and 50 \(\mu \) mesulted in little or no

GDPBS produced 30% inhibition, and 50 µM resulted in little or no blockade (n = 6). A preliminary dose-response curve gave an estimated IC 50 of $^{\circ}$ 2x10-4 M. However, 500 μ M GDP β S also produced 90% blockade of the response to 125 μ M kainate (n = 3) and 30% inhibition of current induced by 25 μ M quisqualate (n = 2). Thus, GDP β S was a relatively non-specific EAA antagonist, but did manifest differential relatively non-specific EAA antagonist, but did maintest differential effects on NMDA/kainate versus quisqualate responses. In this regard, the pattern of blockade by GDPBS of EAA responses in retinal ganglion cells was reminiscent of that previously observed for kynurenate (Aizenman, Frosch & Lipton, J. Physiol. 1988;396;75).

EVIDENCE FOR MG++ DEPENDENCE OF GABA_B RECEPTOR-MEDIATED INHIBITION OF THE NMDA COMPONENT OF SYNAPTIC TRANSMISSION. W.A.Wilson, R.A.Mortisett, D.D.Mott, H.S.Swartzwelder, D.V.Lewis, Depts. of Med. (Neurol.), Pharmacol. and Pediatr. (Neurol.), Duke University and the VA Med. Ctrs., Durham, NC 27710.

We have utilized the non-NMDA receptor antagonist, DNQX, and the GABAA channel antagonist, picrotoxin, to study synaptic activation of NMDA receptors. Under these conditions, large, long-lasting NMDA EPSPs were recorded from s. radiatum of area CA₁ upon stimulation of the Schaffer collaterals. These NMDA EPSPs exhibited sensitivity to competitive and non-competitive NMDA antagonists including Mg⁺⁺. When NMDA EPSPs were paired at interstimulus intervals between 100 and 400 msec, we observed an almost complete block of the second response (see Morrisett et al., this volume). We have demonstrated that paired-pulse inhibition of NMDA EPSPs is dependent upon activation of

GABAB receptors most likely located on CA₁ pyramidal cell dendrites.

We hypothesized that some GABAB receptors located on CA₁ dendrites were in close approximation to NMDA receptor-operated channels. Therefore, the late IPSP that occurred due to GABAR receptor channels. Inerefore, the late IPSP that occurred due to GABAB receptor activation may regulate the voltage across NMDA channels and consequently the Mg++ block of those channels. To test this hypothesis, Mg++ was removed from the bath, resulting in approximately 50 % reduction in paired pulse inhibition of NMDA EPSPs. Removal of Mg++ had minimal effects on non-NMDA EPSPs. These data suggest that GABAB receptors potently regulate NMDA channel operation on the dendrites of CA1 pyramidal cells. (NS #17701, MH #15177-13 and Vet. Admin.).

EXCITATORY AMINO ACID INDUCED INTRACELLULAR CALCIUM CHANGES IN VOLTAGE CLAMPED ISOLATED CATFISH HORIZONTAL CELLS. <u>C.L. LINN AND B.N. CHRISTENSEN.</u> Dept. of Physiology and Biophysics, Univ. Texas Med. Branch, Galveston, TX. 77550

Isolated horizontal cells loaded with the calcium sensitive fluorescent indicator fura-2 were voltage clamped using the patch electrode in the whole cell mode. While voltage clamped at -65 mV, changes in intracellular calcium levels were measured during rapid application of glutamate analogs under concentration clamp conditions. Previous studies by O'dell and Christensen (1986, 1989) have demonstrated that isolatend cone horizontal cells respond to n-methyl-d-aspartate (NMDA), kainate (KA) and quisqualate (QA). NMDA (50 μ M), KA (20 μ M) and QA (10 μ M) each elicited an increase in intracellular calcium corresponding with the agonist induced inward current. The order of the relative efficacy for the three agonists is KA > NMDA > QA. An increase in intracellular calcium can be due to either an influx from the extracellular medium and/or release from intracellular stores. We are currently investigating the mechanisms responsible for the agonist induced increases in intracellular calcium in atfish cone horizontal cells. Supported by Grant 1F32EY-06246 and EY-01897.

ACUTELY DISSOCIATED, SUPERFICIAL DORSAL HORN NEURONS OF THE ADULT RAT: A STUDY OF EXCITATORY AMINO ACID RECEPTOR PROPERTIES. O. Arancio, M. Yoshimura, K. Murase, and A.B. MacDermott, Dpt. Physiol., Ctr Neurobiol. & Behavior, Columbia Univ., New York, NY 10032

In vitro preparations for studying receptor properties of spinal cord neurons include slices of spinal cord, cultured embryonic neurons, and acutely dissociated neurons. Neurons from immature animals or neurons that mature in culture may not express the same receptors as those maturing in vivo. Studying receptor pharmacology in the adult spinal cord in vivo or in slice would overcome these difficulties, but additional problem arise including diffusion barriers, uptake of agonists, and drug-evoked transmitter release. Therefore, we have developed a new preparation of acutely-dissociated superficial dorsal horn neurons (laminae I-II) from the adult rat spinal cord. The properties of the excitatory amino acid (EAA) receptors on these neurons were tested; the effects of the EAA antagonist, CNQX, on quisqualate (Quis), kainate (Kai) and N-methyl-D-aspartate CNCA, on quisqualate (Cuts), kalinate (ka) and N-metryl-D-aspartate (NMDA) evoked responses were studied quantitatively. Cells were tested under whole cell conditions with rapid drug application. Each neuron tested was sensitive to all three agonists; the K_d's for Quis, Kai and NMDA were 4, 140, and 90 uM, respectively. Responses to NMDA and Quis desensitized, while responses to Kai did not. Glycine augmented the responses to NMDA in a dose-dependent manner while APV markedly reduced the NMDA-evoked current. CNQX acted as a competitive antagonist of the Kai and Quis responses and produced noncompetitive inhibition of the NMDA responses that could be partially reversed by increasing glycine concentration. Thus, acutely dissociated adult spinal cord cells have similar receptors, defined pharmacologically, to those found on other CNS neurons.

EFFECTS OF pH AND PROTEIN MODIFYING AGENTS ON THE NMDA INDUCED CURRENTS IN ISOLATED CATFISH HORIZONTAL CELLS.

X.G. WU* AND B.N. CHRISTENSEN. Dept. of Physiology and Biophysics, Univ. Texas Med. Branch, Galveston, TX 77550.

Reactive groups of histidine and cysteine that constitute functional components of the n-methyl-d-aspartate (NMDA) receptor/channel protein were investigated using pH titration and specific protein modifying reagents. A titration curve that measured NMDA induced membrane currents under voltage clamp as a function of pH over the range of 5.5 to 9.5 gave a single pK near 6.5 suggesting that histidine imidazoles provide for one site of functional importance. The histidine modifying reagent diethylpyrocarbonate (DEPC 200 µM, pH 7.5) had two effects on the NMDA response. Initially, the NMDA response was potentiated following a 1-2 min exposure to DEPC. However, the NMDA response decreased to below control values following longer exposure to DEPC. Increasing the glyzine following longer exposure to DEPC. Increasing the glycine concentration had the effect of retarding the time neces-

sary to produce inhibition of the NMDA response with DEPC.

The functional role of cysteines was investigated with iodoacetic acid and dithiothreitol (DTT). Reduction of Reduction of logoacetic acid and dithiothreitol (DIT). Reduction of disulfide bonds with DTT potentiated the NMDA response whereas oxidation of sulfhydryls by iodoacetic acid resulted in a depression. These results suggest that reactive groups on these amino acids play an important functional role in the regulation of the NMDA receptor/channel protein. Supported by grant NEI-01897.

NMDA-MEDIATED INCREASE IN INTRACELLULAR CALCIUM IN HIPPOCAMPUS: EFFECT OF ETHANOL. <u>Laura C. Daniell</u>. Dept. of Pharmacol. & Toxicol., Medical College of GA., Augusta, GA. 30912-2300.

The effect of N-methyl-D-aspartate (NMDA) and L-glutamate on the intracellular free calcium concentration (Caj) and on calcium uptake was determined in microsacs and synaptosomes isolated from mouse brain. L-glutamate and NMDA increased Cai in hippocampal microsacs but had little or no effect on Cai in microsacs isolated from cortex or cerebellum or in synaptosomes. NMDA also increased calcium uptake into hippocampal microsacs. The EC50 values for NMDA-stimulated increases in Cai and calcium uptake in microsacs were about 30 μ M. Maximal responses were observed with 100 μ M NMDA. NMDA-stimulated increases in Ca₁ were dependent on extracellular calcium. increases in Ca₁ were dependent on extracellular calcium. The NMDA antagonists, 5-methyl-10,11-dihydro-5H-dibenzo[a,d]cyclohepten-5,10-imine (MK-801), 2-amino-5-phosphonopentanoic acid (AP-5), Mg, and Zn blocked NMDA responses. Ethanol inhibited NMDA responses in an uncompetitive manner with an IC50 of 51 mM. This is the first demonstration of NMDA-mediated effects on ion flux in a cell-free brain preparation. This preparation may be useful for study of the in vitro effects of drugs or toxins on brain NMDA receptors.

MEMBRANE RESPONSES OF CA1 PYRAMIDAL NEURONS TO L-HOMOCYSTEATE IN THE RAT HIPPOCAMPAL SLICE, L, Provini,*

S. Ito? Y. Ben-Ari and E. Cherubini. INSERM U29, 123 Bd Port-Ryal . 75014 Paris. France. In several brain areas. L-homocysteate (L-HC) is considered to be an endogenous transmitter which preferentially activates NMDA receptors. The aim of this study was to examine the membrane responses of CA1 pyramidal neurons to bath application of L-HC in the rat hippocampal slice, using intracellular recording and current and voltage clamp techniques. In normal ACSF. L-HC (100-200 µM) depolarized the membrane and induced a pronounced burst like firing pattern which resembled that produced by NMDA . In ACSF containing TTX (1 µM), L-HC (100-200 µM) induced at -65mV a depolarization (4-12 mV) which was associated with a small apparent decrease in membrane conductance (5%). These effects were rent decrease in membrane conductance [5%]. These effects were almost completely blocked [90%] by APV (50 µM, n=4). In voltage clamp experiments, at-80 mV L-HC (100-300 µM) induced an inward current, which was voltage dependent and became outward near 0 mV. These effects were similar to those obtained by NMDA. The inward current was reduced by APV (50 µM, to 48%) and fully blocked by APV and 6-cyano-7-nitroquinoxaline-2.3-dione (10 µM). In 4 cells the response to L-HC was studied at two different temperatures (33°C and 20°C). The L-HC-induced inward current was enhanced at 20°C (186 %, at -60mV, 3 out of 4) suggesting that uptake modulates L-HC mediated responses. In contrasts, the response to NMDA was unchanged or even decreased. It is concluded that L-HC acts in CA1 hippocampal neurons as a mixed excitatory amino acid agonist, with a clear preferential effect for NMDA receptors.

BETA-METHYLAMINO-ALANINE NEUROTOXICITY AS A MODEL OF ALS. BETA-METHYLAMINO-ALANINE NEUROTOXICITY AS A MODEL OF ALS. Z. Rakonczay*, Y. Matsuoka*, E. Giacobini and H. Konrad. Dept. of Pharmacology, Southern Illinois Univ. Sch. Med., Springfield, IL 62794 USA Recent studies have raised the possibility that the Guam-type of amyotrophic lateral sclerosis (ALS) may be related to food intake of unusual neurotoxic amino acids acting upon glutamate receptors. We have attempted to develop a rat model for ALS based on amino acid neurotoxicity. Two different methods of administration of beta-N-methylamino-Lalanine (L-BMAA), were used: single daily i.c.v. injections (500 μg) or continuous infusion via Alzet-minipumps (500 µg/day) for 16d, 30d, 40d and 60d. Both cholinergic and glutamatergic systems were investigated in the cerebral cortex. ³H-glutamate and ³H-glutamate binding in the presence of 2.5 µM quisqualate (N-methyl-D-aspartic acid, NMDA) and ³Hpresence of 2.5 µM quisqualate (N-methyl-D-aspartic acid, NMDA) and H-AMPA binding was significantly decreased at 16 days. Following this period, binding progressively increased and at day 60 of administration was either similar (NMDA and AMPA) or higher (glutamate) than controls. There were no differences between L-BMAA injected and vehicle injected sides of the brain. In vitro, L-BMAA was able to displace either AMPA or glutamate binding. H-nicotine binding was significantly decreased at day 40 and 60 of administration while H-ONB binding was unvaried. Acetyl-cholinesterase activity was significantly decreased at 16 days but reached control values at day 60 while choline acetyltransferase activity was unvaried. These biochemical results are consistent with an early damage to cortical neurons carrying glutamate or NMDA as well as nicotinic acetylcholine binding sites. Behaviorally, only single i.c.v. injections produced significant side effects (splay, rigidity and jerking). The symptoms were present during at least 10 days. Our results are consistent with an effect of L-BMAA on both glutamatergic and NMDA receptors in the rat cerebral cortex. (Supported by ALS grant GL-314.00)

THE VOLATILE ANESTHETIC, ENFLURANE, DISRUPTS GLUTAMATE-STIMULATED [SHIMK-801 BINDING IN RAT BRAIN. D.C. Martin and R.S. Aronstam. Departments of Anesthesiology and Pharmacology & Toxicology, Medical College of Georgia, Augusta, GA 30912.

Substantial evidence has targeted N-methyl-D-aspartate (NMDA) receptors as a site of anesthetic action. We investigated the influence of enflurane on [3H]MK-801 binding in rat brain membranes. Rat forebrains were homogenized, treated with Triton X-100 (0.4%) and washed in 5 mM Tris-HCl (pH 7.4). [³H]MK-801 binding was measured following

incubation at 37°C by vacuum filtration and liquid scintillation counting. Enflurane was a potent inhibitor of glutamate-stimulated [³H]MK-801 binding (IC₅₀ = 0.7 mM) but a much weaker inhibitor of glycine-stimulated [³H]MK-801 binding: Maximal inhibition of [³H]MK-801 binding stimulated by 100 uM glycine was 22% with 2.7 mM enflurane. However, in the presence of both glutamate and glycine, enflurane did not affect [3H]MK-801 binding. Moreover, the inhibition of glutamate-stimulated $[^3\mathrm{H}]\mathrm{MK}$ -801 binding by 2.3 mM enflurane was markedly attenuated by glycine in a concentration-related manner; inhibition of $[^3\mathrm{H}]\mathrm{MK}$ -801 binding by enflurane was 50% in the absence of glycine but only 14% in the binding by eliminate was 30% in the assence of grycine but only 14% in the presence of 100 uM glycine. Saturation analyses indicated that enflurance decreased the density of high affinity [3 H]MK-801 binding sites ($B_{\rm max} = 2356 \pm 237$ fmol/mg, control; 1329 ± 193 fmol/mg, enflurane) without affecting the KD (2.8 nM). The present results indicate that 1) enflurane disrupts NMDA receptor-

regulated ion channels by interfering with glutamate stimulation of $[^3H]MK$ -801 binding and 2) glycine reverses this action. (Supported by GM37948 and AA07698)

EFFECTS OF ADENOSINE ANALOGUES ON N-METHYL-D-ASPARTATE (NMDA)-INDUCED LETHALITY IN MICE. <u>D. Lutz, R. Dean and R.T. Bartus.</u>
CORTEX Pharmaceuticals, Inc., Irvine, CA 92718
It is known that glutamate acts as an excitatory amino acid (EAA) in the

It is known that glutamate acts as an excitatory amino acid (EAA) in the CNS. A large body of evidence has shown that excessive accumulation of glutamate results in excitotoxic neuronal cell death mediated by the NMDA-sensitive EAA receptor. This excitotoxicity has been implicated in such neurodegenerative diseases as Huntington's disease and stroke, and may also participate in multi-infarct dementia, Alzheimer's disease, and Parkinson's disease. The endogenous neuromodulator, adenosine, acts presynaptically to inhibit the release of glutamate and postsynaptically binhibition of evoked synaptic potentials. These inhibitory effects of adenosine are mediated through the A1 receptor, which is co-distributed with NMDA receptors, especially in the hippocampus.

receptors, especially in the hippocampus. Initial experiments demonstrated that a systemic injection of NMDA (200 mg/kg, ip) in mice causes severe convulsions, resulting in 85% mortality at 10 minutes post-NMDA administration. Pre-treatment (ip, 30 minute absorption) with various A1, A2, and mixed A1/A2 adenosine agonists delayed the NMDA-induced effects in many cases. Most of these analogues induced profound side effects such as sedation, hypothermia, vasodilation, etc., at pharmacologically active doses. To further elucidate the mechanisms of adenosine modulation of NMDA-induced lethality, both centrally and peripherally active adenosine antagonists were administered prior to analogue administration. These results with adenosine analogues will be compared with drugs which directly affect the NMDA-receptor system, in addition to general CNS acting compounds.

BETA-METHYLAMINO-ALANINE-INDUCED BEHAVIORAL CHANGES IN THE RAT. Y. Matsuoka*, Z. Rakonczay*, E. Giacobini and J. Couch. Dept. of Pharmacology, Southern Illinois Univ. Sch. Med., Springfield, IL 62794 USA

The naturally occurring amino acid, beta-N-methylamino-L-alanine (L-BMAA) is a neurotoxin possibly involved in the pathogenesis of amyotrophic lateral sclerosis (ALS) in Guam and Rota islands. We attempted to elucidate the characteristics of L-BMAA-induced behavioral changes in male rats (SD strain). A single injection of 500 µg/rat of L-BMAA into the lateral ventricle induced splay, repetitive jerking movements, and rigidity in succession lasting 10 min after the injection. A series of single daily injections induced these behavioral changes during a period of at least 3 days in responder rats. These symptoms were attenuated after 10 days. The effects of i.c.v. pretreatment with DNQX (20 or 10 µg), a non-NMDA receptor antagonist, AP-5 (50 or 10 μ g), a NMDA receptor antagonist, and MK-801 (100 or 5 μ g), a non-competitive NMDA antagonist were investigated in a crossing-over study. The duration of jerking movements induced by L-BMAA was reduced significantly by DNQX (20 μ g) but not by AP-5 and MK-801, while the latency of the jerking movements was significantly prolonged by these antagonists. The duration of the splay was not changed by the pretreatment with DNQX or AP-5 but tended to be more prolonged with MK-801. The rigidity induced by L-BMAA was completely inhibited by MK-801 (100 μg) and partly by DNQX (20 μg) (84%) and AP-5 (50 μg) (85%). These behavioral results together with the effects seen with in vitro binding displacement experiments, suggest that L-BMAA may act upon two or more kinds of glutamate type excitatory amino acid receptors. (Supported by ALS grant GL-314.00)

161.12

A NOVEL POTENT NMDA AGONIST: THE (2S,3R,4S) ISOMER OF α -(CARBOXYCYCLOPROPYL)GLYCINE. H. Shinozaki, M. Ishida and Y. Kudo**. The Tokyo Metro. Inst. of Med. Sci., Tokyo 113, and †Mitsubishi Kasei Inst. of Life Sci., Tokyo 194, Japan.

The (2S,3R,4S)isomer of α-(carboxycyclopropyl)glycine

(L-CCG-IV) caused a depolarization in the isolated rat spinal cord more markedly than L-glutamate or NMDA. The depolarization induced by L-CCG-IV was completely blocked by Mg ions, CPP, MK-801 or D-APV, and the effect of the antagonists was fully reversible upon washout, suggesting that L-CCG-IV was a novel potent NMDA type agonist. It is known that the activation of NMDA receptors induces the Ca influx into the nerve cells. L-CCG-IV was about 300 times more potent than NMDA in increasing the intracellular Ca concentration in a molar basis in the cultured rat hippocampal neuron loaded with fura-2. When L-CCG-IV was substituted by methoxymethyl group at the C-6 position, the (6R) isomer only showed similar pharmacological properties to kainate and caused a depolarization of C-fibers in the rat kannate and caused a depolarization of C-libers in the radorsal root. As a possible mechanism for explaining the conversion of L-CCG-IV derivatives into a kainate-type agonist, steric repulsion of active groups of CCG are conceivable. Thus, CCG isomers provide useful information about the interaction of excitatory amino acids and their receptor subtypes.

DESENSITIZATION AND SENSITIZATION TO SUBSTANCE P- AND EXCITATORY AMINO ACID-INDUCED BEHAVIORS IN THE MOUSE. X. Sun and A. A. Larson. Dept. of Vet. Biol., Univ. of Minn., St. Paul, MN 55108.

Sepated intrathecal injections of SP and the excitatory amino acid (EAA) agonist N-methyl-D-aspartic acid (NMDA) result in desensitiza-tion to the caudally directed biting and scratching response (CBS) elicited by SP and MNDA. Repeated injection of kainic acid (KA) and quisqualic acid (Quis) result in sensitization to CBS. The goals of the present study were [1] to characterize the role of interneurons in these effects and [2] to examino-ossible interactions between excitatory transmitters. The NMDA antagonist DL-2-amino-5-phosphono-valeric acid (APV) failed to alter either KA or Quis CBS during sensitization but inhibited all behaviors produced by SP and NMDA, suggesting an NMDA-mediated component in SP-induced behavior. Concanavalin A, which blocks desensitization to electrophysiologic effects of Quis, blocked sensitization to the behavioral effects of both Quis and KA, suggesting downregulation of EAA receptors during behavioral sensitization. Pretreatment with either bicuculline or 5-aminovaleric acid had no effect on KA- or Quis-induced sensitization, but inhibited the development of desensitization to SP and NMDA, suggesting that desensitization is mediated by GABA interneurons. SP and NMDA exhibited cross-desnsitization while KA and Quis exhibited cross-sensitization while KA and Quis exhibited cross-sensitization while KA and Quis also had no effect on subsequent KA-or Quis-induced CBS and pretreatment with NMDA had no effect on subsequent KA-or Quis-induced CBS and pretreatment with SP potentiated the CBS response to KA, and pretreatment with KA inhibited the response to a subsequent challenge with NMDA, and to a lesser extent SP. These data suggest a unique spectrum of modulatory actions for SP and EAAs. Supported by USPHS grants DA04090, DA 04190 and DA00124.

DIFFERENCES IN ANTINOCICEPTIVE ACTIVITY BETWEEN NMDA *AND NON-NMDA ANTAGONISTS IN MICE. J. Näsström, U. Karlsson, C. Post. ASTRA PAIN CONTROL AB, S-151 85 SÖDERTÄLJE, SVEDEN.

Previous behavioural studies have indicated that excitatory amino acid (EAA) antagonists may posses antinociceptive activity. The effects after intrathecal administration of different classes of EAA antagonists have, however, not been thoroughly investigated. We found that competitive and selective NMDA antagonists produced dose dependent and reversible effects in the hot plate and formalin tests, being slightly more potent in the formalin test and with no or negligible effects in the tail-flick test. Non-selective EAA antagonists or non-NMDA (kainate-quis/AMPA) receptor antagonists were equally effective in the hot plate, tail-flick and formalin tests. This heterogenous group of antagonists was slightly more potent in the tail-flick test and slightly less potent in the formalin test than in the hot plate test. The non-competitive NMDA antagonists PCP, MK-801 and ketamine were by themselves without effect in all three tests. Ketamine and PCP had, however synergistic effects with the non-NMDA antagonist DNOX. When given in high doses, all of the EAA antagonists impaired the motor function of the mice.

The present results show that EAA antagonists acting at both NMDA and non-NMDA receptors produce dose dependent and reversible antinociceptive effects. Antagonists that selectively block the NMDA receptor complex have a different profile in the nociceptive tests than the non-selective antagonists.

INHIBITION OF HIPPOCAMPAL PATHWAYS BY CYCLOPROPYL ANALOGS OF 2-AMINO-4-PHOSPHONOBUTANOIC ACID (AP4). N.L. Peterson. H.B. Kroona*. R.L. Johnson*. J.F. Koerner. Dept. of Biochem., Dept. of Medicinal Chem., and Neuroscience Grad. Program, Univ. of Minnesota, Minneapolis, MN 55455.

Program, Univ. of Minnesota, Minneapolis, MN 55455.

AP4-sensitive glutamate receptors in rat hippocampal slices were studied using two synthetic cyclopropyl analogs of AP4: (E)- and (Z)-1-amino-2-(dihydroxyphosphinylmethyl)cyclopropane-carboxylic acid. Extracellular electrophysiological techniques were used to evaluate the effect of these constrained analogs on synaptic transmission. Cumulative concentration-response curves were obtained and the IC50 of each analog was determined. In the lateral perforant path (LPP), both analogs were found to be equipotent having an IC50 of 15μM. In the medial perforant path (MPP), E-cyclopropyl AP4 was found to be more potent than Z-cyclopropyl AP4 was found to be more potent than Z-cyclopropyl AP4 witch is more potent in the LPP than the MPP (IC50=2.5μM vs 2500μM). In the CA1 pathway, E-cyclopropyl AP4 was found to be more potent than Z-cyclopropyl AP4 (IC50=450μM vs 2500μM). AP4 itself has an IC50=1800μM in CA1. The data suggest that glutamate assumes an extended conformation in the LPP AP4 receptor rather than a folded conformation. Furthermore, comparison of rank potencies suggests that the AP4 receptors in the MPP and CA1 pathway, where the E analog was found to be approximately 10 fold more potent than the Z analog, are distinct from the AP4 receptors in the LPP, where the E and Z analogs were found to be equipotent. Supported by NIH NS 17944.

EXCITATORY AMINO ACID ANTAGONISTS AS ANTI-EMETICS. M.T. Price and J. W. Olney. Washington University, St. Louis, MO 63110.

and J. W. Olney. Washington University, St. Louis, MO 63110.

The excitatory amino acid (EAA), glutamate (Glu), has emetic properties in various species, including humans. When present in elevated concentrations in the blood, Glu selectively penetrates a specific brain region (area postrema, AP) that lacks blood brain barriers and comtains neurons that mediate an emesis chemoreceptor trigger (ECT) function; it is believed that Glu induces emesis by excitatory interaction with receptors on the dendrosomal surfaces of AP/ECT neurons. Glu is a mixed EAA agonist that can activate either N-methyl-D-aspartate (NMDA) or non-NMDA subtypes of EAA receptor. Experiments in dogs and ferrets were undertaken to better characterize the emetic properties of various EAA agonists and to evaluate the possibility that EAA antagonists might have useful anti-emetic properties. In dogs, NMDA, kainic acid (KA, a non-NMDA agonist) and Glu induced vomiting in a dose-dependent manner; the NMDA antagonist, D-AP5, blocked emesis induced by NMDA but not by KA or Glu; the broad-spectrum EAA antagonist, vurrenic acid, blocked emesis induced by any of the three agonists. In ferrets we studied the ability of EAA antagonists to prevent malaise and emesis induced by cisplatin, a cancer chemotherapy agent. A high dose of cisplatin (10 mg/kg iy) caused repeated emesis in all controls (n = 5) which was totally prevented in experimental ferrets (n = 5) by IV infusion of a mixture of 10 mg/kg/hr CNQX (non-NMDA antagonist) and 5 mg/kg/hr D-AP5 (NMDA antagonist). Since CNQX and D-AP5 readily penetrate the AP/ECT zone but not more general brain regions, we propose that they prevent cisplatin-induced emesis by blockade of EAA receptors on AP/ECT neurons that perform a central switchboard function connecting incoming and outgoing limbs of an emesis reflex arc. Thus, EAA antagonists may prove useful in the control of any type of emesis induced without cNS side effects.

QUISQUALATE SENSITIZATION OF HIPPOCAMPAL NEURONS.

J.F. Koerner, E.R. Whittemore and R.L. Johnson*. Depts.
of Biochem. and Medicinal Chem. and Neuroscience Grad.
Program, Univ. of Minnesota, Minneapolis, MN 55455.
Sensitization of rat CAl hippocampal neurons to

Sensitization of rat CAI hippocampal neurons to excitatory agonists by quisqualic acid (QUIS-effect) is known to be reversed by L-homocysteinesulfinic acid, L-alpha-aminoadipic acid and L-serine-O-sulfate. We report that these compounds also act as "pre-blockers" which, when added and then removed from the medium, prevent subsequent sensitization by QUIS. This is consistent with a sequestration mechanism in which these compounds may either block QUIS uptake or antagonize its interaction with an intracellular binding site.

Quisqualic acid sensitizes neurons to a unique group

Quisqualic acid sensitizes neurons to a unique group of compounds, all of which have close homology to glutamic acid and which contain a phosphonate, phosphinate, or phosphate group. Although D- and L-2-amino-4-phosphonobutanoic acid (AP4) are equipotent, both the alpha amino and carboxylic acid residues are essential. This is demonstrated by the low activity of 4-phosphonobutanoic acid and 3-aminopropylphosphonic acid. The response to monoanionic 2-amino-4-methyl-phosphinobutanoic acid and a conformationally restricted cis-cyclopentyl-AP4 analogue are strongly potentiated, whereas other conformationally constrained cyclohexyl, cyclopentyl, and cyclopropyl AP4 derivatives are only minimally enhanced. Supported by NIH NS 17944.

THE EFFECT OF EXOGENOUS GLUTAMINE (GLN) ON BASAL AND NEWLY SYNTHESIZED (NEW) EXCITATORY AMINO ACIDS AND GABA IN MOUSE HIPPOCAMPUS IN YITRO. I.M. Kapetanovic, W.D. Yonekawa and H.J. Kupferberg*, Epilepsy Branch, NINDS, NIH, Bethesda, MD 20892.

GLN plays an important role in ammonia, energy, and amino acid (AA) neurotransmitter metabolism and compartmentation often referred to as the 'GABA-GIN-glutamate cycle', GLN is normally present in brain extracellular fluid and CSF in the range of 0.2 to 0.5 mM, but, is not included in artificial cerebrospinal fluid (ACSF) used for brain slices. This study examined levels of basal and NEW GLN, GABA, glutamate (GLU) and aspartate (ASP) and the effect of exogenous GLN in hippocampal slices under different experimental conditions. Isotopic enrichment, after incubation with 'DC_e-glucose, was used to measure NEW AA. Basal and NEW AA were quantitated by gas chromatography-mass spectrometry of the dimethyl t-butyl sliyl derivatives. Basal levels of AA in freshly cut slices were 75-89% of the intact hippocampus and decreased with time in ACSF. After 90 min, GLN levels were only ca. 10% of the intact hippocampus, while the other AA were ca. 65%. ACSF containing 0.5 mM GLN maintained basal levels of all AA much closer to those of in vivo hippocampus, and this concentration of GLN had no electrophysiological effects under control conditions. In the presence of increasing concentrations of a depolarizing agent, K*, GLN helped maintain basal AA levels and increased levels of NEW AA, especially GLN. In the presence of 15 mM K*, basal levels of all AA declined over the 30 min incubation period in ACSF without exogenous GLN, but not in ACSF with exogenous GLN. In addition, in ACSF containing GLN, the levels of NEW GLN were severalfold greater than in ACSF not containing GLN. The data suggest that GLN may function to maintain physiological levels of AA and its presence in ACSF may be important in neurochemical studies.

NMDA INDUCTION OF C-fos mRNA TN RAT PRATN: A QUANTITATIVE in situ HYBRIDIZATION STUDY. P.F. Morgan and M. Linnoila. Studies, NIAAA, Blg10 3C102, Laboratory of Clinical

Studies, NIAAA, Blg10 3C102, 9000 Rockville Pike, Bethesda, MD 20892, USA.

The excitatory amino acid N-methyl-D-aspartate (NMDA) binds to the NMDA sub-population of excitatory amino acid receptors and thereby increases the transmembrane flux of calcium ions. The proto-oncogene transcription factor, c-fos is expressed in response to increases in intracellular calcium. We therefore mapped and measured c-fos mRNA in response to NMDA administration in order to identify NMDA-activated brain structures.

Rats were injected with NMDA (0-375 mg/kg, i.p.). Thirty minutes later the animals were sacrificed and Thirty minutes later the animals were sacrificed and brains rapidly removed and cooled in isopentane at -300C. Brains were then sectioned (12 um) at -15°C, air dried, fixed in paraformaldehyde, then hybridized with a ³⁵S-c-fos murine oligornucleotide probe for c-fos mRNA. Specificity of the probe was assessed by conventional northern techniques. Hybridized message was visualized by exposure to X-omat photographic film. Acute NMDA by exposure to X-omat photographic film. Acute NMDA induced a highly discrete brain distribution of c-fos mRNA which was stereospecifically blocked by MK801 (10 mg/kg, i.p., 20 minutes prior to NMDA).

These results reveal that the dentate gyrus of the hippocampus and the piriform cortex are particularly activated by acute NMDA administration.

GABAA RECEPTORS II

162.1

Lack of involvement of protein kinases A and C in the GABA, receptor-gated Cl channel desensitization in mice spinal cord cultured neurons.

A.K. Mehta and M.K. Ticku. Department of Pharmacology, University of Texas Health Science Center, San Antonio, Texas 78284-7764.

GABA and muscimol produced desensitization GABA and muscimol produced desensitization of GABA, receptor-gated Cl channels, as measured by Cl-influx assay, in mice spinal cord cultured neurons. The desensitization phenomenon was time- and concentration-dependent, and reversible. Both active and inactive forms of forskolin decreased GABA-induced Cl-influx alone as well as when preincubated in conjunction with GABA. Furthermore, 8-bromo-adenosine, 8-bromo-adenosine, CAMP dibutyry CAMP and CAMP also adenosine cAMP, dibutyryl cAMP and cAMP also directly inhibited GABA-induced Cl-influx, without preincubation. However, the inhibitor of protein kinase A, H-8, did not reverse the or protein kinase A, H-8, did not reverse the effect of cAMP analogs on the inhibition of GABA-induced Cl-influx. Moreover, active phorbol ester failed to modify GABA-induced desensitization. These results suggest that cAMP analogs inhibit GABA-induced Cl-influx by acting via an extracellular site without the involvement of protein kinase A.

162.3

CAMP ANALOGS INHIBIT GABA-GATED CHLORIDE FLUX AND ACTIVATE PROTEIN KINASE A IN RAT BRAIN SYNAPTONEUROSOMES Patricia P. Edgar, Gunter Heuschneider, Jonathan A. Cohn, and Rochelle D. Schwartz Depts. of Pharmacology & Medicine, Duke University Med. Ctr, Durham, NC Recent studies of structure and function indicate that the GABA, receptor can be phosphorylated by a cAMP-dependent protein kinase (PKA; Kirkness et al., 1989) and that GABA, receptor-mediated ion flux is inhibited by cAMP analogues (Heuschneider and Schwartz, 1989). We have investigated the regulation of GABA_A receptor function by cAMP analogues in more detail. Cerebral cortical synaptoneurosomes were incubated with the permeant cAMP analogues, dibutyryl, 8-bromo, and 8-chlorophenylthio (CPT) CAMP, 10 min prior to the measurement of muscimol-induced ³⁶Ct uptake. Each analogue inhibited the maximal muscimol-induced ³⁶Ct uptake (CPT> dibutyryl> 8-bromo); the potency of muscimol was not altered. cAMP had no effect, suggesting that the permeant analogues act intracellularly to inhibit the muscimol response. The potency ($IC_{50} = 1$ mM) and maximal inhibition by CPT-cAMP were similar in cortex, hippocampus, striatum and cerebellum. The effect of CPT-cAMP on benzodiazepine potentiation of muscimol-induced ³⁶Cl uptake was also studied. In other studies PKA activity was measured in broken synaptoneurosomes incubated with cAMP analogues. In cortex, cAMP analogues activated PKA with the following order of potencies: (CPT = 8bromo>>dibutyryl). The potency and maximal effect of CPT-cAMP on PKA activity differed in the 4 brain regions. Studies to determine whether CPTcAMP stimulates protein phosphorylation in intact synaptoneurosomes are in progress. These results suggest that GABA_A receptor function can be modulated by cAMP under conditions which activate PKA, although a causal relationship remains to be established. Supported by NSF Predoctoral Fellowship (P.P.E.) and by NS24577 and PMA Foundation (R.D.S.)

MAINTENANCE OF GABAA RECEPTOR ACTIVATED CURRENT MAY NOT REQUIRE PHOSPHORYLATION IN ADULT RAT PRIMARY SENSORY NEURONS. F.F. Weight Alcohol Abuse and Alcoholism, Rockville, MD 20852.

Chen et al. (J. Physiol. 420:207, 1990) reported that within 10 minutes

of gaining access to the interior of isolated hippocampal neurons GABAA receptor activated current was reduced to less than 10% of the initial value when ATP was not added to the internal recording solution under conditions of whole-cell recording. In contrast, we report that when ATP was not added to the internal solution used for recording from freshly isolated dorsal root ganglion (DRG) neurons the amplitude of the GABAA-activated current remained stable. Responses to GABA were evoked within 1 min of rupture of the cell membrane and at 5 min intervals thereafter. At the 20 min time point, current was $94\pm6\%$ (n=6, $10~\mu M$ GABA) and $95\pm4\%$ (n=6, $100~\mu M$ GABA) of current evoked at the 1 min time point when ATP was not included in the internal solution the 1 min time point when ATP was not included in the internal solution (p>0.1, paired t-test). Similar values were obtained at time points of 40 minutes or more. With 4 mM ATP in the internal solution, current was 95±8% of the initial amplitude (p>0.1, n=5, paired t-test) after 20 min. However, in the presence of alkaline phosphatase (100 µg/ml) a decrement occurred over the initial 10 minutes of recording (70±4%) but not between 10 and 20 minutes (70±4% vs 67±3%) in 4 neurons sampled. These results suggest that in DRG neurons a component of GABAA-activated current is sensitive to dephosphorylation but that the current does not require ATP to be maintained. The difference between hippocampal and DRG neurons may lie in GABAA subunit composition or in intracellular regulators of channel function.

162.4

Direct Effects of Second Messenger System Modulators on the GABA Receptor Complex. N.J. Leidenheimer, L.D. Hahner*, M.D. Browning, R.A. Harris. Dept. Pharmacol., Univ. Colorado HSC and Denver VAMC, Denver, CO, 80262

Mouse brain microsacs were incubated with low millimolar concentrations of cAMP, 8BrcAMP or CPTCAMP for 10 min on ice prior to measurement of muscimol-stimulated 36Cl⁻¹ uptake (3 sec). These compounds inhibited muscimol-stimulated 36Cl⁻¹ uptake by 14%, 12% and 76%, respectively (p-0.05). Pretreatment with the protein kinase inhibitor H8 (30-300uM) failed to antagonize the CPTcAMP effect suggesting that CPTcAMP inhibition of 30Cl⁻¹ flux may be independent of phosphorylation. To further investigate this possibility, microsacs were osmotically lysed and resealed in the presence of EDTA (3mM) to inhibit phosphorylation. Inhibition of phosphorylation microsacs were osmotically lysed and resealed in the presence of EDTA (3mM) to inhibit phosphorylation. Inhibition of phosphorylation was confirmed using microsacs loaded with (3²P)-ATP, Under these conditions CPTCAMP inhibited muscimol-stimulated ³⁶Cl⁻ flux by 86%. In both EDTA-treated lysed/resealed microsacs and intact microsacs not treated with EDTA, low millimolar concentrations of cAMP, 8BrcAMP or CPTCAMP significantly (p-0.05) inhibited binding of the GABA A receptor ligand (³H) SR 95531 as did the protein kinase inhibitor H7. IBMX, and forskolin were found to inhibit binding of the Cl⁻ channel ligand [³⁵S] TBPS.

These results indicate that compounds commonly used to alter second messenger systems can affect the receptor sites and function of

second messenger systems can affect the receptor sites and function of the GABA A receptor complex by mechanism which do not involve protein phosphorylation.

POLYCLONAL ANTIBODYS THAT INHIBIT THE PHOSPHORYLATION

POLYCLONAL ANTIBODYS THAT INHIBIT THE PHOSPHORYLATION OF THE BOVINE GABA_A RECEPTOR. E.M. Dudek', S. Endo², M.D. Erowning¹, Olsen, R.W.² Dept. of Pharmacology, Univ. of Colorado Hith. Sci. Cntr., Denver, CO 80262; and ²Dept. of Pharmacology, UCLA Sch Med., Los Angeles, CA 90024

The GABA_receptor (GABA_R) is a member of the family of ligand-gated ion channels. Considerable attention has been focussed on the possibility that this class of receptors could be regulated by phosphorylation. We have recently shown that the β -subunit of the GABA_R could be phosphorylated by both the cAMP-dependent protein kinase (PKC) (Browning et al., PNAS 87:1315,1990). The two kinases appeared to phosphorylate distinct β -subunits based on the migration pattern in SDS-PAGE. We have prepared polyclonal antibodies against the consensus sequence for PKA substrates that is found in the cytoplasmic loop of the bovine GABA_R β -subunit. Antibodies were raised in rabbits and purified on an bovine GABA $_{\rm A}$ R β -subunit. Antibodies were raised in rabbits and purified on an affinity column made with the peptide. We have examined the ability of this antibody to influence the phosphorylation of the GABA $_{\rm A}$ R β in vitro. The antibody produces essentially complete inhibition of the phosphorylation of the bovine produces essentially complete inhibition of the phosphorylation of the bovine GABA_A-R by PKA. A concentration of antibody that produces >90% inhibition of the bovine GABA_A-R produces partial (<30%) inhibition of the phosphorylation by PKA of the rat GABA_A-R. We have also examined the ability of this antibody to inhibit the phosphorylation of the GABA_A-R by PKC. We found that the antibody was equally effective at inhibiting both PKA and PKC phosphorylation of the GABA_A-R. These data suggest that this antibody may be a useful tool for in situ studies of the physiological significance of GABA_A-R phosphorylation. Moreover, the fact that the antibody could inhibit both PKA and PKC phosphorylation of the receptor suggests the possibility that the substrates for PKC and PKA are within close proximity to the cytoplasmic loop domain used to make the antibody. Supported by PHS ergants NSGA77 and domain used to make the antibody. Supported by PHS grants NS26377 and DK40483 to MDB and by NS22071 to RWO.

[3H] FLUNITRAZEPAM PHOTOLABELS THE N-TERMINAL 30 KILODALTONS OF THE GABA-A RECEPTOR ALPHA SUBUNIT. Geoffrey Smith and Richard W. Olsen. Dept. of Pharmacology, UCLA School of Medicine, Los Angeles, CA 90024.

The α subunits of the GABA_A receptor are prominently labeled by benzodiazepine photoaffinity ligands. We have been attempting to identify the domain of this subunit which is involved in ligand binding by generating peptide maps of purified receptor photolabeled with the benzodiazepine ligand [3H]flunitrazepam ([3H]FLU). Receptor was purified from bovine cortex by benzodiazepine affinity chromatography, equilibrated with 10 nM [3H]FLU, then exposed to UV light at 365 nm, resulting in the covalent incorporation of [3H]FLU in a protein band of relative molecular weight (M_r) 52 kD, as determined by SDS-PAGE. After digestion of the labeled protein with Staph. aureus V8 protease, the resultlabeled protein with <u>Staph</u>, <u>aureus</u> W protease, the resulting peptides were separated by SDS-PAGE and transferred to PVDF membrane for N-terminal sequence analysis. This procedure produced four labeled fragments of $M_{\rm r}$ 30kD, 19kD, 13 kD, and 9kD. Sequence analysis of the 30kD fragment revealed a peptide beginning at Leug of the published bovine α_1 sequence, however, sequencer fractions up to residue 22 demonstrated no radioactivity. Thus, it can be shown that the site for photoaffinity modification by benzodiazepine agonists is within the N-terminal 30 kD of the α subunit sequence thereby extending up to the cytoplasmic end of the proposed first transmembrane spanning domain. The smaller fragments ought to allow more precise localization.

162.9

DEVELOPMENTAL DISTRIBUTION OF THE mRNAs ENCODING THE lpha1, lpha2, and lpha4 polypeptides of the rat gaba receptor.

M. Khrestchatisky, K.F. Greif, R. Weatherwax*, and A.J. Tobin, Dept. of Biology, UCLA, Los Angeles, CA 90024

GABA receptors result form the combination of several structurally distinct components including α, β, γ , and δ polypeptides. Some of these polypeptides are essential for the allosteric modulation of the GABA receptor by therapeutically important drugs, such as Benzodiazepines (BZ). BZ receptor subtypes, characterized pharmacologically, have distinct localizations and distinct ontogenetic patterns. Pritchett et al. (Science 245, 1989) have shown that different γ -polypeptides, when combined with β - and γ -polypeptides, largely determine the BZ binding properties of reconstituted receptors. The developmental distribution of GABA receptor mRNAs was studied using in situ hybridization histochemistry with 35-labeled rat $\alpha 1$, $\alpha 2$, and $\alpha 4$ antisense cRNAs. The developmental stages chosen were PO, P4, P7, P10 and P14. In the GABAergic regions examined, the $\alpha 2$ RNAs are present at birth or appear first, closely followed by the $\alpha 4$ -RNAs where they are coexpressed. The $\alpha 1$ RNAs appear later in development (P10), predominate in the cerebellum, and become the major $\alpha\textsc{-RNAs}$ along the neuroaxis after that stage, in agreement with the notion that the $\alpha 1$ polypeptides contribute to the BZ type I receptors. Supported by NS21908 and NS 22256 to AJT.

162.6

ANTISERA AGAINST SYNTHETIC PEPTIDES CORRESPONDING TO SPECIFIC DOMAINS WITHIN GABA, RECEPTOR SUBUNITS. M. E. Charlton, P. M. Sweetnam* and J. H. Neale, Dept. of Biology, Georgetown Univ., Wash. D.C. 20057 and *Nova Pharmaceutical Corp. Baltimore MD 21224.

A series of synthetic peptides have been produced which correspond to specific domains subunits of the GABA within subunits of the GABA, receptor, as deduced from the analysis of bovine and rodent nucleotide sequences. Antisera were prepared immunization of rabbits with peptides as well as peptide-carrier conjugates. antisera were characterized for These their reactivity with the synthetic peptides, brain membranes, brain membrane protein resolved by SDS-PAGE, affinity purified receptor and with brain tissue fixed for immunohistochemistry. Additionally, the ability of antisera and affinity purified antibodies to affinity purified antibodies to immunoprecipitate the receptor complex or individual subunit proteins was determined. Initial results suggest that this approach will provide immunological reagents which are useful in the analysis of GABA, receptor structure and diversity.

SUBUNIT SUBTYPE-SPECIFIC ANTIBODIES REVEAL BRAIN REGIONAL HETEROGENEITY OF GABAA/BENZODIAZEPINE RECEPTORS. <u>Shuichi</u>
<u>Endo and Richard W. Olsen.</u> Dept. of Pharmacology, UCLA
School of Medicine, Los Angeles, CA 90024.

Alpha subunit-subtype specific antibodies were obtained to small synthetic peptides with amino acid sequences specific for bovine αl , $\alpha 2$, $\alpha 3$, and rat $\alpha 4$ subunits of the GABA A/benzodiazepine receptor (GABA-R) deduced from cDNAs. Two GABA-R & subunit-specific antibodies were also obtained:one to a putative extracellular sequence(Sex), the second to a cytoplasmic sequence(&cyt) which encompasses the consensus phosphorylation site for the cyclic AMP-dependent kinase on the bovine &1 subunit.Both the &ex and &cyt antigen peptide sequences have homology among &1,&2, and &3 subtypes. GABA-Rs purified from bovine cortex, hippocampus, and cerebellum were electrophoresed, transferred to nitrocellulose, and probed with these six antibodies (Western blot). In cortex, $\alpha 1$ (53 kDa), $\alpha 2$ (55 kDa), $\alpha 3$ (60kDa), and $\alpha 4$ (61kDa) were detected with α subunit subtype-specific anti-bodies, four bands (61, 59, 57, and 55kDa) were detected with both anti-ßex and ßcyt antibodies. In hippocampus, $\alpha 1$, $\alpha 2$, and $\alpha 4$, and three ß bands (61, 59, and 55kD) were detected (but no $\alpha 3$ or ß57). In cerebellum, only $\alpha 1$ and one major ß band (59 kD) were detected. In these three brain regions, the number of α subunit subtypes detected corresponds to the number of ß bands detected. It is possible that each respective α subunit subytpe is associated with a particular ß subunit subtype of GABA-R. Supported by NIH grant NS22071

162.10

SINGLE CHANNEL PROPERTIES OF HETEROOLIGOMERIC RAT GABAA RECEPTORS EXPRESSED USING DIFFERENT ALPHA SUBUNIT VARIANTS.

T.A. Verdoom, R. S. Kass*, P.H. Seeburg*, and B. Sakmann*. Max-Planck-Institut für med. Forschung and ZMBH Heidelberg, West Germany.

We examined the extent of functional heterogeneity produced in GABA receptors constructed from different combinations of subunits. Receptors were expressed in transiently transfected mammalian fibroblasts and functional properties studied using patch clamp techniques in the whole cell and outside-out configurations. The amplitudes of single channels opened by GABA depended on the presence or absence of the $\gamma 2$ subunit. Exchanging $\alpha 3$ for the $\alpha 1$ subunit did not alter the effect that $\gamma 2$ had on conductance. For example, receptors comprised of the $\alpha 1\gamma 2$ and $\alpha 1\beta 2\gamma 2$ subunit combinations had main states with single channel conductances of 30.8 ± 1.0 pS (n = 7) and 31.5 ± 0.8 pS (n = 5) respectively. GABA receptors constructed from $\alpha 1\beta 2$, subunits showed a markedly smaller conductance (11.3 ± 0.23 pS, n = 6). The pattern of variation in channel conductance was preserved when the $\alpha 1$ subunit was replaced with $\alpha 3$. Thus, $\alpha 3\beta 2$ GABA receptors had a small main conductance state of $13.0 \pm$ 0.4 pS (n = 3), whereas the $\gamma 2$ containing combinations gave larger conductances. GABA receptors comprised of $\alpha 3 \gamma 2$ subunits showed a conductance of 26.7 \pm 0.4 (n = 3) and the conductance of $\alpha 3\beta 2\gamma 2$ GABA receptor channels in two patches was 25.4 and 29.7 pS. Larger conductance channels were also observed in two patches from cells expressing the $\alpha 2\beta 2\gamma 2$ subunit combination (24.0 and 29.5 pS). Noise analysis of whole cell currents indicated that the kinetics of the $\alpha 2\beta 2\gamma 2$ GABA receptor channels were similar albeit slightly slower than that of $\alpha 1\beta 2\gamma 2$ GABA receptors. Two cells transfected with $\alpha 2\beta 2\gamma 2$ subunits gave two component power density spectra (slow: 79.5 and 48.4 mS; fast: 4.08 and 2.59 mS). Two kinetic components are also observed in cells expressing the $\alpha 1\beta 2\gamma 2$ combination (35.7 ± 4.8 and 2.10 ± 0.21 mS, n = 4). These data suggest that the functional heterogeneity contributed by the $\alpha 1, \alpha 2$ or $\alpha 3$ subunits at the single channel level is limited. Further work is necessary to determine if other functional features such as desensitization or allosteric modulation by drugs are affected by exchanging α subunit variants. T.A.V. was supported by the Alexander vonHumboldt Foundation.

KINETIC PROPERTIES OF CLONED $\alpha_1\beta_1$ GABA_A RECEPTOR CHANNELS: REGULATION BY PENTOBARBITAL AND PICROTOXIN. N.M. Porter+, T.P. Angelotti+*, R.E. Twyman+, and R.L. Macdonald+#. Depts. of Neurology+, Physiology#, and Pharmacology*, Univ. of Michigan, Ann Arbor, MI 48104

Chinese hamster ovary cells stably transfected with plasmids containing bovine α_1 and β_1 subunit to DNAs (Moss $et\,al.,$ Euro. J. Pharm., in press) were used to record GABA $_{\rm A}$ receptor currents from excised outside-out patches. GABA evoked single channel currents that opened predominantly to a 19 pS conductance state in contrast to the native spinal cord neuronal GABA $_{\rm A}$ receptor which opens primarily to a 27 pS main conductance state and much less frequently to 19 and 11 pS sub-conductance states. Opening frequency increased by 50% as GABA concentration was increased from 5 to 25 μM . However, mean open time, burst duration, and openings per burst did not change. Open time and burst duration frequency histograms were best fit with 2 exponential functions that did not vary with GABA concentration. In spinal cord neurons, mean open and burst properties increased with GABA concentration and 3 or 4 exponential functions were required to fit the frequency histograms (Macdonald et al., J. Physiol. (Lond.) 410:479,1989). The $\alpha_1\beta_1$ GABA-evoked current was enhanced by pentobarbital by increasing mean channel open time and current was reduced by picrotoxin by decreasing opening frequency. Diazepam did not enhance GABA receptor current.

These studies suggest that the $\alpha_1\beta_1$ GABA $_A$ receptor contains domains that form functional channels with conductance and gating properties that differ from those recorded from mouse spinal cord neurons. In addition, sites are present on the $\alpha_1\beta_1$ GABA $_A$ receptor for allosteric regulation by barbiturates and picrotoxin-like drugs.

SINGLE CHANNEL KINETIC PROPERTIES OF THE GLYCINE RECEPTOR MAIN- AND SUB-CONDUCTANCE STATES OF MOUSE SPINAL NEURONS IN CULTURE. R.E. Twyman+ and R.L. Macdonald+#. Depts. of Neurology+ and Physiology#, Univ. of Michigan, Ann Arbor, MI. Single channel kinetic properties of the 42 pS main- and the 27 pS sub-

Single channel kinetic properties of the 42 pS main- and the 27 pS subconductance states of the strychnine-sensitive glycine receptor were investigated using outside-out patches in symmetrical chloride recording media. At low concentrations (0.5, 1 and 2 μ M), glycine evoked a concentration-dependent increase in average current, opening frequency, mean open duration and mean burst duration of each conductance state.

Analysis of open and closed durations show that at least three open and four closed states existed for each conductance state. Although opening and closing rates differed for each conductance state, open time constants for each conductance state did not vary with glycine concentration. Open state properties suggested that a singly liganded open state existed for both conductance states and that the resultant increased current and mean open time with glycine concentration was due to an increased probability of opening to longer, more stable, fully liganded open states. Similar results were found for bursts.

The data suggested that since the two conductance states have similar general gating characteristics, those protein domains conferring these properties of the receptor were similar. However, both conductance states differed in opening and closing rates and suggested that the receptor domains regulating entry into and exit from each conductance state were different. Although not known, these functional differences may be due different subunit composition. Kinetic schemes for the conductance states will be presented.

162.15

WHOLE-CELL RECORDINGS OF PRE-NATAL RAT HIPPOCAMPAL NEURONS IN CULTURE REVEAL EMBRYONIC GABA_A RECEPTOR FUNCTIONS. A.Y. Valeyev* and J.L. Barker. Lab. of Neurophysiology. NINDS. NIH. Bethesda. MD 20892

Lab. of Neurophysiology, NINDS, NIH, Bethesda, MD 20892. Cells were cultured from embryonic (E) day 17-19 rat hippocampal tissue for one or more days in serum-supplemented growth medium. Intracellular recordings in the whole-cell configuration were made at room temperature using Na+0-free and K+1-free electrolytes. GABAA receptor agonists and antagonists were either applied by pressure pulses from closely positioned pipettes or by gradual diffusion in the extracellular medium. Most of the cells recorded under these conditions responded to one or another ligand. When the equilibrium potential for Cl⁻ was set near 0 mV current responses to GABA or muscimol reversed polarity near 0 mV, suggesting a dominant role for Cl⁻ ions in the conductance response. Dose-response studies of membrane responses to brief pulses of agonist showed that micromolar concentrations of GABA were required for evoking consistently detectable responses. Many cells also responded to the general anesthetics (-)pentobarbital and alphaxalone. Micromolar concentrations of these drugs, like the transmitter GABA, elicited membrane current responses that reversed near 0 mV. Sequental exposure of individual cells to both anesthetics revealed cells sensitive to one but not the other agent as well as sells responding to both. These results indicate that GABAA receptor function emerges pre-natally in rat hippocampal neurons and that barbiturate and steroid binding occurs at different sites on the receptor/channel complex.

162.1

SINGLE CHANNEL KINETIC PROPERTIES OF CLONED $\alpha_1\beta_1\gamma_2$ AND $\alpha_3\beta_1\gamma_2$ GABA_A RECEPTOR CHANNELS: COMPARISON TO THE NATIVE SPINAL CORD GABA_A RECEPTOR. T. Ryan-Jastrow+, T.P. Angeloti+@, R.E. Twyman+ and R.L. Macdonald+#. Depts. of Neurology+, Physiology# and Pharmacology@, Univ. of Michigan, Ann Arbor, MI 48104.

COS and HEK 293 cells transiently transfected with plasmids (SV40 promotor; obtained from E. Barnard) containing GABA $_{A}$ receptor bovine α_{1} and β_{1} and human γ_{2} or bovine α_{3} and β_{1} and human γ_{2} or bovine α_{3} and β_{1} and human γ_{2} subunit cDNAs were used to record GABA-evoked single channel currents from excised outside-out patches. Low concentrations of GABA evoked single channel currents to multiple conductance states that were similar to currents recorded from the native spinal cord GABA $_{A}$ receptor. The dominant or main-conductance state was about 27 pS and was the same as the main-conductance state found in the native receptor. Open, closed and burst durations were analyzed using single channel analysis techniques.

durations were analyzed using single channel analysis techniques. The results suggest that the $\alpha_1\beta_1\gamma_2$ and $\alpha_3\beta_1\gamma_2$ GABA receptors contain domains that form functional channels with conductance and gating properties that were similar to the native mouse spinal cord receptor. However, the open state properties of the $\alpha_1\beta_1\gamma_2$ and $\alpha_3\beta_1\gamma_2$ receptors differed, suggesting that the open state regulatory mechanisms were different. The open state properties of the $\alpha_1\beta_1\gamma_2$ were the most similar to the native GABA_A receptor. Microscopic kinetic reactions schemes consistent with the single channel properties of $\alpha_1\beta_1\gamma_2$ and $\alpha_3\beta_1\gamma_2$ receptors are presented and compared to the native GABA_A receptor.

Inhibitory effects of pregnenolone sulfate on cloned GABAA receptor subunits expressed in Xenopus oocytes. R. Shingai, M. Sutherland, S.Zaman, R. Harvey M. Darlison and E. A. Barnard, Mol. Neurobiol. Unit, Med.Res. Council Cambridge, England

An endogenous steroid pregnenolone sulfate (PS) has an inhibitory effect on GABA_A receptors. Messenger RNAs were made by in vitro transcription from cloned bovine GABA_A receptor subunits $(\alpha 1, \alpha 2, \alpha 3$ and $\beta 1)$ and the human GABA_A receptor subunit $\gamma 2$. Combinations of one of the α subunits with β (two subunits) or combinations of one of the α subunits with β (two subunits) or combinations of one of the α swith the β and γ (three subunits) were injected in Renopus oocytes for expression of receptor complexes. GABA at 0.2-10 μ M, which corresponds to 40-50% of the maximum dose-response, was applied simultaneously with PS to oocytes. In all combinations PS showed an inhibitory effect in the concentration range above 10^{-7} M. The degree of depression by the steroid was in the order of, from a strong to a weak effect, $\alpha 2+\beta+\gamma$ (ED50=4x10⁻⁷), $\alpha 1+\beta$, $\alpha 1+\beta+\gamma$, $\alpha 2+\beta$. $\alpha 3+\beta+\gamma$ (ED50=5x10⁻⁶). Thus addition of the $\gamma 2$ subunit changed the sensitivity to the steroid in different directions depending on the subunit combinations. In about 2.5% of total oocytes expressing combinations with $\alpha 2$ or $\alpha 3$, a small augmentation (110-150%) of the response was observed when PS at 10^{-9} . 10^{-8} M was co-applied with GABA. Pre-application of PS for a longer period and at higher concentration enhanced the inhibitory effect in all combinations of subunits, suggesting that the steroid may have both a direct and indirect effect on GABA receptors; the latter is in the manner such that the PS trapped in the lipid membrane interacts laterally with the receptors. PS alone at above 10^{-6} M produced an outward current in α_1 + β (i=1,2,3) combinations.

ENFLURANE AND HALOTHANE ENHANCE GABA-ACTIVATED CHLORIDE CURRENTS IN CULTURED RAT HIPPOCAMPAL NEURONS. P.A. Brooks 1.M.V. Jones. J.L. Barker 2 and N.L. Harrison. Dept. Anes. and Critical Care, Univ. of Chicago, Chicago, II. 60637; 1 Dept. of Physiology, The Royal Free Hospital Sch. of Med., London, U.K.; 2 Lab. Neurophysiol., NINDS, NIH, Bethesda, MD 20892; SPON: Brain Research Association

We have studied the effects of the inhalant anesthetics enflurane (ENF) and halothane (HAL) on GABA_r-receptor mediated chloride currents in cultured rat hippocampal neurons. Recordings were made at $25^{\circ}\mathrm{C}$ using the whole-cell voltage-clamp technique with an intracellular solution based on K gluconate, and externally perfused with HEPES-buffered saline. Neurons were voltage-clamped at -40mV. GABA was applied in close proximity to the soma by 10-100ms pressure applications from micropipettes containing 25 or $50\mu\mathrm{M}$ GABA. A pulse of GABA elicited transient outward currents $(\mathrm{G}_{\mathrm{GABA}})$, that were blocked by bicuculline and potentiated by diazepam, and had reversal potentials $(\mathrm{E}_{\mathrm{GABA}})$ between -65 and -80mV. Anesthetics were applied either from a vaporizer or via the perfusion medium, and their concentrations were measured using gas chromatography of samples withdrawn from the bath during the experiment. In 19 of 20 experiments in which ENF was present at 0.4 - 1.5mM,

In 19 of 20 experiments in which ENF was present at 0.4 - 1.5mM, application of ENF increased the peak amplitude of I_{GABA} with no change in E_{GABA} . The enhancement of I_{GABA} increased with [ENF] and was fully reversible; up to three-fold enhancements were observed at higher concentrations. Similar increases of I_{GABA} were produced by HAL (0.09 - 0.7mM), In addition, both ENF and HAL alone produced small and reversible increases in membrane conductance. We conclude that clinically relevant concentrations of ENF and HAL modulate the GABA_A-receptors on cultured rat hippocampal neurons to produce a marked increase in GABA-activated chloride conductance.

ZINC AND CADMIUM INHIBIT GABA SENSITIVITY WITH DIFFERENT EFFICACIES. J. J. Celentano*, M. Gyenes*, T. T. Gibbs, D.H. Farb. Dept. of Anatomy and Cell Biology, SUNY Health Science Center at Brooklyn, Brooklyn, NY 11203.

It has recently been shown that the GABA receptor chloride ionophore complex is sensitive to modulation by a variety of divalent cations. We have studied the effects of two such ions, zinc and cadmium, on GABA sensitivity in cultured chick spinal cord neurons. We find that both cations inhibit GABA sensitivity in a saturable manner but neither cation achieves 100% inhibition at saturating concentrations. The maximum inhibition induced by Zn (90%) is greater than that induced by Cd (72%). High concentrations of both cations (3 mM Zn, 5 mM Cd) applied in combination result in an intermediate level of inhibition. This is consistent with a common divalent cation modulatory site at which Zn has a higher intrinsic efficacy than Cd. Inhibition induced by lower concentrations of both Cd and Zn was partially reversed by 5 mM barium which had no significant effect by itself.

The residual GABA response in the presence of high Zn or Cd was pharmacologically similar to the full GABA response. Further inhibition was acheived with bicuculline, SR 95531, picrotoxin, and pregnanolone sulfate. In addition the residual GABA response was subject to stimulation by a benzodiazepine, a barbiturate, and a steroid. These positive modulators did not significantly after the cation dose response curves. The divalent cation site is therefore distinct from the sites used by other known GABA modulators.
