The effects of delta-9-tetrahydrocannabinol (THC), the major psychoactive component of marijuana, on the rapid increases in luteinizing hormone (LH) and prolactin (PRL) levels and hypothalamic norepinephrine (NE) turnover in adult male rats exposed to sexually receptive female conspecifics were investigated. Adult male Sprague-Dawley rats were given p.o. either sesame oil vehicle (controls) or THC (5.0 mg/kg b.w.) and 40 min post-treatment were either placed in an empty cage or a cage containing a sexually receptive female. Males were sacrificed 20 min after exposure (60 min after vehicle or THC treatment) for blood and tissue collection. Some rats received α-methylparatyrosine 30 min prior to sacrifice for NE turnover determinations. In rats given sesame oil vehicle and exposed to a receptive female, there was a significant increase in LH (non-exposed, 0.373 ± 0.055 ng/ml vs exposed, 0.623 ± 0.082 ng/ml; $p < 0.05$) and PRL levels (non-exposed, 9.4 ± 1.5 ng/ml vs exposed, 61.4 ± 14.5 ng/ml; $p< 0.01$) and in median eminence NE turnover rates. In THC-treated rats, basal LH levels (0.199 ± 0.032 ng/ml) and NE turnover were significantly reduced when compared to controls ($p < 0.05$). Moreover, rats treated with THC and exposed to female conspecifics failed to show the rapid increase in LH and PRL levels or in NE turnover rates. In conclusion, these findings indicate that THC inhibits the increase in LH and PRL normally measured in male rats exposed to sexually receptive females and further suggest that THC mediates these actions by altering hypothalamic catecholaminergic activity. NALOXONE REVERSES BUT DOES NOT PREVENT DELTA-9-TETRAHYDROCANNABINOL-INDUCED INHIBITION OF PULSATILE LH SECRETION IN OVARIECTOMIZED RATS. P. Keller*, M. Kohli* and L.L. Murphy. Department of Physiology, Southern Illinois University, School of Medicine, Carbondale IL 62901.

Although the ability of delta-9-tetrahydrocannabinol (THC), the chief constituent of marijuana, to suppress LH secretion in laboratory animals has been clearly documented, the mechanism of this THC action has yet to be elucidated. In the present study, the ability of naloxone (NAL), an opiate receptor blocker, to prevent or reverse the effects of THC on pulsatile LH secretion was examined in ovariectomized Sprague-Dawley rats. Approximately 4 weeks post-ovariectomy, blood samples were drawn, via indwelling intra-atrial cannulae, every 10 min for 60 min pre- and 120 min post-vehicle (control) or THC (0.5 mg/kg b.w., iv) treatment at time 0 for LH determinations. Rats were administered NAL (2 mg/kg b.w., iv) or saline at 20 min pre-THC or vehicle treatment, at time 0, and /or at 20 min post-treatment. The results indicated that THC treatment alone significantly reduced plasma LH levels by 20 min post-treatment to 50-75% of control values ($p<0.05$) through 90 min. Pre-treatment with NAL did not prevent THC-induced suppression of LH release. However, NAL administration at 20 min post-THC treatment reversed the inhibitory effect of THC on LH levels 40-90 min post-THC. Moreover, when NAL was administered prior to THC, concomitant with THC administration, and 20 min post-THC treatment, both the magnitude of LH suppression by THC and the duration of suppression were significantly attenuated. These data suggest that endogenous opiate peptides play a role in the ability of THC to inhibit pulsatile LH secretion, however, the possibility that other CNS mechanisms (ie, norepinephrine) are involved is strongly implicated. (Supported by DA 05042)

EFFECTS OF Δ^9-TETRAHYDROCANNABINOL ON REGIONAL CEREBRAL BLOOD FLOW IN THE RAT. A.S.Bloom, S.A. Fuller*, E.A.Stein. Departments of Pharmacology and Psychiatry, Medical College of Wisconsin, Milwaukee, WI 53226.

Δ^9-Tetrahydrocannabinol (THC), the principal psychoactive ingredient in the marijuana plant, produces a wide range of behavioral and physiological effects. Cannabinoid binding sites have been found to be widely but heterogenously distributed throughout the brain. In order to better determine functional sites of action for the cannabinoids, we have now examined the effects of THC on regional cerebral blood flow (rCBF) in the rat. Conscious rats were injected IV with either 4 or 16 mg/kg of THC or its Emulphor-ethanol vehicle 30 min prior to sacrifice. [^{14}C]Iodoantipyrene was used to determine rCBF according to the method of Sakurada et al. Blood flow was altered in 49/53 regions measured. Two patterns of change were observed. A significant dose related decrease in rCBF was seen in the hippocampus (up to 30%) and its major input and output areas such as the lateral septum, entorhinal cortex and the dentate. In contrast, a dose-related biphasic increase (4 mg/kg>16 mg/kg) in rCBF was seen in such areas as the anterior, lateral and ventromedial hypothalamus and other limbic structures involved in autonomic regulation. Other areas such as the medial septum and claustrum were unaffected. It is significant that the areas where rCBF is altered are involved in the major behavioral and physiological effects of THC such as impairment of short-term memory and increased autonomic activity. The results of this study indicate that alterations in rCBF may be a sensitive technique for the localization of cannabinoid sites of action within the brain. TIMEOUT FROM AVOIDANCE: A NOVEL TEST OF DRUG EFFECTS ON NEGATIVELY-REINFORCED BEHAVIOR. M. Galizio, E. Gregg*, L. Kelly*, R. L. Shriner*, and R. D. Shytle*. Dept. of Psychology, UNC-Wilmington, Wilmington, NC 28403.

Theoretical analysis of the neuropharmacological basis of negative reinforcement has been hampered by difficulties in generating baseline performances comparable to those used with positive reinforcement. The timeout from avoidance procedure permits the study of negatively-reinforced behavior in rats under schedules ordinarily used only with positive reinforcement. Rats were trained on concurrent schedules where responses on one lever postponed shock (avoidance) and responses on another lever produced signaled periods of timeout from avoidance during which the avoidance schedule was suspended. Timeout was programmed on a variable-interval 45-s or a variable-ratio 15 schedule, and generated patterns of behavior similar to those produced by comparable schedules of positive reinforcement. Morphine depressed responding on the timeout lever at doses that increased or did not affect avoidance. Amphetamine selectively increased responding on the timeout lever, but chlorpromazine and buspirone non-selectively decreased responding on both levers. The finding that the effects of some drugs (morphine and amphetamine) depended on the type of negative reinforcer maintaining behavior has implications for theories regarding the neurochemical substrates of negative reinforcement.

CHANGING ENVIRONMENTAL CUES UNIQUELY ASSOCIATED WITH DRUG DELIVERY REDUCES TOLERANCE TO NICOTINE-INDUCED ANOREXIA AND CORTICOSTERONE RELEASE. A.R. Caggiula, L.H. Epstein*, S.M. Antelman* S.Saylor* and K.A.Perkins*. Depts. of Psychology and Psychiatry, Univ. of Pittsburgh, Pittsburgh, PA 15260

We have previously shown that changing environmental cues associated with drug delivery disrupts tolerance to the analgesic and anorectic effects of nicotine in rats. Here we asked whether the effectiveness of nicotine in activating the hypothalamic-pituitary-adrenocortical system, as measured by blood corticosterone levels, can also be brought under environmental control. Secondly, we were interested in further characterizing the nature of this environmental control. Male rats developed tolerance to the anorectic and corticosterone elevating effects of daily injections of 0.33 mg/kg of nicotine bitartrate. When cues uniquely associated with drug delivery were then changed, both behavioral and corticosterone tolerance were disrupted. When there were no unique cues associated with drug delivery per se, changing the environment had no effect on tolerance to either of nicotine's actions. Thus conditioning principles apply to tolerance of the neuroendocrine, as well as behavioral effects of nicotine.

SYSTEMIC NICOTINE INDUCES NEURONAL FOS IMMUNOSTAINING IN DISCRETE BRAIN REGIONS. S.M Sagar. Dept. of Neurology, Univ. of California, and VA Medical Center, San Francisco, CA 94143.

Nicotine, 2 mg/kg s.c, was administered to Long Evans rats, which were sacrificed 1 hr later and processed for Fos immunocytochemistry using a polyclonal antibody that recognizes authentic Fos and Fos-related antigens. Brain regions with high levels of Fos immunostaining following nicotine administration include: the hypothalamic paraventricular and supraoptic nu. (magnocellular neurons), medial habenula, superior colliculus, interpeduncular nu., nu. solitarius, locus coeruleus, and scattered cells in the granule cell layer of the cerebellum. Other regions, including the thalamus, that have high levels of nicotine binding, fail to display Fos immunostaining. These observations demonstrate that (1) nicotine is capable of stimulating Fos synthesis in vivo, although the mechanism is not necessarily direct; (2) some, but not all, neurons with nicotinic receptors synthesize Fos in response to nicotine; and (3) Fos immunocytochemistry may be a useful tool to investigate the effects of nicotine on the central nervous system.

PHENCYCLIDINE-INDUCED ALTERATIONS OF EXTRAPYRAMIDAL AND LIMBIC NEUROPEPTIDE Y SYSTEMS. L.P. Midgley, L.G. Bush, J.W. Gibb and G.R. Hanson. Dept of Pharmacology and Toxicology, University of Utah, Salt Lake City, UT 84112

Phencyclidine-HCl (PCP) causes many effects including behavioral changes which resemble the negative and positive symptoms of schizophrenia. PCP is known to interact with a number of transmitter systems and has recently been identified as an NMDA antagonist. We previously reported that administration of PCP significantly reduces striatal neuropeptide Y (NPY) levels in rats: some of these NPY changes also occurred after treatment with the non-competitive NMDA antagonist, MK-801. In the present study, we observed that PCP administration also caused significant declines in NPY levels in the nucleus accumbens and frontal cortex, but not in the substantia nigra. In order to elucidate the nature of these responses, selective D-1 (SCH 23390), D-2 (sulpiride), sigma (rimcazole), 5-HT-3 (ICS205-930) antagonists and a drug which depletes serotonin (PCA) were administered alone and in combination with PCP. Only SCH 23390 attenuated the PCP-induced change in NPY levels in all sructures examined. These results suggest that D-1, but not D-2, 5HT or sigma receptors play a role in PCP-induced changes of extrapyramidal and limbic NPY systems. (Supported by grants DA 00869 and DA 04222).

DETECTION OF BEHAVIORALLY ACTIVE DOSES OF PHENCYCLIDINE IN RAT BRAIN AND CSF BY HPLC-EC. C.J. Drebing, G.A. Gerhardt, W.F. Phillips*, S. Brock*, and R. Freedman. VA Medical Center, Denver, CO 80220; Dept. of Psychiatry, Univ. of Colorado Health Sciences Center, Denver, CO 80262.

Phencyclidine (PCP) is a drug of abuse that has many behavioral effects. Members of our group have previously shown PCP to increase dopaminergic neurotransmission in the prefrontal cortex of rats (Gratton et al., 1987), but little is known of the behaviorally relevant concentrations of the drug.

We injected male Sprague-Dawley rats, anesthestized with chloral hydrate, with PCP concentrations of 1-5 mg/kg. At one hour the CSF was collected and the brain removed. PCP was analyzed in the samples after a simple acid, then basic buffer-hexane extraction for brain and a basic buffer-hexane extraction for CSF. Dried reconstituted samples were injected into an HPLC-EC with pH 5.5 acetate acetonitrile mobile phase on a cyano 3μ column. Detection was at +.80v on an ESA 5100A Coulochem with a 5010 detector. Each sample required 10 min. elution time.

CSF and cortex PCP concentrations were dose dependent. PCP concentrations in the cortex ranged from 0.4-2.7 μM and PCP concentrations in the CSF ranged from .07-.30μM. The ratio of the PCP concentrations in CSF versus cortex was .15. Supported by NIDA grant, DA-02429.

COPULATING ACTIVITY MODIFICATIONS IN MICE PRENATALLY TREATED WITH DIAZEPAM. Márquez-Orozco, M.C. Hernández-Alvarez, L.A.I., Márquez-Orozco, A., Moralí de la Brena, G. Dept. of Embriology. School of Medicine, UNAM; Biomedical Research Unit, CMN, IMSS. 04510 México, D.F., MEXICO.

Prenatally diazepam treated mice fetuses, young and adult mice show alterations in CNS structure and in behavior. We evaluated the effect of these alterations upon the copulating activity of CD-1 strain mice prenatally treated with diazepam. One group of female mice was i.p. treated with diazepam (2.7 mg/kg/d) from the 6th to the 17th of gestation and another group received an equivalent volume of saline sol. Their offsprings were wet-nursed. On the 6th month, the spontaneous male sexual activity to receptive females was tested in 3 sessions (1/week). Tests were performed during the dark stage of the photoperiod and videorecorder under red light. Precopulating and copulating activities were evaluated. Duration of the introduction of the mount series with ejaculation (MSWE) tended to be longer in the treated mice, incidence of interruptions of intravaginal penetration and the number of interruptions of penile penetrations into MSWE were also greater. Treated animals showed a significant larger incidence of falls and pauses during mount series with intromission ($p < 0.05$). Results indicate alterations in their capacity to mantain an erection or a motor activity failure that interferes with this response.

451.2

CONDITIONED RESPONSE TO BARBITURATE INJECTION WITH THE OPERANT PARADIGM.
P.M. Duncan, T.Buck* and E. Muggenthaler*. Psychology Department, Old Dominion University, Norfolk, VA 23508.

Conditioned responses (CR) to barbiturate treatment were investigated in rats lever pressing for food pellets by presenting an auditory-visual stimulus (CS) 3 min before IP injection of na pentobarbital 15 mg/kg (exp group,n=9) or water (ctrl group,n=8). The exp rats completely stopped responding during the 20-min post-injection period. During 12 conditioning days, the exp group developed CRs to the preinjection CS as indicated by response suppression to 28% of baseline rate, significantly ($p<.05$) different from the 80% ctrl group mean. Sessions in which water only was injected in both groups revealed significant CRs (lower exp group resp rates) to the injection procedure. Both the pre and post-injection CRs lowered response rate, as did the actual drug treatment. Visual observation suggested that the CS elicited locomoter activity which interfered with lever pressing, implying that a compensatory CR was elicited by stimuli associated with the barbiturate treatment.

CARBAMAZEPINE DOES NOT AFFECT ALPRAZOLAM WITHDRAWAL.
W.R. Galpern, D.J. Greenblatt*, R.I. Shader*, L.G. Miller. Div. of Clinical Pharmacology, Depts. of Psychiatry and Pharmacology, Tufts-New England Medical Ctr., Boston, MA 02111.

Discontinuation of the triazolobenzodiazepine alprazolam (ALP) can produce a clinical "withdrawal" syndrome. An analogous syndrome of behavioral hyperactivity and $GABA_A$ receptor upregulation has been reported in mice (Lopez et al., Neuropharmacol, 29:237, 1990). Some clinical evidence indicates that carbamazepine (CBP) may be useful in limiting the symptoms associated with alprazolam discontinuation. To evaluate the effects of CBP on ALP discontinuation in a mouse model, we assessed the effects of an anticonvulsant dose of CBP (50 mg/kg/d) administered after ALP discontinuation, on open-field activity, benzodiazepine binding in vivo and in vitro, TBPS binding, and GABA-dependent chloride uptake in cortex. ALP (2 mg/kg/d) or vehicle were administered for 1 week by implanted osmotic pump; 24 hrs after pump removal, a second pump containing CBP or vehicle was implanted for 1 week. CBP administered after 1 wk treatment with vehicle did not alter open-field activity, benzodiazepine or TBPS binding, or GABA-dependent chloride uptake. As previously reported, ALP followed by vehicle was associated with increases in motor activity, benzodiazepine binding, and chloride uptake 2 and 4 days after ALP discontinuation. Similar findings were observed in mice treated with CBP after alprazolam. Thus, CBP at an anticonvulsant dose does not affect behavioral or neurochemical effects of alprazolam discontinuation.

451.4

EFFECTS OF EARLY EXPERIENCE ON DRUG CHOICE IN A NOVEL ANIMAL MODEL OF MULTIPLE SUBSTANCE ABUSE.
B.Zimmerberg and M.B.Brett*. Psychology Dept., Williams College, Williamstown, MA 01267.

Individuals vary in rates of initiation and maintenance of drug self-administration behavior. One source of these individual differences may lie in differential early experience. Long-Evans rats were weaned at 25 days of age into one of three environmental conditions: social isolate (SI), sibling double-housed (DH), or enriched environment (EE). At 85 days of age, subjects were singly housed and given a choice between drinking a stimulant (d-amphetamine, 0.025 mg/ml), a depressant (barbital, 1 mg/ml) or water for two hours daily. Drug choice was affected by both housing and sex. SI males consumed significantly less depressant than any other group. When forced to choose between the two drugs without a water alternative, EE and SI males showed a clear preference for the stimulant, and SI and DH females for the depressant. These results suggest that males and females respond differently to the stress of social isolation, and appear to contradict the "tension-reduction" hypothesis used to explain depressant drug intake, at least for males.

451.5

TOLERANCE TO PHENOBARBITAL AND CROSS-TOLERANCE TO MUSCIMOL GIVEN IVT TO RATS.
J.A. Richter, S.L. Gatto* & B. Glick*, Depts. Pharmacology and Psychiatry, Indiana Univ. School of Medicine, Indianapolis, IN 46202.

We have found previously that many phenobarbital (PheB) effects including the loss of righting reflex (LRR) and hypothermia can also be elicited by ivt administration of muscimol. In order to test the hypothesis that PheB induces these effects by a GABAergic mechanism we have asked if cross-tolerance occurs between these two drugs. Studies were done in male Wistar rats with indwelling guide canulae directed to the lateral ventricle. These methods were previously used by Mycek and Brezenoff (1976) who found tolerance to the LRR induced by PheB after 4 days of 4x/day ivt injections. We found that 1250 ug NaPheB 4x/day for 4 days induced tolerance to the LRR but not to the hypothermia. Similar chronic administration of 1600 ug NaPheB induced tolerance to the hypothermia and LRR. When these rats were tested on the 5th day with 1 ug muscimol, the hypothermic effect of muscimol was reduced significantly, but the LRR induced by muscimol was not greatly altered. These results support a GABAergic mechanism for barbiturate hypothermia. Further experiments will test whether longer periods of chronic PheB treatment will induce cross-tolerance to the other effects of muscimol, and if chronic muscimol induces cross-tolerance to PheB effects. (Supported by PHS R01 DA00796).

451.6

BEHAVIORAL TOLERANCE TO MULTIPLE CHRONIC DOSES OF MIDAZOLAM ON FIXED RATIO RESPONDING.
M.Kallman, S.Bowen*, E.Ventress*, R.Anderson*, M.Durnam* and S.Fowler. Depts. of Psychol. & Pharmacol., U. of Miss., University, MS 38677.

This investigation explored the importance of chronic dose on behavioral tolerance and behavioral withdrawal with midazolam(MZ). Forty-eight male rats were trained to respond on a fixed ratio (FR) 30 schedule of reinforcement during daily 20 min. sessions. An initial dose effect curve was determined (0.3-10.0 mg/kg) and redetermined following 30 days on chronic exposure. During the chronic exposure period half the rats (N=24)were exposed to drug 15 min. presession(PRE) and half were exposed 30 min. postsession (POST) with 6 rats from each PRE and POST group exposed to 0,1.32, 3.0 or 10 mg/kg during the chronic period. FR performance was observed for 60 days following termination of drug exposure. Behavioral tolerance did develop to MZ with the degree of behavioral tolerance dependent on MZ dose. Behavioral withdrawal was also determined by time of chronic drug exposure and MZ dose delivered.These findings support the contention that behavioral factors are important in the development of tolerance and withdrawal and that behavioral factors are optimal when chronic drug delivery does not produce complete debilitation. Support DA05253.

WITHDRAWAL AND CROSS TOLERANCE IN RATS MADE DEPENDENT ON CHLORDIAZEPOXIDE. S. L. Pugh*, S. Abdel-Malek*, and M. W. Emmett-Oglesby, Department of Pharmacology, TCOM, Fort Worth, Texas, 76107-2690

Rats were trained to detect the anxiogenic drug pentylenetetrazole (PTZ; 20 mg/kg) using a two-lever food-reward choice task. When tested with chlordiazepoxide (20 mg/kg; CDP) in combination with the benzodiazepine antagonist, flumazenil (40 mg/kg), they selected the saline lever. Subsequently, they were treated with CDP (20 mg/kg/8-hr) for 7 days, and then they were retested with the CDP/flumazenil combination at various times after stopping chronic administration of CDP. In contrast to the results obtained prior to chronic CDP, this combination of drugs now resulted in predominately PTZ-lever selection at 8 and 24 hr after the last chronic dose of CDP. Tests at 48 hr or later again resulted in saline-lever selection. A second group of animals was trained to discriminate PTZ (20 mg/kg) from midazolam (1.0 mg/kg) from saline. Using a cumulative dosing procedure, in acute dose-effect tests, PTZ substituted for PTZ, and midazolam, CDP and diazepam substituted for midazolam in a dose-related manner; in addition, low doses of drug resulted exclusively in either responding on the saline lever or responding on the lever that was appropriate for that drug (e.g., PTZ-lever following PTZ). These subjects were then given CDP (20 mg/kg/8-hr) for 7 days and subsequently tested for their detection of midazolam. The dose-effect curve shifted approximately two-fold to the right at 8 hr after the last chronic injection of CDP. Thus, these results support the hypothesis that chronic CDP produces dependence and tolerance that can be detected in an animal model of subjective drug effects.

DISCRIMINATIVE STIMULUS PROPERTIES OF FLUMAZENIL DURING CHRONIC CHLORDIAZEPOXIDE TREATMENT. G.A. Rowan and M.W. Emmett-Oglesby, Department of Pharmacology, TCOM, Ft.Worth, TX 76107-2690

Rats were trained using operant methods to discriminate the stimulus properties of flumazenil (2.5 mg/kg) while maintained on a liquid diet containing chlordiazepoxide (CDP) (100 mg/kg/daily). The animals were given CDP in divided doses: they were trained 6 hours after a 25 mg/kg dose, and after training they were given the remaining 75 mg/kg of CDP. In dose-effect testing flumazenil substituted for the training stimulus in a dose-dependent manner (0.64 - 2.5 mg/kg), producing an ED50 of 0.94 mg/kg. The animals were then taken off chronic CDP. When tested with vehicle the 8th day after withdrawal from CDP the animals responded with a 67% flumazenil-lever selection. In contrast, when tested 14 days after withdrawal the response to vehicle was not significantly different than pre-withdrawal vehicle responding (17% drug lever selection). At this point, the training dose of flumazenil was retested and the animals failed to produce flumazenil-lever selection, indicating that the effects of flumazenil alone were different in the non-dependent subject. These data also indicate a partial substitution between 8-day post-chronic CDP (spontaneous withdrawal) and the flumazenil stimulus trained against the background of CDP (precipitated withdrawal). The animals were then placed back on chronic chlordiazepoxide and trained for an additional three months. Subsequently, the dose effect curve for flumazenil (0.16 - 2.5 mg/kg) was redetermined; the curve was not significantly different from the initial dose-effect curve (ED50 of approximately 0.64 mg/kg), demonstrating a stable discriminative stimulus produced by flumazenil. These data are consistent with having trained the discriminative stimulus properties of precipitated withdrawal from dependence on a benzodiazepine. This research was supported by DA05367 and DA03521.

EVIDENCE THAT THE BENZODIAZEPINE RECEPTOR PARTIAL AGONIST Ro 16-6028 HAS MINIMAL ABUSE AND PHYSICAL DEPENDENCE LIABILITY J.R. Martin[1], A. Kuwahara[2*], I. Horii[2*], J.-L. Moreau[1*], F. Jenck[1*], J. Sepinwall[3] & W. Haefely[1]. [1]Pharmaceut. Res. Dept., Basel, [2]Tox. & Path. Dept., Kamakura and [3]Pharmacol. & Chemother. Dept., Hoffmann-La Roche Inc., Nutley, N.J.

To assess dependence liability, squirrel monkeys received Ro 16-6028 (RO), alprazolam (A) or vehicle po divided into 3 equal doses at 8 h intervals each day over 11 days. Benzodiazepine receptor (BZR) antagonist challenge (.25 mg/kg Ro 15-3505 iv) was given 5 h, 24 h, and 48 h after the 31st and final administration and observations made for 2 h. Pronounced convulsions were observed in 2/4 and 4/4 of the monkeys receiving 1 or 3 mg/kg A daily, respectively. In contrast, only 0/4, 1/4, and 2/4 of the monkeys receiving 3, 10, or 30 mg/kg of RO daily exhibited any pronounced convulsions, respectively. Given the much greater potency of RO than A in diverse pharmacological tests and the relatively low incidence of severe precipitated withdrawal symptoms after the former, RO clearly exhibits lower dependence potential than the BZR full agonist A. This pattern of results was repeated in DBA/2J mice receiving 2, 6, or 20 mg/kg A, 20,60, or 200 mg/kg RO or vehicle divided into two equal daily oral doses for 17 days and challenged with Ro 15-3505 given 5 h after the final administration. Convulsions were precipitated in 60-75% of mice in groups treated with the two higher doses of A, whereas none were induced in any of the RO groups.

To assess its reinforcing effect, RO was offered to 4 cynomolgus monkeys which had previously been trained to self-administer pentobarbital iv on a FR10 schedule during a daily 6-h session. In repeated substitution tests (consisting of at least 5 sessions), RO was shown to lack reinforcing effects at all doses tested (0.001-0.06 mg/kg per injection). Furthermore, these doses were also inactive in 5 monkeys tested in a self-administration initiation paradigm. (For comparison, it has been found that oral RO disinhibited punished operant responding in squirrel monkeys with a MED ≤ 0.02 mg/kg). Thus, RO was not found to be self-administered within a behaviorally active dose range.

451.10

DISCRIMINATION OF THE STIMULUS PROPERTIES OF THE BENZODIAZEPINE INVERSE AGONIST METHYL-6,7-DIMETHOXY-4-ETHYL-BETA-CARBOLINE-3-CARBOXYLATE (DMCM). L.G.Kirby, G.A.Rowan and I.Lucki. Depts. of Psychiatry and Pharmacology, University of Pennsylvania, Philadelphia, PA 19104.

Rats (N=6) were trained to discriminate the stimulus properties of the benzodiazepine (BZ) receptor inverse agonist DMCM from saline in a conditioned taste aversion paradigm. On a drug trial, water-deprived rats were injected with DMCM (.6 mg/kg IP), allowed access to a .25% saccharin solution for 30 min, and then injected with LiCl (1.8 mEq/kg IP). On nondrug trials, saline injections bracketed the drinking period. Unconditioned controls (N=6) were treated with DMCM but never received LiCl. Acquisition of the discrimination was detected after as few as 5 pairings of DMCM with LiCl. In addition, DMCM produced a dose-dependent reversal of the preference for saccharin over water in a two-bottle choice test after DMCM-LiCl pairings, but not in controls.

The inverse agonists beta-CCE (10-18 mg/kg) and FG-7142 (3.2-18 mg/kg) fully substituted for the effect of DMCM, as measured by the reversal of saccharin preference. Partial substitution for DMCM was shown by the BZ receptor antagonist CGS 8216 (3.2-10 mg/kg) and the non-BZ convulsant pentylenetetrazol (11-20 mg/kg). The BZ agonists chlordiazepoxide (.32-5.0 mg/kg), diazepam (.32-10 mg/kg), and alprazolam (0.1-3.2 mg/kg) all failed to generalize significantly to the DMCM stimulus.

SELECTIVE BREEDING FOR NEGATIVE CONTRAST; PRELIMINARY DATA. C.F. FLAHERTY, K.L. Krauss*, G.A. Rowan, M. Weaver* & P.S. Grigson.
Psychology Dept., Rutgers Univ., New Brunswick, NJ 08903

We selectively bred rats differing in degree of negative contrast effect when shifted from 32% to 4% sucrose. Shift ratio (lick frequency on first postshift day/lick frequency on last preshift day) was used as the selection criterion. Reliable differences between the two lines (large contrast (LC) and small contrast (SC)) developed over six filial generations. Selection in the direction of contrast larger than the general population was much more pronounced than selection towards small contrast -- an outcome which reflects the distribution of individual differences in a large sample of unselected rats. The two lines also differ in sensitivity to the contrast-alleviating effects of midazolam -- with the drug reducing contrast in the LC rats but having no effect in the SC rats. The two lines also differ in open field activity (LC rats ambulate and rear more than SC rats), but they do not differ in defecation frequency.

The two lines may provide a vehicle for analyzing behavioral and neurochemical correlates of sensitivity to absolute and relative reward effects. The lines may also differ in sensitivity to anxiolytic drugs and, possibly, other drugs which interact with reward systems.

451.12

EFFECT OF ACUTE PENTOBARBITAL ON EXCITATORY AMINO ACID EVOKED-ELEVATIONS OF CYCLIC GUANOSINE 3',5' MONOPHOSPHOSPHATE IN CULTURED CEREBELLAR GRANULE CELLS. W.W. Morgan, J.L. Bermudez* and S.M. Davis*. Dept. Cellular and Structural Biology, Univ. of Texas Hlth. Sci. Ctr. at San Antonio, TX 78284-7762.

Depressant barbiturates suppress the stimulatory effects of the excitatory amino acids on neuronal activity and perhaps act preferentially on activations mediated via kainate- as opposed to NMDA-related receptors (Collins, G.G.S., Neuropharmacology, 26:167, 1987). To investigate this latter effect further, granule cells were cultured from 8 day old rats. Cultures (9 DIV) were preincubated in buffer or in buffer containing Na+ pentobarbital for 10 min before the addition of kainate or NMDA (12.5-100μM). One minute later each reaction was terminated, and cyclic GMP was determined by RIA. Pentobarbital (200μM) markedly suppressed the elevations of cyclic GMP induced by 25-75μM kainate to near the control value while the effect of 100μM kainate was only partially suppressed. The elevation of cyclic GMP produced by 25μM kainate was significantly reduced by dosages of pentobarbital as low as 10μM, but lower dosages remain to be tested. Similar effects of pentobarbital were observed on NMDA-induced elevations of cyclic GMP. These results demonstrate the suppressive effects of pentobarbital on excitatory amino acid-mediated neuronal stimulation, but, as yet, suggest no selectivity for receptor subtype. CHRONIC BENZODIAZEPINE (BZ) TREATMENT REDUCES GABAERGIC INHIBITION IN HIPPOCAMPUS. X-H. Xie and E.I. Tietz. Dept. of Pharmacology, Medical College of Ohio, Toledo, OH 43699

GABA/BZ complex function was examined 48 hr after 1 week chronic flurazepam (FZP) treatment by testing GABA-mediated inhibition in in vitro hippocampal slices. Male rats (200-280 gm) were offered FZP in the drinking water (100 mg/kg X 3 dy;150 mg/kg X 4 dy). Field potentials elicited by Schaffer collateral stimulation (.1 msec monophasic pulse) were recorded (2M NaCl filled glass pipette, 2-5 mΩ) from CA1 pyramidale cells. Stimuli resulting in ½ maximal evoked responses were determined in treated and control (10.8±.6 V vs. 10.8±.5 V) slices for paired-pulse stimulation (inter-pulse interval (IPI), 10-200 ms). Test responses (P2) were measured as a fraction of conditioning responses (P1). Threshold for a 1 mV response (control, 7.9±.4; treated, 7.7±.4 V) and P1 amplitude (3.1±.3 vs 2.8±.1 mV) did not differ (p>.05). All 13 slices from 6 treated rats showed significantly (p<.01) reduced inhibition at all IPI between 10 ms (-67%) and 40 ms (+3%) in comparison to 12 control slices (n=6; -91% and -44%). The significant shift in IPI_{50} in treated (17.0 ms) vs control (33.5 ms) slices suggests reduced local inhibition at a time after chronic BZ treatment when residual drug level is negligible and BZ anticonvulsant tolerance is still apparent. The findings suggest modulation of GABA/BZ complex function underlies BZ tolerance and shows that the hippocampal slice is useful for studying BZ tolerance mechanisms. EPILEPSY: KINDLING I

452.1

PHARMACOLOGICAL PROFILE OF SUBMAXIMAL CORNEAL ELECTROSHOCK KINDLING: LACK OF INVOLVEMENT OF NMDA RECEPTORS? EW Harris, GC Garske, EF Cregan, LR Freedman and GC Palmer, Fisons Pharm., Div. R & D, Box 1710, Rochester, NY 14603.

Rats receiving repeated submaximal corneal electrical stimulation (60Hz, 8mA x 2sec) exhibit a progression of seizures reminiscent of amygdala kindling (Kupferberg, 1989, Epilepsia 30, S1, S51). The time course and pharmacology of "corneal kindling" have been examined.

Rats were stimulated 1 & 2 hr post oral dosing for 5 days, followed by a 2 day wash out and retest. Vehicle-treated rats reached Class IV-V seizures after 5 days. Established seizures were blocked by phenobarbital (30 mg/kg), carbamazepine (100 mg/kg) or the NMDA antagonist MK-801 (0.33 mg/kg). Seizure progression during kindling was slowed by MK-801, phenobarbital, valproate (708 mg/kg) or clonazepam (1 mg/kg). However, seizure severity jumped markedly with the first test after wash-out of MK-801 or phenobarbital, approximating that in vehicle-treated rats; wash-out of clonazepam or valproate revealed only a slight increase in severity. Kindling was not slowed by phenytoin, remacemide or FPL 13950 (40, 60 & 46 mg/kg, respectively); the latter two block NMDA-induced seizures in mice (ED_{50}=57 & 30 mg/kg). Established seizures also were not blocked by phenytoin, remacemide or FPL 13950 (200 mg/kg).

Corneal kindling differs pharmacologically from MES or PTZ seizures, and some drugs thought to retard kindling (including NMDA antagonists) may only mask its expression.

KINDLING INCREASES THE APV AND CNQX SENSITIVE COMPONENTS OF SYNAPTIC RESPONSES IN BASOLATERAL AMYGDALA (BLA). **D.G. Rainnie, E.K. Asprodini, & P. Shinnick-Gallagher,** Dept. of Pharmacology, Univ. of Texas Medical Branch, Galveston, TX 77550.

Kindling induces burst firing responses in the amygdala. The purpose of these experiments was to analyse the subthreshold synaptic responses underlying this bursting behaviour. Stimulation of the stria terminalis (ST) or lateral amygdaloid nucleus (LA) evokes a multiphasic waveform, consisting of an EPSP, a fast IPSP and a slow IPSP recorded at -60mV using intracellular recording techniques. The EPSP consists of a fast (rise-time 10-90%: 6± 1mS) CNQX (10μM) sensitive component which is enhanced with membrane hyperpolarisation. In the presence of CNQX (10μM) a slow (rise-time 19± 1.5mS) APV (50μM) sensitive component is revealed which is reduced with membrane hyperpolarisation.

Following kindling, increases in both glutamatergic components of the EPSP are observed. In 50μM APV, stimulus intensities evoking a CNQX sensitive EPSP (15± 3.5mV) in control (C) neurones cause burst firing in kindled (K) neurones. Similarly, in CNQX (10μM) significant increases in the APV sensitive component (3.0± 0.3mV, K; 1.4± 0.3mV, C; p = 0.012; -70mV) were recorded at lower stimulus intensities (mean: 24V, C; 10V, K). This APV sensitive EPSP is reduced with membrane hyperpolarisation. At all membrane potentials tested, no significant changes in membrane input resistance were observed following kindling. In addition, firing frequency in response to a transient (100ms) depolarising current step (0.4nA) shows no significant difference (4.6± 0.7, C; 4.1± 0.6, K). Furthermore, APV sensitive EPSPs, recorded in CNQX and bicuculline, in control were smaller than those in kindled neurones. These data suggest that changes in voltage dependent Mg^{2+} block, postsynaptic conductance, firing frequency and/or loss of GABAergic shunt conductance could not account for the enhanced glutamatergic EPSPs. However the data could be explained by pre- and/or post-synaptic changes in glutamatergic transmission. Supported by NS 24643.

THE NMDA-ANTAGONIST, MK-801, REDUCES THE AMOUNT OF GRANULE CELL INHIBITION PRODUCED BY PERFORANT PATH KINDLING. ME Gilbert. NSI Technology Services Corp., RTP, NC, 27709.

Electrical kindling of the perforant path or dentate hilus produces a reduction in inhibition as indexed by paired pulse stimulation. Antagonists of the NMDA-receptor subtype of glutamate delay the development of kindling. The present experiment examined the development of enhanced inhibition in saline- and MK-801-treated rats during kindling of the perforant path. Kindling was induced by daily delivery of stimulus trains (2 s, 60 Hz, 1.0 pulse duration, 800 μ a) to the perforant path 30 min following 0 or 1.0 mg/kg MK-801 (ip). Pairs of stimulus pulses were delivered at 8 interpulse intervals (IPI) ranging from 20 to 1000 ms. The intensity of the conditioning pulse was set at approximately 75% of the asymptotic population spike for a given subject. Over the course of kindling development, this intensity was adjusted to match the size of the population spike at baseline. As previously reported, MK-801 increased AD thresholds and the number of sessions required to reach Stage 5 seizures. Paired pulse functions monitored before kindling (baseline), and 24 hr after the 1st, 2nd, 6th and 15th AD indicated that MK-801 reduced the amount of inhibition that developed during kindling of control subjects. The effects were most pronounced at IPIs ranging from 70-150 ms which result in paired pulse facilitation under baseline conditions. The enhancement of a late period of inhibition occurring between 200 and 1000 ms was also decreased by MK-801. Thus in addition to the suppression of potentiation in excitatory projection pathways that accompanies kindling, NMDA-antagonists may also suppress potentiation of inhibitory circuits.

452.4

NMDA RECEPTOR BLOCKADE PREVENTS LENGTHENING OF AFTER-DISCHARGES AND LOSS OF PAIRED PULSE INHIBITION INDUCED BY RAPIDLY RECURRING HIPPOCAMPAL SEIZURES (RRHS) METHOD OF KINDLING. Jaideep Kapur[1] and Eric W. Lothman[2], Dept. of Neurology, Medical College of Virginia, Richmond, VA 23298 and Depts. of Neurology and Neuroscience, University of Virginia, Charlottesville, VA 22908.

These experiments examine the role of NMDA receptor activation in prolongation of afterdischarges observed in rapidly recurring hippocampal seizures (RRHS) method of kindling. We have previously shown that delivery of RRHS to awake rats causes a rapid kindling and that RRHS in awake and urethane anesthetized rats causes progressive lengthening of afterdischarges and a loss of paired pulse inhibition. Paired pulse inhibition is dominantly GABA mediated.

Pretreatment with NMDA receptor antagonists Ketamine or MK801 prevented RRHS induced lengthening of afterdischarges. Pretreatment with MK801 in a dose of 4mg/Kg simultaneously prevented lengthening of afterdischarges and loss of paired pulse inhibition.

The mechanisms behind kindling are unknown, however theoretical discussions of its pathophysiology focus on the balance between excitation and inhibition. Current and previously reported experiments demonstrate that NMDA receptor activation results in diminution of GABA mediated paired pulse inhibition which in turn mediates prolongation of afterdischarges observed in RRHS method of kindling.

452.5

DECREASE OF AMYGDALOID GABA-IMMUNOREACTIVE NEURONS AFTER KINDLING P.M. Callahan, J.M. Paris, K.A. Cunningham and P. Shinnick-Gallagher Dept. of Pharmacology, Univ. of Texas Medical Br., Galveston TX, 77550.

The inhibitory neurotransmitter GABA appears particularly sensitive to amygdala epileptogenesis. The present study was designed to investigate the in vivo kindling effects on GABA-immunoreactive (GABA-IR) neurons of the lateral and basolateral amygdaloid nucleus in the rat. Male Sprague-Dawley rats were anesthetized and implanted stereotaxically with bipolar stimulating electrodes in the basolateral nucleus. One week after surgical implantation, animals were electrically stimulated with cathodal pulses of 1 ms, 500 uA applied at 60 Hz for 1 s once per day until 3-5 stage 5 seizures were observed. The control group (N=4) consisted of non-stimulated implants and unimplanted rats. Kindled rats developed generalized seizures after an average of 14 days (range: 9-19; N=4). Histological recovery of the electrode tips indicated that placements were in or near the basolateral complex for all subjects. Tissue was processed for GABA on the contralateral side of the brain using avidin-biotin peroxidase immunohistochemical procedures. Within the lateral and basolateral complex, discrete brain sections (-2.12, -2.56, -3.14 and -3.60 mm from bregma, Paxinos & Watson, 1986) were chosen for quantification. The results indicate that, in comparison to controls, fully kindled animals showed a significant decrease in total number of GABA-IR neurons in the amygdala nuclei (ANOVA, $F_{(1,6)}=25.28$, $P<0.002$). Furthermore, GABA-IR neurons throughout each of the four coronal amygdala planes were reduced in kindled animals ($p < 0.05$). The present data suggest that electrical kindling of the amygdala results in a significant reduction of GABA-IR neurons in the lateral and basolateral areas throughout the contralateral amygdaloid nucleus. This reduction may be responsible for the observed loss of GABAergic IPSPs and the spontaneous epileptiform bursting which may ultimately contribute to amygdaloid epileptogenesis (Gean et al., 1989).

452.6

DEVELOPMENT OF LONG-TERM SUBSENSITIVITY TO GABA IN DORSAL RAPHE NEURONS OF AMYGDALA KINDLED RATS.

T.D. Hernandez and D.W. Gallager. Dept. Psychiatry, Yale Univ. Sch. Med., New Haven, CT 06508.

Previously we reported a long-term change in neuronal sensitivity to GABA following amygdala kindling (Hernandez et al., Brain Res, 1990). Dorsal raphe neurons of amygdala kindled rats exhibited significant subsensitivity to GABA 4 weeks after the last fully generalized (Stage 5) seizure. This subsensitivity was equivalent in magnitude to that observed following chronic diazepam treatment; yet, unlike that produced by chronic diazepam treatment, subsensitivity due to amygdala kindling was not reversed by bath application of Ro 15-1788. We hypothesized that this alteration in GABA sensitivity might reflect neuronal changes corresponding to kindled seizure susceptibility and subsequent experiments have investigated this hypothesis.

The development of subsensitivity to GABA during the amygdala kindling process progresses through a continuum that reflects the Stage to which an animal has been kindled. That is, when measured 4 weeks after the last kindled seizure, dorsal raphe neurons are *supersensitive* to GABA following a Stage 2 seizure, *not different from controls* following a Stage 3 seizure and *subsensitive* to GABA following a Stage 5 seizure. In addition, subsensitivity to GABA appears to be permanent in that it is still measurable 3 months after the last Stage 5 seizure. This progression from GABA supersensitivity to subsensitvity parallels that observed following exposure to diazepam: acute diazepam exposure results in increased sensitivity to GABA, while chronic exposure (> 2 weeks) leads to subsensitivity. Unlike kindling, however, changes seen after benzodiazepine exposure return to control levels following drug discontinuation. Thus, amygdala kindling produces long-term, perhaps permanent, changes in neuronal sensitivity to GABA reflecting the Stage to which an animal has been kindled.

REGIONAL ANALYSIS OF GABA-STIMULATED CHLORIDE FLUX IN AMYGDALA KINDLED RATS. E.I. Tietz and T. H. Chiu. Dept. of Pharmacology, Medical College of Ohio, Toledo, OH 43699

GABA-stimulated chloride flux was evaluated in 4 brain regions (cortex, CTX; hippocampus, HIP; midbrain/brainstem, MBR and cerebellum; CER) of amygdala kindled rats. Male rats (n=16) were stimulated 2 X daily in the amygdala until 5 Stage 5 seizures were elicited. Control rats (n=16) were sham kindled. Microsacs, prepared from 4 pooled kindled or control rats 7 days after the last amygdala stimulation, were preincubated 15 min at 30°C. GABA (10 or 50 μM) and Cl^- (0.4 μCi) were added followed in 5 sec by rapid filtration and 2 buffer washes. Basal flux (nmoles mg protein) differed between regions but not between kindled and control groups (CTX, 17.7±.9 vs 17.6 ±1; HIP 21.5±1.1 vs 20.6±1; MBR, 30.6±1.8 vs 33.4±1.3; CER, 23.4±0.6 vs 26.5±1.0). There were significant ($p \leq .01$) decreases in net GABA-stimulated flux in CTX and HIP only at the lower GABA concentration. The decrease in flux in CER (9.7±.7 vs 6.4±.1) was not significant. There was no difference in MBR (3.1±.2 vs 2.9 ±.4). There was also no change in any brain region in the ability of 1 μM midazolam to stimulate 10 μM GABA-mediated flux. These results indicate long-lasting regionally specific changes in GABA complex function following amygdala kindling. The findings contrast those of decreased GABA-stimulated flux in brainstem of entorhinal-kindled rats and support those of decreased GABA complex function with chemical kindling. Supported by grants S07-RR05700 and R01-DA04075.

AUTORADIOGRAPHIC ANALYSIS OF ^{35}S-TBPS BINDING IN THE HIPPOCAMPUS OF KINDLED RATS. J.S. Petrasek, J.N. Nobrega, S.J. Kish and W.M. Burnham. Department of Pharmacology, University of Toronto, and Clarke Institute of Psychiatry, Toronto, Canada.

Previous studies have demonstrated that kindling induces a transitory increase in the binding of both GABA and benzodiazepine receptor ligands within the hippocampus (fascia dentata). We have now chosen to investigate whether a similar change in the binding of ^{35}S-TBPS to the "convulsant" site associated with the GABA-mediated chloride ionophore also occurs in the hippocampus of kindled rats. Subjects (n=7 per group) were kindled via stimulation of the entorhinal cortex and sacrificed with matched controls either 24 hours or 28 days after their sixth Stage 5 seizure. Binding of ^{35}S-TBPS (4 nM) was examined in multiple regions of the hippocampus in kindled and control brains via quantitative receptor autoradiography. No significant change in binding was observed after kindling in any of the hippocampal subdivisions examined, either 24 hours or 28 days after the last seizure. Our data suggest that kindling does not alter the number of chloride ionophore convulsant sites in the rat hippocampus, although it may alter the number of $GABA_A$ and benzodiazepine receptor sites. A detailed analysis of TBPS binding in other regions of the kindled brain is now in progress. (Supported by MRC Grant MA 5611.)

NORADRENERGIC COMPONENTS OF FOREBRAIN KINDLING: THE ROLE OF AMYGDALOID NOREPINEPHRINE. J Nierenberg, CD Applegate and JL Burchfiel. Comprehensive Epilepsy Program, University of Rochester School of Medicine, Rochester, NY 14642.

Forebrain depletion of norepinephrine (NE) facilitates kindled seizure development by reducing the number of trials spent in the early phase of kindling (seizure stages 1-2). We have hypothesized this result indicates the existence of a discrete NE-dependent transition from early to later (stages 3-5) kindling phases (Burchfiel & Applegate, Neurosci. Biobehav. Rev., 13:1989). In this study we have attempted to localize a NE-sensitive forebrain substrate which facilitates this transition. Rats were injected bilaterally into the amygdala with 6-hydroxydopamine (6-OHDA, 10 µg in 1 µl) prior to kindling from either amygdala (n=10) or septal nucleus (n=6). Amygdala-kindled rats with 6-OHDA lesions showed 40% reduction in the number of early, stage 1-2 trials (mean=6.7±1.6) relative to vehicle-injected controls (mean=11.5±1.0). Amygdala 6-OHDA also resulted in a reduced number of stage 1-2 trials in septal nucleus-kindled rats (mean=14.7±3.7) relative to uninjected controls (n=8, mean=22.0±3.9). These data suggest an involvement of amygdaloid NE in the kindling of forebrain structures. Ongoing experiments are being conducted to confirm whether the role of the amygdala is unique in this context or whether it is part of a limbic "loop" which modulates the NE-dependent transition from early to later stages of kindled seizure development.

452.10

AMYGDALA KINDLED SEIZURES AND BRAIN A_1 ADENOSINE RECEPTORS IN RATS. S.M. Anderson and D.D. Walczak*. Department of Medical Neurosciences, Walter Reed Army Institute of Research, Washington, D.C. 20307-5100.

In order to understand the development of post-traumatic epilepsy we are assessing changes in brain neurochemistry during various stages of seizure promotion using an electrical kindling model. The anticonvulsant properties of adenosine and evidence that upregulation of adenosine receptors is accompanied by reduced sensitivity to convulsants, prompted us to investigate the relationship between A_1 adenosine receptors and seizures. Male Sprague-Dawley rats were kindled from a bipolar depth electrode implanted in the left amygdala. Electrical stimulus was applied once every 24 hrs until either two consecutive stage 3 or three successive stage 5 seizures were achieved. EEG was recorded from the electrodes and the corresponding behavioral responses were scored using the rating scale of Racine. Three different control groups were studied at each seizure level: unoperated handled rats, sham-operated rats (implanted with electrodes but not stimulated), and a seizure control group, yolked to the kindled rats, which received suprathreshold stimulation (STS) induced seizures. Rats were decapitated 48 hrs after their last kindled or STS seizure and relevant brain regions were dissected from 2 mm coronal slices. A_1 adenosine receptors were measured in brain membrane homogenates using the selective adenosine analogue, [^{3}H]N^6-cyclohexyladenosine (CHA). We found no relationship between A_1 adenosine receptors and either the occurrence of STS convulsions or the development of seizures by kindling.

452.11

HIPPOCAMPAL KINDLING ENHANCES MEMBRANE-ASSOCIATED PROTEIN KINASE C IN THE BILATERAL HIPPOCAMPUS BUT NOT IN THE AMYGDALA/PYRIFORM CORTEX. A.Daigen*, K.Akiyama, T.Itoh* and S.Otsuki*. Dept. Neuropsychiatry, Okayama University Medical School, Okayama 700, Japan.

The effect of hippocampal (HIPP) kindling on protein kinase C (PKC) was investigated in the rat amygdala/pyriform cortex (AM/PC) and the right (contralateral) and left (ipsilateral) HIPP. Seven days after the last kindled seizure, there was no difference between the control and kindled group in cytosolic PKC activity in any part of the brain. In the kindked rats, a significant increase in membrane-associated PKC activity was found in the left HIPP (by 30%, $p<0.02$) and right HIPP (by 26%, $p<0.05$) as compared to the control. However, there was no significant alterations in the AM/PC. The protein concentrations in the crude cytosolic preparation did not differ between the two groups in any brain area examined, but those in the membrane preparations increased significantly in the left HIPP (by 22%, $p<0.02$) of the kindled rats. In the fraction co-eluted with PKC, significant increase in the protein concentration was confirmed in the ipsilateral HIPP for the cytosolic preparation as well as in the bilateral HIPP for the membrane preparation. These results suggest that activation of PKC may play an important role in the kindling mechanism.

452.12

KINDLING IN RATS: EVALUATION OF A HIGHLY SENSITIVE LOCUS IN THE POSTERIOR PART OF THE PIRIFORM CORTEX. W. Löscher, U. Wahnschaffe* and D. Hönack*.Dept. of Pharmacol.,Toxicol.& Pharmacy,. Sch.of Veterinary Medicine,3000 Hannover 71,FRG

The piriform cortex (PC), especially its deep anterior part (DPC), has been recently suggested to be a crucial epileptogenic site in the rat brain. We investigated the possible role of the posterior part of the PC (PPC) in electrical kindling. A locus in the deep cell layer (layer III) of the rostral portion of the PPC is described, which is considerably more sensitive to electrical stimulation than the DPC and the amygdala (AM). This locus can be readily kindled, and effects of antiepileptic drugs in PPC-kindled rats are similar to effects in AM-kindled rats, although the locus in the PPC tend to be more resistant to anticonvulsant effects. Unilateral lesions of the PPC significantly increase the seizure threshold of rats kindled from stimulation of the ipsilateral AM. The data suggest that the PPC locus described might represent a specific generating site within the PC.

452.13

PYRIFORM CORTEX INVOLVEMENT IN LIMBIC KINDLING. D.C. McIntyre and M.E. Kelly. Dept. of Psychology, Carleton Univ., Ottawa, Ont. K1S 5B6.

The role of the pyriform cortex (PC) in secondary generalization of kindled limbic seizures was investigated in 2 experiments. In the first experiment, rats previously kindled from the dorsal hippocampus (DH) and ipsilateral olfactory bulb (OB) were given systemic kainic acid (12 mg/kg, i.p.) to destroy the PC. Following this treatment, animals with complete loss of the PC exhibited strong hippocampal ADs when stimulated, yet were unable to re-develop secondarily generalized seizures. In addition, the electrographic and convulsive responses previously triggered by stimulation of the kindled OB were lost. In the second experiment, status epilepticus (SE) was induced via 60 min of stimulation to a kindled amygdala focus, producing complete PC damage in the kindled hemisphere. Kindling of the ipsilateral DH was then initiated. Subsequent seizure profiles of these animals suggested that the triggered DH seizure gained access to generalization mechanisms through the intact contralateral PC. Taken together these data suggest that the PC is extremely important, if not critical, to the generalization of kindled seizures from the dorsal hippocampus and olfactory bulb.

452.14

LONG LASTING DECREASE IN HIPPOCAMPAL MOSSY FIBER ZINC AFTER ENTORHINAL KINDLING IN RAT. DD Savage, DY Tso-Olivas* and JT Slevin. Dept. Pharmacology, Univ. New Mexico Sch. Med., Albuquerque, NM, 87131 and V.A. Research Service and Depts. Neurology and Pharmacology, Univ. Kentucky Coll. Med., Lexington, KY, 40536.

We have observed striking reductions in hippocampal formation (HPF) mossy fiber zinc in rats exhibiting kindling-induced spontaneous seizures. This observation prompted an investigation of whether mossy fiber zinc is reduced in rats 1 day or 4 weeks after two Class 5 kindled motor seizures.

Male Sprague-Dawley rats were assigned to one of three groups receiving either: 1) daily entorhinal kindling (EK) stimulations until they exhibited two successive Class 5 motor seizures, 2) daily electroshock (ECS) seizures on the last two days that an EK rat exhibited a Class 5 seizure or 3) a sham operation (electrode implanted unstimulated control). One day or 4 weeks after two successive Class 5 EK seizures, trios consisting of one EK rat, one ECS rat and one control rat were sacrificed and their brains frozen. Quantitative zinc:TS-Q fluorescence was measured in CA3 *stratum lucidum* in coronal sections of dorsal HPF and horizontal sections of ventral HPF.

Compared to control rats, mossy fiber zinc was reduced significantly in ventral but not dorsal HPF of ECS rats and in both dorsal and ventral HPF of EK rats 1 day after cessation of EK stimulations. The mossy fiber zinc reduction persisted in EK rats 4 weeks after EK stimulations. At this later time, mossy fiber zinc in the ECS group was not different from control.

The long lasting reduction in mossy fiber zinc in EK rats parallels the mossy fiber zinc reductions observed in kindling-induced spontaneously seizing rats as well as seizure-naive Genetically Epilepsy-Prone (GEPR-9) rats and alcohol withdrawal seizure prone (WSP) mice. This similarity in four different animal models of epilepsy suggests that a decrease in HPF mossy fiber zinc may be a contributing factor in the manifestation of a seizure prone state in genetically epileptic rodents and the persistence of enhanced seizure susceptibility in kindled rats.

452.15

DENTATE GRANULE CELL EVOKED RESPONSES DURING PROLONGED MAINTENANCE OF THE KINDLED STATE. L. J. Burdette, G. J. Hart* & L. M. Masukawa. Department of Neurology, Graduate Hospital, Philadelphia, PA 19146

Field responses recorded from dentate granule cells have been well characterized during the development of kindled seizures. To mimic more closely the human epileptic condition, we have extended these findings to observations following repeated generalized seizures. Rats were kindled by stimulation of the perforant path. Field responses were elicited by varying stimulus intensity, and by paired pulse and repetitive low frequency (.05 and 1 Hz) stimulation. Potentiation of the excitatory postsynaptic potential observed during kindling continued to increase during a 30 day rest, and did not change further once kindling stimulation was reinstated. The population spike was relatively unaffected throughout, except for an increase in threshold that was noted between 30-60 seizures. At this time, a second population response developed during repetitive low frequency stimulation. These secondary evoked potentials exhibit a latency of 80-120 ms following the triggered response, are intensity-dependent, and occur in the presence of significantly increased inhibition. The appearance of secondary responses has been noted reliably following a 48-72 hour seizure-free period, suggesting they are not immediate post-ictal sequelae. These results indicate that repetitive generalized seizures induce synchronous population discharges. It remains to be determined if these events ultimately contribute to seizure initiation.

453.1

PREFERENTIAL EXPRESSION OF SUPEROXIDE DISMUTASE GENE IN THE NEUROMELANIN-PIGMENTED NEURONS OF THE SUBSTANTIA NIGRA : IMPLICATIONS FOR PARKINSON'S DISEASE.

Zhang P.*, Ceballos* I(1), Hirsch E., Lafon M*., Sinet P. M*(1), Agid Y and F. Javoy-Agid.

INSERM U 289, Hôpital de la Salpêtrière 75013 PARIS, (1) URA CNRS 1335 - Laboratoire de Biochimie Génétique - Hôpital Necker Paris FRANCE

The dopaminergic neurons primarily affected in Parkinson's disease are the melanized neurons of the substantia nigra pars compacta. The involvement of oxygen free radicals has been considered as a potential cytotoxic cause of cell death. This lead to search for specific characteristics of toxic species defense system in these nigral neurons. Superoxide dismutase (SOD) which catalyses the conversion of superoxide radicals to hydrogen peroxide was examined.

The level of CuZn dependent SOD (CuZnSOD) gene expression was studied at cellular level in human mesencephalon post-mortem, by in situ hybridization using a 35-S-labelled cDNA probe homologous to human CuZnSOD mRNA. Labelled cells were densely distributed in the substantia nigra pars compacta, some cells were present in the ventral tegmental area. 95 % of the positively hybridized nigral cells were the large neuromelanin-containing cells, indicating CuZnSOD gene is preferentially expressed in the pigmented dopaminergic neurons. The high levels of CuZnSOD transcripts suggest the biochemical pathways leading to toxic oxygen species formation are active thus requiring a high CuZnSOD protein to facilitate removal of the toxic radicals. Alternatively, a high CuZnSOD activity might contribute to the neurodegenerative process itself.

The nigral melanized neurons represent a subset of dopaminergic cells with respect to their oxygen defense system. This may account for their preferential vulnerability in Parkinson's disease.

453.2

IRON LADEN NEURONS CHARACTERIZE SUBSTANTIA NIGRA RETICULATA AND GLOBUS PALLIDUS IN PARKINSON'S DISEASE. R. C. Switzer III and S. K. Campbell*. The R. H. Cole Neuroscience Lab., Dept. of Pathology, University of Tennessee Medical Center, Knoxville, TN 37920.

The identification of factors unique to the micro-environment of substantia nigra (SN) neurons in Parkinson's disease (PD) may provide valuable clues for understanding its etiology. One such factor may be iron since PD is one of a number of neurodegenerative diseases in which the areas principally affected form a subset of the iron-rich areas of the brain. Also, T2-weighted MRI shows differences in the iron-rich environment of SN in PD that suggest increased Fe or a change in its molecular matrix. In 14/14 cases of PD, 40u freeze-cut brain sections stained for ferric iron with the Perls method displayed a majority of the neurons as iron-positive (FeP) in the pars reticulata of SN and in both sectors of globus pallidus (GP). Neurons in other iron-rich areas did not display the cytoplasmic blue reaction product which had an appearance ranging from diffuse to densely packed granules. Some neurons contained both forms. The FeP neurons were clearly not ferruginated cells. FeP neurons were rare in age matched controls and cases of Alzheimer's disease. A preliminary examination of the compacta neurons with energy dispersive X-ray / EM shows that they also had anomalous iron. Two features distinguish the human SN from other species: 1) it has the highest concentration of iron, & 2) the compacta neurons share the iron-rich matrix of reticulata. Whatever the cause or defect, such excess iron poses a severe liability due to iron's capacity to generate cytotoxic free radicals. The examination of more cases will reveal if this phenomenon characterizes all PD cases or only a subset.

Supported by the Robert and Monica Cole Foundation.

CEREBRAL METABOLIC CHANGES DURING THE "ON-OFF" PHENOMENON IN PARKINSON' S DISEASE: A PET STUDY WITH APOMORPHINE. E. Broussolle*, P. Pollak*, L. Cinotti*, D. Le Bars*, G. Galy*, F. Lavenne*, C. Feuerstein*, F. Mauguière*, G. Chazot*. Dpt Neurology, Hôp. Antiquaille, Lyon; CERMEP, Hôp. Neurologique, Lyon; Dpt Clinic. & Biologic. Neurosci., CHU, Grenoble; France.

Long-term levodopa treatment of Parkinson' s disease (PD) provokes disabling motor fluctuations ("on-off" phenomenon). We measured regional cerebral glucose utilization during the "on" and the "off" motor phases by the (^{18}F)-fluorodeoxyglucose (FDG) method and positron emission tomography (PET) in 5 right-handed non-demented PD patients (4 males, 1 female; mean age ± SD: 60.2 ± 7.5 yrs; duration of disease: 12.2 ± 2.9 yrs; duration of "on-off" phenomenon: 4.1 ± 2.3 yrs). Patients had severe akinesia with no tremor during the "off" phase, and no or few dyskinesia during the "on" phase. Two PET scans were performed 48 hrs apart. Antiparkinsonian medications were discontinued the evening before each PET day. 15 min prior to FDG injection, patients (while in an "off" phase) received s.c. apomorphine (APO), a potent dopaminergic agonist, or the vehicle. The APO dosage (3-6.5 mg) was able to relieve akinesia within less than 15 min, and for a duration of about 1 hr. Patients were taking a peripheral dopaminergic antagonist, domperidone (60 mg/day orally), to block APO effects on cerebral blood vessels. Our results reveal that APO tends to reduce glucose utilization in the whole cerebral cortex (- 8.8 %; p = 0.08, NS; ANOVA) and in most of the 12 regions analyzed (- 5 to - 19 %; significant only in the temporal cortex, p = 0.05, and the cerebellar vermis, p < 0.01).

LEWY BODY NEUROFILAMENT EPITOPE ANALYSIS AND LOCALIZATION. W. D. Hill*, V. M.-Y. Lee*, H. I. Hurtig*, J. M. Murray*, and J. Q. Trojanowski. Dept. of Pathology and Laboratory Medicine, Univ. Pennsylvania Sch. of Med., Philadelphia, PA 19104.

Lewy bodies (LBs) are the pathological hallmark of Parkinson's disease (PD). This study sought to determine the extent to which each neurofilament (NF) subunit (L, M, and H) was present in LBs. A battery of 36 anti-NF antibodies, characterized as to subunit specificity and epitope domain, was employed to probe substantia nigral LBs from 15 PD cases. All 36 antibodies labelled LBs. The epitopes recognized by these antibodies included those in: the NF-L rod domain and C-terminus; the NF-M N-terminus, rod domain, sidearm, multiphosphorylation site (MPR), and C-terminus; and the NF-H rod domain and MPR site. The results showed that nearly the entire length of each subunit is present in LBs. Additionally, the staining pattern of the LBs suggested that the sidearms of NF-M and NF-H beyond the rod domain are altered or missing in the center of the LB core. In contrast, the N-terminus of NF-M, the C-terminus of NF-L, and the rod domain of all 3 subunits were present throughout the LB. Supported in part by AG09215 and AG05465.

STEP FORCE CHANGES IN PARKINSONIAN PATIENTS. F. Muller* and G.E. Stelmach. Motor Behavior Laboratory, University of Wisconsin, Madison, WI 53706.

Force production is an essential part of all motor acts. Previously, Parkinson's Disease patients (PD) have been shown to produce accurate isometric forces (Stelmach, G.E., Worringham, C.J., 1988), but with a higher variability (Stelmach, G.E., et al., 1989). Less interest had been shown for force termination problems in PDs. Eight PDs and eight age matched controls performed step changes of isometric pinch and elbow flexion forces. Starting from 30 % of maximum voluntary contraction level, the task was to increase, and/or decrease the force level by 15 and 30 % as fast and as accurately as possible.

The results showed that absolute peak force levels differed among and between groups. Reaction times indicated a slowing for force release compared to force increase tasks. The accuracy requirements affected finger and elbow joints differentially. Movement time showed a longer duration for release compared to complete release for groups and conditions, while the pinch force increase for normals was the same across pinch force amplitudes. For the pinch task, relative rate of force changes (first derivative) confirmed that the ability of force impulse scaling was impaired in PDs. The unusual accuracy requirements for elbow flexion, however, showed that normals and PDs adopted a movement time scaling strategy.

TEMPORAL-SPATIAL IRREGULARITIES IN PARKINSONIAN INDEX FINGER AGONIST/ANTAGONIST MUSCLE ACTIVITY. C.J. Hunker* and J.H. Abbs Dept. of Neurology, Speech and Motor Control Lab, Waiman Center, Univ. of Wisconsin, Madison, WI 53706.

Normal rapid, goal-directed limb movements are accomplished by regulating the intensity and timing of triphasic antagonistically acting muscles. A striking feature of Parkinson's disease (PD) is abnormally slow movements (**bradykinesia**). Temporal and amplitude scaling aberrations of triphasic muscle activity have been proposed as the pathological substrate for this clinical sign in the limbs. The intent of this study was to examine the pathophysiology of bradykinetic movements not typically mediated by the classical triphasic neural control strategy.

Index finger extension/flexion reversal movements of variable extent and intramuscular EMG activity from extensor digitorum, extensor indicis, and flexor digitorum superficialis muscles were recorded in PD and normal subjects. Movements about the MP joint (IP joints were splinted) were transduced using an electrogoniometer.

A linear relationship between peak velocity and movement amplitude was found in normals. In contrast, PD responses were variable; most were outside the normal 95% confidence interval. Phase plane discontinuities at various points along index finger extension trajectories characterized the bradykinetic movements, but could not be explained by gross EMG burst patterns. However, temporal-spatial irregularities in PD agonist/antagonist muscle activity may underly the abnormal phase plane relationships. (NIH Grant NS-132274)

ANTICIPATORY AND FEEDBACK POSTURAL RESPONSES IN PARKINSON'S DISEASE. •S.L. Glatt, M.E. Melnick, W. Koller, R. Hassanein*, J. Nash*, J. Redford*, G. Jayaraman*. Departments of Neurology, Physical Therapy, and Rehabilitation Medicine, University of Kansas Medical Center, Kansas City, KS 66103.

•The mechanism underlying postural instability in Parkinson's disease (PD) is poorly understood. Anticipatory postural responses precede or coincide with the planned action while subsequent corrections are feedback related. We studied the anticipatory postural response and feedback related response, by measuring the movement of the center of pressure (CP) with forward lifting of a 0.5 kg bar, in 37 PD patients; 16 stage 1 (PD1), 14 stage 2 (PD2) and 7 stage 3 (PD3) compared to 9 elderly (EC) and 15 young controls (YC). Maximal forward displacement, which reflects the deficit in anticipatory responses, was a mean for PD1 of 1.80 cm, PD2 1.96, PD3 2.91, EC 1.60 and YC 1.87. Average position of the CP, which is under feedback control, was for PD1 0.75, PD2 0.85, PD3 1.93, YC 1.19, and EC 0.75. There were differences ($p < .01$) between PD 3 and all other groups in the anticipatory responses and between PD3 and all except YC in the feedback response. Maximal mean CP position for PD3 (2.91 cm) was similar to the biomechanical calculation of CP for the barlift posture with arms outstretched (3.2 cm) without any compensatory responses. There was more impairment in anticipatory than feedback responses. We suggest that abnormalities in anticipatory postural responses are the cause of postural instability and falls in PD.

453.8

COGNITIVE AND MOTOR SEQUENCING IN PARKINSON'S DISEASE. W.W. Beatty and N. Monson*. Neuropsychiatric Research Institute, Fargo, ND 58107.

Previous reports indicate that patients with Parkinson's disease (PD) may have particular difficulty on tasks that require accurate sequencing in time or space. However, in all previous studies, the apparent sequencing deficit could also be attributed to impairment in memory, visual perception or motor function that occurs in PD.

In the present study we administered a very simple untimed test of cognitive sequencing (arranging pictures of highly familiar events in order) and a version of the Luria 3-step test of motor sequencing to 27 patients with idiopathic PD and 25 age-and education-matched normal controls. Both demented and nondemented PD patients displayed impairments on both sequencing measures. The extent of the patients' impairments in cognitive and motor sequencing were positively correlated, and the severity of deficits on both sequencing tasks was related to performance on the Wisconsin Card Sorting Test, but not to neurologic measures of disease severity. These results demonstrate the existence of a cognitive sequencing deficit in PD, and suggested that in PD both cognitive and motor sequencing difficulties may be related to dysfunction of circuits that involve the frontal lobes.

MOVEMENT SEQUENCING IN PARKINSON'S DISEASE. E. A. Roy, J. Saint-Cyr, A. Taylor & A. Lang*. Movement Disorders Clinic and Department of Psychology, Toronto Western Hospital, Toronto, Ontario, Canada M5T 2S8.

The purpose of this study was to examine movement sequencing in Parkinson's disease (PD). Fifteen PD patients and five age-matched normals were required to learn a sequence of 3 or 4 hand movements on a sequencing board. Each trial involved two phases, a perceptual phase in which pictures depicting the movements were present and, if the patient performed correctly, a memory phase in which he attempted to perform the sequence from memory without the aid of the pictures. The criterion for learning was 5 consecutive correct trials in the memory phase. Videotaped performance was examined in terms of trials to reach criterion, errors (sequencing errors and perseverations), total response time and its components, time for each response element and time between each response. There were no group differences in trials to criterion or errors, but marked differences in response timing were apparent. Total response time was significantly longer for the PD patients which was due to both increased time to make each response as well as increased interresponse times. The relative timing reflected in the proportion of the total time spent in each component of the sequence was also significantly different for the two groups. The implications of these findings for understanding the movement sequencing impairments in PD are discussed. (Supported by a grant from The Parkinson's Foundation of Canada.)

PLANNING AND SPATIAL WORKING MEMORY IN PARKINSON'S DISEASE. A.M.Owen*, M.Galton*, P.N.Leigh, C.D.Marsden*, N.Quinn*, B.J.Sahakian, B.Summers* & T.W.Robbins. Institutes of Psychiatry and Neurology, London, U.K. and Department of Experimental Psychology, University of Cambridge, Cambridge, U.K.

Groups of patients with idiopathic Parkinson's disease, either medicated or unmedicated, were compared with a large sample of normal controls on a computerised battery of tests designed to investigate the cognitive processes involved in 'planning'. In a series of problems based on the 'Tower of London' test, a group of medicated patients were shown to be impaired in the amount of time spent thinking about (planning) the solution to each problem. Additionally, an impairment in terms of the number of moves required to reach a solution on this test was only evident in those patients 'later in the course' of the disease and was accompanied by a deficit in associated tests of spatial working memory and spatial span. In contrast, a group of patients who were unmedicated and 'early in the course' of the disease were unimpaired in all respects compared to normal controls.

These data are compared to those from a group of young neuro-surgical patients with localised excisions of the frontal lobes and are discussed in terms of the progressive nature of the cognitive deficit in Parkinson's disease.

453.11

PARKINSON'S DISEASE AND FLUCTUATIONS IN LEVODOPA DO NOT IMPAIR EXPLICIT VISUAL LEARNING. J. Doyon, D. Côté*, A. Pelletier*, G. Brouillette*. Ecole de Psychologie, Université Laval, Ste-Foy, Qc, Canada, G1K 7P4.

Recognition tasks have shown to be very useful for studying memory functions in Parkinson's disease (PD) because they do not require the participation of the motor system. Such paradigm was employed in the present study to evaluate the effects of PD and of fluctuations in levels of levodopa on explicit visual learning. The performance of 10 non-demented PD patients, both during levodopa stimulated and unstimulated states (i.e., approximately 16 hours after the last drug intake) was compared to that of 10 matched healthy controls on the visual paired associates subtest of the Wechsler Memory Scale-Revised. A new version of this task was also created to eliminate any practice effect between the two testing sessions. These tasks were administered on separate days in a counterbalanced order. The results of the control subjects showed that the two versions of the visual learning task were equivalent. The performance of the parkinsonian patients on this task did not differ significantly from that of the controls. Furthermore, the decreased in the level of levodopa did not affect their learning ability, although it produced significant changes in their motor status. Thus, these results suggest that Parkinson's disease and variations in levels of levodopa do not impair explicit visual learning.

LOSS OF SELECTIVE MAO-B INHIBITION WITH LONG-TERM ADMINISTRATION OF L-DEPRENYL IN RODENTS: CROSSOVER TO MAO-A INHIBITION AND CLINICAL CONSIDERATIONS. I.A. Terleckyj, B.A. Sieber, and R.E. Heikkila. Dept. of Neurology, UMDNJ-Robert Wood Johnson Medical School, Piscataway, NJ 08854.

The preliminary evaluation of patients with Parkinson's Disease (PD) in the DATATOP study has shown that l-deprenyl (Selegiline), at a dose of 5-10 mg daily, has been efficacious in delaying the need for therapy with l-dopa. In rats and mice, single doses of 2 mg/kg of l-deprenyl selectively and completely inhibit the B form of monoamine oxidase (MAO), with no significant inhibition of MAO-A activity. However, in the present study with l-deprenyl and other selective, irreversible MAO-B inhibitors (MDL 72145, AGN 1133), the daily administration of clinically relevant doses (0.2 to 2.0 mg/kg) to mice and rats for up to 4 weeks led to a loss in selectivity of MAO-B inhibition, with extensive inhibition of MAO-A occurring in both the brain and periphery. Interestingly, when rodents were given 2 mg/kg of clorgyline, a highly selective MAO-A inhibitor, for the same length of time no crossover to B inhibition was seen. It is possible that long-term administration of l-deprenyl to PD patients also leads to MAO-A inhibition, raising the possibility that these patients may be susceptible to hypertension after ingesting foods containing tyramine (the cheese effect). This correlates with other work done in normal humans showing that daily doses of l-deprenyl increase the pressor effects to a tyramine challenge (Clin. Pharm. & Ther. 46: 1989). Moreover, l-deprenyl is extensively metabolized to l-methamphetamine and l-amphetamine, both of which act as CNS stimulants. All of these observations suggest that the effects of l-deprenyl may not be due solely to its inhibition of MAO-B activity.

(-)-DEPRENYL AND DOPAMINE TRANSMISSION: ELECTROPHYSIOLOGICAL RECORDINGS IN THE RAT CAUDATE NUCLEUS. I.A. Paterson, M.D. Berry and A.V. Juorio, Neuropsychiatric Research Unit, University of Saskatchewan, Saskatoon, Saskatchewan, S7N 0W0.

(-)-Deprenyl is a monoamine oxidase type B (MAO-B) inhibitor with antiparkinsonian actions. It has been postulated that (-)-deprenyl will exert its antiparkinsonian actions by inhibiting the oxidative deamination of dopamine (DA), thus potentiating DA neurotransmission. In the rat striatum, however, doses of (-)-deprenyl which specifically inhibit MAO-B do not affect DA catabolism but rapidly increase the levels of 2-phenylethylamine (PE) (Juorio & Paterson, (-)-Deprenyl and dopamine transmission: lack of effect on striatal dopamine metabolism, this meeting). Single-unit recordings of both spontaneously active and glutamate-driven cells were made in the dorsal caudate nucleus of urethane-anaesthetised male Wistar rats. Iontophoretic applications of R(-) apomorphine (a mixed D1/D2 agonist) and (±) PPHT (a D2 agonist) consistently inhibited the firing of caudate neurones. Iontophoretic and intra-arterial injection (30-100 μg/kg) of PE potentiated the neuronal responses to the DA agonists, reducing the IT_{50} of the responses. (-)-Deprenyl (2 mg/kg, i.p.) potentiated the neuronal responses to apomorphine and PPHT within 15-30 minutes of injection. Studies on the effects of (-)-deprenyl on neuronal responses to SKF-38393 (a D1 agonist) are in progress. These results demonstrate the (-)-deprenyl does potentiate DA transmission but suggest that it does so indirectly by increasing brain levels of PE, an amine which potentiates neuronal responses to DA and DA agonists.

453.14

(-)-DEPRENYL AND DOPAMINE TRANSMISSION: LACK OF EFFECT ON STRIATAL DOPAMINE METABOLISM. A.V. Juorio and I. A. Paterson, Neuropsychiatric Research Unit, M.R. Bldg, University of Saskatchewan, Saskatoon, Sask., Canada. S7N 0W0

(-)-Deprenyl is a specific monoamine oxidase type B (MAO-B) inhibitor which has been used as an adjuvant to L-DOPA therapy because it lowered the daily requirement for L-DOPA and its side effects. Recently, it has been shown that (-)-deprenyl delays the progression of Parkinson's disease in the earlier stages of the disease. It has been assumed that (-)-deprenyl acts mainly by inhibiting the oxidative deamination of dopamine (DA), however, acute administration of (-)-deprenyl does not affect DA metabolism. We propose that the acute action of (-)-deprenyl may involve 2-phenylethylamine (PE), a putative neuromodulator of DA transmission. PE may coexist with DA in the nigro-striatal projection as 6-hydroxydopamine lesions or electrical stimulation of the nigra alters its levels in the striatum. PE is not stored in reserpine-sensitive granules and is released by diffusion down a steady-state concentration gradient between the terminal and glial cells where it is metabolized by MAO-B. In rats, (-)-deprenyl (0.5-4 mg kg^{-1}, i.p.) does not change striatal levels of DA, DOPAC and HVA but increases PE levels (160-350 % of controls). The effects were observed within 1 hour after acute administration of (-)-deprenyl. In electrophysiological studies, (-)-deprenyl (2 mg kg^{-1}) potentiates caudate neurone responses to DA agonists, an effect that is similar to the actions of PE (Paterson et al., (-)-Deprenyl and dopamine transmission: electrophysiological recordings in rat caudate nucleus, this meeting). Taken together, it appears that (-)-deprenyl may increase brain PE levels, resulting in a potentiation of DA transmission.

L-DOPA ACCUMULATES SELECTIVELY IN THE DOPAMINE DEPLETED STRIATUM FOLLOWING CHRONIC TREATMENT. Robert J. Carey Department of Psychiatry SUNY and VA Medical Centers, Syracuse, NY 13210

Rats with unilateral 6-hydroxydopamine lesions were treated with L-DOPA (10 or 20 mg/kg IP) plus Carbidopa (1.0 or 2.0 mg/kg IP). The effects of L-DOPA on Dopamine and L-DOPA metabolism were assessed after acute and after chronic daily injections for up to 2-months. Acute L-DOPA injections induced dose dependent increases in L-DOPA and methyl DOPA in limbic and striatal tissues which were equivalent for the intact and dopamine deficient hemispheres. Parallel increases were found for the dopamine metabolites, DOPAC, HVA and 3MT. Chronic L-DOPA treatment induced a three-fold increase in L-DOPA in the dopamine denervated striatum as compared to the intact striatum. This three-fold increase was found for both the 10 and 20 mg/kg L-DOPA treatments. No differences were observed in terms of methyl DOPA levels between the intact vs. the dopamine depleted striatum. In limbic tissue, there were no differences between intact and dopamine depleted hemispheres in either L-DOPA or methyl DOPA levels. The finding of a selective accumulation of L-DOPA in the dopamine depeleted striatum would appear to have implications for the changes in clinical efficacy that occur with chronic L-DOPA treatment of Parkinson's disease.

IRREVERSIBLE INHIBITION OF DOPAMINE UPTAKE: A NOVEL TREATMENT FOR PARKINSON'S DISEASE. A. Jewell-Smith, S.T. Buxton and L.P. Dwoskin. Div. Pharm. Exp. Ther. Col. Pharmacy, Univ. Kentucky, Lexington, KY 40536.

Reuptake of dopamine (DA) into the presynaptic terminal is the primary means of DA removal from the synaptic cleft. Irreversible blockade of reuptake theoretically would produce a greater synaptic concentration of DA in the cleft upon neuronal firing. This novel approach to the therapeutics of Parkinson's disease may extend the period of normal function in these patients. We recently reported (Dwoskin, et al., Biochem. Pharm. 38: 549, 1989) that DSP4 irreversibly blocks the DA uptake site, indicated by a decreased density with no change in affinity of [3H]mazindol binding sites in rat striatal membranes and a decrease in [3H]DA accumulation by striatal slices. In the present study, in vitro exposure of slices to DSP4 resulted in a decrease in the field-stimulation evoked overflow of endogenous dihydroxyphenylacetic acid (DOPAC). The EC50 was 5 uM. Basal outflow of DOPAC was not altered, indicating a selective effect on evoked release. Therefore, after exposure to DSP4, the DA which was released may have been unable to enter the terminal to be metabolized to DOPAC. Alternatively, the DSP4-induced decrease in DOPAC may be due to a diminished release of DA, since DA was not detected in superfusate, unless nomifensine was present in the superfusion buffer. (Supported by NIH BRSG S07 RR05857-08).

N-0923, A SELECTIVE DOPAMINE D2 RECEPTOR AGONIST, IS EFFICACIOUS IN RAT AND MONKEY MODELS OF PARKINSON'S DISEASE. J.D. Belluzzi, E.F. Domino+, J.M. May* and D.A. McAfee, Whitby Research Inc., Irvine, CA 92715 and +Department of Pharmacology, University of Michigan, Ann Arbor, MI 48109.

Certain aminotetralins are known to be potent dopamine D2 receptor agonists (Horn, *Drugs of the Future*, **12**:220, 1987). N-0923, (-)2-(N-propyl-N-2-thienylethylamino)-5-hydroxy-tetralin, recognized the high and low affinity states of the D2 receptor in membranes from bovine caudate with a K_{low} = 79 nM. Selectivity was D2/D1 = 15 and D2/α_2 = 1.4. N-0923 inhibits dopamine uptake, prolactin secretion and the α_2 receptor.

N-0923 (3-300 nmol/kg, sc) induced dose-dependent contralateral turning behavior in rats with unilateral 6-OH-dopamine lesions of the substantia nigra. The ED_{50} of 30 nmol/kg was effective for 1 hr. The positive enantiomer (N-0924; 300 nmol/kg, sc) was without effect.

A hemiparkinsonian syndrome was induced in 4 *Macaca nemestrina* monkeys by unilateral infusion of the neurotoxin MPTP into the right carotid artery (Bankiewicz, *et al., Life Sci.* **39**:7, 1986). Video recordings of free-moving behavior revealed bradykinesia, disuse of the contralateral upper limb and ipsilateral turning behavior. N-0923 (3-300 nmol/kg, im) induced contralateral turning behavior, exploratory activity and contralateral limb usage. The ED_{50} for turning (30 nmol/kg) was effective for 0.5 hr. The potency order for induction of contralateral rotations was PHNO > N-0923 > bromocriptine. N-0924 (300 nmol/kg, im) was ineffective. We conclude that N-0923 may be useful as a therapeutic agent in the treatment of Parkinson's disease.

453.18

EFFECT OF ADDITION OF CY 208-243 TO CHRONIC BROMOCRIPTINE TREATMENT ON BRAIN DOPAMINE RECEPTORS IN MPTP MONKEYS. C. Gagnon[1], B. Gomez Mancilla[2], P.J. Bédard[2] and T. Di Paolo[1] [1]School of Pharmacy, Laval Univ. and Dept of Molecular Endocrinology, CHUL, Quebec G1V 4G2 and [2]Dept of Anatomy, Fac. Med. , Laval University, Quebec G1K 7P4, Canada

We have compared the effect of chronic treatment of MPTP monkeys with bromocriptine (BRC) (D-2 agonist) alone or in combination with CY 208-243 (D-1 agonist). D-1 and D-2 receptors were quantified by autoradiography of [^{3}H]-SCH 23390 (D-1 antagonist), [^{3}H]-spiperone (D-2 antagonist), [^{3}H]-SKF 38393 (D-1 agonist) and [^{3}H]-N-propylnorapomorphine (D-2 agonist) binding in the right striatum of these animals. Binding on homogenates (left striatum) was also performed for D-1 and D-2 antagonist sites. MPTP monkeys had a decrease of DA of more than 95% vs control as measured by HPLC. D-1 and D-2 antagonist as well as agonist sites were increased following MPTP. Both DA treatments decreased the supersensitivity of D-1 and D-2 antagonist and agonist sites. The affinity of the D-1 antagonist site was increased following both DA treatments compared to control and MPTP animals. The addition of CY 208-243 to the BRC treatment was without effect on D-1 and D-2 agonist and antagonist sites compared to the treatment with BRC alone. Changes in agonist and antagonist sites may explain behavioral recovery seen after both DA treatments. Supported by the Parkinson Foundation of Canada and the MRC.

GM1 GANGLIOSIDE PROMOTES RECOVERY FROM MPTP-INDUCED DAMAGE IN THE DOPAMINE SYSTEMS OF MONKEYS AND CATS AND IN CULTURES OF RAT DOPAMINE NEURONS. J.S. Schneider and L. Iacovitti. Dept. of Neurology, Hahnemann University School of Medicine, Philadelphia, PA. 19102.

In primates and cats, MPTP produces loss of ventral mesencephalic dopamine (DA) neurons (particularly in substantia nigra pars compacta, with relative sparing in other adjacent areas), loss of striatal DA, and some impairment in motor function. Cultures of dissociated embryonic rat (E15) mesencephalon, exposed to MPP+, also show loss of some DA neurons. Most surviving DA neurons have structural damage (shrunken cell bodies, short, fragmented processes). The present study examines the extent to which GM1 ganglioside treatment can reverse the effects of MPTP/MPP+ *in vivo* and *in vitro* and whether GM1 can protect cultured neurons from toxin-induced damage. In cats given 7 days of MPTP and made severely parkinsonian, GM1 treatment (30 mg/kg daily for 6 wks.) significantly increased DA and metabolite levels in the caudate nucleus (85% DA increase after GM1), however, these animals still had 95% loss of caudate DA. Cats which received less MPTP (3-5 days) had less severe dorsal striatal DA loss (90%), less severe damage to ventral mesencephalic DA neurons and had striatal DA levels brought closer to normal (only 75% depletion) with GM1 treatment. Similar results have been obtained with MPTP-treated squirrel monkeys. All GM1-treated monkeys had increased striatal DA levels, with the greatest increases in less severely affected animals. Pre-treatment of rat mesencephalon cultures with GM1 (50 uM) failed to protect against MPP+-induced damage. However, cultures treated with GM1 (50 uM, 24 hrs.) after MPP+ (10uM, 48 hrs.) looked healthier than control cultures and contained DA neurons with numerous finely beaded processes which made extensive plexuses. These results suggest that GM1 has definite reparative effects on injured dopamine neurons in relevant *in vivo* models and stimulates repair and sprouting in injured DA neurons in culture. Supported by the Amer. Parkinson's Dis. Assoc.

Effects of methamphetamine and MK-801 on dopamine in the striatum of awake rats as measured by in vivo brain microdialysis. F.B. Weihmuller, S.J. O'Dell, B.N. Cole*, and J.F. Marshall, Dept. of Psychobiology, University of California, Irvine, CA 92717.

Although the NMDA receptor antagonist MK-801 attenuates methamphetamine (MA)-induced striatal dopamine (DA) neurotoxicity, the mechanism underlying this protection is unknown. We used in vivo microdialysis in awake rats to determine the effects of MK-801 and MA on the levels of extracellular striatal DA (and metabolites) and behavior. A single injection of MA (6.25 mg/kg, sc) induced a prolonged increase (> 6 hrs) in extracellular DA (an 8-fold peak response), reduced DOPAC to 30% of basal levels, and increased sniffing, circling, and locomotion. Given alone, MK-801 (0.5 mg/kg, ip) also produced an increase in extracellular striatal DA (a 2-fold peak response, shorter in duration than that with MA), and increased sniffing and locomotion. In contrast to MA, MK-801 increased extracellular DOPAC and caused head-weaving and hindlimb ataxia. Pretreatment with MK-801 markedly attenuated the MA-induced DA increase and increased rather than decreased DOPAC. Despite its attenuation of MA-induced DA increases, MK-801 potentiated some components of MA-induced behaviors and increased their duration. These findings suggest that although MK-801 alone increases extracellular striatal DA, it reduces the MA-induced striatal DA overflow, which may help explain its attenuation of MA-induced dopaminergic terminal injury.

454.2

INTERACTIONS OF MK-801 WITH GLUTAMATE- AND METHAMPHETAMINE-EVOKED ^{3}H-DOPAMINE RELEASE FROM STRIATAL SLICE. J.F. Bowyer, R.R. Holson, S.F. Ali, and W. Slikker, Jr.* Div. of Reprod. & Develop. Tox., Natl. Ctr. for Tox. Res., Jefferson, AR 72079.

MK-801 effects on L-glutamate (GLU)- and methamphetamine (METH)-evoked release of ^{3}H-dopamine (DA) from striatal slices in untreated and rats treated with toxic doses of METH (5 mg/kg x 4 doses/at 2 hr intervals) were evaluated. Without Mg^{2+} present, 40 µM and 1 mM GLU evoked ^{3}H-DA released (5% or 14% of total ^{3}H-DA stores [TS] over 10 min, respectively) from striatal slices of untreated rats. GLU-evoked release was inhibited by MK-801>>PCP> (+)SKF 10,047. Two weeks after in vivo METH, GLU-evoked release (no Mg^{2+} present) was decreased. With 1.25 mM Mg^{2+} present, 10 mM GLU evoked a slight release of ^{3}H-DA (2.1% TS) which was increased to 4.2% TS when 10 µM nomifensine was present. Release with nomifensine present could be inhibited 35% by 5 µM MK-801. With or without 1.25 mM Mg^{2+}, 0.5 and 5 µM METH evoked a release of ^{3}H-DA (7% and 20% TS over 10 min, respectively) which was additive with GLU-evoked release. MK-801 (5µM) did not affect METH-evoked ^{3}H-DA release with or without Mg^{2+} present. These results indicate that MK-801 protection against METH toxicity is not via presynaptic inhibition of METH-evoked DA release. However, since presynaptic release of DA by METH and GLU is additive; MK-801 might reduce GLU-mediated DA release during METH exposure.

EFFECTS OF HIGH-DOSE METHAMPHETAMINE (MA) ON NOREPINEPHRINE (NE) & DOPAMINE (DA) UPTAKE SITES IN RAT BRAIN MEASURED BY QUANTITATIVE AUTORADIOGRAPHY. D.J. Brunswick, S.M. Tejani-Butt & M. Hauptmann*. Dept. Vet. Affairs Med. Ctr. & Univ. of Pa Sch. of Med., Phila., PA 19104.

It has been reported that high doses of MA cause neurotoxic effects on serotonin (5-HT) and DA neurons in brain. However, NE neurons have been thought to be spared from neurotoxic effects. In addition, the neurotoxic effect of MA on DA uptake sites have previously been examined only in striatum. We have examined the effects of MA on NE and DA uptake sites in rat brain by quantitative autoradiography using ^{3}H-nisoxetine (Tejani-Butt et al., this meeting) or ^{3}H-mazindol, respectively. Rats were treated with either MA (15mg/kg free base, n=10) or saline (n=6) given s.c. every 6 hrs for 5 doses and killed 7 days following the last dose. Areas examined were from brain slices taken at plates 30 and 57 of the atlas of Paxinos and Watson (1986) for NE uptake sites and plates 13 and 37 for DA uptake sites. MA caused significant reductions (17-33%) in NE binding in basolateral and lateral amygdaloid nuclei and dorsomedial hypothalamus. No reductions were seen in any other area, including locus coeruleus, a cell body area. DA uptake sites were decreased by 23-33% in DA terminal areas - caudate putamen, nucleus accumbens and olfactory tubercle; in contrast, they were unaffected in DA cell body areas - ventral tegmental area and substantia nigra. We have previously shown that MA is neurotoxic in 5-HT terminal areas, but not in 5-HT cell body areas (*Brain Res.*, 505:123, 1989). We conclude that 1) MA may be neurotoxic to NE neurons in specific brain areas, and 2) neurotoxicity is limited to terminal field areas for all three monoamines. **(Supported by research funds from the Department of Veterans Affairs & USPHS grant DA 05317).**

BIPHASIC RELEASE OF DOPAMINE (DA) FROM CORPUS STRIATUM (CS) IN VITRO AND ELEVATION OF AMINE NEUROTRANSMITTER METABOLITES IN CEREBROSPINAL FLUID (CSF) OF PUSH-PULL PERFUSED RATS BY AMMONIA. S.Kuhananthan, V.D.Ramirez and R.V.Barresi*. Dept. of Physiology, University of Illinois, Urbana, IL 61801.

Ammonium chloride (0.5-12mM) releases dopamine (DA) and DOPAC in a biphasic manner from fragments of rat CS (n=4). The first phase reaches plateau at 3mM, when the DA release (pg/mg/40min., mean±SEM) reaches 2340±238 and the second phase reaches plateau at 7.5mM, when the DA release reaches 5450±1870. The first phase was associated with a parallel increase in DOPAC and was inhibited by tetrodotoxin (DA release, 841±26), a sodium channel blocker and D-600 (DA release, 375±123), a calcium channel blocker, but not by nomifensine (DA release, 1621±181), a DA uptake blocker. The second phase (DA release; second plateau-first plateau = 3110±698) was not associated by an increase in DOPAC and occurred to a significant extent in the presence of D-600 (DA release, 2150±388). This phase was inhibited by nomifensine (DA release, 809±277), but not by tetrodotoxin (DA release, 5320±891). It is postulated that the first phase is due to selective abolition of IPSP, a known action of ammonia. The second phase may be due to leakage of cytoplasmic DA using the uptake carrier as reversal of transport, analogous to the action of amphetamine. Preliminary results show that intraperitoneal (i.p) injection of 30mg/kg NH_4Cl produces 20 fold elevation in the CSF concentrations of DOPAC and 5-HIAA, in push-pull perfused rats in the lateral ventricle. These high levels last for 2-3h and did not occur in control rats infused with i.p saline. Ammonia concentrations above 1mM are found in hepatic coma and the release of amine neurotransmitters may be responsible in the pathogenesis.

COMPARISON OF METHAMPHETAMINE-INDUCED NEUROTOXICITY IN VARIOUS STRAINS OF MICE K.J. Takacs, D.E. Vitagliano*, P.K. Sonsalla and R.E. Heikkila Dept. of Neurology, UMDNJ-Robert Wood Johnson Med. Sch., Piscataway, NJ 08854

Methamphetamine (METH) administered to mice in repeated high doses is selectively neurotoxic to dopaminergic neurons in the neostriatum. This neurotoxicity is dependent upon the METH-induced release of dopamine. The extent of damage caused by a given dose of METH, which is assessed by decrements in neostriatal dopamine content and tyrosine hydroxylase activity, varies among different strains of mice. For example, in the present study we found that CFW mice were substantially more sensitive to the neurotoxicity induced by METH than were C57bl mice; both strains came from Charles River Breeding Laboratories. A lesser but still significant difference was observed between two strains obtained from Jackson Laboratories; SWR/J mice were more sensitive to METH-induced neurotoxicity than were CBA/J mice. In experiments done with neostriatal tissue slices obtained from untreated mice of the four strains, there were no pronounced differences in the capacity of METH to cause dopamine release. Our laboratory previously demonstrated that MK-801, a non-competitive NMDA receptor antagonist, was able to attenuate METH-induced neurotoxicity, suggesting that glutamate plays a role in mediating the damage. Interestingly, the CBA/J mice are more sensitive than are the SWR/J mice to the stimulatory and lethal effects of the methylxanthines, which are adenosine receptor antagonists. These strains also have different numbers of adenosine receptors. It is possible that variations in the interactions between or among dopamine/glutamate/adenosine may contribute to the observed differences in METH-induced neurotoxicity.

ASSESSMENT OF RAT'S BEHAVIOR IN A RADIAL ARM MAZE DURING EXPOSURE TO MAGNETIC FIELDS. RH Lovely, JA Creim, DL Miller and LE Anderson. Battelle, Pacific Northwest Laboratory, Richland, WA 99352.

This study is to determine if the *in vitro* efflux of calcium ions from animal cortex, that results from exposure to ELF fields, is physiologically significant *in vivo*. Long term potentiation (LTP) and memory in the rat, when performing in a radial arm maze (RAM), have been shown to be casually dependent on movement of free calcium ions in animal cortex. Both effects rely on glutamate binding to the NMDA receptor which in turn causes conformational changes in the Ca^{2+} ion ionophore. The effects and the resulting Ca^{2+} ion current are necessary conditions for LTP and RAM memory in rats. We are assessing RAM performance in rats while they are exposed to ELF and dc magnetic fields (MFs). The exposure system produces uniform (+/- 5%) ELF and dc MFs (vertically and horizontally) within the RAM. The field strengths are a dc MF of 2.6×10^{-5} T (0.26 G) in combination with a 60-Hz MF of 5×10^{-5} T*rms* (0.5 G). Briefly, the RAM consists of eight equal length arms radiating out from a central arena with a door at the entrance and a food cup at the end of each arm. Twenty-four male Sprague Dawley rats were food deprived to 80%-85% of their free feeding weight and then individually assessed in the RAM daily. Twelve rats were exposed during the RAM assessments, while the other 12 rats were sham-exposed. Presently the study is ongoing, but preliminary analysis of errors/group using a repeated measures ANOVA approach significance ($p<0.086$), with the exposed group making more errors. This data, when combined with results of a similar previous study, indicate a significant increase in errors made by the exposed groups ($p<.015$). ROLE OF GANGLIOSIDES AND Ca^{2+}-DEPENDENT ENZYMES IN GLUTAMATE NEUROTOXICITY. H.Manev, A.Guidotti, R.Siman§, and E.Costa. FGIN, Georgetown University, Washington, D.C. 20007; §Cephalon, Inc., West Chester, PA 19380.

The delayed neuronal death, that ensues after abusive stimulation of glutamate receptors, is a Ca^{2+}-dependent process that can be prevented by increasing the neuronal membrane content of natural gangliosides (GM1, GT1b) or by the application of their synthetic derivatives (LIGA4, LIGA20) (J.Pharmacol.Exp.Ther.,1990,252:419). We studied, in primary cultures of rat cerebellar granule neurons, the influence of these sphingolipids on glutamate-induced: (a) activation of Ca^{2+}-dependent cysteine proteinase (calpain) by quantitative immunoblotting of spectrin proteolytic fragments, (b) membrane translocation of protein kinase C (PKC) by immunoblotting and 3H-phorbol ester binding, (c) neuronal death. Calpain activity was dependent on micro-molar concentrations of Ca^{2+} (calpain I) in neuronal, and on millimolar concentrations (calpain II) in glial cultures. Glutamate induced a dose-dependent activation of calpain I and a translocation of PKC only in neuronal cultures. These changes outlasted the removal of a toxic dose of glutamate from the culture and preceded neuronal death. Pretreatment with GM1 or LIGA4 prevented the translocation of PKC, the prolonged activation of calpain I, and neuronal death. In vitro experiments excluded a direct inhibitory action of sphingolipids on calpain I. The prolonged translocation of PKC may be operative in maintaining the increased calpain I activity elicited by neurotoxic doses of glutamate.

OPTIMIZATION OF CONDITIONS FOR SEPARATION OF TEN TRYPTOPHAN METABOLITES BY RP-HPLC. C-Z. Chuang (1,2), F.A. Ragan, Jr. (1,2) and C. Prasad (1,3) Lab. of Neurosciences (1), Pennington Biomedical Research Center; Departments of Pathology (2) and Medicine (3) (Endocrinology Section), LSU Medical Center, New Orleans, LA 70112.

Tryptophan (TRP) hydroxylase and TRP oxygenase (TO) are two major pathways of TRP metabolism in brain. The TO pathway yields many interesting neuroactive metabolites: quinolinic acid, kynurenic acid, kynurenine and 3-hydroxy-kynurenine. Studies into the presence and the roles of these and other potential TRP metabolites (anthranilic, 3-hydroxyanthranilic, xanthurenic, quinaldic, and picolinic acids) in brain are limited by our inability to measure low levels of multiple metabolites in a single biological sample. Therefore, a RP-HPLC method for the separation of ten TO metabolites has been developed by sequential optimization of mobile phase pH, triethylamine concentration and gradient elution. Resolution obtained is very good with an analysis time, including re-equilibration period, of less than 30 min. To our best knowledge this is the first RP-HPLC method that separates TRP and ten metabolites of TO pathway in a single chromatographic run.

TRIMETHYLTIN VERSUS KAINIC ACID TOXICITY: DIFFERENTIAL SELECTIVITY OF DEGENERATION WITHIN CA1 REGION OF THE RAT HIPPOCAMPUS. S. Mennerick, D. Lutz, R.L. Dean, and R.T. Bartus, CORTEX Pharmaceuticals, Inc., Irvine, CA 92718

Kainic acid (KA) and trimethyltin (TMT) are two neurotoxins that apparently work through different mechanisms, yet share the feature of being relatively selective at low doses for hippocampal CA3 neurons. At higher doses both toxins recruit other hippocampal neurons as well as cells in other limbic associated structures. However, we report here that in the rat, using a silver stain (selectively staining degenerating neurons), at doses high enough and at time points long enough to demonstrate damage in the hippocampal CA1 subfield, a subtle difference emerges in the neuropathology induced by each toxin. While administration of KA (ICV and intrahippocampal infusions) at moderate doses recruits neurons clearly localized to the stratum pyramidale of CA1, systemically administered TMT effects are localized to cells bordering on CA1 stratum oriens. At higher doses this selective effect is lost and cells within stratum pyramidale are recruited by TMT and cells in the oriens are recruited by KA.

While the KA effect on CA1 pyramidal cells has been discussed at length previously, this is the first discussion of the preferential vulnerability to TMT toxicity of cells residing on the oriens border of the CA1 pyramidal cell layer. Rostral to caudal and medial to lateral gradients of the selectivity of the TMT effect in CA1 are discussed as well as morphological aspects of argyrophilic cells in CA1. The differences in selectivity between the two toxins are discussed with respect to possible mechanisms of TMT and KA toxicity toward hippocampal CA1 neurons.

IS TAURINE INVOLVED IN THE PATHOGENESIS OF HEPATIC ENCEPHALOPATHY? S.S. Oja, P. Saransaari and U. Wysmyk*. Tampere Brain Research Center, Department of Biomedical Sciences, University of Tampere, Box 607, SF-33101 Tampere, Finland, and Medical Research Centre, Polish Academy of Sciences, 00-784 Warsaw, Poland.

The possible role of taurine in hepatic encephalopathy (HE) was studied with rats injected with thioacetamide (TAA). The spontaneous release of exogenous labeled taurine from superfused tissue slices was not affected in any brain area studied but the potassium-stimulated release was significantly enhanced in the striatum. An exposure of striatal slices to ammonium ions in vitro induced concentration-dependently taurine release. In this respect ammonium ions were more effective than potassium ions. The ammonium ion stimulation was also attenuated in the presence of depolarizing concentrations of potassium ions. In striatal slices the ammonium-stimulated release of taurine was more pronounced in TAA-treated than control animals. The greater potassium and ammonium stimulation of taurine release from striatal slices in TAA-treated rats suggests that taurine may participate in the pathogenesis of HE. Supported by the Polish Academy of Sciences and the Emil Aaltonen Foundation, Finland.

NEUROTOXIC EFFECTS OF CYCASIN ON MURINE CORTICAL ORGANOTYPIC CULTURES. G.E. Kisby, B.G. Gold, and P.S. Spencer. Center for Research on Occupational and Environmental Toxicology, Oregon Health Sci. Univ., Portland, OR 97201.

Cycasin and its aglycone methylazoxymethanol (MAM) are under study as etiological candidates of a prototypical human neurodegenerative disorder with features of amyotrophic lateral sclerosis, Parkinsonism and Alzheimer's disease. Cycasin was isolated from frozen *Cycas circinalis*, L. seed kernels (Guam) and purity established using UV, TLC and HPLC. Murine cortical explant cultures were grown *in vitro* for 2 weeks and treated every other day for 5 days with 50 µM sucrose (control; minor contaminant of crude cycasin) or 10 µM crude cycasin. A majority of cycasin (83 %) and low levels of MAM (<1%) were detected by HPLC in media from cultures treated for 5 days. Thick (1 µm) and thin sections of explants were examined by light and electron microscopy at 1-5 days.

At 1 day, some cell bodies demonstrated vacuolated cytoplasm by light microscopy. By day 3, neuronal cell body necrosis was prominent and extensive vacuolation was observed in the neuropil. Vacules were markedly increased in size at 5 days. Ultrastructrually, these vacuoles consisted of swollen dendritic processes, sometimes associated with recognizable synaptic terminals. Large vacuoles appeared to form from fusion of neighboring swollen processes. Nerve cell bodies also showed marked abnormalities, including patches of dense nuclear chromatin, aggregated ribosomes, swollen mitochondria, and a vacuolated cytoplasm. Stacks of swirled membranes, which appeared to represent disorganized rough endoplasmic reticulum, were found in some neuronal cell bodies.

These observations provide direct evidence that crude cycasin, either directly or via a metabolite, has neurotoxic potential. Based upon the pattern of neuronal damage, the responsible agent might elicit neuronal damage via an excitotoxic mechanism. [Supported by NIH 19611]

455.2

THE NEUROTOXIC EFFECT OF BMAA ON MOTOR NEURONS MAY BE MEDIATED BY ANDROGEN-DEPENDENT CELLULAR FUNCTION. R.C.Yu, R.Hiipakka* and B.G.W.Arnason. Dept. of Neurology and Ben May Lab., University of Chicago, Chicago, Il 60637.

The high incidence of amyotrophic lateral sclerosis(ALS) among the indigenous people of the Marianas Islands, whose diet contained cycads, is linked to the neurotoxic amino acid β-N-methylamino-alanine(L-BMAA), isolated from cycads seeds. Synthetic BMAA induces neuronal injury in culture and causes cynomolgus monkeys to develop neuro-pathological syndromes that closely resemble ALS(extrapyramidal disorders). The molecular mechanism underlying the specific vulnerability of motor neurons(MN) to BMAA remains unknown. MN contain a high level of androgen receptors(AR) and the topographic distribution of AR in the cranial MN of rats correlates with susceptability to the disease. To examine the possible role of AR in the etiology of ALS we studied the effect of BMAA on AR. Rat prostate tissue or a human prostate adenocarcinoma cell line (LNCaP) were exposed to 10^{-4} to 10^{-6} M BMAA for 0.5 to 18 hr. L-β-Oxalyl-α,β-diaminopropionic acid (L-BOAA), (a isomer derived from the Lathyrus plant known to cause cortical disorders) was used as control. We find that BMAA, but not BOAA, interferes with androgen-dependent cell function and its effect is dose-dependent. A 30 min exposure to 10^{-4} M BMAA reduces AR levels in the nuclear fraction of rat prostate tissue by 23%. An 18 hr. exposure to 3 mM BMAA reduces the amount of AR by more than 20% in both nuclear and cytosol fractions of LNCaP cells. This notion of a role for AR in the etiology of ALS is further strengthened by our earlier findings that cyproterone (an androgen antagonist) can significantly reduce the choline acetyltransferase level in spinal cord. Our results suggest a mechanism whereby a common factor can kill the MN in certain regions but spare others within the same CNS; similar mechanisms may be operative in other neuro-degenerative diseases.

455.3

PROCESSED CYCAD FLOUR EXTRACT NEUROTOXICITY IN NEURONAL CELL CULTURE. M.W. Duncan, A.M. Marini, S.P. Markey†* and I.J. Kopin. CNB, NINDS, NIH, & †SAB, NIMH, Bethesda, MD 20814.

A link between cycads and a variant of amyotrophic lateral sclerosis (ALS) in the western Pacific has been suggested. Therefore, we have tested extracts of female gametophyte tissue from *C. circinalis, C. revoluta* and *C. media*, as well as cycad flour, for neurotoxicity using cultured cerebellar granule cells and cultured mesencephalic cells. Neither seed extracts nor 13 of the 17 processed flour samples were significantly more toxic than wheat flour. However, 4 of 17 processed cycad flour extracts exhibited marked neurotoxicity. Analysis of these extracts for the neurotoxin 2-amino-3-(methylamino)-L-propanoic acid (BMAA) indicated that there was no correlation between toxicity and BMAA content, and the BMAA concentrations in the medium were far below those required to kill cultured neurons. In addition, MK-801 did not protect against the neurotoxicity, indicating this response was not mediated via the N-methyl-D-aspartate (NMDA) receptor. The toxic principle could not be extracted into an organic solvent at acidic, basic or neutral pH and was heat and acid stable. All 4 toxic samples were subsequently found to have high content of zinc and this metal was shown to be responsible for the neurotoxicity. We conclude that cycad extracts are not significantly more toxic to cultured neurons than is wheat flour, and that the marked neurotoxicity of 4/17 processed cycad flour samples derived from *C. circinalis* was mediated via zinc. These findings may link zinc to ALS on Guam, perhaps by exacerbating a long-term imbalance in essential trace minerals, or by the direct neurotoxic actions of zinc itself.

ESTROGEN-LIKE EFFECTS OF THE ORGANOCHLORINE INSECTICIDE CHLORDECONE ON LORDOSIS BEHAVIOR. H. Brown* and L. Uphouse. Dept. of Biology, Texas Woman's Univ., Denton, TX, 76204.

The organochlorine pesticide chlordecone acts similarly to estrogens at the chick oviduct: chlordecone binds to oviductal estrogen receptors, induces mRNAs for the proteins ovalbumin and conalbumin, induces the proteins themselves and their secretory apparatus, and initiates oviductal growth. In contrast, estrogen-like effects of chlordecone in neural tissues are understood less thoroughly. For example, chlordecone treatment (50 mg/kg ip), when combined with treatment with 0.5 mg progesterone (P) sc, failed to substitute for estradiol in priming for the lordosis response (Uphouse, L., et al., NeuroToxicology 7: 127, 1986), a behavior known to require estrogen action in the brain. Recently, we reassessed chlordecone's capacity to prime for the lordosis reflex in response to male mounting behavior by giving ovariectomized rats a single injection of 50 mg/kg chlordecone ip followed 44 or 67 hr later by injection of 2 mg P im. When observed 5 to 6 h or 9 to 13 h after P treatment, these rats showed mean ± SE lordosis quotients of 57.9 ± 11.9 and 88.5 ± 5.1. The priming effect of chlordecone was antagonized markedly by injections of 2 mg nafoxidine ip at -24 h and at +24 h relative to the chlordecone injection. Chlordecone bound (K_i = 8 x 10^{-8} M) to cytosolic estrogen receptors from neural areas implicated in the control of lordosis behavior; the collective evidence indicates that chlordecone substitutes for estrogen in priming for the lordosis response of ovariectomized rats, and that the pesticides's effects on lordosis behavior are mediated by neural estrogen receptors.

THE MECHANISM AND DYNAMIC PATTERN OF SOMAN INDUCED BRAIN HISTOPATHOLOGY - A MORPHOMETRIC STUDY. S. Shapira and T. Kadar*, Dep. Pharmacology, IIBR, Ness-Ziona 70450, ISRAEL.

Soman, a highly toxic cholinesterase (ChE) inhibitor, causes chronic brain lesions through a yet unknown mechanism. The present study was designed to clarify the mechanism leading to soman induced brain lesions by comparing them to the effect of either a non-ChE inhibitor convulsant (metrazol) or another toxic ChE inhibitor (DFP) in equipotent (1LD50) doses. Following administration, surviving rats were sacrificed at various time intervals and their brains evaluated by histological and morphometric analysis. All three substances produced severe toxic signs, including convulsions. Soman and DFP also generated signs of cholinergic hyperactivity. Soman injected rats developed CNS lesions already 24 hr after administration, mainly in the hippocampus, frontal and pyriform cortex and thalamus. In three months these lesions have spread to areas which were not involved initially. Morphometric analysis revealed the dynamic pattern of the lesions. No morphological changes were noted in any of the metrazol or DFP injected rats. These findings strongly suggest that soman induced CNS lesions are caused by a direct effect of soman on specific brain areas, and not by convulsions per-se or by ChE inhibition per-se.

EFFECTS OF THREE REPUTED CARBOXYLESTERASE INHIBITORS UPON RAT SERUM ESTERASE ACTIVITY J.P. Chambers[1], S.L. Hartgraves[2], M.R. Murphy[2] and J.J. Valdes[3]. [1]The University of Texas at San Antonio, San Antonio, TX 78285, [2]Radiation Sciences Division, USAF School of Aerospace Medicine, Brooks AFB, TX 78235 and [3]U.S.Army Chemical Research Development and Engineering Center, Biotechnology Division, Aberdeen Proving Ground, MD 21010.

Rats have very high endogenous levels of serum carboxylesterase (CAE) which accounts for the lower sensitivity of rats to toxic organophosphates. In this study, the effects of three reputed CAE inhibitors, 2-(o-Cresyl)-4H-1:3:2-benzodioxaphosphorin-2-oxide (CBDP), bis-p-nitrophenyl-phosphate (BNPP), and tetraisopropyl pyrophosphoramide (Iso-OMPA) on the hydrolysis of several substrates were determined. Respective kinetic constants 'K_m apparent and V_{max}' were derived and inhibitory effects compared using saturating amounts of substrate. Using slab polyacrylamide gel electrophoresis and densitometric scanning, the effects of these inhibitors upon hydrolysis of various substrates by rat serum esterases were monitored and quantitated.

455.7

THE USE OF CARBOXYLESTERASE INHIBITORS TO DEVELOP AN IMPROVED RODENT MODEL OF SOMAN TOXICITY. M.R. Murphy, S.Z. Kerenyi, S.A. Miller, J.P. Chambers, R.F. Noonan[1], and S.L. Hartgraves. USAF School of Aerospace Med., and [1]Systems Research Laboratories, Brooks AFB, TX 78235.

Carboxylesterases (CaE) (aka aliesterases) are non-specific B-esterases of unknown function, except possibly the detoxification of xenobiotics. Because of the rat's high natural level of serum CaE, this species is much less sensitive, relative to primates, to highly toxic organophosphate anticholinesterases such as soman. The purpose of our work was to develop the CaE-inhibited rat as an improved (i.e., more primate like) model of soman toxicity.

We report the results of studies on (1) a comparison of the CaE inhibitors (CaEIs): CBDP, iso-OMPA, and BNPP; (2) the time course of CaE recovery following CaEI administration; (3) the effects of pyridostigmine, physostigmine, and soman on CaE levels; (4) the effects of CaEIs on: brain cholinesterase (ChE), serum ChE, and spontaneous activity; (5) the 7-day chronic inhibition of CaE; and (6) the toxicity of CaEIs.

Research was supported by the USNMRDC.

SOMAN TOXIC SYNDROME (STS). S.A. Miller[1*], M.R. Murphy[1], S.Z. Kerenyi[1*], D.L. Armstrong[3], R.C. Switzer III[2], D.W. Blick[2], S.L. Hartgraves[1]. [1]Radiat. Sci. Div., USAF Sch. Aerosp. Med., and [2]Systems Research Laboratories, Brooks AFB, TX 78235, [3]UTSA.

STS is a soman-induced disorder characterized by extensive, but localized, brain damage and hyperreactivity. In this study, we further examine the nature of this syndrome. In addition to a normal control group (CON), a weight loss control (WLC) group was included to approximate the severe weight loss and subsequent recovery of the STS group. Animals developing STS received extra care (e.g., special diet, dextrose injections, and bedding material). WLC animals were treated similarly.

STS animals displayed hyperreactivity to stimuli in a two-way shuttlebox, but learning was unaffected. However, STS animals did exhibit a loss of long term potentiation in the in vivo hippocampus. In automated activity monitors, STS rats habituated rapidly to the novel environment and exhibited less total exploratory behavior. When given 1.5 mg/kg d-amphetamine, STS animals showed a much more dramatic increase in activity than did WLC animals (Hartgraves *et al.*, these proceedings).

455.9

EFFECTS OF STIMULANTS ON LOCOMOTOR ACTIVITY IN RATS WITH SOMAN TOXIC SYNDROME (STS). S. L. Hartgraves, M. S. Tristan*, S. Z. Kerenyi*, S. A. Miller*, and M. R. Murphy. USAF School of Aerospace Medicine, Brooks AFB, Texas, 78235-5301; University of Texas Health Sciences Center, San Antonio, Texas, 78284.

Soman Toxic Syndrome (STS) is a soman-induced, seizure-related syndrome characterized by extensive, but localized, brain damage, hyperreactivity to physical stimuli, and general hypoactivity (see abstract by S. A. Miller, et al., this conference). The objective of this research is to further analyze the locomotor behavior (measured in automated activity monitors) of STS animals by administering stimulant drugs.

STS animals respond to d-Amph (1.5 mg/kg, s.c.) with 3-fold increases in distance traveled and rearing compared to weight loss controls (WLC). STS animals also show over 20-fold increases in these same parameters compared to their responses to saline injections, whereas WLC animals show only 3-fold increases in distance traveled and rearing (d-Amph vs saline, crossover).

We report here a comparison of STS dose-response curves for d-Amph and for caffeine, a stimulant that enhances locomotor activity independently of the nucleus accumbens (which is closely associated with d-Amph-induced locomotor activity).

455.10

REGENERATION OF ACETYLCHOLINESTERASE IN THE CLONAL NEUROBLASTOMA-GLIOMA HYBRID NG108-15 CELL LINE AFTER SOMAN INHIBITION: EFFECT OF GLYCYL-L-GLUTAMINE. J.J. Yourick, P.A. Eklo, M.P. McCluskey and R. Ray. US Army Medical Research Institute of Chemical Defense, Aberdeen Proving Ground, MD. 21010-5425.

Acetylcholinesterase (AChE) in the clonal NG108-15 cell line has been previously characterized. This cell line may represent a model system in which to study AChE regulation and effects of chemical compounds that may alter AChE activity (Ray et al., Soc. Neurosci. Abstr., 12:889, 1986). Recently, it was shown that glycyl-L-glutamine (GLG) may function as a neurotrophic factor for maintenance of AChE content in denervated superior cervical ganglion of the cat (Koelle et al., 1988). Studies were conducted in undifferentiated NG108-15 cells to characterize the regeneration (de novo synthesis) of AChE activity after soman inhibition. In addition, the effect of GLG on AChE regeneration after soman treatment was investigated. Cells were grown to confluence, treated with soman (10^{-6} M) for 15 min and washed to remove excess soman. GLG (10^{-6}, 10^{-5} or 10^{-4} M), glycyl-L-glutamic acid (10^{-6} M) or vehicle was added to the culture medium immediately after soman treatment and remained in the medium until cell harvest. Cells were harvested at 1, 3, 5, 12, 20, and 24 hours after soman treatment and specific AChE activity was determined. After soman, AChE activity dramatically decreased to less than 1% of control activity at 1 hr. The regeneration of AChE activity gradually increased at 5 (7%), 12 (14%) and 20 (85%) hours, while complete AChE activity was regained 24 hr after soman. GLG and glycyl-L-glutamic acid, at all concentrations tested, did not increase the rate of AChE de novo synthesis after soman inhibition. These studies have characterized AChE regeneration after soman inhibition in the NG108-15 cell line for potential use as a model system to study compounds that alter AChE activity. In this model system, GLG and glycyl-L-glutamic acid failed to act as a neurotrophic factor for AChE synthesis.

HYPERAMMONEMIA, IN THE ABSENCE OF GLUTAMINE SYNTHESIS, DOES NOT ALTER BRAIN FUNCTION. J.Jessy*, M.R.DeJoseph* & R.A.Hawkins. Dept. of Physiology and Biophysics, University of Health Sciences / The Chicago Medical School, North Chicago, IL 60064.

Portacaval shunted rats show many of the typical metabolic alterations found in humans with hepatic encephalopathy. Most of the characteristic changes are established within 24-48 h after surgery and include: raised plasma and brain ammonia, depressed brain function and increased transport of neutral amino acids across the blood-brain barrier. Ammonia is suspected to be an important etiologic factor. An earlier study from this laboratory showed that hyperammonemia caused most of the changes found after shunting, and that the depression of cerebral function was more closely correlated to glutamine, a metabolite of ammonia, rather than ammonia itself. The present experiments were designed to address the question whether ammonia alone, in the absence of net glutamine synthesis in brain, could be responsible for cerebral dysfunction. Plasma ammonia levels in normal rats were raised to values similar to those found after portacaval shunting by the administration of small doses of methionine sulfoximine, an inhibitor of glutamine synthetase. Cerebral energy metabolism in methionine sulfoximine-treated rats remained unaltered. There was no depression in brain glucose consumption. Key intermediary metabolites and high energy phosphates were normal and neutral amino acid transport (tryptophan and leucine) was unchanged. These results indicate that hyperammonemia, when not accompanied by net glutamine synthesis in the astrocytes, does not result in cerebral dysfunction. (Supported by NS16389 and NS 16737).

455.12

PURIFICATION OF ARYLAMINE N-ACETYLTRANSFERASE FROM RAT BRAIN. S.Gaudet, M.Palkovits*, and M.A.A.Namboodiri, Dept. of Biol. Georgetown University, Washington, D.C. 20057,*Lab. Cell Biol.NIMH, NIH, Bethesda, Md. 20892.

The brain arylamine N-acetyltransferase (NAT) activity is about 10-fold higher than the arylalkylamine NAT present in the same tissue. The function and regulation of the arylamine NAT is not known at this time. Recent molecular cloning studies indicate that multiple arylamine NATs, based on their substrate specificity, may exist in different tissues. In the present study, we have investigated the above possibility with respect to rat brain.

Arylamine NAT activity was assayed in micropunch samples, using p-phenetidine as the amine substrate, and was found to be evenly distributed in different areas of the brain. The enzyme activity was purified via a three step procedure involving $(NH_4)_2SO_4$ precipitation, affinity chromatography using methotrexate, and finally, size exclusion HPLC. Analysis of the final preparation using SDS-PAGE showed one major band (Mr=30K) and a few minor bands. The Mr of the native enzyme was found to be approximately 31K. Substrate specificity studies indicate that the enzyme is an arylamine NAT, with only 1-2% activity towards arylalkylamines (i.e. tryptamine). The remarkably high specificity of this enzyme towards arylamines indicates that the brain enzyme may differ from that found in liver. (Supported by NIH grant, DK 37024 to MAAN).

INCREASED RESISTANCE TO CHRONIC ORAL 3-NITROPROPIONIC ACID [3NPA] NEUROTOXICITY IN AGED MICE: EM AND HISTOCHEMICAL STUDIES. Y.D. Tan*, T. Bohlmann*, G.S. Nizamuddin*, F.S. Chu*, R.L. Sufit, B.R. Brooks and H.S. Schutta Neuro. Svc., Wm. S. Middleton VA Hosp. and Neuro. Dept., Univ. Wisconsin Sch. of Med., Madison, WI 53792

Chronic ingestion of the nitroaliphatic neurotoxin 3NPA, a suicide inhibitor of SDH, results in intraneuronal glycogen accumulation in the spinal cord in young mice. The acute single dose LD_{50} was identical in young [221 mg/kg; 95% confidence limits: 166-295] and old [205 mg/kg; 169-249] mice. Following daily gavage feedings, the chronic LD_{50} was significantly [$p<0.04$] higher in old [138 mg/kg; 133-144] compared with young [49 mg/kg; 47-51] mice. Succinic dehydrogenase [SDH] activity was decreased at 10 min but was absent at 30 min post 3NPA. Spinal cord intraneuronal glycogen accumulation was not seen in mice acutely fed 2.5 LD_{50} but was present following chronic feeding of 0.2 or 0.4 LD_{50} 3NPA. Aged mice demonstrated no increased resistance to acute toxic effects of 3NPA on spinal cord neurons but could withstand almost a 3-fold increase in the dose of chronically administered 3NPA. [Supported by MDA Midwest Regional ALS Research and Treatment Program grant and an MDA Research Fellowship grant].

SEX-RELATED DIFFERENCES IN TRIMETHYLOLPROPANE PHOSPHATE NEUROTOXICITY AND PHARMACOKINETICS. J. Rossi III, V.J. Forrest* and J. Gearhart*. Naval Medical Research Institute, Toxicology Detachment, Wright-Patterson Air Force Base, Ohio 45433 and NSI Technology Services Corporation, Dayton, Ohio 45431.

Thermal decomposition of trimethylolpropane-based compounds which contain fire retardant triarylphophate additives allows formation of neurotoxic trimethylolpropane phosphate (TMP-P), a caged convulsant believed to act via GABAergic receptor antagonism.

The effect of sex-related differences after dermally applied TMP-P was evaluated in rats (Fisher 344) with hormonally-altered sex phenotypes and in castrated adult rats with and without hormonal supplementation. Auditory startle was found to be greater in males than females after a sublethal dose of TMP-P (30 mg/kg). Additionally, males exhibited shorter times to convulsion and death than females after a lethal dose (120 mg/kg). Female rats dermally exposed to TMP-P exhibited greater tissue/blood partition coefficients than males. Phenotypically and surgically unaltered animals exposed to TMP-P or the solvent vehicle served as the positive and negative controls, respectively.

A physiologically based pharmacokinetic (PBPK) model was developed to describe the kinetics of TMP-P. The steady state partition coefficients of TMP-P in tissues and urinary excretion rate, determined in subcutaneously dosed animals, was used in the PBPK model to estimate the in vivo metabolism of TMP-P and to simulate the blood and tissue kinetics. The PBPK model was then used to derive a permeability rate constant for TMP-P transfer across rat skin and to explain the effects of tissue/blood partitions on brain levels of TMP-P.

NA-K ATPASE DECREASES IN THE BRAIN IN DIABETES. S.F.Leong. Physiology Dept., Natl. Univ. of Singapore, Kent Ridge, Singapore 0511.

The use of streptozotocin in animal models has shown to develop abnormalities in the nerve similar to those observed in diabetes. Reduced Na-K ATPase activity is often reported for the peripheral nervous system. This study establishes the Na-K ATPase in the regions of the brain during diabetes. Streptozotocin (60mg/kg body wt) was injected i.p. into male Wistar rats (250-300g) and housed for 7 days ad libitum. All animals were checked for diabetes before use. Reduced Na-K ATPase was observed in brain from diabetic animals. All regions showed significant reduction ranging from 31% in the hippocampus to 6% in the striatum and the brain stem. In contrast, a neurotransmitter marker enzyme, acetylcholinesterase, showed that most regions did not show significant changes in the diabetic brain for acetylcholine metabolism. These results showed that diabetes which produces hyperglycaemia not only commonly present reduced Na-K ATPase activity in the peripheral nervous system but also in the central nervous system. Such reduction in the brain, however, are not known widely to show degenerative effects seen in the peripheral nervous system.

NEUROTOXICITY FROM DIRECT CURRENT STIMULATION. R.J. Hurlbert, E. Theriault, C.H. Tator. Playfair Neuroscience Unit, University of Toronto, 399 Bathurst St., Toronto, CANADA M5T 2S8

The effect of continuous direct current stimulation on the normal adult rat spinal cord was assessed over a variety of intensities in 32 animals. Platinum/iridium stimulating electrodes of 2 sq.mm. surface area were implanted 10 mm. apart in an epidural fashion at T1/2, with battery packs buried subcutaneously at the incision. Stimulator intensities ranged from 0 to 18 uA. The animals were allowed to survive for a period of 2-12 weeks undergoing twice weekly inclined plane testing. Following this the spinal cords were harvested, sectioned at 8 um, and stained with Luxol Fast Blue and Hematoxylin and Eosin. Grossly, pathological changes such as discoloration and cavitation were seen under the anode after 3 weeks, with intensities as low as 3 uA. Inclined plane testing was sensitive only to the 18 uA induced changes. These results demonstrate the low tolerance of mammalian CNS tissue to DC stimulation and have implications for continued studies into its therapeutic usefulness.

455.17

NEUTRON/GAMMA IRRADIATION PRODUCES DIFFERENTIAL LOCOMOTOR DECREMENTS IN ISOLATED AND GROUP HOUSED MICE. H.D. Davis, M. Miernicki, M.E. Faccioli, and M.R. Landauer. Behavioral Sciences Department, Armed Forces Radiobiology Research Institute, Bethesda, MD 20814-5145.

Male CD2F1 mice that were either isolated for 5 days or group housed (10/cage) were exposed to 5 Gy of radiation at 1 Gy/min (neutron:gamma = 1:1), or sham irradiated (control) (N=16/group). Locomotor activity (ambulation) of individual mice was monitored for 12 hr postirradiation (PR). There was no significant difference in activity between the isolated and the group housed controls. Irradiated mice exhibited a locomotor decrement within 1 hr PR that fell to 32% of control levels by 4 hr PR in the group housed animals and 62% of control levels by 3 hr PR in the isolated animals. The isolated irradiated animals were not significantly different from the isolated control animals by 4 hr PR, while the group housed irradiated animals remained significantly different from their controls until 8 hr PR. Thus, radiation-induced locomotor decrements in isolated animals were both less pronounced and of shorter duration than those that appeared in group housed animals. This effect cannot be due simply to increased overall activity produced by isolation, because the isolated and group housed controls exhibited similar levels of activity. These findings represent differential effects of radiation in animals housed under different social conditions, with social isolation attenuating the behavioral effects of radiation.

455.18

MODIFICATION OF ACOUSTIC STARTLE REFLEX FOLLOWING EXPOSURE TO IONIZING RADIATION. D.E. Morse and K.M. Manderfield*. Behav. Sci., AFRRI, Bethesda, MD 20814

Inhibition of the acoustic startle reflex, by the presentation of a pre-startle pulse stimulus, has been shown to be sensitive to changes in sensory and motor capacity following toxin exposure. It has been reported that exposure to ionizing radiation, at sublethal doses, severely depresses locomotion and appetitive behavior. The data suggest that these behavioral effects are related to changes in endogenous opioid and dopamine activity. It is not clear whether changes in locomotor capacity or sensory function contribute to these effects. In the present study, male Sprague Dawley rats (300-425g) were exposed to ionizing radiation (1-10 Gy, Linac 18 MVp electrons, 10 Gy/min), or were administered naltrexone (.01-5 mg/kg). The amplitude of the startle response (Startle pulse: 122 dB, 25 ms dur., 2 ms rise), on trials where a pre-stimulus preceded (100 ms) the startle pulse, was compared to startle amplitude when the startle stimulus was presented alone. Baseline responding was measured in a separate session. The results suggest that neither radiation exposure or opioid blockade reduce the amplitude of the response to the startle-eliciting stimulus (when presented alone). However, prepulse inhibition of the startle reflex was significantly reduced following radiation exposure or Naltrexone administration. These data suggest that postirradiation behavioral suppression is not caused by decreased motor capacity, but instead may be mediated by changes in sensory function.

455.19

SEIZURES AND NEUROGENICALLY-MEDIATED CARDIAC ARRHYTHMIAS INDUCED BY BUPIVACAINE IN RATS. F.G. Zavisca,* J.E. Heavner, J. Kytta*, M. Badgwell.* Anesthesia Dept., Texas Tech Univ., HSC, Lubbock, TX 79430.

Bupivacaine is a local anesthetic that produces seizures and cardiac arrhythmias, the latter possibly by a neurogenic mechanism. We examined the relative CNS and CV effects of bupivacaine in five lightly-anesthetized male Wistar rats (264-324 g). EKG and EEG leads, and femoral artery and vein cannulas, were placed under halothane anesthesia. Muscle paralysis was induced with pancuronium 0.1 mg/kg IV and respiration controlled. Body temperature and arterial blood gases were maintained in a narrow range near normal values for the rat. Then, light anesthesia was maintained with 0.5% halothane, 70% N_2O and 30% O_2 for 30 minutes. Bupivacaine infusion 2 mg/kg/min IV was started. Four endpoints were noted in all rats. These endpoints and dose required (mg/kg, mean ± SE) were: 1) dysrhythmia 4.22 + .84; 2) seizures 7.08 + .69; 3 isoelectric EEG 11.05 ± 2.35; and 4) asystole 20.40 ± 2.90. Investigations using this preparation may yield significant new information regarding seizure mechanisms and neurogenic influences on cardiac rhythm.

455.20

OXIDATIVE STRESS ENHANCES PYRUVATE AND PALMITATE OXIDATION IN PC12 CELLS. M. M. Haileck* and F. C. Kauffman. Lab. for Cell. and Biochem.Toxicol., Rutgers University, Piscataway, NJ 08854. Maintenance of high energy phosphates (~P) is compromised in various cells during oxidative stress. Rat pheochromocytoma cells (PC12) exposed to H_2O_2 provide a highly reproducible model to study mechanisms of oxidant injury (Toxicologist **10**:520, 1990) . Cells injured reversibly with 0.1 mM H_2O_2 show transient decreases in ~P whereas cells injured irreversibly (0.25 mM H_2O_2) fail to recover ~P and this event precedes cell death as indexed by loss of adenylate kinase. Energy failure likely occurs subsequent to inhibition of glycolysis and/or oxidative metabolism by H_2O_2 . Accordingly, we examined the oxidation of [6-^{14}C] glucose, [1-^{14}C] pyruvate and [1-^{14}C] palmitate in cells pretreated with 0.1 mM H_2O_2 or 0.25 mM H_2O_2 . Substrates were added 10 min after addition of H_2O_2 to cells. Under experimental conditions employed, H_2O_2 was degraded completely by cells ($t_{1/2} \approx 1$ min).

	Oxidation of ^{14}C-Labelled Substrates		
	[6-^{14}C] Glucose*	[1-^{14}C] Pyruvate **	[1-^{14}C] Palmitate*
Control	25.7	3.59	5.28
0.1 mM H_2O_2	18.9	5.77	9.01
0.25 mM H_2O_2	46.9	6.47	14.88

* pmole/min/mg protein ** nmole/min/mg protein

The high yield of $^{14}CO_2$ from pyruvate compared to that obtained with glucose suggests that mitochondrial oxidation of pyruvate is limited by substrate availability. Cells injured irreversibly with 0.25 mM H_2O_2 oxidized [6-^{14}C] glucose at higher rates than control suggesting that glycolysis was not impaired. Pyruvate and palmitate oxidation was stimulated by H_2O_2 indicating that the capacity of mitochondria to oxidize these substrates was also not compromised by the oxidant. Higher rates of oxidation of mitochondrial substrates in the presence of reduced ~P argues strongly that mitochondria are uncoupled in PC12 cells subjected to irreversible oxidative stress. (Supported in part by ES-05022)

NEUROPATHOLOGY IN THE RETROSPLENIAL CORTEX (RSPC) OF RATS AFTER DEXTROMETHORPHAN (DM) ADMINISTRATION. M.P. Weisend, D. Heard* and D.M. Feeney. Depts.of Psych. and Physiol., Univ. of New Mexico, Albuq., NM 87131.

We previously reported that DM (75 or 50mg/kg;ip) evokes convulsions accompanied by EEG seizure activity in normal male rats (Heard et.al.,Soc.Neurosci.Abst.15:1214, 1989). Because DM is a noncompetitive N-methyl-d-aspartate antagonist and other such drugs produce RSPC pathology, we conducted light microscopic analyses of thionin, thionin/acid fuchsin-stained sections and cytochrome oxidase (CYO) histochemistry for neurotoxic effects of DM. Male rats were randomly assigned to receive 35mg/kg, 50mg/kg or saline every 48hr (6-8 injections) or 75mg/kg once every 24 or 48hr (2-5 injections). Histology was independently rated (interrater reliability r=.8698) for RSPC pathology by observers uninformed of treatment. Pathology characterized by swollen neuronal somata with poorly stained cytoplasm was seen in the pyramidal and deep granule cell layers of the posterior RSPC. Thionin-stained sections indicated statistically significant increases in RSPC pathology with increasing doses of DM. Data from CYO and acid fuchsin is to date inconclusive. There was considerable variability amongst animals, perhaps due to duration of fixation, deaths at high doses, and/or seizure frequency. Supported by DHHS Grants R01NS20220-03, 3-S06-RR08139 and a Biomedical Research Support Grant from the University of New Mexico.

NEUROTOXICITY: OTHER II

456.1

MORPHOMETRIC NEUROHISTOLOGICAL STUDIES OF RHESUS MONKEYS AFTER CHRONIC MARIJUANA SMOKE (MS) EXPOSURE. A.C. Scallet, E. Uemura, A. Andrews*, J. Craven*, R. Rountree*, S. Wilson*, S.F. Ali, J.R. Bailey*, M.G. Paule and W. Slikker, Jr*. Div. of Reprod. & Develop. Tox. National Center for Toxicological Research, Jefferson, AR 72079.

Monkeys were exposed daily for one year to MS. High-dose monkeys smoked a single cigarette (2.6% THC) 7days/wk, while low-dose animals smoked only 2days/wk. Control groups were either sham-exposed or smoked ethanol-extracted marijuana 7days/wk. Seven months after the final dose, the monkeys' hippocampi (HIPP) were evaluated by quantitative dendritic analysis (Golgi-method) or by electron microscopy. Results revealed no effects of MS on the total volume of monkey HIPP, nor on the volumes of its major subdivisions. There were also no net effects of MS on synaptic characteristics, neuronal size, the number of apical or basilar dendrites or the number or length of dendritic branches. However, sham-handled monkeys that were performing operant tasks daily throughout the year of treatment had more highly branched (+ 55%, $p < 0.05$) and longer (+ 47%, $p < 0.01$) dendrites and had fewer mossy-fiber synapses per unit volume (-21%, $p<0.05$) than monkeys that did not perform these tasks throughout the year. Our results indicate that cognitive variables are of importance in neurohistological studies of psychoactive drugs, but fail to confirm previous findings of neurohistological alterations in THC-treated rats. (Supported by NIDA IAG #224-83-005 and NCTR E-6230).

456.2

LEAD INHIBITS PURIFIED PROTEIN KINASE C SUBTYPES FROM RAT BRAIN. G.P. Feng, S.G. Chen, K. Murakami. Dept. of Biochem. Pharmacol., State Univ. of New York, Buffalo, NY 14260.

Protein kinase C (PKC) is an important enzyme in mediating cellular signal transduction. Recently it has been reported that picomolar concentrations of lead activate partially purified PKC from rat brain (Nature 334, 71-73, 1988). Since lead is a neurotoxic heavy metal and its toxicity may be related to the alteration of PKC activity in vivo, we examined lead effects on PKC activation. PKC from brains of Sprague-Dawley rats was purified using a four step liquid chromatography procedure. PKC subtypes I, II and III were further separated using a hydroxy-apatite FPLC column.

Our results showed that lead had strong inhibitory effects on PKC activity of these subtypes as follows:
(1) Submicromolar concentrations of lead acetate strongly inhibited PKC activity induced by phosphotidylserine (PS) in the presence of calcium.
(2) Lead did not mimic the calcium effect on PKC activation in the presence of PS.
(3) Oleic acid activate PKC without calcium. This activation of type I and II PKC was also inhibited by lead acetate at the same concentrations.

Such strong inhibitory effects of lead on PKC may be related to its neurotoxicity, such as memory disorders.

456.3

COMPARISON OF METHODS FOR THE HIGH THROUGHPUT (96 WELL PLATE) DETERMINATION OF LDH RELEASE FOR ASSESSMENT OF NEUROTOXICITY IN LOW DENSITY NEURONAL CULTURES. D. L. Needels. CNS Biology, Bristol-Myers Squibb Co., Wallingford, CT 06492.

The release of cytoplasmic enzymes such as lactate dehydrogenase (LDH) has long been used as a marker for cellular damage, with at least 2 protocols adapted to measurement in 96 well plates. In the absence of serum (which contains LDH), it should be possible to assay LDH released by much lower density neuronal cultures than previously used.

Three assay systems were compared: 1) Forward Reaction (increased NADH, 340 nm); 2) Reverse Reaction (decreased NADH, 340 nm); and 3) Colorimetric Reaction (NADH coupled to tetrazolium salt, 490 nm). Each method was found to have its own advantages and disadvantages in terms of thermodynamics, linear range, sensitivity, and variability. Kinetic analysis eliminates two problems associated with a simple endpoint measurement; relative timing from one well to another, and variations in initial absorbance. Surprisingly, there was no apparent advantage to a linear least squares fit over simply using the first and last data points (double endpoint method). With relatively noisy data (*e.g.* at high OD), equivalent results could be obtained by averaging the first three and last three data points before calculating the slope. Although a quadratic fit modeled the overall reaction curve much better, the variability of initial rates was greater than that observed in the slope of linear fits.

Each of these methods can be used to assay LDH at the levels released by low density (≤ 10,000 neurons/cm2) cultures of hippocampal neurons in response to NMDA. The choice of method will depend on equipment (UV *vs.* visible optics), software (kinetic readings), the LDH range, the number of plates to be assayed, and data analysis capability.

CHOLINERGIC SEPTOHIPPOCAMPAL NEURONS UNDERGO MORPHOLOGICAL ABERRATIONS FOLLOWING LOCAL APPLICATION OF THE NEUROFILAMENT-DISRUPTING AGENT 2,5-HEXANEDIONE (HD). P. L. Di Patre and L. L. Butcher. Dept. of Psychology, UCLA, Los Angeles, CA 90024-1563, U.S.A.

We previously demonstrated that intrafimbrial (i.f.) injection of the microtubule-disrupting agent colchicine induces morphological alterations in fibers running through the distal fimbria and stained with acetylcholinesterase (AChE) and nerve growth factor receptor (NGFr) (Di Patre et al., *Brain Res.*, 1990, in press). In this investigation, we studied the morphological effects of i.f. injection of HD, a drug known to produce axonopathies characterized by local accumulations of neurofilaments. Adult Sprague-Dawley rats were used and i.f. stereotaxical injections were carried out as previously reported (above ref.). Two and 4 days after i.f. injections of HD 0.5 mg, we found that many AChE-NGFr positive axons in the most rostral part of the fimbria were much thicker and grossly distorted as compared to fibers in the homologous region of control rats. At 7 days post-treatment, the affected fibers became more distorted and showed occasional short collateral branches, which resembled newly sprouting ramifications. A reduced number of choline acetyltransferase-reactive neuronal bodies in the lesioned hemiseptum was also observed. A complete recovery of all these changes was seen 6 weeks after HD-treatment. Our data show that i.f. injections of cytoskeletal toxins may constitute a useful experimental model to study the role of the different cytoskeletal components in controlling axonal shape and in regulating the growth of fibers. [Support: NS 10928]

456.5

INCREASE IN CORTICAL BRAIN MICROVASCULARIZATION FOLLOWING CHRONIC ALCOHOLIZATION, CORTICAL INSULT AND AGING IN THE RAT. M. Gewiss*, Ch. Heidbreder* and Ph. De Witte. Lab. of Psychobiology, University of Louvain, Croix du Sud 1, B-1348 Louvain-la-Neuve, Belgium.

The alcoholization by an inhalation procedure seems to be one of the most appropriate experimental models to obtain and maintain chronically high blood ethanol levels. After sejourning 2 to 4 weeks into the alcoholization chamber, rats were perfused with a nuclear emulsion allowing to reveal the cortical vascularization. Furthermore, we also examined the issue of whether chronological ageing and cortical lesion were able to modify cortical microvasculature in non-alcoholized rats. All the vessels including terminal and lateral branches, were measured and the lengths were summed up. Our results provide evidence that animals chronically alcoholized from 2 to 4 weeks displayed enhanced cortical microvascular network. A similar enhancement of microvasculature was observed 1) in the cortex of aged animals (2 years old) when compared to normal adult rats and 2) at the edge around a lesion-induced cavity performed in the cortex of non-alcoholized rats by contrast to the contralateral intact side on the same section. These results show that chronic alcoholization, chronological ageing and brain injury share in common cortical hypervascularization.

456.6

MODULATION OF [^{35}S]t-BUTYLBICYCLOPHOSPHOROTHIONATE KINETICS BY DELTAMETHRIN IN RAINBOW TROUT BRAIN MEMBRANES. R.L. Golden and T.F. Murray. Toxicology Program and College of Pharmacy, Oregon State University, Corvallis, OR. 97331.

Pyrethroid insecticides are known to attenuate [^{35}S]t-butylbicyclophosphorothionate binding to gamma-aminobutyric acid (GABA) gated chloride channels in the vertebrate CNS. Deltamethrin, a Type II pyrethroid, has been shown to inhibit the equilibrium binding of [^{35}S]TBPS in rainbow trout membrane preparations (Eshleman and Murray, Neuropharmacol., in press). To investigate the mechanism of deltamethrin inhibition of [^{35}S]TBPS binding we studied the influence of deltamethrin on the kinetics of [^{35}S]TBPS binding in trout brain membranes. Deltamethrin modulation of [^{35}S]TBPS association and dissociation was examined in the presence and absence of 5 μM GABA. Brain membranes were subjected to three freeze-thaw cycles to remove endogenous GABA as previously described (Eshleman and Murray, Neuropharmacol., in press). The binding of [^{35}S]TBPS was performed at an incubation temperature of 12°C. In the absence of GABA, [^{35}S]TBPS association and dissociation are both adequately described by a single component model. In contrast, in the presence of GABA both association and dissociation reactions of [^{35}S]TBPS binding were better characterized by a two component model. In the presence of GABA the [^{35}S]TBPS association rate increases as a function of GABA concentration. Deltamethrin was found to affect [^{35}S]TBPS association in a GABA dependent manner. Deltamethrin effected a reduction in the rate constants for both the fast and slow components of association. In contrast, deltamethrin had no effect on the [^{35}S]TBPS dissociation rates. These results suggest that the mechanism of the apparent inhibition of equilibrium binding of [^{35}S]TBPS by deltamethrin is a reduction in the association rate of this reaction. (Supported by HHS Grant ES04891)

456.7

NORMALIZATION OF PCB - DEPRESSED CHAT ACTIVITY IN HIPPOCAMPUS AND BASAL FOREBRAIN OF YOUNG RATS BY THYROXINE INJECTION. L.A. Meserve, L.M. Juárez de Ku, T.A. Single*, D.M. Colon*, and M. Sharma*. Dept. Biol. Sci., BGSU. Bowling Green, OH 43403-0212.

Direct administration of polychlorinated biphenyl (PCB) to adult animals, and indirect provision to rat pups via the maternal diet, results in depression of thyroid status. Concomitant with hypothyroidism, young of rats fed PCB display subnormal activity of choline acetyltransferase (ChAT) in hippocampus and basal forebrain at 15 days of age. The present study was done to determine whether injection of thyroid hormone (thyroxine, T_4; or triiodothyronine, T_3) would normalize ChAT activity depressed by PCB. PCB (Arochlor 1254, 250 ppm) was incorporated into the maternal diet from day 1 of pregnancy until pups were 15 days old. Littermates were injected daily ip with either saline or replacement doses of T_4 (50 ng/g bw) or T_3 (10 ng/g bw). At 15 days of age, pups were decapitated, sera collected for T_4 and T_3 determination, and basal forebrains and hippocampi removed to measure ChAT activity. The previously demonstrated depression of ChAT activity by PCB to 33% of normal in hippocampus and 39% of normal in basal forebrain was confirmed. Injection of T_4 increased enzyme activity to 82% of normal in hippocampus and 90% of normal in basal forebrain. Injection of T_3 did not improve ChAT activity. The latter puzzling result may stem from the dosage of T_3 used or from alteration of accessibility of T_3 to the brain after T_3 exposure.

456.8

A WINDOW OF VULNERABILITY FOR DEVELOPING DOPAMINE RECEPTORS? M.H. Schmidt* and T. Lee. Psychopharmacology Unit, Clarke Inst. of Psychiatry, Toronto, Canada, M5T 1R8, and Dept. of Pharmacology, Univ. of Toronto, Toronto, Canada, M5S 1A8.

Prolonged prenatal blockade may impair ontogenic dopamine receptor acquisition in rat striatum (Rosengarten and Friedhoff, Science, 203: 1133, 1979; Scalzo et al., Pharmacol. Biochem. Behav., 34: 721, 1989). A window of vulnerability from embryonic day 15-18 has been described (Rosengarten et al., Birth Defects, 19: 511, 1983), but has not received recent attention.

To test the hypothesis that blockade during this brief period is sufficient to impair dopamine D_2 receptor acquisition, pregnant Wistar rats were given haloperidol, thiothixene or trifluoperazine at doses of 2.5, 5.0 or 7.5 mg/kg/day s.c. from gestational day 15-18. Pups were sacrificed 14 days after birth. Density and affinity of D_2 receptors in pooled striatal membranes of each litter were determined by Scatchard analysis, using [^{3}H]-spiperone ± sulpiride. In control tissues, density was found to be 116 ± 7 fmol/mg, while affinity was 0.18 ± 0.03 nM ($\bar{x}$ ± s.e.m.). The three drugs did not produce consistent, dose-dependent changes in D_2 receptor density or affinity.

The results of this study suggest that the brief period of exposure is insufficient to impair D_2 receptor ontogeny and call into question the concept of a window of vulnerability. [Supported by the Clarke Institute Research Fund and Ontario Graduate Scholarship Program (M.H.S.).]

IN VIVO ELECTROCHEMICAL STUDIES OF DOPAMINE DIFFUSION AND CLEARANCE IN THE STRIATUM OF NEONATAL 6-OHDA-LESIONED RATS. J. Luthman, M.N. Friedemann, B.J. Hoffer and G.A. Gerhardt, Depts. of Pharmacology and Psychiatry, University of Colorado Health Sciences Center, Denver, CO 80262.

Neonatal destruction of dopamine (DA)-containing neurons with 6-hydroxydopamine (6-OHDA) has been shown to produce rats that exhibit hyperactivity. However, few studies to date have explored the diffusional and cellular clearance of DA following these neonatal lesions which produce permanent damage to DA-containing neuronal systems. In the present study, high-speed (5 Hz) in vivo chronoamperometry was coupled with pressure ejection of DA from micropipettes to study the clearance and diffusion properties of DA. These measures were performed in the striatum of urethane anesthetized rats in both control rats and rats that had received neonatal (day 1) injections of 6-OHDA (75 micrograms intracisternal) following pretreatment with desipramine. In the 6-OHDA-treated animals, larger volumes of DA were needed to produce equivalent changes in the detected extracellular levels of DA. Temporal properties of DA signals were also seen to be greater in these rats. In addition, ejection parameters which were seen to produce detectable responses in the 6-OHDA-treated animals often produced no detectable signals in the striatum of control rats. These data suggest that neonatal 6-OHDA treatments change the clearance properties of DA by cellular elements. (Supported by USPHS grants AG06434, AG00441 and NS09199).

FETAL BRAIN CATECHOLAMINES AND INDOLEAMINES FOLLOWING REPEATED NITROUS OXIDE EXPOSURE. S.A. RICE, A. CARUGHI*, and M.T. SERRA*. Departments of Anesthesia, Stanford University and VA Medical Center, Palo Alto, CA 94304

Our previous work showed that repeated prenatal exposure of rats to nitrous oxide (N_2O) results in significant hyperreactivity of the acoustic startle reflex at 30 and 60 days of age (Teratology, Abs., in press). The present study was designed to determine if prenatal N_2O-exposure alters fetal brain catecholamines and indoleamines.

SD rats were exposed to 35% N_2O or air for 4 hr on days 6-15 of pregnancy. 24 hr following the last exposure, rats were killed and fetuses were removed. Brains of 3 fetuses from each litter were pooled (N=6 litters/group); extracted into .1 M acetate buffer, pH 3.5, containing .3 mM EDTA; and analyzed by HPLC with E.C. detection.

Prenatal N_2O exposure significantly decreased brain norepinephrine, epinephrine and MHPG content compared to air-exposed fetuses (110 ± 29 vs. 180 ± 48 fmol/mg; 152 ± 47 vs. 228 ± 54 fmol/mg; and 24 ± 10 vs. 52 ± 10 fmol/mg, respectively). Brain 5-HIAA and HVA contents were significantly increased in N_2O-exposed compared to air-exposed fetuses (460 ± 104 vs. 289 ± 25 fmol/mg; and 1921 ± 750 vs. 719 ± 171 fmol/mg, respectively). Brain dopamine, DOPAC and serotonin contents were not different, nor were fetal weight, protein content or DNA content. [(Supported by VA Medical Center, Palo Alto, CA)]

CNS EFFECTS OF 5-HYDROXYTRYPTAMINE RELATED OXIDATION PRODUCTS, C. L. BLANK, R. N. GOYAL*, M. WRONA*, G. DRYHURST* AND D.J. TURK, Dept of Chemistry and Biochemistry, U. of Oklahoma, Norman, OK 73019.

A variety of unique compounds has been obtained as the result of the investigation of the oxidative behavior of 5-hydroxytryptamine (5-HT) and related indoleamine species. Some of these compounds have exhibited substantial toxic effects when administered intracerebrally in mice. Some have led to interesting behavioral reactions following such administration. In order to establish an appropriate dose at which to examine the effects of these species on endogenous neurochemical levels, preliminary investigations examined the LD_{50} values for each using the Dixon Up-Down method (W.J. Dixon, *J. Am. Stat. Assoc.*, **60**, 967, 1965). The results obtained were:

Compound	LD_{50}, µg
5-hydroxytryptamine-4,7-dione	30 ± 1
7-S-(glutathionyl)-tryptamine-4,5-dione	21 ± 1
6,6'-bi-(5-hydroxytryptamine-4,7-dione)	25 ± 2
5,7-dihydroxytryptamine	52 ± 1
2,7'-bi-(5,6-dihydroxytryptamine)	> 125
7,7'-bi-(5-hydroxytryptamine-4-one)	> 125

Endogenous levels of catecholamines, indoleamines, and acetylcholine, as well as related metabolites, were determined using a NEUBA® Neurobiological Analyzer. This system provides valuable qualitative information involved in the identification of the pertinent species through the use of multiple amperometric electrochemical detectors. It provides rapid throughput by using a multicolumn liquid chromatographic setup. Behavioral effects observed for the compounds listed above included hyperexcitability, sedation, short-term (72 hr) partial motor impairment, and rapid "rolling over."

456.12

NEUROTOXIC EFFECTS OF COCAINE AND METHAMPHETAMINE ON CULTURED DOPAMINE NEURONS. BA Bennett, JE Clodfelter*, M Morris, DK Sundberg* and CR Miller*. Dept. of Physiology and Pharmacology, Bowman Gray Sch. Med. of Wake Forest Univ., Winston-Salem, NC 27103

Stimulant drugs of abuse produce alterations in movement and behavior associated with histological and biochemical effects on mesencephalic (MES) dopamine (DA) neurons while the effects on the tuberoinfundibular DA system of the medial basal hypothalamus (MBH) are not known. These dopaminergic neurons differ from those in the MES by lacking a high affinity uptake system and D2 autoreceptors. This study examined the effects of stimulant agents in cultures of MES and MBH using immunocytochemical methods.

Brains from neonate rats (1-2 days old) were removed and the MES and MBH obtained and dispersed into single cells. Stimulant agents, either cocaine (COC) or methamphetamine (METH; 10^{-3}-10^{-9}M), were added to the cultures on day 2. Cultures were fixed on day 7 with 5% acrolein. The antibodies used were tyrosine hydroxylase (TH) and neuron specific enolase (NSE). Tissues were processed according to the Vectastain protocol. Computerized morphometrics were used for analysis.

There was a generalized neurotoxicity observed with COC and METH (10^{-3}M) as demonstrated by a dramatic decrease (>90%) in both NSE and TH positive cells. With concentrations of 10^{-5} and 10^{-7}M, there was a specific decrement in TH positive neurons with both drugs, but there was a greater decrement in the MES cultures. The effects of COC and METH were very similar. In the presence of 10^{-5} and 10^{-7}M drugs, MBH TH positive neurons were reduced 35% and 15%, respectively. Likewise, MES TH positive cells decreased 50% and 30%, respectively, in the presence of 10^{-5} and 10^{-7}M drugs. Our findings are consistent with previous studies examining the effects of METH on MES cultures (Kontur et al, Dev Br Res 31:7,1987). There was no significant change observed with 10^{-9}M. These results indicate that COC and METH have specific neurotoxic effects on both MES and MBH dopamine neurons. Supported by grant DA05073 (BAB).

MATERNAL TOXICITY AND OFFSPRING DEVELOPMENT FOLLOWING GESTATIONAL EXPOSURE TO COCAINE IN THE RAT. L. M. Donohue*, L. A. Freed, H. E. Hughes and D. L. Dow-Edwards, Laboratory of Cerebral Metabolism, Department of Neurosurgery, SUNY-Health Science Center, Brooklyn, N.Y. 11203.

Clinical and animal studies indicate that prenatal cocaine exposure results in maternal toxicity and neurobehavioral abnormalities in the offspring. The current study investigated the effects of prenatal cocaine exposure on several maternal and fetal indices of toxicity in the rat. Pregnant Sprague-Dawley rats were gastrically intubated with 30 or 60 mg/kg/day cocaine-HCl or vehicle during gestational days (GD) 8-22. Vehicle treated rats were pair-fed/watered to rats receiving the higher dose of cocaine. A non-treated control group was also maintained. Daily maternal body weights and food/water consumptions were recorded during GD 8-22. At parturition, dams were sacrificed and the number of implantation sites recorded. The occurrence of abruptio placentae was also noted. Pups were weighed, sexed, culled to 10 and surrogate fostered. Onset of the following developmental milestones was assessed daily in the offspring: pinna eruption; eye opening; crawling; walking; bar grasp; righting and negative geotaxis. Additional pups were sacrificed at birth to determine the weights of brain, thymus, adrenal gland and kidney. Preliminary data indicate a delay in crawling onset for males and a reduction of adrenal weight in females in the 60mg/kg cocaine group compared to the non-treated group. Maternal toxicity data are forthcoming.

Supported by ADAMHA Grant #DA04118.

EXPOSURE TO TRIMETHYLTIN INCREASES CHOLINE ACETYLTRANSFERASE ACTIVITY IN THE RAT HIPPOCAMPUS Cannon R.L.+, Hoover, D.B.++, and Woodruff, M.L.+ Dept. of Anatomy+ and Pharmacology++, J. H. Quillen Col. of Med., East Tenn. St. U., Johnson City, TN. 37614

Trimethyltin (TMT) damages all parts of the hippocampus, but also enhances acetylcholinesterase (AChE) staining in the dentate gyrus of rats. The purpose of this experiment was to verify TMT-induced enhancement of the cholinergic projection to dentate using a biochemical assay quantifying choline acetyltransferase (ChAT) activity in the dentate. Five male hooded rats were gavaged with 7mg/kg TMT chloride while 5 served as controls. One hundred days later the rats were killed and serial frozen sections were taken of the brain. Micropunch samples were taken from 300 µm sections at three rostral-caudal levels of the dentate gyrus and CA1 of the hippocampus. Micropunches of the caudate-putamen (c-p) were also taken. ChAT activity was measured on all samples. Alternate sections were stained for AChE or with thionin. Inspection of these sections revealed histological changes consistent with previous reports. ChAT activity did not differ between controls and TMT-treated rats for c-p samples, but a significant increase in ChAT was found in TMT-treated rats for all levels of the dentate gyrus and CA1. These results indicate that exposure to TMT increases cholinergic innervation of both the dentate gyrus and the CA1 portion of the hippocampus. (Supported by a grant from the NIH (ES04070-04) to MLW.)

MOLECULAR CLONING AND ANALYSIS OF mRNA EXPRESSED IN TRIMETHYLTIN-SENSITIVE NEURONS. S. M. Toggas*, J. K. Krady*, J. W. Polli* and M.L. Billingsley. Department of Pharmacology and Center for Cell and Molecular Biology, Penn State University College of Medicine, Hershey, PA 17033.

Trimethyltin (TMT) is a selective neurotoxicant that destroys neuronal subpopulations which have no apparent neuro-chemical or anatomic relationships. To isolate gene products common to sensitive neurons, a cDNA subtraction library was created using avidin/biotin-based methods. One clone, pr9T19, gave patterns of hybridization in Northern blot and *in situ* hybridization experiments suggesting that it was expressed in TMT-sensitive neurons. Strong hybridization was seen in cingulate and piriform cortex and hippocampus. pr9T19 was expressed in rat telencephalon on embryonic day 15; the pattern of expression became restricted to the adult pattern by postnatal day 20. *In situ* hybridization in human hippocampus suggested that an mRNA related to pr9T19 was expressed in subpopulations of hippocampal pyramidal cells. High stringency Southern blot analysis indicated that a related gene was present in drosophila, rabbit, rat, and human genomic DNA. Initial sequence analysis suggests that the 3.0 kb mRNA encodes a novel protein of 123 amino acids. Experiments are underway to characterize this protein and to determine its possible role in the neurotoxicology of TMT.

DEGENERATIVE DISEASE—OTHER: BASAL GANGLIA

457.1

PROGRESSION OF BASAL GANGLIA ATROPHY AND FUNCTIONAL DECLINE IN HUNTINGTON'S DISEASE PATIENTS. J.K.A. Roberts and E.A. Loh. Dept. of Neuropsychiatry, Royal Ottawa Hospital, Ottawa, Canada.

Neuroanatomical and functional changes associated with the progression of Huntington's disease (HD) were investigated. CT scans were obtained from 14 individuals at various stages of HD. Scans were digitized, measures of 1) distance between frontal horns of lateral ventricles (FH), 2) distance between caudate nuclei (BICAUD), and 3) width of globus pallidus and putamen regions (GP) were calculated. These measures were compared with patient's scores on the Quantitative Neurological Examination (QNE), Shoulson and Fahn's functional assessment (S&F), and Mini-Mental State (MMS) scales. Measures of the duration of HD and the GP and BICAUD regions were significantly correlated (r's > .70). Further, the GP measure was sig. correlated with MMS and (r =.90) and S&F (r= -.81) scores. Measures more specific to the caudate regions: FH and BICAUD were more strongly related to the motor function score QNE (r > .85). This indicates that atrophy of the GP region may be a better index of functional deterioration than the more commonly used measures of caudate atrophy which were more closely related to motoric decline.

457.2

CLINICAL CORRELATES OF THE VONSATTEL SCORE IN HUNTINGTON'S DISEASE. CE Peyser, SE Folstein, RM Zweig and JC Hedreen. Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205.

Prominent features of Huntington's disease (HD) include a movement disorder and progressive dementia. The most consistent neuropathological changes are neostriatal atrophy and neuronal loss; Vonsattel et al. (1985) developed a widely used grading system based on these changes. The purpose of this study was to examine clinical correlates of the Vonsattel score in well characterized HD cases. For 36 HD patients examined $\leq$ 18 months before death, mean scores on clinical variables for patients with Vonsattel gradings (0+1,2,3,4) were obtained; Spearman rank-order correlations were determined for relationship between Vonsattel severity and the following clinical variables: Mini Mental State Exam (dementia measure; r_S=-.52, p=.001); Quantitative Neurological Exam Score (r_S=.67, p .001); Motor Impairment Score (voluntary motor abnormality score; r_S=.71, p .001); and Activity of Daily Living Scale (functional impairment measure; r_S=.49, p=.002). Similar results were obtained for 42 HD cases with longer intervals between clinical measures and death. We conclude that the Vonsattel score in HD is a powerful measure of disease severity as indicated by its high correlation with extent of neurological, cognitive and functional impairment.

457.3

PATHOLOGICAL CHANGES IN EARLY HUNTINGTON'S DISEASE. J.C. Hedreen. Neuropathology Laboratory, The Johns Hopkins University School of Medicine, Baltimore, MD 21205.

The distribution of histopathological changes in autopsied cases of Huntington's disease (HD) with different pathological grades of severity was examined by means of glial fibrillary acidic protein immunocytochemistry and counts of neurons and astrocytes. Two principal findings were made. First, in three presumed grade-0 HD cases, it was determined that neuronal counts in the dorsal putamen were less than counts in controls; this finding provides a significant aid to diagnosis in very mildly affected cases. Second, in many grade-2 and grade-3 cases, a nonuniform pattern of pathology was seen at the ventrally advancing margin of pathological change. In this region, areas with neuronal cell loss and gliosis were interspersed with relatively normal areas, forming patterns reminiscent of those created by the intrinsic chemoarchitecture of the neostriatum and by striatal afferents. This finding suggests that neuronal injury in HD may initially involve neurochemically specific cell groups in the striatum or striatal zones innervated by specific afferent systems. Identification of these specific cell groups or afferents will have important implications for understanding the mechanism of neuronal injury in HD.

457.4

LOCUS COERULEUS PATHOLOGY: A FEATURE OF ADVANCED HUNTINGTON'S DISEASE. R.M. Zweig, C.A. Ross, J.C. Hedreen, C.E. Peyser*, J.E. Cardillo*, S.E. Folstein* and D.L. Price. Univ. of Nevada Sch. of Med., Reno and Johns Hopkins Hosp., Baltimore.

Numbers of neurons at up to three strictly defined anatomical levels of the locus coeruleus (LC) were determined in 33 patients with Huntington's disease (HD) and in 22 age-matched controls. Distances between rostral and caudal levels (LC length) could be determined in 23 of the HD and in 7 of the control cases. Rostral level cell counts were significantly less in HD patients who had severe dementia than in controls and, at rostral and middle levels, in HD patients with severe dementia compared to those with mild dementia. Fewer rostral and middle level LC neurons correlated with neostriatal atrophy and last recorded motor impairment (MIS) and activities of daily living (ADL) scores. LC length was reduced by >20% in patients with severe dementia compared to those with mild dementia (p=.002) or controls. Reduced LC length correlated with early age of onset, long duration, MIS, and most highly, ADL score (Pearson r=0.72; p<.001). In conclusion, LC pathology, especially as reflected in LC length, correlates highly with clinical features of advanced disease.

457.5

EXCITATORY AMINO ACID RECEPTOR POPULATIONS IN HUNTINGTON'S DISEASE L.S. Dure IV, J.B. Penney, A.B. Young. Department of Neurology, University of Michigan, Ann Arbor, MI 48109 U.S.A.

Huntington's Disease (HD) is an autosomal dominant neurodegenerative disease with onset of dementia and involuntary movements in mid-life. Although the pathogenesis of HD is unknown, the inherent neurotoxicity of excitatory amino acids (EAA) has been implicated. One subtype of EAA receptor, the N-methyl-D-aspartate (NMDA) receptor, has been shown to be decreased in the basal ganglia of HD brains. Using *in vitro* quantitative receptor autoradiography to determine EAA receptor population densities, we studied the binding characteristics of EAA and associated receptors in 15 brains of patients with HD, and 16 control brains. Receptor assays for NMDA-sensitive [^{3}H]glutamate, [^{3}H]glycine (which binds to a putative modulatory site on the NMDA receptor), [^{3}H]MK-801 (which binds to the phencyclidine (PCP) site of the NMDA receptor), [^{3}H]AMPA(α-amino-hydroxy-5-methyl-isoxazole propionic acid), quisqualate-sensitive (metabotropic) [^{3}H]glutamate, and [^{3}H]kainate binding all showed marked decreases when compared to controls. There was a greater loss of NMDA-sensitive [^{3}H]glutamate and [^{3}H]kainate binding in HD compared to the losses of other receptor populations. These data supports the hypothesis that an excitotoxic mechanism mediated by subpopulations of glutamate receptors contributes to the pathology of HD.

Supported by the Huntington's Disease Society of America (LSD) and USPHS grant NS 15655 (JBP and ABY).

457.6

THE KYNURENINES: NEUROTOXINS WITH A POTENTIAL ROLE IN HUNTINGTON'S DISEASE (HD). G.K. Rieke and B. Kurunwune*. Dept. Anat. & Cell Biol., Meharry Med. College, Nashville, TN 37208.

3-Hydroxykynurenine (3HKYN) and L-Kynurenic acid (L-KYN) brain levels are increased 2-3 fold in HD. To satisfy the neurotoxic hypothesis for HD these endogenous compounds must be neurotoxic. We have tested the neurotoxicity of L-KYN, 3HKYN and related metabolites. A cannula coupled to an Alzet osmotic pump was implanted into the striatum. Each pump was filled with buffered L-KYN or quinaldic acid (0.31 ug/uL), or 3HKYN (3.36 ug/uL). L-KYN and 3HKYN produced selective neuron sparing lesions, similar to pathology seen in HD. NADPH diaphorase positive neurons were present in the spongiose zone of the L-KYN and 3HKYN induced lesion. Quinaldic acid, the terminal metabolite of L-KYN, was not neurotoxic. The neurotoxic potential of kynurenine is unknown, while the role of the neurotoxin quinolinate in HD is doubtful. L-KYN and 3HKYN are endogenous neurotoxins. Their role in HD, along with other neurotoxins like pyroglutamate, must be carefully examined. The presence of a specific neurotoxin in specific HD families may reflect subtle errors within the HD gene locus. Supported by NIH S06RR08037.

MET-ENKEPHALIN, SUBSTANCE P, AND GABA LEVELS IN RIGID AND CHOREIC HUNTINGTON'S DISEASE PATIENTS. E. Storey and M.F.Beal. Neurochemistry Laboratory, Mass. Gen. Hosp., Boston, MA 02114.

It has recently been suggested on the basis of immunohistochemical studies that chorea in Huntington's disease (HD) results from early depletion of met-enkephalin (ME)-containing spiny GABAergic neurons projecting to the external segment of the pallidum (GPE), with initial relative sparing of substance-P (SP)-containing GABAergic neurones projecting to the internal segment of the pallidum (GPI). The imbalance between these opposing pathways is thought to result in disinhibition of the ventrolateral thalamus, and increased excitatory input to the cortex, resulting in chorea. In an attempt to confirm this hypothesis, brains from 9 adult choreic HD patients were compared with 9 adult and 6 juvenile-onset rigid cases,and with 12 control brains. All patients were examined clinically within 6 months of death. All but one of the affected brains were grade 3 or 4. There were significant differences in SP, ME, and GABA levels in grade 3 versus grade 4 cases. However, measurements of SP and ME levels by RIA failed to show any preferential preservation of SP versus ME in choreic cases, and indeed ME was better preserved than SP in the striatum. Measurement of GABA levels by HPLC also failed to show preferential preservation in the GPI in cases with chorea versus those with rigidity. The findings were unchanged when only choreic (6) and rigid (5) grade 3 cases were compared. Depletions of SP and GABA in the GPI were not significantly different from depletions of ME and GABA in the GPE when all cases were combined. There was, however, a trend towards relative preservation of GPI SP and GABA in choreic patients. Although a preferential loss of ME-containing GABAergic projection neurones to the GPE may play a role in the genesis of chorea, these results did not demonstrate this in advanced cases.

457.8

TERMINAL STRIATAL SUBSTANCE P- AND MET-ENKEPHALIN-PROJECTIONS IN THE GLOBUS PALLIDUS ARE EQUALLY AFFECTED IN HUNTINGTON'S DISEASE. **R.J. Ferrante, N.W. Kowall, K. Harrington, E.P. Richardson, Jr., Mass. Gen. Hosp. Boston, MA 02114**

Spiny striatal projection neurons are most severely involved in Huntington's disease ((HD). A major subcortical target of these neurons is the globus pallidus (GP). Striatal terminal projections to GP have been identified with a variety of neurochemical markers. We stained contiguous, 50 μm-thick sections of the GP in 17 neurologically normal control and 16 HD brains for substance P (SP), methionine enkephalin (ME), and transforming growth factor alpha (TGF), an amino acid peptide which extensively colocalizes with ME. The HD brains were from cases of low to very severe grades (G0-G4), all adult onset. In both controls and HD, the external pallidal segment (GPe) reacted primarily for ME and TGF with little terminal staining occurring in the internal segment (GPi). SP was primarily located within the GPi. Intense, terminal SP-activity rimmed the GPe with scattered fiber staining within. In HD there was a gradient of SP-, ME-, and TGF-loss in the GP corresponding to the severity of neuropathologic change, with the most marked reductions occurring in the very severe grades. No significant differences in the pattern and relative intensity of SP-, ME-, and TGF-terminal activity was observed in any HD case. Photodensitometric image analysis supported these findings. The density of staining in HD cases, measured as a percent of the normals, was nearly equal for SP, ME, and TGF in each grade (G0=96.2%, G1=85.0%, G2=73.7%, G3=40.2%, G4=9.0%). Our findings suggest that spiny striatal projection neurons are equally involved in HD.

457.9

MUSCARINIC RECEPTORS IN BASAL GANGLIA OF PROGRESSIVE SUPRANUCLEAR PALSY (PSP). N. S. Hermanowicz, J. B. Penney, N. L. Foster, I. Shoulson. Depts. of Neurology, University of Michigan, Ann Arbor, MI 48104-1687 and University of Rochester, Rochester, NY 14642

PSP is characterized by severe nigral, subthalamic, superior collicular and pallidal atrophy with lesser striatal pathology. Choline acetylase and dopamine D2 receptors are reported to be decreased in striatum (Ruberg et al. *Ann. Neurol.* 18:523,1985). We have measured muscarinic cholinergic receptors using quantitative autoradiography in basal ganglia of 8 PSP brains and compared them to 11 control, 9 Huntington's (HD) and 7 Parkinson's (PD) disease brains.

Whole coronal, cryostat sections through medial globus pallidus were incubated at 20°C for 3 hrs. in 1 nM [^{3}H]QNB (Amersham) in 50 mM Tris-HCl. Sections were exposed to Ultrofilm-3H (LKB) for 2 weeks and analyzed with an MCID (Imaging Research). Binding in pm/mg protein (mean±sem) was:

Disease	Caudate	Putamen	Lateral Globus Pallidus	Medial Globus Pallidus
Control	2.30±.30	2.17±.25	.207±.016	.236±.021
PSP	2.06±.14	1.45±.11*	.256±.036	.538±.172*
HD	.822±.092*	.875±.079*	.096±.011*	.079±.009*
PD	2.27±.14	2.16±.17	.219±.022	.296±.061

(*, p<.05 by ANOVA with post hoc pairwise comparisons to control)

In HD striatal cell loss is much more severe than pallidal. Thus, the decreased pallidal QNB binding in HD suggests that these binding sites are on striatal efferent terminals. Decreased putamenal QNB binding in PSP indicates a loss of cells bearing muscarinic receptors in putamen. The increased medial pallidal binding suggests a concentration phenomenon due to the known pallidal cell loss in PSP. These pallidal QNB binding sites in PSP may be on a spared subset of striatal efferent terminals. Supported by USPHS grant AG08671.

457.10

ABNORMALITIES OF DOPAMINERGIC MARKERS IN POSTMORTEM STRIATAL SPECIMENS FROM PATIENTS WITH TOURETTE SYNDROME Harvey S. Singer, In-Hei Hahn, Timothy H. Moran. The Johns Hopkins University School of Medicine. Baltimore, Maryland 21205.

The dopamine hypothesis for Tourette Syndrome (TS) was evaluated in frozen postmortem striatal tissue from three adults (2 males, 1 female) with the diagnosis of TS and up to 13 controls. [^{3}H]Mazindol binding (fmol/mg protein), used to label the DA uptake carrier site, was significantly increased in the striatal region of patients with TS (caudate: TS = 467 ± 22, control = 342 ± 28; putamen: TS = 604 ± 37, control = 404 ± 43). HPLC measurements of dopamine and its metabolite DOPAC were normal to slightly reduced. [^{3}H]SCH 23390 binding, labels the D1 receptor, was not significantly different from controls in either caudate (TS = 39.5 ± 9.4, control = 50.1 ± 7.4) or putamen (TS = 52.8 ± 4.8, control = 43.2 ± 5.5). D2 receptor binding, measured by [^{3}H]spiperone, was slightly greater in caudate (TS = 69.1 ± 12.5, control = 58.9 ± 8.4) and putamen (TS = 39.3 ± 5.3, control = 32.3 ± 2.2).

Our data supports earlier proposals of a dopaminergic abnormality within the basal ganglia. However, rather than a specific dysfunction of postsynaptic D1 or D2 receptors, results from postmortem analyses suggest a significant alteration of DA uptake mechanisms.

457.11

INTRAREGIONAL PATTERN OF STRIATAL CHOLINERGIC ENZYME REDUCTION IN DOMINANTLY-INHERITED OLIVOPONTOCEREBELLAR ATROPHY: POSSIBLE RELATIONSHIP TO FRONTAL LOBE SYSTEM IMPAIRMENT. S.J. Kish, M. El-Awar*, L. Schut*, M. Oscar-Berman*, Y. Robitaille*, J. Deck*, L. DiStefano*, L.J. Chang*, and M. Freedman*. Clarke Inst. Psychiat., Rotman Research Institute of Baycrest Centre, Toronto, Canada; U. Pittsburgh; VA Hosp., Boston/Minneapolis.

We measured the intraregional pattern of the activity of the cholinergic enzyme cholineacetyltransferase (ChAT), the specific cholinergic marker, in striatum of six patients from one family with dominantly-inherited olivopontocerebellar atrophy (OPCA). Previous neuropsychological testing of affected members of this family, including the three patients tested in this study, revealed signs of frontal lobe impairment. As compared with the controls (n=11), mean activity of ChAT was severely reduced in OPCA throughout the subdivisions of the caudate head nucleus with the dorsal portion (-81 to -85%) being the most affected. In contrast, ChAT levels in the putamen were much less markedly reduced (-26 to -61%). In view of the experimental and clinical evidence indicating that the caudate nucleus may be a critical component of pre-frontal cortical-governed behaviour, we suggest that the severe cholinergic reduction in caudate nucleus of our OPCA patients may contribute to the frontal system impairment observed in this disorder. (Supported by U.S.NIH #NS26034.)

SYMPOSIUM: REGULATION OF NICOTINIC ACETYLCHOLINE RECEPTOR EXPRESSION AND FUNCTION. R.J. Lukas, Barrow Neurological Institute (Chairperson); R.L. Huganir, Johns Hopkins Univ. Sch. of Med.; J.P. Merlie, Washington Univ.; D.K. Berg, Univ. of Calif. San Diego; T. Claudio, Yale Univ.

Nicotinic acetylcholine receptors (nAChR) are structurally and functionally diverse members of the ligand-gated ion channel superfamily of multi-subunit transmembrane proteins. nAChR diversity is partly based on heterogeneity of nAChR subunit-encoding genes and may provide teleologically beneficial functional and regulatory flexibility to a plastic and dynamic nervous system. The participants will address this thesis and will show how contemporary multidisciplinary approaches are yielding insight into cellular and molecular mechanisms that regulate nAChR expression and function. Lukas will provide an overview of nAChR biology and a synposis of studies on muscle and neuronal nAChR regulation in model clonal cell lines. Huganir will describe studies on regulation of muscle-like nAChR processing and functional characteristics by serine and tyrosine protein kinases. Merlie will address transcriptional regulation of receptor expression in muscle with specific reference to promoter analysis in transgenic mice. Berg will review work on regulation of neuronal nAChR function and number in autonomic ganglia. Claudio will discuss studies on synaptogenesis and biogenesis of muscle-like nAChR in transfected cells.

SYMPOSIUM: Neuronal regulation of renal function: A model system for nervous system interactions. J.M. Wyss, Univ. of Alabama at Birmingham (Chairman); L. Barajas*, UCLA; U.C. Kopp, Univ. of Iowa; L.P. Schramm Johns Hopkins Univ.; J. Ciriello, Univ. Western Ontario.

The kidney is the most highly innervated peripheral organ, and the relative simplicity of the neural-renal interaction makes this system an important model for future research into all neural-peripheral and neural-neural interactions. *L. Barajas* will examine the intrarenal distribution of the efferent renal nerves along the nephron and vasculature, and the localization of afferent nerves within the kidney. *U.C. Kopp* will discuss the role of the renorenal reflex, which alters renal responses following stimulation of the contralateral kidney. She will also consider the finding that efferent renal nerve activity directly modifies sensory feedback to the spinal cord from the kidney. *L.P. Schramm* will discuss his studies into spinal and supraspinal control of renal function, which have led to an elucidation of inhibitory networks within the spinal cord that regulate the function of peripheral organs. He also will discuss his recent use of pseudorabies virus to localize the preganglionic nerves that project to the kidney. *J. Ciriello* will elucidate the brain mechanisms that contribute to the regulation of renal function and will examine the ability of the kidney (via renal nerves) to modify the activity of the neurons in the brain. *J.M. Wyss* will examine the functional consequence of neural control of the kidney in health and disease. Although the nervous system often has been considered as only an acute regulator of visceral function, current studies into hypertension and renal disease suggest that neural-renal dysfunction may be an important contributor to chronic diseases.

EXCITOTOXICITY V

461.1

FOCAL INJECTION OF AMINOOXYACETIC ACID PRODUCES SEIZURES AND LESIONS IN RAT HIPPOCAMPUS: EVIDENCE FOR MEDIATION BY NMDA RECEPTORS. O.G. McMaster, F. Du, E.D. French[1] and R. Schwarcz. Md. Psych. Res. Ctr., Baltimore, MD 21228, and [1]Dept. Pharmacol., Univ. Ariz. Coll. Med., Tucson, AZ 85724.

Aminooxyacetic acid (AOAA), known to produce both convulsant and anti-convulsant effects in rodents upon systemic administration, was recently found to powerfully inhibit kynurenine aminotransferase, the enzyme responsible for the production of the excitatory amino acid receptor antagonist kynurenic acid (KYNA). We have now used AOAA as a tool to examine the effects of a reduction of KYNA levels in vivo. Intrahippocampal application of AOAA to unanesthetized rats caused dose-dependent seizure activity which was monitored and quantified by EEG. Co-administration of the selective NMDA receptor antagonist D-APH (45 or 225 nmoles) with 225 nmoles AOAA resulted in almost complete abolition of seizure activity. Rats receiving 45 or 225 nmoles AOAA also suffered selective loss of CA1 pyramidal neurons. AOAA-induced neurotoxicity, too, was apparently mediated by NMDA receptors since it was attenuated by co-injection of 45 or 225 nmoles D-APH. Iontophoretic application to CA1 pyramidal cells (N=10) did not reveal any evidence for direct NMDA receptor activation by AOAA. AOAA may therefore precipitate excitotoxicity and seizures indirectly by removing tonic inhibition of KYNA at the NMDA receptor. (Supported by USPHS grant NS 16102).

461.2

EFFECT OF STRIATAL QUINOLINATE LESIONS ON KYNURENINE AMINOTRANSFERASE IN THE RAT BASAL GANGLIA. W. Schmidt, F. Du, E. Okuno and R. Schwarcz. Maryland Psychiatric Research Center, Baltimore, MD 21228.

Kynurenine aminotransferase (KAT), the enzyme responsible for the production of kynurenic acid (KYNA), was studied in the striatum and substantia nigra in normal rats, and in animals 2 and 7 days following a unilateral intrastriatal injection of quinolinic acid (QUIN; 50 μg/1 μl). In normal striata, immunocytochemical studies with anti-rat KAT antibodies revealed a preferential astrocytic localization of the enzyme and a small population of KAT-positive neurons, which was dispersed throughout the striatum. 7 days after QUIN injection, the number of KAT immunoreactive astroglial cells in the striatum was markedly increased as compared to the contralateral side.

QUIN-lesioned striata (glutamate decarboxylase activity: -71.6±4.7% and -87.2±2.0% after 2 and 7 days, respectively) showed a 19.9±2.1% reduction in KAT activity after 2 days and a 186.5±9.8% increase in enzyme activity after 7 days (N=8 each). The early decrease is probably due to the loss of KAT-containing neurons while the later increase may be the result of astrocytic proliferation. KAT activity in the substantia nigra ipsilateral to the lesion was unchanged after 2 days but increased to 141.3±19.1% of controls after 7 days (N=6 each).

Supported by USPHS grant NS 28236.

461.3

EXCITOTOXIC AND NON-EXCITOTOXIC DAMAGE PRODUCED BY 3-HYDROXYANTHRANILIC ACID IN RAT CORTICOSTRIATAL CULTURES. W.O. Whetsell, Jr., B. Christie-Pope, and R. Schwarcz[1]. Vanderbilt Univ., Nashville, TN 37232-2561 and [1]Md. Psych. Res. Ctr., Baltimore, MD 21228.

3-hydroxyanthranilic acid (3HANA) is a brain metabolite and bioprecursor for the excitotoxic agent, quinolinic acid (QUIN). Mature (21 days *in vitro*) organotypic cultures of rat corticostriatal system were incubated in 3HANA (5mM) alone or concomitantly with the NMDA receptor antagonist, D-APH (1mM). Ultrastructural changes were assessed for up to 50 hours of incubation. At 10 hours, cultures exposed to 3HANA alone began to develop post-synaptic swelling and occasional dendritic swelling away from synaptic complexes. By 20 hours, generalized dendritic and axonal swelling was severe and even some neuronal swelling was evident; by 40 hours, cultures were destroyed by the treatment. In contrast, simultaneous incubation with 3HANA and D-APH induced no appreciable ultrastructural change in the cultures until 30 hours when there was scattered non-specific swelling of elements in the neuropil; no distinct post-synaptic swelling could be identified. By 50 hours, wide-spread swelling of neuropil and neurons was evident, but dendrites, axons and neurons were still recognizable. These studies suggest that 3HANA can cause toxic damage by two distinct mechanisms: one appears to be excitotoxic in character, possibly via *in vitro* production of QUIN, and antagonized by D-APH while the other may reflect oxidative cell destruction. (Supported by USPHS Grant NS-28236.)

461.4

SELECTIVE SIGMA LIGANDS PROTECT AGAINST DYNORPHIN A-INDUCED SPINAL CORD INJURY IN RATS. J.B. Long, R.E. Tidwell*, F.C. Tortella, K.C. Rice[1], and B.R. deCosta[1]*, Neuropharm. Br., Dept. of Med. Neurosci., Walter Reed Army Inst. of Res., Washington, D.C. 20307 and [1]Lab. of Med. Chem., NIDDK, Bethesda, MD 20892.

Lumbar spinal subarachnoid injection of dynorphin A (DYN) causes ischemia, neuronal degeneration and persistent hindlimb (HL) paralysis in rats. Excitatory amino acids have been implicated as mediators of DYN-induced spinal cord injury due to the protective effects of competitive and noncompetitive NMDA receptor antagonists, including MK-801, dextrorphan, and dextromethorphan (DM). However, recent evidence suggests that protective effects of DM in this model might involve binding sites in addition to those associated with the PCP/NMDA receptor complex. DM binds to high affinity sites which are quite similar to the sites identified by prototypic sigma (σ) ligands such as (+)-PPP. To address the involvement of DM/σ binding sites in neuroprotective mechanisms, we evaluated the effects of several highly σ selective substituted phenylethylamines (BD 737, BD 738, BD 1008, and BD 1063) on recovery from the persistent motor deficits caused by L4-L5 subarachnoid injections of 20 nmoles of DYN. Immediate preinjection of these compounds (50-200 nmoles, i.t.) failed to block the HL paralysis acutely induced by DYN; however all 4 σ compounds caused significant persistent improvements in HL neurological scores by 24 hr postinjection. These results indicate a potential usefulness of σ receptor ligands in the treatment of CNS injury.

461.5

MK801 INDUCES THE 70kD HEAT SHOCK PROTEIN AND FOS IN THE CINGULATE GYRUS. James W. Sharp, Stephen M. Sagar, and Frank R. Sharp, Depts. Neurology and Physiology, Univ. Calif. and VA Medical Center, San Francisco, CA. 94121

MK801, a non-competitive NMDA receptor blocker, has been shown to protect the nervous system from injury both *in vivo* and *in vitro*. However, recent studies suggest that this drug may selectively kill some neurons (Olney et al., Science *244*:1360; Allen et al., Science *247*: 221) in cingulate cortex.

Because we have proposed that heat shock gene expression (Gonzalez et al., Mol. Brain Res. *6*:93) may be a useful marker of stressed neurons, we have examined the effects of MK801 on HSP70 expression. 1mg/kg of MK801 given intraperitoneally induced HSP70 and Fos, detected immunocytochemically, in many neurons in cingulate and retrosplenial areas of cortex 18h after administration. This is a dose reported to produce reversible vacuolization of these neurons. The effects of 5mg/kg of MK801, a dose reported to produce irreversible neuronal injury in cingulate cortex, is currently being investigated.

The data support the usefulness of HSP70 in identifying cells stressed by a variety of insults. This and other data suggests that cells stressed by various insults that are destined to survive express both HSP70 mRNA and protein, whereas lethally injured cells may or may not express the protein.

461.6

ANTICHOLINERGICS PREVENT NEUROTOXIC SIDE EFFECTS OF NMDA ANTAGONISTS J.W. Olney, J. Labruyere*, G.J. Wang, M.T. Price. Washington University Medical School, St. Louis, MO 63110.

Although antagonists of the N-methyl-D-aspartate (NMDA) subtype of glutamate receptor are potentially useful for preventing neuronal degeneration in certain neurological disorders, treatment of adult rats with these compounds results in neurotoxic side effects consisting of pathomorphological changes in certain neurons of the cingulate and retrosplenial cerebral cortices (Olney et al., Science, 1989). Following low doses, these changes may be reversible, but higher doses can result in irreversible neuronal necrosis (Allen and Iversen, Science, 1990). Both competitive and non-competitive NMDA antagonists cause such effects. Here we report that certain anti-cholinergic compounds, when administered systemically, effectively protect cingulate/retrosplenial neurons against the neurotoxic action of the powerful NMDA antagonist, MK-801. Although all of the effective anti-cholinergic compounds have significant affinity for both M1 and M2 muscarinic receptors, their order of potencies in preventing MK-801 neurotoxicity (scopolamine > benztropine > trihexyphenidyl = atropine > biperiden > procyclidine > benactyzine > diphenhydramine) correlates better with their order of binding affinities for the M1 than M2 receptor. Using the chick embryo retina, we determined that high concentrations of these anticholinergic compounds do not interfere with the ability of MK-801 to protect retinal neurons against NMDA toxicity. These compounds, therefore, provide a simple and safe method for eliminating a potentially serious side effect associated with the use of NMDA antagonists as neuro-protective drugs.

461.7

DOMOIC ACID: A DEMENTIA-INDUCING EXCITOTOXIC FOOD POISON WITH KAINIC ACID RECEPTOR SPECIFICITY G.R. Stewart, C.F. Zorumski, M.T. Price, and J.W. Olney. Dept. of Psychiatry, Washington University Sch. of Med., St. Louis, MO 63110.

Domoic acid (Dom), a structural analog of the excitotoxic amino acid, glutamate (Glu), is believed to be the mussel neurotoxin responsible for a food poisoning incident in Canada in 1987 that killed some individuals and left others cognitively impaired. Since information pertaining to Dom excitotoxicity is limited, we have evaluated the neuroexcitatory properties of Dom *in vitro* (cultured hippocampal neurons) and its neurotoxic properties both *in vitro* (chick embryo retina) and *in vivo* (adult rat).

In vitro, the properties of Dom were compared with those of kainic acid (KA), *N*-methyl-D-aspartate (NMDA), and Quisqualate (Quis), each of which is a prototypic agonist at a different subtype of Glu receptor. Under voltage clamped conditions, currents induced in hippocampal neurons by Dom were identical to currents induced by KA; both displayed a linear current/voltage relationship (in contrast to NMDA currents) and were non-desensitizing (in contrast to Quis currents). Dom currents were not blocked by NMDA antagonists but were blocked by CNQX, an antagonist of non-NMDA receptors. In the chick embryo retina, Dom induced the same distinctive lesion pattern as KA which differed from the NMDA or Quis lesion, and the Dom lesion was blocked by CNQX but not by NMDA antagonists. Subcutaneous administration of Dom (2.5-3 mg/kg) to adult rats resulted in an acute seizure-brain damage syndrome similar to that caused by systemic KA (12 mg/kg), and analogous to the neurotoxic syndrome observed in the human food poison victims.

Supported by T32 ES07066 (GRS); the Klingenstein Fdn., MH45493, PSA MH00630 (CFZ); DA05072, AG05681, and RSA MH38894 (JWO).

461.8

EXOGENOUS EXCITATORY AMINO ACID NEUROTOXICITY IN VITRO CAN BE INDUCED BY CYCLIC AMP. A. Morandi*, L. Facci, D. Milani*, A. Leon and S.D. Skaper. Fidia Research Laboratories, 35031 Abano Terme (PD), Italy.

Glutamate, an excitatory amino acid (EAA) that exerts a trophic effect on immature cerebellar granule cells in culture, is toxic at later stages of cellular maturation. We observed that some granule cell preparations failed to develop this sensitivity to excitotoxin injury. As a first approach to understanding the nature of this resistance, prolonged pretreatment (18h) with db-cAMP or forskolin (FSK) was found to confer, in a dose dependent way, sensitivity to the neurotoxic actions of glutamate, aspartate and kainate. Shorter treatment times, or addition of db-cAMP only during EAA exposure or afterwards failed to be effective. The neurotoxic action of glutamate in these sensitized cells was blocked by Mg^{2+}, ganglioside GM1, and inhibitors of protein synthesis. Following removal of db-cAMP, the granule cells again became resistant to glutamate neurotoxicity after 48 h. These observations may provide new insights into the mechanisms of excitotoxicity and their possible role in human CNS pathologies.

461.9

AMINO ACID NEUROTOXICITY IN CORTICAL SLICES.
H.C.Sullivan and A.R.Kriegstein Dept.of Neurology, Stanford Univ. Med. Center, Stanford, CA 94305.

There is evidence that glutamate neurotoxicity mediates hypoxic injury in select neuronal populations. Studies have shown that dissociated cell cultures of turtle neurons are relatively resistant to glutamate neurotoxicity (Wilson and Kriegstein, Soc.Neurosci.Abst. 15:763.) Because turtle brain is resistant to prolonged periods of anoxia, we have been able to measure delayed neuronal degeneration in adult turtle cortical slices 24 hours after exposure to excitatory amino acids. Cortical slices (400 um) from adult diving turtles were exposed to glutamate (Glu), NMDA, and kainate (KA) for 30 minutes, and incubated for 24 hours. Measurement of LDH released into the bathing media correlated with morphological injury. The LD_{50} values from the dose-toxicity curves for Glu, NMDA, and KA were 2.2mM, 18uM, and 0.3uM respectively. The Glu uptake inhibitor, dihydroKA, reduced the LD_{50} for Glu to 100uM, but threo-OH-aspartate blocked Glu toxicity. APV and CNQX were effective antagonists for NMDA and KA neurotoxicity. We conclude that the slice method is a rapid and reliable means of assessing EAA neurotoxicity in turtle cortex.

461.10

SENSITIVITY TO AMPA INDUCED BRAIN INJURY TRANSIENTLY PEAKS EARLY IN POSTNATAL DEVELOPMENT, William H. Trescher, John W. McDonald, Michael V. Johnston, The Kennedy Research Institute and The Johns Hopkins University School of Medicine, Department of Neurology, Baltimore, MD 21205.

The ontogeny of quisqualate subtype excitatory amino acid (EAA) receptor mediated neurotoxicity was studied in rats at 8 ages between postnatal day (PND) 1-90 (adult). Animals received unilateral, anterior striatial, stereotaxic injections of either alpha-amino-3-hydroxy-5-methyl-4-isoxazoleacetic acid (AMPA) (25 nmol/0.5 ul) or quisqualatic acid (QA) (100 nmol/0.5 ul). Severity of brain damage was evaluated by comparing regional cross-sectional areas of injected and contralateral cerebral hemispheres of brains 5 days after excitotoxin injection. The area of the ipsilateral corpus striatum was reduced by 25% at PND 1, which was equivalent to the severity of damage in adults; neuronal necrosis was limited to the injection tract. Between PND 5 and 28, the extent of AMPA induced neurotoxicity exceeded that in adults, transiently peaking at PND 10, when the damage to the striatum was 4-fold greater than in adults. From PND 5 to 10, the excitotoxic reaction to AMPA spread to progressively larger areas of the ipsilateral hemisphere, and involved medial aspects of the contralateral hemisphere at PND 7 and 10. In AMPA injected animals, ipsilateral cortical cross-sectional area was reduced by 11% in adults. In contrast, at PND 10 there was extensive confluent neuronal necrosis to the cerebral cortex, and the extent of damage exceeded adult values by a factor of 8. After PND 10, the extent of AMPA induced damage gradually decreased in all regions. A similar developmental pattern of sensitivity to QA toxicity was observed with maximal damage to the striatum at PND 10. The data demonstrate that EAA induced neurotoxicity mediated by the QA receptor subtype is enhanced in the developing rat brain with a pattern that is distinct from the other EAA receptor subtypes.

461.11

HYPERBILIRUBINEMIA IS ASSOCIATED WITH ENHANCED SUSCEPTIBILITY TO EXCITOTOXIC BRAIN INJURY. John W. McDonald, Steven M. Shapiro+*, Faye S. Silverstein@ and Michael V. Johnston, Departments of Neurology and Pediatrics, Johns Hopkins University and Kennedy Institute, Baltimore, MD; +Medical College of Virginia, Richmond, VA; and @University of Michigan, Ann Arbor, MI.

The pathophysiology of bilirubin encephalopathy is not well defined. The Gunn rat, which has an inherited deficiency of glucuronyl transferase, is commonly used as a model of human kernicterus. Homozygous (jj) animals have an unconjugated hyperbilirubinemia, and manifest a pattern of brain injury that resembles human bilirubin encephalopathy. Heterozygous (Nj) animals have 50% glucuronyl transferse activity, are not jaundiced, and do not develop signs of bilirubin encephalopathy. To examine the hypothesis that hyperbilirubinemia increases the susceptibility to excitotoxic brain injury, the sensitivity of PND 7 Nj and jj Gunn rats to brain injury induced by the EAA analogue NMDA was compared. In experiment #1, PND 7 littermates received a unilateral intrastriatal stereotaxic injection of 5 nmol NMDA (n= 4 jj, 4 Nj). In experiment #2, 5 jj and Nj littermate pairs received an i.p. injection of 200 mg/kg sulfamethoxazole (SM) 4 hrs prior to unilateral intrastriatal injection of NMDA. The severity of brain injury was quantitated 5 days later by comparison of regional cross-sectional areas in injected and contralateral cerebral hemispheres. NMDA mediated brain injury was enhanced in jj animals compared to Nj littermates (%Damage=%reduction of cross-sectional area in injected compared to non-injected hemisphere, mean±SEM: Striatum, -15.5±3.5% Nj vs -24.1±2.4% jj, $p<0.05$; hippocampus, -8.6±5.1% Nj vs -19.5±6% jj, p=ns). Pretreatment with sulfamethoxazole, which elevates brain tissue bilirubin, markedly increased the severity of NMDA induced brain injury in jj, but not Nj, rats (%Damage, mean±SEM: striatum, -13.8±1.3% Nj vs -34.4±2.5% jj, $p<0.001$; hippocampus, -4.5±9.2% Nj vs -40.0±9.0% jj, $p<0.05$). The results indicate that hyperbilirubinemia in Gunn rats is associated with an increased susceptibility to excitotoxic brain injury.

461.12

ACTION OF OXYGEN FREE RADICALS ON THE REDOX MODULATORY SITE OF THE NMDA RECEPTOR.
E. Aizenman, K.A. Hartnett*, & I.J. Reynolds, Depts. Physiology and Pharmacology, U. of Pittsburgh Sch. of Med., Pittsburgh., PA 15261.

NMDA responses in central neurons can be modified by sulfhydryl redox reagents (Neuron, 2: 1257; 1989). This led us to search for endogenous agents acting at the NMDA receptor redox modulatory site. Fura-2-measured rises in Ca^{2+} produced by 30 μM NMDA + 1 μM glycine in cultured rat cortical neurons were enhanced by 0.3-10 mM of the reductant DTT. Treatment of neurons with the oxidizing agent DTNB (0.5 mM), or with the oxygen free radical generating system of xanthine (X; 1 mM)/xanthine oxidase (XO; 0.05 U/ml), could reverse the effect of DTT and diminish the native response to NMDA & glycine. The actions of X/XO (or DTNB) were further reversed by DTT. It was also observed that the 0.5 mM DTT-induced enhancement of NMDA (50 μM)-mediated toxicity in cortical cultures was always reversed by X/XO (100 μM/0.005 u/ml). These results show that NMDA responses can be modified by an endogenous oxygen free radical generating system acting via the redox modulatory site on the NMDA receptor.

MOLECULAR NEUROBIOLOGY OF 5HT RECEPTORS

462.1

ISOLATION OF A DROSOPHILA SEROTONIN RECEPTOR: AN UNUSUAL MEMBER OF THE G PROTEIN-COUPLED RECEPTOR FAMILY.
Hen R.*, Witz P.*, Maroteaux L.*, Gombos G.#, Borrelli E.* and Amlaiky N.* *LGME/CNRS-U184/INSERM, URA DO589 CNRS, #Centre de Neurochimie, Strasbourg, France.

A Drosophila serotonin receptor cDNA was isolated employing low stringency hybridization with oligonucleotides corresponding to consensus sequences present in G protein-coupled receptor. The deduced protein (5HT-dro receptor), which contains 564 amino acids, exhibits homology to the human 5HT1A receptor. Unlike all other G protein-coupled receptors which have a predicted seven transmembrane domain structure, the hydropathy profile of the 5HT-dro receptor reveals eight putative transmembrane domains. This receptor contains also a 20 amino acid long glycine-serine repeat, which is a potential glycosaminoglycan attachment site. Such repeats are found in certain proteoglycans and in the Drosophila clock protein period. Probes derived from this receptor hybridize to a single mRNA species 5 kbp in length, which is found predominantly in adult Drosophila heads. In order to characterize this receptor we expressed it in NIH 3T3 cells. In these transfected cells serotonin induced an increase in cAMP levels that was concentration dependent and saturable. The half maximum stimulation was obtained with 10^{-7} M serotonin, and stimulation was inhibited by ergot alkaloïds such as dihydroergocryptine.

462.2

COUPLING OF VACCINIA VIRUS EXPRESSED 5-HT1A RECEPTORS TO AN ENDOGENOUS K^+ CHANNEL IN RAT ATRIAL CELLS. A. Karschin, B.Y. Ho*, C. Labarca*, O. Elroy-Stein*, B. Moss*, N. Davidson, and H.A. Lester. Caltech, Division of Biology 156-29, Pasadena, CA 91125, and LVD, NIH, Bethesda, MD 20892.

Recombinant vaccinia viruses (VV) represent unique vectors for heterologous gene expression in eukaryotic cells. We constructed a recombinant VV harboring the human 5-HT1AR and expressed it in primary cultures of neonatal rat atrial myocytes. For maximum expression a novel strategy was used based on coinfection with one virus carrying the 5-HT1AR gene downstream of a bacteriophage T7 promoter and an encephalomyocarditis virus sequence, and a second VV containing the T7 polymerase gene under control of a VV promoter (Elroy-Stein et al., PNAS 86:6126, 1989). The 5-HT1AR subtype seems to couple directly to K^+ channels via G proteins in the hippocampus. A similar pathway is known for ACh in atrial cells, where muscarinic AChRs activate an inwardly rectifying K^+ current (I_{ACh}). We used whole-cell recordings of atrial cells to study whether a VV-expressed 5-HT1AR would functionally couple to an intrinsic K^+ conductance. In cells that were either non-infected or infected with wild-type virus, I_{ACh} was induced by ACh (10 μM), but not by 5-HT (10 μM). Only after the coinfection with the two recombinant viruses, 5-HT activated an inwardly rectifying K^+ current in atrial cells. 5-HT responses were observed as early as 15 h post-infection and could be mimicked by the selective 5-HT1AR agonist 8-OH DPAT. The expressed 5-HT1AR is suggested to couple to a pre-existing muscarinic excitation pathway in cardiac atria. Support: Max-Kade- and Del Webb Foundation, GM-29836, GM-10991 (NIH).

462.3

INTRINSIC ACTIVITY OF TETRAHYDROPYRIDINYL INDOLES AT 5-HT_{1A} RECEPTORS NEGATIVELY COUPLED TO ADENYLATE CYCLASE. L.J.Cornfield, G.Lambert*, T.Dahlgren[1*], S.S.Nikam[1*], Y.Yang[1*], A.R. Martin[1*] & D.L.Nelson, Dept. of Pharmacology & Toxicology and [1]Dept. of Pharmaceutical Sciences, College of Pharmacy, University of Arizona, Tucson, AZ 85721 USA.

This study extends work previously undertaken to determine optimal 5-HT_{1A} affinity and selectivity, using conformationally rigid analogs of 5-HT itself (Taylor et al., Mol. Pharmacol. 34:42, 1988). The series consisted of analogs of 3-(1,2,5,6-tetrahydropyridin-3-yl)indoles (3-THPI) and 3-(1,2,5,6-tetrahydropyridin-4-yl)indoles (4-THPI). Most analogs produced complex inhibition curves in the forskolin-stimulated adenylate cyclase (FSC) assay (DeVivo & Maayani, J. Pharmacol. Exp. Ther. 238:248, 1986) using male Sprague-Dawley rat hippocampus. These inhibition curves contained a pindolol-sensitive component, suggesting at least partial 5-HT_{1A} agonist activity. Analogs producing only weak inhibition of FSC were able to reverse 5-HT-induced inhibition by varying degrees. The 4-THPI analogs generally had higher 5-HT_{1A} binding affinities than the 3-THPI analogs. Within each group of analogs, it appeared that the higher the 5-HT_{1A} affinity, the greater the 5-HT_{1A} agonistic activity. Further analogs must be tested to confirm this trend. Analogs with a carboxamido group in the 5-indole position did not follow these trends.(Sup.by NS16605 and NS01009).

462.4

PRE- AND POSTSYNAPTIC 5-HT_{1A} RECEPTORS EXHIBIT DIFFERENT ELECTROPHYSIOLOGICAL PROPERTIES: I - EFFECTS OF SPIPERONE. C. de Montigny, A. Lista and P. Blier. Neurobiological Psychiatry Unit, Dept. of Psychiatry, McGill University, Montreal, Quebec, Canada H3A 1A1.

Single-cell extracellular recordings were obtained from dorsal raphe 5-HT neurons and from dorsal hippocampus CA_3 pyramidal neurons in chloral hydrate-anesthetized rats.

The effect of microiontophoretic applications of 5-HT and of 8-OH-DPAT, but not that of GABA, onto dorsal raphe 5-HT neurons was readily antagonized by acute spiperone (1 mg/kg, i.v.). The same dose of spiperone did not alter the response of pyramidal neurons of the dorsal hippocampus either to microiontophoretically-applied 5-HT or to endogenous 5-HT released by the electrical stimulation of the ascending 5-HT pathway.

However, the response of dorsal hippocampus pyramidal neurons to both endogenous and exogenous 5-HT was markedly attenuated 24 hr after the i.p. administration of 5 mg/kg of spiperone. Such an inactivation of postsynaptic 5-HT_{1A} receptor response could not be detected 12 hr after the i.p. administration of 5 mg/kg of spiperone, nor 24 hr after lower doses of spiperone (1 and 2.5 mg/kg, i.p.). Neither ketanserine (5 mg/kg, i.p.), a 5-HT_2 antagonist, nor haloperidol (5 mg/kg, i.p.), a D_2 antagonist, modified dorsal hippocampus pyramidal neurons response to either exogenous or endogenous 5-HT, 24 hr after their administration, indicating that the effect of spiperone is attributable to its 5-HT_{1A} affinity rather than its 5-HT_2 or D_2 affinities.

These results show that spiperone acts as a classical antagonist at the somatodendritic 5-HT_{1A} autoreceptor in the dorsal raphe, but not at postsynaptic 5-HT_{1A} receptors in the dorsal hippocampus. The mechanism whereby a single dose of the 5-HT_{1A} antagonist spiperone induces a delayed inactivation of the latter receptors remains to be unveiled.

462.5

PRE- AND POSTSYNAPTIC 5-HT_{1A} RECEPTORS EXHIBIT DIFFERENT ELECTROPHYSIOLOGICAL PROPERTIES: II- EFFECTS OF PERTUSSIS AND CHOLERA TOXINS. P. Blier, A. Lista and C. de Montigny. Neurobiological Psychiatry Unit, Department of Psychiatry, McGill University, Montreal, Quebec, Canada H3A 1A1.

5-HT_{1A} autoreceptors located on the soma of 5-HT neurons and postsynaptic 5-HT_{1A} receptors on the cell body of CA, hippocampus pyramidal neurons are coupled to G_i proteins. In the present experiments, the effect of microiontophoretic application of 5-HT onto dorsal raphe 5-HT neurons and onto dorsal hippocampus CA_3 pyramidal neurons was assessed 1 to 2 weeks following in situ injections of pertussis or cholera toxin (1 µg in 2 µL of saline). In addition, the response of the same postsynaptic neurons to endogenous 5-HT released by the electrical stimulation of the ascending 5-HT pathway was assessed in the same rats, as 5-HT terminals make synaptic contacts on the dendrites of these neurons.

Pertussis toxin, which inactivates G_i proteins, markedly attenuated the response of 5-HT neurons and that of CA_3 neurons to the microiontophoretic application of 5-HT, but left unaltered the effectiveness of the stimulation of the 5-HT pathway in suppressing the firing activity of the latter neurons. In contrast, cholera toxin, which interferes with G_s-coupled mechanisms, did not modify the responsiveness of 5-HT neurons to microiontophoretically-applied 5-HT, but reduced both the effectiveness of the stimulation of the 5-HT pathway and that of the microiontophoretic applications of 5-HT on CA_3 neurons.

These results suggest that: 1) the 5-HT_{1A} autoreceptor of 5-HT neurons is coupled to a G_i, but not to a G_s protein; 2) there may exist on CA_3 pyramidal neurons intra-synaptic 5-HT_{1A} receptors on their dendrites which are coupled to a G_s but not to a G_i protein, and extra-synaptic 5-HT_{1A} receptors on their cell body which are coupled to both G_s and G_i proteins.

462.6

DEVELOPMENTAL REGULATION OF SEROTONIN RECEPTOR (5HT2/5HT1C) AND mRNA LEVELS. Bryan L. Roth, Mark W. Hamblin, Roland D. Ciaranello, Lab Dev Neurochem, Department of Psychiatry, Stanford Univ Med School, Stanford, CA 94305.

Serotonin (5-hydroxytryptamine; 5T) receptors have been shown to be regulated by a diverse array of factors, some of which appear to be developmentally regulated. Two of these receptors (5HT2 and 5HT1c) have been cloned and implicated as mitogens. We have discovered that each receptor appears to have a distinct pattern of receptor and mRNA expression during rat perinatal brain development. The 5HT2 receptor, for instance, increases 8-fold during ontogeny while its corresponding mRNA increases approximately 13-fold (both $p<0.001$); levels of receptor gene expression were unaffected by receptor antagonist (mianserin) treatment during the perinatal or adult periods. The 5HT1c receptor gene appeared to have a number of discrete "bursts" of expression depending upon the brain area and the developmental period. Thus, for instance, a pulse of receptor gene expression occured in the areas of the reticular and raphe nuclei during the second post-natal week while choroid plexus gene expression was evident at the earliest time point studied as assessed by *in situ* hybridization (embryonic day 17). These results imply the existence of distinct developmental "switches" in various brain regions responsible for controlling the expression of different serotonin receptor genes.

462.7

NEONATAL 5,7-DHT LESIONS ALTER [^{3}H]MESULERGINE-LABELLED 5-HT1C RECEPTORS IN RAT BRAIN. M. R. Pranzatelli, Columbia Univ., New York, NY 10032.

5-HT receptor denervation supersensitivity has been proposed to explain behavioral supersensitivity to L-5-HTP in rats with 5,7-dihydroxytryptamine (5,7-DHT) lesions. No upregulation of 5-HT2 binding sites has been found despite supersensitivity to putative 5-HT2,1C drugs. To test the hypothesis that the 5-HT1C properties of these drugs are involved instead, we measured 5-HT1C receptors in rats one month after making neonatal 5,7-DHT lesions by intraperitoneal injection. Sites labelled with [^{3}H]mesulergine (with 10 µM 5-HT as displacer) showed a distinct regional distribution: frontal cortex>> hippocampus>brainstem>diencephalon>>cerebellum. In the presence of 20 nM spiperone to block 5-HT2 sites, 31%, 70%, 65%, 70%, and 73% of the sites remained, respectively. 5,7-DHT lesions upregulated these sites in frontal cortex (+29%) and hippocampus (+25%). There were no changes in Bmax in other regions. Kd and nH were unchanged. Changes in Bmax paralleled 5-HT concentrations measured by HPLC. These data suggest that 5-HT1C rather than 5-HT2 receptor denervation supersensitivity may explain enhanced behavioral responses to 5-HT2,1C drugs in rats with 5,7-DHT lesions. ISOLATION, PURIFICATION TO HOMOGENEITY AND SEQUENCE OF A BRAIN ENDOCOID FOR ^{3}KETANSERIN RECOGNITION SITES (KBI). J.A. Apud*, A. Guidotti, Y. Ito*§, B. Martin*†, M.L. Barbaccia and E. Costa. FGIN, Georgetown University, Washington, D.C. 20007; §Laboratory of Biophysical Chemistry, NHLBI and †Laboratory of Molecular Neurogenetics, NIMH, Bethesda, MD 20892.

A peptide that selectively displaces ^{3}H-KET binding from crude synaptic membranes has been recently extracted, purified to homogeneity and sequenced. Major steps for its purification include: a)homogenization (1:6,w:v) of rat brain with 0.1M CH_3COOH and heat inactivation (90°C, 10 min), b) filtration of the 40,000xg supernatant on Biogel P-10 column equilibrated with 0.1M CH_3COOH:20% CH_3OH, c) precipitation in 60% ammonium sulphate, d) countercurrent chromatography (CCC) of the 40,000 xg supernatant, e)C_{18} µBondapak reverse phase HPLC, f) C_{18} PTH reverse phase HPLC. A partial sequence containing 17 amino acids has been identified using the Edman degradation technique. The hydropathy profile of the partial sequence is in agreement with the physico-chemical behavior of the endocoid revealed both in the CCC and HPLC purification steps. KBI is pronase-sensitive and fails to displace ^{3}H-mianserin and ^{3}H-imipramine at concentrations which inhibit 60% of ^{3}H-KET specific binding. The activity of the KBI on platelet aggregation and on phosphoinositide hydrolysis in rat cerebral cortex indicate that KBI interact with the 5-HT 2 receptor domain.

462.9

AFFINITIES OF THE TWO ENANTIOMERS OF FLUOXETINE FOR SUBTYPES OF SEROTONIN (5-HYDROXYTRYPTAMINE, 5HT) RECEPTORS. D.T. Wong, P.G. Threlkeld*, R.D. Marsh*, F.P. Bymaster*, L.R. Reid* and D.W. Robertson*. Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, IN 46285.

The two enantiomers of fluoxetine exhibit similar pharmacology as 5HT uptake inhibitors, with eudismic ratios near unity (Wong et al, Drug Dev.Res.6:397, 1985). The R and S enantiomers and racemic fluoxetine inhibited 5HT uptake in human platelets at 50% 3.6, 3.9 and 4.6 nM (IC_{50}), respectively, but have relatively weak affinity for 5HT-1 (A,B,D) and 5HT-2 receptors, as indicated by the micromolar IC_{50} concentrations to inhibit binding of radioligands to these receptors. However, the R enantiomer and racemic fluoxetine inhibited ^{3}H-mesulergine binding to 5HT-1C receptors in bovine choroid plexus, with IC_{50} values of 200 and 450 nM, respectively, while the IC_{50} of S-fluoxetine was 17,000 nM. Fluoxetine and the two enantiomers inhibited ^{3}H-LY278584 binding to 5HT-3 receptors, with IC_{50} values at micromolar concentrations. These concentrations were substantially higher than the IC_{50} of 10 nM for fluoxetine to inhibit ^{3}H-quipazine binding to its recognition sites (Schmidt & Peroutka, Eur.J.Pharmacol. 163:397, 1989). Thus, R-fluoxetine, besides being a potent 5HT uptake inhibitor, has an intermediate affinity for 5HT-1C receptors. The effects of racemic fluoxetine appear to be mediated primarily via inhibition of 5HT uptake, but further studies should determine whether occupancy of 5HT-1C receptors is reflected in any pharmacological effects.

462.10

LOCALIZATION OF CENTRAL 5-HT3 RECEPTORS IN THE RAT USING ^{3}H-ZACOPRIDE AND ^{125}I-ZACOPRIDE. L.E. Schechter, F. Bolanos*, A.M. Laporte* M. Hamon*and H. Gozlan*. INSERM U. 288, CHU Pitié-Salpêtrière, 91 Bld. de l'Hôpital, 75634 Paris Cedex 13, France

To date, various lines of evidence have suggested that central 5-HT3 binding sites are involved in anxiety, depression and schizophrenia as well as emesis and pain-modulation. In order to determine the possible loci of action for these effects, the distribution of 5-HT3 binding sites was examined in the rat brain and spinal cord using both membrane homogenates and autoradiography with the tritiated and iodinated derivatives of the potent and selective 5-HT3 antagonist, zacopride. 5-HT3 binding sites were notably found in the nucleus of the solitary tract and the dorsal nucleus of the vagus nerve, i.e. structures perhaps involved in the emetic reflex. High densities of 5-HT3 binding sites were also observed within the spinal trigeminal nucleus and the superficial layers of the dorsal horn of the spinal cord, where 5-HT3 ligands probably act as pain-modulating drugs. Finally, the amygdala (cortical and basolateral nuclei), hippocampus and entorhinal cortex also contained 5-HT3 binding sites, which probably mediate the behavioral effects of 5-HT3 agents. Further investigations in rats treated by 5,7-dihydroxytryptamine, kainic acid or capsaicin indicated that 5-HT3 binding sites are located on postsynaptic targets in limbic areas, and (partly) on primary afferent fibers in the spinal cord.

462.11

RESPONSES OF ENTERIC NEURONS TO ANTI-IDIOTYPIC ANTIBODIES THAT RECOGNIZE 5-HT_3 AND 5-HT_{1P} RECEPTOR SUBTYPES P. R. Wade*, H. Tamir, and M. D. Gershon, Departments of Anatomy and Cell Biology , Columbia Univ. P & S and N.Y. State Psych. Inst. New York, NY.

Two 5-HT receptor subtypes, 5-HT_{1P} and 5-HT_3, have excitatory effects on enteric neurons. The 5-HT_{1P} receptor mediates a long lasting depolarization associated with an increase in input resistance. The 5-HT_3 receptor mediates a transient depolarization during which the input resistance decreases. Polyclonal anti-idiotypic antibodies (anti-id Aß) have been raised by immunizing rabbits with affinity purified antibodies to 5-HT. The resulting crude anti-id Aß were purified by affinity chromatography and shown by immunocytochemistry to bind to a subset of enteric neurons. Anti-id Aß were applied by microejection to guinea pig myenteric neurons and found to mimic both 5-HT_3- and 5-HT_{1P}-mediated responses to 5-HT. Responses to the anti-id Aß were antagonized by desensitization of 5-HT receptors and by renzapride (BRL 24924), which antagonizes responses to 5-HT mediated either by 5-HT_3 or 5-HT_{1P} receptors. Following application of anti-id Aß, both 5-HT_3 and 5-HT_{1P} responses to 5-HT were inhibited (5-HT_{1P} > 5-HT_3). This inhibition appeared to be specific because the anti-id Aß did not affect responses to carbachol or substance P. It is concluded that the anti-id Aß binds to 5-HT receptors. Its affinity appears to be greater for 5-HT_{1P} than for 5-HT_3 receptors. Supported by grants NS 12969, MH 37575 and the PMAF.

PROCESS OUTGROWTH, GROWTH CONES AND GUIDANCE MECHANISMS X

463.1

BEHAVIOR OF LIVE RETINAL AXON GROWTH CONES IN THE OPTIC CHIASM P. Godement* and C.A. Mason, *Inst. Neurosciences, CNRS, Univ. P.M. Curie, Paris 75005, and Dept. Pathology, Coll. Physicians and Surgeons, Columbia University, New York, N.Y. 10032.

Previous studies on a variety of neural systems have demonstrated that growth cone morphology is position-specific, becoming more complex in regions where fibers change direction or sort out among themselves. Our analysis of DiI-labeled axons in the mouse optic chiasm (Godement et al., Neuron, in press) show that within this decision region, the most complex growth cones develop on uncrossed axons as they turn sharply toward the ipsilateral optic tract. To link morphology with behavior, we observed growth cones extending in real time. A semi-intact preparation including retinae, optic nerves and a slab of ventral diencephalon, was dissected from mouse embryos at E14-16, small injections of DiI were made in the retina, and the preparation kept in culture for two days. Growth cone behavior was monitored over several hours using low levels of incident fluorescent illumination and time-lapse video recording. Many growth cones advance steadily at rates of 15-50 microns/hr, while others stall, retracting and regrowing repeatedly. Growth cones rapidly change shape, becoming longer with fewer filopodia when advancing, and spread with more filopodia, when resting. Retraction and regrowth is often associated with slight shifts in directionality of the growth cone. Thus, growth of retinal fibers in their natural environment is a dynamic process, involving changes in form, saltatory growth, and process retraction. This analysis should indicate the role of such growth cone behaviors within pathways of straight growth and in the selection of appropriate trajectories within decision regions. (Supported by NS 27615).

463.2

RETINAL AXON NAVIGATION IN THE MOUSE OPTIC CHIASM: MIDLINE CUES AND CELL-CELL RELATIONS. C.A. Mason, J.P. Misson*, R. Blazeski, and P. Godement**, Dept. Pathology, Coll. Physicians and Surgeons, Columbia University, New York, N.Y., *Dept. Pediatrics, C.H.U. Sart-Tilman, Liege 4000, Belgium, and **Inst. Neurosciences, CNRS, Univ. P. M. Curie, Paris 75005.

As mouse retinal axons navigate through the optic chiasm, axons projecting to the contralateral side of the brain cross through the chiasm midline. Uncrossed axons initally travel with crossed fibers, but turn back abruptly at the border of a 100 micron-wide zone along the midline (Godement et al., Neuron, in press). As uncrossed fibers turn, their growth cones become highly complex. To examine the cellular structure of the chiasm midline, we immunostained the chiasm during the period of axon growth (E14-17) with a number of glial and neuronal cell-surface molecules. Antibodies to RC2, an antigen on immature radial glia in mouse CNS (Misson et al., *Dev. Br. Res.* 44:95, 1988) stained a palisade of radial fibers extending from the floor of the third ventricle through the chiasm to the pia,100-200 microns on either side of the midline. In the lateral chiasm, small cells with short processes were also stained. To understand the cell-cell relations of retinal growth cones in the chiasm, we examined identified DiI-labeled growth cones that were photoxidized and processed for EM. Growth cones on straight-growing fibers fasciculated on bundles of other axons. The complex growth cones on turning fibers contacted multiple processes and abutted cell bodies of unidentified cells. Clear and coated vesicles were prominent in the turning growth cones and in the profiles they contacted. This analysis should aid in identifying the cues for crossed and uncrossed fiber navigation, and may implicate properties intrinsic to each of these fiber populations that underly the differential response to these cues. (Supported by NS 27615).

463.3

AXON NAVIGATION AT THE MAMMALIAN OPTIC CHIASM: DIRECT OBSERVATION USING FLUORESCENT TIME-LAPSE VIDEO MICROSCOPY. D.W. Sretavan. Laboratory of Neurobiology, Rockefeller University, NY 10021.

Developing mammalian retinal ganglion cell axons make highly specific pathway choices at the optic chiasm (Sretavan, D.W. Soc. Neurosci. Abstr., 15: 960, 1989). To better understand axon pathfinding in this region, ganglion cell axons were directly observed growing into the optic chiasm in an intact preparation of the embryonic CNS. To do so, the retinas, optic nerves together with the chiasm and tracts were isolated from E13-E18 mouse embryos. DiI was deposited onto the retina to label ganglion cell axons and preparations maintained at 37°C on an inverted microscope. Time lapse images of axons were obtained every 30-60 seconds up to 12 hours using a CCD camera.

Several axon turning behaviors were seen at the optic chiasm. Retinal axons entering the ipsilateral optic tract often did so by making gradual 90° turns while maintaining continuous growth cone activity. On the other hand, some axons avoided entering the ipsilateral optic tract by retracting the distal 20 μm of its axon and simultaneously extending a new process in a different direction. Episodes where axons belonging to the two eyes encountered each other often resulted in a temporary pause in growth followed by the veering away of axons in a new direction upon recovery. This behavior was seen only in a subset of axon-axon encounters, suggesting that these repulsive interactions occur between axons from specific regions of the two retinas.

Unlike conventional histological methods, this preparation allows the examination of dynamic interactions between retinal axons and axon navigation within the native enivronment of the developing CNS. In addition. it potentially allows the direct perturbation of specific interactions between retinal axons and their environment and thus may help in furthering our understanding of axon guidance mechanisms.

I thank Torsten Wiesel for encouragement and continued support, and Larry Katz and his laboratory for expert advice on video microscopy and the use of equipment.

DYNAMIC BRANCHING PATTERNS IN OPTIC FIBER TERMINAL ARBORS WITHIN THE TECTUM N. A. O'Rourke and S. E. Fraser. Dept. of Physiol. & Biophysics, University of CA, Irvine, CA 92717.

Retinal ganglion cell axons project into the optic tectum where they branch to form terminal arbors, which are arranged in a topographic pattern. *In vivo* observations have revealed the dynamic arborization patterns of these fibers during the initial formation of the retinotopic map. The optic fibers were labeled with a fluorescent vital dye and visualized within the tecta of live *Xenopus laevis* tadpoles using a laser-scanning confocal microscope to resolve the complex three-dimensional structure of the arbors. Observation of the labeled fibers over a period of days has revealed that all the terminal arbors, even those with stable dimensions, were continuously remodeled through branch extension and retraction. To better characterize the branch dynamics, the arbors were visualized at shorter time intervals. Branches formed either through bifurcation at an axon tip or, more commonly, at more proximal positions along the length of another branch. Two classes of branches were found in the arbors. Short branches of less than 4 microns in length, termed "spikes", exhibited a rapid rate of remodeling and were seldom present for more than an hour. Longer branches showed much slower rates of extension and retraction which varied somewhat from one arbor to the next. Interestingly, the branch growth within an arbor was often restricted to one or two branches at any one time, suggesting that the growth machinery within the axon can be shunted selectively to one area of an arbor during the remodeling process. Because all the arbors were dynamic, even those with stable dimensions and tectal positions, these findings suggest that continual remodeling of arbors may be a universal feature of neuronal projections, even in systems previously thought to be static. (NIH EY08363).

463.5

AVOIDANCE RESPONSE AND COLLAPSE OF FISH TEMPORAL RETINAL GROWTH CONES UPON CONTACT WITH CAUDAL TECTAL MEMBRANES OF EMBRYONIC CHICK

C.A.O. Stuermer, M. Bastmeyer, J. Vielmetter,
Friedrich-Miescher-Lab./Max-Planck-Gesellschaft, Tübingen, FRG

Caudal tectal membranes of embryonic chick (Walter et al., 1987) and caudal tectal membranes of adult goldfish (Vielmetter et al., 1990) contain a repellent guiding component for temporal retinal axons. Temporal retinal axons of fish respond to both, the repellent component of fish and to that of E9 chick. The chick component, however, exerts a stronger repellent influence on fish temporal axons than that of fish.

We observed the avoidance behavior of fish growth cones upon contact with chick caudal tectal membranes in a modified in vitro stripe assay with time lapse videomicroscopy.

Axon elongate on 90 μm wide laminin lanes bounded by caudal membranes. Upon contact with caudal membranes on one side growth cones sent up to 20 μm long filopodia and lamellipodia onto the membranes, but retracted them rapidly while the growth cone continued to grow on the laminin lane. At the end of the laminin lane, filopodia and lamellipodia contacted membranes on 3 sides. Here, the growth cones collapsed and the axons retracted leaving thin strands of axon material behind. In control experiments, using rostral instead of caudal membranes, fish temporal axons grew freely into the membranes. The growth cone avoidance behavior will be demonstrated in a time lapse videosequence.

463.6

INTERACTIONS BETWEEN MOTOR NEURON DENDRITES AND DORSAL ROOT AFFERENT AXONS IN DEVELOPING MAMMALIAN SPINAL CORD. W.D. Snider, N. Gorukanti and C. Tsering, Dept. of Neurology, Washington Univ. Med. School, St. Louis, Mo. 63110

We have used two chromophores DiI and DiA (Di-16-ASP) in fixed tissue to study interactions between growing dendrites of spinal motor neurons and Ia afferent axons of dorsal root ganglion cells in mammals. We show here that motor neuron dendritic growth is highly oriented at early developmental stages. Initial dendrites grow in a bipolar orientation along the gray-white border zone and then give off branches into developing white matter. Between E14 and E15 dendrites grow into the gray matter in a pattern that differs between limb and axial motor neurons. Dendrites of axial motor neurons project dorsally along the midline whereas dendrites of limb motor neurons project directly medially. In contrast with the developmental sequence in frog (Jackson and Frank; J.Comp.Neurol. 255:538), we find that dendrites are growing into appropriate regions prior to the arrival of afferent fibers.

At E16 incoming Ia afferent axons segregate in the intermediate region of the cord. Afferents to axial motor neurons have their initial interaction with dorsally-directed dendrites along the midline and grow along these dendrites toward the somata. Afferents to limb motor neuorns contact medially directed dendrites and are guided to the lateral motor pools. Starting at E17 fibers branch repeatedly and elaborate boutons. Somata and proximal dendrites are densely invested whereas distal dendrites, dendrites that project into the white matter and dendrites that cross the midline are spared.

We conclude that, in mammals, motor neuron dendrites grow into regions of contact prior to the arrival of Ia afferent fibers. Afferents to limb and axial motor neuorns find appropriate synaptic partners by contacting different dendritic projections in the intermediate region of the cord. Finally, branching and elaboration of boutons does not occur until afferent fibers are in the region of the motor pools. These results suggest a major role for the target motor neuron in regulating the growth and branching of Ia afferent axons.

463.7

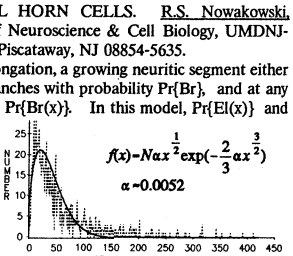
DENDRITIC DISTINCTIONS BETWEEN CALLOSAL AND SUBCORTICALLY PROJECTING PYRAMIDAL NEURONS DEVELOP FROM AN INITIAL COMMON MORPHOLOGY BY ELIMINATION OF EXUBERANT APICAL DENDRITES. S.E. Koester and D.D.M. O'Leary, Depts of Neurosurgery and Anatomy & Neurobiology, Washington Univ Sch Med, St. Louis, MO 63110

In adult rats, subcortically projecting pyramidal neurons, which are restricted to layer 5, have apical dendrites that arborize extensively in layer 1, whereas layer 5 callosal neurons do not send dendrites to layer 1 and are referred to as short pyramids (Hallman et al. 1988, J Comp Neurol 272:149; Games & Winer 1988, Hearing Res 34:1). To examine the development of the short pyramids, we placed DiI into one cortical hemisphere of a series of rat brains that had been aldehyde fixed at successive embryonic and postnatal ages (E22 = P0). Retrogradely labeled cells in contralateral cortex were examined in coronal sections several months later. In the embryonic cases, the retrogradely labeled cells are likely to be layer 5 neurons since most superficial callosal cells have not extended an axon into the contralateral cortex. Postnatally, layer 5 can be clearly discerned. At ages ranging from E19 to P4, virtually all deep callosal cells extend dendrites into layer 1. At the earlier ages, many of these dendrites are tipped with growth cones, while at the later ages most branch extensively in layer 1. Although there seem to be some subtle differences, at early postnatal stages layer 5 callosal neurons are similar in overall form to their subcortically projecting counterparts retrogradely labeled with DiI from the superior colliculus of age-matched pups. Thus, dendritic distinctions between these two classes are sculpted postnatally from an initial common dendritic morphology in a projection class-specific manner. These observations contrast with our findings that the projection distinctions between callosal and subcortically projecting layer 5 neurons are generated by class-specific axon growth rather than by a selective pruning of initially exuberant axons (Koester & O'Leary 1989, Soc Neurosci Abstr 15:960). Support: NEI grant EY07025, McKnight Foundation, NSF Predoctoral Fellowship.

463.8

A SIMPLE STOCHASTIC MODEL OF NEURITIC ELONGATION ACCURATELY DESCRIBES THE DISTRIBUTION OF DENDRITIC SEGMENT LENGTHS IN DORSAL HORN CELLS. R.S. Nowakowski, N.L. Hayes and M.D. Egger. Dept. of Neuroscience & Cell Biology, UMDNJ-Robert Wood Johnson Medical School, Piscataway, NJ 08854-5635.

In our stochastic model of neuritic elongation, a growing neuritic segment either elongates with probability Pr{El} or branches with probability Pr{Br}, and at any given segment-length x, Pr{El(x)} = 1 - Pr{Br(x)}. In this model, Pr{El(x)} and Pr{Br(x)} are functions **only** of segment-length and not of branch order or of total distance from the soma. The histogram (broken line in inset) shows the number of segments/segment-length for N = 1236 measured dendritic segments (in bins of 1 μm) combined from 17 feline dorsal horn neurons labelled intracellularly with HRP. Each segment-length = the distance from the soma or from a branch point to the next branch point or to the termination of the process. The illustrated continuous curve is a predicted frequency distribution derived from one of several possible differential equations in which Pr{Br(x)} = g(x), when g(x) is a generally increasing function of x. This means that immediately after branching, when x is small, Pr{Br(x)} is small, but generally as x increases, Pr{Br(x)} increases. Many such derived functions, corroborated by our computer simulations of rules for dendritic growth, provide good fits to the collected data. Our model implies that much of the variation of dendritic segment-lengths may be attributable to complementary probabilities of elongating and branching which change as a function of **distance grown from the last branch point.** This has significant implications for understanding the development of branching patterns in dendritic trees.



463.9

DEVELOPMENT OF CORTICAL SPINY STELLATE CELLS: RETRACTION OF A TRANSIENT APICAL DENDRITE.
A. Peinado and L. C. Katz. Laboratory of Neurobiology, The Rockefeller University, New York, NY.

The local circuit interactions in which a cortical neuron participates are partly determined by the intralaminar and interlaminar extent of its dendritic tree. Mammalian cerebral cortex contains two broad classes of spiny excitatory neurons: pyramidal cells, which are found in all areas and all layers, and stellate cells, which predominate in layer 4 of primary sensory areas. Spiny stellates are distinguished from pyramids and star pyramids by the absence of an apical dendrite to more superficial layers. To assess the influence of thalamocortical afferents on the emergence of stellate and pyramidal cell morphology we examined the development of neurons in layer 4 of the rat's primary somatosensory cortex. Dendrites were visualized by intracellular injection of Lucifer Yellow in coronal brain slices from rats at postnatal days 2 to 20 (P2-P20). To identify layer 4 *in vitro*, thalamocortical afferents were labeled by anterograde transport of rhodamine injected into the ventrobasal thalamus.

Between P2 and P7 over 90% of the stained neurons in layer 4 (n=90) had an apical process that reached layer 1, where it usually branched at least once. Virtually no spiny stellate cells were apparent. After P7, the number of spiny stellate neurons increased such that by P10 fewer than 30% (n=69) of injected neurons extended an apical process beyond the layer 3/4 boundary. Activity in the thalamocortical afferents provides a critical cue for this remodeling: when we examined the morphology of neurons between P10 and P20 after cutting the infraorbital nerve unilaterally at birth, we found a far greater proportion of neurons (64%; n=81) extending an apical dendrite beyond the 3/4 laminar boundary. Taken together these results suggest that retraction of a transient apical dendritic process initially present in all spiny neurons accounts for a major morphological distinction between the two main classes of excitatory cortical neurons. This transition appears to be controlled at least in part by afferent input.

CEREBELLAR MOSSY FIBER, BUT NOT CLIMBING FIBER, ELONGATION IS INTERRUPTED BY TARGET GRANULE NEURONS IN VITRO.
D.H. Baird, C.A. Baptista, M.E. Hatten, and C.A. Mason Dept. of Pathology, Coll. of Physicians and Surgeons of Columbia Univ., New York, N.Y. 10032.

We have devised an *in vitro* system to study the specificity of axon-target interactions. Explants of the major cerebellar afferent systems, pontine nuclei for mossy fibers, and inferior olivary nuclei for climbing fibers, were co-cultured with purified granule neurons from rat. Explants were dissected from mice at stages when their afferents invade cerebellum (P0 for pontine, and E16-17 for olivary explants) and neurites visualized with the mouse-specific monoclonal antibody M6 (Lund et al., *J. Comp. Neurol.* 247:439,1986). On laminin or poly-lysine substrates or on monolayers enriched for cerebellar astroglia, both pontine and inferior olivary explants displayed extensive neuritic outgrowth. In contrast, pontine explants grown on monolayers of their targets, granule neurons, extended many short neurites which terminated on cells close to the explant. This 'stop signal' is abolished by light fixation of the granule cell monolayer. Granule neurons do not act as a stop signal when plated far from, or on a coverslip above, pontine explants. Together with time-lapse video observations, these results indicate that the stop signal requires living target neurons and is contact-mediated. In addition, the stop signal provided by granule neurons is afferent-specific, at least within the cerebellum. Inferior olivary axons, which innervate Purkinje cells as climbing fibers, elaborate long neurites on granule cells. We are further exploring the specificity of the stop signal by co-culturing both types of afferents with Purkinje cells (Baptista et al., this volume). Supported by NS 16951 to C.M. and NS 08761 to D.B.

A SPECIFIC METALLOPROTEINASE INHIBITOR HAS TRANSIENT EFFECTS ON ACTIVITY OF NEURITES FROM EMBRYONIC CHICK NEURAL RETINA CELLS *IN VITRO*.
Joel B. Sheffield and Erik Dehlinger. Department of Biology, Temple University, Philadelphia, PA 19122

The developing neural retina expresses a set of extracellular proteases. When retina cells are cultured on a fluorescent gelatin substrate, growing fibers digest substrate in their paths. We suggest that the proteases are used by the tips of growing fibers to allow them to migrate within the mass of the tissue *in vivo*. We have examined the effects of an inhibitor, stereoisomer 1 of HS-Leu-Phe-Ala (HS-LFA) Darlack et al., J. Biol. Chem., 1990). Embryonic day 10 retinal cells were dissociated and plated at high density (10^6 ceils/cm^2 of surface area) on untreated plastic or glass substrates in medium containing 10% FBS. On the second day, when processes had begun to grow out, the medium was changed to one containing 10 μM HS-LFA. The behavior of the cells was monitored by time lapse video microscopy. Introduction of the inhibitor caused a cessation of both spike extension and growth cone ruffling, while control media had no effect. The behavior of growth cones was in sharp distinction to that of the cytoplasm, which continued in activity throughout. The inhibition of activity continued for between three and five hours, and the growth cones then gradually recovered their motility. By the end of the period, it appeared as if the culture had been unaffected by the treatment. Two other potential inhibitors were tested. Bathophenanthroline sulfonate, an inhibitor that chelates zinc from the active site of metalloproteinases, was toxic. Recombinant human TIMP (Synergen, Inc.) was inactive. The effects of HS-LFA are consistant with the concept that proteases play a significant role in fiber outgrowth from neural retina cells.

AXON TRAJECTORY-SPECIFIC DOMAINS IN THE HINDBRAIN OF THE CHICKEN EMBRYO.
J.C.Glover. Institute of Physiology, Univ. of Oslo, 0162 Oslo, Norway

The spatial relationships among brainstem neurons that project axons along different trajectories was determined by injecting retrograde tracers into developing axon tracts in 4-5d chicken embryos. Neurons projecting along a specific trajectory were in general organized into one or a few coherent clusters, with the clustering pattern being characteristic for each rhombomere. Injecting different fluorescent tracers into appropriate tracts allowed direct comparison of ipsi- and contra-projecting clusters of reticulospinal, vestibulospinal, and vestibulo-ocular neurons. This showed that such clusters occupy different, often segregated domains, indicating a spatiotopic relationship between soma position and axon trajectory. Whether soma position is involved in determining axon trajectory remains to be seen. Lineage analysis is being performed to determine the extent to which clonal relationships and migration patterns contribute to the formation of trajectory-specific domains.

463.13

THE POSITION OF THE MOTOR NERVE TRUNKS TO THE EMBRYONIC ABDOMINAL MUSCLE IN *XENOPUS* IS DETERMINED BY SOMITE-DERIVED CELLS.
Kathryn Lynch, Uniformed Services University, Bethesda, MD 20814-4799.

It is not yet known what determines the course of major vertebrate nerve trunks. I have used microscopy (EM and LM) to examine the influence of myogenic cells on the distribution of the first motor nerve trunks to the embryonic abdominal muscle (EAM) in *Xenopus*. The first motor axons to the EAM arise from spinal nerves 2-9, and follow clusters of somite-derived myogenic cells that migrate ventrally between epidermis and lateral plate. At N&F St 39-40, the cells in each cluster fuse to form a segment of the EAM. At St 40, trunks of axons are apposed to the boundaries between muscle segments. Because the myotube tips stain for AChE, the narrow boundary zones are visible in AChE-reacted embryos, normally as six dark transverse lines across the broad flat muscle. However, if a premigratory cell cluster is partially or wholly ablated, the regular segmentation of the muscle is disrupted; an intersegmental boundary may be missing or intermittent, with short sections at different rostrocaudal levels. Nerve trunks in such cases are still closely associated with the boundary zones. When a boundary is missing, two trunks may converge on a single boundary. Nerve trunks zigzag between sections of the intermittent boundary zones. Thus the position of the first nerve trunks is determined by the location of the segmental boundaries. This in turn seems to be a function of the somite-derived myogenic cells, not the en vironment into which they migrate. Nerve trunk position in older embryos and after ablation of more than one premigratory cell cluster will also be examined.

DEVELOPMENT OF EXCITABILITY IN DISSOCIATED CAT RETINAL GANGLION CELLS. I.Skaliora*, L.M.Chalupa and R.P.Scobey. Depts of Psychology, Neurology and Neurobiology Graduate Group, Univ. of California, Davis CA 95616.

We are studying the development of excitable membrane properties in acutely isolated retinal ganglion cells from fetal and postnatal animals. Cells are enzymatically dissociated in a papain solution and kept in suspension at 10°C for up to 48 hours after eye removal. Ganglion cells are identified by retrograde labeling with rhodamine beads previously injected into the LGN and SC. The whole cell and the perforated patch variations of the patch clamp technique are used to obtain voltage and current clamp recordings respectively.

Cells from postnatal animals (1 week to 3 months of age), invariably manifest spikes in response to depolarizing steps of current, and generate sustained- and transient-type firing patterns. At embryonic day 40 (E40), the earliest age recorded so far, cells do not manifest impulse activity at any stimulus intensity and the net inward currents are barely detectable. By E45 there is a large increase in inward current amplitudes. At this age, sodium mediated spikes are apparent in most cells, as indicated by their blockade following TTX application. Whereas increasing proportions of the cell population display spike activity as a function of age, there are no significant differences in the duration, rate of rise or amplitude of individual spikes. The data suggest that, in cat retinal ganglion cells, the basic features of excitability are established early in development, shortly before the onset of segregation of their projections into eye specific layers.

LOCALLY CORRELATED SPONTANEOUS ACTIVITY OF NEURONS IN THE DEVELOPING MAMMALIAN RETINA. R.O.L. Wong, M. Meister*, D.A. Baylor and C.J. Shatz. Dept. Neurobiology, Stanford Univ. Sch. Med., Stanford, CA 94305.

Spontaneous electrical activity in retinal ganglion cells during early development is thought to play a key role in guiding the formation of orderly connections in the visual system. This activity is essential for the progressive segregation of retinal axonal terminals into eye-specific layers within the lateral geniculate nucleus. Using a multielectrode recording technique, we previously established that cells in isolated immature cat and ferret retinae fired action potentials in bursts that occurred almost synchronously, and that this activity frequently spreads across the piece of retina as a wave travelling at about 100 µm/sec (Meister et al., Invest. Ophth. Vis. Sci. 31 (Suppl.), 115, 1990). In contrast, there were no distinct bursts or wave-like activity in the adult retina. Rather, adult cells showed continuous spontaneous firing in darkness and gave brisk ON and OFF responses to light, as found *in vivo*. In further studies, periodic bursts were also recorded intracellularly from cells in immature retina which were subsequently identified as retinal ganglion cells by dye injection. Thus, it is likely that some of the cells recorded with the multielectrode array are ganglion cells, suggesting that spontaneously generated patterned activity of these cells may play an instructive role in the segregation of their axons in target structures. The mechanism underlying the synchronous bursting activity during development and the factors responsible for its disappearance by adulthood are currently being investigated.

NMDA ANTAGONISTS DISRUPT NORMAL ON/OFF SUBLAMINAR SEGREGATION OF FERRET RETINOGENICULATE AXONS. J. Hahm, R. B. Langdon and M. Sur. Department of Brain & Cognitive Sciences, M.I.T., Cambridge, MA 02139.

To examine the role of NMDA receptors in the segregation of retinal afferents into ON and OFF sublaminae in the ferret LGN, we chronically applied antagonists during the period of normal segregation. Previously, we have shown that retinal axon arbors become restricted to ON or OFF sublaminae between two and three weeks postnatal (Hahm & Sur, Soc. Neurosci. Abst. 14:460, 1988). At postnatal day 14, ferret kits were chronically infused for one week with one of the NMDA antagonists, APV (0.5mM - 1.6mM), MK-801 (1.23mM - 4.74mM), or CPP (0.063mM - 79.3mM). Control animals received infusion of saline (0.9%). Compounds were administered via an osmotic minipump (1µl/hr), by subcutaneous implant alone (MK-801, CPP) or through a cannula inserted into the brain rostral and medial to the LGN and attached to the minipump (APV, saline).

Intraocular injections of HRP/WGA-HRP (20%/2%) at three weeks of age revealed that APV and MK-801 prevented retinal afferents from segregating into ON/OFF sublaminae. CPP disrupted segregation to block complete separation of sublaminae.

Labeling of single axons *in vitro* in CPP treated animals showed that in addition to incomplete sublaminar restriction of retinal axon arbors, short side branches had sprouted along the main trunk of the axon. Normally, side branches are seen in the first postnatal week, but have disappeared by two weeks of age.

These results suggest that NMDA receptors mediate activity-dependent segregation in the ferret retinogeniculate projection. Since NMDA receptors are crucially involved in retinogeniculate transmission, the effects of NMDA blockade may be a consequence of blocking transmission in the LGN during development.

PRENATAL DEVELOPMENT OF LGN NEURON DENDRITES DURING SEGREGATION OF EYE INPUTS. A. Ghosh, M. B. Dalva* and C. J. Shatz, Dept. of Neurobiology, Stanford Univ., Stanford, CA 94305

To examine postsynaptic changes occurring in the lateral geniculate nucleus (LGN) during segregation of retinal afferents, we have studied the morphological changes in LGN projection neuron dendrites between E43 and E57 in the cat. LGN neurons were retrogradely labeled by injecting diI into the primary visual cortex in aldehyde-fixed brains. At E43, when retinal afferents have not yet formed terminal arbors, the LGN projection neurons already have relatively extensive dendrites. Most cells have several primary dendrites arranged in a fusiform fashion (total dendritic length=654±360µm). During the following two weeks both total dendritic length and higher order dendritic branching continue to increase (at E57 total dendritic length=1049±304µm). To determine whether action potential activity influences dendritic development during ocular segregation, we studied LGN cell morphology following 2 week minipump infusion of tetrodotoxin (TTX) between E43 and E57. We verified that the TTX infusion was successful by injecting diA into the optic tract of the same animal: as expected, retinal terminals had not segregated into eye specific layers. Despite this effect on axon arbors, a study of 23 cells from a TTX treated LGN shows that LGN dendritic development is essentially normal in morphology (total dendritic length=965±298µm). These observations show that there is significant dendritic development during ocular segregation in the LGN; however the pattern of dendritic growth during this period seems to be independent of activity. Thus it appears that within the same structure, blockade of action potential activity can markedly alter the morphology of presynaptic axons while having little effect on postsynaptic dendrites. FORMATION OF AFFERENT PROJECTIONS IN ORGANOTYPIC SLICE CULTURES FROM RAT VISUAL CORTEX. M. Götz(1), N.Novak*(1), V.Staiger*(2), T.Bonhoeffer(2) and J. Bolz(1);(1) Friedrich-Miescher Labor der Max-Planck Gesellschaft and (2) Max-Planck Institut für biologische Kybernetik, 7400 Tübingen, FRG.

Thalamic afferents form very specific connections with their cortical target cells. In order to learn about mechanisms involved in the development of these connections we used a thalamocortical in vitro system. We prepared slice cultures from the visual cortex of young rats (P0 - P8) and cocultured them with slices from the lateral thalamus (E16 - P5). Thalamocortical connections were traced with DiI in cocultures after 4-14 days in vitro. As reported previously, cortical slices survive for several weeks in vitro and the different cell types continue their morphological and neurochemical maturation (Caeser et al., Exp. Brain Res.77,234,1989; Götz and Bolz, Neurosci. Lett. 107,6,1989).To examine the laminar organization of the cortical cultures, cells of different layers were labeled at their birthdates by injecting timed pregnant rats with BrdU. After 1-3 weeks in culture the laminar distribution of labeled cells matched the in vivo situation at the corresponding age. This was also true for the earliest generated neurons situated in the so called "subplate". It has been proposed that subplate cells serve as transient targets for thalamic afferents before they disappear. We found that many subplate cells survive both in vivo and in slice cultures where no afferents are present. In cocultures fibers from thalamic slices obtained from animals up to P2 grew into the cortical explant and terminated in layers 4 and 3, but not in the subplate zone. This specific ingrowth was established whether the thalamic slice was placed at the white matter or at the pial side of the cortex slice. Electrophysiological and optical recording experiments showed that the thalamocortical connections are functional. Thus thalamic afferents form specific connections with their cortical targets in vitro without a "waiting period" in the subplate zone.

464.6

FORMATION OF EFFERENT PROJECTIONS IN ORGANOTYPIC SLICE CULTURES FROM RAT VISUAL CORTEX. J. Bolz, N. Novak* and M.Götz. Friedrich-Miescher Labor d. Max-Planck Gesellschaft, 7400 Tübingen, FRG.

Cortical projection neurons are segregated in cortical layers and there is a close relationship between cell morphology and efferent target. We studied cortical projections in vitro using the culture system described in the preceeding abstract. Slice cultures of the visual cortex were prepared from 0 to 2 day old rats, an age at which the axons of cortical projection neurons have not yet reached their targets. The superficial layers of the cortex are not formed at that time, but BrdU-prelabeling showed that also cells of layer 2/3 are located at their appropriate position after 1-3 weeks in vitro, suggesting that migration continues in the slice cultures. Cortex slices were cocultured either with a slice from a subcortical target (lateral thalamus or superior colliculus) or with another slice of visual cortex. Retrograde tracing with DiI after 4-14 days in vitro showed that almost all cells labeled from subcortical explants were located in the deep cortical layers, exactly where these cells are found in vivo. Cells in the superficial layers did not innervate these targets, but did project into cocultured cortical slices. In cortex-cortex cocultures, some projecting cells were also located in the deeper layers, but their morphology was different from subcortical projecting neurons. Similar differences have been observed in vivo (Hübener and Bolz, Neurosci.Lett.94,76,1988). Thus the laminar origin and cellular morphology of cortical projections formed in vitro are target dependent. Moreover, these specific connections were established irrespective of whether the explanted targets were placed towards the white matter or the pial side of the cortical cultures. With ectopically positioned targets, the axonal trajectories of the projecting cells were always oriented towards their targets and not restricted to particular pathways. This suggests that chemotropic attraction may play an important role in the formation of connections between cortical neurons and their efferent targets.

POSTNATAL DEVELOPMENT OF GENICULOCORTICAL SYNAPSES IN AREA 17. M.J. Friedlander, J.C. Anderson*, C. DeHay*, K.A.C. Martin* and J.C. Nelson*. Neurobiology Research Center, University of Alabama at Birmingham, Birmingham, Al, 35294, and Anatomical Neuropharmacology Unit, Department of Pharmacology, Oxford University, U.K.

Individual geniculocoritcal Y-axons in the cat increase the extent of their innervation of layer 4 in cortical area 18 between 5 postnatal weeks of age and adulthood. During this same period, the individual boutons enlarge, increase their spacing and acquire more postsynaptic targets (Friedlander and Martin, J. Physiol. 416:183-213). To date, similar developmental data are not available for cortical area 17. A comparison of the developmental processes between these two cortical areas is of interest since the type of competitive interactions that occur may differ. In layer 4 of area 18 (innervated only by Y-axons), competition between developing geniculocortical axons is limited to binocular interaction. However, in layer 4 of area 17, competitive interactions may occur between functional cell types (X- vs. Y-cells), as well. In the present study, we used intracellular injections of horseradish peroxidase to label individual physiologically indentified geniculocortical X- and Y- axons that project to area 17 in kittens at 5 postnatal weeks of age and adult cats. The extent of the arborizations in layer 4 (n=5) were digitized and over 100 boutons (≈25 each for 4 or the 5 axons) were serially sectioned and fully reconstructed for electron microscopical analysis. The kitten axons terminated primarily in layer 4 with occasional branches innervating layer I (X-axon). The individual kitten boutons (both X- and Y-) were smaller than their adult counterparts, they formed asymmetric contacts primarily on dendritic spines and they generally contacted only a single, postsynaptic target. Occasionally (5%) kitten boutons made no synaptic contacts. Thus, our preliminary observations on the development of the ultrastructure of geniculocortical synapses for X- and Y-axons in area 17 suggest similar processes to those observed for Y-axons in area 18.

DENDRITIC CHANGES IN GRANULE CELLS OF OWL VISUAL CORTEX FOLLOWING VISUAL DEPRIVATION. J.D. Pettigrew and I.C. Gynther. Vision, Touch and Hearing Research Centre, The Univ. of Queensland, Qld. 4072, Australia.

Investigation of the cortical events underlying monocular deprivation is facilitated by two, technically favorable aspects of the owl's visual cortex. Firstly, the owl's LGN is monocular so that anterograde monosynaptic labelling of the whole input array from one eye is possible. Secondly, ocular dominance columns are not normally present in the owl but appear as a result of deprivation. The fine morphology of granule neurons with known relationships to ocular dominance column boundaries was studied in visual cortex of deprived owls after Lucifer Yellow (LY) microinjection in fixed brain slices. Injections were guided towards ocular dominance columns and their boundaries by rhodamine fluorescence from anterogradely-transported TRITC. Antibodies against LY were used to convert injected cells to a permanent, non-fluorescent form. Spiny stellate cells lying on or close to the boundaries were found to have dendrites oriented with respect to the column boundary. In contrast, comparable neurons from elsewhere in the granular layers had dendrites which were radially symmetrical. A similar difference may apply to the non-spiny stellate cells, but our sample of these neurons is not yet sufficiently large. In addition to the changes induced at column borders as a result of deprivation, we also found alterations of the dendritic trees of stellate cells at another, naturally-occurring boundary, that between the monocular and binocular segments of the granular layer, where there would be natural competition between inputs from the ipsilateral and contralateral eye during development.

DEVELOPMENT OF INTERLAMINAR CONNECTIONS OF LAYER 4 NEURONS IN CAT STRIATE CORTEX. L.C. Katz and E.M. Callaway. Laboratory of Neurobiology, The Rockefeller University, New York, NY 10021.

Clustered horizontal collaterals of layer 2/3 neurons link iso-orientation columns in cat striate cortex. During development, crude clusters emerge at postnatal day 8 (P8) and are refined over the next 3-4 weeks. Because development of horizontal connections is activity dependent (see following abstract) and spiny cells in layer 4 form a major excitatory input to layer 2/3, this input might direct the formation or refinement of crude clusters. Consequently, we examined the development of axons of layer 4 spiny neurons after intracellular staining in slices of cat striate cortex. At P5-8, no cells (0/14) extended axon collaterals into layer 3, but very short (<100μm) collaterals sometimes emerged from a main descending axon within layers 5, 6 and/or the subplate. The first collaterals crossed into layer 3 at P11; about 20% of cells (4/19) had a single collateral extending 50-200μm beyond the laminar boundary. By P15, 80% of cells (16/20) projected to layer 2/3. This proportion was similar to that observed in the oldest animals, but the axonal arbors did not achieve an adult-like extent or appearance until P26. In contrast to the extensive increase in projections to layer 2/3, collaterals within layers 5 and 6 remained short and sparse, and reached roughly adult levels by P15. Since layer 4 spiny neurons do not project into layer 2/3 prior to the appearance of crude clusters, activity relayed through this pathway may not play an important role in cluster emergence. Layer 2/3 neurons might, however, receive orientation information directly from geniculate afferents or from functional connections between layer 4 neurons and the basal dendrites of deep layer 3 neurons. The emergence of projections from layer 4 to 2/3 is closely correlated to the timing of both the refinement of clustered connections and increased visual responsiveness of layer 2/3 neurons, suggesting that activation by layer 4 inputs could play an important role in cluster refinement.

BINOCULAR DEPRIVATION REDUCES THE SPECIFICITY OF CLUSTERED HORIZONTAL CONNECTIONS IN CAT STRIATE CORTEX. E. M. Callaway and L. C. Katz. Laboratory of Neurobiology, The Rockefeller University, 1230 York Avenue, New York, NY 10021.

In the striate cortex of adult cats, pyramidal neurons in layer 2/3 have long, intrinsic horizontal axon collaterals that specifically interconnect iso-orientation columns (Gilbert & Wiesel, J. Neurosci. **9**: 2432). Thus, retrograde tracer injections result in clusters of labeled cells spaced about 1mm apart and extending several mm from the injection site. We previously demonstrated that during the first postnatal week retrograde labeling is unclustered and that a crudely clustered distribution appears during the second week. These crude clusters are subsequently refined by the selective elimination of axon collaterals projecting to incorrect orientation columns (J. Neurosci. **10**: 1134). Here we report that binocular lid suture, which prevents patterned visual activity, did not prevent the initial *emergence* of a crudely clustered pattern of retrograde label. Binocular deprivation did prevent the *refinement* of clusters, indicating that horizontal axon collaterals projecting to incorrect orientation columns were maintained well past the age when they are normally eliminated. Analysis of intracellularly stained layer 2/3 pyramidal cells from binocularly deprived cats revealed that their axonal arbors underwent many normal developmental changes. In particular, rearrangement of the radial positions of long horizontal collaterals and addition of finer branches to distal portions of those collaterals were both observed. Consistent with the lack of cluster refinement, however, the radial distribution of horizontal collaterals from binocularly deprived cells was significantly less clustered than normal. Thus, binocular deprivation did not arrest development at an immature stage, but reduced the specificity with which axon collaterals were added or eliminated. We conclude that patterned visual activity provides a critical cue for the establishment of specific horizontal connections.

POSTNATAL DEVELOPMENT OF INTRACORTICAL CONNECTIONS IN HUMAN VISUAL CORTEX. A.Burkhalter, K.L.Bernardo and V.C.Charles. Dept. of Neurosurgery and McDonnell Center for Higher Brain Function, Washington Univ. Sch. of Med., St. Louis, MO 63110.

Different visual functions emerge at different ages and with different time courses. We have investigated whether such behavioral changes are correlated with the development of specific intracortical circuits. Tracing with the fluorescent dye, dil, was used in postmortem fixed brains of human infants (newborn to 5 years of age) to visualize connections within and between the visual cortical areas V1 and V2.

At birth the connections between V1 and V2 are immature, in that unbranched horizontal fibers are seen only in deep layers and do not show the lamination patterns of forward and feedback projections. During the first 2 postnatal months fibers occur in middle and superficial layers and clustered vertical collaterals emerge. The development of forward and feedback projections proceeds in parallel and the reciprocal circuit between V1 and V2 reaches maturity at 1-2 years of age. At birth the local connections within columns of V1 and V2 appear mature, unlike the local long-range projections within upper layers (Burkhalter and Bernardo, Soc.Neurosci.Abstr. 15:2, 1989). Within V2 horizontal fibers in layer 2/3 emerge during the first postnatal month and develop before those in V1. At 4 months they show terminal clustering similar to adults. In contrast, very few horizontal fibers are seen in upper layers of V1 until 2 years of age.

These results suggest that prominent intracortical circuits are formed after basic spatial, temporal and binocular visual functions have reached maturity (Boothe et al., Annu.Rev.Neurosci. 8:495, 1985).

464.12

C-FOS IMMUNOREACTIVITY IN CAT VISUAL CORTEX. F. Vandesande (1), L. Arckens* (1,2), U. Eysel (3) and G.A. Orban (2). (1) Lab. Neuroendocrinologie, K.U.Leuven, Naamsestraat 59, B-3000 Leuven, Belgium. (2) Lab. Neuro-en Psychofysiologie, K.U.Leuven, Campus Gasthuisberg, B-3000 Leuven, Belgium. (3) Dept. Neurophysiology, Ruhr Universität Bochum, Universit 150, D-4630 Bochum 1, F.R.G.

Cats were perfused under Nembutal anaesthesia with 2 % paraformaldehyde and 1.25 % glutaraldehyde fixative. Brains were sectioned and the sections stained with a polyclonal antibody specific for the c-fos P10 region (Medac) using the PAP technique. C-fos immunoreactivity (ir) was observed in the nuclei of numerous visual cortical cells (area 17 and 18). The ir was lamina specific in that in the middle layer (IV) fewer nuclei were stained.

Double staining with anti-GABA and anti-c-fos revealed very few labeled cells suggesting that most c-fos ir neurons are non-GABAergic.

The effect of visual experience on c-fos ir in visual cortex was assessed by making bilateral retinal lesions and comparing parts of cortex subserving central and peripheral vision and by keeping cats under anaesthesia. Preliminary results indicate that visual stimulation has a short living effect (a few hours) which is lamina and area specific, while the effect of visual deprivation is noticeable only after several days and consists in a decrease of the overall level of staining rather than a change in the laminar pattern.

464.13

PARVALBUMIN IMMUNOREACTIVITY IN THE CAT VISUAL CORTEX DURING NORMAL DEVELOPMENT AND AFTER VISUAL DEPRIVATION. J. R. Naegele[1], K. Fox[2] and N. Daw[2]. Depts. of Ophthalmology and Visual Sciences, Yale University School of Medicine, New Haven CT. 06510[1] and Physiology and Cell Biology, Washington University School of Medicine, St. Louis, MO. 63110[2].

Parvalbumin (PV) is a calcium-binding protein expressed in about 70% of GABA neurons in the mammalian cerebral cortex. Although its exact function is not yet known, PV may effect firing patterns or levels of excitation in fast-spiking types of GABA neurons. One of the most numerous types of PV-immunoreactive (PV-ir) cortical neurons are the basket cells. We have used immunocytochemical staining to study the expression of PV in cortical area 17 in normal and dark-reared kittens. PV was localized with a monoclonal antibody generated against carp muscle parvalbumin (mAb 235, Celio et al., '89, Cell Calcium 9: 81-86) and as controls, we used a panel of molecular markers for basket cells including mAb VC1.1 and the lectin VVA. On the day of birth (P1), PV-ir cells were restricted to layer 6 and the subplate zone. By P14, PV was expressed in layers 4-6 and in the subplate. By P21, PV-ir cells were present in all cortical layers except layer 1. During subsequent maturation, numbers of PV-ir cells increased within layers 3 and 4 and decreased in layers 5 and 6. In dark-reared kittens, the number and intensity of PV-ir cells was markedly reduced, however littermates exhibited normal patterns of PV-ir when exposed to light for 4-10 days, after dark-rearing. Dark-reared kittens also showed deficits in receptive field properties but light exposure resulted in recovery of normal receptive field properties. These findings raise the possibility that in dark-reared animals, deficits in receptive field properties in area 17 may be related to lower levels of PV in the basket cells. (Supported by the Klingenstein Foundation).

CIRCUITRY AND PATTERN GENERATION III

MEDULLARY SLICES THAT GENERATE RESPIRATORY OSCILLATIONS *IN VITRO*. Jeffrey C. Smith, John J. Greer & Jack L. Feldman, Systems Neurobiology Lab., Department of Kinesiology, UCLA, LA, CA 90024 -1586.

We identified a limited region of the ventrolateral medulla critical for generation of respiratory rhythm (Smith et al., Soc. Neurosci. Abs. 15:505, '89). This region, called the preBötzinger region, was identified by combining extracellular recording and precision microsectioning of neonatal rat brainstem-spinal cord preparations *in vitro*. To further test the hypothesis that the region contains cell populations for rhythmogenesis, we cut medullary slices to determine if this region in isolation can spontaneously generate a respiratory oscillation. Brainstem-spinal cord preparations were mounted in a vibratome bath (*ibid.*), sectioned to within 150 μm of the rostral boundary of the critical region, and a single 400-500 μm thick transverse medullary slice containing the critical region was cut. The slices preserved rootlets of glossopharyngeal and hypoglossal nerves, allowing recording of oscillatory motoneuron activity in addition to medullary neuron activity within the slice. These slices contained the critical region and adjacent reticular formation regions, and excluded all other medullary regions hypothesized to contain cells involved in rhythmogenesis (e.g. Ominaru et al., Brain Res. 445: 314, '88). The slices spontaneously generated a rhythmic motoneuronal output, demonstrating that they contained networks sufficient for both rhythm and (pre)motoneuronal discharge pattern generation. By retaining or excluding different amounts of the flanking regions at the slice boundaries, we obtained evidence for the following features of the spatial organization: (1) There is a cell population(s) at the rostral boundary of the critical region that provides an excitatory drive to the rhythm generating cells essential for the production of oscillatory activity; slices without these cells would not generate a spontaneous oscillation unless cells were depolarized by exogenous neuroexcitants, particularly excitatory amino acids acting at nonNMDA receptors. (2) The area bordering the caudal boundary of the critical region is necessary for motoneuronal burst pattern formation. This data is consistent with our model for pattern generation in which there are two functionally and spatially segregated components: (i) a cellular oscillator consisting of conditionally bursting pacemaker neurons requiring excitatory synaptic drive for rhythmogenesis; (ii) separate more caudally distributed populations involved in burst pattern formation that transform the rhythmic drive from the oscillator into a detailed spatiotemporal pattern of (pre)motoneuronal activity. Supported by NIH grants HL 40959 and HL 02204.

465.2

TIME SERIES ANALYSIS OF SPIKE PATTERNS IN CULTURED AND SIMULATED SMALL NEURONAL NETWORKS. J.M.Kowalski*, G. Albert*, and G.W. Gross**. Dept. of Physics, Dept. of Biological Sciences**, Center for Network Neuroscience, Univ. of North Texas, Denton, TX 76203.

Small neuronal networks (100-500 neurons) grown from dissociated mouse spinal cord as monolayer cultures on a photoetched multimicroelectrode matrix can be maintained for several months and monitored continually for several days. These networks exhibit spontaneous, highly patterned activity with extensive course-grained synchronization. Assuming that the underlying system's dynamics are deterministic, one may apply the Taken's embedding theorem to reconstruct the dynamic attractors and estimate their correlation dimension. We discuss the relevance of this method in the network setting, where the recorded variables are arbitrary smooth functions of the network state. It is stressed that the presence of a scaling law alone with small exponent for the correlation dimension cannot be considered as a "proof" that the underlying time series has a deterministic origin. Some other important "caveat's" in the method's application are discussed (selection of the representative scalar variable, error bounds, etc.). We model our networks as ensembles of coupled (via slow variables) Chay's neuromimes, where each unit may exhibit a full activity range (i.e. resting, periodic, quasiperiodic, and chaotic states). Observed network "self-ignition" and synchronization phenomena can be explained within this model. Calculated correlation dimension of such models is compared with those from experimental data.

SEROTONIN ENHANCES SYNAPTIC FATIGUE IN NEURONAL CIRCUITS OF THE LEECH. P.S. Mangan and W. Otto Friesen. Dept of Biology, Univ. of Virginia, Charlottesville, VA 22901

Micromolar concentrations of serotonin (5-HT) elicit swimming activity in isolated leech ventral nerve cords in both normal animals (Willard, J. Neurosci. 1:936-944, 1981) and animals in which endogenous serotonin has been depleted by treatment with reserpine (Friesen et al., Soc. Neurosci. Abst. 14:384, 1988). Previously, 5-HT was reported to modify synaptic transmission between DI motor neuron 102 and central swim oscillator cell 115 (ibid.). We report here serotonin-induced modification of synaptic physiology in three motor neuron pairs of the leech swim circuit. The synapses examined were those between DI cell 1 and DE cell 3, VI cell 2 and VE cell 4, and cells 1 and 2.

Inhibitory synaptic transmission was monitored, prior to and following addition of 50 μM serotonin, in both untreated and reserpine-treated animals. The pre-synaptic cell was injected with depolarizing current pulses (1-3 nA, 1-2 s) and inhibitory post-synaptic potentials resulting from 10-20 identical pulses were recorded, digitized, and averaged. Synaptic fatigue increased substantially with 5-HT application in both untreated (30-fold) and reserpine-treated (80-fold) preparations as compared with controls (untreated, reserpine-treated; normal saline; pooled data from all synapses). Serotonin-induced fatigue was 30% greater in untreated preparations than in reserpine-treated preparations. Half-maximum fatigue was attained in 0.33s and 0.49s in untreated and reserpine-treated preparations, respectively. The increase in synaptic fatigue induced by elevated 5-HT could facilitate oscillatory activity in the reciprocally inhibitory interactions prevalent in the leech central swim network and thus provided the basis for serotonin-enhanced expression of swimming activity in the intact animal. Supported by grants NS08781 (P.S.M.) and NS21778 (W.O.F.)

GLUTAMATE: PUTATIVE NEUROTRANSMITTER IN THE FEEDING CENTRAL PATTERN GENERATOR OF HELISOMA TRIVOLVIS. E.M. McLean and A.D. Murphy. Dept. of Biological Sciences, University of Illinois at Chicago, Chicago, Illinois, 60607.

The feeding central pattern generator of Helisoma trivolvis consists of three subunits (S1-S3) that are independent interneuronal oscillators. These subunits provide excitatory drive to sets of motor neurons. Most feeding-related neurons receive post-synaptic potentials from the S2 subunit. Neurons that receive S2 IPSPs are hyperpolarized by bath application of glutamate or quisqualate, and neurons that receive S2 EPSPs tend to be depolarized by glutamate or kainate. Glutamate and kainate also stimulate robust patterned motor activity. The compound alpha-amino pimelic acid has both glutamate agonist and antagonist effects in this system. It elicits high frequency patterned motor activity, while gradually decreasing the amplitude of S2-driven psps. This work supports the hypothesis that the S2 interneurons are glutamatergic, activating kainate-like receptors at excitatory synapses and quisqualate-like receptors at inhibitory synapses.

CRUSTACEAN CARDIOACTIVE PEPTIDE (CCAP): A HORMONE NEUROMODULATOR OF THE STOMATOGASTRIC NERVOUS SYSTEM.
Lawrence I. Mortin, Sybil T. Lockhart*, and Eve Marder.
Biology Department, Brandeis University, Waltham, MA 02254.

The nonapeptide crustacean cardioactive peptide (CCAP) was isolated and sequenced from the pericardial organs (PO) of the crab *Carcinus maenas* (Stangier et al., PNAS 84:575, 1987) We used a polyclonal antibody raised against synthetic CCAP (Dircksen & Keller, Cell Tissue Res. 254:347, 1988) to study CCAP-like immunoreactivity in the crab *Cancer borealis* and the lobster *Panulirus interruptus*. In *C. borealis*, this antibody stained many nerve fibers and terminals in the PO, but no staining was seen in the stomatogastric nervous system. In contrast, in *P. interruptus*, a pair of cells, one in each commissural ganglion (CG), showed CCAP-like immunoreactivity. Punctate varicosities, resembling neuropil-like structures, were stained in the lateral portion of each CG, as was a single through-fiber within the commissural connective. A single large cell shows CCAP-like staining in the esophageal ganglion.

Preliminary physiological experiments show that bath application of CCAP to the *in vitro* stomatogastric nervous system produces an ensemble of effects on the motor rhythms controlled by this portion of the nervous system, which controls the muscles of the foregut. Motor pattern changes were induced in both *P. interruptus* and *C. borealis* with 1 μM CCAP or less. These results suggest that a CCAP-like peptide may act as a neuromodulator of the central pattern generators of the crustacean stomatogastric nervous system.

Supported by NIH Grants NS08543 (LIM) and NS17813 (EM).

TWO TYPES OF IDENTIFIED MODULATORY NEURON SUBSERVE TWO TYPES OF FUNCTION: MAINTENANCE OR ALTERATION OF A RHYTHMIC MOTOR PATTERN IN CRUSTACEA.
F. Nagy, T. Bal*, P. Cardi* and M. Moulins. Lab. Neurobiologie et Physiologie Comparées, CNRS, Univ. Bordeaux I, 33120 Arcachon, France.

In isolated preparations of the crustacean stomatogastric nervous system, rhythmic activity of the pyloric CPG, and oscillatory properties of its neurons, are strictly dependent upon tonic modulatory inputs from higher centers. A central modulatory neuron (APM) was identified whose discharge can induce rhythmicity in a previously silent pyloric network. However, APM and several other modulatory neurons identified since, are generally not spontaneously active in vitro, and cannot provide the tonic input to maintain normal pyloric activity. We show in the lobster, *Homarus gammarus*, that this sustained modulatory function is fulfilled by a pair of commissural neurons, P and CP. In vitro, they are always (n=63) active with the pyloric network. Silencing them provokes immediate cessation of pyloric activity (n=6). When deprived of P and CP inputs, all pyloric neurons switch from cellular oscillators to passive neurons. When compared to APM, P and CP appear to exert significantly different effects. While all three modulators can induce oscillatory properties in previously passive pyloric neurons, only oscillations induced by P and CP resemble normal activity. Moreover, APM's effects long outlast the duration of its discharge, whereas those of P and CP do not. Finally, during spontaneous pyloric activity, depolarizing either P or CP to fire up to 35 Hz, activates but does not disorganize pyloric activity, whereas a brief discharge of APM at only 10 Hz lastingly transforms the pyloric pattern.

These results, therefore, indicate two classes of modulatory neuron: those like P or CP, whose sustained discharge maintains basic rhythmic activity of a CPG; and those like APM, with strong and longlasting effects but episodic discharge, which induce temporary alteration in the ongoing activity of a CPG.

IONIC CURRENT FINGERPRINTS IN LOBSTER STOMATOGASTRIC NEURONS.
D.K.Hartline, D.V.Gassie*, B.A.Tomiyasu* and B.R.Jones.
Békésy Laboratory of Neurobiology, Univ. of Hawaii, Honolulu, HI 96822

Two-microelectrode voltage clamp recordings were made in lobster (~0.5 kg *Panulirus* spp., 22° C) stomatogastric neurons to determine if unique ionic current patterns are associated with different identified cell types. Standard test pulses to 0 mV (with and without conditioning prepulses) revealed a transient outward current (A), and a calcium-dependent outward current (J) composed of fast (Jf), slow (Js) and maintained (Jm) kinetic components.

Current magnitudes in intact and ligated somata are statistically indistinguishable within a cell type. The pyloric group differs from most of the gastric group by having faster A inactivation and slower J inactivation. Differences within each group are shown by differences in A, J and total outward current. Figures show cell specific current patterns (magnitude of A *vs* magnitude of Jm) for pyloric (left figure) and gastric (right figure) neurons. Possibly significant deviations from cell-specific profiles occur.

Modeling studies suggest that large conductances and outward current sign reduce the space-clamp error (<10-15% at 0 mV) in intact somata.

USE OF MODELING TO ANALYZE ORIGIN OF EMERGENT OSCILLATIONS OF THE GASTRIC MILL CPG IN THE LOBSTER STG.
P.F.Rowat and A.J.Mandell. Biology B-022, U.C. San Diego, La Jolla, CA 92093.

The gastric mill CPG oscillates at low frequency without a pacemaker cell. All component cells and physiological synapses are known, but strengths of ionic and synaptic currents are not well characterized due to limitations of voltage clamp techniques. Most gastric cells display plateau potentials and have conditional bursting properties. On the basis of its behavioral characteristics, we hypothesize that the network has the dynamics of a relaxation oscillator. Modeling and phase portrait analysis are used to analyze how synaptic and electrotonic connections and membrane currents contribute to emergence of network oscillations. Modeling software was developed in which a model runs forever while concurrently allowing variation of all model parameters. As output scrolls across the display, the effects of parameter changes are seen immediately. Our strategy is to start with a minimal network model and extend it as forced by the requirement that model behavior mimic observed oscillatory behavior. New learning algorithms were developed for the adjustment of model parameters to match oscillatory behavior, thus allowing prediction of unobserved values. Conversely, if parameter adjustment is impossible, new model currents must be added. The starting point was Hopfield's network model which only includes passive membrane properties and a non-zero, self-recurrent synaptic term, corresponding to a voltage-gated membrane current. Each synapse is modeled by a saturating current. If the product of the self-recurrent synapse's weight with the slope of the linear portion of its current is greater than membrane leak conductance, plateau potentials appear. Addition of a current with a single control parameter which increases from zero results in a Hopf bifurcation to oscillations with non-zero frequency. Each model cell must transduce observed input signal phases to observed output signal phase. For some cells, notably Int1, this requirement forces addition of another current.

MODELING STUDIES INDICATE THAT SUBTHRESHOLD CURRENTS INTERACT TO SET THE FREQUENCY OF THE NEURAL OSCILLATOR CONTROLLING HEARTBEAT IN THE LEECH.
E. De Schutter* and R.L. Calabrese.
Born Bunge Foundation, University of Antwerp, Antwerp, Belgium and Department of Biology, Emory University, Atlanta, GA 30322

A central neural circuit generates the motor outflow that programs beat timing of the hearts in the medicinal leech. Two pairs of rhythmically active HN interneurons located in the third and fourth segmental ganglia of the ventral nerve cord form the core elements of this neural oscillator; each pair is linked by reciprocal inhibitory synapses and is capable of independent oscillation. Oscillation arises from the interaction of synaptic inhibition and specific ionic conductances. A computer model of one such HN pair was constructed to examine this interaction. It contains equations for fast and slow Ca^{2+} currents, postsynaptic current which depends on presynaptic $[Ca^{2+}]$, the delayed rectifier and an hyperpolorization activated inward current (I_h) derived from voltage clamp studies in the HN neurons. Equations for the fast Na^+ current and A current (I_A) were derived from the literature.

When I_h is blocked in *in vitro* experiments, HN cells stop bursting (Angstadt, J.D. and Calabrese, R.L., J. Neurosci., 9:2846, 1989. This happens in the model but only when a strong A current is present. The actual bursting frequency is determined by the interaction of these two subthreshold currents I_h and I_A.

GENERATION OF THE SHORTENING MOTOR PATTERN IN THE MEDICINAL LEECH.
G. Wittenberg and W. B. Kristan, Jr. Department of Biology, University of California at San Diego, La Jolla, CA 92093-0322.

Shortening behavior in the leech is on a gross level a simple multisegmental reflex, but detailed analysis of its motor pattern reveals surprising complexities. The gross appearance of the behavior is longitudinal shortening of several segments near the site of mechanical stimulation. However, recordings from motor neurons [MN] innervating longitudinal muscle reveal that the segment closest to the stimulus is bending away from it. A one-sided dorsal stimulus results in excitation of both dorsal excitatory MN and the ipsilateral ventral excitor, and inhibition of the contralateral ventral excitor. A ventral stimulus results in excitation of both ventral excitors and the ipsilateral dorsal excitor, and inhibition of the contralateral dorsal excitor. Inhibitory MN are inhibited ipsilateral to the stimulus, and excited contralaterally. Thus both the inhibitor and excitor MN to the same muscle may be excited, an unexpected finding, but in accord with von Holst's maxim that nervous systems "need the reins just as much as the whip." This is borne out in the responses of MN in the two ganglia anterior and two ganglia posterior to the ganglion in which sensory neurons are stimulated: all longitudinal excitors and inhibitors are excited (with a few exceptions), with the net result the observed longitudinal shortening.

In order to determine the neuronal circuitry responsible for these motor patterns, the connections of several interneurons have been studied. Cell 115, an interneuron involved in both swimming and local bending behavior, plays a role in shortening but excites only dorsal excitors and thus is not sufficient for the whole behavior. Unexpectedly, inhibitory MN contribute to shortening behavior by affecting motor output in adjacent ganglia. For instance, depolarization of the dorsal inhibitory MN causes inhibition of the dorsal excitor in the same ganglion, but causes excitation of the dorsal excitor in the adjacent posterior ganglion. This effect can be explained by the Friesen's finding that the inhibitors make feedback connections to certain swim CPG interneurons, including cell 115. Thus an important role in patterning a "simple" reflex is played by the motor neurons themselves.

EFFECTS OF SEROTONIN ON SWIM-GATING NEURONS IN THE MEDICINAL LEECH. J.D. Angstadt and W.O.Friesen. Department of Biology, University of Virginia, Charlottesville, VA 22901.

Prolonged activation of swim-gating cells (e.g. cell 204) is an important step in the initiation of leech swimming behavior (Weeks, J.C. and Kristan, W.B., J. Exp. Biol. 77:71, 1978). Previous studies (Willard, A.L., J. Neurosci. 9:936, 1981) showed that the probability of spontaneous swimming in intact animals or swim-associated electrical activity in isolated nerve cords is increased by the neurotransmitter serotonin (5-HT). We examined the effects of 5-HT on the cellular properties of cell 204 in isolated ganglia (G10-G14). Data from ganglia exposed to 50 μM 5-HT for a minimum of 30 min (n=24) were compared to controls (n=24). Cell 204 was penetrated with a single microelectrode and voltage responses to 1 sec current pulses (-2 to +2 nA) were measured using discontinuous current clamp. We also measured the peak-amplitudes of postinhibitory rebound (PIR) at the offset of hyperpolarizing current pulses and of hyperpolarizing undershoots at the offset of depolarizing current pulses. The I-V curves obtained in the presence of 5-HT were identical to controls except for a small increase in the hyperpolarizing responses to -0.5 and -1.0 nA current pulses. However, in the presence of 5-HT, the peak-amplitude of PIR and of hyperpolarizing undershoots were increased by an average of 190% and 330%, respectively. In Na-free saline, the peak amplitude of PIR was significantly reduced compared to controls. In addition, the serotonin-mediated increase in PIR observed in normal Na saline was eliminated in Na-free saline. These data suggest that ionic conductances intrinsic to swim-gating cells are modulated by 5-HT. Supported by NIH grants NS08089 (JDA) and NS21778 (WOF).

REAL TIME OPTICAL DETECTION OF RHYTHMIC MOTONEURON AND INTERNEURON ACTIVITY IN THE ISOLATED SPINAL CORD USING DIGITAL IMAGING OF CALCIUM TRANSIENTS. Michael O'Donovan, Wayne Yee & Miklos Antal. Laboratory of Neural Control, NINDS,NIH,Bethesda,MD 20892.

We have used real time digital imaging of calcium transients to identify active motoneurons and interneurons in the lumbosacral spinal cord of E8 to E12 chick embryos during spontaneous, stimulated and NMDA evoked motor activity. The cord was loaded with the calcium indicator Fura-2AM, mounted in a perfusion chamber on the stage of a fluorescence microscope and excited at 340 or 380nm during episodes of motor activity. The fluorescence (F) of loaded cells was monitored with an intensified video camera, and recorded on video tape together with hindlimb muscle nerve activity. At E12, when antagonist motoneurons alternate, the active cells were widely distributed throughout the spinal cord but were concentrated in the lateral motor column (LMC), the intermediate region dorsal to LMC and in the dorsal horn. Fewer active cells were found medial to the LMC. At E8 when the motor pattern is less mature, the active cells were more restricted in their distribution and were concentrated in the LMC and the intermediate region.

During motor activity motoneurons exhibited oscillations of fluorescence ($\Delta F/F = 15$-50%) in phase with rhythmic neural activity recorded from the muscle nerves. Cells in the intermediate region and the dorsal horn, presumed to be interneurons, also showed large fractional changes in fluorescence during motor activity. Some were rhythmically active in phase with motoneurons whereas others were tonically active throughout the episode. In some experiments the calcium transients have been measured in over 50 cells simultaneously. Experiments are now in progress to characterize the active cells histologically.

NMDA RECEPTORS CONTRIBUTE TO PROLONGED EXCITATION OF THE SCRATCH REFLEX CIRCUIT IN THE TURTLE SPINAL CORD.

Scott N. Currie and Paul S.G. Stein, Department of Biology, Washington University, St. Louis, MO 63130.

Cutaneous stimulation in the turtle produces an increase in the excitability of scratch reflex that outlasts the stimulus by several seconds (J. Neurophysiol. 60:2122, '88). We recently identified "long-afterdischarge" cutaneous interneurons in the midbody spinal cord that may participate in multisecond excitability storage in the scratch reflex pathway (Abstr. Soc. Neurosci. 15:1118, '89). Two characteristics of long-lasting excitation demonstrated for scratch reflex motor patterns are also exhibited by long-afterdischarge interneurons: 1) responses can continue for many seconds after a brief cutaneous stimulus, and 2) strong temporal summation occurs when single electrical pulses are applied to cutaneous afferents at multisecond intervals. In the present study, we tested the ability of D-2-amino-5-phosphonovaleric acid (APV), a specific antagonist of the N-methyl-D-aspartate (NMDA) receptor, to block prolonged cutaneous-evoked excitation. We applied APV to the exposed dorsal surface of a midbody spinal cord segment that receives cutaneous input from the rostral scratch receptive field. We simultaneously recorded single-unit activity from interneurons in the exposed segment and rostral scratch activity from hindlimb motor nerves. 50 μM APV strongly suppressed the activation of long-afterdischarge interneurons and completely blocked the temporal summation of scratch motor output when electrical stimuli were applied to the shell at multisecond intervals; it also greatly attenuated interneuron and scratch responses to higher frequency electrical stimulation and constant-force mechanical stimulation. We conclude that NMDA receptors assist in producing the long-lasting excitation that is a critical component of sensory integration in the scratch reflex pathway. TRANSCRANIAL DOPPLER ULTRASONOGRAPHY DURING COGNITIVE STIMULATION. R.E. Kelley, N.J. Tischenkel*, J.Y. Chang*, B.E. Levin*, R.C. Duncan* S-J. Lee*. Dept. of Neurology, University of Miami School of Medicine, Miami, FL 33101

Transcranial Doppler ultrasonography was evaluated for its potential to detect selective cerebral activation during cognitive tasks in 21 normal subjects. Mean and maximum flow velocity of the anterior cerebral arteries (ACAs), middle cerebral arteries (MCAs) and posterior cerebral arteries (PCAs) were measured during performance of a commercial video game with right handed manipulation of the joystick. We also measured flow velocity of the ACAs in 18 subjects during a mental arithmetic task. Serial measurements of the right and left sides were made via a headband with two probes and pCO_2 was monitored throughout the study. We observed global increase in flow velocity above baseline measurements during task performance. During the video game, both MCAs ($t=2.67$, $P=.008$ for the left, $t=4.86$, $P<.001$ for the right) and the left PCA ($t=2.13$, $P=.034$) had selective increase in mean flow velocity compared to the ipsilateral ACA. This selective activation was most prominent in the right MCA where the side to side difference was borderline significant at $F=4.16$, $P=.05$ for mean velocity and $F=3.85$, $P=.06$ for maximum velocity. We did not observe selective activation during the math task. This technique has the potential to allow noninvasive monitoring of circulatory correlates of cognitive activity.

MOTOR EVOKED POTENTIALS (MEP) INDUCED BY TRANSCRANIAL MOTOR CORTEX STIMULATION: MEP CHARACTERISTICS IN HUMANS WITH REDUCED BRAIN INPUT TO THE SPINAL CORD. M.R. Dimitrijevic, M.A. Lissens*, W.B. McKay. Division of Restorative Neurology and Human Neurobiology, Baylor College of Medicine, Houston, Texas 77030.

We studied motor evoked potentials (MEP's) in 32 subjects with chronic spinal cord injury. MEP's were elicited by transcranial stimulation of the motor cortex and recorded from pairs of surface electrodes placed over the muscles of the lower/upper limbs and trunk. The EMG signals were amplified and recorded by a 16 channel ink-writer and magnetic EMG recorder. The 32 subjects were divided in 5 groups according to the severity of spinal cord lesions.

We found that MEP's were present in subjects with preserved volitional activity and absent in those paralyzed. When analyzing the latency time of MEP's, we found that it was prolonged when compared to healthy subjects. On some occasions, such prolonged latency time could be shortened by conditioning stimuli or suprasegmental maneuvers. However, when volitional activity was well preserved, we also recorded nearly normal MEP latency times.

The results reported suggest that volitional activity is essential for the presence of MEP's and that the characteristics of MEP's depend upon the newly established functional relationship between segmental and suprasegmental structures.

REPRESENTATION OF MOVEMENTS IN PREMOTOR CORTEX OF SQUIRREL MONKEY: EVIDENCE FOR A HOMOLOG OF THE ARCUATE PREMOTOR AREA. R.J. Nudo. Dept. of Neurobiology & Anatomy, Univ. of Texas Medical School, Houston, TX 77030

We have recently reported that primates possess a unique source of corticospinal fibers, originating within Area 6 in the lateral portions of frontal cortex in prosimians and New World monkeys, and buried in the caudal bank of the inferior arcuate sulcus in Old World monkeys ("Region C"; Nudo & Masterton, 1990). While these results suggest that Region C is common to extant mammals, the functional organization and intracortical connections of this region have been described only in macaques ("arcuate premotor area"; e.g., Muakkassa & Strick, 1979). The present study was undertaken in order to determine whether the functional properties of Region C in squirrel monkey (*Saimiri sciureus*) are similar to those found in the arcuate premotor area in macaque monkey. We employed intracortical microstimulation and retrograde tracing techniques to examine the representation of movements in primary motor (MI) and premotor cortex (Areas 4 and 6, respectively) as well as their intracortical connections. These experiments revealed a distal forelimb representation within premotor cortex of squirrel monkeys, which was well segregated from the more caudo-medial distal forelimb representation within MI. Injection of retrograde tracers into the MI forelimb representation resulted in labeled cells within the Region C forelimb representation. Taken together with our prior descriptions of corticospinal projections from Region C, these results lead further credence to the notion that this cortical region is a homolog of the arcuate premotor area in macaques, and probably emerged in a remote primate ancestor. Supported by NIH NS 27974 and the Whitehall Foundation.

466.4

MICROSTIMULATION MAP OF THE MONKEY PREMOTOR CORTEX. M. Godschalk, A.R. Mitz, J. van der Burg* and B. van Duin*. Department of Anatomy, Erasmus University Rotterdam, POBox 1738, 3000 DR Rotterdam, The Netherlands.

Interpretations of premotor cortex (PM) somatotopy differ between the relevant anatomical (Muakkassa & Strick, Brain Res. 177:176, 1979) and single unit recording (Kurata, Exp. Brain Res. 77:245, 1989) studies. Coarse microstimulation of PM did not resolve this issue (Rizzolatti et al., Exp. Brain Res. 71:491, 1988). A more detailed and complete microstimulation map of the periarcuate and surrounding cortex was necessary.

A large chronic chamber was implanted over the arcuate (AS), superior precentral (SPCS), and central sulci. Biphasic constant-current pulses of up to 65 μA were delivered along 110-180 tracks in each of 4 macaque monkeys.

Movements were evoked from nearly every penetration into PM. Thresholds were typically below 40 μA, and often below 20 μA. Orofacial movements were evoked from the fundus and the caudal bank of the lateral limb of AS. Arm and hand movements were elicited from the caudal bank of AS, along the genu and the adjacent lateral limb. Forelimb sites continued onto the convexity medially and caudally towards SPCS. Thresholds increased with distance from AS caudally. Leg movements were elicited from an area around SPCS. Based upon these results, PM contains a whole body representation nearly parallel to MI, not one that follows the curvature of AS.

466.5

CONTRASTING PROPERTIES OF THREE FRONTAL REGIONS G. di Pellegrino and S. P. Wise Lab. Neurophysiol., NIMH, Poolesville, MD 20837.

Do the reported physiological differences between prefrontal cortex (PF) and frontal motor areas reflect valid contrasts in their properties or do they result instead from the diverse behavioral and physiological methods used to study them? To address this question, a monkey (*Macaca mulatta*) was conditioned to begin each trial by contacting the central of three touch pads. Next, a 1 s-long red or green stimulus appeared directly in front of the monkey, followed by 1.25 s (the first delay period). Then one red and one green light, simultaneously appeared peripherally, each above a potential target. The monkey withheld its response for an *instructed delay period* of 1.25 s, then touched the pad under the peripheral cue matching the first stimulus.

We sampled the dorsolateral, homotypical PF cortex ventral to and within the principal sulcus (97 neurons), the agranular dorsal premotor area (PM, 55 neurons), and a dysgranular region rostral to dorsal PM termed dorsomedial frontal cortex (DMF, 76 neurons). The proportion of movement-related neurons was not significantly different among the three regions explored. However, cells with apparent selectivity for stimulus attributes were found only in PF (10%). Further, during the first delay, phasic responses were prevalent in PF and DMF, but absent from PM. During the instructed delay period, phasic discharges predominated in PF (84%) and DMF (78%), whereas in PM fewer cells (26%) showed this type of activity. Conversely, in PM, tonic discharges were most common (60% *vs.* 9% in PF & 11% in DMF). Onset latency, peak activity latency and activity duration differed between PM and the other two areas. Thus, we found that the previously reported differences between PF and PM are reliable, and do not reflect species, individual, or methodological variation. In addition, the neural properties of DMF and PF more resemble each other than those of PM.

In a task variation, the green stimulus did not appear on trials in which the correct response was to the target beneath the green peripheral light. None of the 6 PM cells tested showed any effect of eliminating the central green stimulus. By contrast, 6 of 9 PF neurons were dramatically affected.

ACTIVITY OF THE PRECENTRAL MOTOR CORTEX (MI) NEURONS WITH CORTICOCORTICAL AND THALAMOCORTICAL INPUTS. J. Tanji and H. Aizawa., Dept. Physiol., Tohoku Univ. Sch. Med., Sendai, 980, JAPAN

The aim of the present study was to identify cortico-cortical and thalamocortical inputs to MI neurons whose activity properties in relation to a learned motor task were examined. Monkeys (Macaca fuscata) were trained to reach for and push one of two push buttons according to visual instruction signals. When the animal pressed a key for 2 sec, either a right or left push button, placed in a panel facing the animal, was illuminated for 500 ms with an LED from behind. The animal then had to wait for 2.5 to 4.5 sec before releasing the key and push the illuminated button. The neuronal activity in MI was classified into two broad categories, the activity immediately preceding the reaching movement (M) and the activity during the instructed wait-period (I). Under general anesthesia and aseptic conditions, stimulating electrodes were chronically implanted into the supplementary motor area (SMA), postcentral cortex (Post) and thalamus (Thal). MI neurons exhibiting only the I response were frequently activated by SMA but less frequetly by Thal stimulation. Hardly any of them were activated by Post stimulation. Neurons with M responses were most frequently activated by Thal and Post stimulation, and less frequently by SMA stimulation.

466.7

FUNCTIONAL CHARACTERISTICS OF A DIRECT GABAERGIC PATHWAY FROM ZONA INCERTA TO NEOCORTEX IN RODENTS AND PRIMATES. C-S.Lin, M.A.L.Nicolelis, J.K.Chapin and J.H.Kaas. Dept. Physiol., Hahnemann Univ., Phila., PA. 19102, Dept. Psych., Vanderbilt Univ., Nashville, TN 37240

Recently, we have demonstrated a previously unknown but sizable direct GABAergic projection from zona incerta to the neocortex in rats (Science, in press, 1990). This pathway is corticotopically organized and bilateral. To determine whether this pathway is also present in other species, the retrograde fluorescent tracers Fluoro-Gold, Fast Blue, and rhodamine and fluorescein coated microspheres were injected into several cortical areas in the owl monkey. Results of these studies confirmed that this incerto-cortical GABAergic pathway is also present in New World monkeys. Next, to elucidate the functional character of the ZI, single units were recorded in the ZI of rats anesthetized with pentobarbital. Since the trigeminal nuclei are known to project to the ZI, somatosensory mapping studies were carried out. Neurons in the dorsal subregion of the ZI were found to possess very large receptive fields (RFs) on the fur or whiskers of the contralateral or bilateral face. By contrast, neurons in the more ventral subregions of ZI possessed RFs on the ipsilateral face. Both slowly and rapidly adapting responses were found in ZI. In addition, circular visual RFs were found and both on and off cells were identified. Single unit recordings in the general region of ZI in awake, freely behaving rats also revealed neurons with combined somatosensory RFs (whiskers) and visual RFs (covering the visual space in front of the whiskers). These cells were maximally activated during complex coordinated movements of the whiskers when the animal searched the surrounding space or novel objects. Units also responded strongly when an object was rapidly moved toward the eye of the animal. Our present data suggest that ZI may be involved with both sensorimotor integration and attention. *Supported by grants NS26722, AAO6965, KO2-AA00089, AFOSR-90-0266 and FAPES 88/4044-9.*

FIRING PROPERTIES AND SYNAPTIC RESPONSES HAVE INVERTED LAMINAR DISTRIBUTIONS IN REELER NEOCORTEX. B.W. Connors, L.R. Silva and M.J. Gutnick, Sect. of Neurobiology, Div. of Biology and Medicine, Brown Univ., Providence, RI 02912.

Reeler is a mouse mutation that alters neuronal migration during development, yielding an inversion of the laminar organization of the neocortex. We recorded *in vitro* from slices of normal and reeler parietal cortex to study the influence of laminar position on neuronal membrane properties and synaptic responses. Dye injections in reeler pyramidal neurons revealed atypical morphologies, including distorted apical dendrites and cell inversion. The intrinsic firing patterns, action potential width and height, resting membrane potential, input resistance and evoked EPSPs and IPSPs did not differ between reelers and controls when data were grouped. However, the laminar distribution of intrinsic firing patterns (TINS 13:99, 1990) was inverted in the reeler: intrinsically bursting neurons were found only in layer 5 in the normal mouse, but they were found exclusively in superficial layers of the reeler cortex. The laminar distribution of synaptic responses in the reeler was also inverted: very prominent IPSPs were characteristic of upper layer neurons in the normal mouse, but in the reeler similar responses were observed in deep infragranular layers. We conclude that neurons develop the membrane and synaptic properties appropriate to their function, not their position.

LAYER 5 NEURONS CAN INITIATE NMDA-DEPENDENT, 4-7 HZ SYNCHRONIZED RHYTHMS IN NEOCORTEX. L.R. Silva and B.W. Connors, Section of Neurobiology, Div. of Biology & Medicine, Brown University, Providence, RI 02912.

We have studied a cellular mechanism of synchronized rhythms in slices of rat SI neocortex *in vitro*. Slices bathed in nominally zero Mg^{++} showed spontaneous synchronized discharges that were highly rhythmic. Field potentials revealed epochs of 4-7 Hz discharges. Each epoch typically lasted 1-4 sec, and recurred 1-9 times per min for hours. Synchronized rhythms were dependent on NMDA receptors, since they were completely blocked by the specific antagonist AP5. When slices were cut vertically into narrow segments (~1 mm wide), rhythmic spontaneous activity continued in each piece. When segments were then cut horizontally, rhythms continued only in fragments with an intact layer 5. Fragments consisting *only* of layer 5 were also spontaneously rhythmic. Recordings revealed that layer 5 pyramidal neurons whose apical dendrites were severed at the layers 4/5 border had normal firing properties; the majority could oscillate endogenously at 5 to 15 Hz (cf. Silva et al. *Neuro. Abst.* 15:660, 1989). Since layer 5 was necessary and sufficient to produce rhythmic synchronized discharges in this frequency range, we suggest that some EEG rhythms are generated by a network of endogenously oscillating pyramidal neurons in layer 5.

Supported by the NIH, the NIMH, and the McCormick Fund of Stanford University.

INTRINSIC SUBTHRESHOLD 10-50 HZ MEMBRANE OSCILLATIONS IN INTERNEURONS IN THE FOURTH LAYER OF THE FRONTAL CORTEX.
K. D. Walton, Y. Yarom[1] and R. Llinás, Dept. of Physiology and Biophysics, N.Y.U. Medical Center, 550 First Ave., N.Y., N.Y., 10016 and Dept. of Neurobiology, Hebrew University, Life Sci. Inst. Givat Ram, 91904, Jerusalem, Israel.[1]

Intracellular recordings from interneurons in the layer IV of frontal cortex slices from adult guinea pig generate subthreshold membrane potential oscillations near 40 Hz by the activation of slow Na and K conductances (Llinás and Grace, *Soc. Neurosci. Abst* 15:660,1989. These neurons were identified as belonging to the category of sparsely spinous stellate cells usually considered to be GABAergic interneurons. Further study of the layer IV neurons revealed that, in addition to the 40 Hz oscillatory interneurons, in which an all-or-none plateau potential generates a close-to-fixed frequency oscillation (35 to 46 Hz), a second category of cells exists where the subthreshold oscillation may vary from 10 to 40 Hz. As this second type of cell is depolarized, the oscillatory frequency increases and may reach spike firing level to activate short duration spike bursts at 20 to 40 Hz. We propose that these two types of cells represent two functionally distinct categories of interneurons. In one type a plateau potential, generated by a persistent sodium conductance, may force the cell to oscillate within a narrow frequency range near 40 Hz. The second type of neuron responds with sub-threshold oscillations of variable frequency, depending on the level of membrane depolarization. Both types of neurons are likely to send inhibitory oscillatory input to cortical Pyramidal cells as well as to other neurons within a cortical column. This interneuron network may serve to transform desynchronized thalamic input into 40 Hz oscillatory Pyramidal cell firing, triggered as a rebound response to the synchronized IPSP input from the interneurons. This cortical circuit is proposed to be a part of the cellular mechanism for the "binding" or "conjunction" properties presently considered to be a main function of the 40 Hz rhythm in the brain.

LONG-TERM RECORDING OF CORTICAL UNITS USING THE CONE ELECTRODE IN MONKEYS. **P.R.Kennedy, R.A.E.Bakay, N.Ovesiku and D.M.Banks*. Georgia Tech and Emory Univ., Atlanta, GA.**

Recording the electrical activity of cortical neurons over many years with adequate signal-to-noise ratios will allow patients to control prosthetic devices. Multi-units, or for more selective control, single units must be recorded for years from voluntary motor areas. From cortical area 4, we have recorded multiple single units for over a year in one monkey, and six months in another. From these signals, we separated single units that were identified over these time periods and related them to movements.

The recording electrode consists of a tiny glass cone with a recording wire fixed inside. Neurites are attracted to grow into the cone by sciatic nerve fibers placed inside at implantation. Details of fabrication, implantation, histology and recording the electrical activity of the ingrown neurites in rat (J. Neurosci. Meth. 29:181-193,1989) are similar in monkey. The multiple units are separated using waveshape matching paradigms (Brainwave Systems Inc., Denver, CO). In one monkey, seven units were identified, of which four were still present at six months when the experiment was terminated. In the other monkey still ongoing at a year, the same three units are identified each month.

The monkeys are videotaped while taking food. On review, the single units are separated using the waveshape parameters determined at earlier sessions. Individual units are reviewed one at a time in synchrony with the videotaped hand and finger movements, thus revealing the relationships between the units and movements.

TOTAL NUMBER OF NEURONS IN HUMAN NEOCORTEX RELATED TO AGE AND SEX. B. Pakkenberg, S.M. Evans, A. Møller, H. Brændgaard* & H.J.G. Gundersen. Neurological Research Laboratory, Hvidovre University Hospital, Copenhagen and Stereological Research Laboratory, Aarhus University, Denmark.

A method for an unbiased estimation of the total number of neurons in the human neocortex has recently been introduced and applied to 50 brains from normal individuals of different age-groups and both sexes. The sampling was designed so that the majority of cerebral cortex was left intact providing the possibility for resampling and further analysis. Uniform sampling for total neuron number was performed in each neocortical area. Total cortex volume was estimated precisely according to Cavalieri's principle, and neuronal numerical density estimates made in 35 μm thick plastic sections using optical disectors. Normal humans have approximately $20 \cdot 10^9$ neocortical neurons with an inter-individual variation of 15%. There is a decline in the number of neurons with age by 50 to $100 \cdot 10^6$ neurons per year. Females have about 15% fewer neurons than males of same age.

DEPOLARIZATION MODULATES CILIARY GANGLION NEURONAL RESPONSES TO NEUROKINES. F.Fuller, A.Lam*, J.Kloss, B.Cordell, S.Varon† and M.Manthorpe†. California Biotechnology Inc., 2450 Bayshore Pkwy, Mountain View, CA 94043; †Dept. Biology, UCSD, La Jolla, CA 92093.

Neurotrophic agents, including depolarizing concentrations of potassium, prevent the death of cultured chick E8 ciliary ganglion (cCG) neurons. To examine the effects of neurokines independent of their survival activities, we have tested a variety of factors on viable cCG cultures maintained in 40 mM K^+ on a laminin substratum. Without added factors, neurite outgrowth was essentially absent and choline acetyltransferase (ChAT) activity decreased with time. However, IGF-I/Insulin, FGF and CNTF were potent stimulators of both ChAT and neurite outgrowth. FGF elicited the largest increase in ChAT (2 to 3 fold), while CNTF was the most potent (ED_{50} ~5 pg/ml). Under nondepolarizing conditions (4 mM K^+), IGF-I was not active while FGF and CNTF were both able to support survival and neurite outgrowth of cCG neurons and to prevent loss of ChAT activity. Furthermore, CNTF was 10 fold less potent in low potassium compared to ChAT induction in high potassium. These observations suggest that, in vivo, afferent evoked depolarization could similarly modulate neuronal response to neurokines. Supported by NIH 16349.

REGULATION OF PROTEIN TYROSINE PHOSPHORYLATION IN DEVELOPING MOUSE BRAIN BY EGF, IGF-1 AND INSULIN
Jean-Antoine Girault[1], Gloria Bertuzzi*, James K.T. Wang[2], Dennis Pang* and Paul Greengard Rockefeller University, New York, NY 10021;
[1] INSERM U114, Collège de France, Paris, France;
[2] Tufts University School of Medicine, Boston, MA 02111.

Insulin-like growth factor 1 (IGF-1), insulin, and epidermal growth factor (EGF) have trophic effects on neuronal development *in vitro*. Since their receptors possess tyrosine kinase activity, we have investigated the effects of these growth factors on protein tyrosine phosphorylation in reaggregate cultures from embryonic mouse cerebral cortex, using antiphosphotyrosine antibodies. In the absence of growth factor, two main proteins phosphorylated on tyrosine were observed and designated p120 and p180 on the basis of their apparent molecular weights on SDS-PAGE. EGF enhanced the phosphorylation of p180 and induced the appearance of a 110 kDa and a 170 kDa phosphoprotein, the latter probably corresponding to the EGF receptor. Insulin and IGF-1 increased the phosphorylation of p180 and of a 160 kDa phosphoprotein distinct from the EGF receptor. Platelet derived growth factor, basic fibroblast growth factor, nerve growth factor and bombesin had no effect on protein tyrosine phosphorylation.

In the brains of intact mice, at various ages from embryonic day 16 to the 8th postnatal week, p120 and p180 were the two main proteins phosphorylated on tyrosine observed in basal conditions. The apparent levels of phosphorylation of these 2 proteins increased during development *in vitro* and *in vivo*, reaching a maximum during the postnatal period, earlier for p120 than for p180.

We propose that the phosphoproteins identified in the present study mediate some of the effects of EGF, insulin and IGF-1 in developing central nervous tissue.

467.3

REDISTRIBUTION OF FIBROBLAST GROWTH FACTOR AFTER NEURITIC INJURY Timothy J. Neuberger and George H. De Vries Dept. of Biochemistry, Medical College of Virginia, Richmond VA., 23298

We previously reported the presence of fibroblast growth factor (FGF) in Schwann cells (Sc) and neurons (Nc) in dissociated dorsal root ganglion (dDRG) cultures (Neuberger et. al., 1990). In this study we crushed the neuritic field of established dDRGs and visualized the distribution of FGF at various times after injury. At 1 and 3 days post-injury (DPI), the distribution of FGF appeared unchanged from the normal control culture; FGF immunoreactivity was observed in the cytoplasm of both Nc and Sc but only on the outer membrane of Nc. By 4 DPI, FGF detected on the plasma membrane of the Nc bodies was decreased, whereas FGF associated with the cytoplasm of Nc and Sc remained unaltered. At 4 DPI, the outer membrane of Sc also demonstrated intense FGF immunoreactivity. Most Sc appeared morphologically normal; however, the membrane of a few Sc demonstrated extensive blebbing. At 6 DPI, the FGF distribution was similar to that seen at 4 DPI. In this study, we demonstrate that neuritic injury results in a significant redistribution of FGF; the outer membrane of Sc become positive for FGF while the outer neuronal membrane demonstrates decreased immunoreactivity. The potential role of this redistribution of FGF, in peripheral nerve regeneration is under active investigation. (Supported by NS10821 and NS15408)

IN VIVO TREATMENT WITH BASIC FIBROBLAST GROWTH FACTOR DURING DEVELOPMENT DOES NOT ALTER NATURALLY OCCURRING NEURONAL DEATH. R. W. Oppenheim, D. Prevette and F. H. Fuller, Dept. of Neurobiology and Anatomy, Bowman Gray School of Medicine, Winston-Salem, NC 27103 and California Biotechnology, Inc., Mountain View, CA 94043

Basic (bFGF) and acidic (aFGF) fibroblast growth factors are polypeptides which act as mitogens for a variety of mesenchymal derivatives. In addition, both aFGF and bFGF promote the in vitro survival of neurons from several different regions of the developing brain and spinal cord and on that basis have been considered as putative neurotrophic factors (NTF). To further explore the role of bFGF as a NTF, we have examined its effects on the survival of several populations of avian neurons in vivo that exhibit naturally occurring cell death. These include: spinal motoneurons, neurons in the ciliary, sympathetic and dorsal root ganglia, and sympathetic preganglionic neurons. Daily treatment of chick embryos in vivo with a wide range of doses of human recombinant bFGF (with and without heparin) during the normal cell death period for the various neuronal types failed to alter the course or magnitude of cell loss. By contrast, in vivo treatment with bFGF was mitogenic for non-neuronal cells as measured by increased numbers of bromodeoxyuridine (BUdR) immunostained cells in the CNS. These data do not support the role of bFGF as a NTF in the survival of avian neurons in vivo.

BRAIN-DERIVED NEUROTROPHIC FACTOR, BUT NOT NEUROTROPHIN-3 STIMULATES SEPTAL CHOLINERGIC NEURONS IN CULTURE. EFFECTS ON NIGRAL DOPAMINERGIC NEURONS. B. Knüsel, J.W. Winslow, A. Rosenthal, L.E. Burton, D.P. Seid, K. Nikolics and F. Hefti. Andrus Gerontology Center, Univ. of Southern California, Los Angeles, CA 90089 and Genentech, Inc., South San Francisco, CA 94080.

Brain-derived neurotrophic factor (BDNF) and neurotrophin-3 (NT-3), two recently cloned molecules closely related to nerve growth factor (NGF), were produced from human cDNA expressed in human embryonic kidney cells. The recombinant proteins were tested in cultures of dissociated fetal rat brain. BDNF but not NT-3 stimulated the differentiation of basal forebrain cholinergic neurons, similarly effective as bFGF (Knüsel, B., et al., *J. Neurosci.*, 10:558, 1990) and as NGF which is well established as neurotrophic factor for these cells. In contrast to NGF and NT-3, BDNF also increased protein content of the cultures. BDNF, as bFGF, was most effective at an early time *in-vitro*. Maximal increase of choline acetyltransferase activity after 3 days treatment with BDNF was approximately 300% of control. Possible actions of BDNF and NT-3 on dopaminergic neurons of ventral mesencephalon in culture are currently studied. Our findings suggest an important role of BDNF in mammalian brain development with a spectrum of actions different from that of NGF.

FIBROBLAST GROWTH FACTORS IN THE NERVOUS SYSTEM: DISTRIBUTION AND CHANGES AFTER INJURY. F.P. Eckenstein, G.D. Shipley*, R. Nishi. Dept. of Cell Biology & Anatomy, Oregon Health Sci. Univ., Portland OR 97201

Acidic and basic fibroblast growth factors (aFGF and bFGF) are known to stimulate mitogenesis in of a variety of non-neuronal cell types. In addition, recent work has established that FGFs also can act as neurotrophic factors that promote the survival and regeneration *in vitro* of a variety of neurons. The present study addresses the function of aFGF and bFGF *in vivo* by using a mitogenic bioassay on AKR-2B cells coupled with Western blot analysis to quantify levels of aFGF and bFGF in different areas of the rat nervous system. Acidic FGF and bFGF from extracts of nervous tissue were found to differ considerably in their relative dependencies upon heparin to potentiate their mitogenic activities: the effect of aFGF was completely dependent upon heparin whereas the effect of bFGF was only slightly potentiated by heparin. Heparin was also found to stimulate differentially the mitogenic activity of extracts prepared from different areas of the nervous system, indicating that spinal cord, cortex, pituitary, and optic nerve contained different ratios of aFGF to bFGF, whereas sciatic nerve contained extremely high levels of only aFGF. These results were confirmed in Western-blot-experiments, using antibodies specific for either aFGF or bFGF. Transsection of nerves had opposing effects in sciatic and optic nerves: aFGF rapidly declined in the sciatic nerve distal to the cut, whereas FGFs increased slightly in the distal portion of the cut optic nerve. This differential responsiveness of FGF levels in the central versus distal nerve stumps may reflect the differential regenerative potential of these two nerves.

CILIARY NEUROTROPHIC FACTOR IN ADULT SCIATIC NERVES IS BIOCHEMICALLY IDENTICAL TO TROPHIC ACTIVITY IN EMBRYONIC CHICK EYES. R. Nishi, T.Holbert* and F.P. Eckenstein. Dept. of Cell Biology & Anatomy, Oregon Health Sci. Univ., Portland, OR 97201

Neurons in the chick ciliary ganglion undergo a marked period of cell death during development that is dependent upon the presence of target tissues in the eye. It has been postulated that the degree of cell death is regulated by neurotrophic factors. Recently, the cDNAs coding for rat (Stöckli et al, 1989. Nature 342: 920) and rabbit (Lin et al, 1989. Science 246: 1023) sciatic nerve ciliary neurotrophic factor (CNTF) were reported; however, because northern blot analysis indicated that the mRNA coding for rat CNTF was not detected in developing tissue, the possibility was raised that the activity of CNTF may be exerted only under "pathophysiological" conditions rather than during neuronal development. We have recentiy (1990, Neuron, Apr) reported the >80,000- fold purification of a growth promoting activity (GPA) from adult chick sciatic nerves that is 50% homologous to rat and rabbit CNTF, thus GPA may be the chicken form of CNTF or a related molecule . In order to test whether this molecule is biochemically identical to a trophic activity previously reported in embryonic chick eyes we ran parallel purifications of chick eye and sciatic nerve material. The chromatographic retention times of the active material from both sources were identical through every step of the purification which included DEAE chromatography, gel filtration, chromatofocusing, and two runs of reverse phase HPLC. In addition, SDS PAGE analysis of the active fractions of both preparations revealed co-migrating 21.5 kD bands that co-purified with the biological activity. Thus, embryonic chick eyes contain a considerable amount of trophic activity for CG neurons that is biochemically indistinguishable from that found in adult chick sciatic nerves, supporting the notion that there is a developmentally relevant function for this molecule. Funded by NS25767 (RN), ALSA (RN), AG07424 (FPE), and March of Dimes (FPE).

GENE EXPRESSION OF A TROPHIC FACTOR DURING DEVELOPMENT OF EMBRYONIC CHICK CILIARY GANGLION NEURONS. A. Parent, F.P. Eckenstein, and R. Nishi. Dept. of Cell Biology and Anatomy, Oregon Health Sci. Univ., Portland, OR 97201.

It has been postulated that the survival and development of ciliary ganglion (CG) neurons is regulated by neurotrophic factors released by target cells in the eye. Previously, a growth-promoting activity (GPA) was identified in chick eye extracts (Nishi & Berg, 1981), and we have recently reported the >80,000-fold purification and characterization of GPA from chick sciatic nerves (Eckenstein et al., 1990). Amino acid sequence analysis of a proteolytic digestion fragment of GPA shows a 57% homology with a carboxy terminal region of rabbit and rat sciatic nerve CNTF (Lin et al., 1989; Stöckli et al, 1989). The biological activity of GPA and its homology to mammalian CNTF suggests that GPA is the chicken form of CNTF or a related factor. In order to test whether GPA is a neurotrophic factor in vivo for CG neurons we are examining the developmental- and cell- specific expression of the GPA gene. Degenerate oligos were synthesized based on the GPA amino acid sequence and used in a PCR reaction with cDNA synthesized from chick eye and sciatic nerve RNA. Both sources of RNA produced amplification products that hybridized at low stringencies to a rabbit CNTF probe. Thus, the RNA coding for GPA is found in the developmentally relevant source. We expect to use these amplification products as probes to isolate a full-length GPA clone from a cDNA library. The PCR-derived probe will also be used concurrently to analyze GPA gene expression with northern blots. The sequence of the cDNA clone will allow comparison of eye and sciatic nerve GPA with mammalian CNTF. We are especially interested in whether chick eye GPA contains a consensus signal sequence that is lacking in the sciatic nerve GPA. Supported by NS25767 (RN), AG07424 (FPE), March of Dimes (FPE), and the ALS Association (RN).

FIBROBLAST-DERIVED NERVE GROWTH FACTORS: BIOLOGICAL AND IMMUNOLOGICAL CHARACTERIZATIONS. A. Acheson, P.A. Barker, R. Hodges*, F.D. Miller and R.A. Murphy. Dept. of Anatomy and Cell Biology, Univ. of Alberta, Edmonton, Alberta.

We have investigated the relationship between salivary nerve growth factor (ßNGF) and fibroblast-derived NGF. E10 chick dorsal root ganglia (DRG) contain two subpopulations of neurons, 40% depending on ßNGF for survival and 40% depending on brain-derived neurotrophic factor (BDNF). L929 fibroblast-conditioned medium (LC CM) promotes the survival of 95% of DRG neurons, suggesting that it contains both NGF- and BDNF-like molecules. LC CM also promotes neurite growth from retinal explants, which do not respond to ßNGF, and L cells contain mRNA coding for BDNF. Antibodies to ßNGF completely blocked the survival- and neurite-promoting effects of LC CM, suggesting that molecules with BDNF-like activity are related immunologically to ßNGF. Surfaceplot analyses predict that ßNGF and pig BDNF have similar regions exposed to an aqueous environment and may share common antigenic sites. Antibodies to two synthetic peptides of ßNGF confirm that both NGF- and BDNF-like activities in LC CM arise from molecules that share at least one functionally important epitope. In addition, NGF-like molecules in LC CM can be distinguished immunologically from ßNGF. Thus NGF- and BDNF-like molecules in LC CM may differ from ßNGF and pig brain BDNF, and L cell-derived forms of NGF and BDNF are immunologically related.

467.10

PARTIAL REGIONAL COLOCALIZATION OF HDNF/NT-3 AND BDNF mRNA IN THE RAT BRAIN.

PATRIK ERNFORS, CYNTHIA WETMORE LARS OLSON* AND HÅKAN PERSSON

Department of Medical Chemistry, Laboratory of Molecular Neurobiology, and Department of Histology and Neurobiology, Karolinska Institute, Box 60400, S-104 01 Stockholm, Sweden; and The entry of molecular genetics in the field of neurotrophic factors has recently led to the discovery that nerve growth factor is a member of a family of neurotrophic factors. We have recently isolated and characterized a molecular clone encoding a novel member of this family, named hippocampus-derived neurotrophic factor/neurotrophin-3. We have used *in situ* hybridization to map the expression of both HDNF and BDNF in the rat brain and in the periphery. BDNF mRNA labeled neurons were found in several areas of the brain, whereas HDNF mRNA expressing neruons were restricted to a few regions of the brain. On the contrary, in the periphery cells expressing BDNF mRNA were only found in few tissues. Exept for one structure in the brain stem, HDNF mRNA expression in rat brain was only detected in the hippocampus and developmentally related structures, where it was expressed by neurons in the medial part of CA1, CA2 and dentate gyrus. BDNF mRNA expressing neurons were also seen in the hippocampus, primarily in the hilar region, CA3 and dentate gyrus. Both factors where expressed in a rostro-caudal, dorso-ventral arrangement that were partially overlapping in the hippocampus. In addition, BDNF mRNA expressing neurons were present in the pyramidal layers of cerebral cortex, claustrum and olfactory bulb. In the periphery, HDNF mRNA expressin cells were found in the glomeruli of kidney, in secondary and tertiary follicles in ovaries and in the rat submandibular gland.

467.11

PRIMARY STRUCTURE AND BIOLOGICAL ACTIVITY OF A NOVEL HUMAN NEUROTROPHIC FACTOR NEURONOTROPHIN-3 (NT-3) AND HUMAN BRAIN-DERIVED NEUROTROPHIC FACTOR (BDNF). J.W. Winslow, K. Nikolics, A. Shih*, G.R. Laramee*, T. Nguyen*, D.V. Goeddel*, and A. Rosenthal*. Departments of Molecular Biology and Developmental Biology, Genentech, Inc., South San Francisco, CA 94080.

The structural similarity between NGF and BDNF and their neuronal specificity suggest that additional, functionally distinct members of this protein family may exist. Degenerate oligonucleotides derived from regions conserved between NGF and BDNF were used as primers to amplify human placental DNA by polymerase chain reaction (PCR). Fragments of the expected size (200bp.) were generated and identified as either NGF, BDNF, or a novel related sequence designated human neuronotrophin-3 (hNT-3). A single 1.4kb rat NT-3 clone containing a 258 amino acid open reading frame and two 0.6kb partial hNT-3 cDNAs were isolated from rat and human cDNA libraries. A complete hNT-3 sequence encoding 257 amino acids was obtained by screening a human genomic library while a complete hBDNF 1.2kb clone, encoding a 247 amino acid protein, was obtained from screening a human brain cDNA library. The hNT-3 precursor protein is 44.2% and 38.5% identical to those of the hNGF and hBDNF precursors, respectively, while the putative mature forms shared 57.6% and 55.6% identity. The putative mature forms of human and rat NT-3, and human and porcine BDNF, are identical. Northern blot analysis revealed a broad organ distribution of rat NT-3 poly A+ mRNA including heart, kidney, liver, spleen, lung, and in several brain regions. Rat BDNF mRNA was most prevalent in the brain, however, BDNF mRNA was detected in heart and lung suggesting a role in the peripheral nervous system. Recombinantly expressed and purified hNT-3 was active in the survival of dispersed chick embryonic day-10 sympathetic ganglia (SG) neurons. Purified hNT-3 had potent neurotrophic activity in nodose ganglia (NG), however, only 40-60% of dorsal root ganglia (DRG) neurons survive relative to those in the presence of NGF. Thus, NG and DRG sensory neurons, which innervate mainly visceral and somatic tissues, respectively, may respond to distinct trophic factors because of different target specificities.

467.12

DETECTION OF BRAIN-DERIVED NEUROTROPHIC FACTOR-LIKE (BDNF) BIOLOGICAL ACTIVITY AND mRNA IN SCIATIC NERVE FIBROBLASTS AND SCHWANN CELLS. P. Barker, A. Acheson, S. Pareek, F.D. Miller, and R.A. Murphy. Dept. of Anatomy and Cell Biology, Univ. of Alberta, Edmonton, Alta., Canada T6G 2H7.

BDNF promotes the survival *in vitro* of chick DRG neurons not responsive to NGF, some placode-derived sensory neurons, and retinal ganglion cells. BDNF is produced in the mammalian CNS and may promote neuronal survival centrally in a manner analogous to NGF in peripheral tissues (Nature 341,149, 1989). NGF is produced by non-neuronal cells in the PNS, including fibroblasts and Schwann cells, but cellular sources of BDNF have not been identified.

Our data suggest that BDNF may also be produced by tissues outside the CNS. We have detected BDNF mRNA of sizes 1.7 and 4.0 kb (identical to those in rat brain) in cultured fibroblasts from rat skin and sciatic nerve, in cultured Schwann cells, and in rat sciatic nerve. We also tested the ability of media conditioned by these cells to promote the survival of E10 chick DRG neurons, 40% of which require NGF, and 40% BDNF. Conditioned media (CM) from cultures of dermal fibroblasts and sciatic nerve Schwann cells promoted the survival of 75% and 63% of the neurons respectively, including neurons from both NGF- and BDNF-dependent subpopulations. Chick sympathetic neurons (which require NGF and not BDNF), survived better in NGF-supplemented medium (71% survival) than in CM from fibroblasts (15% survival) or Schwann cells (26% survival). These results suggest that at least two cell types in peripheral tissues that produce NGF may also produce BDNF.

RECEPTOR MODULATION: UP AND DOWN REGULATION II

468.1

LACK OF EFFECT OF CHRONIC ADMINISTRATION OF AGONISTS AND ANTAGONISTS ON RAT CNS RECEPTOR mRNA LEVELS. Z. Zang, M. Riva, H. H. M. Van Tol*†, O. Civelli†-and Ian Creese. Center for Molecular & Behavioral Neuroscience, Rugters, The State University of New Jersey, Newark, NJ 07102, †Vollum Institute for Advanced Biomedical Research, Oregon Health Sciences University, Portland, OR 97201.

Chronic treatments with agonist or antagonist drugs can change the density of CNS receptors. To gain some understanding of the molecular basis of the receptor regulation the present studies examined the mRNA levels for the muscarinic receptors (M_{1-4}) in frontal cortex, hippocampus and brain stem, dopaminergic receptor (D_2) in striatum, as well as the serotonergic receptor ($5\text{-}HT_2$) in striatum and frontal cortex by using Northern blot analyses. Following two to three week treatments via implanted minipumps with scopolamine (10 mg/kg/day) a muscarinic receptor antagonist, haloperidol treatment (0.5 mg/kg/day) a dopamine receptor antagonist, DOI (7.5 mg/kg/day) a serotonergic agonist or ketanserin (7.5 mg/kg/day) a serotonergic antagonist, we found no differences between the control and experimental groups' levels of mRNAs for M_{1-4}, D_2 or $5\text{-}HT_2$ receptors respectively in any brain regions, even though receptor binding showed that these chronic treatments had produced an increase or decrease in the total population of receptors. Within the sensitivity of the assays, these results suggest that the up-regulation of muscarinic receptors and the D_2 dopaminergic receptor by antagonist treatment as well as the down-regulation of the $5\text{-}HT_2$ serotonin receptors by either agonist or antagonist treatments may not be directly regulated at the level of gene transcription.

468.2

PROTEIN SYNTHESIS IS REQUIRED FOR THE DENERVATION-INDUCED UP-REGULATION OF ACETYLCHOLINE RECEPTOR GENES. Huey-Jen Tsay*, Craig M. Neville*, and Jakob Schmidt. Department of Biochemistry and Cell Biology, State University of New York at Stony Brook, Stony Brook, New York, 11794.

Denervation of skeletal muscle stimulates transcription of acetylcholine receptor genes. To determine if this activation is mediated by the appearance of an activator or the loss of an inhibitor we have investigated the effect of the protein synthesis blocker cycloheximide on the denervation response. White Leghorn chicks (3 d old) were subjected to unilateral section of the sciatic nerve, and cycloheximide treatment (i.p. injections of 0.2 mg/kg at 4-h intervals) was begun. 24 hours later the denervated muscle was assayed by probe excess solution hybridization for acetylcholine receptor α-subunit message and by transcript elongation analysis for α-subunit gene activity. In the presence of cycloheximide the increase in α-subunit message that normally follows denervation was not observed, and α-subunit gene activity dropped to about non-denervated control levels. Block of transcriptional activation was also seen in the case of the receptor δ- and γ-subunit genes. Several nonreceptor genes were not affected by cycloheximide, either in their steady-state levels or in the transcription rates of their mRNAs. During cycloheximide treatment of chronically denervated animals, α-subunit gene transcripts decayed with a half-life of one day. These results suggest that the de novo synthesis of a transcriptional activator is required as a mediating event in the signalling pathway linking the plasma membrane and acetylcholine receptor gene expression.

468.3

DESENSITIZATION OF MUSCARINIC RECEPTORS THAT INHIBIT ADENYLATE CYCLASE IN CEREBELLAR GRANULE CELLS INVOLVES HOMOLOGOUS LOSS OF MUSCARINIC m_2 RECEPTIVE PROTEIN (66K Da) AND HOMOLOGOUS INCREASE IN m_2-mRNA CONTENT. W.J. Wojcik, S. McLeskey, A. Dobrenski and I. Mocchetti§. FGIN and §Anatomy, Cell Biology Dept., Georgetown University, Washington, D.C. 20007.

In primary cultures of cerebellar granule cells, carbachol (carb 100 μM) maximally desensitizes muscarinic receptors that inhibit adenylate cyclase (M-AC). However, muscarinic receptive protein(s) that comprises the M-AC response is unknown and it may be presumptuous to assume the M-AC to be the muscarinic m_2 subtype. Irreversible labeling of muscarinic receptors on membranes prepared from granule cells with ^{3}H-propylbenzilylcholine mustard (PBCM) and separation by SDS-PAGE shows proteins of 92 K Da and 66 K Da in molecular size. In membranes treated with carb (100 μM, 1 hr), ^{3}H-PBCM labels only 92 K Da proteins, suggesting that the desensitized M-AC receptor is a 66 K Da protein. Methoctramine, an antagonist that is 600Xs more potent at M-AC than M-PI, is also shown to prevent the binding of ^{3}H-PBCM to the 66 K Da protein. Desensitization of M-AC involves two events, a short-term process (carb. 100 μM, 1 hr) whereby the M-AC response returns within one hour of resensitization (1 μM atropine, 1 hr) and a long-term process (carb. 100 μM, from 6 to 24 hrs) whereby the M-AC response does not reappear after 1 hr of resensitization. Muscarinic m_2 and m_3 receptor mRNA content was analyzed by Northern blot analysis using probes provided by Dr. T. Bonner, NIMH. Comparisons between Northern blots of poly A$^+$ RNA, that was extracted from cultures exposed to carb (100 μM) for 1, 6 and 24 hours, showed an increased m_2-mRNA content at 6 hrs only and no change in m_3-mRNA. Thus, the M-AC receptor is shown to be the m_2 subtype and desensitization of M-AC results in homologous loss in the 66 K Da protein and homologous increase in m_2-mRNA content.

A cAMP RESPONSE ELEMENT IN THE β_2-ADRENERGIC RECEPTOR GENE CONFERS TRANSCRIPTIONAL AUTOREGULATION BY cAMP. S.Collins*, J.Altschmied*, J.Bell, M.G.Caron, P.Mellon* and R.Lefkowitz*. HHMI, Duke Univ. Med. Ctr., Durham, NC 27710, Salk Institute La Jolla, CA 92136 and Glaxo Inc., Res. Tri. Pk., NC 27709

The β_2-adrenergic receptor (β_2AR) gene is transcriptionally upregulated in response to agonist or forskolin stimulated cAMP levels. Previous studies show this autoregulation resides in the 5'-flanking region of the β_2AR gene (PNAS, 86:4853,1989). A 34 bp sequence from the β_2AR promoter (-70 to -37), containing the sequence GTACGTCA, confers responsiveness to cAMP in either orientation 5' to a thymidine kinase promoter-CAT reporter gene when transfected into rat C6 glioma or human JEG-3 choriocarcinoma cells. Specific mutations in this sequence completely abolished stimulation. Overexpression of the catalytic unit of protein kinase A fully substituted for the induction of CAT activity by forskolin.

A 43 kD transcription factor (CREB; cAMP response element binding protein) confers cAMP responsiveness through binding to specific sequences. Purified CREB bound to the β_2AR cAMP response element (CRE) in gel-mobility shift assays with an affinity identical to that for the CRE from the human glycoprotein hormone α-subunit gene, and failed to bind to mutated elements.

These results demonstrate an autoregulatory mechanism by which a receptor (β_2AR) stimulatory for adenylyl cyclase exerts positive feedback regulation on its own expression.

THE ENDOGENOUS NEUROPEPTIDE PEC-60 REDUCES THE AFFINITY OF DOPAMINE D-2 AGONIST BINDING SITES IN RAT NEOSTRIATAL MEMBRANES G. von Euler, S. Ferré*, V. Mutt[1] and K. Fuxe Depts. of Histology and Neurobiology, and [1]Biochemistry, Karolinska Institutet., Box 60400, S-10401 Stockholm, Sweden

Recently, immunoreactivity towards a PEC-60 (peptide with N-terminal glutamic acid, C-terminal cysteine and a total of 60 resudues) antiserum has been demonstrated in all catecholaminergic neurons in the rat brain including dopaminergic nerve terminals in the neostriatum. In order to investigate possible interactions with dopamine D-2 receptors, the effects of PEC-60 were analyzed in vitro on S(-)[N-propyl-^{3}H(N)]-propylnorapomorphine ([^{3}H]NPA; a D-2 agonist in vitro) binding in crude membrane preparations of the rat neostriatum.

PEC-60 was found to produce a concentration-related increase in the K_D value of [^{3}H]NPA binding in rat neostriatal membranes with a maximal increase of 34±18 % at 10-100 nM of PEC-60 (basal K_D values of [^{3}H]NPA binding were 226±15 pM). The number of binding sites were not affected by PEC-60 at these concentrations.

These results indicate the presence of functional PEC-60 receptors in the neostriatum that interacts with dopamine D-2 receptors within the plasma membrane. The present findings may be of relevance for the understanding of D-2 receptor regulation and of D-2 related diseases such as schizophrenia.

DIFFERENTIAL REGULATION OF [^{3}H] (+)-3-PPP AND [^{3}H] DTG LABELED SIGMA BINDING SITES IN GUINEA PIG BRAIN MEMBRANES BY SUBCHRONIC HALOPERIDOL ADMINISTRATION. W. Karbon and K. Naper*. Nova Pharmaceutical Corporation, Baltimore, MD 21224-2788.

A previous study (Naper, K. et al., *Neurosci. Abstr.*, 1989, 1236) indicated that [^{3}H] (+)-3-PPP and [^{3}H] DTG label pharmacologically distinct sigma binding sites in guinea pig brain membranes, suggesting that these sites might be differentially regulated in vivo. To test this hypothesis, male Hartley guinea pigs were treated for 14 consecutive days with either vehicle or the sigma agent haloperidol (1 mg/kg, i.p.), sacrificed 4 days after the final drug treatment, and brain membranes prepared and assayed for [^{3}H] (+)-3-PPP and [^{3}H] DTG binding. Whereas haloperidol treatment caused a 70% decrease in [^{3}H] (+)-3-PPP binding, only a 15% reduction in [^{3}H] DTG binding was observed. The decrease in [^{3}H] (+)-3-PPP binding most likely reflects a B_{max} change since the affinity of the remaining sites for (+)-3-PPP was unaffected by drug treatment. A significant reduction in [^{3}H] (+)-3-PPP binding, but not [^{3}H] DTG binding, was seen in membranes prepared from guinea pigs sacrificed 28 days after the final drug treatment. 14 day administration of chlorpromazine (30 mg/kg, i.p.) or clozapine (20 mg/kg, i.p.) did not affect sigma binding. These results suggest that [^{3}H] (+)-3-PPP and [^{3}H] DTG labeled binding sites can be differentially regulated in vivo by subchronic haloperidol treatment, an effect which may contribute to the therapeutic efficacy of haloperidol. Furthermore, the findings suggest that haloperidol may not function as a sigma "antagonist" in vivo, since receptor down-regulation is most commonly observed in response to prolonged agonist exposure.

REGULATION OF TYPE II GLUCOCORTICOID RECEPTOR-LIKE IMMUNOREACTIVITY IN A SUBGROUP OF RAT BRAIN TEL- AND DIENCEPHALIC NEURONS. R.S. Ahima and R.E. Harlan. Dept. of Anatomy, Tulane Univ. Sch. Med., New Orleans, LA 70112.

The rat central nervous system has been mapped for Type II glucocorticoid receptor-like immunoreactivity using monoclonal antibodies. In non-adrenalectomized rats, neuronal immunoreactivity is predominantly nuclear. In most neurons, adrenalectomy abolishes nuclear immunoreactivity and reduces numbers of immunoreactive neurons, while treatment with glucocorticoids increases the intensity of nuclear immunoreactivity as well as numbers of immunoreactive neurons.

Using BUGR2, a monoclonal antibody against the rat liver glucocorticoid receptor, we have localized a subgroup of neurons in CA1 and CA2 of the hippocampus, caudate-putamen, globus pallidus and habenula which show a different pattern of immunoreactivity. Adrenalectomy confers immunoreactivity, while treatment with corticosterone or aldosterone abolishes immunoreactivity. Thus, alterations in intracellular localization of type II glucocorticoid receptor immunoreactivity following adrenal cortical steroid manipulations are dependent on the neuronal type in the brain.

CHRONIC NALTREXONE TREATMENT INCREASES PREPROENKEPHALIN GENE TRANSCRIPTION. R.S. Roginski, C.M. Knapp and R.S. Zukin. Dept. Neuroscience, Albert Einstein College of Medicine, Bronx, NY 10461.

Long-term blockade of brain opioid receptors by the opiate antagonist naltrexone increases preproenkephalin (PPE) and preprotachykinin (PPT) mRNA in the striatum (Tempel, A., Kessler, J. and Zukin, R.S., *J. Neurosci.*, 10:241-247, 1990). To determine whether transcription of these genes is enhanced, we examined the *in vitro* incorporation of ^{32}P-ribonucleotide triphosphates into nascent RNA in nuclei isolated from rat striatum. Nuclei were isolated from striata of naltrexone-treated or control rats (tissue from 3 brains per treatment group was pooled) and were pulse-labeled with α-^{32}P-UTP for 20 min. Transcription products were quantitated by hybridization on nitrocellulose filters to the cDNAs encoding PPE, PPT, cyclophilin (1B15, a constitutive mRNA) and pSP64 (as the vector control). Autoradiograms were analyzed by computerized densitometry and values for PPE, PPT, 1B15 and pSP64 were determined. Transcription of the PPE and PPT genes were increased by about 128% and 74%, respectively, in the naltrexone group relative to the control group. Since naltrexone increases PPE mRNA 11-fold and PPT mRNA 6-fold, we conclude that a combination of transcriptional and post-transcription processes accounts for the observed upregulation of PPE and PPT gene expression. Moreover, these data support a role for opioid systems in the regulation of PPT gene expression.

TOWARDS A MODEL OF GERSTMANN-STRÄUSSLER-SCHEINKER SYNDROME IN TRANSGENIC MICE. K. Hsiao*, M.Scott*, D. Foster*, S. J. DeArmond and S. B. Prusiner. Depts. of Neurology, Neuropath., Biochem. and Biophys., Univ. of California, San Francisco, CA 94143.

Gerstmann-Sträussler-Scheinker syndrome (GSS) is an autosomal dominantly inherited human neurodegenerative disease that can be transmitted to non-human primates and rodents through intracerebral inoculation of brain homogenates from patients. Recent studies of GSS demonstrated significant genetic linkage between GSS and a leucine substitution at codon 102 of the human prion protein (PrP) gene (Hsiao, K., et al., *Nature*, 338:342-345, 1989). A founder transgenic mouse, line Tg 174, containing a murine PrP gene with a leucine substitution at codon 101 (homologous to codon 102 in humans) was well until 33 weeks of age when it became lethargic, ataxic, rigid, and paraparetic, rapidly deteriorating over 3 days. The brain of founder Tg 174 showed diffuse spongiform changes and proteinase K-resistant protein reactive with PrP antiserum. Transmission studies of founder Tg 174 brain homogenate to mice are in progress. Two progeny of the Tg 174 founder are well at 19 weeks. Two other founder transgenic mice containing the same PrP gene construct are well at 20 and 26 weeks. If additional Tg mice expressing this PrP mutation develop spontaneous CNS disease, then our results will argue that the clinical and pathological features of GSS may be reproduced in a Tg mouse paradigm. Successful horizontal transmission of disease from Tg 174 would impose new constraints upon models of prion structure.

GENE TRANSFER OF LACZ TO CNS NEURONS IN ADULT RATS USING REPLICATION-DEFICIENT HERPES VIRUS VECTORS. X.O. Breakefield, E.A. Chiocca, B.B. Choi, W. Cai, N.A. DeLuca, P.A. Schaffer, M. DiFiglia and R.L. Martuza. Depts. of Neurology and Neurosurgery, Mass. General Hosp.; Dana-Farber Cancer Inst.; Neuroscience Prog. and Dept. of Microbiology and Mol. Genetics, Harvard Med. Sch., Boston, MA., 02115.

Our group is developing herpes simplex virus type 1 (HSV-1)-derived vectors that can deliver genes into neurons in the brain without marked toxicity. Three mutant viruses have been tested which possess E. coli lacZ substitutions in the genes encoding the immediate early viral proteins, ICPO and ICP4, and the early protein, thymidine kinase (TK). In all cases lacZ is under viral promoters active early in infection. These mutants are compromised or defective in their ability to replicate, although they can still enter latency. [The TK mutant, RH105, was kindly provided by Drs. D. Ho and E. Mocarski (Stanford Univ.)]. Direct intracerebral inoculation of these vectors (200,000 pfu) into the caudate nucleus and frontal cortex proved relatively nonpathogenic over a 2-4 week period, whereas injection of wild-type KOS virus produced seizures and death within 6 days. The ICPO mutant yielded ß-galactosidase expression in a substantial number of neurons and glia around the inoculation site and at some distance from it for up to 14 days, with evidence of retrograde transport. Inoculations of the ICP4 and TK vectors produced only a few labelled cells in areas immediately adjacent to the injection tract over a few days.

469.3

CIRCLING BEHAVIOR EXHIBITED BY A TRANSGENIC INSERTIONAL MUTANT. A.K.Ratty[a], L.W.Fitzgerald[b], M.Titeler[b], S.D.Glick[b], J.J.Mullins[a*] and K.W.Gross[a]. [a]Dept. of Molecular & Cellular Biology, Roswell Park Cancer Institute, Buffalo, NY 14263, [b]Dept. of Pharmacology & Toxicology, Albany Medical College, Albany, NY 12208.

During the course of making transgenic mice, we found an insertional mutant that expressed an abnormal circling behavior. Mice homozygous for the transgene insertion expressed the circling phenotype, while heterozygous mice did not. The inheritance of the phenotype was consistent with an autosomal recessive made at a single locus. We found that the dopamine D_2 receptor binding sites in pooled striata (both sides combined) of the circling mice were significantly elevated by about 31% compared to striata of normal heterozygous transgenic mice. We found no changes in the levels of several neurotransmitters (dopamine, serotonin, norepinephrine) and their metabolites (dihydroxyphenylacetic acid, homovanillic acid, 5-hydroxyindoleacetic acid) in the striata, nucleus accumbens, frontal cortex and hypothalamus of mutants compared to heterozygous mice. We also did not find evidence of any hearing loss or inner ear deformities or degeneration in our insertional mutant. A DNA fragment from the host genome flanking the 3' end of the integrated transgene was found to map to mouse chromosome 16 by analysis of the strain distribution patterns of RFLPs in recombinant inbred strains. The transgene integration in the TgX15 mouse line disrupted an endogenetic locus affecting motor function. This is the first instance in which insertional mutagenesis has resulted in a well-characterized behavioral abnormality.

PROFILE OF MESENCEPHALIC DOPAMINE NEURON LOSS IN WEAVER MUTANT MICE DURING LIFE-SPAN. B. Ghetti and L.C. Triarhou. Department of Pathology (Neuropathology) & Program in Medical Neurobiology, Indiana University School of Medicine, Indianapolis, IN 46202

Weaver mutant mice (wv/wv) live up to 24-30 months on the B6CBA-A^{w-J}/A hybrid stock; loss of midbrain dopamine (DA) neurons by P20 and P90 is part of their phenotype (Exp. Brain Res. 70: 256-265, 1988). In the present study we (1) investigated whether midbrain DA cell loss occurs in wild-type (+/+) B6CBA-A^{w-J}/A mice with age, and (2) extended the information on DA cell loss in weaver mutants by obtaining a profile throughout their life-span. Counts of TyrOHase immunoreactive neurons did not reveal loss in any of the mesencephalic DA cell groups (A8, A9, A10) of +/+ animals at 18 (n=2) or 30 (n=2) months. The average number of neurons (± SEM) from +/+ mice of all ages (n=10) was 1270 ± 42 DA cells in A8, 3951 ± 292 in A9 and 3786 ± 126 in A10. Weaver mutants were studied at 20 days (n=3), 3 (n=3), 12 (n=3), 18 (n=1), and 24 (n=3) months. During the first year of life, the maximum loss, amounting to 50% in A8, 70% in A9 and 20% in A10, is already observed at 3 months. At 2 years of age, losses are severer and amount to about 60% in A8, 85% in A9 and 35% in A10. These findings indicate that there is a second wave of DA cell loss in weaver mice, taking place in an older age but at a slower rate; it remains to be established whether such a loss represents an accelerated form of aging of genetically susceptible neurons or an effect of the mutation irrespective of aging phenomena. (Supported by PHS RO1-NS14426).

DOPAMINE CONTENT, TYROSINE HYDROXYLASE ACTIVITY, AND DOPAMINE UPTAKE IN THE STRIATUM OF THE WEAVER MUTANT MOUSE. E.H. Stotz, J.R. Simon, B. Ghetti. Prog. Med. Neurobiol., Indiana Univ. Sch. of Med., Indpls., IN 46202.

Compared to normal (+/+) mice, the weaver mutant mouse (wv/wv) has decreased dopaminergic input to the striatum from the substantia nigra (SN). In 5 pairs of 3 month old +/+ and wv/wv mice, dopamine (DA) levels and tyrosine hydroxylase (TH) activity were determined by HPLC-EC, and DA uptake was measured in sucrose homogenates from the same striatal samples. DA levels and TH activity in the wv/wv mice were decreased approximately 60% relative to +/+ controls. Striatal DA uptake in the wv/wv was decreased by 95%, thus being more severely affected than either DA content or enzyme activity. The present neurochemical data on DA content and TH activity are in agreement with previous morphological data on cell loss in the SN. Since DA uptake is more severely affected than the aforementioned parameters, it appears that the remaining DA neurons in the wv/wv striatum are functionally inadequate.

Kinetic analyses of TH was carried out in other mice and indicated that the wv/wv enzyme had a higher Km and a lower Vmax than control. While neither the changes in Km nor Vmax alone seem to account for the observed reduction in TH activity in the wv/wv, such reductions may be attributed to the combined kinetic shifts. (RO1 NS 14426)

ALTERED DEVELOPMENTAL AND TISSUE SPECIFIC REGULATION OF GENE EXPRESSION IN MOUSE TRISOMY 16, A MODEL OF DOWN SYNDROME. D. M. Holtzman, R. M. Bayney*, C. N. Berger*, C. J. Epstein*, and W. C. Mobley. Depts. of Neurology, Pediatrics, and Biochemistry, UCSF, San Francisco, CA 94143; Molecular Therapeutics Inc., West Haven, CT 06516

Our goal is to understand better how mammalian aneuploidy affects gene expression. Mouse trisomy 16 (Ts 16), an animal model for Down syndrome, provides an opportunity to study the regulation of gene expression in cells with a 50% increase in normal gene dosage. We have examined expression of the gene encoding the amyloid precursor protein (APP), located on mouse chromosome 16 and human chromosome 21, in the brain and other organs of fetal Ts 16 mice and adult Ts 16/2N chimeras. Although a 1.5 fold increase in APP mRNA levels per trisomic cell might be expected, there are examples in human Ts 21 and mouse Ts16 of greater increases in brain. APP has 3 RNA transcripts which code for proteins 770, 751, and 695 amino acids in length. We used northern blot analysis and the polymerase chain reaction to quantitate total APP mRNA as well as the mRNA transcripts encoding APP 695, 751 and 770. In all organs examined, total APP mRNA expression was increased by at least 2 fold in Ts 16 versus controls; however, the increases were both developmentally regulated and tissue dependent. APP 695 mRNA was found in very low levels in normal fetal lung whereas this transcript was of greater or equal abundance than both other APP transcripts in Ts 16 fetal lung. All 3 APP transcripts were increased 2 fold in fetal Ts 16 whole brain versus control littermates. Interestingly, adult Ts 16/2N chimera brain, which was 40-50% Ts 16, showed approximately a 5 fold increase in all APP transcripts versus controls. This increase is 9 times more than expected if a strict gene dosage effect were operative as has been observed for other loci. Although the mechanism of these changes is unclear, our results with this gene suggest that an increase in gene dosage may initiate a complex change in gene expression which is tissue specific, developmentally regulated, and likely to be important in the pathogenesis of a number of abnormalities found in the nervous system and other organs in aneuploid conditions.

^{99m}TECHNETIUM AUTORADIOGRAPHIC ANALYSIS OF BRAIN LESIONS IN T-CELL RECEPTOR TRANSGENIC AUTOIMMUNE MICE.

JM Mountz, JD Mountz*, PS Sherman*, PE McKeever, JM Rowe*. Univ. of Michigan, Ann Arbor, MI 48109 and Univ. of Alabama, Birmingham, AL.

We have established that MRL-*lpr/lpr* (MRL-*l*) systemic lupus erythematosis (SLE) mice show multiple regions of decreased tracer uptake in the central nervous system (CNS) on ^{99m}Tc Hexamethylpropyleneamine Oxime(HMPAO) autoradiography which can be attributed to loss of blood brain barrier (BBB) integrity. These autoradiographic defects are not seen in MRL+/+ normal controls. The histopathologic nature of these defects are unlike other organ specific lesions in that they do not show characteristic perivascular cuffing, and thus may be mediated by autoantibody production. To determine if auto-reactive T cells were involved, experiments utilizing MRL-*l* mice backcrossed to T-cell receptor (TCR) transgenic (TR) mice were performed. In TCR-TR mice, most thymocytes are reactive with H-2D^{b} and the male H-Y antigen. The mouse brains were prepared for autoradiography after an I.V. injection of ~4 mCi of ^{99m}Tc HMPAO in 0.1 ml of sterile saline. These and other brains were also stained with hematoxylin and eosin. Serial 20 micron thick sections showed no identifiable characteristic defects in the TCR-TR MRL-*l* mice as was observed in non TR MRL-*l* mice. Using the horseradish peroxidase (HRP) method to evaluate BBB integrity, there was no evidence of parenchymal infiltration of HRP as seen in MRL-*l* mice. In conclusion, the presence of the T-cell receptor transgene eliminated the characteristic defects seen in MRL-*l* mice. This suggest that a normal T-cell receptor repertoire is necessary for development of the lesions, but direct interaction of T cells with the brain might not be required. We propose a two step model for development of the CNS defects: 1) antigen specific T cell autoreactivity with endothelial antigens distant from but cross reactive with BBB endothelium and 2) the production of autoantibodies which cross react with BBB endothelium. This model supports the use of medical therapy that enhances BBB integrity rather that those that suppress direct lymphocyte mediated tissue inflammation in the treatment of CNS disease of SLE.

COMPLEX NEURAL SYSTEMS AND BEHAVIORS: A NOVEL STRATEGY FOR THEIR GENETIC DISSECTION.

C. Vadasz[1,2], I.Laszlovszky[1], P.Kabai[1*], M.Sasvari[1*], I.Sziraki[1*], I. Vadasz[1*], A.Lajtha[1,2]. [1]Neurochem. Div., N.S.Kline Inst. for Psychiatric Res.,Orangeburg,N.Y.,10962 & [2]Dept. of Psychiatry, New York University Medical Center, 550 First Avenue, New York, N.Y. 10016

Most aspects of brain function are complex and genetically variable. To eliminate major obstacles in the genetic analysis of catecholamine neurotransmitter mechanisms, we initiated a study to transfer genes that influence the activity of mesencephalic tyrosine hydroxylase (TH/MES), the rate limiting enzyme in catecholamine biosynthesis, to the same genetic background. The transfer of genes was carried out by backcross-intercross cycles with concomitant selection for TH/MES. We have succesfully completed five cycles establishing replicated high (B6.C alpha and beta) and low (B6.I alpha and beta) genetically standardized stocks. The B6.C and B6.I populations evince a highly significant difference in TH/MES, while at cycle M_5 the probability of incrosses at any nonlinked, nonselected locus is 0.948. Development of sets of congenic recombinant inbred, neurological animal model lines with different mesencephalic dopamine systems provides an analytical tool for mechanism-oriented experimentation.

SYNAPTOSOME UPTAKE OF [3H] NOREPINEPHRINE, [3H] DOPAMINE and [3H] SEROTONIN IN CANINE NARCOLEPSY

Delphine Valtier, William C Dement and Emmanuel Mignot*. Sleep Research Center, Stanford University School of Medicine, Palo Alto CA 94304 (USA).

Canine narcolepsy, a model of the human REM sleep disorder, is associated with altered catecholamine metabolisms in various brain areas. A possible explanation for these global changes could be the existence of specific defects in monoamine uptake processes. In order to investigate this hypothesis, we have studied the uptake of [^{3}H] norepinephrine (NE), [^{3}H] dopamine (DA) and [^{3}H] serotonin (5-HT) in synaptosomes prepared from slowly frozen brain cortical tissues (Dodd, Neurochem Path 4: 177-198.1986) in six narcoleptic (N) and six control (C) doberman pinshers (age and sex matched). The effect of the freezing protocol has been tested and no differences were found between fresh and frozen maximal velocity (Vmax) or affinity (Km) for the transporter. All subsequent experiments were then carried out using frozen tissues. Significant uptake processes for [^{3}H] NE, [^{3}H] DA and [^{3}H] 5-HT were found in all control and narcoleptic dog cortical brain samples studied. No signiticative differences in Vmax or Km were observed between narcoleptic and control animals. Noticably, [^{3}H] Norepinephrine Vmax and Km were found to be higher in both fresh and frozen samples of the control dogs. Further animals will be studied to confirm this observation and the same protocol will be applied to the amygdala, a structure were monoaminegic abnormalities have been well characterized in narcoleptic dogs. Research supported by NS 23724-03.

NEW INBRED RAT STRAINS: WK-HT WITH GENETIC HYPERTENSION, AND WK-HA WITH GENETIC HYPERACTIVITY.

E.D.Hendley and W.G.Ohlsson*. Univ. of Vermont, Burlington VT, 05405.

The spontaneously hypertensive rat (SHR), and normotensive, Wistar-Kyoto (WKY) controls,are widely employed in studies of essential human hypertension. SHR are also behaviorally hyperactive, and this led us to use genetic means to separate the hyperactivity trait from the hypertensive trait a decade ago. We recombined the genes of SHR and WKY by crossbreeding, then selected brother/sister pairs in the F2 and successive generations to produce two new strains, now nearly fully homozygous. WK-HTs are hypertensive but normoactive, and WK-HAs are hyperactive but normotensive. Since SHR have both traits and WKY have neither, we use all four inbred strains to seek correlations of biological differences with one or the other of both traits. Longitudinal studies revealed that hypertension persists throughout at least two years in SHR and WK-HTs, and similarly, hyperactivity persists in SHR and WK-HAs for at least two years. Studies in the four strains also revealed that not all behaviors of the SHR are present in WK-HAs, and not all cardiovascular changes in SHR are associated with hypertension. We suggest that WK-HTs are an improvement over the SHR as a model of hypertension, and that WK-HAs provide a unique animal model of hyperactivity. Supported by NIH RO1-NS26390, and NSF R11-860679.

GENES THAT CAN MUTATE TO INDUCE NEURONAL DEGENERATION IN *C. ELEGANS*.

M. Driscoll* and M. Chalfie. Dept. of Biological Sciences, Columbia University, New York, NY 10027

Rare dominant alleles of two genes, *mec-4* and *deg-1*, produce abnormal, toxic products that result in the vacuolar degeneration of small groups of neurons in the nematode *Caenorhabditis elegans*. Three dominant alleles of *mec-4* induce degeneration of six touch receptor neurons. In order to understand the molecular causes of degeneration, the *mec-4* gene has been cloned and sequenced. *mec-4* appears to be a membrane protein that does not show extensive homology with current GenBank entries. The amino acid changes in the degeneration-inducing *mec-4* variants have been determined. Studies of the molecular requirements for degeneration will be discussed.

The *mec-4* gene and the *deg-1* gene are members of a *C. elegans* gene family. Molecular analysis has demonstrated that the encoded proteins are 50% identical over a large portion of their legnths. We call the proteins encoded by this family of genes "degenerins". Homology relationships among degenerins will be discussed.

CELLULAR LOCALIZATION OF 5-HT$_{1A}$ RECEPTOR mRNA IN THE RAT BRAIN. J.M.Palacios, M.Pompeiano* and G.Mengod. Preclinical Research, Sandoz Pharma Ltd., CH-4002 Basel.

Different oligonucleotides from the coding region of the rat 5-HT$_{1A}$ receptor gene were used to examine the distribution of cells containing transcripts for this receptor in the rat brain by using in situ hybridization histochemistry. The specificity of the hybridization signals was verified in control experiments and Northern analysis. The results obtained revealed that the presence of transcripts was abundant in the hippocampus, lower in the midbrain and cortex, and absent in the cerebellum. The highest levels of hybridization signal were seen in the hippocampus, entorhinal cortex, septum, nucleus of the vertical limb of the diagonal band, interpeduncular nucleus, all raphe nuclei, ventral nucleus of the lateral lemniscus, olfactory bulb and cerebral cortex. This distribution was in very good agreement with that of receptor binding sites labeled with [^{3}H]8-OH-DPAT. These results demonstrate that different neuronal populations express the 5HT$_{1A}$ receptor mRNA. They also suggest that the same gene codes for presynaptic autoreceptors in the raphe, presynaptic heteroreceptors in the cholinergic cells of the septum and postsynaptic receptors in the hippocampus.

IN VIVO STUDIES OF σ RECEPTORS WITH RADIOLABELED HALOPERIDOL DF Wong, R Gibson†*, ED London, HD Burns†*, E Shaya*, RF Dannals*, HT Ravert*, AA Wilson*, HN Wagner Jr.* Johns Hopkins Medical Inst., Baltimore, MD 21205 and Merck (MSD Res. Labs) West Point PA† 19486.

We have assessed the use of [^{18}F]haloperidol (FHAL) for imaging and quantification of brain σ receptors in vivo. FHAL uptake in striatum (ST), cerebellum (Cb), and cortex (Cx) peaked at 30 min post-injection (~8% injected dose/g tissue); a slow dissociation was observed. Competition with IV d-pentazocine (d-PENT, 25 mg/kg) produced 15-30% inhibition in several brain regions. Studies with IV SKF 10,047 (d-NANM; 25 mg/kg) produced 23% inhibition in Cb. As FHAL binds to dopamine as well as σ-receptors, we tested the effect of spiperone on FHAL uptake in ST. Spiperone (0.5 mg/kg IP) inhibited FHAL binding by 27%. However, both d-PENT and d-NANM increased FHAL binding by 30-40%. These results suggest that d-PENT and d-NANM may decrease synoptic dopamine, which would compete with FHAL for D_2 dopamine receptor. We have confirmed these results using [^{3}H]haloperidol (HHAL). HHAL binding in ST increased 60-70% with d-PENT 5 mg/kg and d-NANM 25 mg/kg and declined by 57% in the presence of d-amphetamine 7 mg/kg.

These studies support development of radiolabeled haloperidol as an in vivo ligand for σ receptors, and support an action of σ ligands to decrease endogenous dopamine.

Supported in part by USPHS RO1 MH42821-01.

470.3

EXPRESSION OF THREE ALPHA-2 ADRENERGIC RECEPTOR SUBTYPES IN RAT TISSUES: IMPLICATIONS FOR ALPHA-2 RECEPTOR CLASSIFICATION. W. Lorenz*, J.W. Lomasney*, S. Collins*, A.L. Sylvia, M.G. Caron and R.J. Lefkowitz*, H.H.M.I. and Depts. of Medicine and Cell Biology, Duke University Medical Center, Durham, NC 27710.

Based on ligand binding studies in various tissues and species, evidence for several α_2-adrenergic receptor subtypes has accumulated. Currently the α_2-adrenergic receptors are classified exclusively by pharmacological criteria. The molecular cloning of three distinct genes for human α_2-adrenergic receptors confirmed the demand for multiple α_2-adrenergic receptor subtypes. According to their localization on human chromosomes the genes were termed α_2-C10, α_2-C4, and α_2-C2. The relationship between the pharmacological classification of α_2-receptors and the isolated genes has yet to be clarified. Using northern blot hybridization we analyzed the expression of the three cloned α_2-adrenergic receptor genes in 13 rat tissues, and in cell lines previously described as model systems for pharmacologically defined α_2-adrenergic receptor subtypes. The α_2-C10 receptor corresponds to the α_{2A} subtype and is expressed in rat brainstem, cerebral cortex, hippocampus, pituitary gland, cerebellum, kidney, aorta, skeletal muscle, spleen and lung. Messenger RNA coding for the α_2-C4 receptor was detected only in brain regions, not in peripheral tissues, whereas the α_2-C2 message was found only in liver and kidney. Hybridization experiments with RNA from model systems which formed the basis for pharmacological α_2-receptor classification lead to the conclusion that the pharmacological subtype α_{2B} represents two distinct receptor molecules; the α_2-C4 and a subtype previously undetected by classical ligand binding approaches. Furthermore, our experiments suggest that the pharmacological subtype α_{2C} is an inter-species variation of α_2-C4 rather than a separate subtype. Finally, the α_{2B}-like receptor α_2-C2 was found not to be covered by the current pharmacological classification.

AUTORADIOGRAPHIC LOCALIZATION OF PUTATIVE SIGMA RECEPTORS IN THE PRIMATE AND HUMAN BRAIN. A.E. Ciarleglio and D. C. Mash, Departments of Neurology and Pharmacology, University of Miami School of Medicine, Miami, FL. 33101

Sigma receptors are the current target for antipsychotic drug development. Novel antipsychotic agents which possess selective and high affinity for the putative sigma binding site have demonstrated beneficial effects in schizophrenic patients in recent clinical trials. These agents may serve as an alternative to the principal neuroleptic drugs currently in clinical use which mediate extrapyramidal side effects and dyskinesias through their blockade of dopamine receptors. We have used *in vitro* autoradiography to localize putative sigma receptors labelled with (+)-[^{3}H]-3-(3-hydroxyphenyl)-*N*-(1-propyl) piperidine ([^{3}H]-PPP) in the primate and human brain. The binding characteristics of [^{3}H]-PPP in the primate brain were comparable to those previously described in the rodent. Saturation analysis demonstrated a single class of sites in cerebellar and hippocampal membranes (K_D = 10-20 nM). Computer-assisted densitometry demonstrated that all paralimbic and limbic regions including the amygdala, hippocampus, orbitofrontal, cingulate, insular, and temporopolar areas displayed peak densities of [3H]-PPP binding. Moderate labelling of sigma receptors was seen throughout the hypothalamus. A striking enrichment of binding was apparent over the suprachiasmatic and supraoptic nuclei. Moderate to low levels of sigma binding sites were observed over the ventromedial soctors of the caudate and the putamen. Within the brainstem, sigma receptors were elevated over the cerebellar vermis. Taken together, these observations suggest an association of sigma receptors with the limbic system. The targeting of novel sigma-selective agents to limbic brain areas may explain, in part, the beneficial effects of these drugs in schizophrenia. Supported by DA06227.

PARTIAL OVERLAP IN THE DISTRIBUTION OF MONOAMINE OXIDASE TYPE A (MAO-A) AND SIGMA RECEPTORS IN RAT AND MOUSE BRAIN. M. Basile, D. C. Mash, and Y. Itzhak, Depts. Neurology, Pharmacology, Biochemistry and Molecular Biology, University of Miami School of Medicine, Miami, FL. 33101.

Biogenic amines are metabolized by monoamine oxidase. Selective inhibitors of MAO type A (i.e., clorgyline) exhibit high affinity for sigma binding sites (Eur. J. Pharmacol. 176: 107, 1990). The present study was undertaken to examine the distribution patterns for [^{3}H]-MPTP binding to MAO-A and [^{3}H]-3-PPP binding to putative sigma receptors. MAO-A sites were labelled in rat and mouse brain with [^{3}H]-MPTP in the presence of sufficient deprenyl to occlude [^{3}H]-MPTP binding to MAO-B. Adjacent, slide mounted sections were labelled with 8 nM (+) [^{3}H]-3-PPP to visualize putative sigma receptors. Sigma receptor densities were elevated in the superficial layers of the cerebral cortex, the dentate gyrus of the hippocampus, the hypothalamus, the locus coeruleus and the cerebellum. Moderate [^{3}H]-3-PPP binding was observed in the caudate-putamen and in parts of the thalamus. [^{3}H]-MPTP binding sites associated with MAO-A were dense in the ventral sector of the striatum, the dentate gyrus of the hippocampus, the hypothalamus and the locus coeruleus. Very low levels of [^{3}H]-MPTP binding were detected over the cerebellum and cerebral cortex. These observations demonstrate a partial overlap in the distribution of MAO-A and sigma binding sites. Taken together, the in vitro binding and autoradiographic studies provide support for the possible existence of sigma receptor subtypes. One subtype of sigma binding site may be associated with the enzyme, MAO-A. Supported by a grant from the NPF, Miami, FL. 33101.

MUSCARINIC BINDING SITES IN THE DORSOMEDIAL MEDULLA: AUTORADIOGRAPHIC AND BIOCHEMICAL STUDIES. P. Ernsberger, Depts. of Medicine & Neuroscience, Case Western Reserve Univ. School of Medicine, Cleveland, OH 44106.

Structures in the dorsomedial medulla (DMM) mediate cardiorespiratory control. Muscarinic receptors participate in central autonomic regulation. In this study, muscarinic receptors labeled with [^{3}H]QNB were characterized in rat brain sections and cow DMM membranes. Quantitative image analysis of autoradiograms from rat medulla sections (15 μm) labeled with [^{3}H]QNB (1 nM in Krebs', 60 min at 22°C) revealed that muscarinic binding (fmol/mg tissue, mean±SE of 15-66 determinations) was heterogeneously distributed in the hypoglossal complex (*m*: 316±8, *vl*: 267±4, *d*: 299±3, *n Rotter*: 101±4) and the NTS region (*vl*: 136±3, *v*: 126±3, *m*: 142±4, *dmnv*: 290±6, *dl*: 140±3, *ni*: 122±4, *nI*: 149±3, *AP*: 52±3, *C2 area*: 147±6, *n parasolitarius*: 89±3). Outside the DMM, muscarinic binding was abundant in the bed nucleus of the transtegmental tract (112±2) but not the parapyramidal area (54±2). Membrane binding assays with cow DMM showed a high density (B_{max} = 231±10 fmol/mg protein) of high-affinity (K_d = 0.46±0.05 nM) [^{3}H]QNB binding sites. Muscarinic antagonists competed for [^{3}H]QNB binding with the following order of potency (K_i in nM): scopolamine (1.6±0.3) > 4-DAMP (2.9±0.3) > atropine (5.1±0.7) >> pirenzepine (110±6) = methoctramine (129±9), a profile consisitent with the M3 subtype. Hill slopes were close to one, indicating a single population of sites. For agonists, the order of potency was: oxotremorine (102±8) > pilocarpine (1100±120) > methacholine (8100±830) > McN-A-343 (16,000±1700), also consistent with the M3 subtype. In DMM, muscarinic binding sites are present in structures with cardiorespiratory function and appear to be exclusively of the M3 subtype.

PHOSPHOINOSITIDE TURNOVER: AUTORADIOGRAPHIC IMAGING IN THE BRAIN DIFFERENTIATES GLUTAMATERGIC AND CHOLINERGIC SYNAPTIC RESPONSES. P.M. Hwang, D.S. Bredt and S.H. Snyder. Johns Hopkins Univ. Sch. of Med., Dept. of Neurosci. Baltimore, MD 21205

The phosphoinositide (PI) second messenger system mediates numerous neurotransmitter effects in the brain, which, with some exceptions, have not been readily assigned to specific cellular sites. Localization of neurotransmitter synaptic responses in the brain has been explored by autoradiographic mapping of receptor binding sites, but these sites sometimes do not reflect known synaptic input. Ideally, one would like to image functional, second messenger responses to neurotransmitters at specific loci in the brain. However, monitoring the generation of [^{3}H]inositol phosphates in response to neurotransmitter agonists is not compatible with anatomical localization. Recently, Godfrey (Biochem. J. (1989) 258, 621) measured PI turnover in brain slices with [^{3}H]cytidine as a precursor. In this technique the generation of [^{3}H]cytidine diphosphate diacylglycerol ([^{3}H]CDP-DAG) reflects PI turnover. Since CDP-DAG is membrane bound, we attempted to localize [^{3}H]CDP-DAG by autoradiography, rinsing away water soluble metabolites. Using [^{3}H]cytidine as a precursor, we report discrete localizations of phosphoinositide turnover in brain slices and peripheral tissue by selective autoradiography of [^{3}H]CDP-DAG.

470.8

AUTORADIOGRAPHIC LOCALIZATION OF FLUNITRAZEPAM BINDING SITES IN DIAZEPAM-SENSITIVE AND -RESISTANT MICE. E.J. Gallaher, S.E. Gionet*, J.K.Belknap. VA Medical Center and Depts. of Pharmacology and Medical Psychology, Oregon Health Sciences Univ., Portland, OR 97201.

Diazepam-sensitive (DS) and -resistant (DR) mice were developed by selective breeding based on the duration of impairment on the rotarod following a standard dose of diazepam. Initial studies of [3H]-flunitrazepam (FLU) binding failed to indicate differences between DS and DR mice in either whole brain or in dissected brain areas (hippocampus, cortex, cerebellum). However, significant differences in small anatomical areas would not be observed using this method. We therefore initiated an autoradiographic study to survey the density and location of various GABA-benzodiazepine receptor ligands throughout the mouse brain. In the current study we report the distribution of [3H]-FLU binding throughout the brain of DS and DR mice.

Brains were sliced into16-micron sagittal frozen slices, thaw-mounted on slides, and stored frozen until incubation with ligand. Slices from paired DS and DR mice were incubated simultaneously with [3H]-FLU, and were then exposed to [3H]-sensitive film for seven days. Images were photographed with a video camera, digitized, stored on a hard disk drive, and analyzed with a MicroComp DS microdensitometry system. Brain areas were delineated and receptor densities were determined after subtraction of background density.

We quantified receptor density in whole brain, cerebellum, cortex, hippocampus, hypothalamus, thalamus, corpus striatum, superior and inferior colliculi, and substantia nigra. Our initial analyses suggest that differences between DS and DR mice are either small or insignificant, consistent with the earlier studies. These findings indicate that behavioral differences observed in DS and DR mice are not a result of differences in receptor number, suggesting that DS/DR behavior is a result of alterations in receptor subunit structure and function.

PERIPHERAL BENZODIAZEPINE RECEPTOR SITES IN HUMAN BRAIN GLIOMAS. M. Diksic, A. Takada and Y.L Yamamoto. Montreal Neurological Institute, McGill University, Montreal, CANADA, H3A 2B4

Peripheral benzodiazepine (PBZ) receptors have recently been shown to be abundant in brain tumors. It was also reported that antagonist which binds to the PBZ receptors can reduce the rate at which cells grow in the tissue culture from brain tumors proliferate.

Here we report measurements of the B_{max} and K_D on brain tumor surgical specimens. The measurements were done on six malignant gliomas (grade III and IV) and two low grade gliomas (grade II). The surgical specimens were cut into 15 μm thick slices, mounted on gelatine coated microscope glasses and incubated for 60 min in baths containing increasing concentrations of PK-11195 and constant amounts of [^{3}H]-labelled PK-11195. Non-specific binding was done in the bath with 1 μM of PK-11195. The kinetic experiments, both association and dissociation, were done at 1 nM. K_D estimates obtained from the kinetic and saturation measurements agreed well. In malignant brain gliomas we found only one receptor site, however, in the grade II astrocytomas both kinetic and saturation measurements showed the presence of two receptor sites. In malignant gliomas K_D and B_{max} were 7.1 $\pm$ 0.1 nM and 1.15 $\pm$ 0.16 nmol/g-brain, respectively. Two sites in grade II astrocytomas showed a K_D of 1.8 and 23.7 nM, with corresponding B_{max} of 0.1 and 2.1 nmol/g-brain. For the normal human cortex we found a K_D of 15 $\pm$ 2 nM and a B_{max} of 0.4 $\pm$ 0.1 nmol/g-brain. This work was supported by the USPHS grant NS-22230.

CHARACTERIZATION OF PAF-INDUCED ELEVATION OF CYTOSOLIC FREE CALCIUM LEVEL IN NEUROHYBRID NCB-20 CELLS. T.L.Yue*, M. Gleason* and G. Feuerstein, Dept. of Pharmacology, SmithKline Beecham, King of Prussia, PA 19406-0939

The effects of platelet-activating factor (PAF) on intracellular level of free Ca^{2+} ($[Ca^{2+}]_i$) were studied in neurohybrid NCB-20 cells. In fura-2-loaded NCB-20 cells, PAF induced immediate and concentration-dependent increase in $[Ca^{2+}]_i$ a maximum increase of 334$\pm$27nM Ca^{2+} (n=25). PAF-induced $[Ca^{2+}]_i$ mobilization was inhibited by PAF antagonist, BN50739, WEB2086, SRI63-441 and BN52021, with IC_{50} of 12, 38, 897 and 45000nM, respectively. Calcium channel blockers had no effect on PAF-induced increase in $[Ca^{2+}]_i$. Extracellular Ca^{2+}-depletion reduced a large fraction (70%) of PAF-induced increase in $[Ca^{2+}]_i$, suggesting the majority of $[Ca^{2+}]$ mobilization was originated from extracellular milieu; however, a small portion (30%) was originated from intracellular sources, which was inhibited by TMB-8. NCB-20 cells exhibited a homologous desensitization to sequential addition of PAF, but no heterologous desensitization between PAF and bradykinin or ATP was observed. These data suggested that PAF-induced neuronal receptor activation results in increased $[Ca^{2+}]_i$ via a non voltage calcium channel mechanism and intracellular Ca^{2+} release.

EFFECTS OF ANGIOTENSIN CONVERTING ENZYME INHIBITORS (CEI) ON BRAIN ANGIOTENSIN II (AII) BINDING. K.H. Berecek and B.H. Swords* Hypertension Res., Univ of Alabama, Birmingham, AL 35294

Brains and neuronal cells from SHR have an increased number of AII receptors in comparison to controls. In order to determine whether there was an alteration in AII binding in SHR after CEI, we compared ^{125}I AII binding in neuron-enriched primary cultures of whole brains from 1 day old SHR pups treated in utero with Captopril (CAP) vs control SHR (CON) pups and studied the effect of short term incubation of neuronal cells from CON and CAP SHR and normotensive rats (NR) with CAP or lisinopril (LIS). ^{125}I AII binding in neuronal cultures from CAP SHR was decreased when compared to cells from CON SHR. Scatchard analysis revealed no differences in Kd but Bmax was less in CAP SHR (7.5) than CON SHR (9.3 fmol/mg protein). Short term (24 h) incubation of cells with CAP or LIS (10^{-5}M) did not affect AII binding in neuronal cultures from NR. AII binding was decreased in SHR cells treated with CAP (CON SHR: Kd = 0.28 nM, Bmax 9.3 fmol/mg protein vs CON SHR + CAP: 0.3, 7.5) moreover, a significant decrease occurred by 1/2 h of incubation. AII binding was also decreased in SHR treated in utero with CAP (CAP SHR 0.32, 7.1; CAP SHR + CAP 0.29, 6.1) but to a lesser extent than CON SHR. These data suggest that CEI decrease ^{125}I AII binding in brain from SHR by competitive inhibition or receptor internalization and the AII receptor in SHR may be regulated differently from that of NR.

AUTORADIOGRAPHIC LOCALIZATION OF ANGIOTENSIN II RECEPTOR SUBTYPES IN THE RAT BRAIN. B.P. Rowe, K.L. Grove*, D.L. Saylor* and R.C. Speth. Dept. Physiology, Col. of Med., East Tennessee State Univ., Johnson City, TN 37614 and Dept. VCAPP, Washington State Univ., Pullman, WA 99164-6520.

Recent studies with new, selective angiotensin II (AII) antagonists have revealed AII receptor subtypes (Chiu et al, Biochem. Biophys. Res. Comm. 165: 196, 1989). Since these receptors can be discriminated by their binding sensitivity to sulfhydryl reducing agents, and our studies indicate that central AII receptors are influenced differentially by mercaptoethanol (M) in the rat (Rowe et al, FASEB J. 4: A600, 1990), we reasoned that central AII receptors occur as different subtypes also. We conducted competitive autoradiography experiments with the non-peptidic AII receptor subtype selective antagonist, DuP753 (gift from duPont). Rat brain sections were incubated with 240-270pM ^{125}I sar^1 ile^8 AII (^{125}I SIAII) alone, with AII (10^{-6}M), or with DuP753 (10^{-4} - 10^{-8} M). ^{125}I SIAII binding was displaced by 10^{-6}M DuP753 (designated AII_α receptor subtype) at some sites, but was unaffected by 10^{-4} M DuP753 at other sites (AII_β subtype). Based upon the selective competition with DuP753 we have categorized nuclei as having predominantly AII_α or AII_β subtypes as follows: AII_α: solitary tract nucleus (n), parabrachial n., anterior pituitary, para and periventricular hypothalamus, subfornical organ, organum vasculosum, and median eminence. AII_β: inferior olive, locus coeruleus, inferior and superior colliculus, most thalamic areas, and medial amygdala. ^{125}I SIAII binding is inhibited by M at AII_α sites but not AII_β sites. [Supported by Amer. Heart Assoc., Tenn. Affiliate and NIH (NS-24388)].

471.3

ANGIOTENSIN III AND P-AMINOPHENYLALANINE^6 ANGIOTENSIN II DISPLAY SELECTIVITY FOR BRAIN AII_β RECEPTOR SUBTYPE BINDING SITES. K.L. Grove, B.P. Rowe and R.C. Speth, Dept. of VCAPP, Washington State University, Pullman, WA 99164-6520 and Dept. Physiol., E. Tenn. State Univ. Johnson City, TN 37614

Competition binding studies with selective antagonists and differential effects of sulfhydryl reducing agents indicate subtypes of angiotensin II (AII) receptors: a DuP 753-sensitive site (AII_α) and a DuP 753-insensitive site (AII_β, see Rowe et al., this volume). Competition for the binding of ^{125}I-sarcosine^1, isoleucine^8 AII (^{125}I-SI AII, 300 pM) to 20 μ-thick rat brain sections by the selective AII_α antagonist (DuP 753, 5 x 10^{-7} M) was compared to that for the heptapeptide, angiotensin III (AIII, 100 nM) and p-aminophenylalanine^6 AII (pNH_2F AII, 1 μM) using quantitative densitometric analysis of autoradiograms. Both AIII and pNH_2F AII displaced ^{125}I-SI AII binding in brain regions where AII_β receptors predominate, e.g., septum, medial amygdala, thalamus, subthalamus, colliculi, locus coeruleus and inferior olive, but it was a poor competitor for ^{125}I-SI AII binding in brain regions where AII_α receptors predominate, e.g., circumventricular organs, median preoptic nucleus, hypothalamus, piriform cortex, solitary tract nucleus, vagal motor nucleus, spinal trigeminal tract. This indicates that agonists, including the endogenous peptide AIII, can distinguish brain region-specific AII receptor subtypes. Supported by NIH (NS24388) and Am. Heart Assn., TN affiliate. DuP 753 was a gift from Dr. Pieter Timmermans (Dupont).

COUPLING BETWEEN MITOCHONDRIAL BENZODIAZEPINE RECEPTORS AND HORMONE STIMULATED STEROIDOGENESIS. K.E. Krueger, A.G. Mukhin*, and V. Papadopoulos* Fidia-Georgetown Institute for the Neurosciences and Dept. of Anatomy & Cell Biology, Georgetown Univ. Med. Sch., Washington, D.C. 20007.

Our previous studies demonstrated that peripheral-type benzodiazepine receptors (PBR) regulate steroid synthesis by mediating cholesterol transport within mitochondria. In these studies we have used the ACTH-responsive Y-1 adrenocortical and the hCG-responsive MA-10 Leydig cell lines to examine the relationship between PBR and hormone-stimulated steroidogenesis. Most PBR ligands tested had no effect on steroidogenesis by ACTH or hCG, however, flunitrazepam, at submicromolar concentrations, inhibited steroid production induced by these hormones in Y-1 and MA-10 cells, respectively, or by 1 mM dibutyryl cyclic AMP. This inhibition by flunitrazepam was characterized by a decrease in the efficacies but not in the potencies of the hormones suggesting that this benzodiazepine affected a step following activation of the hormone receptors. Higher affinity PBR ligands such as PK 11195 and Ro5-4864, at concentrations which were 10-50 fold lower than those of flunitrazepam, blocked this inhibition. These findings support the possibility that hormone-stimulated steroidogenesis includes a mechanism involving the direct participation of PBR, for which flunitrazepam, a low intrinsic activity agonist, may act as an antagonist.

471.5

TWO PROLACTIN CELL SUBPOPULATIONS IN THE LACTATING RAT EXPRESS DIFFERENT SUBTYPES OF D2 RECEPTORS. L.A. Kukstas*, V. Hanin*[1], J. Demaille[1]*, C. Domec[2]*, J. Bonner[2]*, J.M. Israel*, and J.D. Vincent, INSERM U176, rue St. Saëns, Bordeaux 33077. [1] CRBM, CNRS, rte de Mende, Montpellier 34033. [2] IBCN, CNRS, rue St. Saëns, Bordeaux.

Dopamine (DA) the major prolactin (PRL) inhibiting factor has been shown to act by different mechanisms in the two subpopulations of PRL cells present in the adenohypophysis of the lactating rat (Israel *et al.* Neuroendocrinology 51 p113 1990). Since two subtypes of D2 DA receptors have been recently described (Monsma *et al* Nature 342, Dec 1988), their implication in this discrepancy has been investigated. Bidimensional electrophoresis of total cell phosphorylated proteins followed by autoradiography confirmed the presence of the D2 receptor in both subpopulations of PRL cells as expected from electrophysiological studies. An antibody was produced against a sequence of 18 amino acids within the D2 receptor sequence (Bunzow *et al* Nature 336 Dec 1989). This antibody was shown to recognise one of the two D2 subtypes. Western blots of proteins extracted from the two PRL cell subpopulations were analysed with this antibody, and the receptor was revealed for only one of them, suggesting that each of the two PRL cell subpopulations expresses a different D2 receptor subtype. Finally, the polymerase chain reaction (PCR) was applied to cDNA prepared from the two PRL cell subpopulations; the primers for the PCR were synthetic oligonucleotides (30 mer) complementary to sequences widely flanking the differentially expressed part of the D2 receptor. Electrophoresis of the reaction media after PCR showed the length of the amplified sequences from the two cell types to differ by approximately 100 nucleotides. This corresponds to the difference expected for the two D2 subtypes. These results strongly suggest that two subpopulations of lactotroph express two types of D2 receptor. As it is hypothesised that the two subtypes bind with different G proteins, these results could account for the distinct mechanisms brought into play by DA in the two subpopulations.

471.6

MELATONIN RECEPTORS ARE PRESENT IN THE FERRET PARS TUBERALIS AND PARS DISTALIS, BUT NOT IN BRAIN. D. R. Weaver and S. M. Reppert, Laboratory of Developmental Chronobiology, Children's Service, Massachusetts General Hospital & Harvard Medical School, Boston MA 02114.

The distribution of melatonin receptors varies widely among mammalian species. We continue to examine melatonin receptor distribution in photoperiodic species in an effort to identify conserved sites of melatonin action.

Three female ferret brains with pituitary attached were generously provided by Dr. K.D. Ryan, U Pittsburgh Med Sch. Coronal sections (20 micron) at 120 micron intervals throughout the brain were processed for autoradiographic localization of 2-125I-iodomelatonin (I-MEL) binding as previously described (J Neurosci 9: 2581-2590, 1989).

Specific binding of I-MEL (40 pM) was observed only in the pars tuberalis (PT) and pars distalis (PD) of the pituitary. The entire PT was intensely labeled. Specific binding also extended throughout the PD, at levels lower than in the PT. There was no specific labeling in brain.

The consistent presence of high-affinity melatonin receptors in the PT of all photoperiodic species examined so far suggests that the PT plays a major role in mediating the effects of melatonin on the hypothalamic-pituitary-gonadal axis. The absence of melatonin receptors in ferret brain reinforces the hypothesis that neural sites of melatonin binding may not be necessary sites of melatonin action for the regulation of reproduction.

471.7

DIFFERENTIAL EXPRESSION PATTERNS OF A MOLLUSCAN INSULIN-RELATED GENE FAMILY IN NEUROENDOCRINE CELLS OF *LYMNAEA STAGNALIS*. W.P.M. Geraerts[1], A.B. Smit[1], K.W. Li[1], A. ter Maat[1] and H. van Heerikhuizen[2]. Depts. of Endocrinology[1] and Biochemistry[2], Free University, De Boelelaan 1087, 1081 HV Amsterdam, The Netherlands

A gene family that codes for unique and remarkably diverse precursors of molluscan insulin-related peptides (MIPs) has been identified in the snail, *Lymnaea stagnalis*. All members of the MIP gene family have an intron/exon organization similar to the one found in vertebrate insulin genes, with 3 exons and 2 introns. Exon 2 encodes the signal peptide, the B chain and a few amino acids of the C-peptide(s), whereas exon 3 encodes the remainder of the C-peptide(s) and the A chain. The sequence diversity among MIPs is much larger than that observed among vertebrate insulins. A model is presented which explains the extraordinary MIP diversity by the occurrence of macroscale evolutionary events involving exchanges of parts of the MIP genes by intergenic crossing-over. Four MIP genes are expressed in the 200 cerebral neuroendocrine light green cells (LGCs), which control growth and associated metabolic processes. We show that various environmental conditions result in a strongly altered steady state concentration of the different MIP-RNAs, suggesting that the MIP genes are subjected to a stimulus-specific transcriptional regulation. Pulse-chase experiments show that the C-peptides are proteolytically cleaved out of the precursors, thus giving rise to mature 2-chain MIPs. Physiological concentrations of D(+) glucose induce spiking activity in the LGCs and a concomitant release of MIPs. This creates an interesting parallel with the β cells of the pancreatic islets in vertebrates

471.8

APOMORPHINE STIMULATES OXYTOCIN RELEASE IN MALE AND FEMALE MONKEYS. I.A. Amico, S.M. Pomerantz, L.M. Layden* and I.L. Cameron, Depts. of Medicine, Physiology and Psychiatry, Univ. of Pittsburgh School of Medicine and Oakland VAMC, Pittsburgh, PA 15260.

In male rats the dopamine receptor agonist, apomorphine, has been shown to stimulate the release of oxytocin from the neurohypophysis and this release is associated with increased yawning and penile erection. The present study was designed to investigate whether dopaminergic agents may exert similar neuroendocrine and behavioral effects in primate species. Three female rhesus monkeys and one male cynomolgus monkey were implanted with chronic indwelling venous catheters and outfitted with standard jacket/tether/swivel systems to allow remote blood sample collection. Blood samples were collected at 15 and 1 min prior to administration of an i.v. injection of apomorphine and at intervals 1 to 120 min after apomorphine. Low doses of apomorphine (25-100 μg/kg) which reliably elicited yawning generally failed to alter plasma oxytocin secretion over the two hour post-apomorphine sampling period. By contrast, higher doses of apomorphine (200-400 μg/kg) elicited stereotypic behaviors (e.g. gnawing, scratching, head-bobbing) in the monkeys as well as a dose-dependent stimulation of oxytocin secretion. Apomorphine's stimulation of both oxytocin secretion and stereotypy was extremely rapid with an initial increase being observed within two minutes of apomorphine administration and a peak response generally occurring within 10-15 min following apomorphine administration. These results indicate that apomorphine acts as a potent stimulus to release oxytocin from the neurohypophysis in male and female monkeys and is therefore likely to be a useful pharmacological tool for further studies exploring the physiological and behavioral actions of oxytocin in primate species.

471.9

SURVIVAL OF VASOPRESSIN (AVP) AND OXYTOCIN (OT) NEURONS IS IMPAIRED BY HYPONATREMIA IN RATS WITH PITUITARY STALK INJURY. Janos Dohanics, G. E. Hoffman, and J. G. Verbalis Deparments of Medicine & Physiology, University of Pittsburgh, Pittsburgh, PA 15261.

We have recently reported that compression of the pituitary stalk (SC) results in a functional neurolobectomy; 21 days after this lesion approximately 70% of AVP and 30% of OT neurons died in the supraoptic (SON) and paraventricular nuclei (PVN). Other studies have shown that loss of AVP but not OT neurons following neurolobectomy is greater in rats treated with DDAVP. However, since DDAVP by itself does not change metabolic activity in magnocellular neurons, in this study we determined the effect of chronically altered metabolism on the survival of magnocellular neurons following SC. Chronic hyponatremia (CH) was chosen, because such rats are known to have markedly inhibited AVP and OT secretion in response to osmotic and volemic stimulation, as well as decreased synthesis of AVP and OT mRNA. CH was induced in adult rats fed a nutritionally balanced liquid diet as their only food source and infused with DDAVP (5 ng/h s.c.). After 10 days of sustained hyponatremia SC was performed, and 6 days later plasma [Na^+] was slowly increased to the normonatremic range. Following correction of CH, water intake of SC rats exceeded 500 ml a day. Twenty-one days after SC rats were perfused with Zamboni fixative and the brains stained for AVP-neurophysin and OT-neurophysin immunoreactivities. The table below shows the percentage of surviving neurons:

Treatment	AVP-NP		OT-NP	
	SON	PVN	SON	PVN
Sham operated	100 %	100 %	100 %	100 %
SC	33 %	35 %	70 %	58 %
Hyponatremic+SC	1.3 %	6.5 %	13.6 %	26.6 %

Thus, while DDAVP treatment alone decreases survival rates of only AVP neurons following axonal injury, CH markedly impairs survival of both AVP and OT neurons. These results therefore demonstrate that suppressed metabolic activity represents an additional risk factor for neuronal survival following injury.

CATECHOLAMINE DEPLETIONS OF THE DIAGONAL BAND OF BROCA (DBB) ATTENUATE BARORECEPTOR SENSITIVITY OF RAT SUPRAOPTIC (SON) VASOPRESSIN NEURONS. J.T. Cunningham, R. Nissen, & L.P. Renaud, Neuroscience Unit, Ottawa Civic Hospital, Ottawa, Canada K1Y 4E9.

In the rat, stimulation of peripheral baroreceptors by acute drug-induced increases in blood pressure will transiently inhibit the spontaneous activity of SON vasopressin-secreting neurons. Previous research indicates this response is mediated via the DBB. The present study evaluated the importance of the catecholaminergic innervation of the DBB in the barorecepetor senstivity of vasopressin neurons in the SON. Adult male Long Evans rats anesthetized with nembutal were injected in the DBB with 6-OHDA (4 ug/2 ul). Controls were injected with either vehicle (0.1% ascorbic acid in 0.9% NaCl) or the same dose of 6-OHDA after administration of the norepinephrine uptake inhibitor desmethylimpramine (DMI, 25 mg/kg ip). Two weeks later, the rats were reanesthetized with nembutal and prepared for extracellular recording of identified neurons in the SON using a transpharyngeal approach. In vehicle and DMI control experiments, all phasically-firing vasopressin neurons were inhibited by increases in blood pressure produced by metaraminol (10 ug/10 ul iv). Equivalent metaraminol-induced pressor responses inhibited less than half of the phasic vasopressin neurons (8/18) in rats with 6-OHDA injected into the DBB. This decrease in baroreceptor sensitivity in the rats injected with 6-OHDA was significantly different from vehicle injected controls ($X^2(df=1)=4.07$, $p < 0.05$) and from DMI pretreated rats ($X^2(df=1)=8.64$ $p < 0.05$). The results suggest that the noradrenergic innervation of the DBB is involved in the baroreceptor inhibition of vasopressin neurosecretory neurons in the SON. STRONG INTRINSIC INHIBITION IN CAT MAGNOCELLULAR NEUROENDOCRINE CELLS. R.D. Andrew and M. Fagan. Dept. of Anatomy, Queen's University, Kingston, Ontario. K7L 3N6.

Most magnocellular neuroendocrine cells (MNCs) in the cat supraoptic nucleus (SON) synthesize and release vasopressin systemically from their neurohypophysial axon terminals. Unlike in rat, cat MNCs discharge slower and are incapable of the phasic firing that facilitates vasopressin release. The reasons were examined using intracellular recording from feline and rat SON in coronal hypothalamic slices.

Cat MNCs displayed a higher mean input resistance (301 MΩ,n=56) than rat (150 MΩ,n=105). Spike hyperpolarizing afterpotentials were 16.5±0.5 mV mean amplitude, more than twice that of rat. An evoked spike train was followed by a prominent afterhyperpolarization (AHP) several times the duration of its counterpart in rat. The AHP reversed near the equilibrium potential for K^+, represented an increased membrane conductance and was eliminated in low Ca^{2+} saline or by the $I_{K(Ca)}$ blockers apamin (100 nM) or d-tubocurarine (200 μM). Both blockers decreased spike frequency adaption but did not unmask phasic firing, confirming that cat MNCs lack a regenerative burst mechanism. Increasing osmolality by 10-85 mOsm increased firing in 75 of 85 rat units and in 120 of 150 cat units. Phasic firing evolved in 47% of slow units in rat but no cat units became phasic. We conclude that a prominent $I_{K(Ca)}$ helps cat MNCs resist bursting and rapid firing. However their osmosensitivity is comparable to rat and therefore independent of the current that drives phasic firing in rat. This study illustrates that dramatic differences in the intrinsic properties of homologous neurons can exist across mammalian species.

471.12

A MINIMAL MODEL OF NEUROHYPOPHYSEAL HOMEOSTASIS. M.D. Fitzsimmons, M.M. Roberts, A.G. Robinson. Division of Endocrinology. University of Pittsburgh. PA. 15261.

Posterior pituitary vasopressin (AVP) content is dynamic and depends on physiologic conditions; prolonged stimulation can reduce store size to 5-10% of control levels, while removing the stimulus allows recovery to 100% basal or greater. Over a broad range of stimulus conditions, the rate of AVP synthesis in rats remains directly proportional to AVP mRNA levels. These results suggest that magnocellular neurons may regulate vasopressin synthesis exclusively through transcriptional mechanisms. We tested whether regulation at a single site (transcription) explains broad shifts in pituitary content using a computer model of vasopressin synthesis. Mathematical analysis reveals two central characteristics of the model: 1) solely transcriptional regulation can only achieve equilibrium if the rate of mRNA transcription varies linearly with hormone release rate and 2) the dynamics of neurohypophyseal hormone storage depend heavily on AVP mRNA half-life (the longer the half-life, the slower the synthetic response). Our half-life estimate (4.6 days) comes from experimental measurements.

Although computer simulations of this minimal model coincided well with pituitary depletion resulting from increased release, the model underestimated the rate of recovery of stored hormone after prolonged stimulation. Thus, we tested several modifications to the model: decreased hormone release during recovery, non-linear transcription, and mRNA half-life regulation. Cytoplasmic control of AVP mRNA decay proved the most promising modification for describing the time course of pituitary recovery. By mimicking physiological conditions, the computer model of transcriptional regulation provides a theoretical basis for observed dynamics of AVP mRNA and pituitary AVP content and allows development of testable hypotheses.

PAIN: PATHWAYS II

472.1

ONGOING INPUT FROM A PUTATIVE FOCUS OF NOCICEPTOR DISCHARGE MAINTAINS THE ABNORMAL PAIN SENSATIONS OF REFLEX SYMPATHETIC DYSTROPHY. S. Lynch, R.H. Gracely*, and G.J. Bennett. Neurobiology and Anesthesiology Branch, NIDR, NIH, Bethesda, MD 20892.

Many patients with reflex sympathetic dystrophy (RSD) perceive light tactile stimuli to be very painful. It is known that in many cases this mechanical allodynia is dependent upon input from Aß low-threshold mechanoreceptors (AßLTM). We have found that AßLTM-dependent mechanical allodynia can be eliminated transiently (thereby normalizing touch-evoked sensations) by lidocaine infusion into a putative focus of nociceptor discharge in the affected extremity. Our observations are illustrated by an advantageous case with a painful focus that was distant from an area of allodynia. The patient had spontaneous pain and mechanical allodynia in the left forearm and hand. The pain was of 23 months duration and appeared subsequent to an ulnar nerve transposition at the elbow. The allodynia was shown to be AßLTM-dependent by testing with v. Frey hairs and transcutaneous electrical stimulation before and after a differential ischemic block. Palpation of the painful focus (an atrophic, hyperpigmented area just distal to the surgical scar) caused intense shooting pains throughout the arm and hand. Completely anesthetizing this region with subcutaneous 1.5% lidocaine relieved the spontaneous pain and mechanical allodynia in all areas. Testing detection thresholds for warm, cold, hot, v. Frey hair, and electrical stimuli showed that the relief was not due to the spread of lidocaine to the innervation of the areas that previously exhibited allodynia. Allodynia and spontaneous pain returned along with the return of sensibility to the injected area. On a separate occasion, lidocaine given in the other arm had no effect on the painful side, showing that the pain relief was not due to a systemic drug effect.

Such observations support a model that proposes that an ongoing nociceptor input maintains a central processor in an abnormal state. The abnormal central state is dynamic - when the nociceptor input is blocked, it reverts to normal. The ongoing nociceptor input may be driven, completely or in part, by sympathetic activity and it may arise from several sources (e.g., neuroma discharge, poorly healed joint injury).

472.2

SIGNALLING OF A STEP-LIKE CHANGE IN INTENSITY OF A NOXIOUS MECHANICAL STIMULUS: SEPARATING "SENSORY" FROM "AUTONOMIC" RAT SPINAL DORSAL HORN NEURONES Jennifer M.A. Laird & Fernando Cervero* Dept.of Physiology, University of Bristol Medical School, Bristol, BS8 1TD, U.K.

A noxious stimulus evokes a variety of responses; sensory (pain), motor (withdrawal reflex) and autonomic (cardiovascular, etc). Peripheral nociceptors provide the input to all of these systems. The first possible point of division is the dorsal horn of the spinal cord. However, which dorsal horn cells participate in the different systems is not clear. An approach to this problem was suggested by the results of experiments in which human subjects rated the intensity of the pain sensation produced by a noxious mechanical pinch applied to an interdigital web. The 120s stimulus had a step-like increase or decrease in intensity after 60s. Subjects detected a step increase but rarely a step decrease. Skin vasoconstrictor activity was also measured and found to follow both the step increase and the step decrease.

We have now investigated the ability of neurones in the sacral dorsal horn of the rat to signal step changes in 120s pinch stimuli. Four pinches, 2 with a step increase and 2 with a step decrease in intensity (4N-6N, 6N-8N, 8N-6N and 6N-4N), were delivered in random order to the neurone's receptive field on the tail. Cells with a nociceptive input, either exclusively (class 3) or in addition to a low threshold input (class 2) fired throughout the 120s pinch. The 26 cells could be divided into 4 groups depending on their responses to the pinch stimuli as follows: i) signalling both a step up and a step down (n=13) ii)signalling only a step up (n=7) iii) signalling only a step down (n=4) iv) signalling neither (n=2). Each of these groups contained both class 2 and class 3 cells, located throughout the dorsal horn.

These results show that there are groups of dorsal horn neurones that follow the autonomic and the sensory output patterns. We conclude that different sub-groups of class 2 and 3 neurones appear to be involved in both sensory and in autonomic aspects of nociception.

LAMINA I TRIGEMINOTHALAMIC PROJECTIONS IN THE MONKEY. A.D. Craig, Div. of Neurobiology, Barrow Neurological Institute, Phoenix, AZ 85013

Thermoreceptive and nociceptive lamina I neurons constitute half of the spinal input to the thalamus, and their termination sites signify important loci for temperature and pain sensation. Lamina I projections from the trigeminal dorsal horn have been identified in the cynomolgus monkey by using the PHAL anterograde tracing method previously employed successfully in the cat. Dense terminal clusters bearing large boutons are concentrated at the ventrocaudal (probable nociceptive region) and dorsomedial (possible thermoreceptive region) aspects of VPM. Strong medial thalamic terminations in the ventral aspect of caudal MD (adjacent to Pf), which could be homologous to the submedial projection in the cat, are similar to the "paralaminar MD" projection described by Ganchrow (JCN 178:281, 1978) in the squirrel monkey. These findings offer unambiguous, substantive evidence for the location of clinically critical thalamic sites for trigeminal pain sensation.

RESPONSES OF SPINOTHALAMIC AND SPINORETICULAR NEURONS TO INTRACARDIAC INJECTION OF PHENYLBIGUANIDE, A 5-HT$_3$ RECEPTOR AGONIST. R.W. Blair, D.C. Bolser, and R.D. Foreman. Univ. Okla. Hlth. Sci. Ctr., Okla. City, OK 73190, and Shering-Plough Corp., Bloomfield, NJ 07003.

5-HT$_3$ receptors are located on vagal afferents; activation of these receptors produces a Bezold-Jarisch-like response. The purpose of this study was to determine whether phenylbiguanide (PBG), a 5HT$_3$ agonist, could influence spinal neurons by activating cardiac sympathetic afferents. Nine cats and 10 monkeys were anesthetized with chloralose and/or pentobarbital. Electrophysiological techniques were used to record activity of thoracic spinothalamic (N=17, STT), spinoreticular (N=6, SRT), STT-SRT (N=1), or non-projecting (N=4) neurons. PBG was injected into the left atrium using doses that had little or no effect on neuronal activity when injected into the ascending aorta; the most effective doses were 30-40 μg/kg. In response to PBG, 17 neurons were excited, 6 were inhibited, and 5 were unaffected. Three responsive neurons were tested pre- and post-vagotomy. Two of these cells were excited by PBG, and the response was comparable or bigger after vagotomy. The other cell was inhibited, and the inhibition blocked by vagotomy. In 10 neurons responsive to PBG and assessed for responses to left vagal afferent stimulation, the vagal response was in a different direction than the PBG response. Taken together, the results suggest that thoracic STT and SRT cells are influenced by 5-HT$_3$ mediated excitation of cardiac sympathetic afferents. (Supported by NIH grants HL22732 and HL29618)

472.5

SPINALL NEURONS WITH BRANCHED AXONS PROJECTING TO THE SOLITARY TRACT AND DORSAL COLUMN NUCLEI. G.W.Lu, Z.Meng*, L.Luo* and Y.Yamakami*. Dept. of Neurobiol. Capital Institute of Medicine, Beijing. 100054, China.

Retrograde labeling and antidromic activation techniques were used to identify the dual projection of spinal neurons to both the solitary tract nucleus(STN) and dorsal column nuclei(DCN).

Experiments were conducted on adult rats anesthetized with sodium-pentobarbital. Propidium iodide(PI) and Bisbenzimide (Bb) were injected into the STN and DCN respectively in 10 rats. Antidromic stimulation was alternatively delivered to STN and DCN in another group of 26 rats. The distribution of PI and Bb labeled cells and STN and DCN activated neurons were respectively identified in the lumbosacral dorsal horn.

Two hundred and eighty two cells were found to be labeled by PI and/or Bb in the laminae III-VI. Eighteen percent of the sample (51 cells) were found to be labeled by both PI and Bb. A total of 92 neurons in laminae III-VI were found to be driven by stimulation of the STN and/or DCN. Of them, 38 and 54 neurons were found to antidromically and synaptically respond to both the STN and DCN stimulation. Synaptic responses were also shown in 8 of the 38 neurons that responded antidromically to both the STN and DCN.

These results indicate that some spinal neurons issue branched axons projecting to both the STN and DCN and some of these dual projection neurons are innervated in turn by the STN and/or DCN. In addition, some spinal neurons are doubly innervated from both the STN and DCN.

472.6

PHYSIOLOGY AND MORPHOLOGY OF NOCIRECEPTIVE AND THERMORECEPTIVE PARABRACHIAL NEURONS. RM Slugg and AR Light, Dept. Physiology, UNC-Chapel Hill, Chapel Hill, NC 27599.

Neurons in the parabrachial nucleus were examined for cutaneous input in anesthetized rats. Of the 90 neurons characterized, 71 (79%) responded to noxious stimuli. Of these 71 neurons, 50 were excited only by noxious mechanical or noxious mechanical and noxious thermal stimuli, and 5 were excited only by noxious thermal stimuli. Receptive field (RF) size ranged from a small area on one limb to the entire body surface. Most RF's were contralateral or, if bilateral, had a greater responsiveness from contralateral stimuli. Of the remaining neurons, 17 (19%) were classified as innocuous cooling, and 2 (2%) as slow brush. Fifteen neurons were intracellularly labeled with HRP, biocytin, or neurobiotin. All labeled neurons were within the lateral parabrachial nucleus, and did not appear to be segregated by RF or modality. These neurons were characterized by a few long thin dendrites, which extended beyond the border of the subnucleus in which the soma was located, either rostrocaudally, dorsoventrally, or mediolaterally. Labeled axons were extremely thin, and projected medially and rostrally but were not observed to cross midline. Thus, neurons in the lateral parabrachial nucleus may act as specific relays for nociceptive and thermoreceptive information. Supported by grants PHS DA04420 and NS16433.

472.7

PROJECTIONS TO THE VENTRAL PERIPHERY OF THE CAT'S THALAMIC VENTRAL POSTEROMEDIAL NUCLEUS (VPM$_{vp}$). C. Vahle-Hinz and K.-D. Kniffki. Physiologisches Institut, Universität Würzburg, D-8700 Würzburg, FRG.

The VPM$_{vp}$ is a thalamic nucleus in the nociceptive system of the cat. Neuronal tracers (HRP, WGA-HRP, WGA-HRP-gold) were injected into this region to retrogradely label the neurons of origin of its inputs from brainstem, thalamus and cortex.

All tracers used produced similar results, however, the number of labeled neurons was substantially higher with WGA-HRP-gold. Retrogradely labeled neurons were found contralateral to the injection site in the spinal trigeminal complex, especially in the marginal laminae of nucleus caudalis, in the ventral principal trigeminal nucleus and in the periaqueductal grey. Ipsilateral to the injection neurons were labeled in the dorsal principal trigeminal nucleus, the parabrachial complex, the periaqueductal grey, the thalamic reticular nucleus and the cingulate cortex.

Since the VPM$_{vp}$ is small and several pathways traverse this region, some spread of the tracer to VPM proper and retrograde labeling via damaged fibers of passage have to be taken into account. However, the responsiveness of VPM$_{vp}$ neurons to noxious stimuli on the head, to stimulation of visceral organs and baro- and chemoreceptors suggests that fibers from the spinal trigeminal and parabrachial nuclei may serve these inputs and terminate within VPM$_{vp}$. In addition, neurons from the cingulate cortex, the thalamic reticular nucleus and the periaqueductal grey may exert modulatory influences.

THALAMIC PROCESSING OF CRANIOVASCULAR PAIN IN THE CAT: A 2-DEOXYGLUCOSE STUDY. P.J. Goadsby and A.S. Zagami[1]. The National Hospitals for Nervous Diseases, Maida Vale, London England & [1]Institute of Neurological Sciences, The Prince Henry Hospital, Sydney, Australia.

The superior sagittal sinus (SSS), as well as other cranial vessels and the dura mater, is known to be pain sensitive in man. Studies of the central processing of pain from intracranial structures have focused on the first order neurons of the trigeminal system that synapse in the trigeminal nucleus. We have shown that electrical stimulation of the SSS causes metabolic activation of the trigeminal system and have now extended these data by assessing the thalamus. The SSS was electrically stimulated in the chloralose-anesthetized (60mg/kg,ip), paralysed and ventilated cat. Metabolic activity in the thalamus was determined using the 2-deoxyglucose method with quantitative tissue autoradiography. In a group of animals metabolic activity was measured after bilateral trigeminal ganglia abalation. Stimulation of the SSS in the intact cats increased glucose utilization in the ventrobasal complex of the thalamus by 160% while no change was seen in surrounding structures including the lateral geniculate nucleus or cerebral cortex. This response was blocked by bilateral abalation of the trigeminal ganglia. These data are the first demonstration of metabolic activation in second order neurons in the trigeminovascular system. Furthermore these data clearly implicate the ventrobasal complex in processing craniovascular nociception.

472.9

NOCICEPTION AND NOCICEPTIVE MODULATION OF TASK-RELATED RESPONSES IN AREA 7B CORTEX OF MONKEYS. W.K. Dong and V.J. Roberts. Department of Anesthesiology and Multidisciplinary Pain Center, University of Washington School of Medicine, Seattle, WA 98195.

Three distinct functional groups of neurons with somesthetic responses have been identified in the inferior parietal lobule (area 7b) of monkeys that performed an appetitive tolerance-escape task. Monkeys were allowed to initiate and terminate thermal stimulation of the face and were reinforced for completing trials that sometimes required tolerance of noxious temperatures. A nociceptive group of neurons had peak discharge frequencies that increased monotonically in response to graded thermal pulses. Maximal discharge frequencies were at temperatures near the pain tolerance level (~50% escapes). A task-related group of neurons displayed inhibition of background activity during button pressing which led to reinforcement. This may be a nonspecific mechanism for decreasing background noise and enhancing neural responses to an anticipated perceptual event (i.e., cued button release or cued food reinforcement). A reversal of this inhibitory period by presentation of tolerable warming pulses was seen in some task-related neurons, but optimal reversal of inhibition required intolerable warming pulses at the pain tolerance level in other task-related neurons. A third group of neurons had both trigeminal somatosensory and visuosensory properties; their cutaneous and visual receptive fields were aligned along common spatial coordinates. Slowly adapting discharges were elicited by a visual stimulus approaching and staying near a face cutaneous receptive field. These groups may be part of a polysensory neuronal assembly that processes information used to guide the body away from stimuli that threaten tissue injury or to strengthen learned strategies that avoid or tolerate noxious stimuli. Supported by NIH grants DE05130, DE07617 and NS07217.

SEROTONIN IV

473.1

LONG-TERM ADMINISTRATION OF THE NOVEL ANXIOLYTIC GEPIRONE LEADS TO CHANGES IN HIPPOCAMPAL EPSP ACTIVITY STUDIED IN VITRO. M.H. O'Regan* and J.D. Kocsis. Depts. Neurology and Pharmacology, Yale Med. Sch. and VA Med. Ctr., West Haven, CT. 06516.

The novel anxiolytics, buspirone and gepirone, do not exert their actions until about two weeks. In this study we examined the effects of chronic gepirone administration on synaptic transmission in the CA1 region of rat hippocampus, and compared the acute effects of buspirone and serotonin. Mini-osmotic pumps were loaded with gepirone or with saline and implanted into the peritoneal cavity to deliver 10 mg/kg/day. After 13 to 18 days, hippocampal slices were prepared for electrophysiological study using standard procedures. In slices obtained from rats treated with chronic gepirone there was a reduction in frequency-dependent potentiation of both the presynaptic and postsynaptic components of the field potential. In control slices, bath applied buspirone (100 μM) led to a distinct reduction in the EPSP elicited by stimulation of stratum radiatum, as well as a reduction in presynaptic axonal excitability. Following chronic treatment with gepirone, the effects of acute buspirone application on both presynaptic and postsynaptic potentials were significantly reduced. Additionally, while serotonin (100 μM) had minimal effect on the postsynaptic potential and no effect on the presynaptic fiber volley in control slices, chronic gepirone treatment resulted in serotonin-evoked depression of the EPSP.

These results indicate that chronic treatment with gepirone reduces synaptic facilitation and leads to changes in the acute effects of buspirone and serotonin on synaptic transmission in the hippocampal slice. This implies that the delayed effects of chronic buspirone or gepirone treatment with respect to their anxiolytic action may be retained in the in vitro slice, thereby providing a system to study the long-term modulatory action of these agents on a cellular level.

473.2

REINFORCING EFFECTS OF THE SEROTONIN RECEPTOR AGONIST 8-OH-DPAT:INVOLVEMENT OF THE NUCLEUS ACCUMBENS. T.S. Shippenberg*, C. Stein and A. Herz*. Dept. Neuropharmacology, Max-Planck Inst. for Psychiatry, D-8033 Martinsried, FRG

Place preference conditioning and in-vivo microdialysis were used to examine the motivational effects of the serotonin (5-HT) agonist 8-OH-DPAT and the neural substrates mediating such effects. Rats showed a marked place preference in response to 0.1-0.25 mg/kg 8-OH-DPAT. Other doses were without effect. The 5-HT1a receptor antagonist spiperone or 5,7 dihydroxytryptamine lesions of the n. accumbens (NAC) abolished the effects of 8-OH-DPAT. D-1 but not D-2 dopamine (DA) receptor blockade also abolished 8-OH-DPAT place conditioning.Microdialysis studies revealed a marked decrease in 5-HIAA overflow in the NAC following 0.25 mg/kg 8-OH-DPAT.A slight but significant later-onset inhibition of NAC DA release was also observed. These data demonstrate that 8-OH-DPAT is a secondary reinforcer and that this effect involves both 5-HT1a and D-1 DA receptors. Furthermore, they suggest an important role of the NAC and the 5-HT fibers projecting therein in the mediation of this effect.

DOSE RELATED EFFECTS OF PRENATAL 5-METHOXYTRYPTAMINE (5-MT) ON DEVELOPMENT OF SEROTONIN TERMINAL DENSITY AND BEHAVIOR. A.V. SHEMER, E.C.AZMITIA and P.M.WHITAKER-AZMITIA. Dept. Psychiatry, SUNY, Stonybrook, N.Y. & Dept. Biology, N.Y.University, N.Y.

We have previously shown that 5-MT has a biphasic effect on development of serotonergic neurons in culture and the present study was carried out to determine if this was also observable in vivo. Pregnant Sprague-Dawley rats were injected s.c. with 0.1, 1 or 3 mg/kg 5-MT from gestational day 12 through birth. Terminal density was determined at postnatal day (PD) 1,15 & 30 by measuring uptake of ^{3}H-5-HT. Serotonergic behaviors were tested at PD 5, 15 & 30. The lowest dose of 5-MT produced no change in terminal density at any timepoint, but did produce significant behavioral changes at PD 30. The medium dose produced both a decrease in terminal density and behavioral changes at all timepoints. The highest dose produced an increase in terminal density at all timepoints, but behavioral changes only at early timepoints. These results confirm our findings on development of terminals and also suggest a role for serotonin in " receptor programming " and subsequent serotonin behavioral sensitivity.

473.4

IMPAIRED 5HT FUNCTION AND PROLACTIN RESPONSE TO 5HT AGONISTS IN THE RHESUS MONKEY. G.R. Heninger, S. Evans*, and H. Landis*. Ribicoff Research Facilities, Yale. Univ. Sch. of Med., Conn. Mental Health Ctr., New Haven, Ct 06510.

Depressed patients have a blunted prolactin (PRO) response to i.v. tryptophan (TRP). A 90% reduction in plasma TRP following a low TRP diet and a TRP-free amino acid drink (AAD) produces a return of symptoms in 2/3 of depressed patients recently remitted on antidepressant medication. To evaluate the role of 5HT in the blunted PRO release and the mechanism by which TRP depletion reverses antidepressant effects, the effects of TRP depletion on the PRO response to 5HT agonists was compared to the effects of the 5HT synthesis inhibitor para-chlorophenyalanine (PCPA). Adult male chair trained rhesus monkeys received i.v. TRP at 200 mg/kg or the 5HT1A agonist i.v. gepirone (GEP) at .25 mg/kg to stimulate PRO release. The AAD consisted of 15 essential amino acids with or without TRP added and was administered at 1.5 gm/kg through oral tube, as was PCPA. The TRP and GEP infusions began 4 hours following the AAD and PRO values were measured before and during the infusion with standard RIA methods. The AAD minus TRP produced an average of approximately 60-80% reduction in plasma TRP, along with an 80% reduction of PRO response to infused TRP, and a 40-80% reduction of PRO response to GEP. The AAD with TRP added also reduced the PRO response to TRP and GEP but to a lesser degree, 60 and 30% respectively. PCPA at a total of 300 mg/kg over a 6 day period produced 20 to 40% reduction in the PRO response to TRP and a 25 to 200% increase in PRO response to GEP. The blunted PRO response to TRP following TRP depletion and PCPA and the augmented response to GEP following PCPA are consistent with prior data. The blunted PRO response to GEP following TRP depletion and the blunted response to both TRP and GEP following the TRP augmented AAD suggest that the metabolic changes induced by the amino acid load cause more complex alterations in 5HT function than those observed following the more selective 5HT synthesis inhibitor PCPA. Supported by MH36229 and MH25642.

SECONDARY CHANGES IN THE EVOKED RELEASE OF SEROTONIN FROM FRONTOCORTICAL NERVE TERMINALS INDUCED BY FLUOXETINE, A SEROTONIN REUPTAKE BLOCKER. A.M.Gardier and R.J.Wurtman. Dept. of Brain and Cognitive Sciences, MIT, Cambridge, MA, 02139.

Previous studies in our laboratory have suggested that the evoked release of serotonin (5-HT) was diminished in rats after chronic administration of fluoxetine, a 5-HT uptake blocker, or d-fenfluramine (d-fen), a drug which both releases 5-HT and blocks its reuptake. However, the treatment then chosen to evoke the 5-HT release was a drug, d-fen which must itself be taken up by the 5-HT uptake system in order to exert its effect. Thus, we decided to evoke 5-HT release by depolarizing 5-HT terminals with a high concentration of KCl, a process that is undependent of 5-HT uptake. We gave rats saline (2ml/kg), fluoxetine (30mg/kg), or d-fen (7.5mg/kg) i.p. for 3 days and measured frontocortical 5-HT release in anesthetized rats (using brain in vivo microdialysis) 24 hours after the last dose. After extracellular frontocortical 5-HT levels stabilized, KCl 120mM was added to the perfusion fluid for 15 min. All samples collected for 15 min. were assayed for 5-HT and 5-HIAA using LC-ECD. Chronic fluoxetine decreased basal 5-HT and 5-HIAA release while chronic d-fen decreased 5-HIAA efflux only. Unlike the situation in d-fen pretreated rats, KCl-evoked 5-HT release was suppressed following fluoxetine pretreatment. This blockade of evoked 5-HT release, and of basal 5-HT and 5-HIAA release were not dependent on the dose of fluoxetine studied, appearing after 7.5, 15, 30 or 60mg/kg. Although 5-HT and 5-HIAA release ultimately returned to normal, blockade did persist after a drug washout period of 7 days. These findings suggest that, unlike d-fen, fluoxetine can cause prolonged impairements in evoked 5-HT release.

STUDIES WITH NEUROTOXIC AND NON-NEUROTOXIC ANALOGUES OF 3,4-METHYLENEDIOXYMETHAMPHETAMINE (MDMA). M. P. Johnson and D. E. Nichols. Depts. of Pharmacology and Toxicology, and Medicinal Chemistry and Pharmacognosy, School of Pharmacy and Pharmacal Sciences, Purdue Univ., W. Lafayette, IN 47907.

It has previously been reported that rigidification of the α-side chain of *p*-chloroamphetamine (PCA) to give 6-chloro-2-aminotetralin (6-CAT) attenuates the serotonergic neurotoxicity of the parent compound (Fuller, R. W., et al., Arch. Int. Pharmacodyn. Ther. 212:141, 1974). This led us to the synthesis of rigid analogues of MDMA that retained the behavioral activity but lacked the apparent long-term neurotoxicity of the parent compound (Nichols, D. E., et al., J. Med. Chem. 33:703, 1990). One of these rigid analogues is 5,6-methylenedioxy-2-aminoindan (MDAI). The levels of monoamines at short time periods after high doses of MDMA and MDAI were examined. In the frontal cortex and caudate of rats, there are significant differences in the effects on DA and its metabolites with the neurotoxic and non-neurotoxic amphetamine analogues.

This report also describes several additional analogues of MDMA as well as short-term and long-term effects of these analogues. For example, the importance of ring substitution was investigated by examining 3-methoxy-4-methylamphetamine (MMA) and 5-methoxy-6-methyl-2-aminoindan (MMAI). The serotonergic neurotoxicity of these compounds was determined by examining ^{3}H-paroxetine binding and monoamine levels one week following acute doses of 10 or 20 mg/kg s.c. or two weeks following subacute dosing (2x/day for 4 days) of 20 mg/kg. None of the treatments led to changes in serotonergic markers with either MMA or MMAI. These neurotoxic and non-neurotoxic substituted amphetamines were examined for their relative potencies in a number of bioassays. The relative ability of the amphetamines to release and to inhibit the uptake of ^{3}H-5-HT, ^{3}H-DA and ^{3}H-NE was examined. The results will be discussed in terms of the relative importance of these short-term actions on the long-term effects of certain substituted amphetamines.

This work was support by USPHS grant DA-04758 from NIDA.

IMMUNOCYTOCHEMICAL DEMONSTRATION OF THE ABSENCE OF LONG LASTING EFFECTS OF D-FENFLURAMINE ON NEOCORTICAL SEROTONERGIC AXONS: EVIDENCE AGAINST NEUROTOXICITY. M. Kalia and L. S. Miller*. Dept. Pharmacology, Jefferson Medical College, Philadelphia, PA 19107.

Parenteral administration of D-fenfluramine to rats in massive doses (20-80 mg/kg/day for 4 days) has been reported to selectively remove 5HT-immunoreactivity from axons in the neocortex and striatum up to 4 weeks post-treatment *(Molliver and Molliver, Soc. Neurosc. Abst. 15:210,1988, Molliver and Molliver, Brain Res. 511:165,1990)*. Since these results have significant implications, we repeated this study using D-fenfluramine in **orally** administered (gavage) doses ranging from 2-48 mg/kg/day for 4 days with post-treatment survival periods up to 2 weeks. 5HT-immunoreactive axons were examined in serial, sagittal, 30 um sections in identical regions of the neocortex of D-fenfluramine-treated rats and pair-fed controls. At 24 hrs post-treatment, a progressive, dose-dependent reduction in 5HT-immunoreactive axons in the neocortex was observed. Doses of 12 mg/kg/day for 4 days produced the first evidence of abnormal 5HT-immunoreactive profiles. This dose (12 mg/kg/day for 4 days) and adjacent doses (8 & 16 mg/kg/day for 4 days) were used for the 2 week post-treatment study. Under these conditions neocortical 5HT-immunoreactive axons in the treated animals were comparable to controls. These results demonstrate that D-fenfluramine does not produce permanent loss of 5HT immunoreactive axons in the rat neocortex. Furthermore, the initial loss of 5HT-immunoreactivity does not appear to reflect neuropathology since the immunoreactivity reappears at 2 weeks post-treatment with a pattern similar to that in controls.

CLONING AND CHARACTERIZATION OF cDNA ENCODING TRYPTOPHAN HYDROXYLASE FROM CENTRAL SEROTONERGIC NEURONS. K. S. Kim, T. Wessel, D.M. Stone, C. Carver, T.H. Joh and D.H. Park. Lab. Mol. Neurobiol., Cornell Univ. Med. Coll. at Burke Rehab. Center, White Plains, NY 10605.

Tryptophan hydroxylase (TPH), the first enzyme in serotonin biosynthesis, is expressed in dorsal raphe nucleus (DRN) and pineal gland (PG). Although higher activity is found in DRN, the levels of mRNA are much greater in the PG. Moreover, biochemical characteristics, such as pI, indicate that different forms may be expressed in DRN and PG. These data raise the question as to whether different forms of TPH exist in these two tissues. To address this question, we analyzed TPH cDNA's by polymerase chain reaction (PCR) using poly A^{+} mRNA purified from both tissues. Several combinations of oligonucleotide primers representing different regions of the coding sequence of pineal gland TPH (Darmon et al., J. Neurochem., 51, 312, 1988) were employed to amplify the TPH signal. The PCR and the subsequent analyses by gel electrophoresis and southern blotting indicated that the same form of TPH message exists in both tissues. Further, the nucleotide sequence of three independent isolates containing the full length coding region was identical to that of PG. In situ hybridization in the DRN indicates that the PG form also is present in the central nervous system. However, TPH mRNA was not detectable in DRN by Northern blot probably due to the low abundance in this tissue. Our results suggest that primary structure cannot alone account for the different behavior and regulation of TPH in the DRN and PG. These experiments do not exclude the possibility that an additional form of TPH not sharing the sequences selected with oligonucleotides is present in the DRN; however, the data clearly indicate that the PG form is expressed in the DRN. Supported by MH44043.

SEROTONIN IS A SPECIFIC INDUCER OF MOVEMENTS IN UNHATCHED ATLANTIC SALMON (Salmo salar) LARVAE.
B.T. WALTHER, J.V. HELVIK*, D. OPPEN-BERNTSEN* & C. RONG.* Dept. of Biochemistry, Univ. of Bergen, N-5009 Norway.

Exogeneous neurochemicals advance or delay the time of hatching of salmon eggs (Oppen-Berntsen et al.,1990, AQUACULTURE 88, in press). After hatching light induces salmon larvae to initiate bursts of swimming. We tested a number of neurochemicals (40 mg/l) and found that only serotonin caused immediate and recurrent increases in movements of larvae inside eggs posed for normal hatching in daylight. Serotonin induced movements in all larvae after a lag in individual larvae of from a few secs to 15 min at 4 C. Stimulation lasted about 30 min at 4 C, and about 60 min on ice. While normal movements of larvae involve slight rocking or at most a full rotation, serotonin induced 2-5 vigorous rotations. On average control larvae initiate such motions 1.1 times per hour. Serotonin induces a 26.7 fold increase in (more vigorous) rotation motions, while tyramine, dopamine, noradrenalin, adrenalin, histamine and melatonin had no effect. Weak stimulatory compounds were found: tryptamine gave 3.0x increase; N-acetyl-serotonin and 5-hydroxytryptophane both 2.2x increases over control. In these salmon eggs close to term only tyramine appeared to accelerate hatching.Control and treated eggs all had hatched 24 hours after our test, except the adrenalin-treated eggs. Stimulation of hatching movements in salmon larvae is distinct from stimulation of hatching.

ALTERATION OF NEURONAL REGULATION OF ASTROCYTOMA PROLIFERATION BY INSERTIONAL MUTAGENESIS. R.A.A. TORRES, R.K.H. LIEM AND M.L. SHELANSKI: COLLEGE OF PHYSICIANS AND SURGEONS OF COLUMBIA UNIVERSITY, NEW YORK CITY,N.Y.10032

It has been previously shown that neuron-astrocyte cell contact results in the arrest of astrocyte DNA synthesis and that this inhibition is membrane-mediated (Hatten, M.E., J. Cell Biol. 104: 1353,1987). In addition, cerebellar granule cell membranes will also inhibit the growth of astrocytoma cell lines derived from rodent and man (Hatten, M.E. and Shelanski, M.L., J. Neurosci. 8: 1447, 1988). In the current experiments we used the retroviral shuttle vector pZIPNEOSV(X) to create a selectable alteration (insertional mutation) in a mouse astrocytoma cell line (G2624), which normally shows growth inhibition in response to granule cell membranes. Successfully infected G-2624 mouse astrocytoma cells were isolated by G-418 selection. These were then again selected for resistance to growth inhibition both by intact neurons and neuronal membrane preparations. Of several hundred G-418 resistant clones that were isolated, one, RM-31 shows significant resistance to neuronal inhibition of DNA synthesis. Indirect immunofluorescent staining for GFAP is strongly positive in both wild-type G-2624 and clone RM-31, with wild-type astrocytic morphology preserved. Quantitation of phenotypic effects by thymidine incorporation and by cell count show that RM-31 has an increased growth rate (1.5 X wild type) and that neuronal inhibition is reduced to 15% that of the wild-type G-2624. ^{35} S-Methionine labeling and extraction shows a decrease or absence of proteins at 210, 110 and 90 kd. Southern blot analysis confirmed viral insertion. The results suggest that we have isolated an astrocytoma mutant in which regions of DNA, normally encoding for proteins which mediate the neuronal regulation of astrocyte DNA synthesis have been altered or disrupted. This lesion could either be at the receptor for the neuronal membrane or at any point along the complex cascade of events regulating cellular proliferation. We are currently in the process of sequencing and amplifying the sequences which flank the proviral genome by inverse Polymerase Chain Reaction (Supported by NS21457).

EGF- AND TGFα-RESPONSIVE STRIATAL EMBRYONIC PROGENITOR CELLS PRODUCE BOTH NEURONS AND ASTROCYTES. B.A. Reynolds, W. Tetzlaff and S. Weiss. Neuroscience Research Group, Univ. of Calgary, Calgary, Canada.

The effects of EGF or TGFα (15-20 ng/ml) on embryonic CNS progenitor cells were tested by plating E14 mouse striatal cells (1250 cells/cm^2) on poly-l-ornithine coated coverslips in defined, serum-free media. Division of precursors (1-3 cells/cm^2) was first observed at 5-7 days in vitro (DIV); by 14 DIV, these dividing precursors formed proliferating clusters. Untreated cultures showed no such proliferation. Indirect immunocytochemistry with neuron specific enolase (NSE) and glial fibrillary acidic protein (GFAP) was utilized to identify neurons and astrocytes, respectively. At 14-21 DIV, NSE- and GFAP-immunoreactive (IR) cells were found in the proliferating core with some IR cells migrating from the centre. After 21-35 DIV, a large number of cells were GFAP-IR and stellate in appearance; many of the GFAP- and NSE-IR cells had migrated from the proliferating core. While the majority of cells were GFAP- and NSE-IR, a large number of rounded cells with multipolar morphology were negative for both markers. EGF and TGFα effects were similar, yet in TGFα-treated cultures the NSE-IR cells displayed elaborate processes and non-stellate GFAP-IR cells were present. These findings demonstrate that EGF and TGFα induce multipotential CNS precursors in vitro to produce both neurons and astrocytes.

POSTEMBRYONIC NEUROGENESIS IN THE BRAIN OF *MANDUCA SEXTA*. K.A. Sorensen, N.T. Davis, and J.G. Hildebrand. ARL Division of Neurobiology, University of Arizona, Tucson, AZ 85721.

The nervous system of insects that undergo complete metamorphosis is dramatically reorganized in the transition from larva to adult. One aspect of this reorganization is the postembryonic addition of new neurons to the embryonically derived larval nervous system by divisions of neural stem cells termed neuroblasts [*Wilhelm Roux' Arch.* **164**:247 (1970); *J. Comp. Neurol.* 255:548 (1987); *Dev. Biol.* 125:145 (1988)]. We are studying the origins of the neurons of the primary olfactory center, the antennal lobe (AL), in the brain of the adult sphinx moth *Manduca sexta*. To begin to determine the contribution of postembryonic neurogenesis to the formation of the AL, we used the thymidine analog 5-bromo-2'-deoxyuridine (BrdU), which selectively labels the genome of mitotic cells, to reveal proliferative neuroblasts and the time course of their appearance.

Incorporation of BrdU was achieved by feeding larvae normal diet in which BrdU had been dissolved (0.5 mg/ml). The incorporated nucleotide was then visualized at successive stages of development by means of whole-mount immunocytochemistry employing anti-BrdU antibody and PAP. Scattered neuroblasts were first detected at mid-first instar, with successive increases in the level of staining over the course of the remaining stadia. Labeling is seen first in the brain and subsequently in the subesophageal ganglion and segmental ganglia, developing in an apparently anterior-to-posterior temporal gradient. Staining appears in all ganglia by the beginning of the second larval instar. Whole-mount preparations reveal 3-7 putative neuroblasts that lie close to the larval antennal center and thus may contribute to its metamorphosis into the adult AL. We will use sectioned preparations and cell lineage tracing techniques to ascertain cellular relationships and fates.

NEUROGENESIS OF THE AMYGDALOID COMPLEX IN THE RHESUS MONKEY. P. Piescinski*1,J.H. Kordower1, P. Rakic2,. 1Dept. of Anatomy and Cell Biology, Univ. Illinois Sch. Med.Chicago Ill. 60612; 2Section of Neuroanatomy, Yale Sch. Med. New Haven Ct. 06510, USA.

The present experiment assessed the developmental window during which neurogenesis of the amygdaloid complex takes place in the fetal primate brain. Nine pregnant rhesus monkeys received an injection of tritiated thymidine between embryonic [E] days 27 and E56 of their 165 day gestation. Offspring were sacrificed in the postnatal period and 8 μm coronal brain sections were processed for autoradiography and counterstained with toluidine blue [Rakic, *Science* 183: 425, 1974].

No radiolabeled neurons are present within any amygdaloid nuclei on E27. A few labeled neurons were observed in the case exposed to tritiated thymidine on E30 making the amygdala, concomitant with the magnocellular basal forebrain nuclei, the earliest developing structure in the telencephalon. At E33, significant labelling was principally located within the central and medial amygdaloid nuclei. A few heavily labeled neurons were present within the lateral nuclear groups as well. Significant neurogenesis occurs for all amygdaloid nuclei by E38 with a peak neurogenesis at E43. There are significantly fewer heavily labeled neurons by E48 and neurogenesis is complete by E56. Thus, all neurons that comprise the amygdaloid nuclei are generated within the first third of gestation. Although a pronounced dorsal to ventral gradient of neurogenesis was observed, the counterclockwise rotation of the amygdala, which begins during the second trimester of morphogenesis, suggests that the actual pattern of cellular development occurs across a medial to lateral gradient. [AHAF, NS 25655; JHK, NS 14841 PR].

CELL CYCLE KINETICS OF THE E14 MURINE CEREBRAL VENTRICULAR ZONE: ESTIMATES BASED UPON S-PHASE LABELING WITH BUdR. T. Takahashi, M. Jacobson*, R. S. Nowakowski and V. S. Caviness, Jr. Dept. of Neurology, Mass General Hospital, Boston, MA 02114 and Dept. of Neuroscience and Cell Biology, UMDNJ-Robert Wood Johnson Medical School, Piscataway, NJ 08854.

Proliferating cells in S-phase in the cerebral ventricular zone (VZ) of E14 mouse embryos (E0 = day of conception) were labeled cumulatively in utero with BUdR over 12.5 hours. Embryos were harvested at 0.5, 2.0, 3.5, 6.5, 8.0, 9.5 and 12.5 hr following the initiation of labeling. After immersion and overnight fixation in 70% ethanol, the brains were embedded in paraffin, sectioned at 4 μm in the coronal plane, stained immunohistochemically for BUdR and counterstained with basic fuchsin. Labeled and unlabeled nuclei were counted in the dorsal cerebral wall within a 100 μm wide sector of the VZ. The labeling index (LI = labeled/total population) for the VZ increased approximately linearly from a 0.5 hr value of 0.25 (extrapolated to 0.2 at T0) to 1.0 after an estimated interval of 10.9 hr. The growth fraction is thus 100%, which means that all cells of the VZ are proliferating. The linear increase in LI implies that there is only a single proliferative population. A maximum value for the length of the overall cell cycle (Tc) is computed to be 13.6 and S-phase (Ts) 2.7 hr. Since labeled mitoses were observed 2.0 hr after the initiation of labeling, the approximate length for the G2+1/2 M phases was estimated to be 2.0 hr. With the exception of Ts, these values fall within ranges estimated by cumulative ^{3}H-thymidine labeling in rat embryos of comparable age (E16) by Waechter and Jaensch (*Brain Res.* 46: 235-250,1972): Tc = 12.8 - 16.5 hr, Ts = 6.6 hr, T_{G2+M} = 2.5 hr. Among the considerations that might explain the Ts disparity are a substantial underestimation of the numbers of unlabeled nuclei with the ^{3}H-thymidine labeling method or the possibility that the ^{3}H-thymidine had been available to label S-phase cells for a time substantially longer than a few minute "pulse." It may also be due to differences between the two species.

DIFFERENTIATION OF ONCOGENICALLY ALTERED CHICK NEURORETINAL CELLS BY SUCCINYLATED CONCANAVALIN A. G.M. Seigel and M.F.D. Notter, Department of Neurobiology and Anatomy, University of Rochester Medical School, Rochester NY 14642.

The orderly course of chick retinal cell differentiation was disrupted *in vitro* by infection with a temperature-sensitive mutant of Rous sarcoma virus (LA29). The result was a continuous retinal cell culture (LA29NR) which remained mitotically active at 42°C, yet rapidly adopted a transformed phenotype upon activation of the pp60src oncogene product at 37°C. As further indication of proliferation, LA29NR cells expressed the proto-oncogene c-fos equally at 42°C and 37°C, as shown by immunocytochemistry and western blot analysis.

Highly proliferative LA29NR cells proved refractory to standard differentiating agents such as cAMP, prostaglandin E1, and retinoic acid. In our novel approach, Succinylated Concanavalin A (SCA), a non-toxic derivative of the lectin Concanavalin A, induced dramatic, reversible morphological changes in LA29NR, including neurite outgrowth and increased cell-to-cell adhesion. SCA also effectively inhibited the growth of LA29NR as evidenced by a massive reduction in tritiated thymidine incorporation.

Since there is a precedent for modulation of proto-oncogene expression during SCA-induced growth inhibition of virally transformed fibroblasts, we currently are assessing the status of v-src and c-fos proteins during SCA-induced differentiation of LA29NR cells.

A VASOPRESSIN AND OXYTOCIN CONTAINING NUCLEUS IN THE PIG HYPOTHALAMUS THAT SHOWS AN INCREASE IN NEURON NUMBER DURING PUBERTY. F.J.C.M. van Eerdenburg*, P. Poot*, G.J. Molenaar, F. van Leeuwen and D.F. Swaab*. Dept. Functional Morfology, Faculty of Veterinary Science University of Utrecht, Yalelaan 1, 3508 TD Utrecht, The Netherlands.

The hypothalamus has been studied in the pig since the timing of its brain growth spurt in relation to birth and gonadal steroid levels would be comparable to that of human beings. In the present paper the results of a morphometric and immunocytochemical study of a vasopressin and oxytocin containing nucleus in the pig hypothalamus are presented. This nucleus has not been described before. Neuron numbers and volumes were measured at four different ages i.e. 1 day, 7 weeks, 16 weeks and 30 weeks post natally with a computer assisted method. There were no sex differences found at any of the ages studied. At birth an average of 1200 neurons is found, in the first 7 weeks post natally the number decreased to 770. A striking finding was that between 16 and 30 weeks (i.e. during puberty) an increase from 700 to 1800 (260%) neurons is seen. Immunocytochemistry (antibodies were a gift from Dr. A. Hou-Yu, Columbia University, New York) revealed vasopressin and oxytocin immunoreactive neurons. This increase in the number of vasopressin and oxytocin containing neurons in the pig hypothalamus is much later in development than has been reported so far.

474.8

A MOUSE HYPOTHALAMIC CELL LINE (V1) IMMORTALIZED WITH A TEMPERATURE SENSITIVE LARGE T ANTIGEN. **V. Quinones-Jenab, S. Choi-Kwon, S. Farinelli, S. Jenab*, I. Terleckyj, and H. M. Geller, Department of Pharmacology, UMDNJ-Robert Wood Johnson Medical School and Rutgers University, Piscataway, NJ 08854.**

Dissociated cells from embryonic day 14 mouse hypothalamus were infected with a retroviral construct containing the tsa58 variant of the large T antigen of SV40 and the neo gene (Cepko et. al., Cell 37:1053). Southern blotting and single cell cloning techniques demonstrated that the V1 cells are clonal in origin. This cell line gives rise to flat, GFAP+ astrocyte-like cells **and** round neuronal-like cells which express neurofilament protein. Following single cloning experiments both morphologies appeared, suggesting that we have immortalized a multipotential cell. Flow cytometric analysis indicates that the flat cells express typical glial markers including: NCAM, thrombospondin, and tenascin/cytotactin. These cells have low glutamine synthetase activity, but they express both monoamine oxidase (MAO) A and B. The MAO-A activity increased at 39°C. Levels of these cell specific markers varied between permissive (33°C) and restrictive (39°C) temperatures. The neuronal-like cells developed an inward current after switching to 39°C (see Phelan et al.). All of these data suggest that V1 cells are capable of differentiation after oncogene inactivation, suggesting that these cells can be used as a model to study neuronal and glial differentiation.

USE OF PCR TO IDENTIFY PRE- AND PERINATAL LETHAL MUTANTS: APPLICATION TO HOMOZYGOUS LURCHER MICE. J. M. Soha and K. Herrup. E.K. Shriver Center, Waltham, MA 02254.

Lurcher is an autosomal dominant mutation located on chromosome 6 of the mouse. Heterozygote (+/*Lc*) animals become ataxic during the first postnatal month in association with the loss of 100% of their cerebellar Purkinje cells as well as other presynaptic neurons. The homozygote condition (*Lc*/*Lc*) has never been described and is presumed to be a pre- or perinatal lethal. To identify *Lc*/*Lc* embryos and, later, *Lc*/*Lc* ↔ +/+ chimeras, a molecular assay has been developed. C57BL/6 and AKR/J mice exhibit a HinFI restriction fragment length polymorphism in the Ig-J_K locus about 2 centiMorgans from the *Lc* locus. AKR/J males were crossed with C57BL/6-+/*Lc* females and the F1 +/*Lc* mice were intercrossed. In the resulting F2 generation, PCR amplification of a 820 bp fragment around the HinFI site, followed by HinFI digestion, lead to a positive identification of any fetus or newborn pup (with about 96% certainty). Homozygous (*Lc*/*Lc*) animals have only the C57BL/6 form of the polymorphism, wild type (+/+) have only the AKR/J form, while heterozygous (+/*Lc*) animals have both.

At E18, *Lc*/*Lc* embryos identified by this method exhibit cerebella that are clearly smaller in cross-section in both the sagittal and coronal planes compared to either +/*Lc* or wild type embryos. Cerebellar volume is decreased by about 40%. Development of folia is also severely retarded. In addition, a greater incidence of pycnotic profiles is seen among cells of the cortical plate in the *Lc*/*Lc* embryos.

474.10

ROLE OF ELECTRICAL ACTIVITY IN THE DEVELOPMENT AND SURVIVAL OF CULTURED HYPOTHALAMIC NEURONS. D.S.F. Ling, R.E. Petroski, and H.M. Geller. Departments of Pharmacology and Biomedical Engineering, UMDNJ-Robert Wood Johnson Medical School and Rutgers University, Piscataway, NJ 08854.

Hypothalamic neurons exhibit a gradual, consistent increase in spontaneous action potential discharge in long-term culture. To examine the role of electrical activity on neuronal bioelectrical development and survival, we have examined the effects of tetrodotoxin (TTX) and high KCl on cultured hypothalamic cells.

Dissociated neurons from E17 rat hypothalami were plated onto a layer of cortical astrocytes in either microwell trays or on glass coverslips. Starting at 1 day *in vitro*, cultures were treated with TTX and/or high KCl. Neuronal survival was assessed by counting cells on an inverted phase microscope. The development of spontaneous action potentials was examined using an extracellular loose patch recording technique. Cell counting and electrophysiological experiments revealed that TTX caused a marked reduction in both cell survival and the percentage of spontaneously active cells as compared to controls. Concurrent treatment with high KCl inhibits the deleterious effects of TTX on cell survival and the development of spontaneous activity.

When taken together, the results of these experiments suggest that the suppression of electrical activity selectively increases the death of spontaneously active hypothalamic neurons and that the long-term survival of spontaneously active cells may depend on continual membrane depolarization. (Supported by NIH NS 25168)

474.11

SELECTIVE DEGENERATION OF LARVAL THORACIC MUSCLE BY KILLER-CELLS DURING METAMORPHOSIS IN DROSOPHILA. W.J. Costello. Basic Sciences/COM & Dept. Zool./Biomed. Sci., Ohio University, Athens, OH 45701.

Holometabolous insects must undergo complete reorganization to change from larval form to adult form. Hormone release, temporally and quantitatively, plays an integral role in controlling this complex process. Larval muscles and neurons respond to varying levels of specific hormones; degeneration of these tissues occurs in response via programmed cell death. I have observed a large (6X13 um), unique cell type appearing in the thoracic region during early metamorphosis in Drosophila which plays a role in muscle degeneration. These cells become prevalent in the early prepupa (5h), first appearing at ventral sites and then migrating dorsally along body wall muscles. Each cell attaches to a muscle prior to any sign of degeneration in the muscle itself. Subsequently, the cell extends processes into the muscle and degeneration of the muscle rapidly results. This event occurs progressively from the prothoracic region to the metathoracic region. The migration of these cells to the muscles happens through an active identification process. Although most thoracic bodywall muscles are attacked by the "killer-cells", a few adjacent muscles lack the cells. These persistent muscles serve as substrates for adult myocytes which will form the adult indirect flight muscles.

Such "killer-cells" appear to be another important factor in programmed cell death of muscles during metamorphosis. Their ability to avoid selectively the persistent larval muscles implies a recognition process by these cells. The basis of this selection and the hormonal control of these cells' activity are being studied.

475.1

MARKERS OF NEURONAL MATURATION IN NEUROBLASTOMA CELLS TREATED WITH NEOCARZINOSTATIN. N. F. Schor, M. R. Gilbert*, J. Lowengrub*, and C. F. Lagenaur, Children's Hospital of Pittsburgh, Pittsburgh, PA. 15213, The Johns Hopkins Hospital, Baltimore, MD. 21205, and University of Pittsburgh, Pittsburgh, PA. 15261

Treatment of murine neuroblastoma cells with the antineoplastic natural product neocarzinostatin results in morphologic differentiation. The cells extend processes, stop dividing, and, unlike their "immortal" untreated counterparts, die after 14 days in culture. We have looked at these cells for the presence of several known chemical markers of neuronal maturation to better define the effects of neocarzinostatin upon them. Cells treated with neocarzinostatin for 1 hour on day 0 express nerve cell adhesion molecule (N-CAM) by day 3 in culture, as shown by bright cell surface staining with fluorescent polyclonal antibodies to N-CAM; untreated cells do not stain for N-CAM. Staining with antibodies directed against L-1 or HNK-1 demonstrates no change in these antigens upon treatment of neuroblastoma cells with neocarzinostatin. Both L1 and HNK-1 are cell adhesion molecules which share a common carbohydrate epitope with N-CAM. Electron microscopy, histochemical staining, and Northern blotting indicate that neurofilaments are not present in treated or untreated cells. No change in the amount of mRNA for GAP 43 is found by Northern blotting at 24, 48, 72, or 96 hours after treatment of neuroblastoma cells with neocarzinostatin; this protein is normally associated with axonal outgrowth. These studies suggest that the processes extended by neuroblastoma cells are not normal axons, and that the morphologic differentiation induced by neocarzinostatin is not indicative of "normalization" of neuroblastoma cells.

IMMORTAL CELL LINES FROM EMBRYONIC RAT HIPPOCAMPAL PRECURSOR CELLS . E.M.Eves[1], H.J.Lee[3], M.S.Tucker[1], M.R. Rosner*[1] and B.H. Wainer[1,2,3]. Depts.[1]Pharm. & Phys. Sci., [2]Path. and [3]Comm. on Neurobio., The University of Chicago, Chicago, IL 60637.

Temperature-sensitive alleles of the SV-40 large T-antigen have been used to immortalize hippocampal cells from embryonic day 17 (E17) and E18 rats. The resultant cell lines proliferate at the permissive temperature (33°); at the non-permissive temperature (39°) proliferation ceases and the cells undergo morphological changes. A lowered concentration of fetal calf serum (1%) at 39° induces the formation of cellular processes in many of the lines; in some, these appear neuritic and this morphological differentiation is potentiated by phorbol ester. Immunostaining for neurofilament proteins (NFP) and glial fibrillary acidic protein (GFAP) reveals several phenotypes. Of 12 lines examined, 7 are NFP+ GFAP-, 2 are NFP- GFAP+, and 3 have both NFP+ and GFAP+ cells indicating that the immortalized lines include progenitor types not yet committed to a neuronal or a glial pathway, as well as already committed cells. Microtubule-associated protein 2 (MAP2) and growth-associated protein (GAP43) have been visualized by immunostaining in several NFP+ lines. The former has been reported to be present in the dendrites and the latter in the axons of mature neurons. In developing neurons both are distributed throughout the cell. In our cell lines these markers tend to be assymetrically distributed in the perinuclear region except in the most differentiated (by morphology) cells. Since the proportion of cells undergoing morphological differentiation and the combinations of the listed markers vary from line to line it is likely that we have immortalized several distinct types of hippocampal precursor cells. (Supported by NS-25787 and the Alzheimer's Disease and Related Diseases Assn.)

475.3

EXPRESSION OF EPIDERMAL GROWTH FACTOR RECEPTOR IN IMMORTALIZED RAT HIPPOCAMPAL CELL LINES. M.S. Tucker[1], E.M. Eves[1], X.Y. Hou[2*], B.H. Wainer[1,3,4], and M.R. Rosner[1*]. Depts. [1]Pharm. & Phys. Sci., [2]Mol. Gen. & Cell Bio., [3]Path. and [4]Comm. on Neurobiology, The University of Chicago, Chicago, IL 60637.

Epidermal growth factor (EGF) is a potent mitogen for fibroblast and epithelial cells. In order to characterize the EGF receptor in a nonproliferating cell system, we utilized hippocampal cell lines capable of terminal differentiation. We had previously shown expression of EGF receptor in primary hippocampal cultures by immunostaining. After cell line differentiation, serum failed to stimulate DNA synthesis, although the retraction of cell processes was observed. We screened several of the cell lines for EGF receptor by binding EGF before and after differentiation. One line, WH19-4, exhibited a 20-fold decrease in binding activity while another line, H19-7, increased its binding activity 8-fold after differentiation. Experiments in which these two cell lines were transfected with the EGF receptor promoter suggest that the changes in EGF receptor binding result from changes in receptor transcription. Thus, these two hippocampal cell lines provide powerful tools for studying both positive and negative regulation of growth factor receptor transcription during hippocampal cell development, as well as allowing us to investigate nonmitogenic cell signalling pathways by the EGF receptor tyrosine kinase. CELLULAR INTERACTIONS BETWEEN SCHWANN CELLS AND PC12 CELLS *IN VITRO*. J.-H. Tao-Cheng, O. Okuda*, D. L. Simpson*, L. Chang* and M. W. Brightman, Lab. of Neurobiology, NINDS/NIH, Bethesda, MD

A rat pheochromocytoma cell line, PC12, was co-cultured with dissociated Schwann cells (SC) from sciatic nerves of 2 day old rats. SC were usually seeded first. They were spindle shaped and formed clusters of closely spaced cell bodies with processes radiating outward. Naive PC12 cells, when added, randomly settled initially, then gradually migrated toward the clusters of SC. By 3-4 days, 60-80% of the PC12 cells were aggregated on top of the SC. Differentiated PC12 cells, e. g., nerve growth factor NGF-primed or K-ras virus infected, exhibited this affinity toward SC even earlier: by 24-36 hrs in co-culture. There was no aggregation of PC12 cells over contaminating fibroblasts in the SC preparations, or over other types of control cells, such as astrocytes, brain and aortic endothelial cells. The close PC12-SC association consisted of PC12 cells stacked, sometimes 5-8 cells deep, on top of SC. Ultrastructurally, in solo SC cultures, the cells usually contained many more intermediate filaments (IF) than did SC *in vivo*. Sometimes, the IF were packed in crystalline form in the cell body. Microtubules were prominent in the cell processes. In co-culture with PC12 cells, some SC underwent differentiation: an increase of rough endoplasmic reticulum, a decrease of intermediate filaments and ensheathment of PC12 neurites by flat SC processes. The wrapping of PC12 neurites by sciatic nerve SC is in contrast to the report of non-ensheathment by SC from dorsal root ganglia. Conversely, both SC and SC derived extracellular matrix supported neurite extension from PC12 cells. Theses neurites contained abundant microtubules, dense core granules (100 nm) and small, clear vesicles (50 nm). In these co-cultures, the production of choline acetyltransferase, assessed biochemically, increased by 50-100% while that of acetylcholinesterase was largely unchanged.

CHARACTERIZATION OF BI-LAMINAR CULTURES FROM E16 RAT SEPTUM. J.D. Zucker, M.V. Jones, N.L. Harrison, H.J. Lee, J.D. Roback and B.H. Wainer. University of Chicago, Chicago, IL 60637.

The bi-laminar culture system, developed by Banker and Cowan in the hippocampus, allows for isolation of pure neurons at low density and selective enrichment for neuronal sub-populations depending on age of embryonic tissue. In the current study, such cultures derived from E16 rat septum have been established and partially characterized. Glia derived from P2-P3 rat cortices are grown to confluence in 30-65mm culture wells. E16 rat septal cells are then plated at low density (approx. $5000/cm^2$) on coated glass coverslips which are inverted and supported less than one millimeter above the glial plane by paraplast "feet". The cultures are treated with an antimitotic agent at day 4 to inhibit glial growth, and maintained for up to five weeks in N2.1 medium (serum-free). The cultures have been characterized with respect to cytoskeletal and neurochemical markers. In the glial plane, greater than 99% of cells stain positively for the glial marker glial fibrillary acidic protein (GFAP), with occasional neurons expressing neurofilament proteins (NFP). Conversely, in the neuronal plane, over 99% of the cells stain positively for NFP. Staining for growth associated protein GAP-43 and microtubule associated protein MAP-2 reveals neuritic specialization into axons and dendrites. Immunostaining for the neurochemical markers choline acetyl-transferase (ChAT), g-aminobutyric acid (GABA), and nerve growth factor receptor (NGFr) was performed on cultures grown in the presence or absence of NGF. In cultures grown in the absence of NGF, the proportion of ChAT-positive cells is less than 1%, while 65±4% stain for GABA and 24±9% stain for the NGF receptor. When cultured in the presence of 100 ng/ml NGF, the number of ChAT-positive cells increases significantly to 11±8%, while GABA and NGFr staining remains unchanged. There is no discernable effect of NGF on morphology or cell survival. The bi-laminar system shows a greater proportion of ChAT-positive cells than previously described monolayer culture systems in the presence of NGF. This initial study provides a baseline neurochemical characterization of E16 septal cultures in the presence and absence of NGF, against which both other time points and other trophic factors may be compared (Supported by NS 25787).

475.6

COMPARISON OF TOTAL CELL PROTEIN PRODUCTION IN ORGANOTYPIC CULTURES FROM MOUSE SPINAL CORD WITH THAT IN INTACT MICE H. L. Stewart, J. A. Birk*, N. A. Mills* and M. H. Droge, Dept. of Biology, Texas Woman's Univ., Denton TX 76204.

The goal of our research is to establish an in vitro mammalian spinal preparation suitable for investigating the mechanisms underlying motor pattern generation. One model system currently under investigation involves organotypic cultures from 300 µm transverse sections of neonatal mouse lumbar spinal tissue. To ascertain relative developmental and maturational indices between the cultured tissue and that of intact mice at similar postnatal ages, the current study compares morphology and total cell protein production in both preparations.

Lumbar spinal tissue obtained from neonatal mice was sliced and established in roller drum culture; fresh, noncultured tissue was similarly obtained and sliced. At similar postnatal intervals, samples from each group were incubated in medium containing ^{35}S-methionine and ^{3}H-thymidine and examined for 1) precipitable counts via scintillation counting, and 2) protein patterns from electrophoresis. Cultured and fresh tissue were stained for identification of cholinergic neurons at day 0 (day of culturing), three weeks, and five weeks. Preliminary data indicate that the total cell protein profile reflects the changes seen in size and density of cholinergic neurons at the sampled intervals tested. (Supported by NIH1R29 NS 25250-01)

475.7

DIFFERENTIAL MODULATION OF PROTEIN KINASE C ISOZYMES IN DIFFERENTIATION OF PC12H CELLS STIMULATED BY DIBUTYRYL C-AMP. S. Shimohama, Y.U. Kunugi*, H. Tamura*, T.Taniguchi*,H.Ninomiya*,J. Kimura* and T. Saitoh. Dept.of Neurology, Kyoto Univ. Sch. of Med.,Dept. of Neurobiology, Kyoto Pharmaceutical Univ., Kyoto 606, Japan., Dept. of Neurosciences, Univ. of California, San Diego, La Jolla, CA 92093,USA.

PKC is a family of closely related enzymes, and the role of each PKC isozyme remains unknown. Rat pheochromocytoma PC12 cells can be induced to differentiate into cells with typical neuronal morphology by a number of substrates, however, the molecular mechanisms are not clear. To clarify the different functional role of each isozyme, we examined the differential modulation of four types of isozymes in the differentiation of PC12h cells by using immunoblotting analyses. We have employed four anti-PKC antisera raised against C-terminal variable region of PKC(α),(βI),(βII), and (γ). Two types of PKC isozymes, α and βII were predominantly detected in PC12h cells. When exposed to 1mM dibutyryl cAMP, PC12h cells clearly began to exhibit the neurite outgrowth at around 30 min. In this stage, neurites looked narrow and unstable. After 24 hours, these neurites became much stable and wide ribbon-like shapes. When immunoblotting was carried out for the homogenates of dibutyryl cAMP-stimulated PC12h cells, we found the prompt and temporary accumulation of PKC(α), whereas the accumulation of PKC(βII) was prolonged for nearly 24 hours following the addition of dibutyryl cAMP. These results suggest that PKC(α) and PKC(βII) may be involved in different cellular processes and regulate the specialized physiological responses in the differentiation of PC12h cells and that concerted action between protein kinase C and cAMP-dependent protein kinase systems may work on the differentiation process of PC12h cells.

475.8

SURVIVAL AND DIFFERENTIATION OF PURIFIED PURKINJE CELLS FROM MOUSE CEREBELLUM C.A. Baptista, M.E. Hatten, and C.A. Mason, Dept. Pathology, College of Physicians and Surgeons, Columbia University, New York, N.Y. 10032

In our studies of axon-target interactions *in vitro* (Baird et al., this volume), we have shown that purified cerebellar granule neurons specifically signal their appropriate afferents, the pontine mossy fibers, to stop growing. To examine afferent growth cone behavior and interactions with Purkinje cells, we have developed affinity methods to purify this cell population. Because Purkinje cells are relatively more numerous in fetal life, we dissociated cerebellum from E15-18 and immunoabsorbed Purkinje cells to plastic dishes previously coated with antibodies against Thy 1.2. Cells were subsequently replated on polylysine-coated dishes. The purity was assessed with an antibody to calbindin (gift of S. Christakos), which is specific for Purkinje cells. Although the yield of Purkinje cells was very high with this method, neurite outgrowth and cell polarity were impaired, and survival was limited to 1-2 days. In contrast, in the presence of glial cells and other neurons, Purkinje cells survived for up to two weeks, and developed long axons and elaborated characteristic dendrites. Studies are in progress to identify the factors (substrates, growth factors, and surface molecules) critical to the survival and differentiation of purified Purkinje cells. This culture system will in turn allow us to test the specificity of axon-target interactions, and the effect of olivary (climbing fiber) afferents on Purkinje cell morphogenesis. Supported by NS 16951.

BUBBLE-LIKE MINISPHERES OF AVIAN EMBRYONIC NEUROEPITHELIUM: A MODEL FOR STUDYING FLUID TRANSPORT. M. E. Desmond and M.C. Field*. Department of Biology, Villanova University, Villanova, PA 19085.

To date, it is unknown when the neuroepithelium (NE) first becomes secretory in the vertebrate embryo and whether this capability to secrete is ubiquitous initially to all three primary brain vesicles. A method has been devised to culture the primary brain vesicles along with their associated head mesenchyme and skin ectoderm (SE). Embryonic brain explants were cultured in mini-wells containing either Hanks BSS or BSS plus bovine fetal calf serum plus antibiotics. From a total of 224 explants cultured in BSS and 71 explants in enriched medium, it is concluded that fluid -filled mini-spheres form from both SE and NE; these mini-spheres appear identical irrespective of embryonic brain origin; the size of the mini-sphere formed depends on the size of the brain vesicle explant; SE explants form mini-spheres 24-48 hrs earlier than neuroepithelial explants; and mini-spheres form preferentially in enriched medium. In order to clearly distinguish between NE and SE explants, blastodiscs of 70 embryos of neural plate stages (HH stages 4-9) were treated for 20 min at 4^{0} C in 1% crude trypsin, rinsed in 5 washes of BSS, 5 min each and then microsurgically manipulated to separate the neural plate from the skin ectoderm. From nineteen preliminary SE and NE explants cultured in enriched medium, 79% of the SE (after 18-24 hrs) and 32% of the NE explants (after 72 hrs) formed mini-spheres. (Supported by NIH grant No. HD24710).

DIFFERENTIATION, MORPHOGENESIS AND DEVELOPMENT: FOREBRAIN

476.1

PROTO-ONCOGENE PROTEIN EXPRESSION DURING MOUSE BRAIN DEVELOPMENT. J.B. Hutchins. Department of Anatomy, University of Mississippi Medical Center, Jackson, MS 39216-4505.

Proto-oncogenes and their protein products are believed to play a key role in mammalian development. Proteins transcribed from proto-oncogenes are known to regulate the expression of numerous genes, and by this mechanism they may determine a cell's fate.

The pattern of expression of the growth factor PDGF (which can exist in AA, AB or BB dimeric forms) as well as the proto-oncogene proteins Myc and Sis (homologous to platelet-derived growth factor B chain, $PDGF_B$) were studied during prenatal mouse CNS development (embryonic days 10 through 16, E10-E16). All three proteins have been implicated in control of CNS cell lineage.

Expression of PDGF-like immunoreactivity has begun by the earliest time point studied (E10 spinal cord, E12 retina). Long, thin, spike-like processes extend out from these labeled cells in both regions. However, in pros-, mes- and rhombencephalon, $PDGF^+$ cells are still round and clustered in the ventricular zone. Later, $PDGF^+$ cells in all three encephalic regions take on a more differentiated appearance. No appreciable PDGF immunoreactivity is seen in the brain of juvenile or adult animals.

Myc-like immunoreactivity in the developing CNS is not seen until about E15. In the E15 retina, Myc^+ nuclei cluster in the developing ganglion cell layer, near the vitreal surface. No Myc^+ cells are seen in the presumptive outer layers of the retina. Myc^+ nuclei are scattered throughout the spinal cord at E16 in an apparent random distribution.

The pattern of Sis-like immunoreactivity is similar to that of Myc in both time course and distribution. The distribution of Sis^+ cells is strikingly different from cells labeled with the antibody to PDGF. The specificity of the PDGF antiserum is still being explored, but may reveal interesting disparities between the localization of Sis/$PDGF_B$ and the putative distribution of AA or AB dimers. A ROLE FOR Ic IN REGULATING ACTION POTENTIAL DURATION IN HIPPOCAMPAL NEONATAL NEURONS OF RABBIT. J.V. Sanchez-Andres and D.L.Alkon. Laboratory of Molecular & Cellular Neurobiology, NIH, Bethesda, MD 20892.

Duration of the action potentials (AP) in CA1 cells of hippocampus in developing cats is prolonged when compared with adults. This effect has been attributed to the slower rate of repolarization (Purpura et al. 1968). Schwartzkroin (1982) confirmed this observation in newborn rabbits, and observed that the APs showed a duration similar to that of adult cells by about day 8 post partum. Furthermore, Storm (1988) proposed that the last two thirds of the AP repolarization phase are generated by Ic in CA1 neurones.From the above, we propose that Ic is incompletely developed at birth and that this contributes to the long AP duration. We recorded both Ic and I_{AHP} (Ca^{2+} dep-K^+ currents) in CA1 neurones from newborn (1st-8th days after birth) and adult rabbits using a single electrode voltage-clamp (SEVC) method. Semilogarithmic I-V curves for the net Ic current values at the steady state, closely fit straight lines (regression coeff.:M±SE:adult, .98±.01; newborn, .96±.01). The slope values for the neonates were clearly reduced (M±SEx10^{-2}:4.06±.29, n=16) compared with the adults (5.83±.50, n=18), ($p<0.01$, unpaired, two tailed t test). The rising phase of I_{AHP}, usually unobservable in adults, was clear in the neonates, although there were not significant differences in I_{AHP} amplitudes.

These data a) suggest that a small Ic is responsible for the longer duration of the AP in neonates, b) raise the possibility that neonatal CA1 K+ currents are not yet affected by learning-induced reductions as previously demonstrated for adults (Coulter et al., 1988; Sanchez-Andres and Alkon, 1989).

DEVELOPMENT OF BASAL FOREBRAIN CHOLINERGIC PROJECTIONS TO CEREBRAL CORTEX: ACHE HISTOCHEMICAL STUDIES IN RATS AND HAMSTERS. R.T. Robertson, G.H. Kageyama, K.A. Gallardo* and J. Yu. Departments of Anatomy and Neurobiology and Physical Medicine and Rehabilitation, College of Medicine, University of California, Irvine, CA 92717.

The structure and function of basal forebrain cholinergic systems have attracted a great deal of attention in recent years, but development of these projections is not well understood. We are studying development of basal forebrain projections to cerebral cortex by AChE histochemical techniques.

Normal rat and hamster pups from postnatal day 0 (P0) to P14 were deeply anesthetized and sacrificed by vascular perfusion with aldehydes. Frozen sections cut in the transverse, parasagittal, tangential, or oblique planes were processed for AChE histochemistry, using the techniques of Tago et al (1986) or Koelle and Friedenwald (1949). Adjacent sections were Nissl stained.

AChE-positive axons destined for cerebral cortex appear to travel along either medial or lateral routes. AChE-positive axons traveling the medial route pass rostrally and dorsally from the nucleus of the diagonal band, coursing around or through the genu of the corpus callosum, to reach the cingulate bundle and supracallosal stria. Axons traveling laterally pass from the substantia innominata and medial globus pallidus to gain access to the subcortical white matter. AChE-positive axons can be seen leaving the basal forebrain region by both routes in P0 rats and hamsters. Large numbers of these axons appear to reach the deep layers of frontal cortex by P0, but only a very few have reached the occipital pole by this time. AChE-positive axons appear first in deeper layers of cortex, and grow into more superfical layers as these layers differentiate from the cell dense cortical plate. AChE-positive axons appear to grow very rapidly, and assume adult-like areal and laminar distributions by the third postnatal week.

Subplate Cortical Neurons of the Rat: Studies *in vivo & in vitro*. Casey M. Annis, Glenn H. Kageyama, Richard T. Robertson and Jen Yu, Depts. of Anatomy & Neurobiology and Physical Medicine and Rehabilitation, College of Medicine, University of Calif., Irvine, Ca., 92717.

The subplate region of the developing cerebral cortex is believed to play a crucial role in the development of the cortical plate. We report here a broad characterization of the subplate region of the rat, both *in vivo* and *in vitro*. Immunocytochemical, histochemical and (^{3}H)-thymidine autoradiography techniques were used to analyze the development of the subplate region in frozen sections and in organotypic slice cultures (Annis et al., '90) of fetal & newborn rat pups of varying age (E19-P14). (^{3}H)-thymidine autoradiography, in sections of parieto-occiptal cortex, indicates that subplate neurons in the rat are born between E13-14 and an identifiable subplate zone can be detected up to adulthood. Immunocytochemistry with antibodies against GABA, NPY, Somatostatin, and VIP indicate that populations of subplate neurons both *in vivo & in vitro* stain positively with these antisera. Histochemical data indicate that a population of subplate neurons also stain strongly for acetylcholinesterase, *in vivo & in vitro* . These cells are horizontally or vertically oriented bipolar & multipolar neurons. A subpopulation of these AChE positive neurons demonstrate pseudopyramidal morphologies. Comparison of these data with those obtained by other investigators in cat and primate indicate strong similarities between the subplate neurons of the rat and those of other mammals.

Supported by NSF grant 87-08515 and NIH grant NS 25674.

476.5

DEVELOPMENT OF NEUROARCHITECTURE AND SENSITIVITY TO EAA NEUROTOXICITY IN CULTURED HUMAN CEREBRAL CORTICAL NEURONS. B. Rychlik, J.-S. You*, J. E. Sisken* and M. P. Mattson. Center on Aging, Depts. of Anatomy & Neurobiology, Immunology & Microbiology, Univ. of Kentucky, Lexington, 40536.

The development and aging of the human cerebral cortex occurs over a time period greatly prolonged when compared with that of the most commonly studied laboratory animals. In addition, the human brain is vulnerable to developmental (e.g., Downs syndrome) and age-associated (e.g., Alzheimer's) disorders not evident in lower species. We have initiated experiments aimed at understanding the cellular and molecular bases for such species-specific differences. Low density cell cultures of fetal human and rat cerebral cortex were established and maintained under identical conditions. Neurons in the human cultures extended axons at a much slower rate, and lived much longer than did rat neurons. Culture medium exchange experiments indicated that these differences were probably not due to cell-derived factors released into the culture medium. In human neurons, excitatory amino acids (EAAs) elicited calcium responses in a supopulation of neurons at 2 weeks in culture and by 35 days EAA neurotoxicity occurred. Responses to EAAs developed much more rapidly (within 6 days) in the rat neurons. Perturbations of calcium homeostasis demonstrated a superior calcium buffering ability in the human neurons. The slower development and longer in vitro "life span" of the human neurons suggests that species-specific differences in brain development and aging may result from differences in the individual neurons. Further direct comparisons of neurons from long- and short-lived species may provide insight into fundamental mechanisms of neuronal growth and aging. (supported by a PSP grant and an ADRDA Faculty Scholar Award to MM).

CONNECTIVITY OF FETAL LIMBIC CORTEX TRANSPLANTED INTO NON-LIMBIC CORTEX. M.F. Barbe and P. Levitt, Medical College of Pennsylvania, 3200 Henry Ave., Phila., PA 19129.

Previous studies using a molecular marker of limbic phenotype, in combination with brain tissue transplants, has shown that there is an early critical period for irreversible commitment of developing cortical neurons to exhibit limbic features. The present study was undertaken to determine whether there is also an early specification of projection phenotypes in the limbic or neocortical transplants. Limbic (perirhinal) and nonlimbic (sensorimotor) fetal tissue was transplanted into P1 rat host perirhinal or sensorimotor cortex. Animals were sacrificed 2 weeks later and DiI crystals precipitated onto pieces of finely-pulled glass micropipettes inserted into the transplant area. The brains were incubated at 37^{o}C for 6-7 weeks. Afferent and efferent projections of homotypic and heterotypic transplants were analyzed. DiI labeling of perirhinal cortex transplanted into sensorimotor cortex retrogradely labeled limbic-associated thalamic nuclei (e.g. lateral dorsal, parafascicular), as well as normal somatosensory thalamic nuclei (e.g. VPM, VPL). In addition, DiI-labeled efferents from the transplants could be traced to similar nuclei in the thalamus. Perirhinal transplants into perirhinal regions show exclusively limbic labeling. Sensorimotor transplants into sensorimotor regions did not show any limbic projections. Experiments are in progress to examine heterotypically transplanted sensorimotor into limbic cortex. The data suggest that while molecular specification is under relatively strict regulation, phenotype as defined by projection patterns are subject to more complex environmental influences. Supported by NIH grant MH 45507.

GROSS MORPHOMETRY OF FRONTAL, PARIETAL, AND TEMPORAL CORTEX IN MONOZYGOTIC TWINS C.E. Thomas*, M.J. Tramo, W.C. Loftus*, C.H. Newton*, and M.S. Gazzaniga Program in Cognitive Neuroscience, Dartmouth-Hitchcock Medical Center, Hanover, NH 03756

We considered the role of genetic influences in the development of the cerebral cortex and regional variation therein by comparing the size and shape of the frontal, parietal, and temporal cortex of two pairs of monozygotic twins using the cortical flat-mapping technique of Jouandet et al. (J Cog Neurosci 1:88-117,1989).

All subjects were young right-handed women. Monozygosity was determined by red blood cell surface marker assays and a standardized questionnaire. Straight-line two-dimensional computer reconstructions of the unfolded cortical surface ("brainprints") were generated from thin-section T1-weighted coronal magnetic resonance images. The per cent surface area overlap of each map was determined by: 1) superimposing two maps of a given lobe aligned at the dorsomedial-most sulcus of that lobe on the brainprint (cingulate sulcus for the frontal and parietal lobes, lateral fissure for the temporal lobes); 2) tracing by hand the outer border of the superimposed maps and the region of overlap within it; 3) measuring by computerized planimetry the surface area contained within the former and the latter; and 4) calculating their per cent overlap. Maps of each lobe were paired within and across twins.

In twin pair A, left frontal, parietal, and temporal cortex showed 81%, 71%, and 79% overlap and the right 82%, 70%, and 83% overlap, respectively. In twin pair B, left frontal, parietal, and temporal cortex showed 75%, 78%, and 82% overlap and the right 79%, 71%, and 76% overlap, respectively. The mean overlap of left frontal, parietal, and temporal cortex of the unrelated twin pairings (N=4) was 82%, 71%, and 81% and of the right 75%, 67%, and 77%, respectively. The mean overlap of all pairings combined (N=12) was 79%, 70%, and 80% for frontal, parietal, and temporal cortex.

These preliminary findings raise the possibility that the gross morphometry of parietal cortex varies more than that of frontal and temporal cortex. No striking difference was observed in twin pairs versus unrelated pairs. [Supported by ONR N00014-89-J-3035 (MJT & MSG) and AFOSR-89-0437 (MSG)]

BRAINPRINTS: INTER- AND INTRA-OBSERVER RELIABILITY M.L. Jouandet, M.J. Tramo, C.E. Thomas*, C.H. Newton*, W.C. Loftus*, John B. Weaver*, and M.S. Gazzaniga Program in Cognitive Neuroscience, Dartmouth-Hitchcock Medical Center, Hanover, NH 03756 and Dept. of Radiology, The New York Hospital-Cornell Medical Center, NY, NY 10021

We recently described a new in vivo method of unfolding, mapping, and measuring the human cerebral cortex using straight-line two-dimensional computer reconstructions of magnetic resonance images (Jouandet et al. 1989; J Cog Neurosci 1:88-117). In order to consider the error inherent in our reconstruction procedures, inter- and intra-observer reliability were assessed by having four observers independently map one hemisphere and a fifth observer map one hemisphere three times.

Among the four observers, total hemisphere surface area (SA) ranged from 930-1067cm^2, frontal lobe SA 229-249cm^2, parietal lobe SA 219-249cm^2, temporal lobe SA 193-222cm^2, occipital lobe SA 132-145cm^2, and limbic/paralimbic cortical SA 134-160cm^2. As an index of inter-observer reliability, the coefficient of variation (CV) of each region of interest (ROI) SA measurement was calculated by dividing the population standard deviation by the population mean; in addition, pair-wise correlations across ROI SAs for the four observers were calculated. For total hemisphere, frontal, parietal, temporal, and occipital SA, CV was 5.4%, 3.5%, 6.4%, 2.7%, and 15%, respectively. Among the 27 ROIs, SA measurements showed the least variation in the orbitofrontal gyri and pars triangularis (3.0%) and the greatest in the superior lateral occipital gyrus (28%); ROI median CV was 9.4%. Pair-wise correlations ranged from 95.9-99.0%. CVs were also calculated to estimate intra-observer reliability. For total hemisphere, frontal, parietal, temporal, and occipital SA, CV was 2.7%, 2.1%, 3.7%, 4.4%, and 8.3%, respectively.

These results compare favorably with accuracy estimates of regional cortical SA measurements obtained using the contour method of flat-mapping post-mortem animal cortex (Van Essen and Maunsell 1980) and indicate that our brainprinting technique yields reasonably reliable estimates of regional cortical SA in vivo.

RADIAL GLIAL IMMUNOREACTIVE FIBERS IN THE REGION OF SPONTANEOUS MICRODYSGENESIS IN NEWBORN NEW ZEALAND BLACK MICE. G.F. Sherman, D.M. Press*, G.D. Rosen, and A.M. Galaburda. Department of Neurology, Harvard Medical School, and Beth Israel Hospital, Boston, MA 02215.

The New Zealand Black mouse strain (NZB) spontaneously develops severe autoimmune disease which produces premature death at about 16 months of age. In adulthood 20-40% of these mice have ectopic collections of neurons in layer I with underlying distortion of the cortical layers (Sherman et al., Acta Neuropathol., 74:239-242, 1985). These ectopic collections most likely are formed during the time of neuronal migration, which extends in the mouse from the late part of gestation to the early postnatal period. In the present study we examined newborn NZB pups with ectopias in layer I for evidence of a disturbance to radial glial fibers.

Newborn NZB pups were transcardially perfused with 4% paraformaldehyde, the brains removed and immersed overnight in paraformaldehyde. The brains were cut coronally at 30μm, every tenth section was stained with thionin, and an adjacent series was stained for radial glial fibers using Rat-401 antibody (provided by S. Hockfield). Thus far, 3 brains with ectopias have been stained.

There was aberrant organization of radial glial fibers focally in the area of the ectopias. Specifically, the external limiting membrane, which was enhanced by antibody staining, was interrupted in the area of the ectopia and it appeared as though neurons had migrated into the space created by the interruption. In addition, a slight increase in the density of radial glial staining in the cortical columns underlying the ectopia was seen. Some radial fibers extended into the space containing the ectopia and reached the overlying pia; however, most fibers stopped beneath the cell collection and seemed to be dangling. This is in contrast to those fibers at the edges of the ectopia which curved outward, as if their anchoring points had retracted as the limiting membrane space was created. Finally, a few horizontally-orientated glial fibers within the ectopia were seen.

We suggest that neurons associated with the ectopias migrate along radial glial fibers and move into a space created by an interruption in the external limiting membrane. The neurons are contained within that space by the overlying pia and the intact edges of the membrane. (Supported in part by NIH grant HD 20806.)

RADIAL GLIAL AND GFAP-IMMUNOREACTIVE FIBERS IN A REGION OF INDUCED MICRODYSGENESIS IN THE NEWBORN RAT NEOCORTEX. G.D. Rosen, D.M. Press*, G.F. Sherman, and A.M.Galaburda. Beth Israel Hospital and Harvard Med. School, Boston, MA 02215.

Freezing lesions to the left neocortex were produced in postnatal day 0 (P0) and P1 rats. The animals were sacrificed at either 1,2,3,5,7, or 10 days after the lesion by anesthetized transcardial perfusion with 4% paraformaldehyde. The brains were removed, sectioned coronally, and stained for Nissl substance with thionin, for radial glial cell-like immunoreactivity with Rat-401 antibody (obtained from S. Hockfield), and for GFAP-like immunoreactivity.

Neonatal freezing lesions produce severe cerebrocortical microdysgenesis consisting mainly of microgyri when examined in adulthood (Humphreys et al., *Soc. Neurosci Abs.*, **15**: 1120). During the first few post-lesion days, the area of damage shows an intact layer I subjacent to which there is a wide area of damage containing pycnotic cells and tissue necrosis. By P5 the typical infolding of the cortical surface is visible, and by P10 the appearance of adult-like microdysgenesis is present.

Many, but not all radial glial-like immunoreactive cells appear damaged within the first two days after the freezing lesions, showing bulbous varicosities at their foreshortened terminations lying within the area of necrosis. By P5 some radial glial-like fibers can be seen to traverse the damaged area and reach through overlying cell-dense areas up to the the external limiting membrane. From P5-P10, there is increased density of radial fibers within the area of damage, which may represent a collapse of surrounding radial fibers toward the center of the lesion.

Between P1 and P5, GFAP-like immunoreactive cells are present mostly as reactive astrocytes in the area of damage. On P7 and P10 some radial glial cells, too, express GFAP, but only within the area of neocortical damage.

These results suggest that layer I is relatively spared in this type of lesion, which may explain the paucity of molecular layer ectopic cell nests (See Sherman et al., this volume). The spared radial glial cells may permit subsequent neuronal migration to upper layers. The microgyrus may reflect physical forces of collapse. DEVELOPMENT OF ANTERIOR COMMISSURE ADOPTS PROGRESSIVE, NOT REGRESSIVE, STRATEGIES. R. Lent and R.Z. Guimarães*.Instituto de Biofísica, UFRJ, Rio de Janeiro 21944, Brazil.

The perinatal development of anterior commissure connections was studied in hamsters by use of dil crystals implanted either into the commissure or into the ventrolateral prosencephalon.A fascicle of growing commissural fibers was seen close to the midline on E14. On E15 it had entered the opposite hemisphere and reached the borders of the targets. No detectable waiting period was observed, since on E16 axons were already seen arborizing into most targets. All regions projecting through the commissure in adults had labelled cells on P1, namely: the anterior olfactory nuclei, olfactory tubercle , piriform cortex,nucleus of the lateral olfactory tract, bed nucleus of the stria terminalis, insular, perirhinal and entorhinal cortices and the amygdaloid complex. No evidence of topographical exuberance was ever seen. Counts of labelled neurons showed that the number of commissural cells increased gradually after birth. It was concluded that the anterior commissure adopts progressive developmental strategies, lacking the regressive phenomena that are characteristic of the more recent corpus callosum.

MYELINATION OF CORTICOHIPPOCAMPAL RELAYS CONTINUES THROUGH ADVANCED ADULTHOOD IN HUMAN BRAIN. F.M. Benes, M. Turtle, P. Farol, J.P. SanGiovanni. Quantitative and Molecular Neuroanatomy Lab, McLean Hospital, Belmont, MA 02178 and the Program in Neuroscience, Harvard Medical School.

A recent study has suggested that myelination of the perforant path (PP) and cingulum bundle (CB) in human brain is actively occurring between 11 and 17 years of age. To explore this question further, a cohort consisting of 146 post-mortem brain specimens from Boston Childrens Hospital (aged 0-33 yrs) and 21 similarly processed cases from the Massachusetts General Hospital (aged 36-76 yrs) were obtained. Transverse sections that included the hippocampal formation and entorhinal cortex had been taken at approximately the same posterior level. The extent of myelination along the superficial portion of the subiculum, presubiculum and entorhinal cortices was blindly assessed using a subjective rating scale and a computer-assisted digitization of the area occupied by myelin-staining. There was a fourfold increase in the amount of myelin-staining between 0 and 40-50 years of age that best fit a second order polynomial function with r = 0.71 and 0.76 for the subjective and areal determinations, respectively. Microdensitometric determinations of the intensity of myelin-staining showed a 31% increase up to approximately 62 years of age. These results are consistent with the idea that the numbers of myelinated axons in the PP and CB are increasing in a curvilinear fashion for approximately 5 decades, while the amount of myelin occurring in relation to individual axons may show a slower increase into the seventh decade. It will be important to know whether these developmental changes in key corticolimbic relays are genetically and/or experientially determined. Supported by MH00423 and MH42261.

NEONATAL CORTICAL AND THALAMIC LESIONS DISRUPT THE NORMAL PATTERN OF PROJECTION NEURONS, BUT NOT PRIMARY AFFERENT AXONS IN RAT TRIGEMINAL NUCLEUS PRINCIPALIS. R.W. Rhoades, C.A. Bennett-Clarke and N.L. Chiaia. Dept. of Anatomy, Medical College of Ohio, Toledo, OH 43699.

Erzurumlu and Ebner (Dev. Brain Res.; 44:302, 1988) recently showed that perinatal cortical lesions disrupt the vibrissa-related pattern of cytochrome oxidase (CO) activity in trigeminal (V) nucleus principalis (PrV), but not in V nucleus interpolaris (SpI). If normal and altered patterns of CO in PrV reflect distributions of primary afferents, then corticofugal axons must somehow affect primary afferent terminations. We tested this directly by making either cortical or thalamic lesions on P-0 and labelling V primary afferents with HRP on P-5. In other lesioned animals, we assayed the distribution of V-thalamic projection neurons via retrograde transport of fluorescent tracers. Sections from all animals were also reacted for CO. Both cortical and thalamic lesions disrupted the normal CO pattern in PrV, but not in SpI. However, the distributions of V primary afferents in both nuclei were generally normal. Cortical and thalamic damage disrupted the pattern of V-thalamic projection neurons in PrV. These results indicate that cortical and thalamic lesions alter the CO pattern in PrV via their effects upon brainstem neurons rather than primary afferents. The lack of effect in SpI probably reflects the fact that only a minority of its cells project to thalamus. Supported by DE 07734 and BNS 85 17537

THE ARACHNOID AND SUBARACHNOID SPACE IN THE HY-3/HY-3 MOUSE WITH HYDROCEPHALUS. T. Inagaki*, W. Goossens*, S. Nakahara*, D.G. McLone and P.A. Knepper. Division of Neurosurgery, Children's Memorial Hospital and Northwestern University Medical School, Chicago, IL 60614.

One mechanism for hydrocephalus may be an alteration in the development of the arachnoid and subarachnoid space (SAS). We studied the cerebrospinal fluid (CSF) outflow pathway of postnatal day 14 Hy-3/Hy-3 mice with hydrocephalus, normal littermates, and C-57 BL/6J mice by light and scanning electron microscopy (SEM).

The normal arachnoid consisted of two components: An outer continuous layer of cells adjacent to the dura and inner arachnoid trabeculae (AT) of the SAS. By SEM, normal AT consisted of highly branched cells with smooth surfaces and numerous openings and perforations: Stomata within AT as intratrabecular spaces and oval perforations between AT cells. These findings were observed in the AT of the basal cistern, the interhemispheric fissure and over the convexities. In contrast, the arachnoid of Hy-3/Hy-3 was an abnormal continuous sheet of flattened squamous cells without stomata or oval perforations over the convexities but was more typical in the interhemispheric fissure and basal cistern. These results suggest that portions of the SAS may be blocked in Hy-3/Hy-3 which may be a causative factor in hydrocephalus or may be a secondary "compressive" result of increased CSF pressure.

EFFECTS OF PRENATAL COCAINE EXPOSURE ON BRAIN METABOLISM IN THE 21 DAY OLD RAT. D.L. Dow-Edwards, L.A. Freed, L.M. Donohue*, and H.E. Hughes. Laboratory of Cerebral Metabolism, Department of Neurosurgery, SUNY-Health Science Center, Brooklyn, N. Y. 11203.

Human infants prenatally exposed to cocaine exhibit growth and neurobehavioral deficits. Recent animal studies suggest that cocaine directly affects brain development. We have observed long-term changes in functional activity in several brain regions in the adult rat following prenatal (gestation days 8-22) and postnatal (days 1-10 or 11-20) cocaine exposure. The present study investigated rates of glucose utilization in various brain structures of weanling rats prenatally exposed to cocaine in comparison with control offspring.

Sprague-Dawley rats were gastrically intubated with 30 or 60 mg/kg/day cocaine HCl or vehicle only during gestational days 8-22. Vehicle treated rats were pair-fed/watered to rats receiving the higher dose of cocaine. A non-treated control group was also maintained. At parturition, litters from all four groups were surrogate fostered. Local rates of cerebral glucose utilization were determined in 21 day old male and female offspring using the deoxyglucose method of Sokoloff et al. (J. Neurochem. 28:987, 1977). The effects of prenatal cocaine exposure on patterns of brain metabolic activity as well as physiologic variables such as blood pressure, hematocrit and body temperature in 21 day old rat pups will be discussed.

ETHANOL EFFECTS ON THE DEVELOPING FROG OPTIC TECTUM. L.C. Towns, P.S. Sexton* and N.J. Uray. Kirksville College of Osteopathic Medicine, Kirksville, MO 63501

Experiments were conducted to assess the effect of ethanol on morphological development of the optic tectum in bullfrog tadpoles. Groups of tadpoles were placed in a 1% (v/v) ethanol at two week intervals from the time of hatching to 22 weeks of age and all tadpoles were sacrificed at 6 months of age. In treated animals, a large continuous space develops between the ependymal and subependymal layers. When treatment is begun later, at 20 or 22 weeks, the disruption at the ependymal-subependymal boundary is generally restricted to the areas of the posterior tectum which are currently developing. Previously developed portions of anterior tectum show less disruption. Similar spaces are present in untreated controls but they do not reach the size or continuity seen in ethanol-treated animals. These data indicate that ethanol treatment induces morphological alterations in proliferative areas of the optic tectum. This disruption may result from edema due to alterations in microvasculature as previously reported in cerebellum. Supported by NIAA 07537.

ETHANOL-INDUCED ALTERATIONS IN THE MICROVASCULATURE OF THE TADPOLE BRAIN. N.J. Uray and P.S. Sexton*. Department of Anatomy, Kirksville College of Osteopathic Medicine, Kirksville MO 63501.

The purpose of this study was to examine the effect of chronic ethanol exposure on the microvasculature of tadpole brains for morphological alterations which may be associated with edema formation. Bullfrog tadpoles were raised in 1% (v/v) ethanol after which the animals were killed and the brains were prepared for light microscopy. Observations were made of the choroid plexus vasculature, along with examination of the brain tissue for signs of extravasation. Our observations suggest that after chronic ethanol exposure 1) the vessels of the choroid plexus were more tortuous in the ethanol-treated animals than in control animals and 2) the average vessel diameter in ethanol-treated animals (9.9±0.6 μm) was significantly ($P \leq 0.001$) greater than in control animals (6.0±0.2 μm). Furthermore, in the brain tissue of some of the ethanol-treated animals, red blood cells were observed in the extracellular spaces. These findings support the notion that some of the morphological changes induced by chronic ethanol exposure observed in the developing tadpole brain may be attributable to changes in the microvasculature, rather than altered neurogenesis. (Supported by NIAA grant 07537.)

AN AUTORADIOGRAPHIC STUDY OF THE EFFECTS OF REM-SLEEP ON OCULAR DOMINANCE PATCH FORMATION IN VISUALLY DEPRIVED KITTENS. J.P. Shaffery, G.A. Marks, S.G. Speciale, and H.P. Roffwarg, Dept., of Psychiatry U.T. Southwestern Med. Sch., Dallas, Tx 75235.

The influence of stimulus generated neural activity on brain development has been most convincingly demonstrated in visual system studies, where it has been shown that during the "critical period" monocular occlusion affects lateral geniculate nucleus cell sizes and the formation of ocular dominance patches (ODPs) in layer IVc of visual cortex. Monocular deprivation (MD) during the critical period results in larger than normal ODPs for the open eye and smaller patches for the occluded (deprived) eye. Previous MD studies, however, have not accounted for the possibility of an lessening of the effects of visual restriction on ODP formation that might occur during sleep. Rapid eye movement (REM) sleep is partly characterized by large amounts of endogenously generated bilateral activity that impinges upon visual thalamus and the primary visual cortical receiving area during this phase of sleep. Recent studies have indicated that combining MD with REM sleep deprivation increases the interlaminar cell size disparity usually observed in the lateral geniculate nucleus following MD alone. These data suggest the possibility of similar parallel effects occurring in the development of ODPs. The data also implicate an active role for REM-sleep in neural ontogeny and development. The data presented here test our ontogenetic hypothesis on REM-sleep and brain development. A tritiated protein was injected into either the oculed or non-occluded eyes of REM-sleep deprived or control kittens at the start of the peak of their critical period. Results from computer-aided densiotometry of ODP autoradiographs in MD kittens indicate patch size differences across groups.

DIFFERENTIATION, MORPHOGENESIS AND DEVELOPMENT: POSITION AND FORM

HOMEOBOX GENES EXPRESSED IN ADULT MOUSE CEREBELLUM. Robert F. Bulleit and Timothy A. Bunting*. Dept. of Pharmacology, University of Maryland School of Medicine, Baltimore, MD 21201

Homeobox genes encode one class of transcriptional regulatory proteins which may play a role in differentiation of brain neurons. Homeobox genes are expressed in several populations of vertebrate neurons. In invertebrates the expression of some homeobox genes is required for differentiation of certain neurons. Our interest is to identify homeobox genes that are involved in the differentiation of cerebellar neurons. We have focused on two classes of homeodomain proteins. One class includes the murine Hox family of proteins which contains a highly conserved homeodomain. The second class includes the POU/Homeo domain proteins which also contains an additional highly conserved POU domain. The polymerase chain reaction (PCR) has been used to amplify and clone cDNAs encoding members of these homeodomain protein families that are expressed in the adult mouse cerebellum. Two sets of full codon degenerate oligonucleotide primers were synthesized for use in the PCR experiments. The first set of primers is based on two regions in the homeodomain of the murine Hox proteins. The second set of primers is based on two conserved regions in the POU/Homeo domain proteins, one in the homeodomain and the second in the POU domain. The length of sequence between the two primers provides an indication of the size of DNA fragment expected to be amplified by PCR. The template DNA used for PCR was cDNA synthesized from poly A^+ RNA obtained from adult mouse cerebella. Using these two sets of primers we have been able to amplify DNA fragments of the appropriate size as observed on ethidium bromide stained 2% agarose gels. The amplified DNA was extracted from the gel and cloned into the pGEM7Z vector. Individual clones were selected and are being sequenced to determine the number of different homeodomain sequences identified from the adult cerebellum. *In situ* hybridization on tissue sections of the cerebellum will be employed to characterize the cellular distribution of the expressed homeobox genes.

IDENTIFICATION OF HBH-1, A HOMEODOMAIN-CONTAINING TRANSCRIPT FROM HUMAN FETAL BRAIN. D. J. Selski, M. Moon*, A. B. Wadhams*, P. D. Coleman, N. Thomas*, K. E. Rogers, Departments of Neurobiology and Anatomy and Dermatology, University of Rochester Medical Center, Rochester, N.Y. 14642, USA

Homeobox proteins are thought to be involved in the differentiation and function of specialized cells. In order to determine which homeobox proteins are active during neuronal development we have designed a mixed oligonucleotide probe corresponding to amino acid positions 44-55 of the conserved antennapedia homeodomain and used that probe to screen a human fetal brain cDNA expression library. Approximately 1×10^5 clones were screened using low stringency conditions and a single strongly hybidizing clone was isolated. The length of this clone, HBH-1 (human brain homeoprotein), was 1950 bases and contained an open reading frame of 400 amino acids. The full length message was judged to be 2800 base pairs by Northern blot analysis. HBH-1 sequence has been compared to known homeobox-containing sequences in the GenBank/EMBL data base and has been shown to be a unique, previously undescribed, transcript containing a region homologous to other homeodomains. Preliminary studies have demonstrated HBH-1 transcripts present in human fetal brain tissue from 11 through 21 weeks of age.(Supported by NIH grant AG 00107 and ADRDA PRG 89-120)

ALTERNATE EXPRESSION OF THE HNK-1 EPITOPE AND DEVELOPMENT OF NEURONS IN RHOMBOMERES OF THE CHICK EMBRYO. S.C. Kuratani. Department of Anatomy, Medical College of Georgia, Augusta, GA 30912-2000.

To investigate developmental changes occurring in central nervous system and neural crest, a series of chick embryos were immunostained with several monoclonal antibodies. HNK-1-immunoreactivity appeared in rhombomeres(r)3 and r5 around stage 12. This immunoreactivity was the most intensive at stage 15, when r2 and r4 were not stained. This alternating pattern is similar to the Krox-20 gene expression in the mouse embryo (Wilkinson et al., 1989a). At levels of r2 and r4, neural crest cells were attached to the hindbrain. An accumulation of neurons was observed in these rhombomeres near this attachment. The above observations seem to suggest that the alternate HNK-1 immunoreactivity in rhombomeres might be related to pair-rule-like segmentation of the nervous system in concordance with the branchiomerism. This phenomenon is the first example of a phenotypic differentiation of CNS seemingly related to homeobox-containing gene expression.

POSSIBLE ROLE OF BASIC FIBROBLAST GROWTH FACTOR IN THE DEVELOPING AND REGENERATING RETINA OF GOLDFISH. Pamela A. Raymond and Linda K. Barthel, Univ. Michigan, Dept. Anatomy & Cell Biology, Ann Arbor, MI 48109

Antibodies to basic FGF isolated from bovine brain bind to various specific cells or laminae in the larval and adult goldfish retina; the most intense immunoreactivity (blood vessels excepted) is in horizontal cells (HCs) and outer plexiform layer (OPL). This observation is intriguing since in this retina, rod photoreceptors are added continuously through mitotic divisions of rod precursor cells located along the edge of the outer nuclear layer adjacent to the OPL. Double label studies with GABA antibodies (which stain the predominant type of HC in fish) suggest that some but not all of the FGF immunoreactivity co-localizes with GABAergic HCs. It has been proposed that GABAergic HC's may play an organizing role during development of photoreceptors and outer retina. We have tested the hypothesis that FGF may be involved in this function by inserting ethylene vinyl acetate pellets containing FGF antibodies into the eyes of normal fish and those with regenerating retinas. Preliminary results indicate that the cytoarchitecture of developing retina may be affected by FGF antibodies: laminar organization is disrupted and some neurons are in ectopic positions. Supported by NIH EY04318.

NUCLEATION OF STRIATAL PATCHES: EARLY BORN PATCH COMPARTMENT NEURONS SHOW GREATER ADHESIVENESS THAN LATER BORN PATCH COMPARTMENT NEURONS. J.G. Johnston, L.A. Krushel and D. van der Kooy, Neurobiology Research Group, Department of Anatomy, University of Toronto, Toronto, Ontario, Canada, M5S 1A8.

The mammalian striatum can be divided into the patch and matrix compartments based on the distributions of neurochemical markers and anatomical connections and based on striatal development. The patch and matrix compartment neurons are born at different times during rat development, with majority of patch neurons becoming postmitotic (embryonic (E) days 13-15) before the majority of matrix neurons (E18-20). Cell lineage studies suggest that the striatal compartments develop from separate pools of precursor cells. The neurons of the patch compartment are adhesive to one another, as shown by their ability to selectively reaggregate in culture. In order to investigate within compartment adhesion, we asked if adhesion differed amongst neurons of the patch compartment. Maternal injections of one of ^{3}H-thymidine or bromodeoxyuridine were made on E13 and were followed in the same pregnant rats by injections of the alternate label on E15, in order to mark new postmitotic patch neurons at early and late times of patch neurogenesis. Animals sacrificed at postnatal day 30 revealed that early born neurons are preferentially located towards the centers of patches, whereas later born patch neurons are preferentially distributed towards the peripheries of the patches. Thus, in addition to a previously described qualitative difference in the self-adhesiveness of striatal patch neurons versus the lack of such a self-adhesiveness among striatal matrix neurons, there is also a difference in adhesiveness among neurons of the patch compartment. The increased adhesiveness of the earlier born patch neurons may serve to nucleate the patches during striatal development.

477.6

POSTMITOTIC STRIATAL PATCH AND MATRIX NEURONS INTERMIX BEFORE COMPARTMENTS ARE FORMED. L.A. Krushel, G. Fishell and D. van der Kooy Dept. of Anatomy, Univ. of Toronto, Toronto, Ont. Canada, M5S 1A8.

Neurons of the patch compartment in the rat striatum become postmitotic earlier in neurogenesis than neurons of the matrix compartment. The previously demonstrated selective adhesion of patch cells to one another may be an important mechanism in the development of striatal compartmentalization. We examined both *in vivo* and *in vitro* whether the selective adhesion of patch cells is expressed before or after the migration of the majority of the matrix neurons into the striatum. *In vivo*, patch neurons were labeled by a fluorescent retrograde tracer (true blue) injected into the substantia nigra on embryonic day (E) 19 (patch cells are the first neurons to project out of the striatum). Matrix neurons were labeled with a maternal injection of bromodeoxyuridine (Brdu - a birthdate marker) on E18. On E20 true blue labeled patch cells were found intermixed with the Brdu labeled matrix neurons in the medial striatum, however further laterally small clusters of labeled patch cells were present. By postnatal day 2 there was a complete segregation of the clusters of labeled patch neurons from the matrix neurons in the striatum. This process was also modeled *in vitro*. The patch and matrix compartments were labeled *in vivo* with different birthdate markers (^{3}H-thymidine or Brdu) on E13 and E18, respectively. On E20 the striatal tissue was removed, dissociated and reaggregated in suspension cultures. After 1 day *in vitro*, labeled patch and matrix cells were randomly intermixed within the reaggregates. Examination of the cultures after 2.5 and 4 days *in vitro* revealed clumping of the labeled patch cells towards the centers of the reaggregates. Over this same period, the labeled matrix neurons did not clump and were dispersed towards the periphery of the reaggregates. Thus, the selective adhesiveness of patch neurons is either expressed after the later born matrix neurons begin to migrate into the striatum or is unable to overcome the force of the massive migration of matrix neurons. We conclude there is a migratory phase when committed patch and matrix neurons intermix before expressing their adhesive phenotype in the postmitotic striatum.

TRANSPLANTATION: RECEPTOR EXPRESSION

478.1

RAT FETAL NEOCORTEX TRANSPLANTS HAVE BOMBESIN/GRP RECEPTORS. J.M. Rosenstein, R. Getz* and T.W. Moody, Depts. Anatomy and Biochemistry & Molecular Biology, George Washington Univ. Sch. Med., Washington, D.C. 20037.

Fetal brain grafts contain numerous neurotransmitters and receptors. Of particular interest is bombesin/gastrin releasing peptide (BN/GRP) whose receptors develop on fetal neocortex transplants into the adult fourth ventricle (Getz et al., Neurosci. Lett. 79:97 (1987). BN/GRP functions as a potent satiety and grooming agent in the rat CNS and stimulates the growth of certain neuroendocrine cells. Here the binding properties of these fetal cortex transplants were investigated using in vitro autoradiographic techniques. High densities of (^{125}I-Tyr^4)BN grains developed in fetal cortex transplants into the host ventricle or adult cortex but not on cerebellar or superior cervical ganglia transplants. These data indicate that the development of BN/GRP receptors is a function of the transplant and not the host tissue. The autoradiographic grains, which were analyzed on an Amersham RAS 3000 densitometer, developed 3 weeks after tranplantation in the graft tissue and were retained for 3 months. The amount bound was a function of (^{125}I-Tyr^4)BN concentration. Scatchard analysis indicated that radiolabeled (Tyr^4)BN bound with high affinity (Kd = 4 nM) to a single class of sites (Bmax = 110 fmol/mg protein). GRP and GRP$^{18\text{-}27}$ but not GRP$^{1\text{-}16}$ inhibited specific (^{125}I-Tyr^4)BN binding with high affinity (IC_{50} = 2, 5 and >10,000 nM respectively). Also, BN receptor antagonists such as (Psi^{13,14}, Leu^{14})BN and (D-Arg^1, D-Pro^2, D-Trp^{7,9}, Leu^{11})substance P competed for the (Tyr^4)BN binding sites (IC_{50} = 100 and 1000 nM respectively). Because BN/GRP receptors develop on fetal cortex transplants, they may facilitate the growth of the graft tissue. Supported by NIH grant NS-17468 and NSF grant 88-15133.

478.2

CHANGES IN STRIATAL DOPAMINE RECEPTOR BINDING FOLLOWING ADRENAL MEDULLA GRAFTS. E.J. Curran and J.B. Becker. Neuroscience Program and Department of Psychology, The University of Michigan, Ann Arbor, MI 48109.

We have previously shown that intraventricular adrenal medulla (AM) grafts transplanted adjacent to the dopamine (DA) denervated striatum produce a decrease in rotational behavior induced by either amphetamine (AMPH) or apomorphine (APO). Experiments using quantitative autoradiography were conducted to determine whether changes in striatal DA receptors are associated with this behavioral recovery.

Adult rats with unilateral substantia nigra lesions were tested for APO- and AMPH- induced rotational behavior prior to and after receiving intraventricular AM grafts. Ten to twenty days following the last drug treatment, the rats were decapitated, the brains were rapidly removed, frozen on dry ice, and stored at -70°C. Twenty micron coronal sections through the striatum of control animals and animals with behaviorally effective or ineffective AM grafts were assayed for [^{3}H]SCH 23390 binding to D1 receptors or [^{3}H]spiperone binding to D2 receptors. Preliminary experiments revealed that D2 receptor binding increased in the DA denervated striatum. Behaviorally effective AM grafts attenuated this increase. In contrast, no apparent change was seen in D1 receptor binding in the DA denervated animals. (Supported by grants NS 22157 & UM 363669).

478.3

BEHAVIORAL RECOVERY ASSESSED WITH D_1 AND D_2 DOPAMINE AGONISTS AFTER VENTRAL MESENCEPHALIC GRAFTS INTO DOPAMINE DENERVATED RAT STRIATUM.

J.B. Becker[1], M.A. Ariano[2], & D.K. McFarlane[1]. [1]Psychology Dept & Neuroscience Prgm, Univ. Michigan, Ann Arbor, MI 48104; [2]Anatomy and Neurobiology, UVM, College of Medicine, Burlington, VT 05405.

Stimulation of both D_1 and D_2 dopamine (DA) receptor subtypes synergistically activates behavior mediated by the intact striatum. Following unilateral DA denervation, this facilitatory receptor interaction is thought to be uncoupled; administration of either a D_1 or a D_2 DA receptor agonist will induce rotational behavior (**J. Pharm. Exp. Ther.**, 247:180, 1988). Previous experiments have demonstrated that turning behavior induced by either apomorphine (APO) or amphetamine (AMPH) is decreased after grafts of fetal dopaminergic tissue into the DA denervated striatum. Since APO and AMPH will activate both DA receptor subtypes, this experiment was conducted to determine whether behavioral recovery is associated with a single DA receptor population.

Female rats with a unilateral 6-OHDA lesion of the substantia nigra underwent behavioral testing before and 2-3 months after intrastriatal grafts of fetal ventral mesencephalon. Animals were tested with: the full D_1 agonist, SKF82958 (0.5 mg/kg); the D_2 agonist, LY171555 (0.1 mg/kg); and AMPH (5.0 mg/kg). Survival of DA containing grafted cells was confirmed histologically 4 months post-graft with catecholamine histofluorescence.

Preliminary data indicate that the transplantation of DA containing fetal brain tissue can produce decreases in rotational behavior induced by SKF82958 (range = -18 to -75%), LY171555 (-15 to -99%) and AMPH (-15 to -96%). We conclude that behavioral recovery induced by fetal mesencephalic grafts in this animal model of Parkinson's Disease involves compensatory responses by both D_1 and D_2 DA receptor subtypes.

478.4

D_1 AND D_2 RECEPTOR MORPHOLOGY AFTER PLACEMENT OF VENTRAL MESENCEPHALIC GRAFTS IN DOPAMINE DEPLETED RAT STRIATUM.

M.A. Ariano, J.B. Becker,[1] L.D. McVittie,[2] & D.R. Sibley[2]. Anatomy & Neurobiology, UVM College of Medicine, Burlington, VT 05405; [1]Psychology Dept., Univ. Michigan, Ann Arbor, MI 48104; & [2]ETB, NINDS-NIH, Bethesda, MD 20892.

There are two distinct dopamine (DA) receptor subtypes. The D_1 receptor stimulates adenylyl cyclase. Striatal D_1 binding sites are found morphologically associated with neurons containing cAMP immunoreactivity. Stimulation of striatal D_2 receptors inhibits cAMP production. Striatal DA denervation produces specific receptor changes; the association between D_1 binding sites and cAMP immunoreactivity is abolished and there is an increase in the number of D_2 receptors. This study was initiated to determine whether transplanting fetal mesencephalon into the DA-denervated striatum could induce recovery of these morphochemical indices of DA receptor function.

Female rats with a unilateral 6-OHDA nigral lesion, underwent behavioral testing (results reported separately) before, and 2-3 months after transplantation. Cellular distributions of the DA receptors were examined after 4 months. The striatal distribution of both DA receptor subtypes was determined by application of rhodamine derivatized antagonist ligands (**PNAS 86**:8570, 1989). The morphochemical aggregation pattern of D_1 receptors was assessed by *in vitro* autoradiography with immunohistochemical staining of cAMP (**Brain Res. 443**:204, 1988). D_2 receptor distribution was further characterized by specific antibodies generated against portions of the peptide sequence for the native protein (**FASEB J. 4**:A601, 1990). Preliminary data suggests that the transplantation of DA-containing fetal brain tissue provides a sufficient milieu for recovery of the DA receptor distribution. The data suggest a morphological basis for behavioral improvements induced by grafts of fetal ventral mesencephalon in this animal model of Parkinson's Disease.

[Supported by USPHS NS 23079 (MAA) and NS 22157 (JBB)].

478.5

AUTORADIOGRAPHIC STUDY OF D-1 AND D-2 RECEPTORS IN THE EFFERENT REGIONS OF THE STRIATUM AFTER CHRONIC TREATMENT WITH L-DOPA IN 6-OHDA LESIONED RATS WITH OR WITHOUT NIGRAL GRAFT. L. Rioux, D. Gaudin, P.J. Bédard, C. Gagnon and T. DiPaolo. Lab Neurobiol. Dept. Anatomy and Dept Mol. Endocrinol.and School of Pharmacy Univ. Laval, Québec, (Qc), CANADA G1K 7P4.

We have previously shown that fetal DA neuron transplants in the rat striatum prevent supersensitivity of the DA receptors induced by denervation itself or by repeated administration of L-Dopa (Gaudin, et al., Soc. for Neurosc.abstr.,15: 1355,1989). In the present work, we have studied the effects of a similar striatal graft on dopamine D-1 and D-2 receptors in the target structures of the striatum. Two group of rats were prepared with a unilateral lesion of the nigro-striatal DA pathway with 6-OHDA. One month later, one group received a graft of 1.5 $X10^6$ midbrain cells. Each group of animals received 14 injections of L-Dopa. After four months the animals were sacrified for autoradiography of the D-1([^{3}H]-SCH 23390) and D-2 ([^{3}H]-Spiperone) receptors. The results show a decreased density of D-1 receptors in the GP (77%), EP (36%) and no change in the SN of the grafted side compared to the lesioned ungrafted side of the second group. On the other hand, an increased density of D-2 receptors was observed in the GP of the grafted side (25%) and surprisingly of intact side of grafted animals (77%). In the SN, the density of D-2 dopaminergic receptors was decreased on the lesioned and grafted side (57%). Our results show that a fetal nigral graft can modulate the changes of D-1 and D-2 receptors caused by dopaminergic denervation and by chronic levodopa treatment in striatal target structures. The modifications of dopaminergics receptors in the efferents regions of striatum of grafted animals may also explain the absence behavioral superpersensitivity (Gaudin et al., Br. Res.,506: 1, 166-168, 1990) after chronic treatment with L-Dopa.

EFFECT OF EMBRYONIC DOPAMINERGIC NEURONS TRANSPLANTED TO THE 6-OHDA DENERVATED RAT ON DOPAMINE D_1 AND D_2 RECEPTOR DENSITIES : AN AUTORADIOGRAPHIC STUDY.

F. MENNICKEN, D.N. ABROUS*[1], J.P. HERMAN*[1], M. LE MOAL[1], C. FEUERSTEIN and M. SAVASTA, INSERM-LAPSEN U.318, Pavillon de Neurologie, CHU de Grenoble, 38043 Grenoble cedex and 1. INSERM U.259, Domaine de Carreire, 33077 Bordeaux cedex.

Three experimental groups (control group, lesion group and lesion + graft group) of rats were used for this study. The mesotelencephalic system of adult animals was unilaterally destroyed by 6-OHDA injected into the medial forebrain bundle. Three weeks after the lesion, a cell suspension containing embryonic dopaminergic neurons was implanted into the denervated striatum. Six months after, animals were sacrified. D_1 and D_2 dopamine (DA) receptors densities were examined autoradiographically using ^{3}H-SCH 23390 and ^{3}H-Spiperone (or ^{3}H-Raclopride) respectively. The distinction between reinnervated and non reinnervated striatal regions by the graft was achieved by the autoradiographic visualization of a DA uptake inhibitor, the ^{3}H-GBR 12935, on adjacent sections. Autoradiograms were quantified by image analysis (SAMBA 2005). The results obtained can be resumed as follows:

- Six months after the DA denervation, the density of D_1 receptors was not modified in the denervated striatum, confirming previous results obtained after a post lesional delay of 1 month (SAVASTA et al, Biogenic Amines 4-6 : 419, 1987). On the other hand, the density of D_2 receptors was increased (25 to 45%) preferentially in the lateral part of the striatum as previously described (SAVASTA et al, Neurosci. Lett., 74 : 180, 1987).
- After implantation of embryonic DA neurons in the depleted DA striatum, the D_2 DA receptor density returned to control values in the reinnervated striatum.

These results provide evidence that functionnal recovery of embryonic DA neurons graft is probably associated to a receptor mediated mechanism.

EFFECT OF EMBRYONIC DOPAMINERGIC NEURONS TRANSPLANTED TO THE 6-OHDA DENERVATED RAT ON THE EXPRESSION OF THE mRNA CODING FOR D_2 RECEPTOR : AN IN SITU HYBRIDIZATION HISTOCHEMISTRY STUDY.

M. SAVASTA, M. CHRITIN, D.N. ABROUS*[1], J.P. HERMAN*[1], M. LE MOAL[1] and C. FEUERSTEIN, INSERM-LAPSEN U.318, Pavillon de Neurologie, CHU de Grenoble, 38043 Grenoble cedex and 1. INSERM U.259, Domaine de Carreire, 33077 Bordeaux cedex.

Three experimental groups (control group, lesion group and lesion + graft group) of rat were used. The mesotelencephalic system of the animals was unilaterally destroyed by 6-OHDA injected into the medial forebrain bundle. Three weeks after the lesion, a cell suspension containing embryonic dopaminergic neurons was implanted into the denervated striatum. Six months after the graft animals were sacrified. Autoradiographic studies carried out in parallel from consecutive sections of the same animals evidenced an increase of D_2 dopamine (DA) receptors density which was reversed by the implantation of embryonic dopaminergic neurons. In the present study, using in situ hybridization techniques, we examined whether levels of mRNA coding for D_2 DA receptors vary in the same way than those of the D_2 receptor protein itself. [^{32}P]-labelled oligonucleotide derived from the coding region of the rat DA D_2 receptor cDNA has been used as a probe to localize in the rat brain sections the cells containing the mRNA coding for this receptor. The distribution of mRNA was comparable to that of the dopamine D_2 receptor binding sites as visualized in adjacent sections by autoradiography of ^{3}H-Spiperone or ^{3}H-Raclopride. The lateral part of the striatum presented high mRNA content comparatively to the other subregions of this structure. In the denervated striatum, the mRNA levels were preferentially increased in the lateral striatum as described for the supersensitive D_2 receptors, after implantation of embryonic dopamine neurons the expression of mRNA for this receptor was normalized. These results provide evidence that functional recovery of DA neurons graft is mediated at least in part through the modulation of the genetic expression of the D_2 receptor.

WEAK ELECTRICAL FIELDS SPEED UP REGENERATION OF MOTONEURONS IN THE CRUSHED SCIATIC NERVE OF NINE MONTH OLD RATS. J.I. Campbell and B. Pomeranz. Dept. of Zoology, Univ. of Toronto, Toronto, Canada M5S 1A1

Our lab has previously reported that motoneuron regeneration is accelerated when treated with weak electrical fields in cut and sutured but not crushed sciatic nerve of 10 week male rats (McDevitt, L. et al., Brain Res., 416:308, 1987). The present study was conducted to determine whether: 1. the speed of nerve regeneration is slowed with age, and 2. if so, will 10 μA direct current stimulation accelerate regeneration in the old animals with crushed nerves?

Seventeen 10 week male Wistar rats underwent a crush of the right sciatic nerve. This group was called Young Crush (YC). In 18 rats the crush was made at 9 mo of age (Old Crush =OC). Seventeen 9 mo rats received a crush and had battery driven wick electrode devices implanted in the neck region with the cathode distal wick passing by the site of the lesion (Old Crush Cathode Distal = OCCD). These implants drove a current of 10 μA by the nerve throughout the recovery period. Fifteen 9 mo rats underwent a crush and were implanted with sham devices (Old Crush Sham = OCS).

On post-operative day 29, EMG's were recorded by stimulating the sciatic nerve transcutaneously via micro-alligator clips while recording pins were inserted in one of 12 identified sites in the rat's right foot. 70.8% of all sites were innervated in the YC while only 26.7% of the sites were innervated in the OC suggesting that regenerative speed slows with age. Also, the OCCD had 68.8% of all sites innervated, while the OCS had only 18.8%, indicating that DC fields speed up the rate of regeneration.

QUESTIONING THE PROPOSED ENHANCEMENT OF PERIPHERAL NERVE REGENERATION BY APPLIED ELECTRIC FIELDS. M. E. McGinnis. Center for Paralysis Research, School of Veterinary Medicine, Purdue University, West Lafayette, IN 47907.

Several papers have been published reporting an enhancement of the rate of peripheral nerve regeneration in rats due to the application of weak DC electric fields. Having been unable to demonstrate any effect of such fields on peripheral nerve regeneration in guinea pigs, I undertook to repeat as closely as possible two of the published positive reports. An experiment by Politis, Zanakis, and Albala (J. of Trauma **28**:1375-1381, 1988) consisted of placing a transection and anastomosis site within a silicone tube with electrodes at either end. An unregulated current source passed 1.5 μA through the tube for 12 days with a resulting 4 fold increase over controls in the number of neurofilament positive profiles found 14 mm distal to the anastomotic site. My repeat of this experiment showed that the devices only pass 0.23 μA, most of which follows the low resistance pathway around the outside of the tube rather than going through it. At the time and distance indicated, I found no difference in the number of neurofilament positive profiles, or myelinated or unmyelinated fiber density.

Another paper (Román *et al.* Exp. Neurology **98**:222-232, 1987) reported a 5.5 fold increase in the number of myelinated fibers regenerating through a silicone tube (across a 5mm gap) when a cathode delivering 10 μA was located in the center of the tube. A repeat of this experiment with a larger sample size than originally used demonstrated no effect of the applied fields.

From these experiments it is apparent that the effects of applied fields on peripheral nerve regeneration is still open to question, and should remain so until a robust, repeatable effect can be demonstrated by several labs. Supported by NIH grant NS 26251

EFFECT OF VARIOUS ELECTRICAL PARAMETERS ON PERIPHERAL NERVE REGENERATION. M.F. Zanakis*, L. Nguyen, C. Kaiser, A. Feller, S. Fettahlioglu, and B. Hallas. *American Bio-Interface Corporation. New York, NY and New York College of Osteopathic Medicine, Dept. of Neuroscience, Old Westbury, NY 11568.

Studies have shown that cathodally-directed D.C. stimulation of damaged mammalian peripheral nerves results in an increased rate of regeneration toward target muscles. Constant D.C. current was regulated by a resistor or an I.C. at two voltage levels in the lesioned PNS. Rat sciatic nerves were transected and then frozen with dry ice, and a galvanic nerve cuff was placed over the lesion site with the cathode located 10 mm distal to the lesion. The electrodes delivered A) either 1.4 or 14uA at 1.4V limited by a resistor or B) delivered 1.4 or 14uA at 9V limited by an I.C. Animals were allowed to survive for 6 to 15 days post lesion/treatment. Frozen serial sections of the nerve were reacted with fluorescent antibody to neurofilament protein. Results at 8 days showed that the electrodes at 1.4 and 14uA (at 1.4V) whose current was limited by a resistor demonstrated equivalent numbers of axons, yet contained significantly more axons than the I.C. regulated group animals, whose axon counts were also equivalent in that group. At 15 days, the axon counts were elevated by about 20% in all groups, but no statistical differences were found between groups.

REGENERATION OF DORSAL ROOT AXONS IS INFLUENCED BY INTERCELLULAR REACTIONS IN THE DORSAL ROOT GANGLION. X. Lu* and P.M. Richardson. Montreal General Hospital and McGill University, Montreal, Canada H3G 1A4.

Do cellular interactions within the dorsal root ganglion contribute to the regenerative propensity induced in sensory neurons by peripheral nerve injury? To study this question, axonal regeneration was assayed in rat L_5 dorsal spinal roots following a variety of interventions designed to inhibit or enhance such regeneration. Counts of thinly myelinated fibres 17 days after crush injury were increased by injection into the ganglion of isogenous macrophages or the inflammatory agent C. Parvum. Chronic intrathecal infusion of mitomycin C did not significantly retard the relatively vigorous dorsal root regeneration induced by cutting of the sciatic nerve. As assessed by thymidine radioautography, this infusion of mitomycin C did reduce the proliferation of satellite cells that normally follows sciatic nerve transection. These observations raise the possibility that perikaryal regenerative responses after nerve injury are not directly induced by axonal interruption but indirectly by secondary reactions of satellite glial cells surrounding the nerve cell body. However, satellite cell proliferation is not essential for this stimulation.

TRANSDIFFERENTIATION OF *XENOPUS* RETINAL PIGMENT EPITHELIAL CELLS INTO GLIAL-LIKE CELLS IN CULTURE. D.S Sakaguchi. Dept. Biol. B-022, UCSD, La Jolla, CA 92093

The retinal pigment epithelium (RPE) of amphibians can transdifferentiate into neurons and lens cells in culture. I report here that the RPE, in addition, is capable of transdifferentiating into glial-like cells. For these studies the posterior two-thirds of larval *Xenopus* (stages 45-53) RPE was enzymatically dissociated and placed into primary culture. After 1 week RPE cells were harvested and replated under limiting dilution conditions. Using this approach several clonal cell lines were established from single RPE cells, 2 of which are discussed here. To identify different cell types which transdifferentiated in culture a panel of cell-type specific antibodies was used. Initially all RPE cells were labeled by an RPE specific mAb (XAR1), and were not labeled by glial cell markers (anti-vimentin, anti-GFAP or R5 mAb). However, after two months in culture, RPE clonal cell lines had lost their pigmentation and were no longer immunoreactive to the RPE specific mAb. In addition, the RPE derived clonal lines were now labeled by the glial cell markers. These cell lines were then examined for their ability to promote neurite outgrowth from embryonic retinal explants. Although collagen alone was relatively ineffective at promoting neurite outgrowth, collagen substrates directly conditioned by the RPE derived cell lines were capable of promoting neurite outgrowth following chemical extraction with Triton X-100. This ability of RPE cell line derived extracellular matrices to support neurite outgrowth is a feature shared with the XR1 cell line, a *Xenopus* glial cell line derived from the retinal neuroepithelium.

ACTH PEPTIDES IMPROVE ENDPLATE PARAMETERS DURING THE REGENERATION OF THE DEVELOPING PERIPHERAL NERVOUS SYSTEM. L.A. Zuccarelli and F.L. Strand. Department of Biology and Center for Neural Science, New York University, Washington Square, New York, New York 10003.

ACTH/MSH peptides accelerate peroneal and sciatic nerve regeneration in the adult rat, improving qualitative and quantitative aspects of extensor digitorum longus (EDL) muscle reinnervation, and affecting the morphology of the neuromuscular junction (NMJ) [1,2,3,4]. These peptides act effectively during critical developmental periods [5,6]. Here we investigate the role of α-MSH and ACTH 4-10 on the regeneration of the developing motor system after trauma. Two-day old Sprague-Dawley rats are subjected to sciatic nerve crush with a #5 forceps producing a .5 mm wide lesion. Peptide treatment (10 μg/kg/48 h) is from time of surgery continuing 6 or 8 days. At days 7 and 15, the EDL muscles are fixed in situ and the NMJs are prepared for light microscopy with a modified silver-cholinesterase stain. At day 7, both peptides significantly increase interior endplate branching, while MSH also increases area and perimeter as compared to saline controls. Muscle fiber diameter is decreased with both peptides, significantly by ACTH 4-10 only. At day 15, both peptides increase NMJ area, perimeter and fiber diameter; interior branching is comparable in all groups. These results continue to support the efficacious role of ACTH/MSH peptides in PNS regeneration. 1. Strand & Kung,(1980) Peptides 1:135-138; 2. Saint-Come & Strand (1985) Peptides 6(s.1)77-83; 3. ENDPLATE MORPHOLOGY AND WALKING TESTS ARE ENHANCED BY BIM 22015 (ACTH 4-10 ANALOG) DURING PERIPHERAL NERVE REGENERATION. T.S. Lee, S.J. Lee, I. Bell*, K. Foster*, and F.L. Strand. Department of Biology and Center for Neural Science, New York University, Washington Square, New York, New York 10003.

Sprague-Dawley rats (175-200g) are subjected to peroneal nerve crush under 8% choral hydrate anesthesia. A #5 forceps is used, resulting in a 1 mm wide lesion. Starting at the time of the surgery, an ACTH 4-10 analog (BIM 22015, 0.1μg/48hrs i.p.) is administered for 5 or 7 days. 5 days after nerve crush BIM-22015 treated animal show a significant increase in endplate perimeter and nerve terminal interior branching. At 7 days post-surgery peptide treatment increases endplate area, internal branching and muscle fiber diameter.

The walking test consist of having the animals walk up an inclined pathway, after having their feet dipped in non-toxic ink[1]. The resulting footprints permit the measurement of toespreads, print length and the calculation of the Peroneal Function Index[2]. The contralateral foot is used as a control for the lesioned foot and parameters are compared to saline-treated controls. BIM 22015-treated rats show enhancement of recovery as determined by these parameters. Several ACTH peptide fragments (ACTH 4-10 and a ACTH 4-9 analog, Org 2766) improve peripheral nerve regeneration and endplate morphology following nerve crush[3]. This ACTH 4-10 analog, BIM 22015, can now be included in this family of neurotrophic peptide. 1. De Medinaceli, L., *et al.,* (1982) *Exp. Neurol.* 77:634; 2. Bain, J.R., *et al.,* (1989) *Plas. SEX DIFFERENCES IN REGENERATION AFFECT ACH RECEPTOR CONCENTRATION AND MOTOR RECOVERY J. Kume and F.L Strand, New York University, Dept. Biology & Neural Science, NY, NY 10003

Sex steroids have recently been shown to affect the non-androgen sensitive muscle, the extensor digitorum longus (EDL)(Segarra,A.,Bleisch,B. and Strand,F.L. 3rd Intnl Nerve Regen. Symp., Dec.1989). We thus investigated the relationship between acetylcholine receptor (AChR) concentration and motor recovery in the EDL, after nerve-crush in castrated and normal rats. Male and female rats were divided into 3 groups: sham-crushed; nerve crushed; and castrated, nerve crushed. Under anesthesia, the peroneal nerve was crushed at the site of innervation. For the AChR assay, males were castrated using an LHRH antagonist (BIM-21009, Biomeasure,Inc., 5mg/kg,s.c.). Females were surgically castrated. AChR concentration was found by radiolabelled binding of $I^{125}\alpha$-bungarotoxin. Motor tests were done on rats used for the AChR assay, and in a separate trial where some males underwent nerve-crush and surgical castration during the peripubertal stage. Digit Distance 1-5 (DD1-5) was measured by the method described by Bain (Plastic & Reconst. Surg.,1989, 83:129). Nerve crush increases AChR concentration, especially in castrated animals. At 9 days post-crush, a sex difference between castrated groups appears, males having 28% higher AChR concentration than females. This difference is not seen in rats with normal steroid levels. However, when relating this difference to DD1-5, only denervated, non-castrated males had a larger toespread than their female counterparts. In the second trial, no such motor difference was noted for any nerve-crushed groups. In fact, when comparing relative DD1-5, print length, and peroneal functional index ratios, these males recovered less than females. Crushing during the peripubertal stage, when male testosterone levels have not yet peaked to adult levels restrains the positive neurotrophic pattern of recovery from occurring. (Supported by NIMH training grant# MH18882-03.)

THE EFFECT OF LOCAL ADMINISTRATION OF EXTRACELLULAR MATRIX AND NERVE GROWTH FACTOR ON FUNCTIONAL OUTCOME FOLLOWING NEONATAL THORACIC SPINAL CORD TRANSECTION IN THE RAT. B.B.Walters, J.R.Encarnacion* and T.E.Melin*. Div. of Neurosurgery, Univ. of North Carolina at Chapel Hill, NC 27599-7060.

40 Sprague-Dawley rats have been studied in a chronic spinal injury protocol designed to demonstrate the effects of local application of extracellular matrix with or without additional growth factors on functional outcome. An open procedure was performed under methoxyflurane anesthesia with an operating microscope in the mid-thoracic region within 36 hours of birth. 13 had laminectomies alone (LAMI), 11 had intradural transection and one segment myelectomy (TRANS), 9 had myelectomies with implantation of approx. 7 µl of matrigel (ECM), and 7 had implants containing approx. 3.5 µg of 2.5S NGF (NGF). The animals were evaluated by the combined behavioral score of Wrathall (Exp.Neurol. 88:123, 1985) 3 times weekly for 15 weeks in blinded fashion. The LAMI animals performed significantly better ($p<0.00003$, ANOVA) than all other groups on weeks 3-15. From 5-8 weeks ECM animals outperformed TRANS animals ($p<0.05$ at 5 & 8, $p<0.001$ at 6). In contrast, NGF animals performed the same as TRANS animals through week 6 and then performed more poorly ($p<0.05$ to <0.001). The neuroanatomical correlates of these results are being investigated. Supported by the American Paralysis Association.

A NEUROTROPHIC FACTOR RELEASED FROM PRIMARY HEPATOCYTE CULTURES PROMOTES NEURITE REGENERATION FROM NERVE-TRANSECTED TERMINALS OF ADULT MOUSE DORSAL ROOT GANGLIA IN VITRO. H.HORIE[1], Y. BANDO*[1], N. FUKUDA*[2], AND T. TAKENAKA, Dept. of Physiol. and [2]Surgery, Sch. of Med., Yokohama City Univ., Yokohama, 236 Japan

Dorsal root ganglia with nerve fibers, dissected from 3-month-old mice, were embedded in collagen gel. After perfusion with 0.05% collagenase, livers of 3~4-month-old mice were dissected and dissociated by mild pipetting. Hepatocytes were cultured on a collagen coated dish in a Ham's F12 medium with 10% fetal calf serum . When the explants were cultured in the hepatocyte condition medium, the number and average length of regenerating neurites were 25.8 and 459µm after 3 day in culture, 33.0 and 617 µm after 5 days and 40.0 and 1020 µm after 8 days. When the explants were cultured in a serum containing medium with NGF, the number and average length were 18.0 and 394 µm after 3 day in culture , 16.9 and 644 µm after 5 days and 12.4 and 992 µm after 8 days. Similar effects were observed in a serum free hepatocyte condition medium. The hepatocyte condition medium promotes the growth as well as NGF, but the effects on the number of regenerating neurites and the cell survival are more remarkable than those of NGF. These results indicate that hepatocytes might secret an essential factor for regeneration from nerve-transected terminals of an adult mouse.

479.11

ORGANIZATIONAL PATTERNS OF REGENERATING NERVE FIBERS AFTER SPINAL CORD COMPRESSION INJURY. C.P. Barrett, R. Rees*, and L. Guth*, Dept. of Anatomy, Sch. Med., U. MD, Balt.

Spinal lesion sites in untreated compression injury of rat spinal cords reveal necrosis that begins a few days post injury and eventually spreads rostrocaudally for 3-4 spinal segments. In such lesions neuritic outgrowth is severely restricted or absent. However, similar injury in lipopolysaccharide treated rats (0.1 mg/kg i.v. twice daily for 8 weeks) is followed by less severe reactive changes, reduced necrosis and gliosis, and the formation of cellular bridges between the cranial and caudal edges of the lesion. Silver and immunocytochemical staining subsequently reveal neuritic regeneration associated with the bridges. Electron microscopy further reveals tubular shaped bridges consisting of regenerating neurites, myelinating Schwann cells, occasional macrophages and astroglia, blood vessels, fibroblasts and collagen. The time course of appearance and the arrangement of the fibroblasts and Schwann cells in relation to the neurites resembles conditions observed in peripheral nerve regeneration. Since the cellular substratum in peripheral nerves is an effective pathway of trophic support and chemotactic guidance for regenerating peripheral or central neurites, the cellular bridges could afford a means for central regeneration. To test this, we injected unconjugated type V HRP rostral to the lesion site of saline or LPS treated rats and examined spinal nuclei and dorsal root ganglia caudal to the lesion. Preliminary results showed that in the LPS treated rats there were more labeled cell bodies in spinal nuclei and dorsal root ganglia, indicating that both central and peripheral regenerating neurites are present in the lesion.

ALTERATIONS IN ROTATIONAL AND OPEN-FIELD BEHAVIOR FOLLOWING 6-OHDA LESIONING OF THE SUBSTANTIA NIGRA AND ADMINISTRATION OF ORG 2766. F.J. Antonawich and F.L. Strand. Department of Biology, New York University, N.Y., N.Y. 10003

ACTH peptide fragments that have little or no corticotropic activity have potent neurotrophic effects on peripheral nerves in situ and central neurons in culture. Unilateral lesioning of the substantia nigra, which depletes the striatum of dopamine, has been shown to alter unidirectional behavior in rats, which provides a feasible model for central regeneration. Male Sprague Dawley rats were lesioned unilaterally with 6-hydroxydopamine (8µg/4µl), infused into the substantia nigra over a ten minute period, resulting in unilateral Parkinsonism. They were subsequently treated with 10 µg/kg i.p. of ORG 2766 (ACTH 4-9 analog) or saline every 24 hours starting immediately after the infusion. Rotational behavior was analyzed using apomorphine (0.5 mg/kg) or amphetamine (2mg/kg) every 48 hours, with a challenge injection schedule organized to observe any compensatory mechanisms involved in recovery. Open-field behavior was also observed, looking for changes in grooming, rearing and exploratory behavior.

Preliminary rotational behavior analysis shows that ORG 2766 accelerates apomorphine-induced rotation to the contralateral side, suggesting the acceleration of a compensatory mechanism; however, amphetamine-induced rotation in ORG 2766 treated animals has, of yet, shown no difference from their saline counterparts. In open-field behavioral analysis, a trend is developing, over time, which shows a greater number of rearing episodes in ORG 2766 treated animals as compared to saline, with no apparent difference in the number of grooming and exploratory episodes.

479.13

PLASMINOGEN ACTIVATOR AND SCHWANN CELL PLASTICITY IN PERIPHERAL NERVE REGENERATION. N. Kalderon. The Rockefeller University, New York, NY 10021.

Plasminogen activator (PA) is a key enzyme controlling extracellular proteolytic activities. Mammalian cells produce 2 molecular forms of PA, urokinase type (u-PA) and tissue type and at least 2 types of PA inhibitors (PAIs), PAI-1 and PAI-2. The u-PA in concert with PAIs regulates cell migration and related tissue plasticity events. Undifferentiated Schwann cells express high PA activity levels (Kalderon, 1984, PNAS, 81:7216) primarily of the u-PA type (Kalderon, 1990, in Regulation of Extravascular Fibrinolysis in Nervous System Development & Disease, Plenum).

We are examining whether these plasticity properties of Schwann cells are instrumental in their support of nerve regeneration; the effects of protease inhibitors on rat sciatic nerve regeneration through a 10mm silicone chamber are being studied (Kalderon et al. 1987, SN Abstr 13:1208). The nerve stumps are sutured to a silicone tubing which is filled with a physiological salt solution. The inhibitors are injected into the chamber at 7 days postsurgery when a massive cell migration ensues, and their effect on nerve regeneration (Schwann cell migration and axonal growth) was examined a week later. Reported here, PAI-1 (1µg/ml) and aprotinin impaired cell migration at 52% and 48%, respectively, as compared with control samples; accordingly, axonal regrowth was delayed. These results and previous data (Kalderon et al., 1987) suggest that PA and plasmin activities are elaborated by the Schwann cells for migration and are essential for successful nerve regeneration.

TESTOSTERONE EFFECTS ON AXONAL REGROWTH FOLLOWING FACIAL NERVE INJURY. K.A. Kujawa and K.J. Jones. Dept. Cell Biology and Anatomy The Chicago Medical School, North Chicago, IL 60064.

We have previously demonstrated that testosterone propionate (TP) accelerates functional recovery from facial paralysis induced by facial nerve injury in castrated male hamsters. In this study, we tested the hypothesis that TP accelerates the regrowth of axons following facial nerve injury. Male hamsters were received as castrates from the supplier. Following anesthetization, the animals were each subjected to a right facial nerve crush, with the left side serving as internal control. One-half the animals immediately received subcutaneous implants of TP, with the others sham-implanted with blank capsules. Postoperative times ranged from 3-7 d. 18 h prior to sacrifice, stereotaxic injections of ^{3}H-amino acids into the right facial nuclear groups were done. Following sacrifice, the radioactivity in 1-mm segments of the right and left facial nerves was determined, and plotted as a function of postoperative time. The furthest distance point at which the radioactivity was > 2 S.D. above background levels defined the outgrowth distance of the fastest growing axons. The percentage of total radioactivity of nerve segments was also calculated and a profile of labeling of the entire population of regenerating axons obtained. The results indicate that TP accelerates the regrowth of both the fastest growing axons and the more slowly growing fibers which represent the bulk of the regenerating nerve. We are currently examining whether this acceleration of axonal regrowth involves an effect of TP on regeneration rate, delay of sprout formation or both.

TESTOSTERONE EFFECTS ON RIBOSOMAL RNA LEVELS IN REGENERATING HAMSTER FACIAL MOTONEURONS. N.B. Kinderman and K.J. Jones. Dept. Cell Biology and Anatomy,The Chicago Medical School, North Chicago, IL 60064.

We have previously demonstrated that testosterone propionate (TP) accelerates functional recovery from facial paralysis induced by facial nerve injury in castrated male hamsters. In this study, we tested the hypothesis that the effects of TP on nerve regeneration occur at the level of the neuron and through a mechanism involving priming of the genome. Analysis of the effects of TP on rRNA levels was accomplished using *in situ* hybridization and rDNA probes. Male hamsters were received as castrates from the supplier. Following anesthetization, the animals were each subjected to a right facial axotomy (AX), with the left side serving as internal control. One-half the animals immediately received subcutaneous implants of TP (TP + AX), with the others sham-implanted (AX only). Postoperative (PO) times ranged from 30' to 14 d. At the appropriate PO time, the animals were sacrificed by ether overdose and decapitation, and the brains rapidly blocked and frozen. Standard *in situ* hybridization and autoradiographic procedures were done on 8-µm, postfixed sections using a ^{3}H-28S rDNA probe. Computerized image analysis was employed for data collection. For both TP + AX, and AX only groups, the rRNA levels were expressed as a percentage of left side control. The results indicate that TP accelerates the initial rRNA increases observed with AX alone, as well as producing a dramatic effect on the magnitude of the response. Supported by an SCRF grant (KJJ).

REINNERVATION OF MEDIAL CORTEX BY CHOLINERGIC PROJECTIONS FROM BASAL FOREBRAIN: AN *IN VIVO* MODEL TO TEST HYPOTHESES ABOUT REGENERATION WITH GROWTH FACTORS. T.W. Farris and L.L. Butcher. Dept. of Psychology, UCLA, Los Angeles, CA 90024-1563.

To determine further the regenerative effects of putative growth-promoting factors on cholinergic projection neurons (previously assessed for GM1 ganglioside and estradiol), we administered thyroxine (T4, 2.5 mg/kg, ip) or saline daily for 14, 30 or 60 days to 8 week-old female rats with unilateral knife-cut axotomies of the medial cholinergic pathway arising from the cholinergic basal nuclear complex (CBNC) and projecting to cingulate and occipital medial cortices. Brain tissue was processed histochemically for acetylcholinesterase (AChE); immunohistochemically for choline acetyltransferase (ChAT), dopamine β-hydroxylase (DBH) and nerve growth factor receptor (NGFr); and for Nissl substance. Computerized densitometry performed via light microscopy showed, in both groups, the expected accumulation and depletion of all markers proximal and distal, respectively, to the cortical cut. However, the rate of recovery from distal depletion was significantly greater in T4-treated rats. Fluoro-gold placed distal to the cut revealed cell bodies in the vertical limb of the diagonal band and magnocellular preoptic nucleus. It was possible to directly assess axonal regeneration by observing fibers crossing the cut, as occurred in a few cases in 30 and 60 d T4 rats. These data (1) support previous findings from this laboratory that CBNC neurons are sensitive to thyroid hormones and (2) demonstrate that medial pathway axotomy is a useful model for determining whether factors known to possess growth-promoting activity *in vitro* induce axonal regeneration *in vivo* . [Support: NIH NS 10928]

MAP-2 AND TUBULIN DEGRADATION BY CATHEPSIN D. J.M. Litersky, G.V.W. Johnson, and J.N. Whitaker. Depts. of Neurology, Psychiatry, Cell Biology Univ. of Alabama and the VA Medical Center, Birmingham, AL 35294.

The proteolysis required for the normal turnover of neuronal cytoskeletal proteins, such as MAP-2 and tubulin is poorly understood. Cathepsin D (EC 3.4.23.5), an aspartyl endopeptidase present in lysosomes and endosomes is abundant in many neurons. In this study, the in vitro degradation of MAP-2 and tubulin by cathepsin D was measured at various enzyme-to-substrate ratios and pH conditions using quantitative immunoblot techniques. MAP-2 showed a much greater sensitivity to cathepsin D than tubulin. At pH 3.5 and a 1:20 enzyme-to-substrate ratio, MAP-2 was totally degraded after 20 min, whereas tubulin under the same conditions was only 35% degraded after 20 min, and showed little additional substrate loss even after 60 min. The pH dependence of the cathepsin D-induced hydrolysis of MAP-2 and tubulin was also very different. At pH values between 3.0 and 5.0 the rate and extent of cathepsin D-mediated MAP-2 hydrolysis was not significantly different, however at pH 5.5 there was significant inhibition and at pH 6.0 only a small amount of the MAP-2 was degraded even after 60 min. In contrast, the hydrolysis of tubulin by cathepsin D was optimal at pH 4.5. At pH values of 3.0, 3.5, 5.0 and 5.5, tubulin was degraded by cathepsin D, but at significantly decreased rates, at pH 6.0 there was no significant hydrolysis of tubulin.

These results demonstrate that MAP-2 and tubulin are unequally susceptible to degradation by cathepsin D. These data also imply a potential for rapid degradation of MAP-2 by cathepsin D either in lysosomes, or in endosomes of the neuron. It appears unlikely that tubulin is a major substrate for cathepsin D. An understanding of these degradative pathways may contribute to our understanding of the processes involved in neurodegenerative diseases such as Alzheimer's disease, where abnormal processing of cytoskeletal proteins may be a contributing factor.

AGE RELATED CHANGES IN *c-fos* EXPRESSION IN MICE. A.D'Costa, R.M. Booze, C.R. Breese*, R.L. Boyd, and W.E. Sonntag. Department of Physiology and Pharmacology, Bowman Gray School of Medicine, Wake Forest University, Winston-Salem, NC 27103.

c-fos belongs to a class of genes that encode for nuclear proteins presumed to participate in the regulation of cellular growth and differentiation. It is thought to act as a "third messenger" molecule in signal transduction systems and its expression has been shown to be induced by a variety of exogenous and endogenous stimuli. Recent data indicate that the expression of the gene is repressed in senescent human fibroblasts (T. Seshadri et al., Science:247, 1990) which suggests a possible involvement in the mechanism of aging at the cellular level.

This experiment examines the differential expression of *c-fos* in various brain areas after a single electroconvulsive shock in four, eleven and twenty-five month old C57/BL6 mice. The animals received an acute electroconvulsive shock (90V for 0.2s), without prior anesthesia, through earclip electrodes. All animals exhibited generalized tonic-clonic seizures lasting 35-40s. An hour after the seizure, animals were anesthetized and perfused with 4% paraformaldehyde. The brains were Vibratome-sectioned (50 microns) and examined using *c-fos* antibody (1:1000;CRB), directed against a conserved region of both mouse and human *c-fos*, by standard ABC immunocytochemical methods. *c-fos* immunostaining was evident in the amygdala, granular layer of the dentate gyrus of the hippocampus and in the superficial layers of the cortex in the young animals. The oldest group showed a decrease in *c-fos* expression in these areas relative to the young animals, whereas the middle aged animals exhibited no difference. This reduced induction of *c-fos* in aging animals may serve as an indicator of brain aging. (This work was supported by NIH grant AG 07752 to W.E. Sonntag).

DISTINCT FORMS OF THE ALZHEIMER'S AMYLOID PRECURSOR ARE PRESENT AT HIGHER LEVELS IN FETAL THAN IN ADULT HUMAN CORTEX. K. Sambamurti*, M. Mohamadi*, J.P. Anderson*, P. Knott and N.K. Robakis, Mount Sinai Medical Center, One Gustave Levy Place, New York, N.Y. 10029.

The ß/A4-amyloid protein, which is the major component of the neuritic plaque that accumulates in the brains of Alzheimer patients, derives from a larger precursor protein (ßAPP). We have used antisera raised against a series of peptides derived from ßAPP to study the various forms of the precursor in adult and fetal cortex. Two independent antisera specific to the extracellular domain (R3 and R5) detected three bands in brain extracts migrating at 98, 105 and 110 KD which were present at significantly higher levels in fetal than in adult brain. This difference was not due to masking of antigenic sites in the adult brain due to either phosphorylation or glycosylation. In contrast, and in agreement with published data, an antibody against the cytoplasmic domain (R1) detected bands in the range of 110 to 120 KD were not significantly different in the fetal and adult brain. Concomitant with the loss of the three ßAPP bands, two new protein bands of approximately 50 KD and 40 KD were detected in adult but not fetal brains. All these bands were specific as demonstrated by peptide competition. These results suggest that certain forms of ßAPP are developmentally regulated.

REDUCTION OF RAT BRAIN SOMATOSTATIN mRNA EXPRESSION DURING AGING. T. Florio, C. Ventra, O. Meucci*, A. Scorziello*, and G. Schettini. Dept. of Pharmacology, II Medical School, Univ. of Naples, via S. Pansini 5, 80131 Naples, Italy.

In the past years, a growing bulk of studies demonstrated that the blockade of central somatostatin neurotransmission caused an impairment of learning and memory processes in the experimental animals. Moreover, clinical studies reported that, in patients affected by the dementia of the Alzheimer's type, the somatostatinergic neurotransmission is quite affected. Thus, a primary role for the brain somatostatin in the modulation of cognitive functions has been suggested. In this report we studied whether an alteration in the brain somatostatinergic neurotransmission "naturally" occur during the aging process in the rat. For this purpose we analyzed the somatostatin mRNA expression in different rat brain areas (frontal cortex, parietal cortex, hippocampus, striatum) derived from 2, 6, 12, and 25 months old rats, by means of both northern and dot blot analysis, using pre-prosomatostatin cDNA (kind gift of Dr. R. H. Goodman) as probe. A clear reduction of somatostatin mRNA expression occurred in both frontal and parietal cortex in the aged rats.

EXPRESSION OF HEAT SHOCK mRNAs IN AGED RAT BRAIN. J.D. Raese, S. Pardue*, K. Groshan*, E.K. Miller*, B. Border, R. Gonzales* and M. Morrison-Bogorad. Departments of Psychiatry, Neurology and Biochemistry, University of Texas Southwestern Medical Center, Dallas, Texas, 75235, and The Schizoprenia Research Center, V.A. Medical Center, Dallas, Texas, 75216.

mRNAs encoding strictly heat inducible (hsp70) and constitutively-expressed (hsc70) members of the heat shock 70 gene family show different cell distributions in adult rat brain. Nothing is known about possible alterations in the heat shock response in different cell types of aged brain. We compared in situ hybridization of oligos specific for the hsp70 and hsc70 mRNAs in cerebellum and hippocampus of 4 adult and 3 aged rats, each subjected to a heat stress of identical duration and intensity. Rats were sacrificed 3 hours after initiating the heat stress. Grain counts in each cell type in different animals were normalized by hybridization of adjacent sections to an 18S rRNA oligo. In 3/4 adults, hsp70 mRNA induction was several fold greater in granule cells of the dentate gyrus than in granule cells of the 3 aged rats. In the adult rats, hsp70 mRNA levels were also higher in CA1 and CA4 pyramidal neurons. There was a very strong glial response in both age groups. Hippocampal hsc70 mRNA distribution was very different. This mRNA was abundant in neurons and very low in glia. Relative levels of hsc70 mRNA varied in different animals but there was no consistent difference between adult and aged rats or between the relative levels of either mRNA in cerebellar cells of either age group. However, hybridization with the 18S oligo showed that levels of 18S rRNA were lower in Purkinje cells of aged rats. These results show that there are age-related changes in the stress response of hippocampal neurons. Such changes may predispose these cells to stress-related injury or death. MODULATION OF TYROSINE HYDROXYLASE GENE EXPRESSION IN THE RAT ADRENAL GLAND BY RESERPINE: EVIDENCE FOR UNCOUPLING OF TRANSCRIPTIONAL AND POSTTRANSCRIPTIONAL MECHANISMS DURING AGING. R. Strong, C. Hale, M. A. Moore and M. Wessels-Reiker. Departments of Pharmacology and Medicine, St. Louis Univ. Sch. Med. and GRECC, VA Med. Cntr. St. Louis, MO 63125

Plasma catecholamine levels are increased during aging. Because tyrosine hydroxylase (TH) is the rate limiting enzymatic step in catecholamine synthesis, we are studying alterations in the regulation of TH gene expression during aging. Tyrosine hydroxylase, TH messenger RNA (TH mRNA) and dopamine (DA) were measured simultaneously in adrenal glands of individual Fischer 344 rats aged 2, 6, 13 and 23 months. Between 2 and 23 months TH activity rose 2 fold as compared to the youngest group. TH mRNA content of the adrenal gland rose 3 fold between 2 and 23 months. A 3 fold increase in adrenal DA content, the first catecholamine product of TH, provides evidence that the increases in TH gene expression are functionally significant.

To determine if mechanisms that regulate gene expression are altered by aging, the effects of reserpine on induction of TH mRNA and TH activity were compared in another group of rats aged 2, 12 and 27 months. Consistent with the results of the first experiment, there were age-related increases in both TH activity and TH mRNA in the age-matched control groups. TH activity rose 2 fold and TH mRNA rose more than 6 fold between 2 and 27 months. The discrepancy in the relative magnitudes of increases in TH mRNA and TH protein suggest an uncoupling of regulation of TH mRNA and TH protein levels. Moreover, there were significant age-related differences with respect to modulation of TH gene expression by reserpine treatment. TH activity was induced by reserpine in the youngest group, but not in the two older age-groups. In contrast, reserpine caused significant induction of TH mRNA in all age-groups. These results provide evidence that aging is accompanied by alterations in TH gene expression at transcriptional and post-transcriptional levels.

EFFECTS OF AGING AND DENERVATION ON ADRENERGIC RECEPTORS OF THE CEREBRAL CORTEX AND CEREBRAL MICROVESSELS IN RATS. S.I. Harik, S. Sromek* and R.N. Kalaria. Dept. of Neurology, Case Western Reserve Univ. Sch. of Med., Cleveland, OH 44106.

Locus ceruleus (LC) lesions cause cerebral norepinephrine loss and increased density of ß adrenoceptors in the cortex and its microvessels (mv). This "denervation supersensitivity" implies that these receptors are responsive to LC input. We studied the effect of aging and denervation on these adrenoceptors in 3 age groups of Fisher-344 rats: young (3-4 months), middle-aged (12-13 months), and old (25-26 months). Unilateral LC lesion was induced by microinjection of 4 µg of 6-hydroxydopamine. Two weeks later, the rats were killed and samples from each cerebral cortex were assayed for norepinephrine and for adrenoceptor assays. The rest of cerebral cortical mantles from ipsilateral and contralateral cortices were pooled from 5-6 rats and their mv harvested and assayed for α_1 and ß adrenoceptors using [^{125}I]-HEAT and [^{125}I]-pindolol. We found that ß receptor density increased by about 50% in both cortex and mv ipsilateral to lesion in all age groups, but there were no significant changes in α_1 receptors. Also, aging had no effect on the density of both adrenoceptors in the contralateral cortex and mv.

VESICULAR FAST AXONAL TRANSPORT RATES FOR RAT SCIATIC NERVE AXONS AS A FUNCTION OF ANIMAL AGE. N.A. Kreiter* and T.A. Viancour. Department of Biological Sciences, University of Maryland, Baltimore County Campus, Catonsville, MD 21228.

We report the results of a pilot study of vesicle transport in aging axons. Longitudinally moving vesicles in dissected, myelinated axons from rat (Fisher 344 strain) sciatic nerves were observed by high resolution, video-enhanced-contrast microscopy at an experimental temperature of 37 ± 0.2°C. Transport rates of individual vesicles were determined by measuring the transit time through a 2-3µm long speed trap which was electronically superimposed on the video image of the moving vesicles. Transport rates of more than 8,000 vesicles were measured for both a young (ca. 8 wks) and an old (ca. 2 yr) age group.

Under these conditions, average transport rates of both anterograde moving vesicles and retrograde moving vesicles were significantly slower in the older animals ($p << 0.001$, Student's T-test). Among the yet to be tested explanations of these data is the possibility that vesicle movements are impeded by age-dependent properties of the axonal cytoskeleton.

Transport Direction	Young Age Group avg ± SEM (n)	Old Age Group avg ± SEM (n)
Anterograde (µm/s)	3.02 ± 0.02 (3765)	2.41 ± 0.03 (2012)
Retrograde (µm/s)	2.89 ± 0.01 (5439)	2.50 ± 0.01 (6166)

SEGMENTAL DEMYELINATION IN HINDLIMB NERVES OF AGED CATS. A.M. Adinolfi, J.Yamuy, F.R. Morales and M.H. Chase. Dept. of Anatomy & Cell Biology, Dept. of Physiology and Brain Research Institute, UCLA School of Medicine, Los Angeles, CA. 90024.

This study of the ultrastructure of sciatic nerve branches in normal old cats provides evidence that segmental demyelination is one cause for the decrease in old age in the mean axonal conduction velocity of hindlimb nerves. Eight cats, one to 17 years old, were prepared for peripheral stimulation of hindlimb nerves and intracellular recording from lumbar motoneurons. Samples of unperturbed nerves from the opposite hindlimb were processed for electron microscopy. The mean conduction velocity, calculated by dividing conduction distance by the latency of the antidromic spike, slowed from 102.8 m/s±10.8 (SD) at one year to 70.6 m/s±7.9 (SD) in the oldest cats. In these animals, 8-12 % of nerve fibers showed focal abnormalities of the myelin sheath. These changes included 1) lipoid and granulo-vacuolar debris in distended inner adaxonal and outer cytoplasmic parts of the Schwann cell, 2) retraction of paranodal myelin loops to widen nodes of Ranvier and 3) disruption of one or more contiguous segments of the myelin sheath by intralamellar ballooning along major dense and intraperiod lines. BLOOD-NERVE BARRIER PERMEABILITY AND NERVE VASCULAR SPACE IN THE PERIPHERAL NERVE OF RATS OF DIFFERENT AGES. J. Koistinaho, K.C. Wadhwani, A. Balbo and S.I. Rapoport. Lab. of Neurosciences, NIA, NIH, Bethesda MD 20879. The permeability-surface area products of (14C)-sucrose at the blood-nerve barrier, PA(BNB), of the sciatic nerve; and at the blood-brain barrier, PA(BBB), were determined in Fischer-344 rats at 3, 11 and 30 mo of age, using an in vivo i.v. bolus injection technique and a two-time point graphical method. Nerve vascular space in the tibial nerve of these rats was also determined using quantitative morphometry. There was no significant difference of mean PA(BNB) between any age group [PA(BNB) at 3 mo=1.1±0.1(SE), at 11 mo=1.8±0.3; and at 30 mo=1.4±0.2 x10(-5) ml/s.g wet wt; n=5-8 rats], nor any difference in PA(BBB). The mean ratio of surface area of endoneurial blood vessels/nerve cross section (%) of the tibial nerve also did not differ between any group [3 mo: 16±2 vessels; mean surface area ratios =2.11±0.10 %, n=6; 11 mo= 22±3 vessels and 2.48±0.21 %, n=5; and at 30 mo= 26±1 vessels and 2.40±0.23 %, n=4). Our results indicate that BNB and BBB integrities are not altered in senescent Fischer-344 rats.

UNBIASED STEREOLOGICAL ESTIMATION OF THE TOTAL NUMBER OF NEURONS IN THE AGING HUMAN HIPPOCAMPUS

M. J. West and H.J.G.Gundersen*

Stereological Research Lab., Univ. of Aarhus, Denmark

The total numbers of neurons in the dentate granule cell layer, the hilus, regio-inferior, regio superior and subiculum were estimated with unbiased stereological techniques and systematic sampling in 16 patients ranging from 15 to 85 years of age. Total neuron number was calculated as the product of the numerical density, N_V, and the reference volume, V_{ref}, of the layer containing perikaria. N_V was estimated with optical disectors, V_{ref} by point counting. Sampling in both cases was carried out systematically, i.e., with a random start and a predetermined periodocity. The sampling scheme was designed so that the major contribution to the variance of the group was the true biological difference amoung individuals. Preliminary data indicates that is there a significant correlation between age and neuron number in regio superior. This is an inverse relationship indicating a loss of 50% of the neurons in regio superior, but not in other hippocampal subdivisions, during adult life.

J. Comp. Neurol. 296: 1-22, 1990

AGE-RELATED REGRESSIVE CHANGES IN MOTONEURON NUMBER AND MORPHOLOGY IN AN ANDROGEN-SENSITIVE RAT SPINAL NUCLEUS. E.M. Kurz and D.R. Sengelaub. Program in Neural Science, Dept. of Psychology, Indiana University, Bloomington, IN 47405.

Motoneurons in the sexually dimorphic spinal nucleus of the bulbocavernosus (SNB) in rats are sensitive to androgens during development and at adulthood. Developmentally, androgens regulate motoneuron number, soma area, and dendritic morphology. In adults, reductions in androgens after castration produce significant declines in SNB soma area and dendritic length, and these can be restored by androgen treatment. Androgen titers decline during normal aging in male rats, and testosterone titers in aged males are about 1/3 of young adult levels. We examined whether this age-related, naturally occurring decline in androgens altered SNB motoneuron number, soma area, or dendritic length.

SNB motoneuron number and morphology were assessed in aged (22 months old; n=5) and young adult (70 days old; n=4) males after retrograde labeling following unilateral muscle injection with cholera-toxin HRP and counterstaining with thionin. Aged males had significantly fewer SNB motoneurons than young adults (144 *vs.* 172); counts of HRP-labeled motoneurons were also lower in aged males (45 *vs.* 51). HRP-labeled SNB motoneurons in aged males were significantly smaller than those of young adults in both soma area (760 *vs.* 843 sq μm) and dendritic length (1891 *vs.* 4114 μm). Weights of the androgen-sensitive SNB target muscles (bulbocavernosus/levator ani) were also significantly lower in aged males (0.92 *vs.* 1.23 g). These data suggest that age-related regressive changes in SNB motoneuron number, soma area, dendritic length, and target muscle weight may result from declining androgen levels. SEX- AND AGE-RELATED DIFFERENCES IN MIDSAGITTAL AREAS OF THE CEREBRAL CORTEX AND CORPUS CALLOSUM: AN MRI INVESTIGATION. N. Raz, W. Spencer, and I. Torres. Dept. Psychology, Memphis State University, Memphis, TN 38152. We examined sex- and age-related differences in the area of the cerebral cortex (Cx), corpus callosum (CC), and subdivisions of the CC. Midsagittal magnetic resonance (MR) images were obtained from a sample of 51 normal volunteers and pseudoneurological controls (age 17 - 87). Males had larger Cx, CC, and splenial areas than females [t(49)=6.63, p<.001, t(49)=2.07, p<.05, and t(49)=2.74, p<.01, respectively]. However, the correlations between the areas of CC and splenium, and Cx were also significant (r=.28, p<.05; r=.33, p<.02, respectively). The Cx area is an estimate of the brain size, and as such is influenced by gender differences in body size. After controlling for this index of brain size, we found no significant effects of gender on CC or splenium area. The Cx area was weakly associated with age (r=-.32, p<.02), but no age-related differences were found in CC area or its subdivisions. Supported by BRSG S07-RR0-5366-26 and MSU Center for Applied Psychological Research.

MAGNETIC RESONANCE IMAGES OF THE CEREBRAL INFARCTION OF AN AGED RHESUS MACAQUE. H. Uno, W.D. Houser*, and J.E. Holden*. Wisconsin Regional Primate Research Center and Medical Physics, University of Wisconsin, Madison, Wisconsin 53715-1299.

Magnetic resonance imaging of a 30 year old, male rhesus macaque suffering from ataxia of the bilateral fore and hind limbs for approximately one year was performed at 6 month intervals. After the 2nd test, the animal was euthanized due to severe locomotive failure. The formalin-fixed whole brain was also examined by MRI, then sliced into 5 mm thicknesses along the horizontal plane. Scanning was performed in a 1.5 tesla (GE) unit. The images of horizontal, coronal, and sagittal planes were obtained using a Tr (repetition rate) = 2000 msec and either TE (echo time) = 20 msec for spin density or TE = 90 msec for 2nd echo images. In the 2nd echo (T_2 dependent) images, irregular opaque shadows were found in the left inferior parietal lobe along the lateral sulcus, right parietal lobes and bilateral cerebellar cortex. However, the images of spin density in pre- and post-mortum brain confirmed that the opaque shadows showing in T_2 images were caused by CSF accumulation in widened meningeal spaces associated with a defect of the cortex (old infarction). Pathology of the brain showed multiple infarctions (old and liquified lesions) in the above regions. Different relaxation times [CSF = water (400-450 msec); brain cortex (250-300 msec)] produced the contrasting grey tone in spin density and 2nd echo (T_2); e.g. CSF, black in the former and white in the latter and brain cortex, vice versa. A combination of different Tr and TE times is necessary to determine the real nature of pathological lesions.

Aging of the Human Brain: Assessment with 1.5 Tesla MRI

P. Murali Doraiswamy, Gary Figiel, Mustafa Husain, Orest Boyko, William McDonald, Sunjay Shah, Everett Ellinwood, and Ranga Krishnan. Duke University Medical Center and Washington University School of Medicine, St. Louis, MO.

Brain MR images of 39 normal volunteers, aged 26 to 79 yrs were used to assess neuroanatomical and biophysical changes in the aging brain. Axial MR images revealed a significant increase in the frequency of subcortical hyperintensities in older subjects. Older subjects also demonstrated significantly smaller caudate and putamen volumes compared to younger subjects. Sagittal images revealed significant age-related dimensional changes in the corpus callosum, pituitary gland, midbrain, septum pellucidum and cortex. Coronal multi TR/TE images showed a significant increase in T1 relaxation times in the hippocampus, corpus callosum, frontal and temporal white matter in the older subjects when compared with younger subjects.

These data represent the first in vivo study to simultaneously document anatomical as well as biophysical tissue changes in specific regions in the human brain in normal aging. Neurocognitive studies are underway in these subjects to evaluate the potential functional correlates of these findings and to establish structure-function relationships in the aging human brain.

480.16

BIOMARKERS OF HIPPOCAMPAL AND RETINAL AGING ARE NOT ALTERED BY DIETARY RESTRICTION. W.K. O'Steen, L.B. Cadwallader*, S. Vinsant*, and P.W. Landfield. Depts. Neurobiol. & Anat. and Physiol. & Pharmacol., Bowman Gray Sch. Med., Wake Forest Univ., Winston-Salem, NC 27103.

Dietary restriction is one of the few established methods for prolonging life span in mammals, and development of several biomarkers of aging has been found to be slowed by prolonged restriction. However, much less is known about the effects of restriction on markers of brain aging. In the present studies, therefore, we have investigated the effects of long-term dietary restriction (60% of ad lib diet, beginning at 16 weeks of age) on quantitative morphometric measures of aging in the hippocampus and the retina of Fischer 344 male rats. The animals were maintained by the NIA Biomarkers program at the Nat. Center Tox. Res. Each experimental group ranged in size from 8 to 16 rats.

A gradual thinning of the retinal outer nuclear layer of photoreceptor nuclei occurs with aging in the control ad lib groups. However, the restricted diet did not influence retinal aging in 18, 21, or 27 mo-old rats, as judged by photoreceptor cell death, outer nuclear layer thickness, and pattern of cell loss.

Hippocampal pyramidal cell density and astrocytic inclusions correlate closely with aging in F344 rats. In two studies, no differences in hippocampal neuronal density were found between *ad lib* (AL) and dietary restricted (DR) animals in the older groups (26-27 mo-old). However, in the 18 mo-old and 21 mo-old animals, a small (about 10%), but significant difference was found, with DR animals exhibiting higher neuronal density. In 26 mo-old rats, no significant effects of dietary condition were found on quantitative E.M. measurements of glial inclusions, neuronal lipofuscin, rough endoplasmic reticulum or Golgi apparatus.

These results are in contrast to studies of restriction on non-neuronal markers of aging, including basic longevity, and suggest that a different aging mechanism may modulate at least some aspects of brain aging. (Supported by AG07767)

480.17

EFFECT OF LIFELONG VOLUNTARY ETHANOL CONSUMPTION ON AGING IN RATS. K. Kiianmaa[1], M. Sarviharju[1]*, P. Jaatinen[2]*, P. Salmi[2]*, A. Hervonen[2]. [1]Res. Labs., Alko Ltd., 00101 Helsinki, and [2]Lab. of Gerontology, Univ. Tampere Med. School, 33101 Tampere, Finland.

The effect of 20 months of voluntary ethanol consumption on aging was studied in several generations of high drinking AA (Alko alcohol) rats. After the initial test of individual voluntary ethanol intake at the age of three months the rats were housed in group cages. One half was given free access to food, tap water, and 10 % (v/v) ethanol solution, while the other half had only food and water available. The survival curves of both ethanol exposed and ethanol non-exposed groups were monitored. Several generations were pooled together or compared within the generation. No changes were found in the population longevity up to the age of 24 months when the rats were used for experiments. The ethanol exposed group consumed slightly more ethanol than the non-exposed group when measured at the age of 24 months. They did not show any difference in ethanol sensitivity when tested for ethanol-induced (2 g/kg ip) motor impairment on the tilting plane, for the duration of ethanol-induced (3.5 g/kg ip) loss of righting reflex, or for ethanol-induced (3.5 g/kg ip) hypothermia. The groups did not differ in the rate of ethanol elimination either. Determination of the concentrations of brain monoamine neurotransmitters and their major metabolites did not reveal any differences between the ethanol exposed and non-exposed old rats, while the levels tended in both groups generally to be higher than in 3-4 month old rats. Dendritic spine counts after Golgi-stain were not different either. The ethanol-feeding regimen used thus did not produce any measurable negative interactions of ethanol on aging.

480.18

AGE-DEPENDENT CHANGES IN VISUAL INTENSITY DIFFERENCE THRESHOLD IN PIGEONS. M. Kurkjian* and W. Hodos. University of Maryland, College Park, MD 20742.

Recent studies have reported age-related deficits in visual acuity and retinal morphology in pigeons. The study reported here was designed to determine the effects of age on intensity difference thresholds (IDT) in pigeons. 76 pigeons, aged 1-17 years, were trained to discriminate two stimuli that differed in luminance by 0.6 log unit. When this discrimination was established, the subjects were presented with two series of progressively smaller luminance differences. IDT was calculated from psychometric functions by determining the luminance difference that corresponded to 75% correct. The coefficient of correlation between age and IDT was +0.26, which indicates a small, systematic relationship between IDT and age; i.e., age accounts for approximately 5% of the variance in IDT. This is in contrast to visual acuity in pigeons in which age accounts for 82% of the variance. The results reported here, which are in agreement with human literature, indicate that age-related deficits in visual acuity and other visual tasks in pigeons are not due to a general deterioration of the visual system or to some non-specific global performance deficit.

AGING AND EYE MOVEMENT ON COPYING FIGURE. S. Murakami*, J. Miyazawa**, M. Fujii**, R. Fukatsu**, Y. Aizawa**, N. Nakano**, N. Takahata**, T. Fukuda***, M. Yamada***. Yamanoue Hospital*, Dept. of Neuropsychiatry, Sapporo Medical College, Sapporo, 060**. NHK Science and Technical Lab., Tokyo, 110***.

Eye movement, to move the eyes so that the point of interest will be seen with the visual center of the retina, tells us valuable information about a human higher brain function including visual cognition. In this experiment, we investigate the development time course of eye movement on copying a cube by using a new technique, Vision Analyser (TKK 939), experimented in 30 subjects (6-81 year-old).

In 6-7 years, eye velocity on copying was diffuse to a wide range and no peak, as developing the most used eye velocity was appeared and going slower. A mean eye velocity was 76.6 deg/sec in 6 years, 32.6 deg/sec in 25 years and 23.2 in 81 years old. On the other, total eye fixation time was going longer as developing, but it made a peak at 20-30 years old. And gazing points localized more on the model figure in young below 10 years old and on the copyed figure in older than 10 years.

The development time course of eye movement on copying a cube is obtained for the first time objectively, so these results indicate that a development of ability of visual cognition and hand writing due to visual information, is to increase until 20-30 years and hold on.

AGE-RELATED DECLINE OF NEURONAL RESPONSES TO SENSORY STIMULATION IN THE RAT SI VIBRISSA CORTEX. J.M. Greuel, W. Scheip*, K.M. Bode-Greuel, M. de Jonge, T. Schuurman*, T. Glaser, J. Traber*. Institute for Neurobiology, Troponwerke GmbH & Co.KG, Berliner Str.156, 5000 Köln 80, F.R.G.

Performance of aged rats in a number of behavioral tests is disturbed when compared to young rats. It has been hypothesized that altered brain functions contribute to the reduced performance. We investigated whether the aging process affects the processing of sensory information. Young (3-4 months) and aged (>32 months) rats were anaesthetized and the rat SI vibrissa cortex was exposed for single unit recording. Single whiskers were stimulated by using hand-held probes. The neuronal responses to the sensory stimulation were assigned to either of four classes according to their response vigour. It was found that in the aged rats less cells responded to the applied stimuli. Of those responding to the stimuli the neurons of the aged animals responded less vigourously, thus leading to a shift in the response quality distribution towards lower response qualities. Taken together, the results suggest i) that changes in cerebral function that may contribute to altered behavioral performance can be detected at the level of sensory processing and ii) that the vibrissa cortex of the rat can be a suitable model to study age-related changes in cortical function.

INCREASED PLASTICITY OF AGING MOUSE PECTINEUS NEUROMUSCULAR JUNCTIONS OBSERVED IN VIVO N. Robbins, J. Hill* and R. Hill*, Dept. Neurosciences, Case Western Res. Schl. of Medicine, Cleveland, OH 44106.

In order to delineate dynamic cellular processes underlying age changes at the neuromuscular junction (NMJ), living identified NMJ's were observed at intervals of 1 week or 1 month in adult (6 mo.) and old (27-29 mo.) CBF-1 mice. Fluorescent stains for pre- and post-synaptic elements were, resp., Texas Red-tetanus toxin C fragment (recombinant, Boehringer Mannheim, or proteolytic-derived) and FITC-alpha-bungarotoxin. At first observation, old NMJ's revealed more separate synaptic regions, more nerve terminal (NT) constrictions, and a greater area of NT outgrowth per NMJ than did adult NMJ's. Over 1 week (but not 1 mo.), more focal constrictions appeared and more pre-existing NT constrictions expanded in old NMJ. Over 1 month, NT outgrowth/retraction was greater in old NMJ, with 50% of old NMJ's (vs., 14% adult) showing 3 or more types of change, some markedly so. In sum, increased focal NT withdrawal may eventually produce the constrictions and multiple regions characteristic of old NMJ's, whereas enhanced in- and outgrowth of NT may account for increased abandoned postsynaptic folds. These dynamic events could result from decreased adhesion of NT to synaptic matrix and possibly increased perijunctional adhesion. Supported by NIH AG 06641.

LONG-TERM REGULATION OF TRANSMITTER RELEASE FROM CRAYFISH MOTOR TERMINALS BY DEPOLARIZATION OF THE MOTONEURON CELL BODY. S.J. Hong and C.A. Lnenicka. Dept. of Biol. Sci., State Univ. of New York, Albany, NY 12222.

Previous in vivo studies demonstrated that electrical stimulation of a crayfish phasic motor axon, proximal to a TTX conduction block produced long-term changes in transmitter release: less initial transmitter release, and greater fatigue-resistance (J. Neurophysiol. 61:91-96, 1989). In order to further examine this effect, the cell body of a phasic motoneuron was depolarized in vitro by current injection, and the physiology of its neuromuscular synapses examined. The cell body of the abdominal fast flexor motoneuron F3 was depolarized at a level subthreshold for impulse generation (30-40 mV; 30 mS duration) at 5 Hz for 2 hrs. At 5 hrs after this period of conditioning, the initial EPSP amplitude of the conditioned side (16.6 $\pm$ 2.0 mV) was significantly smaller than the control side (20.0 $\pm$ 1.8 mV, $p < .001$; $n = 17$). This reduction in initial EPSP amplitude (17%) is similar to the 25% reduction seen 24 hrs after in vivo central stimulation (J. Neurophysiol. 61:91-96, 1989). The present result shows that depolarization of the cell body can influence transmitter release from distant neuromuscular synapses.

SEASONAL CHANGES IN THE PHYSIOLOGY AND MORPHOLOGY OF IDENTIFIED CRAYFISH MOTOR TERMINALS. G.A. Lnenicka and Y. Zhao, Dept. of Biol. Sci., State University of New York, Albany, N.Y. 12222.

Seasonal changes in synaptic terminal physiology and morphology were studied in the crayfish fast closer excitor (FCE), a phasic motoneuron innervating the claw closer muscle. FCE EPSPs recorded from closer muscle fibers in summer animals showed a significantly lower initial EPSP amplitude (8.7 $\pm$ 1.5 mV) compared to winter animals (14.7 $\pm$ 1.7 mV, $p < .02$), and a significant increase in fatigue-resistance. During 30 min. of 5 Hz stimulation, FCE EPSP amplitude in summer animals decreased only 1%, while EPSP amplitude in winter animals decreased 82% ($p < .02$). In some animals, HRP was intracellularly injected into the FCE axon to examine terminal morphology, and it was found that the motor terminals in summer animals possess significantly more synaptic varicosities (.92 $\pm$ .10 varicosities/10 μm terminal) than those in winter animals (.40 $\pm$ .05 varicosities/10 μm terminal, $p < .001$).

The physiology and morphology of the FCE terminals in summer animals is similar to that seen after in vivo stimulation of the FCE in winter animals. It is proposed that high activity levels in summer animals are responsible for the seasonal change in the synaptic terminals.

EFFECT OF VARYING CALCIUM CONCENTRATIONS ON JUNCTION POTENTIALS RECORDED FROM NORMAL AND REPRESSED SYNAPSES IN THE CRAYFISH. A. Gupta* and S.J. Velez Dept. of Biological Sciences, Dartmouth College, Hanover, N. H. 03755

The synaptic connections of the neurons innervating the superficial flexor muscles of the crayfish Procambarus clarkii become repressed (no junction potentials are detected under normal physiological conditions) when the nerve is cut at the center of the muscle field and the lateral fibers are removed (Prosser & Velez, Soc. Neurosci. Abst. 12: 1575, 1986). We suggested that calcium ions could be involved in this repression. In the present work we study the effects that changes in calcium concentrations have on the junction potentials (jp's) recorded from normal and repressed animals. The same type of surgery was performed to obtain a pool of repressed animals, which were analyzed between three to five weeks after the operation (the peak time for repression). Analysis consisted of recording from medial muscle fibers with a microelectrode the jp's generated by the spontaneous firing of neuron 3. The microelectrode was left in the fiber while changing Ringers solutions which varied in calcium concentration from 30 to 200%. Normal animals showed a 60-90% increase in jp's sizes with increasing calcium concentrations while repressed animals showed only a 2-20% increase. Since repressed synapses do not respond to changes in calcium concentrations as normal synapses do, this suggests that calcium is indeed involved in the mechanisms underlying repression in this system.

DIFFERENTIAL ALTERATIONS IN VISCERAL SENSORY NEUROTRANSMITTERS OF THE NODOSE (NG) AND PETROSAL GANGLIA (PG) IN RESPONSE TO AXOTOMY. C.J. Helke and A. Rabchevsky*. Dept. of Pharmacol., Uniformed Services Univ., Bethesda, MD 20814.

Acute peripheral axotomy of the visceral sensory neurons of the vagus and glossopharyngeal nerves removes peripheral depolarizing and trophic influences to their sensory ganglia. Whereas transmitter expression is altered by axotomy of somatic sensory neurons, axotomy-induced transmitter changes in visceral sensory neurons are largely unexplored. To study this, rats were sacrificed 1, 3, 7 or 14 days after transection of either the cervical vagus or the glossopharyngeal nerves. The numbers of calcitonin-gene related peptide (CGRP) immunoreactive (ir), tyrosine hydroxylase (TH)-ir, and vasoactive intestinal peptide (VIP)-ir neurons in the respective ganglia (NG & PG) were analyzed in axotomized vs. control ganglia. In the NG, axotomy of the cervical vagus resulted in a rapid (by 1 d) reduction in the number of TH-ir cells. CGRP-ir cells were decreased at 7 and 14 days, whereas VIP-ir neurons were dramatically increased in number by 3 days. In the PG, axotomy of the glossopharyngeal nerve similarly reduced the TH-ir cells but had less effect on CGRP-ir cells and did not increase the number VIP-ir neurons. Thus, peripheral axotomy of visceral sensory neurons differentially changed the content of putative transmitters in their cell bodies. These data have implications for immunocytochemical-retrograde tracing studies with tracer application to cut axons and for studies of cultured visceral ganglia. (NS20991)

ULTRASTRUCTURE OF "SPROUTED" SAPHENOUS AFFERENTS IN THE RAT LUMBAR DORSAL HORN AFTER SCIATIC DEAFFERENTATION INDUCED BY INJECTION OF THE SCIATIC NERVE WITH PRONASE. A. El-Bohy, S. E. Kapadia, and C. C. LaMotte. Section of Neurological Surgery, Yale Univ. Sch. Med., New Haven, CT. 06510.

We have previously demonstrated expansion of the terminal field of the saphenous nerve 4 months following deafferentation by injection of the sciatic nerve with proteolytic enzymes (Pronase)(JCN, '89). In these experiments, the sciatic nerve was injected with 20mg Pronase; the opposite side served as a control. Four months following the injection, the saphenous nerves on both sides were injected with 0.5 mg WGA-HRP and .05 mg bCT-HRP, and the animal sacrificed after 48 hours. Sections demonstrating maximal expansion were prepared for EM, using the AHM (ammonium heptamolybdate) method for the peroxidase reaction. Low magnification EM montages were prepared, covering the labelled territory on the pronase and the control sides. All labelled terminals were located on the montage and rephotographed at 10K. In each animal, 70-100 terminals on each side were classified by location and by type (simple or glomerular), and the number of synaptic contacts made by each terminal counted. There was an increase in terminal number in all laminae on the pronase side, particularly laminae IIi and III. Quantitative analysis of lamina II revealed that there was an increase in the ratio of glomeruli/simple terminals on the pronase versus control side while the number of synapses per glomerulus was similar on both sides. (NIH grant NS 10174).

INCREASED LEVELS OF TYROSINE HYDROXYLASE (TH) AND NEUROPEPTIDE Y (NPY) IN CILIARY GANGLIA OF SYMPATHECTOMIZED RATS. Sophia Tyrrell, Ruth E. Siegel and Story Landis. Dept. Neurosci. and Pharm., Case Western Reserve Univ. Sch. of Med., Cleveland, OH. 44106.

The mechanisms that determine and regulate the expression of transmitters in different neuronal classes are incompletely understood. We have examined several neurotransmitter properties in the adult ciliary ganglion of control and sympathectomized rats. Although the ciliary ganglion is parasympathetic and functionally cholinergic, it has been shown to express properties characteristic of noradrenergic neurons; in adult rats some ciliary neurons have TH-IR and NPY-IR and following neonatal sympathectomy with 6-OHDA both the number of TH-IR cells and the intensity of TH-IR increases. We have counted the number of neurons expressing detectable levels of TH and/or NPY in adult ciliary ganglia. 52% of neurons in control ganglia and 71% of neurons in ganglia from 6-OHDA treated animals contained TH-IR while 25% of control cells and in 45% of 6-OHDA treated animals possessed NPY-IR. TH and NPY were preferentially but not exclusively colocalized. Immunoblots with anti-TH disclosed a 62Kd band in extracts of sympathetic and ciliary ganglia but not liver; this band is twice as intense in ciliary extracts from 6-OHDA treated rats. *In situ* hybridization revealed that both TH and NPY message were present at varying levels in most ciliary neurons. Interestingly, while the message for TH was increased in 6-OHDA rats, reflecting the increase in TH-IR in the ganglion, NPY message was present in the same proportion of cells at the same level in control and 6-OHDA rats. This raises the possibility that posttranscriptional events, either translation or processing, are responsible for the increased peptide. Because nerve growth factor is more available to parasympathetic neurons in sympathectomized animals, it is a candidate for mediating the increase in TH and NPY in 6-OHDA treated rats. Consistent with this possibility, we found that almost all ciliary neurons in control and sympathectomized rats expressed IR for the NGF receptor. Thus, the levels of TH and NPY in the ciliary ganglion are regulated by environmental factors but the level of regulation differs for the two proteins.

481.8

TWO POPULATIONS OF ADULT RAT DRG NEURONS THAT DIFFER IN THEIR READINESS TO EXTEND NEURITES. D.S. Smith and J.H.P Skene. Dept. Neurobiology, Stanford University, Stanford, CA 94305

We are using primary neuronal cultures to investigate the signals for and the intracellular changes involved in the initiation of axonal growth. Cultured neurons from adult rat dorsal root ganglia (DRG) contain two populations of neurons distinguishable by rapid vs. delayed neurite outgrowth. Within 12 hrs after plating, approximately 20% of neurons have extended neurites, and the percentage of process-bearing neurons plateaus at this level for the next ten hours. Beginning at 22 hours the number of neurons with processes increases rapidly, so that by 32 hours 85% of neurons have neurites. The biphasic shape of this growth curve suggests that a small population of adult DRG neurons are in a 'primed' or prepared growth state. Peripheral axotomy performed *in vivo* one week prior to culturing results in a shift from a biphasic to a monophasic growth curve. In these cultures, approximately 70% of neurons possess neurites by 16 hours and 90% by 22 hours, which corresponds to the end of the early plateau observed in control cultures. This finding suggests that normal, mature ganglia contain a population of cells which constitutively exist in a growth state exhibited by the majority of neurons only after axotomy. Previous studies have shown that a subpopulation of uninjured, adult DRG neurons express high levels of the growth-associated protein GAP-43. We are investigating the possibility that normal adult ganglia contain a population of cells that maintain both a capacity for axon growth and a pattern of gene expression usually associated with developing or regenerating neurons.

NEURONAL PROPERTIES OF IDENTIFIED CORTICOSPINAL CELLS IN VITRO FOLLOWING SPINAL AXOTOMY IN VIVO. G.-F. Tseng,D. A. Prince. Dept. Neurol. & Neurol. Sci., Stanford Univ., Sch. of Med., Stanford, CA 94305.

We investigated the effects of axotomy on the physiology and morphology of mammalian corticospinal neurons. Control recordings in neocortical slices from nonaxotomized cells, retrogradely labeled with rhodamine beads and double-labeled with biocytin, showed that 3 types of spiking behavior (adapting, regular spiking and regular spiking with depolarizing afterpotentials) were present in the identified corticospinal neurons(Tseng & Prince, Soc.Neurosci.Abstr.,15:660). In the present experiments we examined the physiology and morphology of double-labeled corticospinal cells, 3(n=11), 9(n=13), and 12 months(n=20) following axotomy at the C2-3 level. Although all 3 types of spiking behavior were present, there were significant alterations in several membrane parameters in the axotomized cells. The input resistance, slope of steady-state firing rate versus applied current, steady-state firing rate at a fixed amplitude of current injection, and the membrane time constant were all significantly increased ($p<0.05$). Also, fewer axotomized cells generated a measurable slow AHP, compared to control cells. No qualitative differences in evoked synaptic responses were noticed between control and axotomized neurons. Morphologically, axotomized cells retained their typical pyramidal shape, dendritic domain, axonal arborization and dendritic spines, however quantitative analysis of these variables has not yet been completed.

Our physiological and morphological results confirm the long survival of mammalian corticospinal neurons after distant (spinal) axotomy. These cells retain their general physiological characteristics such as a diversity of spiking behavior. However there are significant alterations in intrinsic membrane properties evidenced by increases in input resistance, membrane time constant, and f/I slope. These changes suggest that remodelling of basic membrane properties occurs following axotomy, which tends to increase neuronal excitability and the response to depolarizing inputs. These alterations may contribute to increases in brain excitability following CNS injury. Supported by NIH grants NS06477 and NS12151 from the NINDS and a Pimley Postdoctoral Fellowship to G.-F. T.

FURTHER EVIDENCE FOR SYNAPTIC REARRANGEMENTS OF INPUTS TO ONUF'S NUCLEUS (ON) FOLLOWING SPINAL CORD TRANSECTION IN ADULT CATS. J.C. Bresnahan, L.H. Lin*, M.G. Leedy and M.S. Beattie. Depts. of Anatomy and Surgery, and Neuroscience Program, Ohio State Univ., Columbus, OH 43210.

We have previously reported a shift in the size and type of terminals apposed to proximal dendrites and somata of ON motoneurons (MNs) after spinalization. We have extended this EM analysis to distal dendrites (DD) in ON using similar quantitative methodology. DDs located in close proximity to MNs labelled with HRP applied to the pudendal nerve were examined in normal (N), acute (Ac; 4 day) and chronic (Ch; 10-11 wk) spinalized cases (n=4/grp). There were fewer terminal appositions per DD and fewer terminals per unit of DD membrane in the Ac as compared to the N group, with some recovery in the Ch. A reversed pattern was observed for glial apposition (Ac>Ch>N). Terminals apposed to DD were smaller in both the Ac and Ch as compared to Ns, and there was a greater proportion of terminals containing round synaptic vesicles in the Ac and Ch groups vs. Ns. These results indicate similar synaptic rearrangements on DD of ON neurons as were observed on the proximal regions of ON MNs. (Supported by NS-10165)

WILL PRIOR SPINAL INJURY ENHANCE RECOVERY OF HINDLIMB MOTOR FUNCTION AFTER SPINAL TRANSECTION IN ADULT CATS? S.P. Lahr, and M.E. Goldberger, Med. Col. of Pennsylvania, Philadelphia, PA 19129.

The present studies were designed to determine if recovery from a previous spinal cord hemisection will enhance recovery of hindlimb locomotion in adult cats after a subsequent spinal transection. Previous studies have shown a reduction of spinal segmental reflex depression (spinal shock) with this paradigm (Chambers et al., 1966). Preoperatively, adult cats were trained to perform bipedal treadmill locomotion and monopedal hopping (at 0.2 - 0.6 m/s). One group (n=3) received a T13 spinal transection and a second group (n=4) received a right spinal hemisection at the T13 level followed 1-2 months later by a spinal transection one segment rostrally. Locomotion was assessed quantitatively using a motion analysis system. In animals with only spinal transection, recovery of air stepping, monopedal hopping, and bipedal stepping is not seen until the end of the second week p.o. at the earliest. In contrast, in animals with spinal hemisection + transection, recovery is seen during the first week p.o. following the spinal transection, and begins on the chronic side (ipsilateral to the hemisection) as early as the second day p.o. Although both hindlimbs exhibit precocious recovery, there is also a temporary asymmetry in motor function between the two hindlimbs. The time course of recovery after transection was also related inv ersely to the magnitude of the deficit seen after the preceding hemisection. We conclude that spinal shock interferes with recovery of motor function since reducing spinal shock enhances hindlimb motor recovery following spinal transection and that the reorganization that occurs after the first lesion contributes to recovery after the second. (Supported by the American Paralysis Foundation and NIH Grant NS24707).

USE-DEPENDENT MODIFICATION OF Ia AFFERENT SYNAPTIC STRENGTH. C.B. Webb and T.C. Cope Physiology and Biophysics, Hahnemann Univ., Phila. PA 19102

The silencing of a large fraction of afferent input to the lumbosacral cord leads to enhanced synaptic strength of the Ia afferent to alpha-motoneuron connection (Manabe et al., J. Neurosci. 1989). The present study employs EMG confirmation of osmotic mini-pump delivery of TTX through a nerve cuff around the cat MG nerve to examine specific disuse-induced changes in synaptic efficacy independent of changes in the remaining hindlimb afferent input. In cats whose MG nerve had been silenced for two weeks, the mean aggregate Ia EPSP amplitude was 3.1mV ± 2.1(SD), significantly different (unpaired t-test, $p<.01$) from that recorded in control animals, 2.2mV ± 1.7(SD). Rise time, half-width, rheobase, AHP, and Vm for the two samples were not significantly different. The ratio of LG/MG EPSP amplitude in LG motoneurons (greater than one in controls) was less than one in 20% of the cases measured following TTX treatment. The present study confirms that the silencing of afferent input leads to an increase in aggregate Ia EPSP amplitude, and further, shows that the disuse of a specific set of synaptic connections leads to an increase in the strength of those connections. This lab is currently using spike-triggered averaging to measure connectivity and EPSP amplitudes of single Ia afferents following disuse to address possible mechanisms, e.g. increase in functional contacts, or increased transmitter release. (Supported by NIH NS21023)

EXPRESSION OF CHOLINE ACETYLTRANSFERASE (ChAT) AND NERVE GROWTH FACTOR RECEPTOR (NGFr) WITHIN HYPOGLOSSAL MOTONEURONS FOLLOWING NERVE INJURY. D. Armstrong, R. Brady, R. Hayes, and R.G. Wiley. FGIN, Georgetown University, Washington, D.C. 20007.

In the present study we employed light microscopic immunocytochemistry in order to investigate the temporal response of ChAT and NGFr within hypoglossal motoneurons following unilateral transection or crushing of the XII nerve. In control rats (i.e., sham operated) virtually all the motoneurons of the XII nucleus were darkly labeled for ChAT and devoid of NGFr immunoreactivity. Transection (ChAT): Three days following nerve transection the intensity and the number of ChAT-positive neurons were markedly reduced on the axotomized side compared to the non-lesioned side. This decrease in labeling continued until nine days when virtually no ChAT-labeled cells were present on the lesioned side. In contrast, no loss of hypoglossal neurons were found using Nissl stains. Importantly, the persistence of these motoneurons suggests that the absence of ChAT is not an absolute indicator of cell death. This absence of ChAT immunolabeling persisted for several days, yet by 30 days many motoneurons begin to re-express the enzyme. Transection (NGFr): As early as one day following the lesion motoneurons begin to express NGFr immunoreactivity. This response was very robust three days following the lesion and continued throughout all time points thus far examined. Importantly, NGFr immunoreactivity could be seen at times after many motoneurons began to re-express ChAT. Crush (ChAT): Crushing of the hypoglossal nerve resulted in a transient reduction in the overall intensity of ChAT immunoreactivity yet produced little if any loss in the number ChAT neurons. The decrease labeling was most apparent 3 to 12 days following the lesion. Crush (NGFr): Nerve crush also resulted in the transient expression of NGFr immunoreactivity which was most robust 3 to 9 days following the lesion. At present the mechanism underlying the lesion induced expression of NGFr is under study.

IMMUNOHISTOCHEMISTRY OF HYPOGLOSSAL AFFERENTS AND EFFECTS OF AXOTOMY. R.G. Wiley, K. Crews* & C. Hunt*. Experimental Neurology, DVAMC, Nashville, TN 37212 and Vanderbilt University.

In the present study, we sought to determine which neurotransmitters can be demonstrated in the nucleus using immunohistochemical techniques and the effects of hypoglossal nerve transection on those inputs. Adult Sprague-Dawley rats of both sexes were anesthetized and underwent unilateral hypoglossal transection with suture ligation of the proximal stump. After 3-66 d, rats were perfused with aldehyde fixative and frozen sections of the medullas processed for indirect peroxidase immunohistochemistry. Leu-enkephalin and glutamate gave moderate terminal labelling in the hypoglossal nucleus. Substance P, NPY, Met-enkephalin, CRF, PNMT and beta-endorphin gave light terminal labelling. DBH, VIP, CCK, neurotensin and somatostatin did not stain the nucleus. Glutamate staining was decreased in the hypoglossal nucleus ipsilateral to chronic axotomy. These results suggest several transmitter systems for studies of the reaction to axotomy or loss of motor neurons. (Supported by DVAMC.)

c-FOS AND SILVER DEGENERATION REACTIONS IN ADULT RAT BRAIN STEM FOLLOWING ACUTE AND CHRONIC DENTAL INFLAMMATION. M.R. Byers, L.E. Westrum, W.K. Dong, M.J. Iadarola. Anesthesiol., Biol. Structure, Neurol. Surgery; Univ. of Washington, Seattle, WA 98195; Neurobiol. & Anesth., NIDR, NIH, Bethesda, MD 20892.

We have used immunocytochemistry to analyze the expression of c-Fos and Fos related antigens in the brain stem of the rat adult at 5-6 hr after pulp exposure injury to the right maxillary first and second molars. The acute group was compared to others with the same injury that survived 5-6 days or 15 days. Postoperative behavior and weight gain were normal after this surgery. After fixation alternate transverse sections were processed for Fink-Heimer silver stain or immunocytochemistry. Three different response patterns were found. Acute Fos/Fra response included many ipsilateral caudalis neurons, fewer contralateral caudalis neurons, plus many bilateral stained neurons in the periobex VL reticular zone, lamina X, medial and lateral solitary nuclei and area postrema. Chronic Fos/Fra response only occurred in caudalis neurons and a cluster of neurons in the rostral lateral solitary nucleus at the level of interpolaris, both with a predominantly ipsilateral response. Silver Degeneration was not prominent in the Fos reactive sites but was located more rostrally, especially in interpolaris/oralis. These distinctive responses to dental inflammation in the rat offer a useful model for analysis of central plasticity in response to peripheral inflammation. Supported by NIH grants DE05159 and DE04942.

481.16

CAPILLARY GROWTH IN CEREBELLAR CORTEX OF ADULT RATS AFTER EXTENSIVE PHYSICAL EXERCISE. A.A. Alcantara, J.E. Black, K.R. Isaacs, B.J. Anderson, & W.T. Greenough. Beckman Inst, Depts Psychol and Cell & Struct Biol, Neuroscience Prog, & Coll Med., Univ Illinois, Urbana, IL 61801 USA.

Previous work has demonstrated new capillary formation in visual cortex of rats in association with synaptogenesis and tissue volume expansion (e.g., Black, et al, Neurosci Lett, 83:351, 1987; Black, et al, Neurobiol Aging, 10:353, 1989). Angiogenesis might also occur when neuropil metabolism is chronically elevated, such as repetitive activation of neurons and synapses.

We examined microvasculature in the paramedian lobule (PML) of the cerebellum of 38 adult female rats put in 4 experimental groups for 30 days. Acrobatic Condition (AC) rats were given extensive visuomotor training on difficult tasks, e.g. traversing rope ladders and thin dowels. This group tested effects of learning on synaptic connectivity. Forced eXercise (FX) rats ran on a treadmill, and those in the Voluntary eXercise condition (VX) had free access to a running wheel. Inactive Condition (IC) rats did not have access to either learning or exercise. Semithin sections of PML were drawn using a camera lucida, and the area density of blood vessels in the molecular layer was determined. Previous work demonstrated substantial synaptogenesis and volume expansion in the AC rats and none in the other groups. The significant increase in vessel density in the FX and VX groups without changes in neuropil volume indicates infiltration of this tissue by new blood vessels. The PML is activated by limb movements, and presumably the increased metabolic demand in the exercise groups elicited compensatory angiogenesis.

5'NUCLEOTIDASE (5'N): A NEW CYTOCHEMICAL MARKER OF PLASTIC STATUS OF SYNAPSES IN THE CEREBELLAR CORTEX OF X-IRRADIATED RATS AND REELER MICE. Y. Bailly*, S.W. Schoen*, N. Delhaye-Bouchaud*, G.W. Kreutzberg and J. Mariani. Inst.Neurosc. Univ. P.& M. Curie, Paris, France and Max-Planck Inst., Martinsried, FRG.

We reported recently that a single postnatal (P5/P6) X-irradiation of the rat cerebellum impedes the elimination of redundant synapses between climbing fibers (CFs) and Purkinje cells (PCs) that occurs during normal development. A similar polyneuronal innervation is also maintained on ectopic PCs in the reeler mouse cerebellum. Cytochemical detection of 5'N, an adenosine producing ecto-enzyme, revealed its transient appearance on the synapses made by the climbing, mossy (MF) and parallel fibers (PF) in normal developing rats. Interestingly,the elimination of CF synapses and 5'N labeling occur within the same days. Using identical cytochemical methods, we now report at the electron microscopical level a conspicuous 5'N activity in most of the CF synapses in the cerebellum of adult X-irradiated rats and reeler mice. In the X-irradiated rats, 5'N activity is also maintained in many MF and some PF synapses. These results suggest that 5'N is a functional cue to characterize the maturation of the excitatory synapses in the rat cerebellar cortex. In the CF synapses it could herald an immature plastic status that is maintained until adulthood in the synapses of the cerebella studied.

482.1

BIOCHEMICAL COMPARISON OF ASTROCYTE MATURATION *IN VITRO* AND *IN VITRO*. George M. Smith[1], James Jacobberger[2], and Robert H. Miller[2]. [1]Dept. of Neurosurgery, Baylor College of Medicine, 6560 Fannin, Houston, Texas 77030; [2]Dept of Neurosciences, Case Western Reserve Univ., Cleveland, Ohio 44106.

The ability of astrocytes to support axon outgrowth diminishes during maturation of the central nervous system. This reduction also occurs as cultured astrocytes aged *in vitro*. Several molecules, including NCAM and laminin have been demonstrated by antibody inhibition studies to be involved in astrocyte mediated axon outgrowth. In this study, the expression of HNK-1, NCAM, laminin, and GFAP was compared during *in vivo* and *in vitro* astrocyte maturation by indirect immunofluorescence, and analyzed by flow cytometry. In parallel experiments, tissue sections of maturing rat brain were similarly labeled and examined. The results indicted that at birth the majority of cortical astrocytes expressed high levels of the three cell surface molecules. While number of astrocytes expressing HNK-1 and NCAM diminished, both *in vivo* and *in vitro*, during astrocyte maturation, there was no significant decrease in the number of astrocytes expressing laminin. To distinguish between differentiation of a single astrocyte population or differential replication of multiple astrocyte populations, *in vitro* samples were labeled for NCAM or HNK-1, counter stained for DNA content, and analyzed by flow cytometry. Cell cycle phase fraction analysis indicated no significant difference in replication rated between those astrocytes that did and did not express HNK-1 and NCAM. Therefore, the reduction in HNK-1 and NCAM expression correlates with the reduction in axon outgrowth promoting properties of astrocytes. Furthermore, using the above markers, astrocyte maturation appears temporally and biochemically indistinguishable *in vivo* and *in vitro*.

FGF and PDGF Differentially Regulate the Developmental Course of Oligodendrocyte Progenitors Placed in Culture. A.L. Gard and S.E. Pfeiffer. Department of Microbiology, University of Connecticut School of Medicine, Farmington, CT 06032.

Three consecutive stages of the oligodendrocyte (OL) lineage are distinguished immunocytochemically in rodent brain and optic nerve by the ordered appearance of cell surface antigens, A2B5, O4 and galactocerebroside (GalC). Recently we demonstrated that OL progenitors bearing the $A2B5^+O4^+GalC^-$ phenotype, termed "proligodendrocytes," represent a distinct lineage interval *in vivo*. When placed in culture these cells differentiate in a chemically defined medium to sequentially express GalC and the major myelin proteins (Gard and Pfeiffer, Development 106: 119, 1989). To examine whether this stage is targeted by mitogens implicated in OL development, proligodendrocytes purified directly from postnatal telencephalon were cultured under defined conditions with either basic fibroblast growth factor (FGF) or platelet-derived growth factor (PDGF) added at the time of seeding. At physiologically relevant concentrations, FGF acted as a potent mitogen for multipolar proligodendrocytes (ED_{50} = 1 ng ml^{-1}), producing a maximal 5-fold increase in bromodeoxyuridine labeling index (20% in 6 hrs) compared to control cultures (4%) at plateau levels (2-5 ng ml^{-1}), without altering the timecourse of differentiation into $GalC^+$ OL (20% by 1 DIC, 80% at 2 DIC). In contrast, PDGF caused ~70% of the proligodendrocytes to transiently revert by 1 DIC to cells resembling their precursors (ED_{50} = 3 ng ml^{-1}), characterized by an $A2B5^+O4^-$ phenotype and bipolar morphology. Reverted cells proliferated, re-expressed O4 on their surface after 1-2 days as bipolar cells, and finally resumed differentiation on a delayed schedule. The reversion was verified by single cell analysis, and also apparent in cultures of dissociated 7-day optic nerve cells of which proligodendrocytes comprised the predominant lineage stage at the time of seeding. The results suggest that exogenously administered PDGF rapidly resets the differentiation program of cultured proligodendrocytes born *in vivo*, which otherwise utilize FGF as their mitogenic signal. Supported by NIH Grant NS10861.

MHC ANTIGEN EXPRESSION IN THE RAT RETINA FOLLOWING INTRACRANIAL OPTIC NERVE SECTION. K. Rao,J.D.Radel and R.D.Lund. Department of Neurobiology Anatomy and Cell Science, University of Pittsburgh, School of Medicine, Pittsburgh, PA 15261

Previous studies (Streit,W.J.,et al., Exp. Neurol.,105:115,1989) have shown that axotomy of motorneurons causes expression of both class I and class II MHC antigens on microglia around cell bodies. We have examined here, MHC antigen expression patterns in the adult rat retina after intracranial optic nerve section, using the opposite (unlesioned) eye as a control. In this system, regeneration does not normally follow axotomy and the microglia are more broadly distributed throughout the retina. The animals are fixed at regular intervals following optic nerve section and cryostat sections are stained with antibodies against microglia and MHC antigens. Within 3 days of axotomy, scattered microglia within the inner plexiform layer express class I MHC antigens. By 11 days the majority of expressing cells are closely associated with the optic fiber layer. Although cells in the choroid in the normal and experimental retina express class II antigens, no staining of class II-positive cells was seen in any of the retinal layers.

This suggests that under conditions of retrograde degeneration, like those in orthograde degeneration (Smetanka,et al., Brain Res.,in press), expression of MHC class I antigens can be present without class II expression. It also indicates that expression patterns associated with retrograde degeneration vary depending on the system studied.

ASTROCYTES RELEASE A NITROSYL COMPOUND WITH VASORELAXANT PROPERTIES. S. Murphy and G. Welk*. Dept. of Pharmacology, College of Medicine, Univ. of Iowa, Iowa City, IA 52242.

Astrocytes release a variety of vasoactive eicosanoids. In addition, these cells release a non-prostanoid, labile vasodilator in response to bradykinin (Murphy et al., J. Neurochem. 54, 1990) which we have termed astrocyte-derived relaxing factor (ADRF). This factor is nitric oxide (NO) or a nitrosyl compound derived from arginine. To investigate further the regulation of ADRF release, primary astrocyte cultures were exposed to a variety of agents which interact with surface receptors or with intracellular effectors, and NO release determined by a chemiluminescence technique.

Quisqualate and norepinephrine, but not a range of other receptor agonists, were effective in evoking NO release from astrocytes. The noradrenergic effect was not inhibited by ß-receptor antagonists, was not mimicked by clonidine or blocked by yohimbine, but was reversed by the α_1 antagonist prazosin. AMPA did not mimick the effect of quisqualate, suggesting involvement of the metabotropic excitatory amino acid receptor. Both A23187 and thapsigargin, a non-phorbol tumor promoter which selectively discharges intracellular calcium, also evoked NO release. Thus, astrocytes, like endothelial cells and neurons, release a NO-containing compound which could potentially interact with soluble guanylate cyclase in adjacent cells, and so act as an intercellular signal.

482.5

ACTIVATORS OF PHOSPHOLIPASE D IN ASTROCYTES G. Bruner and S. Murphy Dept. of Pharmacology, College of Medicine, Univ. of Iowa, Iowa City, IA 52246

Astrocytes synthesize and release eicosanoids upon stimulation with purinergic agonists and agents such as calcium ionophore and phorbol esters. The precise mechanism by which this process occurs is unknown, but could involve phospholipase D (PLD). To determine the mechanism of PLD activation, and learn more about its potential role in eicosanoid production, primary astrocyte cultures were prelabeled with [^{3}H] myristate, and the formation of phosphatidylethanol (PEt) was determined in the presence of ethanol after stimulation with various agents for 30 min. Formation of PEt by phorbol myristate acetate (PMA; EC_{50}=6nM) was abolished by prior down-regulation of protein kinase C (PKC). Receptor agonists which might be predicted to stimulate PLD through activation of PKC include ATP, bradykinin, glutamate, and carbachol; each of these agents failed to stimulate formation of PEt in astrocyte cultures. Thapsigargin (Tg), a novel compound which has been reported to selectively discharge intracellular calcium stores but not activate PKC, mobilized arachidonic acid and evoked thromboxane A_2 production in a dose dependent manner (EC_{50}=12nM). Tg also stimulated PEt formation, however the effects of Tg on PLD were abolished when PKC was first down-regulated. It is apparent that PLD is not coupled to surface receptors in astrocytes, including purinergic receptors which are known to be linked to eicosanoid production. Physiological regulators and the role of PLD in astrocytes have yet to be defined.

SV40 T ANTIGEN MEDIATED IMMORTALIZATION PRESERVES THE NEURITE OUTGROWTH PROMOTING PHENOTYPE OF CNS ASTROCYTES. P.S. Frisa*, M.N. Goodman, G.M. Smith, J. Silver and J. Jacobberger. Case Western Reserve University, Depts. of Genetics and Neurosciences, Cleveland, OH 44106

CNS maturation is accompanied by an attenuated neural regeneration capacity that is correlated with a change in the neurite outgrowth promoting properties of astrocytes. Similarly, the outgrowth phenotype of astrocytes in vitro is dependent on the age of the animal at the time of astrocyte isolation as well as length of time in culture. In general, immortalization by single dominant oncogenes correlates with inhibition of cellular differentiation. Thus, immortalization of astrocytes at timed intervals from the maturing brain should yield cell lines trapped in differentiated states representative of the maturing CNS. This hypothesis has been tested by transducing rat and mouse cortical astrocyte cultures with SV40 large T antigen.

Morphologically, the resulting clonal cell lines are type 1 astrocytes. Many express GFAP and T antigen, are contact inhibited, and capable of entering a quiescent cell cycle phase. These cell lines have been tested for the ability to promote neurite outgrowth using embryonic chick retinal ganglion cells. Clonal lines derived from aged primary mouse astrocyte cultures expressed a range of abilities to promote neurite outgrowth, however, the mean value for all mature lines tested was equivalent to primary aged cells. Two cell lines derived from primary rat 2 day cultures both supported neurite outgrowth at the same level as primary 2 day cultures.

Thus, it has been demonstrated that SV40 T-immortalized astrocytes are phenotypically similar to the differentiating astrocyte population extant in the maturing CNS at the time of isolation and culture, that the outgrowth phenotype is stable, and that the cells are relatively non-tumorigenic in transformation phenotype.

NEUROTRANSMITTER REGULATION OF GLYCOGEN METABOLISM IN CULTURED ASTROGLIA. O. Sorg*, D. L. Feinstein and P.J. Magistretti. Institut de Physiologie, Faculté de Médecine, Université de Lausanne, CH-1005 Lausanne, Switzerland.

In recent years astrocytes have been shown to possess receptors for various neurotransmitters.These observations further support the notion of neurotransmitter-mediated functional interactions between neurons and astrocytes.We have previously demonstrated that NA, VIP, adenosine (all via cAMP) and K^+ (via Ca^{+2}) promote the hydrolysis of ^{3}H-glycogen newly synthesized from ^{3}H-glucose in mouse cerebral cortical slices. Since, in vivo, glycogen is predominantly localized to astrocytes, we screened these and other neuroactive agents for their potential glycogenolytic effect in primary cultures of astrocytes prepared from neonatal mice. Cultures were grown for 2 to 3 weeks in DMEM containing 10% FCS and 25 mM glucose. On the day of experiment serum was removed and glucose levels decreased to 5 mM; after 4 hrs, substances under scrutiny were added for 30 min. Endogenous glycogen was measured by the hexokinase/glucose-6-phosphate dehydrogenase fluorometric procedure following amyloglycosidase treatment of the samples. In agreement with our observations in slices and with early experiments in cultured astrocytes in which glycogen had been pre-labelled with ^{3}H-glucose, NA (100µM) and VIP (1 µM) hydrolyzed ≈ 70 % of endogenous glycogen; other active agents included adenosine, isoproterenol, dopamine, dbcAMP and the phorbol ester PDBu, all at 100 µM. In contrast to slices, K^+ at 25 mM was inactive; however in the presence of the Ca-channel agonist BAY-K 8644, K^+ elicited ≈ 40% glycogen hydrolysis. A glycogenolytic response to K^+ (≈30%) was also observed in cultures treated with 1 mM dbcAMP for 3 days prior and up to 5 hrs before the experiment. This treatment also results in increased (≈4-fold) glycogen levels and in a decreased response to NA, VIP and adenosine.The mechanism(s) of this "desensitization" is currently being investigated.

VIP RECEPTORS AND VIP-STIMULATED cAMP FORMATION IN CULTURED ASTROGLIA AND CEREBRAL MICROVESSELS. D.L. Feinstein, C. Rossier*, N. Yu*, J.-L. Martin, P.J. Magistretti. Institut de Physiologie, Faculté de Médicine, Université de Lausanne, CH-1005, Lausanne, Switzerland.

In mouse neocortical slices, VIP interacts synergistically with noradrenaline (NA), adenosine and phorbol esters to increase cAMP levels. However, it is not known which cell type(s) are the target(s) for these interactions. We have therefore begun a series of studies in cultured astroglia and acutely isolated microvessels to determine if in either of these preparations a synergistic response occurs. We first characterized VIP binding to cultured astroglia. Specific binding of ^{125}I VIP was rapid, saturable, and reversible, and revealed the presence of 2 types of binding sites, a high affinity site with a Kd of 1 nM and Bmax of 150 fmoles/mg protein, and a low affinity site with a Kd of 85 nM and Bmax of 1500 fmoles/mg protein. The related peptide PHI inhibited VIP binding with an IC_{50} of 10 nM, while secretin at up to 1 µM had no effect on VIP binding. The presence of 0.1 µM VIP for 30 minutes elicited an increase in cAMP levels (4-8 fold over basal levels). Increases were also observed with NA (10 µM) and adenosine (7.5 µM), but not with the phorbol ester PDBu. Preliminary experiments indicate that all 3 of these molecules interact synergistically with VIP. Serum deprivation for 4 days caused loss of the synergism with NA and adenosine, while the interaction with PDBu was maintained. In acutely isolated mouse cerebral microvessels, both NA and VIP elicited increases in cAMP (EC_{50} of 500 nM and 50 nM, respectively). However, no synergism was found as the response to the combination of these drugs was the sum of the individual responses.

INHIBITORS OF GLYCOPROTEIN PROCESSING GLUCOSIDASES BLOCK OLIGODENDROCYTE DIFFERENTIATION. N.R. Bhat. Department of Biochemistry and Sanders-Brown Center on Aging, University of Kentucky, College of Medicine, Lexington, KY 40536.

Previous studies (Bhat, N.R., J Neurosci Res. 20, 158, 1988) have shown that inhibitors of processing glucosidases reversibly inhibit oligodendrocyte (OL)-specific activities in heterogeneous cultures of developing rat brain cells. The present study examines the direct effect of processing inhibitors on the proliferation and differentiation of isolated OL progenitor cells. The OL progenitor cells isolated from mixed glial cultures of newborn rat brain undergo an initial period of active proliferation (peaking 2-3 day post-plating) followed immediately by a marked induction of differentiated properties of OL, i.e, sulfogalactolipid synthesis and 2', 3'-cyclic nucleotide 3'-phosphohydrolase activity. Castanospermine (cast), a potent inhibitor of processing glucosidases inhibited the induction of these activities without affecting cell proliferation. The effect was concentration-dependent with a maximal 60-80% inhibition observed at 25µg/ml cast. Swainsonine, an inhibitor of processing mannosidases, had no effect on OL differentiation even though it, like cast, prevented the formation of complex-type oligosaccharides. It is concluded that core glycosylation and initial processing of oligosaccharides may be critical for the functioning of specific glycoproteins essential to OL differentiation. (Supported by NMSS grant # RG1927).

HOMOGRAFTS OF CULTURED FETAL SPINAL CORD ASTROCYTES INCREASE THE SEVERITY OF LESION-INDUCED HIND LIMB DEFICITS J.J. Bernstein, L.A. Gillespie*, P. S. Wilson* and W.J. Goldberg. CNS Injury & Regen., V.A. Med. Ctr., Wash., DC; Depts. Neurosurg. & Physiol., Geo. Wash. Univ. Sch. Med., Wash., DC.

We have previously demonstrated that grafts of unoriented pieces of E14 fetal spinal cord into C3 fasciculus gracilis (C3FG) aspiration pockets ameliorate the deterioration of hindlimb performance. We have now tested the effects of cultured astrocyte grafts, placed in the same aspiration site, on hindlimb performance. Fourteen, 250g Sprague-Dawley rats were placed on a 23-h off and 1-h on water schedule and trained to traverse a 2'x4" horizontal ladder (1/8" bars, 1" apart) for a water reward. Criterion was established as 10 complete ladder traverses on 2 consecutive days. The numbers of hindlimb slips were determined from video tapes. In a "blind" experimental design, trained animals were coded and laminectomy performed at C3. The C3FG was bilaterally sectioned at the rostral and caudal borders of the segment and then aspirated. Seven subjects were chosen at random to receive grafts of 10^5 cultured E18 rat astrocytes. Lesion-only and grafted subjects were tested at 14, 30 and 45 days. Prelesioned animals had 3 hindlimb slips in 20 traverses. At 14 days, lesion-only animals had 10 slips whereas grafted animals had 40 slips. Slips remained at these levels to 45 days. Astrocyte grafts placed in the lesion pocket resulted in decreased rather than increased hindlimb performance as was previously demonstrated using unoriented whole spinal cord grafts. CYSTEAMINE INDUCES THE 'GOMORI' PHENOTYPE IN CULTURED ASTROGLIA. H.M. Schipper, D.E. Scarborough*, R.M. Lechan and S. Reichlin. Dept. of Neurology, Jewish General Hosp., McGill Univ., Montreal, Canada H3T 1E2 and Dept. Endocrin., New England Med. Center, Tufts, Univ., Boston, MA 02111

Gomori-positive astrocytes have been identified in the periventricular brain in situ and in diencephalic explants on the basis of their endogenous peroxidase activity, affinity for chrom alum hematoxylin, and orange-red autofluorescence. In dissociated fetal rat brain cultures, astrocytes containing cytoplasmic inclusions with the above tinctorial and fluorescent properties represented less than 1% of GFAP-positive astrocytes at day 10 in vitro (DIV). There was a marked increase in the fraction of Gomori-positive astrocytes and their granule content between 10 and 46 DIV. Cysteamine and cystamine, but not ethanolamine or L-cysteine, induced a massive accumulation of Gomori-positive astrocytes when administered from DIV 6-18. As in situ, the peroxidase activity induced by cysteamine appeared to be non-enzyme-mediated insofar as it catalyzed diaminobenzidine oxidation over a wide range of pH (3-11) and could not be inhibited by tissue pre-heating or the catalase inhibitor, aminotriazole. Metallo-porphyrins probably mediate both the pseudoperoxidase activity and autofluorescence in these cells. Alterations of the redox microenvironment or induction of porphyrin/heme biosynthetic enzymes may be the mechanisms responsible for this cyst(e)amine effect.

482.12

INTRACELLULAR pH REGULATION IN CULTURED ASTROCYTES: A MICROELECTRODE STUDY. W. Walz and W. Wuttke*. Dept. of Physiology, Univ. of Saskatchewan, Saskatoon, S7N 0W0, Canada.

Transmembrane transport processes involved in regulating intracellular pH in astrocytes were studied. Primary cultures of cortical astrocytes from newborn Swiss mice were impaled with two-channel pH-sensitive microelectrodes. In bicarbonate-buffered saline pH_i was 7.05 and in HEPES-buffered saline 6.68. In both solutions H^+ was not in electrochemical equilibrium; pH_i was 0.7-1 pH unit more alkaline than expected from passive H^+ distribution. The regulatory mechanisms were studied in bicarbonate-free HEPES-buffered saline. The cells were acidified by applying NH_4^+ for 20-60 sec and the subsequent regulation of pH_i back to normal baseline values was investigated. The mean rate of pH_i recovery was 0.2 pH units min^{-1} which was not changed by removal of external Na^+ or by amiloride (1 mM) exposure. Thus, the cells recovered from an acid load independently of Na^+-H^+ exchange, Na^+-HCO_3^- cotransport or any other bicarbonate- or Na^+-dependent mechanism. Cultured astrocytes have a very high lactate prodution and release rate. During normal conditions the lactate : H^+ ratio is higher than 1.0. We suggest that lactate-H^+ cotransport via passive diffusion and the monocarboxylic acid carrier is responsible for the extrusion of the acid load.

482.13

NEURITE OUTGROWTH PROMOTION BY RAT OLFACTORY BULB CULTURES AND CELL LINES. M. N. Goodman[1], J. Silver[2] and J. W. Jacobberger[1]. Depts. of Genetics[1] and Neurosciences[2], Case Western Reserve University, Cleveland, OH 44106.

The rat olfactory bulb (OB), an area of the CNS re-innervated throughout life, contains two glial cell types within the outer lamina and glial limitans. Bulb astrocytes are morphologically and antigenically like type 1 astrocytes while the ensheathing cells of the bulb are like non-myelinating Schwann cells. Both cell types are intermingled, but sensory axons associate preferentially with ensheathing cells. When the adult OB is lesioned, bulb astrocytes at the lesion site form a glial scar, however, re-innervation occurs by growth of axons around the scar. To investigate the role of each cell type in adult bulb re-innervation, the neurite outgrowth promoting ability of immortalized adult OB cell lines, neonatal and adult OB glial cultures, cerebral cortex (CC) astrocyte cell lines, and CC astrocyte cultures were measured and compared.

Neonatal OB and CC cultures promoted outgrowth equivalently. Adult OB cultures promoted outgrowth at an intermediate level between neonatal cultures (the highest observed levels) and adult CC cultures (the lowest levels). Adult ensheathing cell lines promoted higher levels of outgrowth than adult astrocyte lines derived from either OB or CC, and were equivalent to or greater than OB and CC neonatal cultures. Neurite outgrowth over adult OB and CC astrocyte lines was equivalent to or lower than that over adult OB cultures.

These results suggest that ensheathing cells retain a high level of axon growth-promoting capacity relative to OB astrocytes, and that the neurite outgrowth capacity of OB astrocytes, like CC astrocytes, is reduced during maturation. Purification of ensheathing cells and astrocytes from OB cultures for neurite outgrowth studies is in progress.

482.14

THE VARIABLE MITOTIC RESPONSE OF ADULT RAT OLIGODENDROCYTES RS Vick' and GH DeVries Dept Biochemistry, Medical College of Virginia, Richmond, VA 23298

Adult oligodendrocytes (OLGs), isolated and cultured according to Vick, et al. (J Neurosci Res 25:524-534, 1990), were stimulated with pituitary extract (PX) or co-cultured with dorsal root ganglion (DRG) neurites for various times up to 6 d. ^{3}H thymidine was added for the final 48 h in the DRG co-culture experiments. Previous studies demonstrated that adult OLGs are virtually unresponsive to most soluble and particulate mitogens (Vick and DeVries, J Neurosci Res, submitted 1990). Fluorescence activated cell sorting (FACS) demonstrated that 100 % of the unstimulated cultured OLGs were in a quiescent (G_0/G_1) state. Autoradiography demonstrated that 20 % of the PX stimulated OLGs proliferated after 3 d; FACS analysis of the OLGs demonstrated that this proliferation was not synchronized. Co-culture of OLGs for 2, 3, and 4 d yielded a labeling index (LI) of 7 %. By 5 d the LI increased to 25 % and by 6 d 40 % of the cells were labeled. The variability in the lag of the mitogenic response of the adult OLGs indicates that they are in variable states of responsiveness to mitogens. Thus the morphologically and immunologically homogeneous population of adult OLGs respond to mitogens in a heterogeneous manner. (Supported by NIH NS07288 and MS Society 5073)

INTERLEUKIN-1 AND TUMOR NECROSIS FACTOR INCREASE [3H]Ro5-4864 BINDING IN TYPE-1 ASTROCYTES IN CULTURE. Y.J. Oh, G.J. Markelonis, T.H. Oh, and J.W. Francis. Dept. Anat., Univ. Maryland Sch. Medicine, Baltimore, MD 21201.

Injuries to CNS tissue induce a number of biochemical changes within astrocytes including the up-regulation of glial fibrillary acidic protein (GFAP) and peripheral benzodiazepine (PBZD) receptors. Since our laboratory has been investigating whether particular cytokines influence these changes, we determined the effects of physiological levels of both interleukin (IL)-1 and tumor necrosis factor (TNF) on PBZD receptors using [3H]Ro5-4864 as a ligand. Both type-1 and type-2 astrocytes were prepared from neonatal rat brain. Specific binding of 2 nM ligand to type-1 astrocytes reached equilibrium between 30 to 60 min and was half maximal at 10 min. Surprisingly, [3H]Ro5-4864 binding to type-2 astrocytes was barely above the level of non-specific binding and measured only 0.5% of the binding observed in cultures of type-1 astrocytes. After treating cultures with IL-1 beta for 5 days, the binding of [3H]Ro5-4864 to type-1 astrocytes doubled, whereas no changes were seen within type-2 astrocytes. Both IL-1 alpha and TNF were shown to increase the binding of [3H]Ro5-4864 in a dose-dependent manner. Regardless of treatment, specific binding to type-2 astrocytes was less than 0.5% of the binding to type-1 astrocytes. These data suggest that (i) PBZD receptors are present only in type-1 astrocytes, (ii) specific binding of [3H]Ro5-4864 can be increased by IL-1 and TNF in a dose-dependent manner, and (iii) cytokines may play a role in the "activation" of astrocytes following injury to the brain. Supported in part by NIH grant (NS 15013) and the Bressler Research Fund.

DYSMYELINATION IN BOVINE ß-MANNOSIDOSIS: WHITE MATTER LESIONS IN A LYSOSOMAL STORAGE DISEASE IN SALERS CALVES. K.L. Lovell, M.Z. Jones, and B. Abbitt*. Dept. Pathology, Mich. State Univ., E. Lansing, MI 48824 and Texas Veterinary Medical Diag. Lab., College Station, TX 77841

An inherited defect in lysosomal ß-mannosidase activity has been previously reported in goats and humans. Affected goats are unable to rise and show neurological deficits, including intention tremor, while most of the human cases have shown mental retardation and deafness. Pathological changes in affected goats include cytoplasmic vacuolation and myelin deficits, with consistent regional variation. In this study of bovine ß-mannosidosis, the glial cell and myelin abnormalities were investigated in Salers calves recently identified as affected with ß-mannosidosis. Brain and spinal cord tissues from three affected animals and one control animal were examined. Paraffin-embedded sections were stained with hematoxylin & eosin and with luxol fast blue-periodic acid Schiff-Holmes stains. Semi-thin Epon-embedded sections were stained with toluidine blue. In the cerebral hemispheres, there was a substantial decrease in the volume of white matter in the affected calves. Myelin deficiency was apparent throughout the brain, with marked variation in severity among regions. For example the myelin deficit was more severe in the corpus callosum, where practically no myelin sheaths were present, than in the cerebellar white matter. The spinal cord showed much greater amounts of myelin than brain regions examined. In regions of severe myelin deficiency, gliosis, with an increase in astrocytic processes, was prominent. The regional pattern of white matter lesions in bovine ß-mannosidosis was similar to that previously reported in caprine ß-mannosidosis and very different from the pathological changes reported in bovine α-mannosidosis, the most closely related lysosomal storage disease. The specific causal relationship between ß-mannosidase deficiency and myelin deficits has not yet been defined. Supported by NS 20254 to KLL and NS 16886 to MZJ.

EFFECTS OF CULTURE CONDITIONS AND ENDOCRINE FACTORS ON ANGIOTENSINOGEN PRODUCTION BY RAT PRIMARY ASTROGLIAL CULTURES AND IMMORTALIZED ASTROGLIAL CELLS. K.R.Zahs, L.O.Hong, V.B.Bigornia, S.D.Collins, R.H.Edwards and C.F.Deschepper. Dept of Physiology Box 0444, University of California, San Francisco CA 94143

Rat astroglial primary cultures were found to produce different amounts of angiotensinogen (AOG) according to the brain region from which they were derived. Cultures from pons produced more than cultures from diencephalon, while cultures from cortex produced small or undetectable levels of AOG. A similar regional distribution was observed whether the cells were derived from fetal or neonatal rats. The cultures produced more AOG at 39°C than 37°C, and more in Coons medium than in MEM. AOG production was increased in a dose-related fashion by dexamethasone (DEX) and triiodothyronine (T3). Dibutyryl cyclic AMP (dbcAMP) 10^{-3}M increased AOG secretion and potentiated the effect of DEX, but did not modify the effect of T3. Immortalized astroglial cell lines were obtained by transforming astroglial cells derived from the diencephalons of ld-old rats with the A58 temperature-sensitive mutant of SV-40 large T antigen. At 39°C, selected cell lines displayed astroglial characteristics and secreted AOG in a DEX-sensitive fashion. These cells may therefore be a useful model to study the region-specific expression and endocrine regulation of the AOG gene in rat brains. Supported by USPHS Grants HL29714 and HL38774.

TRANSGENIC ABLATION OF SCHWANN CELLS DURING DEVELOPMENT. A.Messing, G. Lemke, R.R.Behringer*, J.P.Hammang, R.D.Palmiter*, and R.L.Brinster*. Sch. of Vet.Med., Univ. of Wisc., Madison, WI 53706; Sch. of Vet.Med., Univ. of Penn., Philadelphia, PA 19104; Salk Institute, La Jolla, CA 92037; H.H.M.I., Univ. of Wash., Seattle, WA 98195.

In order to explore cellular interactions during development of peripheral nerve, we generated transgenic mice expressing the diphtheria toxin A chain gene under the control of regulatory elements from the rat P_0 gene. Seventy-eight pups were born from fertilized eggs microinjected with the P_0-DT construct, of which sixteen had integrated the transgene. One of these founder animals, although phenotypically normal, produced transgenic offspring with a generalized hypomyelinating peripheral neuropathy and shortened lifespan. Peripheral nerves of offspring in this line show marked depletion of myelin, but occasional fibers had apparently normal myelin sheaths. Proliferation occurred in the non-myelinating population of Schwann cells. Some non-myelinating Schwann cells had shortened processes and incompletely enclosed bundles of small-diameter axons. These mice should prove useful for studies on the secondary responses of Schwann cells and axons to primary Schwann cell diseases.

MURINE MONOCLONAL ANTIBODIES SPECIFICALLY KILL A HUMAN GLIOBLASTOMA CELL LINE IN VITRO. C. Matute,[1] V. Sánchez*[1], C. Río*[1], B. Conde*[2] and E. Sinués*[2]; 1-Department of Neurosciences, University of País Vasco, 48940-Leioa; 2-Department of Morphology, University of Zaragoza, 50009-Zaragoza, Spain.

We have produced murine monoclonal antibodies (mAb) to a human glioblastoma cell line (T2) recently established in our laboratory. Balbc mice were immunized using as antigen1-2 millions of T2 cells grown in nude mice . MAbs binding to T2 cells but not normal human central nervous tissue were selected to test their cytotoxic effects on T2 cells in vitro. ^{3}H-thymidine incorporation and total protein content assays showed that mAbs 1A1-B7 and 1D4-G3 were able to alter the normal growth of T2 cells. However, these mAbs did not significantly changed the growth rate of other malignant human cell lines or rat primary astrocytes. An hour incubation with .3 mg/ml of ammonium sulphate precipitated ascitic fluids containing mAb 1A1-B7 followed by .05 mg of rabbit complement applied for two hours was sufficient to kill 74% of T2 cells and 23% of the rat glioma cell line C6, whereas cultured astrocytes grew as in control wells. Irrelevant mAbs, complement itself or a combination of both were not cytotoxic at this concentrations. Preliminary immnunoblot experiments indicate that mAb 1A1-B7 and 1D4-G3 recognize a 200 Kd band. These mAbs bind to a T2 molecule which might show some partial homology to a molecule/s present in rat glioma C6. The mAbs reported here are specific for a human glioblastoma cell line and they might be valuable immunotherapeutical probes.

THE RETINAL PIGMENT EPITHELIUM (RPE) GENERATES AN INCREASE IN SUBRETINAL SPACE VOLUME IN FROG RETINA. B. Huang and C.J. Karwoski. Vision Research Laboratory, Department of Psychology, University of Georgia, Athens, GA 30602.

Membrane impermeable ions, combined with ion-selective electrodes, can be used to measure changes in extracellular space (ΔECS). We have recorded ΔECS in the subretinal space (SRS) in Rana pipiens during normal light-evoked activity. Eyecups were superfused with the ECS marker cations tetramethylammonium (TMA) or tetraethylammonium, or the anions hexafluoroarsenate or α-naphthalene sulphanate.

A light-evoked decrease in concentration of these ions was measured. This decrease is caused by an expansion of the SRS, rather than by uptake mechanisms, because: (1) The amplitude and time course of cation and anion responses are similar; (2) The TMA response recovers to baseline during a long-duration stimulus; (3) The resistance across the SRS is decreased by light.

Glutamate analogues (2-amino-4-phosphonobutyrate+kynurenate or aspartate) do not block the TMA decrease, which indicates mechanisms postsynaptic to photoreceptors are not involved. A TMA decrease is not observed in the isolated retina, therefore the RPE is involved in generating the TMA decrease. The TMA decrease is depressed by Ba^{2+}, a K^+ channel blocker, but is not affected by blockers of anion transport mechanisms.

We conclude that during light the RPE cells shrink, leading to an increase in SRS volume. Light-evoked ΔECS will affect extracellular concentrations of all substances.

Supported by NIH grant EY-03526.

ISOLATION OF cDNAs EXPRESSED IN THE ADULT MOUSE CHOROID PLEXUS. E. Lecain*, T. Rhyner*, J. Mallet* and B. Pessac, Centre de Biologie Cellulaire, CNRS, 67 rue Maurice Günsbourg, 94205 Ivry sur Seine cedex, France.

We have previously reported the construction of a subtracted cDNA library from a mouse cerebellum astroglial cell clone (Rhyner, T. *et al.*, J. Neurosci. Res., in press). The recombinants isolated from this library, whose sizes range from 100 to 200 bp, have been characterized by nucleotide sequencing and by their pattern of expression in various mouse adult tissues and regions. Two recombinants code for smooth muscle α actin and fibronectin.

The sequences of two other recombinants did not reveal any significant homology with any cDNA described to date when compared with data bases.These recombinants hybridize to mRNAs present in the brain and in various tissues including kidney, testis and muscle, as well as in primary cultures of cerebellar astrocytes. To identify the cell types responsible for mRNA expression, *in situ* hybridization experiments were carried out with RNA probes. The antisens RNAs gave a clear signal in choroid plexuses of the lateral and 4th ventricules as well as in few ependymal cells. In addition, one recombinant hybridized to limited areas of kidney cortex, i.e. some glomerulus cells and the proximal tubule.

These results show that the strategy used in this study has led to the isolation of undescribed cDNAs that hybridize to mRNAs expressed in astrocytes and other cell types outside the CNS.

EVIDENCE THAT NORMAL ASTROCYTES DO NOT MIGRATE UNDER NON-INVASIVE (NON-TRANSPLANT) CONDITIONS. J.D. Hatton, J.P. Finkelstein & H.S. U*, Div. of Neurosurgery, UC San Diego, La Jolla, CA

Previous research has shown that grafted astrocytes have the ability to migrate throughout most of the rat central nervous system. Reactive host astrocytes have been shown to migrate into superior cervical ganglion autografted into the brain as target tissue. However, the ability of normal astrocytes to migrate under non-invasive conditions has not been explored. To investigate this question, host astrocytes must be labelled without invasive damage. Thus, rats were anaesthetized and placed in a stereotaxic. A burr hole in the skull exposed the dura mater, which was peeled back under a surgical microscope. The pia mater was gently punctured several times with the tip of a 31g needle. The area was overlaid with gelfoam containing fluorescent polyspheres in tissue culture medium. After two hours, the gelfoam was removed and the wound was closed. After 2-4 weks of recovery, rats were perfused with aldehydes and their brains removed and sectioned on a cryostat for fluorescence histology.

Fluorescent polyspheres were taken up by both pial fibroblasts and astrocytes at the pial-glial margin. Labelled astrocytes (identified by GFAP staining) were confined to the area of the original labelling site, and did not migrate either laterally across the pial margin or ventrally into the corticsal layers. Labelled astrocytes did not appear to be either hyperplastic or hypertrophic. Although minimal damage may have occurred during labelling, these results suggest that astrocytes do not migrate in the absence of some invasive stimulus.

GENE STRUCTURE AND FUNCTION IV

483.1

ROLE OF AP2 AND NEGATIVE REGULATORY CIS-ACTING ELEMENT IN GLUTAMINE SYNTHETASE EXPRESSION. H.J. Purohit*, R.G. King and J.F. Mill. Lab. of Molecular Biology, NINDS, NIH, Bethesda, MD 20892.

Glutamine synthetase (GS) plays a central role in nitrogen metabolism and ammonia detoxification in the central nervous system, where its expression is confined to astrocytes. The gene for GS was cloned and the 5′ flanking region isolated. A series of deletion and site-directed mutants of the promoter region were generated by the polymerase chain reaction, cloned into the chloramphenicol acetyl transferase (CAT) expression vector pSV_0CAT, and expressed in various cell lines.

The deletion mutants demonstrate that 421 bp upstream of the transcriptional start site is sufficient for cell type specific expression. This construct is expressed at high levels in primary astrocytes, C6 glioma and HepG2 cultures, and at only low levels in PC12, and HeLa cell lines.

We have identified two regions of importance for the regulation of GS expression, an AP2 site (CCCAGCC) located at -222, and a silencer region (CCTCTGTAG) at -797. Expression of a 251 bp fusion construct with a site-directed mutation in the AP2 site shows an increase when compared to the wild type constructs. When this same mutation is made in a 1086 bp construct containing the silencer region, all expression is suppressed.

483.2

DISTRIBUTION OF KETAMINE-INDUCED FOS IMMUNOREACTIVITY IN RAT BRAIN. R.A. Mueller, K. Gilliam*, L. Grimes, and G.R. Breese. Dept. of Anesthesiol. and Bio. Sci. Res. Cent., School of Med., UNC-CH, Chapel Hill, NC.

To determine the distribution of fos immunoreactivity induced by the dissociative anesthetic ketamine (KET), rats were injected with 40, 80, or 120 mg/kg of KET or 80 mg/kg/ KET plus 10 mg/kg naloxone (NAL) and were perfused 2 hr later with 4% paraformaldehyde plus 0.2% glutaraldehyde. 30 μm Vibratome sections were stained for fos protein. A prominent band of immunoreactive nuclei was detected in posterior but not anterior cingulate cortex. Quantification of intensely stained nuclei revealed maximal expression at 80 mg/kg. NAL attenuated but did not eliminate staining for fos. Other areas exhibiting fos immunoreactivity were: a) central n. amygdala, b) n. Edinger-Westphal, c) paraventricular, parafasicular, medial dorsal, lateral posterior and reuniens n. of thalamus, c) paraventricular, supramammillary, centromedian, and dorsomedial n. of hypothalamus, d) subthalamic n., and e) layers IV and VI of cortex. No staining was noted in neostriatum or hippocampus. These results suggest that KET may alter the metabolism of neurons involved in the affective component of pain perception.

STRONG EVOLUTIONARY CONSERVATION OF NEUROPEPTIDE Y; CHARACTERIZATION OF SHARK GENE. D. Larhammar, I. Lundell*, and A. G. Blomqvist*. Department of Medical Genetics, Uppsala University, Box 589, S-751 23 Uppsala, Sweden.

Neuropeptide Y (NPY) is an abundant and widely distributed neuropeptide in the CNS and PNS of all mammals investigated. NPY potently influences several physiological parameters, notably blood pressure and food intake which are both increased by NPY. NPY is a member of a peptide family which also includes peptide YY (PYY) and pancreatic polypeptide (PP) as well as the fish pancreatic peptide PY.

To investigate the degree of conservation of NPY at the structural level during evolution, we have recently isolated DNA clones encoding chicken and goldfish NPY. We have previously reported that chick and goldfish NPY reveal a remarkable degree of homology as they display only 1 and 5 differences out of 36, respectively, to human NPY.

Using a chick NPY probe we have now screened a genomic library from horned shark (kindly provided by Dr. G. Litman, Tampa Bay Res. Inst., St. Petersburg, FL). Several clones were found which contain exon two of the shark NPY gene encoding the signal peptide and 34 of the 36 amino acids of mature NPY. Mature shark NPY shows only three differences to the human sequence. The shark sequence displays no unique amino acid residues as compared to the other known NPY sequences. This suggests that shark NPY may be identical to NPY of the common ancestor of cartilaginous fishes, bony fishes, and mammals.

We are now in the process of characterizing lamprey cDNA clones and screening a Torpedo cDNA library.

The impressive similarity of shark NPY to human NPY makes this peptide one of the most highly conserved known; 92% identity.

POSITIVE AND NEGATIVE REGULATORY ELEMENTS IN THE 5' FLANKING REGION OF THE MUSCLE NICOTINIC ACH RECEPTOR γ-SUBUNIT GENE. B.P. Gilmour and P.D. Gardner. Program in Molecular and Cellular Neuroscience and the Department of Biochemistry, Dartmouth Medical School, Hanover, NH 03756.

AChR expression is profoundly influenced during the development of skeletal muscle. Several lines of evidence suggest that this regulation is mediated in part at the level of transcription. Our laboratory is characterizing transcriptional control elements located in the 5' flanking regions of the AChR subunit genes. Previously we have shown that 720 bp of 5' flanking DNA of the mouse muscle AChR γ-subunit gene are sufficient to direct cell type-specific and developmentally regulated transcription of a reporter gene in transfected muscle cells. To further delineate the elements responsible for this regulated transcription, we have carried out deletion analysis of the 720 bp region. Deletion of a 172-bp region (nucleotides -526 to -355 relative to the transcription start site) resulted in a 2-fold increase in reporter gene expression. Placement of this 172-bp putative repressor region upstream of a heterologous promoter (e.g. SV40) resulted in a 5-fold decrease in reporter gene expression. Further deletion of the 5' flanking DNA (nucleotides -354 to -131 relative to the transcription start site) resulted in a 2-fold decrease in expression. These data suggest the presence of both negative and positive regulatory elements in the 5' flanking DNA.

Characterization of Type I and Type II $GABA_A$-Benzodiazepine Receptors through Domain Swapping. Sutherland, M., Blake, A., Martin, I.L., Shingai, R., Leech, C.*, Darlison, M.G., Davies, W., Barnard, E.A. Mol.Neurobiol. Unit, Med.Res. Council Cambridge, England, *Department of Zoology, University of Cambridge, Cambridge, England.

Distinct subtypes of the $GABA_A$-benzodiazepine receptor have been characterized in the mammalian CNS using ligands which interact with the benzodiazepine recognition site on this protein. Recent evidence from combinations of $GABA_A$ receptor subunits expressed in transfected mammalian cells suggests that type I benzodiazepine receptors, as characterized by high affinity for CL 218 872 and methyl β-carboline-3-carboxylate are associated with the α_1 subunit, while type II characteristics, which correspond to a low affinity for the above two ligands, are found if α_1 is replaced by α_2 or α_3 subunits in the transfected cells.(1)

In order to delineate these differences further we have exchanged the N-terminal extracellular domain of the bovine $GABA_A$ α_1 subunit with the bovine α_3 subunit and expressed these chimeras in combination with β_1 and γ_2 $GABA_A$ subunits in transfected mammalian cells. The expressed receptors in the cell membranes were characterized by displacement of either [^{3}H] flunitrazepam or [^{3}H] Ro 15-1788 with CL 218 872 or methyl β-carboline-3-carboxylate. Channel integrity and function were studied by electrophysiological analysis. Our results will be discussed in this presentation.References (1) Pritchett, D.B. *et al.* (1989), Science 245, 1389-1392.

483.6

SPECIES-SPECIFIC COMPARISON OF PREPROENKEPHALIN PROMOTERS. R.J. Schroeder, G. Weisinger and E.F. La Gamma, Pediatrics & Neurobiology, SUNY at Stony Brook, NY 11794.

Despite the high degree of homology between the human and the rat preproenkephalin (ppENK) promoters, (89% from +1 to -140, 50 to 60% beyond) expression of this gene varies between tissue and cell type, (La Gamma et al, Int J Devl Neurosci 7:499, 1989). This raises the question, is it the cell background or the DNA sequence that confers this specificity? We made chimeric ppENK-CAT promoter constructs extending to -497, -370, -249, and -152 base pairs from the start site of the rat gene (confirmed by sequencing and restriction analysis). ppENK promoter constructs of the rat and human (pENKAT-12) were transfected into CV1 cells. Transfection efficiency was controlled by Southern analysis of Hirt lysates and beta-galactosidase co-transfection. Basal expression was not detected in any of these constructs. Human ppENK was induced by treatments that increase intracellular cAMP (Forskolin or TPA plus IBMX); similar treatments had no effect on any of the rat constructs. Although the CRE's of the human ppENK promoter are responsible for most of the cAMP inducibility of this gene, this appears not to be the case in the rat. We found five single base pair differences in the region of CRE1 and 2 (Durkin et al, Neurosci Abs, 1990). Sequence differences and/or cell-specific transcription factors, could generate complex patterns of gene expression. Supported by NSF #BNS8719872.

RAT PREPROENKEPHALIN GENE STRUCTURE: 5′ PROMOTER SEQUENCE DETERMINATION (-1.5 KB) & ANALYSIS. R.C. Durkin, G. Weisinger and E.F. La Gamma, Pediatrics & Neurobiology, SUNY at Stony Brook, NY 11794-8111.

Regulation of gene expression involves the interaction of a multiplicity of factors that bind to specific regions of the gene to influence transcription. Although previous work has focused on the regulation of human preproenkephalin (ppENK) by CRE regulatory sequences close to the transcriptional start site (-70 bp to -133 bp), few studies have investigated DNA regulatory regions further 5′ or for other species. To begin to define other features of gene structure and putative upstream cis-acting DNA elements, we have sequenced up to the BamHI site at -1.5 kb of the rat ppENK gene. Sequence data from -1.5 kb to -370 bp is new information. Additionally we report 5 corrections to the previously published rat sequence in the region of the CRE. Corrections to the sequence in the CRE region could account for species-specific regulatory differences by this element (see R. Schroeder et al, Soc Neurosci, 1990). Additional analysis has revealed 85 to 100% homology with several recognized regulatory motifs including CTF/NF-1, c-Jun/AP1, SP1 etc. Furthermore, several open reading frames potentially coding for polypeptides up to 50 amino acids in length have been noted. Current research seeks to further clarify the biological significance of the 5′ upstream region in basal and induced states by analysis of DNAse I hypersensitivity patterns. NSF grant #BNS8719872.

CHARACTERIZATION OF THE HUMAN TRYPTOPHAN HYDROXYLASE GENE. K.L. Newell[1,2], K.J. Black*[1,2], L.B. Morgenstern*[1,2], S.L. Winfield*[2], B.M. Martin[2], B.K. Stubblefield*[2], K. Maysak*[2], J.L. Weller*[3], D.C. Klein*[3], and E.I. Ginns[2]. [1]Howard Hughes Medical Institute-NIH, [2]Section on Molecular Neurogenetics, NIMH, and [3]Section on Neuroendocrinology, NICHD, Bethesda, MD 20892.

Tryptophan hydroxylase (EC 1.14.16.4) catalyzes the hydroxylation of tryptophan to form 5-hydroxytryptophan in the pathway of serotonin biosynthesis. As the rate-limiting enzyme in this neurotransmitter pathway, it is important in maintenance of vascular homeostasis, intestinal motility, and central nervous system functions. Tryptophan hydroxylase, along with phenylalanine and tyrosine hydroxylases, comprise a family of aromatic amino acid hydroxylases that require tetrahydrobiopterin and molecular oxygen for the oxidation of the respective amino acids. The structural homology shared by these aromatic amino acid hydroxylases probably reflects their common origin in a single ancestral gene. Although the genes for human and rat phenylalanine and tyrosine hydroxylases have been isolated and characterized, only cDNAs for rabbit and rat tryptophan hydroxylases have been described. We now report the isolation and characterization of genomic DNA for human tryptophan hydroxylase. The genomic DNA is intermediate in size to that encoding tyrosine and phenylalanine hydroxylases, spanning over 15 kb. A Msp I restriction fragment length polymorphism has been identified using a 5' genomic fragment as a probe, and its use for studies of possible involvement of tryptophan hydroxylase in human genetic disorders will be presented.

483.9

SPECIES AND REGIONAL DIFFERENCES IN THE EXPRESSION OF CELL-TYPE SPECIFIC ELEMENTS AT THE HUMAN AND RAT TYROSINE HYDROXYLASE GENE LOCI. G.T. Coker III, K.-Y. Gandelman, M. Moffat*, and K.L. O'Malley. Dept. of Anatomy and Neurobiology, Washington Univ. School of Medicine, St. Louis, MO 63110.

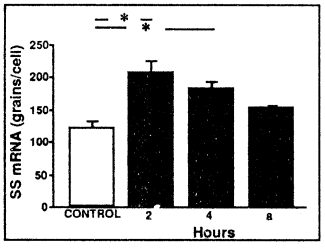
The expression of tyrosine hydroxylase (TH) is confined to different types of neuroendocrine cells. Using a transient assay system, we examined >10 Kb of the human gene and 9.5 Kb of sequence surrounding the rat gene for DNA elements that confer cell-type specific expression. Results derived from the PC12 pheochromocytoma, LAN-1 neuroblastoma, and HepG2 hepatoma cell lines localized cell-type specific sequences for the rat and human genes. Surprisingly, these elements do not appear to be conserved in position or sequence across species. When plasmids containing DNA sequences -749 bp from the transcription start site of the rat gene were introduced into PC12 cells, 2 to 6 fold higher levels of expression were observed compared to the same fragments introduced into HepG2 cells. In contrast to the rat gene, analogous fragments of the human 5' flanking sequence failed to confer cell-type specific expression. However, when plasmids containing a thymidine kinase promoter and either orientation of a 700 bp 3' human gene fragment were introduced into PC12 and LAN-1 cells, we observed a 6 and 3.5-fold increase, respectively, over that observed for HepG2 cells. Deletions of this fragment led to significant activation of transcription, as much as 50-fold over control level. These data suggest the presence of positive and negative elements contributing to the tissue specific expression of tyrosine hydroxylase genes.

mRNA REGULATION: NEUROPEPTIDES

484.1

RAPID STIMULATION BY GROWTH HORMONE OF SOMATOSTATIN mRNA IN THE PERIVENTRICULAR NUCLEUS OF THE ADULT MALE RAT. E Redmond*, P Zeitler*, DK Clifton, and RA Steiner Univ of WA, Seattle, WA 98195

We have recently demonstrated that both SS and GHRH mRNA content in the hypothalamus of adult male rats vary in a manner consistent with the existence of an ultradian rhythm. However, the mechanism underlying this rhythm is unknown. Since previous investigations have demonstrated that GH can stimulate SS mRNA content, at least over a period of days, we tested the hypothesis that GH can stimulate SS mRNA content with a time course sufficiently rapid to account for the ultradian rhythm. Hypophysectomized adult male rats were fitted with jugular catheters, injected with either GH (1 mg) or vehicle and sacrificed at 2, 4 and 8 h after injection (n=4 at each time).



Using *in situ* hybridization, we measured SS mRNA levels in individual neurons of the PeN and compared these levels among experimental groups. We report results (based on ~50 cells per animal) that SS mRNA content is increased at 2 and 4 h after the GH injection and returns to control values by 8 h. **Conclusion:** Rapid feedback of GH on SS gene expression may underlie, at least in part, the ultradian rhythm in SS mRNA content in the hypothalamus of the adult male rat.

484.2

IDENTIFICATION OF PROTEIN-SOMATOSTATIN PROMOTER DNA COMPLEXES IN BRAIN REGIONS SUBJECT TO TIME- AND TISSUE-SPECIFIC SOMATOSTATIN mRNA EXPRESSION C.L. Szymeczek, D.A. Bayliss and D.E. Millhorn, *University of North Carolina, Chapel Hill, NC 27599-7545.*

Somatostatin (SOM) mRNA decreases in rat hypoglossal nuclei (12N) from birth through postnatal day 14 (FASEB J. 3:A391, 1989), after which time it disappears from 12N but remains in other brain nuclei, e.g. nucleus tractus solitarii (NTS). This tissue- and time-specific expression may be due to the presence of different trans-acting regulatory factors (i.e. proteins) in particular brain nuclei at different ages. Therefore, we performed gel shift assays by incubating crude nuclear protein with ^{32}P-labelled fragments of the SOM 5' flanking region. Resultant DNA-protein complexes were examined by polyacrylamide gel electrophoresis. To study time-dependent SOM expression, crude nuclear protein extracts from whole brainstem at ages 0, 7, 14, 21, and 28 days were assayed. To examine tissue-specific SOM expression, crude nuclear protein extracts prepared from adult rat 12N and NTS were used. In both sets of experiments, several specific DNA-protein complexes were identified as far as 750 bases upstream of transcription start site. These findings show that proteins isolated from brain tissue exhibit specific binding to the SOM promoter region. Significance of these DNA-protein interactions in tissue- and time-specific SOM expression in brain is unclear. (NIH HL33813, AHA 881108)

484.3

HALOPERIDOL RAPIDLY INCREASES NEUROTENSIN mRNA LEVELS IN RAT NEOSTRIATUM. K.M. Merchant, M.A. Miller, E.A. Ashleigh* and D.M. Dorsa. GRECC, Seattle VA Medical Center and Depts. of Medicine and Pharmacology, University of Washington, Seattle, WA 98108.

Several recent studies have demonstrated that treatment of rats with antipsychotics such as haloperidol increases neurotensin (NT) immunoreactivity in the neostriatum. The purpose of the present work was to investigate the response of the NT/ neuromedin N gene in striatal cells following acute and chronic treatment with haloperidol. Male Wistar rats were treated with a) a single dose of haloperidol (0.5 mg/kg, i.p.) and were sacrificed 1 h later or b) multiple doses of haloperidol ((0.5 mg/kg/day x 21 d, i.p.) and sacrificed 20-22 h after the last treatment; controls were treated with the vehicle of the drug. In situ hybridization histochemistry using a ^{35}S-labeled antisense riboprobe was employed to determine the level and distribution of NT-mRNA. A computer-assisted image analysis system was used to evaluate the data. In control brains labeled cells were observed in the striatum, nucleus accumbens, median forebrain bundle, olfactory tubercle and the septal nuclei. In anatomically matched striatal sections a sampling of the dorsolateral region showed that there was a dramatic increase in the number (control:42±13, haloperidol:154±30 unilaterally) as well as the optical density of hybridization-positive cells within 1 h after a single dose of haloperidol ($P<0.02$, ANOVA). Such an increase was not observed in the dorsolateral striatum 20 h after the chronic treatment. Thus haloperidol may acutely enhance the expression of the NT/neuromedin N gene in the neostriatum. (Supported by NS 20311).

484.4

HIPPOCAMPAL DYNORPHIN EXPRESSION FOLLOWING SEIZURE, G.L. Yount, J.C. Lauterborn, C.M. Gall and J.D. White, Div. Endocrinology, SUNY, Stony Brook, NY 11794 & Dept. Anatomy and Neurobiology, UC, Irvine CA 92717

The opioid peptides dynorphin (DYN) and enkephalin (ENK) are expressed differentially in dentate granule cells in that DYN is expressed at high levels in the basal state while basal expression of ENK is low. However, following hilus-lesion (HL) induced recurrent limbic seizures, all granule cells also express preproENK mRNA at high levels. In this study we examined preproDYN expression following HL-induced seizures to examine the regulation of expression of co-localized transmitters. Unilateral HL were placed sterotaxically in ketamine-xylazine anesthetized male Sprague-Dawley rats. This procedure reliably produces bilateral electroencephalographic seizures within 90 min of lesion placement that recur for up to 10 hr thereafter. At selected times after HL, animals were killed and dentate gyrus/CA1, CA3, entorhinal and neo-cortical subfields dissected. Total RNA was isolated from these samples and the amount of preproDYN mRNA present in each individual sample was measured by nuclease protection analysis. In dentate gyrus/CA1 samples, preproDYN mRNA levels were found to increase 4-fold and 8-fold above control values by 6 hr and 12 hr post-HL respectively. PreproDYN mRNA levels returned to control values by 24 hr post-HL and were then suppressed 3-fold below control values at 96 hr post-HL. In situ hybridization analyses confirmed that these changes in preproDYN expression occurred in granule cells; additionally, these latter studies also revealed a small population of CA1 pyramidal neurons that were induced to express preproDYN by 48 hr post-HL. Preliminary results suggest that in entorhinal but not neocortex, preproDYN expression was also elevated during recurrent seizure. These findings contrast with those for ENK expression and suggest that different cellular mechanisms regulate expression of these two opioid peptide genes in hippocampal neurons. NIMH 42074, 00801 (JDW); NIH NS 26748 (CMG)

TRANSSYNAPTIC REGULATION OF ADRENAL PREPROENKEPHALIN: A PARADOX. B.L. Agarwal, J.D. DeCristofaro and E.F. La Gamma, Peds & Neurobiology, SUNY at Stony Brook, NY 11794.

In the adult rat, hypoglycemic-induced transsynaptic mechanisms only partially account for augmented levels of preproenkephalin (ppENK) mRNA (Kanamatsu, PNAS 83:9245, 1986). To validate a transsynaptic process, neonatal rats were made hypoglycemic at a time when functional synapses are deficient. Pups were treated with 20 U/kg of insulin or saline vehicle and sacrificed 24 hours later. ppENK mRNA in medullae from adult rats increased 60-fold but there was no change in the newborn. To prematurely induce functional synaptic activity, thyroid hormone was given to newborn rats on day 2 and 3 of life (Lau, Dev Br Res 44:109, 1988). Controls received saline vehicle or were left unmanipulated. Hypoglycemia resulted in a 20-fold increase in adrenomedullary ppENK mRNA levels only in T3/insulin treated pups. To identify effects of hypoglycemia independent of insulin treatment, intracellular glycopenia was produced by injecting adult rats with 2 deoxy-glucose (500 mg/kg). Similar to the insulin-hypoglycemia group, there was an increase in adrenomedullary ppENK mRNA. We conclude that enkephalin biosynthesis like co-stored catecholamines appears to be induced by a transsynaptic process. However, decreasing transsynaptic activity by denervation or ganglionic blockade also increases ppENK mRNA, a paradox which remains unexplained. Supported by the March of Dimes Foundation.

NATURE AND DISTRIBUTION OF PREPROTACHYKININ mRNAS IN HUMAN BASAL GANGLIA. M.S. Poosch, D.M. Haverstick, A. Mandal*, I.C. Xue, K. Shibata, L.J. Dragovic* and M.J. Bannon. Center for Cell Biology, Sinai Hospital, and Wayne County Medical Examiner's Office, Detroit, MI 48235.

Preprotachykinin (PPT, i.e. substance P/neurokinin A-encoding) mRNAs in human basal ganglia tissues obtained at autopsy were quantitated using various human PPT cDNA clones isolated from basal ganglia (courtesy of T. Bonner, NIMH) or hypothalamic cDNA libraries. The size of PPT mRNAs by Northern blot analysis was approximately 1300 bases, confirming the postmortem stability of these mRNAs. Gross anatomical analysis indicated a roughly even distribution of PPT gene expression throughout the entire human caudate-putamen but an absence of PPT mRNAs in the globus pallidus. Solution hybridization (RNA protection) experiments established that approximately 80% of PPT mRNA was beta-PPT (full length) and 20% gamma-PPT (minus exon 4) mRNA, with no detectable alpha-PPT (minus exon 6) mRNA. Thus the proportion of various PPT mRNAs encoding different combinations of tachykinin peptides in human basal ganglia differs significantly from bovine and rodent tissues. The quantitation of PPT primary transcript versus mature PPT mRNA is currently being undertaken using an incompletely spliced hypothalamic PPT cDNA clone containing both exon and intervening sequences.

DIFFERENTIAL AFFECTS OF ADRENALECTOMY ON NPY mRNA LEVELS IN THE ARCUATE NUCLEUS AND BRAIN STEM. B.D. White, R.G. Dean* and R.J. Martin. Dept. of Foods and Nutrition, University of Georgia, Athens, GA 30602

Neuropeptide Y (NPY) is a potent inducer of food intake. Its site of action is thought to be at the paraventricular nucleus (PVN) of the hypothalamus. Cell bodies of NPY nerve terminals in the PVN are located within the arcuate nucleus of the hypothalamus and within various nuclei of the brain stem. We have previously shown that adrenalectomy (ADX) decreases NPY mRNA levels in some regional brain areas (in press, Neurosci. Lett.). To determine if ADX decreases NPY mRNA levels in areas which innervate the PVN, we examined the affect of ADX on NPY mRNA levels in the arcuate nucleus and brain stem. Thirty rats were divided into three groups: ADX, ADX + corticosterone, or Sham. Four days after surgery, tissues were taken and the total RNA isolated. Dot blots were made and hybridized with a cRNA probe to rat NPY mRNA. NPY mRNA was quantitated by densitometry. ADX decreased NPY mRNA levels in the arcuate nucleus by 50% ($p<0.05$). The decrease was reversed by corticosterone replacement. ADX had no affect on NPY mRNA levels in the brain stem. These results suggest that glucocorticoids may have a differential affect on the gene expression of NPY in the arcuate nucleus and brain stem. This implies that a regulatory difference may exist between the arcuate nucleus and brain stem in the control of NPY levels in the PVN.

ALTERED NEUROPEPTIDE GENE EXPRESSION IN EXPERIMENTAL DIABETES. P.Fernyhough, W.J.Smith* and D.R.Tomlinson*. Dept. of Pharmacology, St. Bartholomew's. Medical College, London EC1M 6BQ, U.K.

The aim was to determine whether altered levels of substance P in diabetic rats could be explained by changes in gene expression of the precursor protein, preprotachykinin (PPT). Rats were studied 4 wk after induction of streptozotocin (50 mg/kg i.p.) diabetes. Dorsal root (L_4 and L_5) and trigeminal ganglia were removed rapidly at death and total RNA isolated. Northern blots were prepared and probed using a [^{32}P]-labelled 39-mer oligonucleotide probe complimentary to PPT. Portions of sciatic nerve (1 cm) were removed from the same rats at death, snap frozen in liquid N_2, substance P extracted (< 2h later), and substance P-like immunoreactivity (SPLI) was measured by radioimmunoassay. Sciatic nerve from diabetic rats contained much less SPLI (46.8±5.6 [sem] pg/cm) than segments from control rats (87.4±12.5 [sem] pg/cm; $p < 0.01$). This was associated with markedly reduced levels of the PPT mRNA (relative to total RNA) in the dorsal root ganglia of the diabetic rats compared to control rats. PPT mRNA levels in trigeminal ganglia were, however, greatly increased in diabetic rats compared with control rats. These findings indicate that fundamental changes in gene expression for substance P occur in experimental diabetes.

CHARACTERIZATION OF A NUCLEAR PROTEIN BINDING SITE IN THE 5' FLANKING REGION OF THE MOUSE POMC GENE. J.F. Bishop and M.M. Mouradian, Experimental Therapeutics Branch, NINDS/NIH, Bethesda, MD 20892.

Several protein binding sites have been identified in the 5' flanking region of the mouse POMC gene using AtT-20 cell nuclear extracts in exonuclease protection assays. In this study, the binding site located between -137 and -131 was further characterized because of its sequence homology (TCAGCCA) to AP-1 binding site (5 of 7 bases), and inducibility of POMC mRNA in these cells by phorbol esters. A double-stranded oligonucleotide probe containing 3 copies of this sequence was used in gel retardation experiments with AtT-20 cell nuclear extract. A heat labile factor(s) exhibited specific binding which was abolished by a 50-fold excess of unlabeled homologous DNA, and was unaffected by oligos containing other known transcription factor binding sites, including AP-1, CTF/NF-I and Pit-1. These observations suggest that a major exonuclease protection site with homology to AP-1 site in the promoter region of the mouse POMC gene is a target for an as yet unidentified nuclear protein which has DNA binding characteristics different than those of authentic AP-1.

OXYTOCIN mRNA IS PRESENT IN THE RAT NEUROINTERMEDIATE LOBE

Brooks, P.J., Lund, P.K., Caldwell, J.D., Jirikowski, G.F., and Pedersen, C.A. The Neurobiology Curriculum and the Departments of Physiology and Psychiatry , University of North Carolina at Chapel Hill, Chapel Hill, NC

The mRNAs encoding vasopressin (AVP) and oxytocin (OXY) are synthesized in cells located in the paraventricular and supraoptic nuclei. At last years Neuroscience meeting, two groups (Lightman et al, 142.5, McCabe et al, 142.8) presented evidence indicating the presence of AVP mRNA in the posterior pituitary. In the present experiment, we used a solution hybridization–ribonuclease protection assay to detect OXY mRNA in the rat neurointermediate lobe.

Pituitary glands were removed from lactating female rats and dissected into anterior (AL) and neurointermediate (NIL) lobes. Total RNA was isolated from the tissues and hybridized in solution with a 162 base 32P labelled cRNA probe transcribed from plasmid PGEM4–OXY3c (plasmid provided by Dr. Tom Sherman, Univ. of Pittsburgh). After hybridization and ribonuclease treatment, the protected products were analyzed by polyacrylamide gel electrophoresis.

A protected band corresponding to OXY mRNA was seen in RNA samples from the NILs, but not from the AL. This result indicates that, like AVP mRNA, OXY mRNA is also present in the rat NIL. Ongoing experiments are designed to determine whether NIL OXY mRNA may be present in axons from magnocellular OXY neurons.

CALCIUM IN DROSOPHILA NEURONS IN CULTURE. W. Dale Branton and Marla S. Rudnick*. Department of Physiology, University of Minnesota, Minneapolis, MN 55455.

Using the fluorescent [Ca^{++}] indicator fura 2, we have imaged [Ca^{++}] in neurons which were allowed to differentiate in culture from disassociated 4-5 hr *Drosophila* embryos. We could consistently produce a rise in [Ca^{++}] levels in cell bodies, processes and growth cones by either raising external [K^+] or by application of toxins from scorpion venom (*Tityus serrulatus*). The scorpion toxins produce high rates of firing of action potentials in neurons via effects on voltage dependent sodium channels. In either case the rise in [Ca^{++}] could be prevented by zero [Ca^{++}], 1 mM EGTA in the solution bathing the cells. The scorpion toxin-induced rise in [Ca^{++}] could also be prevented by TTX, which prevents the depolarizing action of the toxin by blocking sodium channels. Preliminary results indicate that pre-incubation of the cells with *Plectreurys* toxin (PLTX, Branton et al, J. Neurosci 7(12):4195-4200, 1987) can prevent virtually all the rise in [Ca^{++}] in the soma, processes and growth cones. PLTX has been previously shown to block Ca^{++} currents in these cells measured under voltage clamp in whole cell patch configuration (Leung et al, Neuron 3:767-772, 1989). These findings with fura are consistent with the previous findings and support the idea that the currents measured in whole cell patch are representative of currents in intact neurons. We are also investigating *Hololena* toxin (HoTX, Bowers et al PNAS 84:3506-3510, 1987), a selective blocker of non-inactivating Ca^{++} currents in these cells (Leung et al, Neuron 3:767-772, 1989), to determine if its action is spatially selective.

485.2

HIGH POTENCY NIMODIPINE EFFECTS ON WHOLE CELL CALCIUM METABOLISM: SINGLE CELL, POPULATION RESPONSES AND OSCILLATORY BEHAVIOR IN GH CELLS. J. Chisholm, J. Davis* and V. Diaz*. Inst. Preclin. Pharmacol., Miles Inc. West Haven, CT 06516

Single-cell ionized cytosolic calcium (Ca_i) responses to depolarization (high K^+), measured with fura-2, were potently inhibited by nimodipine (NIM) in the highly differentiated clonal GH_3 cell line. Individual cells which responded to high K^+ were qualitatively similar to cell population responses: basal Ca_i (150nM) increased to an initial high peak phase (over 400nM), followed by an extracellular Ca^{2+} (Ca_e)-dependent plateau phase (200 nM), persisting more than 30 min in the absence of NIM. A majority of cells (60%) also fired NIM sensitive spontaneous oscillatory Ca_i spikes, heterogenous with respect to both amplitude (up to 200 nM) and frequency (up to 0.2 Hz). Some cells with stable Ca_i developed spiking activity and/or reverted spontaneously. Oscillations were inhibited under depolarized conditions without drug. The high K^+-induced sustained influx of Ca_e was completely eliminated by NIM, both in cell suspensions (<10 nM), and in single cell determinations in monolayer (addition <50 nM). This correlated with potent NIM block of high K^+ induced cell-associated ^{45}Ca (IC_{50}=0.2 nM). These data support both the physiological significance of sustained Ca^{2+} influx to whole cell calcium metabolism, and the functional activity of NIM at nanomolar concentrations on plasma membrane Ca conductance.

485.3

DEPOLARIZATION-INDUCED CHANGES IN CYTOSOLIC FREE CALCIUM CONCENTRATION IN ISOLATED NERVE TERMINALS FROM RAT POSTERIOR PITUITARY. J. T. Russell, Section on Neuronal Secretory Systems, LDN, NICHD, Bethesda, MD 20892.

Nerve endings (neurosecretosomes), isolated from rat posterior pituitaries were placed on protamine coated coverslips and perfused with balanced salt solutions. Cytosolic free calcium concentration in these nerve terminals was measured by monitoring the fluorescence of the calcium indicator, fura-2 using high resolution video microscopy. Intracellular calcium ion concentration rapidly rises in some of the terminals upon perfusion with solutions containing elevated potassium concentration (25 to 55 mM K_o) or veratridine (60 μM). The initial rise is followed by a slow decline in $[Ca^{2+}]_i$ to resting levels. The depolarization-induced increase in $[Ca^{2+}]_i$ was inhibited by the presence of nimodipine, and ω-conotoxin, two voltage-dependent calcium channel antagonists. Removal of sodium from the perfusion medium also caused a rapid rise in the intracellular calcium levels presumably due to the abolition of sodium-calcium exchange.

485.4

ACTIVITY-DEPENDENT INCREASES IN $[Ca^{2+}]_i$ IN CULTURED RAT SEPTAL NEURONS.

D. Bleakman, [1]N.L. Harrison, J.D. Zucker, B.H. Wainer & R.J. Miller. Dept. of Pharmacological & Physiological Sciences and [1]Dept. of Anesthesia and Critical Care, Univ. of Chicago, Chicago, IL. 60637.

We have begun to study the cellular processes which are involved in the buffering of physiological Ca^{2+} signals in CNS neurons. Simultaneous whole-cell patch clamp recordings and fura-2 based microfluorimetric recordings of $[Ca^{2+}]_i$ were made from cultured rat septal neurons at 25°C. Neuronal resting potentials were -55 to -65mV, input resistances 200-800MΩ and basal $[Ca^{2+}]_i$ values 130 ± 20nM (n=13). Neurons were held at -60mV by constant current injection and action potentials (AP's) evoked by brief depolarizing current pulses.

Trains of AP's elicited increases in $[Ca^{2+}]_i$ that returned to basal values with approximately exponential kinetics ($\tau \approx 3$s.). High frequency (≥ 25Hz) trains of AP's produced larger increases in $[Ca^{2+}]_i$ than low frequency (≤ 10Hz) trains for a given number of AP's, indicating a significant decline in the $[Ca^{2+}]_i$ between successive AP's at lower frequencies. The relationship between the number of AP's and $[Ca^{2+}]_i$ approached an asymptote at high $[Ca^{2+}]_i$ loads as previously observed in rat dorsal root ganglion cells (DRG) (S.A. Thayer and R.J. Miller, J. Physiol., in press). However, this asymptote was reached at 100-150 AP's compared to 20-60 AP's in DRG cells. Preliminary results suggest that both mitochondrial buffering and Na/Ca exchange mechanisms contribute to the recovery of the rise in $[Ca^{2+}]_i$ following activity in cultured rat septal neurons.

SPATIAL AND TEMPORAL RESOLUTION OF CALCIUM TRANSIENTS PRODUCED BY STIMULATION OF DIFFERENTIATING AMPHIBIAN SPINAL NEURONS. J.Holliday[1], R.J.Adams[2], T.J.Sejnowski[2], and N.C.Spitzer[1]. Dept. of Biology and Center for Molecular Genetics[1], University of California, San Diego, and Laboratory for Computational Neurobiology[2], Salk Institute, La Jolla, CA.

Action potentials evoked from *Xenopus* spinal neurons exhibit a calcium dependence at initial stages of differentiation that shifts to a sodium dependence over a 24 hr period (Spitzer and Lamborghini, 1976). Therefore, stimulation is expected to produce greater calcium influx at early stages of differentiation than during later periods of development. However, the intracellular free calcium level attained upon stimulation is likely to be influenced by other factors such as the release of calcium from intracellular stores and calcium sequestration and buffering. These variables may also change over development.

Changes in the intracellular calcium levels produced by depolarization have been examined in intact (non-dialyzed) cultured neurons using the calcium indicator, fluo-3 and high speed confocal image analysis. Elevations of intracellular free calcium in response to depolarization occur throughout the cell, most notably in the nucleus. The initial onset of increased indicator fluorescence is not detectably delayed in the nucleus relative to the cytosol under measurement conditions with a time resolution as fine as 2 msec. The fluorescence increases to peak values within approx. 200 msec. The initial fluorescence decay was fitted to first order kinetics with a rate constant of about -0.15 sec^{-1}. After stimulation-evoked increases began to decline, slower elevations in fluorescence occurred. The contributions of calcium release from intracellular stores and calcium buffering to observed changes in intracellular calcium are considered. The effects of neuronal maturation on patterns of stimulus-evoked fluorescence will be described.

Supported by grants from the NIH to JH and NCS and from the NSF to TJS.

CA^{++} STORES IN PURKINJE CELLS: LOCALIZATION OF $INSP_3$ RECEPTOR AND CALSEQUESTRIN. K. Takei*, A. Metcalf*, G. Mignery[1*], P.Volpe[2*], T. Südhof[1*], and P. De Camilli. Dept. Cell Biol. Yale Univ. Med. Sch., New Haven, CT; [1]Dept. Mol. Gen. and HHMI, Univ. Texas, SWMC, Dallas, TX; [2]Dept. Phys. Biophys. Univ. Texas Med. Branch, Galveston, TX.

It is now well established that intracellular Ca^{++} stores play an important role in cellular regulation. Ca^{++} is stored within membranous organelles from which it can be released by second messengers. A large fraction of Ca^{++} within these stores is bound to Ca^{++}-binding proteins which in the striated muscle and chick cerebellum include calsequestrin. To further elucidate the nature of Ca^{++}-storing organelles in neurons, we have carried out a comparative analysis of the distribution of the InsP3-gated Ca^{++} channel (IP3R) and calsequestrin immunoreactivity in cerebellar Purkinje cells (PC).

As previously observed by us (Nature 342: 192-195, 1989), immunogold labeling of PC revealed a widespread distribution of the IP3R throughout the smooth endoplasmic reticulum (sER), including tubules and cisternae present in dendritic spines and axon terminals. In addition, peculiar stacks of sER cisternae were frequently observed in all regions of the PC cytoplasm. Portions of these cisternae apposed to each other were particularly enriched in IP3R (for the concentration of the IP3R at these sites see also Satoh et al. JCB in press), and appeared to be connected by feet-like structures reminiscent of those connecting sarcoplasmic reticulum and T-tubules at muscle triads.

Calsequestrin immunoreactivity was concentrated selectively in a subset of PC smooth surfaced tubules and vesicles which appeared to be part of the sER but was not enriched in the lumen of InsP3 receptor-rich stacks of sER cisternae. In addition, it was not detectable in the rough ER. These findings are consistent with the existence of structurally specialized subcompartments in Ca^{++} storing organelles.

INOSITOL 1,4,5-TRISPHOSPHATE ACTIVATES A PUTATIVE CALCIUM POOL-REFILL CHANNEL IN *XENOPUS* OOCYTES. B. Gillo, S. Mundamattom, S.C. Sealfon Dept. of Neurology and Fishberg Center in Neurobiology. Mount Sinai Medical School. New York, N.Y. 10029

Plasma membrane inositol phospholipid-operated calcium channels have previously been found in lymphocytes and mast cells and postulated to be involved in filling endoplasmic reticulum calcium stores. We demonstrate in intact *Xenopus* oocytes that inositol 1,4,5-trisphosphate (IP_3) activates a calcium influx (measured via the native calcium activated chloride current) which is antagonized by cadmium with an IC_{50} of about 200μM. This conductance was insensitive to the VSCC antagonists verapamil and amiloride. Measurement of the conductance changes and reversal potential in the presence of barium ions supports the existence of a native IP_3-activated calcium channel ($Ca_{(IP3)}$) in the oocyte. We find that the opening of this channel is accompanied by refilling of the IP_3-sensitive calcium pool from the extracellular medium. We propose that a second messenger-operated calcium channel may contribute to the refill of IP_3-releasable intracellular calcium stores.

GENERATIONAL ACETALDEHYDE (AlCHO)EFFECT ON MITOCHONDRIAL CNS Ca^{2+} UPTAKE. E. Egaña & M.T. Ramirez* University of Chile; Faculty of Medicine; Institute of Experimental Medicine; Laboratory of Neurochemistry; Santiago 7-Chile

It has showed in several models of experimental alcoholism that AlCHO the first product of EtOH oxidation reaches all organs, including several CNS areas all connected to metabolism of the toxic. The cell membrane is one of the target structure of deletereous effect; in neuronal tissue affects transport, depolarization, neurotransmittion, neurosecretion, etc. most of these processes linked to Ca^{2+} transmembrane transport. Our Institute has created an experimental model whose rats during seven generations were expossed to AlCHO along their lives from embrion to adult including crossing (Egaña et al. since 1987).

Adult albino Wistar rats♂ & ♀Normal and "AlCHO/G rats these last were injected dayly 200 mg/Kg rat AlCHO i.p. during their life; intrauterine, lactation (by mother injection), inmature and adult age, during 7 generations. Five mitochondrial CNS' areas were studied: brain cortex, hypothalamus, hyppocampus, cerebellum & midbrain. Site I mitochondrial electron transport and Ca^{2+} influx were studied with a polarigraph and "ad hoc" selective electrod in a 4.5 ml chamber with adequate reactional medium.

Results showed that Ca^{2+} uptake was decreased in "AlCHO/G rats" compared with normal, particularly when hypothalamus, hyppocampus and cerebellum were studied.

PHOTOLYSIS OF THE CAGED Ca^{2+} CHELATOR DIAZO-4 RAPIDLY DECREASES Ca^{2+} ACCUMULATION AND Ca^{2+} CHANNEL INACTIVATION IN *APLYSIA* NEURONES. M.W. Fryer and R.S. Zucker. Dept. of Mol. & Cell Biology, Univ. of Calif., Berkeley, CA 94720.

Ca^{2+}-mediated Ca^{2+} channel inactivation in *Aplysia* neurones is seen as either a decline of Ca^{2+} current during long depolarizing pulses or as the loss of peak current in a test pulse (P2) following a pre-pulse (P1). We used the photolabile Ca^{2+} chelator diazo-4 (Adams et al., J. Am. Chem. Soc., 211, 7957, 1989) to generate rapid decreases in intracellular free Ca^{2+} ($[Ca^{2+}]_i$) under both sets of conditions. Left upper quadrant neurones from the abdominal ganglion were injected with a diazo-4/CsCl mixture to a final diazo-4 concentration of 2-5mM. When a brief, intense light flash was given during a long depolarizing step the decline of Ca^{2+} current was markedly slower than the control. Separation of the overlayed current relaxations was apparent after approximately 10ms. In paired-pulse experiments, a light flash given in the inter-pulse interval increased the P2/P1 peak Ca^{2+} current ratio and hence accelerated the recovery from inactivation. The results show that diazo-4 may be used to rapidly buffer the high local $[Ca^{2+}]_i$ that is present near Ca^{2+} channels during and after activity. The kinetics of such changes are somewhat more rapid than expected from Ca^{2+}-dependent enzymatic mechanisms of inactivation development and recovery. Supported by NIH Grant NS 15114 and NH&MRC (Aust.) C.J. Martin fellowship to MF.

CONTROL OF NEURONAL CALCIUM CURRENT BY INTRACELLULAR CALCIUM. B.D. Johnson* and W.L. Byerly. Dept. of Biol. Sci., University of Southern California, Los Angeles, CA 90089.

It has been suggested that molluscan neuronal calcium channels are modulated intracellularly both by cAMP- and Ca^{2+}-dependent processes. Using an internal perfusion, voltage clamp technique on isolated Lymnaea neurons, we have identified a Na^+ current activated at the resting potential by a combination of cAMP and theophylline, which appears in the absence of any effect on the voltage dependent calcium (I_{Ca}) or potassium (I_K) currents. The magnitude of this current can be reversibly reduced if ATP is not added to the internal perfusate, suggesting that cAMP-dependent phosphorylation may selectively modulate this current over I_{Ca} and I_K. In contrast, I_{Ca} is modulated by internal calcium. Inactivation, as measured by a double-pulse paradigm, is reversibly enhanced by decreasing the concentration of intracellular calcium buffer (EGTA), and the long-term disappearance of I_{Ca} (washout) is increased with a larger calcium load. Maximal calcium currents, stimulated every six seconds with 500ms pulses, increased the rate of washout over four times, as compared to cells monitored with 20ms pulses every minute. We hope to further delineate calcium's role in regulating I_{Ca} using photorelease of caged Ca^{2+} to produce sudden increases in intracellular Ca^{2+}.

485.11

EXOGENOUSLY-ADDED ATP PROMOTES ^{45}Ca INFLUX IN PC-3M CELLS. M.A. Oleshansky, M.L. Koenig, M.A. Jackson*, and J.B. Trepel*[1] Dept. of Medical Neurosciences, Walter Reed Army Institute of Research, Washington DC 20307 and [1]Lab of Pathology, NCI, Bethesda, MD 20892.

It has been reported recently that addition of ATP to the extracellular medium can transiently increase cytosolic Ca^{2+} concentrations in cultured neuronal cells (J. Neurochem., 50:295-301) and is associated with synaptic potentiation in hippocampal slices (Brain Res., 491:356-9). To further characterize the effect of exogenous ATP on Ca^{2+} homeostasis, we have studied PC-3M cells, a prostate tumor cell line which demonstrates a large transient increase in free intracellular Ca^{2+} in response to added ATP. We now show that at least part of the ATP-dependent increase in intracellular Ca^{2+} levels in PC-3M cells can be attributed to an enhanced influx of Ca^{2+}. The ATP-stimulated uptake of ^{45}Ca is saturable, does not appear to be voltage-gated, and is relatively slow ($t_{1/2}$=5 min). The response is dose-dependent with maximal influx at an added ATP concentration of 3mM. Influx is markedly reduced at higher concentrations of the purine. Preliminary experiments with verapamil and a number of inorganic Ca channel antagonists suggest that the influx occurs via an ion channel. Dihydropyridine channel blockers appear to be unable to block the ATP-stimulated uptake of Ca^{2+}. These results indicate that ATP is able to alter Ca^{2+} homeostasis by a direct effect on a non-voltage gated Ca^{2+} channel.

486.1

CALCIUM CHANNEL REOPENINGS AT RESTING MEMBRANE POTENTIALS FOLLOWING PRIOR DEPOLARIZATION.

P. A. Slesinger & J. B. Lansman. Graduate Neuroscience Program, Univ. of Calif. Med. School. San Francisco, CA 94143.

Neurotransmitter release depends critically on Ca influx through voltage-dependent Ca channels. Although Ca current is inhibited by a wide variety of substances, mechanisms for potentiation of Ca current are less well known. Unitary Ca currents were recorded with 90 mM Ba in the pipette from mouse cerebellar granule cells grown *in vitro*. Granule cells possess a single class of dihydropyridine-sensitive Ca channels (21 pS) that open with depolarizations positive to -30 mV (V_h=-100 mV). Depolarizations to ~0 mV for 100 ms elicit brief openings with a mean open lifetime of ~0.5 ms. Following the termination of the voltage step, Ca channels close with a rate too fast to be detected at -70 mV. By contrast, two types of Ca channel activities are observed following termination of very positive prepulses (>+50 mV): channels that remain open at the end of the prepulse and channels that close, but reopen briefly after a delay. We analyzed the kinetics of Ca channels that were open following the prepulse. Distribution of open time durations for all openings following the prepulse was fit by a single exponential with a τ=4.5 ms. Distribution of latencies to first reopening was fit by a single exponential with a τ=7.7 ms. With shorter, positive prepulses (<25 ms), fewer reopenings are produced and the time constant for the first latency histogram was faster. Thus, Ca channel reopenings depend on both the amplitude and duration of prepulse. These results are consistent with Ca channels returning from an inactivated or blocked state and suggest that following a train of action potentials, the opening of Ca channels at membrane potentials far from the equilibrium potential for Ca would produce a large component of Ca influx.

486.2

CALCIUM AND CALCINEURIN INCREASE THE INACTIVATION RATE OF L-TYPE CALCIUM CHANNELS IN PLANAR BILAYERS.

Y. Hirschberg, P.A. Koplas & R.L. Rosenberg. Curr. in Neurobiology and Dept. of Pharmacology, Univ. of N. Carolina, Chapel Hill, NC 27599.

Inactivation of L-type Ca channels is voltage- and Ca-dependent. To study Ca-dependent inactivation, we reconstituted cardiac and neuronal L-type Ca channels into planar bilayers where it was possible to control internal Ca^{2+} and Ca-dependent proteins. Inward Ba currents were evoked by 800 ms pulses to 0 mV, and inactivation timecourses were observed in ensemble averages of single-channel records. The stimulatory G-protein, G_s, and DHP agonist 202-791 were included to increase channel lifetime and open time.

In contrast to previous reports (RLR et al.,1988, JGP 92;27), reconstituted L-type Ca channels did express Ca-dependent inactivation. Addition of 15-500 μM Ca^{2+} to the internal solution increased the inactivation rate in 5/11 experiments (see Fig.). Addition of calcineurin (0.1 mg/ml) and Ca^{2+} (5-500 μM) increased the inactivation rate in 5/7 experiments where increased Ca^{2+} alone had no effect. There was no effect of calcineurin in the absence of Ca^{2+}. This suggests that calcineurin and similar proteins in the membrane preparations can be activated by Ca^{2+} and increase the rate of Ca channel inactivation. The Ca-dependent inactivation of reconstituted channels (with or without calcineurin) did not appear to result from dephosphorylation, because the effect of Ca^{2+} was reversible even in the absence of Mg^{2+}-ATP (4/4 trials).

MONOCLONAL ANTIBODIES TO THE ω-CONOTOXIN-SENSITIVE CALCIUM CHANNEL FROM RABBIT BRAIN MEMBRANES

Junshi Sakamoto, K.K. Stang* and K.P. Campbell. Howard Hughes Medical Institute and Dept. of Physiology and Biophysics, University of Iowa College of Medicine, Iowa City, IA 52242.

The high affinity ω-conotoxin receptor of the calcium channel from rabbit brain membranes has been characterized using monoclonal antibodies. Mice were initially injected with isolated rabbit brain membranes and boosted with heparin-agarose eluate from rabbit brain membranes, which was enriched in the ω-conotoxin receptor. Hybridoma supernatants were screened for immunoprecipitation of ω-conotoxin binding activity. Monoclonal antibodies from hybridoma culture supernatants were preincubated with goat anti-mouse IgG-Sepharose beads (GAM beads) to form monoclonal antibody GAM beads. These beads were then tested for their ability to immunoprecipitate the ^{125}I-ω-conotoxin-prelabeled receptor from CHAPS-solubilized rabbit brain membranes. Three monoclonal antibodies were found to specifically immunoprecipitate the ω-conotoxin-labeled receptor. The ω-conotoxin sensitive calcium channel has been isolated from total rabbit brain membranes using a combination of heparin-agarose chromatography, sucrose gradient centrifugation, and WGA-Sepharose chromatography. The monoclonal antibodies specifically precipitating ω-conotoxin binding activity are being used to characterize and identify the subunit composition of the ω-conotoxin-sensitive calcium channel isolated from rabbit brain membranes. K.P. Campbell is an Investigator of the Howard Hughes Medical Institute.

Isolation of a Rabbit Brain Transcript with Homology to the β Subunit of the Skeletal Muscle Dihydropyridine Sensitive Calcium Channel.

M. Pragnell, S.D. Jay, C.J. Leveille and K.P. Campbell Howard Hughes Medical Institute, Neuroscience Program and Dept. of Physiology and Biophysics, University of Iowa College of Medicine, Iowa City, IA 52242.

The dihydropyridine sensitive calcium channel, enriched in rabbit skeletal muscle T-tubules, consists of four subunits (α_1, α_2, β and γ). All of these subunits have been recently cloned. Sequence information suggests that α_1 is the principle transmembrane subunit which contains the pore of the ion channel. The cDNA sequence of the β subunit predicts numerous consensus phosphorylation sites (Ruth et al., Science 245:1115) consistent with in vitro studies suggesting a regulatory role. We have isolated a cDNA for the γ subunit (Jay et al., Science 248:490) and the β subunit. cDNA probes derived from the skeletal muscle β subunit message have been shown to crosshybridize with a 3 Kb mRNA species in rabbit brain. This is significantly larger than the 1.8 Kb message observed in skeletal muscle. We have screened a rabbit brain cDNA library with probes made from the skeletal muscle β subunit cDNA clone. A 0.5 Kb and a 2.2 Kb insert were isolated that crosshybridized with the skeletal muscle β sequence. These inserts were then used as probes to rescreen the library and isolate full length cDNA clones. Following completion of sequence analysis a comparison will be made between the predicted structure of the encoded protein and that of the skeletal muscle β subunit. This will test the hypothesis that a homologous brain protein exists which has a calcium channel regulatory function analogous to that proposed for the skeletal muscle β subunit. K.P. Campbell is an investigator of the Howard Hughes Medical Institute.

486.5

PRIMARY STRUCTURE AND EXPRESSION OF THE RAT BRAIN CLASS-A CALCIUM CHANNEL.

T.V. Starr, W.A. Prystay* and Terry P. Snutch. Biotechnology Laboratory, Univ. of British Columbia, Vancouver, B.C., Canada V6T 1W5.

We have isolated a number of rat brain cDNAs which are homologous to the alpha-1 subunit of the dihydropyridine receptor/Ca channel of rabbit skeletal muscle and heart. Preliminary analysis shows that at least four distinct classes of Ca channel genes are expressed in rat brain. Currently, we are investigating the functional and molecular relationships between the different neuronal Ca channel family members.

Using Northern blot analysis, rat brain class A cDNAs (rbA) hybridize to two major transcripts of approx. 8.3 and 8.8 kilobases (kb). Partial DNA sequence analysis of 20 class A cDNAs indicates that these clones fall into two subfamilies that differ at their 3' ends. One class A clone, rbA-126, has been entirely sequenced and contains a single open reading frame of 6.9 kb. The deduced amino acid structure of rbA-126 shows that it contains four repeated homology domains, each containing six putative transmembrane segments. The four repeated domains share approx. 55% amino acid identity with the cardiac Ca channel. In addition, rbA-126 possess two large hydrophyllic domains not related to sequences found in previously cloned Ca channels. One of these is a 470 amino acid segment that separates domains II and III. The second is an approx. 600 amino acid region which follows domain IV. The significant structural differences between rbA-126 and other cloned Ca channels suggest the possibility that functional differences may also exist.

486.6

PRIMARY STRUCTURE AND EXPRESSION OF THE RAT BRAIN CLASS-B CALCIUM CHANNEL.

S.J. Dubel and T.P. Snutch. Biotechnology Laboratory, Univ. of British Columbia, Vancouver, B.C., Canada V6T 1W5.

We have found that rat brain expresses a family of genes (Class A, B, C and D) that are related to the alpha-1 subunit of skeletal muscle and cardiac Ca channels (Snutch et al, PNAS 1990). Northern blot analysis reveals that a set of cDNAs designated rat brain class B (rbB) hybridize to a brain transcript of approx. 10 kilobases (kb). A series of overlapping cDNAs were isolated, sequenced and found to contain a single open reading frame of 6.8 kb. The predicted rbB peptide is most closely related to the rat brain class A Ca channel sequence (with greater than 90% identity in the four repeated homology segments; see abstract by Starr et al.). However, homology between the class A and B Ca channel peptides differs significantly in two putative cytoplasmic domains. The first of these domains is located between homology repeats II and III (approx. 430 amino acids in rbB), while the second follows repeat IV (approx. 600 residues). In both the class A and class B peptides these two regions contain a number of potential cAMP-dependent phosphorylation sites. Studies are now underway to examine the temporal and spatial expression patterns of the rbB gene in the rat CNS, and to express a full-length rbB cDNA in a number of test systems.

486.7

ISOLATION OF cDNA CLONES FOR α1 SUBUNITS ISOFORMS OF THE L-TYPE CALCIUM CHANNEL FROM MOUSE BRAIN. W-J. Ma* and M. Uhler. Mental Health Research Institute, Univ. of Mich., Ann Arbor, MI 48109.

The α1 subunit is the major transmembrane component of the L-type calcium channel. Furthermore, it contains the binding site for dihydropyridines and has been proposed to form the ionic pore of the channel. In order to characterize the neural expression of the a1 subunit we have used a synthetic oligonucleotide complementary to the sixth transmembrane segment of the third repeat of the α1 subunit of the rabbit skeletal muscle calcium channel. cDNA clones related to the rabbit skeletal α1 sequence were isolated from mouse brain cDNA libraries. Two classes of cDNA clones were obtained. The first class of cDNA clones hybridizes to messenger RNAs of 8 and 14 kb in mouse brain and appear to code for the mouse cardiac form of the α1 subunit. This cDNA codes for a protein that is 98% identical in amino acid sequence to the rabbit cardiac α1 subunit. The second class of cDNA clones hybridize to mRNAs of 10 and 12 kb. This second type of cDNA codes for a protein highly homologous (75% identical) to the cardiac α1 subunit but contains many differences in nucleotide sequence from both the cardiac and skeletal sequences. These findings suggest that this class of cDNA results from transcription of a novel α1 subunit genomic sequence.

SINGLE CHANNEL PROPERTIES OF Ca CHANNELS EXPRESSED FROM RAT BRAIN mRNA IN *Xenopus* OOCYTES. Lin, J-W.and Llinás, R. Dept. Physiology and Biophysics, NYU Med. Ctr, NY, NY 10016.

Calcium channels expressed from rat brain mRNA in *Xenopus* oocytes have been shown to be different from L, N and T types in that this calcium current is activated by high voltages, with little inactivation, and is insensitive to dihydropyridine or ω-conotoxin (Leonard et al., J. Neurosci. 7, 875, 1987). We have shown: (1) this current can be blocked by spider toxin (Lin et al., PNAS, in press, 1990)(FTX) from *Agelenopsis aperta* (Llinas et al., PNAS. 86, 1689; Cherksey et al., Soc. Neurosci, abtr, 15, 652, 1989) and (2) the effect of the toxin is dependent upon the concentration of divalent cations. In order to further characterize this current, single channel recordings were obtained from on cell patches, using an intracellular electrode to monitor membrane potential. The patch was clamped at -100 mV and 40 msec pulses were used to activate voltage sensitive calcium channels. With 70 mM $BaCl_2$ and 1 μM TTX in the patch pipette, an inward unitary current of 0.58 pA was recorded at -20 mV and its amplitude decreased with further depolarizations. I-V plot of this unitary current, ranging from -40 mV to 0 mV, gives a slope conductance of 13 pS. In addition, in some patches, we observed a large unitary current with a slope conductance of 20 pS. The two unitary currents exhibited different sensitivities to depolarizations. For example, in one patch, the large unitary current was observed in 30% of the traces at 0 mV whereas the small unitary current in the same patch appeared in more than 65% of the traces at -20 mV. Both unitary currents appear throughout the duration of depolarizing pulses, suggesting a non-inactivating nature similar to the macroscopic calcium current recorded in this preparation. The effect of FTX on these channels are under investigation. (Supported by Fidia Research Foundation and NIH grants NS13742 to R. Llinas, GM26976 to B. Rudy).

EXPRESSION OF A RECOMBINANT OMEGA-CONOTOXIN IN YEAST. M.W. McLane*[1], R.A. Lampe[1], D. Shields*[2], A. Salama[1] and M.M.S. Lo[1]. [1]ICI Americas, Wilmington, DE 19897, and [2]Dept. of Developmental Biology and Cancer, Albert Einstein College of Medicine, Bronx, NY 10461.

Omega-conotoxins are potent blockers of N-Ca^{++} channels within various species. Several naturally occurring variants have been isolated from the venom of Conus snails. These complicated small peptides, which contain 24-29 residues, are highly homologous, and are predicted to have a rigid structure constrained by 3 intramolecular disulfide bridges. These peptides offer a substantial challenge for their correct processing, folding and secretion in yeast, which results in the production of a biologically active molecule. A synthetic oligonucleotide encoding a variant of omega-conotoxin was fused to the pro-alpha-factor sequence. Yeast strains, transformed with the recombinant pro-alpha-factor-toxin construct, produced a major low molecular weight peptide. The amino acid sequence is being determined on a reduced and carboxymethylated fraction. Disulfide bridge assignment will be determined in the native yeast product after purification by reverse phase HPLC. The biological activity of the recombinant conotoxin will be initially determined by a toxicity assay in goldfish, and further characterized by inhibition of ^{125}I-conotoxin (G6A) to rat brain membranes.

MULTIPLE BINDING SITES FOR 1,4-DIHYDROPYRIDINES ARE ASSOCIATED WITH SKELETAL MUSCLE CALCIUM CHANNELS. S.M.J.Dunn, C.Bladen* & R.P.Thuynsma*. Department of Pharmacology, University of Alberta, Edmonton, Alberta T6G 2H7.

The binding of (+)-[^{3}H]PN200-110, a calcium channel antagonist, to membrane preparations from rabbit skeletal muscle has been investigated in equilibrium and kinetic experiments. At equilibrium, binding is to an apparently homogeneous class of high affinity sites characterized by a K_d of 0.30 ± 0.05 nM (25 mM Hepes-Tris pH 7.4, 1 mM $CaCl_2$, 25°C). Measurements of the kinetics of association have suggested that complex formation is a simple bimolecular process. Under pseudo-first order conditions, the association reaction was monophasic, and the rate increased linearly with ligand concentration (0.1 - 2.0 nM). From these data, association and dissociation rate constants have been estimated to be 5.5 x 10^6 $M^{-1}s^{-1}$ and 0.0033 s^{-1} respectively. Direct measurements of the dissociation of (+)-[^{3}H]PN200-110 have, however, revealed a number of complexities. When dissociation was initiated by the addition of excess unlabelled (+)PN200-110, (±)nitrendipine or (±)Bay K8644, the dissociation rate increased with the concentration of competing ligand above 1 μM. The isomer, (-)PN200-110, at concentrations up to 30 μM, did not accelerate the dissociation rate. These results suggest the presence of an additional low affinity site (or sites) for 1,4-dihydropyridines (Kd ≈ 10 μM) which cannot be detected in direct binding studies. The low affinity site is stereoselective and its occupancy increases the rate of dissociation of [^{3}H]PN200-110 from its high affinity site. (Supported by NIH GM-42375.)

IDENTIFICATION OF RYANODINE BINDING PROTEINS IN THE AVIAN NERVOUS SYSTEM: LOCALIZATION IN PURKINJE CELLS DIFFERS FROM IP3 RECEPTORS. Mark H. Ellismanψ Thomas J. Deerinck*ψ Yannan Ouyang*ψ Claudia F. Beck*Σ Steven J. TanksleyΦ Philip D. Walton*Φ Judith A. Airey*Φ John L. Sutko*Φ.

ψNeurosciences, U.C. San Diego, La Jolla, Calif., 92093; Σ Biochemistry, Univ. of Idaho, Moscow, Idaho, 83843; Φ Pharmacology, Univ. of Nevada, Reno, Nevada, 89557.

We have identified ryanodine binding proteins in cells of the avian central nervous system. Monoclonal antibodies against avian skeletal muscle sarcoplasmic reticulum foot proteins were used to localize and isolate the brain proteins. Neuronal ryanodine binding protein-like immunoreactivity was found on components of the internal membrane system of cerebellar Purkinje neurons. The subcellular distribution of the immunoreactivity in these cells was established using laser confocal microscopy of thick sections, immuno-EM of peroxidase labelled semi-thick sections and by immuno-gold labelling of ultrathin cryosections. The ryanodine binding protein-like immunoreactivity was found within membrane systems of the perikaryon, the dendritic arbor and the axoplasm. Ryanodine binding proteins were not found in dendritic spines. Double immunolabeling experiments, comparing the distributions of the ryanodine binding protein to the IP3 receptor and to calbindin, revealed differences in cytoplasmic distributions. For example, the IP3 receptor immunoreactivity is prominent in the RER and dendritic spines (c.f. Mignery et al., Nature 342:192-195,1989) while the ryanodine binding protein appears absent in spines and is not distributed throughout the RER. Immunoprecipitation and [3H]epiryanodine binding experiments revealed that the cerebellar ryanodine binding proteins have a native molecular weight of ~2,000 kd and are composed of two high molecular weight (~500 kd) polypeptide subunits. A comparable protein having a single high molecular weight polypeptide subunit was observed in the remainder of the brain. If the ryanodine binding proteins in muscle and nerve are similar in function, then the neuronal proteins may participate in release calcium from intracellular stores that are distinct from those of the recently characterized IP3-activated calcium channel.

PHARMACOLOGICAL CHARACTERIZATION OF HIGH AFFINITY [^{3}H]RYANODINE BINDING SITES TO SUBCELLULAR FRACTIONS OF RAT BRAIN. R.A. PADUA, * J.D. GEIGER, W. WAN, * J.I. NAGY. Depts. Pharmacol. & Physiol., Univ. of Manitoba., Winnipeg., MB. R3E OW3 CANADA.

Ryanodine, at low nanomolar concentrations applied to neurons in vitro, inhibits the release of calcium from caffeine-sensitive intracellular sites that appear to be localized to endoplasmic reticulum. In analogy to muscle sarcoplasmic reticulum, this inhibition in neural tissues may be mediated through high-affinity ryanodine binding sites. To investigate whether specific [^{3}H]ryanodine binding sites are present on CNS tissues we conducted a series of studies using standard radioligand binding methods. Optimal binding was obtained at pH 8.0 in the presence of 550 μM ATP, 100 μM Ca^{2+}, and 1.0 M KCl. [^{3}H]Ryanodine binding was linear at membrane protein concentrations ranging from 0.02 to 0.13 mg. In association experiments, equilibrium was reached within 15 min at 37°C and levels of [^{3}H]ryanodine binding were stable for at least 2 hr. K_D values for P_1 (nuclear), P_2 (mitochondrial), and P_3 (microsomal) fractions derived from saturation experiments were comparable at about 5 nM. The number of [^{3}H]ryanodine binding sites in P_3 fractions was approximately 4-fold greater than that in P_1 or P_2 fractions. [^{3}H]Ryanodine may be binding to sites that mediate intracellular calcium release. (Supported by MRC of Canada).

CHARACTERIZATION OF A PUTATIVE INSECT CNS CALCIUM CHANNEL, USING THE PHENYLALKYLAMINE [^{3}H](±)VERAPAMIL. J.M. Skeer* and D.B. Sattelle. AFRC Laboratory of Molecular Signalling, Department of Zoology, Downing Street, Cambridge CB2 3EJ, U.K. Spon: Brain Research Association

Membranes prepared from the CNS of the cockroach, Periplaneta americana, have been found to contain a saturable, specific phenylalkylamine binding site, based on studies using [^{3}H](±)verapamil. Scatchard analysis has revealed a single population of binding sites with a dissociation constant (K_D) of 57 ± 5nM (mean ± SD, n=3) and a binding capacity (B_{max}) of 70 ± 20pmol per mg membrane protein (mean ± SD, n=3). Hill plots of the data yield a Hill coefficient of 0.98 ± 0.02 (mean ± SD, n=3) that does not depart significantly from unity, indicating the absence of co-operativity. Displacement studies using a range of putative calcium channel ligands reveal that the pharmacological profile of this [^{3}H](±)verapamil receptor in cockroach CNS membranes differs from that of the well-documented vertebrate phenylalkylamine binding receptor that is a component of an L-type calcium channel. In particular, the insect CNS phenylalkylamine receptor is dihydropyridine-insensitive, in contrast to the finding for the corresponding site in vertebrates which is dihydropyridine-sensitive. These data indicate the presence of a putative calcium channel in the insect CNS that is not readily classified using pharmacological criteria established for vertebrate tissues.

IMMUNOHISTOCHEMICAL CHARACTERIZATION OF DISSOCIATED RAT LOCUS COERULEUS NEURONS IN CULTURE. C.G. Frondoza, J.-M. Fritschy, R. Grzanna, and M. Geffard. Johns Hopkins Univ., Depts. Immunology & Infectious Diseases and Neurosci., Baltimore, MD 21205, and University of Bordeaux, Lab. Immunol. and Neurobiol., 33076 Bordeaux, France.

Rat locus coeruleus (LC) neurons contain norepinephrine (NE) and several neuropeptides. To develop an experimental model system for studies of factors that may play a role in specifying transmitter phenotypes, we have grown LC neurons in culture following the protocol of Nakajima *et al.* In this study we identified by immunohistochemistry neurochemical markers of cultured LC neurons. The LC was isolated from 1-3 day old rats, dissociated and plated on a feeder layer of astrocytes. After 7-14 days incubation, culture plates were processed for immunohistochemistry using antibodies to glial fibrillary acidic protein, neuron specific enolase, tyrosine hydroxylase (TH), dopamine-ß-hydroxylase (DBH), NE, neuropeptide Y (NPY), serotonin and choline acetyl-transferase (ChAT). Between 50-70% of the neurons could be identified by TH immunohistochemistry as LC neurons. The morphologic appearance of these TH+ cells was very similar to that seen in the rat LC. Most TH+ cells were large, multipolar and formed extensive arrays of fine varicose processes. Most of the small TH+ cells were bipolar. All TH+ neurons also stained for DBH and NE. Many neurons in the culture stained for NPY and about half of those also stained for TH. In TH/NPY positive neurons the staining of the cytoplasm was consistently faint while their varicose processes were intensely stained. Neurons which contained only NPY had darkly stained cell bodies. Almost all TH positive neurons also contained serotonin, but none could be stained with ChAT. Dissociated LC neuron cultures should provide a valuable experimental model to identify and characterize factors that determine the neurotransmitter phenotype in these neurons. DISTRIBUTION OF LOCUS COERULEUS NEURONS THAT PROJECT TO RAT VB THALAMUS AND BARRELFIELD CORTEX. D.W. Altman, C-S. Lin and B.D. Waterhouse. Dept. Physiol. and Biophys., Hahnemann Univ., Phila., PA. 19102

Previous studies from this laboratory have demonstrated a topographic relationship between projection neurons of the locus coeruleus (LC) and target regions of the neocortex and subcortical visual structures within the rat brain. The present investigation was conducted to examine the distribution of LC neurons that project to the ventrobasal (VB) nucleus of thalamus and the barrelfield region of the somatosensory cortex. An additional goal of the study was to determine if regions along the same sensory pathway receive collateral inputs from the same LC neuron. Long-Evans hooded rats (275-400 g) received unilateral pressure injections (1.0 ul) of various combinations of green and red fluorescent latex (rhodamine) microspheres into the barrelfield area of the somatosensory cortex and the VB nucleus. Coronal sections (80-100 um) through the LC were examined by fluorescence microscopy and the distribution of retrogradely labeled cells was recorded. LC neurons labeled from barrelfield injections were primarily located throughout the rostrocaudal dimension of the ipsilateral nucleus. By contrast, neurons projecting to VB thalamus were distributed bilaterally with a slight ipsilateral predominance. In the coronal plane, coeruleo-cortical projection neurons tended to be localized within the dorsal half of the LC, while cells projecting to VB thalamus had a tencency to be displaced more ventrally. Cells which were double-labeled were concentrated in the region of the ipsilateral nucleus where the subsets of cortical and thalamic projection neurons overlapped. In summary, the distribution of retrogradely labeled cells observed here suggests a rough topographic ordering of LC neurons with respect to somatosensory projection sites. Furthermore, the presence of double-labeled cells suggests that individual LC neurons may simultaneously influence the sequential processing of information at different levels within the afferent somatosensory pathway. NEURONS IN THE ROSTRAL MEDULLA PROJECT TO BOTH THE LOCUS COERULEUS (LC) AND THE NUCLEUS OF THE SOLITARY TRACT (NTS) IN THE RAT. E.J. Van Bockstaele[1,2], Yan Zhu[1*] and G. Aston-Jones[1]. [1]Dept. Mental Health Sciences, Hahnemann Univ., Phila., PA. 19102, [2] Dept. of Biology, New York University, N.Y., 10003.

Numerous anatomical and physiological studies have confirmed the existence of projections from the rostral ventrolateral medulla (RVLM; nuc. paragigantocellularis) and dorsomedial medulla (DMM; nuc. prepositus hypoglossi) to the LC. The functional significance of these circuits, however, remains unclear. To better understand their function, we have examined other connections of these LC afferents using double retrograde labeling techniques. Iontophoretic deposits of Fluoro-Gold (FG) were made into the LC and pressure injections of a complex of wheat germ agglutinin-conjugated apo (inactivated) horseradish peroxidase coupled to colloidal gold particles (WGA-apoHRP-Au) were placed into the NTS or into the ventrolateral portion of the periaqueductal gray (PAG). The silver intensification of the WGA-apoHRP-Au procedure did not appear to compromise the intensity or sensitivity of the fluorescent retrograde tracer, FG. The labels were identified within the same tissue section with fluorescent and light microscopy. Many doubly labeled neurons were seen in the RVLM following injections into the NTS and LC. Doubly labeled neurons were occasionally observed in the DMM immediately dorsal to the medial longitudinal fasciculus. In contrast, only a small number of doubly labeled neurons within the RVLM, and none within the DMM, were found following injections into the PAG and LC although singly labeled neurons for the two tracers were interdigitated. These results indicate that separate populations of neurons project to the LC and the PAG from RVLM and DMM. However, many RVLM neurons and some DMM neurons send collaterals to both the LC and the NTS. These results link the NTS and LC by their common afferents, indicating that these nuclei are closely coordinated in their functions. Supported by PHS grants NS24698 and DA06214.

THE EFFECTS OF VAGOTOMY ON THE FIRING PATTERNS IN LOCUS COERULEUS NEURONS. **C.L. Williams, E.J. Barea, S.E. Krahl, R.A. Jensen, and D.C. Smith. Department of Psychology, Southern Illinois University, Carbondale, IL 62901.**

This study investigated the role played by peripheral factors in the regulation of maintained discharge of locus coeruleus (LC) neurons. The response characteristics of these cells can be affected by systemic administration of substances which do not freely enter the brain. For instance, Holdefer and Jensen (Br. Res., 417:108, 1987) found a small decrease in spontaneous activity of LC cells following peripheral administration of 8.2 mg/kg 4-OH amphetamine, and an increase in maintained discharge with 10.0 mg/kg of epinephrine. The activity of these cells can also be affected by surgical interventions which remove some of the peripheral neural input to the CNS. For example, Svensson and Thoren (Br. Res., 172:174, 1979) showed that increasing blood volume alters the spontaneous activity of LC cells, and this effect was abolished by cervical vagotomy.

The present study was designed to examine the effects of vagotomy on the response characteristics and maintained discharge of neurons in the LC. Complete subdiaphragmatic vagotomy was performed on Sprague-Drawley rats 2 weeks prior to all testing. Electrophysiological recordings of single-units were measured in normal and vagotomized rats under urethane anesthesia with tungsten microelectrodes. In the vagotomized animals, we found a loss of spontaneous activity in some LC cells, as well as an altered response pattern to noxious external stimuli when compared to normal rats. These data suggest that peripheral factors transmitted to the brain via the vagus nerve play an important role in the modulation of the neuronal discharge patterns of CNS catecholamine systems. (Supported in part by NIMH 1 T32 MH-18882 to E.J.B.)

CHOLINERGIC MODULATION OF LOCUS COERULEUS: POSSIBLE ROLE IN CHOLINOLYTIC SEIZURES. M. El Etri, M.T. Shipley, M. Ennis, and W.T. Nickell. Depts. of Anatomy and Physiology, Univ. Cinti. Coll. Med., Cinti, OH. 45267.

Approximately 50% of rats given a systemic dose (0.7 LD_{50}) of the anticholinesterase soman develop convulsions. HPLC revealed a 50-90% reduction of forebrain norepinephrine (NE) in convulsing animals 50-120 min after AChE inhibition. Convulsing rats also had rapid (30-60 min) induction of c-fos in LC and layer of II piriform cortex, the most vulnerable site of soman-induced neuropathology. These results suggest that AChE inhibition induces a rapid elevation of LC neuronal activity and tonic NE release. This could result either because seizures increase LC activity or because AChE inhibition leads to hypercholinergic stimulation of LC neurons.

Microinjections of soman into LC rapidly and tonically (2-3 hrs) increased LC discharge rates 3-6 fold over baseline values. This activation was completely reversed by scopolamine (0.5 mg/kg, iv) but not mecamylamine (1.0 mg/kg, iv). Subsequent histochemical analysis revealed that AChE inhibition was confined to LC. In addition, c-fos expression was induced in LC and layer II of piriform cortex. These results suggest that LC neurons receive a tonic ACh input, that AChE inhibition leads to tonic ACh overstimulation of LC neurons causing tonic release of forebrain NE. AChE inhibition thus may cause combined ACh and NE hyperstimulation of cortical neurons. This may block afterhyperpolarization mechanisms leading to excessive cortical firing rates, seizures and cell death. (Supported by US Army DAMD17-86-C-6005 and PHS Grant NS24698).

487.6

ASYMMETRIC ORIENTATION OF LOCUS COERULEUS (LC) DENDRITES IN THE PERICOERULEAR REGION: BIOCYTIN-FILLED LC NEURONS IN VITRO. M.T. Shipley, G. Harris, J. Williams, E. Van Bockstaele, G. Aston-Jones, and M. Ennis. Dept. Anatomy, Univ. Cinti., Cinti, OH 45267; Hahnemann Univ, Philadelphia, PA 19102; Oregon Hlth Sci. Univ, Portland, OR.

We previously reported that LC neurons extend processes 400-500 um into two pericoerulear zones which we designated the rostromedial and caudal juxtaependymal pericoerulear regions. EM-immunocytochemical analysis demonstrated that virtually all of these processes are dendrites which are heavily targeted by several morphologically distinct classes of extrinsic synapses. These results suggest that the pericoerulear dendrites comprise a significant site for afferent synaptic regulation of LC neurons. However, it is not known whether the existence of extensive pericoerulear dendrites is a characteristic of many or only a subset of LC neurons. To address this issue we are analyzing the dendritic arbors of LC neurons impaled and filled with biocytin in horizontal brainstem slices.

Results to date suggest that: (1) most LC neurons have pericoerulear dendrites: (2) the longest of these dendrites extend into either the rostromedial or caudal juxtaependymal pericoerulear regions, or both: and (3) neurons in all parts of LC sampled exhibit this preferential dendritic organization.

These results suggest that many LC neurons receive significant afferent inputs on extranuclear dendrites which extend into two pericoerulear zones. EM double labeling methods are necessary to determine which afferents to pericoerulear regions terminate on LC dendrites, pericoerulear neurons or both. (PHS Grant NS24698).

487.7

EFFECTS OF LOCUS COERULEUS (LC) INACTIVATION ON ELECTROENCEPHALOGRAPHIC (EEG) ACTIVITY IN NEOCORTEX AND HIPPOCAMPUS. S.L. Foote, M.E. Page[1], C.W. Berridge, and R.J. Valentino[1]. Dept. Psychiatry (M-003), UCSD, La Jolla, CA 92093; (1) Dept. Mental Health Sci., Hahnemann Univ., Philadelphia, PA 19102.

The hypothesis that the noradrenergic neurons of the LC can influence forebrain EEG activity was investigated by inactivating these neurons in halothane-anesthetized rats while simultaneously recording neocortical (ECoG) and hippocampal (HEEG) EEG activity. LC discharge activity was reduced by infusing the alpha-2 noradrenergic agonist clonidine into LC. Unilateral infusions (240 ng/240nl/over 2 min), whose effects on LC activity were verified by microelectrode recordings, were followed by high-amplitude, low-frequency ECoG activity and mixed frequency HEEG activity. Bilateral clonidine infusions induced a nearly complete blockade of foot-pinch elicited EEG activation in this preparation. This blockade was potentiated by systemic or ICV clonidine. These results suggest that inhibition of LC activity may induce "hypersynchrony" in ECoG activity and may "disenable" or "block" HEEG theta activity under the conditions of this experiment. They also suggest that LC may influence forebrain EEG activity in the unanesthetized state. The present data complement our observations that LC activation in this preparation produces ECoG desynchronization and HEEG theta activity (Berridge et al., this meeting).

487.8

EFFECTS OF LOCUS COERULEUS ACTIVATION ON EEG ACTIVITY IN NEOCORTEX AND HIPPOCAMPUS. C. W. Berridge and S. L. Foote. Dept. Psychiatry, Univ. of Calif., San Diego, CA 92093.

The hypothesis that noradrenergic locus coeruleus (LC) neurons participate in forebrain activation as measured by EEG was examined. In halothane-anesthetized rats, small infusions (75-150 nl) of the cholinergic agonist, carbachol, were used to reversibly activate LC neurons while simultaneous recordings of LC neurons verified this activation. Power spectrum analyses of frontal neocortical and hippocampal EEG were performed. In 11 animals in which histologically verified peri-LC infusions activated the LC, the findings were: 1) LC activation was followed, within 2 to 30 sec, by a shift from low-frequency/high-amplitude to high-frequency/low-amplitude EEG activity in neocortex and the appearance of intense theta rhythm in the hippocampus; 2) In neocortex, absolute power of all frequency bands decreased; the largest decrease was observed in the 0.8-3.0 Hz band. Relative power increased in the 25.0-50.0 Hz and decreased in the 0.8-3.0 Hz bands; 3) Hippocampal relative power increased in the 3.0-7.0 Hz and decreased in the 0.8-3.0 Hz bands; 4) whether infusions were made lateral or medial to LC, forebrain EEG changes followed LC activation with similar latencies; 5) infusions that did not activate LC neurons (e.g., placed 1 mm dorsal or ventral to LC), had no effects on forebrain EEG activity; 6) EEG patterns returned to baseline with about the same time course as the recovery of LC activity (10-20 min). These observations indicate that LC activation is the crucial mediating event for these infusion-induced changes in forebrain EEG.

Supported by the U.S. Air Force (OSR) and the MacArthur Foundation.

STRESS-ELICITED ACTIVATION OF THE LOCUS COERULEUS (LC) BY NITROPRUSSIDE IS ASSOCIATED WITH EEG CORRELATES OF AROUSAL. M.E. Page and R.J. Valentino *Dept. of Mental Health* Sciences, Division of Behavioral Neurobiology, Hahnemann University, Phila, PA 19102.

Stressors have been shown to increase spontaneous discharge rates of LC neurons (Svensson, 1987). Recently, hemodynamic stress produced by nitroprusside infusion was found to increase LC discharge; this activation required endogenous corticotropin-releasing factor (CRF), suggesting that LC activation during stress is mediated by CRF (Valentino and Wehby, 1988). It was hypothesized that one function of LC activation is to increase or maintain arousal during hemodynamic stress. To test this hypothesis, the effects of nitroprusside on cortical and hippocampal EEG and LC spontaneous discharge were investigated in halothane-anesthetized rats. I.V. infusion of nitroprusside (10ug/30ul/min: 15 min) increased LC spontaneous discharge rate 31% ±13 (N=9). The increases in LC discharge were temporally correlated with EEG changes indicative of arousal, i.e., low amplitude, cortical desynchronization and onset of hippocampal theta rhythm. To elucidate the role of CRF in stress-induced EEG activation, a CRF antagonist, alpha-helical CRF_{9-41} was locally infused (100-150 ng) into LC prior to nitroprusside administration. Preliminary studies suggest that alpha-helical CRF_{9-41} (150 ng) may delay the onset, and shorten the duration of EEG activation. This work was supported by PHS Grants MH40008 and MH42796.

EFFECTS OF THE 5-HT REUPTAKE INHIBITOR FLUVOXAMINE ON ANXIETY INDUCED BY YOHIMBINE. A.W. Goddard, D.S.Charney, G.R. Heninger, S.W.Woods . Dept. of Psychiatry, Yale U. Sch. of Med., 34 Park St., New Haven, CT 06508.

The alpha-2 adrenergic receptor antagonist yohimbine (YOH) produces robust anxiogenic effects in panic disorder (PD) patients.This study investigated the effects of chronic treatment with the 5-HT reuptake inhibitor fluvoxamine (FLUV) on YOH-induced anxiety. METHODS: Fifteen patients with DSM III-R PD completed a double-blind placebo controlled study of FLUV. YOH (0.4 mg/kg IV) and placebo challenges were performed during a three week drug-free period and again after nine weeks of treatment. Within challenge measurements included visual analog scale (VAS) anxiety, DSM III-R somatic panic symptoms, blood pressure and heart rate, plasma cortisol (CORT), and 3-methoxy-4-hydroxy-phenethyleneglycol (MHPG). RESULTS: Six of 8 patients responded to FLUV, as compared to 2 of 7 receiving placebo. FLUV produced a greater reduction in the net YOH VAS anxiety response than placebo did, (with FLUV, 48.8±47.9 mm to 11.8±44.8, $p<.06$; with placebo, 41.9±20.9 to 40.7±26.3, NS; between FLUV and placebo, $p<.04$). FLUV but not placebo reduced somatic panic symptoms after YOH. Baseline and peak MHPG levels after YOH did not differ in FLUV compared to placebo treated patients. CORT levels in both groups rose after YOH but there was no significant effect of treatment in either group. Blood pressure and heart rate after YOH were not affected by FLUV treatment. DISCUSSION: Effective chronic treatment with FLUV appears to reduce YOH-induced anxiety and somatic symptoms. These results suggest that interactions between the 5-HT and noradrenergic systems may have a role in the therapeutic mechanism of the 5-HT reuptake inhibitors in PD.

PRIOR EXPOSURE TO CHRONIC STRESS RESULTS IN ENHANCED NOREPINEPHRINE SYNTHESIS IN RESPONSE TO A NOVEL STRESSOR. L.K. Nisenbaum, M.J. Zigmond, and E.D. Abercrombie. *Department of Behavioral Neuroscience and Center for Neuroscience, University of Pittsburgh, Pittsburgh, PA 15260*

We have shown that prior exposure to chronic cold stress results in enhanced hippocampal norepinephrine (NE) release in response to a novel stressor (Nisenbaum et al., Soc. Neurosci. Abstr., 15: 413, 1989). One factor that may contribute to this phenomenon is increased synthesis of neurotransmitter. To test this hypothesis, several measures of NE synthesis were carried out comparing naive and chronically cold stressed rats. Analysis of hippocampal tyrosine hydroxylase (TH) activity in vitro revealed no significant difference between the two groups, suggesting that chronic stress does not produce a detectable increase in the maximal amount of hippocampal TH enzyme activity. The synthesis of NE in vivo was assessed in two ways. First, the accumulation of 3,4-dihydroxyphenylalanine (DOPA) in hippocampus 30 min after administration of the aromatic amino acid decarboxylase inhibitor NSD-1015 (100 mg/kg, i.p.) was examined. Under basal conditions, DOPA accumulation was the same in both groups. In contrast, tail shock produced a greater increase in DOPA accumulation in chronically stressed animals (101 ± 15%) than in naive animals (45 ± 8%). Second, the level of extracellular 3,4-dihydroxyphenylacetic acid (DOPAC) was quantified in the hippocampus using in vivo microdialysis. The basal level of DOPAC did not differ between the two groups. In response to tail-shock stress, however, the increase in DOPAC efflux was larger in chronically stressed rats (136 ± 9%) than in naive animals (75 ± 8%). Thus, while the basal synthetic rate of NE does not differ between the two groups of animals, activation of TH by a novel stressor appears to be greater in chronically stressed rats than in controls.

CONTRIBUTION OF NORADRENERGIC AND DOPAMINERGIC NEURONS TO 3,4-DIHYDROXYPHENYLACETIC ACID (DOPAC) CONCENTRATIONS IN REGIONS OF THE HYPOTHALAMUS CONTAINING INCERTOHYPOTHALAMIC DOPAMINERGIC (IHDA) NEURONS. Y. Tian, K.J. Lookingland, and K.E. Moore, Dept. Pharmacol/Toxicol., Mich. State Univ., East Lansing, MI 48824

IHDA neurons have cell bodies (A_{13} group) in the medial zona incerta (MZI) and axons that project to the dorsomedial nucleus (DMN). The concentration of norepinephrine (NE) in these regions exceeds that of dopamine (DA), reflecting a higher density of NE nerve terminals; this can complicate interpretation of studies employing neurochemical techniques to estimate IHDA neuronal activity. The purpose of this study was to determine if concentrations of the DA metabolite DOPAC in MZI and DMN reflect the activity of IHDA neurons. Administration of apomorphine decreased, while haloperidol increased DOPAC concentrations in MZI and DMN. Injection of a NE neurotoxin (5-amino-2,4-dihydroxy-α-methylphenylethylamine) into the ventral NE bundle, reduced NE concentrations in the MZI and DMN by 80% while DA and DOPAC concentrations were unaltered. Activation of NE neurons with the α_2-adrenergic receptor antagonist idazoxan increased concentrations of 3-methoxy-4-hydroxyphenylethylene glycol and DOPAC in MZI and DMN in intact but not in ventral NE bundle-lesioned rats. These results reveal that DOPAC in MZI and DMN reflect the activity of IHDA neurons, but that when NE neurons are activated, significant amounts of DA are metabolized to DOPAC in NE terminals in these regions. (Supported by NIH Grant NS 15911.)

FUNCTIONAL AND NEUROCHEMICAL EVIDENCE THAT TUBEROHYPOPHYSIAL DOPAMINERGIC NEURONS IN THE RAT PROJECT FROM THE PERIVENTRICULAR NUCLEUS TO THE INTERMEDIATE LOBE OF THE PITUITARY. J.L. Goudreau, S.E. Lindley, K.J. Lookingland, K.E. Moore, Dept. of Pharmacol, Mich. State Univ., E. Lansing, MI 48824

Tuberoinfundibular dopaminergic neurons projecting to the median eminence tonically inhibit the release of prolactin, while tuberohypophysial dopaminergic (THDA) neurons projecting to the intermediate lobe (IL) of the pituitary inhibit the release of α-melanocyte stimulating hormone (αMSH). It was initially proposed (Björklund, et al., Brain Res. 51:171, 1973) that cell bodies of both of these neuronal systems in the rat were located in the arcuate nucleus (A_{12} cell group). Results of a more recent anatomical study (Kawano and Daikoku, J. Comp. Neurol. 265:242, 1987) suggest that THDA neurons originate from the A_{14} cell group in the periventricular nucleus. In the present study a Halasz knife cut in the ventral hypothalamus between A_{12} and A_{14} reduced by 50% the concentrations of dopamine (DA) and its metabolite, 3,4-dihydroxyphenylacetic acid (DOPAC) in IL, but had no effect on DA or DOPAC concentrations in the median eminence. Electrical stimulation of the periventricular nucleus increased the DOPAC/DA ratio in IL and reduced the secretion of αMSH; in the same animals the DOPAC/DA ratio in the median eminence and secretion of prolactin were unaltered. These results provide neurochemical and functional evidence that THDA neurons project from periventricular nucleus to the IL. (Supported by USPHS grant NS15911.)

D2 DOPAMINE AGONISTS ACUTELY INCREASE THE ACTIVITY OF TUBEROINFUNDIBULAR DOPAMINE NEURONS. S.A. Berry* and G.A. Gudelsky, Departments of Pharmacology and Psychiatry, Case Western Reserve University, Cleveland, OH 44106.

The activity of tuberoinfundibular dopamine (TIDA) neurons, in contrast to that of nigrostriatal neurons, is not acutely affected by typical dopamine antagonists, e.g., haloperidol, or agonists, e.g., apomorphine. However, we have reported that the activity of tuberoinfundibular dopamine (TIDA) neurons is acutely suppressed by D1 type dopamine agonists (Neurosci. Abstr. 15:1000, 1989). In the present study, we have examined the effects of the selective D2 agonists quinpirole and quinelorane on the activity of TIDA neurons, as judged from DOPAC concentrations and the in vivo accumulation of DOPA after decarboxylase inhibition in the median eminence. The accumulation of DOPA in the median eminence was dose-dependently increased by quinpirole (0.1-2.5 mg/kg, ip) and quinelorane (0.025 mg/kg, ip). Quinpirole and quinelorane also significantly increased the concentration of DOPAC in the median eminence. The activity of TIDA neurons was increased within 1 hr after the administration of quinpirole, and it remained elevated for 4 hrs. The stimulatory effect of quinpirole on TIDA neurons was completely antagonized by haloperidol (1 mg/kg, ip) but was unaffected by SCH 23390 (0.5 mg/kg, ip). It is concluded that D2 receptor stimulation results in an acute increase in the activity of TIDA neurons.

DOPAMINE NEURONS IN THE GUINEA PIG HYPOTHALAMUS: ELECTROPHYSIOLOGICAL PROPERTIES AND EFFECTS OF OPIOIDS. M.D. Loose, O.K. Ronnekleiv and M.J. Kelly. Dept. Physiology, Ore Hlth Sci Univ., Portland, OR 97201.

Dopamine-containing (DA) neurons in the arcuate nucleus of the guinea pig were recorded in hypothalamic slices. DA neurons, identified immunocytochemically by the presence of tyrosine hydroxylase, had a mean length to width profile of 14.9 ± 4.4 X 11.5 ± 3.1 μm (N = 14), a Na^+ action potential of short duration (0.8 ms) and an after-hyperpolarization of 6-9 mV with a decay half-time of ≈1.5 sec following induction of repetitive firing (20 to 50 Hz). DA cells exhibited a low threshold spike (LTS) which induced 1-4 Na^+ action potentials. The LTS was identified as an inward current which activated positive to -70 mV and was sensitive to high Mg^{2+}/low Ca^{2+} media but not to TTX. DA neurons also had a time-dependent inward current at potentials negative to -70 mV. Cs^+ blocked this conductance. The μ-opioid agonist, Tyr-D-Ala-Gly-MePhe-Gly-ol, hyperpolarized (14 ± 3 mV) DA neurons via induction of an outward current (93 ± 44 pA) which had a reversal potential similar to that of a selective potassium conductance. TTX did not block the opioid effects. Therefore, DA neurons of the arcuate nucleus differ in their intrinsic conductances and their responsiveness to opioids from other CNS DA neurons. Furthermore, opioid activation of a potassium conductance in DA neurons of the arcuate nucleus may underlie the effects of opioids on dopamine-mediated prolactin release.

CENTRAL D1 AND D2 DOPAMINE RECEPTORS STIMULATE HYPOTHALAMIC-PITUITARY-ADRENAL (HPA) ACTIVITY. B.Borowsky and C.M.Kuhn. Dept. of Pharmacology, Duke University Medical Center, Durham, NC 27707.

Non-selective and D2 selective DA agonists as well as cocaine and other inibitors of DA uptake stimulate the secretion of ACTH and corticosterone (CS) in rats. We now report that both D1 and D2 DA receptors contribute to this HPA stimulation, and that brain regions accessible to the third ventricle, such as the hypothalamus, may be involved in this response. Both the D1 selective agonist (±)SKF38393 (1 to 20 mg/kg, i.p.) and the D2 selective agonist quinpirole (0.1 to 3.0 mg/kg, i.p.) produced dose-dependent elevations in serum ACTH and CS. The HPA response to SKF38393 was attenuated by the D1 selective antagonist SCH23390 (0.25 mg/kg) while the HPA response to quinpirole was attenuated by the D2 selective antagonist (±)sulpiride (50 mg/kg). Administration of either SKF38393 or quinpirole (1 to 100 ug) to the third ventricle via chronic indwelling cannulae caused a dose-dependent elevation in ACTH secretion. Pretreatment with SCH23390 or sulpiride (i.p.) attenuated the ACTH response to i.c.v. SKF38393 or quinpirole, respectively. Similarly, administration of the selective DA uptake inhibitor GBR12909 (3 to 60 ug, i.c.v.) dose-dependently elevated serum ACTH and CS levels. These results suggest that DA terminals near the third ventricle play a role in the regulation of HPA activity through actions on both D1 and D2 DA receptors. In addition, the DA system mediating this endocrine response appears to be independent from forebrain DA systems mediating locomotor and rewarding responses. Supported by NIDA P50 DA05303-01A1.

EFFECT OF LONG TERM TREATMENT WITH PHORBOL ESTERS ON THE RELEASE OF NORADRENALINE FROM THE MOUSE ATRIA. S. Foucart*, I.F. Musgrave*, H. Majewski* and J. de Champlain. Department of Pharmacology, University of Melbourne, Parkville, Victoria, 3052, Australia.

The role of protein kinase C (PKC) in sympathetic neurotransmission was investigated by down regulation induced by long term exposure to phorbol esters. In the present study, mouse atria were incubated for 10 hours at 37°C in the presence of either phorbol myristate acetate (PMA, 1 μM) or phorbol dibutyrate (PDB, 1μM). The atria were then incubated with [^{3}H]-noradrenaline and following 60 min of washing, the atria were field stimulated at 5 Hz and the stimulation-induced (S-I) outflow of radioactivity was taken as an index of noradrenaline release. In control experiments, PMA (1 μM), PDB (1 μM) or a combination of 8-bromo cyclic AMP (90 μM, 8-Br) and isobutylmethylxanthine (100 μM, IBMX) significantly increased the S-I outflow to 177%, 230% and 169% of control respectively. Pretreatment with PMA or PDB completely abolished the enhancing effect of subsequent exposure to PMA and PDB suggesting down regulation of PKC. The effect of 8-Br + IBMX was significantly reduced by PMA pretreatment and abolished by PDB. The results observed with 8-Br + IBMX suggest that there is an interaction between PKC and protein kinase A. Moreover, since the pretreatment with PMA and PDB did not alter the absolute release of noradrenaline, it appears that protein kinase C is not implicitely involved in the noradrenaline release process.

IMMOBILIZATION STRESS INDUCES TRANSLOCATION OF PROTEIN KINASE C(PKC) IN RAT BRAIN. K.Yurko, H.Y. Wang and E.Friedman, Dept. of Psychiatry and Pharmacology, Medical College of PA., Philadelphia, PA. 19129.

PKC's role in mediating neurophysiological and behavioral events is expanding. Modulation of PKC activity was investigated with the paradigm of immobilization stress which induces both a physiologically and behaviorally "activated" state of the animal. Male Sprague-Dawley rats were subjected to immobilization stress for 2 hrs/d (acute:1 d stress;chronic:10 d stress) and sacrificed 24 hrs. after last stress session. The cytosol(c) to membrane(m) distribution of PKC activity in brain slices and synaptosomes in control animals was 60:40%. Cortical and hippocampal slices showed significant shifts in PKC activity from c to m in chronically, but not acutely stressed rats vs. controls. Hippocampal synaptosomes also showed significant PKC translocation from c to m under these conditions. In cortical synaptosomes significant PKC translocation from c to m was found in both acute and chronically stressed rats vs. controls. Responses to the phorbol ester, PMA(162nM) were significantly attenuated in both acute and chronically stressed rats vs. controls in all preparations used. PKC translocation induced by immobilization stress may serve to modulate neurotransmission involved in stress responses. The mechanism for this effect is currently unknown.

488.3

ROLE OF PROTEIN KINASE C (PKC) IN MEDIATION OF DYNORPHIN(1-8) (DYN) AND MET^5-ENKEPHALIN (MET) RELEASE INDUCED BY ANGIOTENSIN II (ANG), ARACHIDONIC ACID (AA) AND PGE_2 IN PRIMARY CULTURED BOVINE CHROMAFFIN CELLS. H. H. Suh, M. K. McMillian, P. Hudson* and J. Hong. LMIN, NIEHS/NIH, Research Triangle Park, NC 27709.

We have previously reported that 24 hr treatment of chromaffin cells with ANG, AA and PGE_2 caused an increase of MET secretion. In the present study, effects of ANG, AA and PGE_2 on the release of DYN were examinedin bovine chromaffin cells. MET and DYN contents were measured by radioimmunoassay. We found that long-term stimulation (24 hrs) of the chromaffin cells with ANG (20 nM), AA (100 μM) and PGE_2 (10 μM) caused increases in secretion of DYN as well as MET. The amount of DYN secreted from chromaffin cells was approximately 1000-fold less than MET. To examine possible involvement of PKC, effects of protein kinase inhibitors on increases in secretion of MET and DYN induced by ANG, AA and PGE_2 were studied. Staurosporin (10 nM), a protein kinase inhibitor which has a high affinity (Ki=0.7 nM) for PKC, almost completely inhibited increased release of MET and DYN induced by ANG, AA and PGE_2. However, an equal nanomolar concentration of K252a, a protein kinase inhibitor which has a low affinity (Ki=25 nM) for PKC, had no effect. Our results indicate that PKC appears to be involved in increases of secretion of MET and DYN induced by ANG, AA and PGE_2.

EFFECTS OF NOREPINEPHRINE ON PROTEIN KINASE C IN RAT CEREBRAL CORTEX. G.S. Dhillon, D.L. Yourick, R.D. Greenwald & J.L. Meyerhoff. Dept of Medical Neurosciences, Walter Reed Army Inst. of Research, Washington D.C. 20307-5100.

Biological effects of hormones and neurotransmitters are believed to be mediated through the activation of either cAMP or calcium-regulated cellular events. We have previously reported (Soc. Neurosci. Abstr. 15: 1321, 1989) the effects of a number of peptides with neuromodulatory properties on adenylate cyclase activity in cortex. In the present study we investigated the effects of norepinephrine (NE) on protein kinase C (PKC) in rat cerebral cortex.

Slices were prepared by the method of Maier and Rutledge (JPET 240:729-736, 1987). Slices were treated for 10 minutes and total cytoplasmic and membrane (solubilized) PKC activity was recovered by DEAE cellulose chromatography. Calcium and phospholipid-dependent PKC activity was determined by monitoring [^{32}p]-γ-ATP incorporated into histone H1 substrate by a slight modification of methods of Kikkawa, U. et al. (JBC 257:13341-13348, 1982) and Thomas, P. et al. (Methods in Enzymology, vol. 141:399-411, 1987). NE (100 uM) significantly increased PKC activity in membrane solubilized and, to a lesser degree, in the cytosolic fraction. These results suggest that PKC as well as adenylate cyclase, serves as a signal transduction mechanism for NE in cerebral cortex. Modulatory interactions may possibly exist between adenylate cyclase and protein kinase C activity.

NEUROTENSIN INCUBATION WITH RAT STRIATAL SLICES: EFFECTS ON CALCIUM/CALMODULIN-DEPENDENT PROTEIN PHOSPHORYLATION. J.W. Kasckow, S.T. Cain and C.B. Nemeroff. Duke Univ. Med. Ctr., Durham, North Carolina 27710

Neurotensin (NT) is an endogenous brain tridecapeptide which fulfills many of the requisite neurotransmitter criteria. Both high and low affinity NT receptors have been identified (J Neurochem 50:1026, 1988). To characterize the mechanism of NT signal transduction we have investigated the action of NT on calcium/calmodulin-dependent phosphorylation in rat striatal slices. Striatal slices were incubated with or without NT (5 or 50 nM) for 3, 10, 16 or 30 minutes. This was followed by in vitro phosphorylation, electrophoresis and autoradiography. NT altered the calcium/calmodulin-dependent phosphorylation of specific proteins. For example, following incubation with 5 nM NT, phosphorylation of the 62 KDa protein was decreased at 3 minutes and 10 minutes relative to control; at 16 minutes it was increased. In contrast, with 50 nM NT, 62 KDa protein phosphorylation was increased at 3 minutes, but decreased by 16 minutes. NT produced no changes in the phosphorylation of this protein in the presence of cAMP. This 62 KDa phosphoprotein is likely the β subunit of the calcium/calmodulin dependent protein kinase. These changes above may reflect the ability of NT to modulate calcium-mediated transduction at the 3rd messenger level.

ABSENCE OF A CHANGE IN DARPP-32 PROTEIN OR mRNA IN NEONATAL-6-OHDA-LESIONED RATS. G.R. Breese, J.O'Callaghan, M. Ehrlich, H.E. Criswell, R.A. Mueller, and P. Greengard. UNC School of Medicine, Chapel Hill, NC; EPA, RTP, NC; and Rockefeller University, NY.

DARPP-32 is a protein that is enriched in neurons associated with DA_1-receptors. Neonatal-6-OHDA (N-6-OH) lesioned rats are known to develop sensitized DA_1-receptors after repeated treatment (i.e., primed) with a DA_1 agonist. The present investigations determined whether priming of DA_1-receptors or acute treatment with SKF-38393 would alter the content of DARPP-32 protein or its mRNA in N-6-OH-lesioned rats. Rats were sacrificed by either focused microwave irradiation or decapitation, respectively, for these determinations. DARRP-32 content in the striatum, measured by immunoassay, was not affected by any of the treatments when compared to the concentration in unlesioned rats. A change in DARPP-32 mRNA as measured by Northern blot analysis also was not apparent in N-6-OH lesioned rats after priming of DA_1-receptor responses. Studies are underway to determine if the content of phosphorylated DARPP-32 is altered in N-6-OH lesioned rats. (Supported by NS-21345, HD-23042, NS-06801, and MH-02714).

DOPAMINE STIMULATES THE PHOSPHORYLATION OF SPECIFIC PROTEINS IN PHEOCHROMOCYTOMA CELLS. L. Janocko and R.M. Lewis. Allegheny-Singer Res. Inst. and Dept. NACS, Univ. Pittsburgh, Pittsburgh, PA 15261.

We are developing a cell culture assay for studying the short- and long-term effects of dopamine on protein phosphorylation and gene expression in the nervous system. We chose DARPP-32 as a model protein because its phosphorylation is increased by dopamine *in vivo*, and because the rat and mouse cDNAs are available. We tested PC12 (rat adrenal pheochromocytoma) cells first because of their similarity to neuronal cells, and because DARPP-32 is found in adrenal medulla. Confluent PC12 cells were incubated with dopamine in RPMI medium supplemented with ascorbate. The cells were collected, rapidly frozen and homogenized on ice. Half of each sample was incubated for 30' at 30°C to allow endogenous phosphatases to remove all phosphate groups, and thereby permit measurement of total phosphorylatable sites. Both sample halves then were quenched with zinc acetate, dissolved in citric acid, neutralized, phosphorylated by exogenous cAMP-dependent protein kinase and [γ-^{32}P]-ATP, resolved by SDS/PAGE and autoradiographed. A band at M_r~32K was phosphorylated in a dose and time dependent manner. The phosphorylation of numerous other bands was not affected. We currently are attempting to confirm that the band is DARPP-32, and to determine whether the effect is D1, D2 or autoreceptor specific.

POTENTIATION OF ENDOTHELIN- AND ATP-INDUCED PHOSPHOINOSITIDE TURNOVER BY CALCIUM IONOPHORES IN C_6-GLIOMA CELLS. W.-W. Lin, C.Y. Lee* and D.-M. Chuang. Biological Psychiatry Branch, NIMH, Bethesda, MD 20892 and Dept. of Pharmacology, National Taiwan University, Taipei, Taiwan

Endothelin-1 (ET) and ATP induce a robust increase of phosphoinositide (PI) metabolism in C_6 glioma cells and primary cultures of cerebellar astrocytes. In this study, we investigated interaction between Ca^{2+} ionophore, A23187 and ET- and ATP-induced ^{3}H-inositol monophosphate (^{3}H-IP$_1$) in these cells prelabeled with ^{3}H-myo-inositol. In C_6 glioma, A23187 dose-dependently potentiated the responses to ET and ATP with an EC_{50} of about 0.3 μM. The maximal stimulation of PI turnover induced by ET (30 nM) and ATP (100 μM) was increased from 23 to 42-fold and from 8 to 19-fold, respectively, by the presence of 10 μM A23187, which alone induced a 3.5-fold increase of ^{3}H-IP$_1$ accumulation. The EC_{50} values of ET (2 nM) and ATP (84 μM) were unchanged by this Ca^{2+} ionophore. Ionomycin also potentiated the efficacy of ET-induced PI hydrolysis in concentration range of 10^{-8}-10^{-6} M. In contrast to C_6-glioma, in cultured cerebellar astrocytes A23187 failed to induce synergistic effects on PI metabolism induced by ET, ATP, norepinephrine, angiotensin, bradykinin, and neurotensin, although the ionophore alone induced a more than 4-fold increase in ^{3}H-IP$_1$ accumulation. These results indicate that entry of Ca^{2+} has an important role in amplifying PI turnover stimulated by ET and ATP in C_6-glioma cells but not in cerebellar astrocytes.

INHIBITORS OF PROTEIN KINASES DECREASE PEPTIDE SECRETION IN APLYSIA BAG CELL NEURONS. K.J. Loechner, J. Mattessich, and L.K. Kaczmarek. Dept. of Pharmacology, Yale Univ. Sch. Med., New Haven, CT 06510.

The bag cell neurons (BCNs) provide a model system for the study of neuropeptide release and its regulation by second messengers. Following electrical stimulation, the BCNs fire repetitively (afterdischarge) and release several neuroactive peptides including egg-laying hormone (ELH). During the afterdischarge, cAMP levels increase and phosphoinositide (PI) hydrolysis is stimulated leading to an activation of the kinases PKA and PKC. We have tested the effects of H8 and H7, two kinase inhibitors that act in intact cells with preferential specificity for PKA and PKC respectively, on the release of ELH. BCNs in intact ganglia were arterially perfused with artificial seawater (ASW), H8 (100μM) or H7 (50-100μM) for 30 min prior to stimulation of an afterdischarge. The surrounding medium was exchanged at 5 min intervals throughout the afterdischarge and the released material analyzed using HPLC. Release at each 5 min interval as well as total ELH release during the entire afterdischarge were reduced in both H8 (n=6) and H7 (n=10) as compared to ASW controls (n=8). These results were found with afterdischarges of various durations (range: 10-35 min). In sum, these data suggest that both PKA and PKC may modulate the amount of ELH released during an afterdischarge.

CORRELATION OF PHORBOL ESTER-INHIBITED PHOSPHOINOSITIDE METABOLISM WITH PROTEIN KINASE C-MEDIATED PHOSPHORYLATION OF RAT HIPPOCAMPAL MEMBRANE PROTEINS. L. M. Shaffer, Y. F. Han, and L. A. Dokas#. Departments of Biochemistry and Neurology#, Medical College of Ohio, Toledo, OH 43699.

In the brain, acetylcholine stimulates the breakdown of phosphatidylinositol 4,5 bisphosphate (PIP_2) to inositol triphosphate and diacylglycerol (DG), which activates protein kinase C (PKC). Active phorbol esters, which have been shown to block cholinergic stimulation of PIP_2 breakdown and which stimulate PKC, were used to identify membrane-associated protein substrates of this enzyme. When rat hippocampal slices were incubated with 10 μM 12-O-tetradecanoyl-phorbol-13-acetate (TPA), there was inhibition of cholinergic stimulation of PIP_2 breakdown, correlated with altered phosphorylation of two membrane proteins. Using 2-dimensional gel electrophoresis, post-hoc phosphorylation assays and western blotting, one protein was identified as B-50/GAP-43 (M_r~48,000, pI~4.5), a protein which may be involved in feedback inhibition of the PIP_2 second messenger cycle. The second protein responsive to TPA appears as a doublet on SDS-PAGE with a M_r of about 74,000 and a major component with a pI of about 6.9. Increased phosphorylation of this protein is the more prominent effect following incubation of hippocampal slices with $^{32}P_i$ and TPA. Further characterization of this protein is currently under way. Supported by grants from NIH (NS 23598) and the Ohio Department of Aging.

PROTEIN KINASE C AND CALCIUM/CALMODULIN KINASE II-STIMULATED PROTEIN PHOSPHORYLATION IN THE RODENT ANTERIOR PITUITARY J.C. Pryor & F. Sulser, Depts. of Psychiatry & Pharmacology, Vanderbilt Univ. Sch of Med., Nashville, TN 37232

Protein phosphorylation is recognized as a primary regulator of cell metabolism, including stimulated-secretion of hormones. In the past we have demonstrated the presence of cAMP-, calcium/phospholipid- and calcium/calmodulin-stimulated protein phosphorylation of endogenous anterior pituitary protein substrates in crude homogenates of the rat anterior pituitary. We have extended these findings to investigate the presence of endogenous anterior pituitary phosphoproteins in crude sucellular fractions of the rat anterior pituitary.

Normal male rats were killed by decapitation and the anterior pituitaries were removed and homogenized in ice cold buffer. The homogenates were centrifuged at 100,000x g for 1 hour, and the supernatant removed and designated the cytosolic fraction. The pellet was resuspended in the same volume of buffer and designated the particulate fraction of the tissue specimen. Protein phosphorylation was performed in the presence and absence of calmodulin (5 μg/ml), the calcium calmodulin kinase II inhibitor mastoparan (3 μM), phosphatidyl serine (35 μg/ml), and calcium (1mM). The reaction was carried out for 60 seconds. The samples were boiled and electrophoresed on 10% acrylamide SDS-PAGE gels. Autoradiographs of the gels were prepared and analyzed by scanning densitometry.

Proteins with molecular weights of 85.5 and 53.2 kD were identified in the cytosolic fraction to be phosphorylated in the presence of calmodulin (putative calcium/calmodulin kinase II activity), and those with molecular weights of 74.3 and 17.4 kD were identified in the cytosolic fraction to the phosphorylated by protein kinase C. Those with molecular weights of 23.3 kD, 19.7 kD, and 14.1 kD were identified in the particulate fraction to be phosphorylated by calcium/calmodulin kinase II, and those of 92.1 & 59.0 kD were phosphorylated by protein kinase C.

PROTEIN KINASE C ISOFORMS DISTINGUISH MAJOR CELL TYPES IN RAT HIPPOCAMPUS. J.F. McGinty, W.T. Bohler*, M. Couce* and K. Ways*. Depts of Anatomy and Cell Biology and [1]Medicine, East Carolina University School of Medicine, Greenville, NC 27858.

Protein kinase C (PKC) types II/III (alpha/beta) immunoreactivity (IR) has been reported to be present in putative hilar basket cells and pyramidal cells of the hippocampal formation (Stichel and Singer Exp. Brain Res. 72:443, 1988). The present study investigated the distribution of PKC alpha, beta, and epsilon immunoreactivity (IR) and mRNA in the hippocampus using selective antisera and oligonucleotide probes in immunocyto- chemistry (ICC) and in situ hybridization histochemistry (ISHH) respectively. PKC antisera were raised against synthetic peptides with non-overlapping sequences and were found to be specific for each isoform by Western blot analysis. ICC was performed with standard avidin-biotin-peroxidase method. PKC alpha antisera preferentially stained two sets of neurons; hilar neurons shaped like basket cells subjacent to the granule cell layer displayed homogeneous cytoplasmic IR whereas CA3 pyramidal cells displayed a punctate reaction product (Stichel & Singer's type 1 and 2 cells). The neuropil in stratum radiatum and stratum oriens was also labeled in the terminal distribution pattern of Schaffer collaterals. PKC beta antisera stained CA3 pyramidal cells most intensely with a punctate distribution of IR. PKC epsilon antisera stained dentate granule cells and mossy fibers most intensely. Absorption controls demonstrated the specificity of each antiserum. ISHH substantiated the distributions revealed by ICC: PKC alpha mRNA was densest in the CA3 pyramidal cell layer although the CA1 pyramidal cell layer contained a less intense signal. The opposite distribution was true for PKC beta mRNA whereas PKC epsilon was most intense in the granule cell layer. Thus, different isoforms of PKC are preferentially expressed by the major cell types in the hippocampal formation. The regulation of expression of these different isoforms is under investigation. **Supported by DA 03982.**

488.14

PROTEIN KINASE C α-SUBSPECIES IS PRESENT IN GABAERGIC NEURONS OF THE MONKEY FRONTAL CORTEX. N. Saito, T. Tsujino*, S. Tominaga*, T. Oishi†, K. Kubota†, and C. Tanaka*. Dept. of Pharmacol., Kobe. Univ. Sch. of Med., Kobe 650, †Dept of Neurophysiol. Primate Res. Inst., Kyoto Univ. Inuyama, Aichi 484, Japan.

Protein kinase C (PKC) has been demonstrated to be a large family consisting of more than four PKC-subspecies (α, βI, βII and γ) by molecular cloning studies and PKC acts as a key enzyme in various neuronal signal transduction. We examined immmunocytochemically the distribution of each PKC subspecies in the frontal cortex of 3 monkeys (macaca fuscata) and Wistar rats. Detailed techniques were described elsewhere (J. Neurosci. 10, 870, 1990). Cells in layer I were stained by α-PKC but not by other subspecies in monkey, while the α-PKC-immunoreactive cells in layer I were not found in rat. The stained cells were oval or round in shape, 10-15 μm in size,and occationally stained with 1-3 proximal dedrites. Distributions and numbers of the staind cells in different cortical areas (Brodmann's areas 4, 6, 8, and 46) were comparable to those stained by GABA immunocytochemistry, indicating that almost of all GABA neurons in layer I are immunoreactive for α-PKC. Further, cells of similar shape and size were found in layers II-VI, being the most frequent in layer II and then in superficial part of layer III. These stained cells were also similar to GABA-immunoreactive cells. It appears that GABAergic neurons in the monkey frontal cortex contain α-PKC, suggesting that phosphorylation by α-PKC within GABAergic neuron is resposible for the frontal cortical functions of primates.

AMINO ACID ANALYSIS AND SEQUENCING OF RAT BRAIN PROTEIN PHOSPHATASE 2A. G.N. Barnes, T.C. Vanaman* and J.T. Slevin. Veterans Administration & U.Kentucky Med Ctrs, Lexington, KY 40536

Protein phosphatase 2A [pp2A], identified in rat hippocampus as a histone protein phosphatase activity, was totally inhibited by 1 nM Okadaic acid. Substrate specificity studies suggested that pp2A regulates autophosphorylated Ca^{+2} and cAMP-dependent protein kinases. With neuronal depolarization, pp2A activity redistributed from cytosol to synaptic plasma membranes. Purified rat brain pp2A is a trimer of 63, 55 and 38 kDa polypeptides. Amino acid (AA) analysis of the 63 and 38 kDa subunits revealed a composition nearly identical to the 65 and 38 kDa subunits, respectively, of pig kidney and rabbit skeletal muscle pp2A. Sequencing & AA analysis of 2 of 6 isolated CNBr fragments of the 38 kDa subunit suggest it is highly homologous to published sequences of the pp2A catalytic subunit. Sequencing & analysis of a 17 kDa CNBr fragment & a 12 kDa trypsin fragment of the neuronal 63 kDa subunit suggest its primary structure is highly homologous to the α isoform of the 65 kDa subunit from pig kidney and HeLa cells. Supported by V.A.Medical Research Funds.

EXCITATORY AMINO ACIDS: NON-NMDA RECEPTORS

489.1

STEREOSELECTIVITY AND MODE OF INHIBITION OF PHOSPHOINOSITIDE-COUPLED EXCITATORY AMINO ACID RECEPTORS BY 2-AMINO-3-PHOSPHONOPROPIONIC ACID B.G. Johnson, D.D. Schoepp, E.C.R. Smith*, and L.A. McQuaid, Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, IN 46285.

D,L-2-amino-3-phosphonopropionic acid (AP3), a phosphonate-substituted derivative of aspartic acid, has been shown to be an inhibitor of excitatory amino acid-stimulated phosphoinositide hydrolysis in rat brain slices. In this study, the enantiomers of AP3 were synthesized and used to further characterize the stereoselectivity and mechanism of interaction of this compound for inhibiting phosphoinositide-coupled (metabotropic) excitatory amino acid receptors. L-AP3 was 3-5 times more potent than D-AP3 as an inhibitor of ibotenate-stimulated ^{3}H-inositol monophosphate formation in slices of the rat hippocampus or quisqualate-stimulated ^{3}H-inositol monophosphate formation in neonatal rat cerebral cortical slices. Carbachol-stimulated phosphoinositide hydrolysis was not inhibited by L-AP3, and L-AP3 had no appreciable affinity for ionotropic excitatory amino acid receptors at concentrations required to inhibit metabotropic excitatory amino acid responses. The inhibitory effects of L-AP3 or L-2-amino-4-phosphonobutyric acid on phosphoinositide hydrolysis were non-competitive since they could not be surmounted by increasing concentrations of ibotenate or quisqualate. L-AP3 inhibition also could not be prevented by washing the tissue prior to incubating with ibotenate. Although L-AP3 is a stereoselective inhibitor of metabotropic excitatory amino acid receptors with little affinity for ionotropic receptors, the site at which it acts to inhibit metabotropic excitatory amino acid receptors remains to be determined.

489.2

PHARMACOLOGICAL BLOCKADE OF OSCILLATORY CURRENTS INDUCED BY *TRANS*-ACPD AND QUISQUALATE IN RAT BRAIN mRNA-INJECTED *XENOPUS* OOCYTES. G.B. Watson, D.T. Monaghan[1] and T.H. Lanthorn. CNS Diseases Research, G.D. Searle & Co., Skokie, IL 60077 and [1]Dept. of Pharmacology, University of Nebraska, Omaha NE 68105.

It has been suggested that *trans*-ACPD may be a selective agonist for the metabotropic quisqualate-sensitive receptor. In *Xenopus* oocytes injected with rat cortex mRNA, quisqualate induced both smooth and oscillatory currents indicating that it acts at more than one receptor. *Trans*-ACPD induced only oscillatory currents suggesting that it selectively activates the metabotropic receptor. The threshold concentration for *trans*-ACPD was approximately 30 μM. Oscillatory currents induced by both quisqualate and *trans*-ACPD were blocked by intracellular injection of EGTA. These oscillatory currents were also blocked by the application of 30 μM NMDA plus 10 μM glycine but not by NMDA alone. Depolarizing current injection did not mimic the effect of NMDA plus glycine. Oscillatory currents which had been blocked by EGTA could occur when NMDA plus glycine was co-applied with *trans*-ACPD. Smooth currents induced by quisqualate were unaffected by either EGTA or NMDA plus glycine. Oscillatory currents were not blocked by the non-selective acidic amino acid antagonist DNQX (10 μM).

489.3

A NEW POTENT METABOTROPIC GLUTAMATE RECEPTOR AGONIST. M. Ishida, H. Akagi[+], Y. Shimada* and H. Shinozaki. The Tokyo Metro. Inst. of Med. Sci., Tokyo 113, and [+]Mitsubishi Kasei Inst. of Life Sci., Tokyo 194, Japan.

α-(Carboxycyclopropyl)glycine(CCG) is a conformationally restricted analogue of glutamate and has eight stereoisomers theoretically. The (2S,3S,4S)isomer of CCG (L-CCG-I) caused a marked depolarization due to activation of non-NMDA, non-kainate or non-AMPA type receptors. The development of this new and potent agonist opens the possibility for extensive studies of the glutamate receptor subtypes. Peak amplitudes of responses to a possible metabotropic agonist, trans-ACPD, and L-CCG-I were significantly decreased when the temperature was decreased, while those of other excitatory amino acids was markedly increased, suggesting that the intracellular enzyme systems were related to the depolarization induced by L-CCG-I. Application of L-CCG-I induced the oscillatory responses in the Xenopus oocyte with injection of mRNA from rat brain, suggesting that L-CCG-I is a metabotropic receptor agonist. L-CCG-I is more potent than trans-ACPD in causing a depolarization in the rat isolated spinal cord. L-CCG-I depressed monosynaptic reflexes of the rat isolated spinal cord in considerably low concentrations. At the moment, it is not clear that this depression of monosynaptic reflexes is through activation of metabotropic receptors.

489.4

SENSITIZATION TO L-2-AMINO-4-PHOSPHONOBUTANOIC ACID (L-AP4) IS INDUCED BY AGONISTS SELECTIVE FOR PHOSPHOINOSITIDE-LINKED RECEPTORS. E.R. Whittemore and C.W. Cotman, Dept. of Psychobiology, Univ. of Calif., Irvine, CA 92717

Quisqualic acid (QA) sensitizes neurons to depolarization by D- and L-2-amino-4-phosphonobutanoic acid (AP4). This 30- to 100-fold sensitization persists for hours, and is induced through the interaction of QA with a receptor distinct from the QA/AMPA receptor ionophore. Only QA has been shown to induce this 'QUIS-effect'.

In order to test whether the QUIS-effect is induced via phosphoinositide (PI) - linked receptors, we assayed compounds reported to stimulate PI turnover for the ability to induce sensitization to L-AP4. Extracellular field potentials were recorded from the CA1 region of rat hippocampal slices. IC_{50} values for L-AP4 were obtained before and after exposure of slices to test compounds. Sensitization to L-AP4 was induced by trans-1-aminocyclopentane-1,3-dicarboxylic acid (trans-ACPD)(100 μM), ibotenic acid (100 μM, in the presence of 1 mM D-2-amino-5-phosphonopentanoic acid) and carbachol (500 μM). These compounds and concentrations are reported to stimulate phosphoinositide (PI) turnover in biochemical assays. However, the sensitization induced by these compounds was less (2- to 5-fold) than by QA (>30-fold), and reversed much more rapidly. For example, a 4 minute exposure to 100 μM trans-ACPD shifts the IC_{50} for L-AP4 from the pre-exposure value of 1800 μM to approximately 500 μM. In contrast, 16 μM QA shifts the IC_{50} for L-AP4 to 55 μM. These data suggest that the QUIS-effect may be induced in part via a PI-linked mechanism, and may represent a long-term physiological response to PI turnover in the CNS.

489.5

Effects of Quisqualate on Cytosolic Free Calcium in Single Cultured Rat Cerebellar Granule Cells. A.J. Irving*, G.L. Collingridge,*, L. Haynes,* & J.G. Schofield * (SPON: Brain Research Association) Departments of Biochemistry, Pharmacology and Zoology, University of Bristol, Bristol, BS8 1TD, UK.

Quisqualate can mobilize intracellular free calcium ([Ca]i) via a receptor that is linked to phospholipase C. This "metabotropic" receptor is believed to be present on cerebellar granule cells. We have studied the relationship between activation of this receptor and [Ca]i by obtaining simultaneous measurements from several individual granule cells within a field. Cells were loaded with FURA-2-AM and imaged using an intensified CCD camera linked to a Joyce-Loebl magical system.

In Ca free medium, 1 uM quisqualate caused a rapid transient elevation of [Ca]i. This effect declined following repeated applications but could be recovered following exposure to 1 mM [Ca]o. Reproducible transient responses could be obtained by applications of 1 uM quisqualate in the presence of 1 mM [Ca]o and 20-40 uM CNQX. In some cells, these responses were reversibly antagonised by 1 mM DL-AP3. These results are consistent with the notion that granule cells contain a Ca mobilising, quisqualate-activated receptor.

489.6

LACK OF EFFECT OF NBQX ON QUISQUALATE STIMULATED INOSITOL PHOSPHOLIPID HYDROLYSIS. P.D. Suzdak, A.J. Hansen, M.J. Sheardown, P. Jacobsen and T. Honoré. Novo Nordisk CNS Division, Sydmarken 5, DK-2860 Soeborg, Denmark.

2,3-dihydroxy-6-nitro-7-sulfamoyl-benzo(f)quinoxaline (NBQX) is a potent and selective inhibitor of binding to the ionotropic quisqualate receptor (IC_{50} for inhibition of ^{3}H-AMPA binding = 150 nM). NBQX protects against global ischemia when administered up to 6 hours after reperfusion. The present report examines the effect of NBQX on the quisqualate receptor, coupled to inositol phospholipid hydrolysis (IPH). The effect of excitatory amino acids on IPH (as measured by the accumulation of ^{3}H-inositol monophosphate in the presence of LiCl) in cerebellar granule cells in culture from 7-day-old mice was examined. Quisqualate (0.1 - 300 μM), ibotenic acid (1 - 300 μM) and glutamate (10 - 300 μM) stimulated IPH in a dose-dependent manner. The ability of quisqualate to stimulate IPH was unaffected by CNQX (30 μM), whereas APV (1 mM) blocked the increase in inositol phospholipid hydrolysis produced by glutamate. NBQX (0.1 - 300 μM) was without effect on the basal levels of IPH. Furthermore, NBQX (0.1 - 300 μM) did not alter the stimulation of IPH produced by quisqualate (100 μM). NBQX (30 μM) also had no effect on the ED_{50} value for quisqualate stimulated IPH. The effect of NBQX in ibotenic acid and kainic acid stimulated IPH will also be discussed. These data suggest that the neuroprotectant effect of NBQX is mediated via the ionotropic, and not the metabotropic, quisqualate receptor.

489.7

CNQX AND APV INSENSITIVE GLUTAMATE RESPONSES IN RAT SUBSTANTIA GELATINOSA NEURONS. M. Yoshimura & T. M. Jessell, Center for Neurobiology and Howard Hughes Medical Institute, Columbia University, New York, NY. 10032

We have examined the pharmacological properties of l-glutamate evoked responses and primary afferent-evoked epsps in substantia gelatinosa (s.g) neurons using intracellular and whole cell voltage clamp recording from slices of adult rat spinal cord which retain dorsal root inputs. In addition, recordings were obtained from acutely isolated dorsal horn neurons from adult rats.

Stimulation of primary afferent evoked monosynaptic fast epsps in more than 70 % of s.g neurons. These epsps were markedly depressed by amino acid receptor antagonists, kynurenate and CNQX supporting the idea that glutamate or related amino acid is the transmitter mediating fast epsps. Bath applied glutamate produced a depolarization and inward current in a dose-dependent manner. The glutamate-evoked response was reduced in amplitude by only 20 % in the presence of non-NMDA receptor antagonist CNQX (5 uM). The CNQX-resistant component of the glutamate-evoked response did not result from activation of NMDA receptor.

We also examined glutamate-evoked currents in neurons isolated from the superficial dorsal horn of adult rat spinal cord. In about 60 % of neurons, inward currents evoked by glutamate, quisqualate (QA) and kainate (KA) were almost completely eliminated by CNQX (10 uM). However, in 40 % of neurons, CNQX depressed glutamate response by only about 30 %, even though QA and KA responses in the same neuron were depressed by more than 90 %. The CNQX-resistant glutamate response was not blocked by APV. These observations support the idea that a subset of dorsal horn neurons express two distinct non-NMDA receptors with differing sensitivities to CNQX.

489.8

NBQX, (2,3-DIHYDROXY-6-NITRO-7-SULFAMOYL-BENZO (f)QUINOXALINE): ANTICONVULSANT EFFECTS IN MICE. M. D. B. Swedberg, P. Jacobsen * and T. Honoré *. Novo Nordisk, Ferrosan CNS Division, Sydmarken 5, DK-2860 Soeborg, Denmark.

NBQX, an analog of the quinoxalinedione antagonists to non-NMDA glutamate receptors, potently and selectively inhibits AMPA receptor binding with no activity at NMDA or glycine sites, and protects against cerebral damage after global ischemia (1). The anticonvulsant effects of NBQX were evaluated by the intraperitoneal (ip) and the intraveneous (iv) routes against audiogenic seizures in DBA/2 mice, and against seizures induced by 150 mg/kg DMCM (ip; 30 min) in NMRI mice, at 5, 15 and 30 min prior to test. Sedation was assessed in a rotarod apparatus.

In DBA/2 mice NBQX was 5-17 (ip) and 2-3 (iv) times more potent as an anticonvulsant, ED50's (mg/kg) being 13.0, 8.2 and 3.5 (ip) and 1.9, 4.5 and 15.5 (iv) at 5, 15 and 30 min, respectively, than in producing ataxia. Against DMCM induced seizures, NBQX was ineffective at doses up to 30 mg/kg (ip), or ataxic at doses equal to, or lower than, the anticonvulsant doses (iv).

NBQX shows anticonvulsant effects in mice probably thru suppression of the activity of the non-NMDA excitatory amino acid quisqualate.

QUISQUALATE RECEPTOR ANTAGONISTS IN THE SUB-PALLIDUM (SP) DECREASE THE HYPERMOTILITY RESPONSE TO AMPHETAMINE. D.L. Willins*, D.E. Supko*, R.A. Hill*, L.J. Wallace*, D.D. Miller* and N.J.Uretsky. College of Pharmacy, The Ohio State University, Columbus, OH 43210.

Previous studies suggest that quisqualate (QUIS) receptors in the SP are involved in the stimulation of locomotion (LMA). AMPA, a QUIS agonist, upon injection into the SP, stimulates LMA. This effect is antagonized by the non-NMDA receptor antagonist DNQX and GAMS. We have recently found that both GAMS and DNQX can inhibit the hypermotility response to systemically administered amphetamine (AMPH). In order to determine whether the inhibitory effects of DNQX are mediated through the blockade of QUIS receptors, we have evaluated the effects of structural analogs of DNQX on ^{3}H-AMPA binding and on their ability to inhibit the hypermotility response to AMPH. DNQX, 2-hydroxy-3,5 dinitrotyrosine (DNT), and AFQX, an analog of DNQX, inhibited the binding of ^{3}H-AMPA with IC_{50} values of approximately 0.5 μM, 10μM, and 100 μM respectively. The doses of DNQX and DNT that inhibited AMPH-stimulated locomotion by 50% were 0.4 and 3.3 nmoles respectively, while AFQX at a dose of 5 nmoles did not exert an inhibitory effect. The order of potency for these compounds was similar for both inhibition of ^{3}H-AMPA binding and AMPH stimulated LMA. These studies suggest that the ability of DNQX to inhibit the hypermotility induced by AMPH is due to the blockade of QUIS receptors.

489.10

IN SITU HYBRIDIZATION OF OLIGONUCLEOTIDE PROBES TO mRNA ENCODING A KAINATE SENSITIVE GLUTAMATE RECEPTOR (GluR-K1). D.W. Bonhaus, D.A. Hosford, Z. Cao* and J.O. McNamara. V.A. and Duke Univ. Med. Ctrs. Durham NC 27705.

The recent isolation of cDNA clones encoding functional excitatory amino acid (EAA) receptors opens new avenues for investigating EAA receptor pharmacology. One key step in characterizing cloned receptors is to compare the anatomic distribution of the cloned molecule with pharmacologically and electrophsyiologically characterized endogenous receptors. Thus we used oligonucleotide probes to map the anatomic distribution of an mRNA which encodes a kainate activated, glutamate receptor. Two [^{32}P] labelled probes, complementary to non-overlapping regions of the GluR-K1 clone (Hollman et al.), were hybridized to 10 uM sections of rat brain. Northern blot analysis showed that the probes bound to identically sized bands of poly A^+ RNA. Similarly, the anatomic distribution of binding was identical for the two probes. The greatest density of binding was in the hippocampus; in hippocampus, binding was enriched in the dentate granule and CA3-1 pyramidal cell layers. The absence of a selective enrichment of binding over the granule or CA3 pyramidal cells argues against this mRNA encoding the high affinity [^{3}H]kainate binding site localized to area stratum lucidum. This suggests that the protein encoded by the GluR-K1 clone, while capable of generating kainate evoked currents, is not a part of the high affinity [^{3}H]kainate binding site. This in turn suggests that kainate evoked currents are mediated by a receptor other than that defined by high affinity [^{3}H]kainate binding. Which (if any) of the pharmacologically characterized EAA receptors includes the protein encoded by the GluR-K1 clone is unknown. However, the anatomic distribution of the mRNA together with the electrophysiologic properties of the expressed GluR-K1 clone raise the possibility that this protein may be part of a, quisqualate insensitive, AMPA receptor.

CHRONIC KAINATE TREATMENT DECREASES K^+-STIMULATED RELEASE OF ENDOGENOUS AMINO ACIDS FROM CULTURED CEREBELLAR NEURONS. M.L. Simmons and G.R. Dutton, Department of Pharmacology, University of Iowa, College of Medicine, Iowa City, IA 52242.

Cultured rat cerebellar neurons containing $\geq$90% granule cells, 5-7% inhibitory interneurons and 3-5% glial cells were used to identify the neuronal subclass of origin of released endogenous amino acids. Cultures were treated for 4 days, 5-8 days in vitro (DIV), with 50μM kainic acid (KA) which has previously been shown to selectively kill the GABAergic neuronal population (Drejer and Schousboe Neurochem. Res. 14:751-754, 1989). These conditions, under which a $\geq$80% loss of glutamic acid decarboxylase (GAD) immunoreactivity was seen, produced a complete loss of 50mM K^+-stimulated release of GABA, and a significant reduction in the release of aspartate, glutamate, taurine and adenosine at 9 DIV. These KA-induced effects were prevented by concurrent treatment with 50μM or 100μM, but not 10μM, 6-cyano-7-nitroquinoxaline-2,3-dione (CNQX). Treatment with CNQX alone caused the release of all these substances above control levels.

Results indicate that glutamate and aspartate originate from granule neurons, GABA from inhibitory neurons, and adenosine and taurine possibly from both neuronal classes. KA treatment may decrease endogenous amino acid release from granule neurons by possibly depleting releasable pools or by downregulating KA receptors.

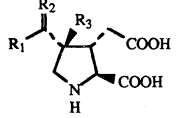
TOPA OXIDIZES IN SOLUTION TO FORM AN AMINO ACID WHICH IS A NON-NMDA AGONIST. D.S. Crawford, E. Aizenman, R.H. Loring, and P.A. Rosenberg. Dept. Physiol., U. of Pittsburgh Sch. Med., Pittsburgh, PA; Dept. Pharm., Northeastern U. and Depts. Med. and Neurol., Children's Hosp. and Harv. Med. Sch., Boston, MA 02115.

Application of solutions of 2,4,5 trihydroxyphenylalanine (topa) to rat cortical neurons or the chick eyecup preparation produces membrane responses which can be blocked by the non-NMDA antagonist CNQX (Soc Neurosci. Abstr., 15, 768, 1989). Topa is unstable in solution. Pharmacological activity depends upon the formation of an oxidation product. In order to identify the active compound, we have performed quantitative amino acid analysis with ninhydrin detection on solutions of dopa and topa, using a Beckman 7300 analyzer. Oxidized topa was prepared by dissolving topa in 50 mM sodium phosphate buffer at pH 6.8. Two peaks were found, one at the elution time for topa (20.7 minutes), containing 18% of the starting material, and a new peak at 10.3 minutes, containing 51% of the starting material. Incubation of the sample prior to analysis led to diminuition of this peak without appearance of new peaks. These data suggest that topa in solution oxidizes to a more stable amino acid, which is likely to be topa quinone; this derivative subsequently degrades to a substance which is not an amino acid. Of note, topa has recently been demonstrated in bovine plasma amine oxidase.

489.13

LY207328 AND LY207193: TWO POTENT KAINIC ACID AGONISTS. L. A. McQuaid, R. N. Booher*, D. D. Schoepp, M. M. Foreman and D. Lodge. Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, Indiana 46285 and Royal Veterinary College, London, NW10TU, UK.

Kainic acid (R_1=CH_3, R_2=CH_2, R_3=H), isolated from *Digenea simplex*, is a powerful excitatory amino acid (EAA) agonist and neurotoxin. We wish to report two new potent kainic acid (KA) agonists, LY207328 (R_1=Ph, R_2=CH_2, R_3=H) and LY207193 (R_1=CH_3, R_2=NOH, R_3=H). LY207328 and LY207193 displace ^{3}H-KA with IC_{50}s of 4.0±0.1 nM and 36.5±0.8 nM, respectively. In addition, LY207192 (R_1=CH_3, R_2=CH_2, R_3=OH) demonstrated a more modest affinity for the ^{3}H-KA binding site with an IC_{50} of 526 nM. Both LY207328 and LY207193 were found to stimulate the release of ^{3}H-norepinephrine from rat hippocampal slices as well as the release of ^{3}H-choline from rat retinal tissue. LY207192 produced only a minimal response in the release assays. In electrophysiological studies on rat cortical wedges, LY207328 and LY207193 were potent depolarising agonists. These responses were sensitive to CNQX but not to CGS19755, suggesting an action via non-NMDA receptors as might be predicted from their structural similarity to KA.



490.1

NMDA-EVOKED OUTWARD CURRENTS IN CULTURED NEOCORTICAL NEURONS USING NYSTATIN-PERFORATED PATCH RECORDINGS. J.J. Hablitz and D.K. Mistry*. Neurobiology Research Center, University of Alabama at Birmingham, Birmingham, AL 35294.

The nystatin-perforated patch technique (Horn & Marty J. Gen. Physiol. V.92:145) was used to examine whole-cell responses to NMDA under conditions where loss of cytoplasmic factors was minimized and endogenous calcium buffering mechanisms were operational. The pipet contained (mM) 140 KC1 7 $MgC1_2$ 10 mM HEPES and 100 µg/m1 nystatin. At -60 mV, responses to 100 µM NMDA were biphasic, consisting of an initial inward current which decayed to a final steady-state value. No run down of either component was seen. Steady-state/peak ratios were similar in nystatin and conventional recordings suggesting similar rates of desensitization. When holding potentials from -40 to 0 mV were used, the initial inward current was followed by a slowly developing outward current. Near 10 mV, NMDA evoked an initial small decaying outward current followed by a large sustained outward current. At more positive holding potentials, NMDA evoked an initial outward current which decayed to a steady-state value. If cesium was substituted for potassium in the pipet, NMDA-induced outward currents were not observed.

Thus, under conditions where endogenous calcium buffering mechanisms are operational, NMDA evokes an outward current in cultured neocortical neurons. This is attributed to activation of a Ca-dependent K current via Ca entry through NMDA channels. (Supported by NS18145)

490.2

WHOLE CELL PATCH-CLAMP RECORDING OF ENDOGENOUS SYNAPTIC CURRENTS IN MAMMALIAN MOTONEURONS IN INTACT BRAINSTEM-SPINAL CORD. Guosong Liu & Jack L. Feldman. System Neurobiology Laboratory, Dept of Kinesiology, UCLA, Los Angeles, CA 90024-1568.

We previously reported that an excitatory amino acid (EAA)-like substance is the neurotransmitter involved in the bulbospinal transmission of inspiratory drive to phrenic motoneurons (Liu & Feldman, Soc. Neuro. Abs. 15:643, '89; Liu et al. J. Neurophysiol. In Press). To further characterize this endogenous excitatory synaptic transmission, whole cell patch-clamp techniques were employed in a brainstem-spinal cord preparation *in vitro (ibid.)*. We used standard intracellular recordings to locate the phrenic motoneuron pool, then lowered a patch electrode (~3-5 MΩ) into the pool (~180-260 µm from surface). The tip of the patch electrode was kept clean by continuous positive pressure. Gigaohm seals (~1-5 GΩ), and whole cell patch clamp, were obtained by suction. The measured input resistances of these motoneurons were 100-500 MΩ, compared to values of ~20-50 MΩ from standard intracellular recordings. The electrode was judged to be attached to the soma if large whole cell capacitance, and appropriate shape and voltage-dependence of the fast Na current, were measured Two types of synaptic currents were found. One occurs during inspiration and is mediated by an EAA-like transmitter. The associated EPSCs had very fast rise-time (< 0.2 ms) and decay-time (~3-5 ms) constants, reversal potentials near 0 mV, and were blocked by the non-NMDA receptor antagonist CNQX. The change of shape of EPSCs at different holding potentials suggest they are voltage-dependent. Another synaptic current was present during expiration. This current had slower rise-time and longer decay-time (~40 ms) constants and reversed near -40 mV. We interpret the later current as an inhibitory synaptic current carried by $GABA_A$ channels.

In summary, whole cell patch clamp technique is feasible in neurons receiving **endogenous** synaptic drive. This should permit the study of synaptic transmission under more physiological conditions than in preparations that require stimulated release of neurotransmitter. Supported by NIH Grant NS 24742.

490.3

QUINOLINIC ACID EFFECTS ON HIPPOCAMPAL PYRAMIDAL NEURONS. J.E.Monckton*, N.T.Carnevale and J.J.Halperin. Departments of Neurology and Neurobiology, SUNY, Stony Brook, NY 11794.

We examined effects of quinolinic acid (QA) on pyramidal neurons in the in vitro rat hippocampal slice. At concentrations >= 100µM, this NMDA agonist was reported to decrease the amplitude of antidromically evoked action potentials (APs) recorded extracellularly in the CA1 region (bath application [Stone]), and to depolarize cultured hippocampal neurons (pressure ejection from micropipette [Tsuzuki et al.]).

Our extracellular recordings from CA1 found that bath application of 100-200µM QA depressed or abolished the EPSP and population spike evoked by stimulating the Schaffer collaterals ([Mg++]o = 2mM). Intracellular recordings disclosed that QA reversibly depolarized CA1 pyramidal neurons to a variable degree, and attenuated or eliminated EPSPs. Injecting depolarizing currents triggered slow, regenerative depolarizing waves. In some cells, QA eliminated APs evoked synaptically or by current injection. These effects were reversibly blocked by APV, and resolved after washing with Ringer.

This work was supported in part by the Department of Veterans Affairs (NTC) and by a grant from New York State for Lyme Disease research (JJH).

UNILATERAL RHYTHMIC VIBRISSAE MOVEMENTS INDUCED BY KAINIC ACID INJECTED IN DEEP STRATA OF SUPERIOR COLLICULUS. B. S. Grunwerg*, J. Krol*, M. M. Corton* and G. M. Krauthamer. Dept. of Neuroscience and Cell Biology, UMDNJ, Robert Wood Johnson Med. Sch., Piscataway, N.J. 08854.

During the course of an unrelated study we made the unexpected observation that the injection of small amounts of kainic acid in the deeper strata of the anterior third of the superior colliculus induced an acute and transient phase of rhythmic whisker movements. Since the vibrissae are extensively represented in this part of the superior colliculus and its neurons entertain both bilaterally descending as well as asending projections we believe that this observation may be of some interest.

Nine Long--Evans rats were anesthetized with 350 mg/kg chloral hydrate. Two to four unilateral injections of 0.5 ul kainic acid (3.52 nM) were made at 2-5 min intervals into the intermediate and deep strata. Within 1-3 min of the last injection, a 2-5 Hz rhythmic whisker movement developed lasting about 5-15 min. The movement was always confined to the vibrissae ipsilateral to the injection site; in some animals it included the ipsilateral nostril. No other movements could be observed during this time. Neither the EEG nor bipolar recordings from the hippocampus indicated typical seizure activity nor could we detect any hippocampal neuronal damage in rats sacrificed within one hour of the excitotoxin injections.

At this time we cannot entirely rule out the possibility of an abortive limbic seizure due to the susceptibility of the hippocampus to kainic acid action "at a distance". On the other hand, the possibility should be considered that the induced rhythm reflects the transient activation of glutamatergic kainate receptors of tectal neurons. (Supported by NS20626).

490.5

NMDA RECEPTORS MEDIATE A COMPONENT OF GRANULE CELL RESPONSES TO LOW FREQUENCY STIMULATION OF PERFORANT PATH AFFERENTS *IN VIVO*. T.A. Blanpied, G. Barrionuevo, and T.W. Berger. *Depts. of Behavioral Neurosci. and Psychiatry, U. of Pittsburgh, Pgh., PA, 15260.*

Previous studies using *in vivo* preparations have reported that extracellular EPSPs recorded in the hippocampal dentate gyrus in response to low frequency (<0.2Hz) stimulation of the medial perforant path are not reduced by the selective NMDA receptor antagonist D-APV. However, intracellular studies of the dentate *in vitro* have found that CNQX, an antagonist selective for kainate/quisqualate receptors eliminates all but a small D-APV sensitive portion of the granule cell EPSP. We examined population EPSPs recorded from the molecular layer of the rabbit dentate gyrus *in vivo*, while administering CNQX, D-APV, or saline by microinfusion through a multibarrelled pipette positioned 100-500µm from the recording site.

CNQX (25-50µM) reduced the evoked EPSP by 70-95% (n=12) without affecting the afferent fiber volley; however, in all cases tested (n=8), subsequent addition of D-APV (50-100µM) substantially reduced the remaining response. For greater resolution of the component sensitive to D-APV, we used digital subtraction of responses evoked during the application of CNQX and D-APV from those evoked in the presence of CNQX alone. The residuals clearly revealed that D-APV eliminated a negative-going potential with a peak latency 25-200% longer than the control peak ($\bar{x}$=10.0ms vs 5.1ms control) and a peak amplitude of up to 20% ($\bar{x}$=11%) of the control amplitude. In separate experiments, D-APV was applied alone and evoked responses were subtracted from those recorded in the presence of saline. These remainders had a time course very similar to the CNQX-APV residuals. In 4 experiments in which responses were recorded simultaneously from the cell body and molecular layers, the D-APV sensitive components observed in the two laminae were of opposite polarity. Parametric manipulations (n=8) indicated that the amplitude of this component is strongly frequency dependent, and is greatly enhanced (200% of single impulse amplitude) in response to 2-5 impulses delivered with a 2ms interstimulus interval.

REDUCTION OF ACTIVITY OF THE GLYCINE SITE AT THE NMDA RECEPTOR COMPLEX INTERFERES WITH THE INDUCTION OF LTP *IN VIVO*. E. Thiels, D. J. Weisz and T. W. Berger. *Departments of Behavioral Neuroscience and Psychiatry, University of Pittsburgh, Pittsburgh, PA 15260.*

Glycine has been shown to markedly potentiate synaptic events mediated by the NMDA receptor complex in *in vitro* preparations. Conversely, antagonist activity at the glycine site has been demonstrated to block NMDA receptor-mediated responses *in vitro*, which suggests that activation of the glycine site is necessary for NMDA receptor-mediated events. We examined whether or not the selective glycine site antagonist, 7-chlorokynurenic acid (7-Cl-Ky), prevents the induction of LTP at the commissural-CA1 synapse of the rat hippocampus *in vivo*, and furthermore, whether or not antagonist effects could be overcome by concurrent application of the glycine site agonist, D-serine.

Microinjection 400-500µm from the recording site of 7-Cl-Ky at doses ≤ 200µM (n=4) did not notably alter the population spike (PS) of CA1 pyramidal cells evoked by low frequency (0.1 Hz) stimulation of commissural fibers, and prevented the induction of LTP following high frequency stimulation (100Hz for 1s) in only one case. PS amplitude at threshold level increased from M=0.3 to 2.4mV, compared to an increase from M=0.2 to 5.1mV during injection of vehicle solution (n=4) or a change from M=0.3 to 0.1mV during injection of the selective NMDA receptor antagonist, D-APV (100µM; n=4). Application of 7-Cl-Ky at a dose of 400µM (n=4) slightly increased PS threshold and attenuated the induction of LTP in three cases; PS amplitude increased from M=0.2 to 1.1mV. Injection of 400µM 7-Cl-Ky combined with 1mM D-serine (n=3) did not alleviate the effect of 7-Cl-Ky on PS threshold, but reinstated the induction of LTP; PS amplitude increased from M=0.2 to 4.1mV. We conclude that activity at the glycine site can modulate NMDA receptor activation in the intact brain. (Supported by NIMH: MH45156 and MH00343, and NSF: BNS8945137).

ROLE OF EXCITATORY AMINO ACIDS IN THE NEURAL CIRCUIT MEDIATING THE ACOUSTIC STARTLE REFLEX. M.J.D. Miserendino, N.M. Boulis, R.F. Spiera, and M. Davis. Dept. of Psychiatry, Yale Univ. Sch. of Med., 34 Park St., New Haven, CT. 06508

Acoustic startle is a short latency reflex elicited by a brief auditory stimulus. The neural circuit mediating the acoustic startle reflex is thought to consist of: the ventral cochlear nucleus (VCN); the paralemniscal zone, an area just medial to the ventral lateral lemniscus (VLL); the nucleus reticularis pontis caudalis (RPC); and motor neurons of the lumbar spinal cord. Infusion of selective competitive excitatory amino acid antagonists into these sites causes significant and dose-dependent decreases in the magnitude of the startle response.

Specifically, local infusion into the VCN showed that while the non-NMDA antagonist CNQX (6-cyano-7-nitroquinoxaline-2,3-dione) attenuated the startle reflex, the NMDA-specific antagonists AP5 (DL-2-amino-5-phosphonopentanoic acid) and CPP (3-((+)-2-caboxypiperazin-4-yl)-propyl-1-phosphonic acid) were without effect. In the VLL or RPC, NMDA and non-NMDA antagonists were equipotent in blocking startle; however, RPC showed a much greater sensitivity to these drugs than other startle circuit sites. Intrathecal infusion of AP5 and CNQX into the lumbar cord region again showed both these compounds to be about equipotent in attenuating whole-body startle. A finer analysis of acoustically elicited startle measured electromyographically from the quadriceps femoris complex in the hindlimbs showed that intrathecal CNQX preferentially blocked an early, short latency (~8 msec) EMG component of startle, while AP5 preferentially blocked a late (~15 msec) component.

These findings indicate that excitatory amino acids may mediate or modulate the acoustic startle reflex at each nucleus within its neural pathway, and suggest that the temporal and relative contribution of NMDA and non-NMDA receptors, and their sensitivity, may vary as a function of site.

ELECTROPHYSIOLOGICAL EVIDENCE THAT A TAURINE-LIKE AMINO ACID IS THE NEUROTRANSMITTER AT A FAST EXCITATORY SYNAPSE. Peter A.V. Anderson and H.G. Trapido-Rosenthal. Whitney Laboratory and Depts of Physiology and Neuroscience, Univ. of Florida, St. Augustine, FL 32086.

Neurons in the motor nerve net of the jellyfish *Cyanea capillata* are connected by fast relay synapses. The average delay between the peak of the presynaptic action potential and the onset of the EPSP is 1 msec suggesting that the neurotransmitter at these synapses cannot be peptidergic, as appears to be the case at many cnidarian synapses. Previous work involving applications of 25 putative transmitter substances to exposed synapses failed to evoke any activity consistent with the normal EPSPs at these synapses. However, applications of taurine and ß-alanine, but not alanine, and some, but not all analogs, evoked reproducible depolarizations of the cells. These were associated with a conductance increase. The reversal potential of the response averaged +6.8 mV, close to the average reversal potential of EPSPs at these synapses (+4 mV). This physiological evidence for a role of a taurine-like transmitter is supported by finding that neurons from this animal contain large amounts of taurine, ß-alanine, alanine and GABA. If release studies, currently underway, confirm the role of a taurine-like neurotransmitter at these synapses, this will constitute the first convincing demonstration of their role as neurotransmitters.

DESCENDING AND SEGMENTAL GLUTAMATERGIC INPUTS MEDIATE TWO DISTINCT EPSPs IN RAT SYMPATHETIC PREGANGLIONIC NEURONS. E. Shen, N. Mo* and N. J. Dun. Dept. of Pharmacol., Loyola Univ. Med. Ctr., Maywood, IL 60153

Intracellular recordings were made from antidromically identified sympathetic preganglionic neurons (SPNs) in thin (500 µm) transverse neonate (12-22 day) rat thoracolumbar spinal cord slices. Electrical stimulation of dorsal roots elicited in SPNs a long latency (1-5 ms), relatively slow rising and falling EPSP, referred to as a DR-EPSP. Hyperpolarization and depolarization from the resting potential of about -60 mV reduced and increased the DR-EPSPs. The response was potentiated in Mg-free solution, often giving rise to a burst of spike discharges. DR-EPSPs in the presence or absence of Mg ions were suppressed by the NMDA receptor antagonists APV (1-10 µM) and ketamine (10-20 µM) but resistant to the KA/QA receptor antagonists DNQX and CNQX (1-10 µM). Stimulation of lateral funiculus evoked a short latency (< 1 ms), relatively fast rising and falling EPSP, the LF-EPSP. The responses were increased by hyperpolarization and reduced by depolarization. Mg-free solution had no appreciable effects on LF-EPSPs. Contrary to the DR-EPSP, the LF-EPSP was antagonized by DNQX and CNQX but not by APV and ketamine. The results indicate that SPNs receive two glutamatergic inputs: a polysynaptic connection from dorsal roots and a monosynaptic input from supraspinal neurons via lateral funiculus. Activation of these two inputs elicits two distinct EPSPs mediated by NMDA and non-NMDA receptors, respectively. (Supported by NS18710).

ELECTRICAL ACTIVITY IN THE SUPRACHIASMATIC NUCLEUS, EVOKED BY OPTIC TRACT STIMULATION, CAN BE RECORDED USING VOLTAGE-SENSITIVE DYES. H. Komuro*, A.L. Obaid, and B.M. Salzberg, Dept. of Physiology, Univ. of Pennsylvania School of Medicine, Phila., PA 19104-6085.

In an effort to understand the functional organization of the suprachiasmatic nucleus (SCN), we have used a system for Multiple Site Optical Recording of Transmembrane Voltage (MSORTV) and the potentiometric pyrazo-oxonol dye RH 155 to monitor electrical events that follow stimulation of the retino-hypothalamic pathway. Coronal slices, 300 um thick, were cut at the level of the optic chiasm of adult mice, stained for 30 minutes in a 0.2 mg/ml solution of the dye, and imaged onto a 124 element photodiode array using a 10X, 0.4 n.a. objective. Brief stimuli (100-200 us) were delivered to the optic tract by means of a bipolar electrode. Each photodetector monitored changes in transmitted light intensity which were proportional to the potential changes of the plasma membranes in its 100 um square receptive field. These extrinsic optical signals derived mainly from retinal ganglion cell axons and neurons of the SCN, and exhibited waveforms having at least two components whose relative sizes depended upon location within the slice as well as the origin of the slice on the rostral-caudal axis. The first component was very fast, TTX-sensitive, and appeared to be dominated by the axonal spike. The slower portion of the optical signal had a wider distribution in more rostral slices. It was sensitive to high (11 mM) $[Mg^{2+}]_o$ and to blockers of glutaminergic transmission such as kynurenic acid (1 mM), and a spatial organization of these effects could be discerned. 6-Cyano-7-nitroquinoxaline-2,3-dione (CNQX) eliminated the slow component at a concentration of 20 uM. These findings suggest that the second component of the absorption change reflects postsynaptic voltage changes in SCN neurons.

HOW NMDA AND NON-NMDA RECEPTORS CONTRIBUTE TO RESPONSES IN VISUAL CORTEX. N.W. Daw and K. Fox. Dept. Cell Biol., Washington Univ. Med. Sch., St. Louis, MO 63110

We have observed the effect of glutamate agonists and antagonists on contrast response curves of cells in cat visual cortex. NMDA increases the slope of the curve without changing the levels of contrast that give threshold and saturation, while APV reduces the slope and quisqualate shifts the curve upwards.

We have developed a model that accounts for these results using parameters for the cell biology of glutamate receptors from the hippocampus. The NMDA channel conductance has a Boltzmann voltage dependancy with exponent -0.07V, while glutamate binds at non-NMDA and NMDA receptors with Hill coefficients of 1 and 2 respectively. Release of glutamate from terminals in the cortex is assumed to be related to contrast by a hyperbolic tangent formula, C/C+K, where C is contrast and K is a constant.

Several conclusions can be drawn. NMDA receptors contribute to the visual response multiplicatively, while non-NMDA receptors contribute additively. The NMDA receptor is active at low as well as high contrasts, accounting for a constant percentage of the response at all contrasts. It does not act as a switch that turns on Calcium inflow at some particular level of input. Consequently NMDA receptors contribute to the visual response in both adult and developing visual cortex in a graded fashion.

CHARACTERIZATION OF GLUTAMATE RECEPTORS AND THEIR MODULATION BY VASOPRESSIN IN RAT HYPOTHALAMIC MAGNOCELLULAR NEUROSECRETORY CELLS (MNCS). B. Hu and C.W. Bourque *Centre for Research in Neuroscience, MGH, McGill University, Montreal, Québec, Canada H3G 1A4*

Glutamate receptor antagonists have been shown to block evoked excitatory synaptic transmission in the supraoptic nucleus (Gribkoff et al, J. Neurophysiol. 1990). Experiments on ventral septal neurons have previously shown that glutamate evoked firing can be modulated by vasopressin (VP) (Disturnal et al, CJPP 1987). Since 50% of supraoptic MNCs release VP, we have characterized the glutamate receptor subtypes on supraoptic neurons and examined the effects of VP on their activation by selective agonists. Forty eight supraoptic MNCs were recorded using current- or single electrode voltage clamp techniques. Bath applications of NMDA, quisqualate, kainate or glutamate consistently induced a dose-dependent, TTX-insensitive inward current or membrane depolarization (n=11) at resting potential. The I-V relationship of the NMDA-induced current revealed a Mg^{++}-dependent zone of negative resistance between -100 to -45mV (n=9). In contrast, currents evoked by quisqualate and kainate displayed linear I-V relationships. NMDA induced responses were reversibly antagonized by APV (10 to 40 µM; n=5), while quisqualate responses were selectively blocked by CNQX (10 to 20 µM; n=4), suggesting that both NMDA and non-NMDA receptors are present on MNCs. Bath application of vasopressin (10^{-8} to 10^{-6} M) reversibly attenuated NMDA induced responses (50% to 100%; n=7) in a concentration-dependent manner. In contrast, quisqualate induced responses in the same cells were unaffected or enhanced by VP (n=5). The modulatory effects of VP may be relevant to the physiological control of supraoptic neurons as well as their peculiar resistance to glutamate toxicity. Supported by MRC, FCAR and FRSQ

NOVEL ACTIVATION OF NMDA RECEPTORS POTENTIATES SENSORY RESPONSES OF BRAIN NORADRENERGIC NEURONS. R. Shiekhattar and G. Aston-Jones. Div. Behav. Neurobiol., Dept. Mental Health Sci., Hahnemann University, Philadelphia, PA 19102.

Noradrenegic locus coeruleus (LC) neurons receive prominent excitatory amino acid (EAA) and GABA inputs from their two major afferents in the rostral medulla (Ennis and Aston-Jones, J. Neurosci., 8: 3644 ; 9 : 2973 1988;1989), and the characteristic activation of these cells by sciatic nerve stimulation is mediated by an EAA in LC. Using this system, we examined possible GABAergic modulation of synaptic EAA-mediated transmission *in vivo*. Extracellular recording was combined with local microinfusion of drugs into LC. Direct application of the GABA antagonist bicuculline methiodide (BIC; 50 or 500 μM) onto LC neurons enhanced their sensory responsiveness by 234% ($p<.004$, $n=7$). This increased responsiveness was due to the long-lasting expression of a new, N-methyl-D-aspartate (NMDA) receptor-mediated component of the synaptic response, as it was completely blocked by infusions of the specific NMDA antagonist, 2-amino-5-phosphonovalerate (AP5). This action of BIC was neither mimicked by other GABA-A (picrotoxin or penicillin) or GABA-B (2-hydroxy-saclofen) antagonists, nor by agents that directly depolarize LC neurons (vasoactive intestinal polypeptide or carbachol). This BIC-potentiated response component was eliminated by direct application of the neurotransmitter GABA.

These results indicate that BIC, acting at a novel site, unmasks NMDA receptors which can be activated by sensory stimuli. This new site may be a point of convergence whereby interactions between two major neurotransmitter systems potently modulate signal transmission in the brain. Support: PHS grants NS24698 & DA06214.

THE BLOCKADE OF POTASSIUM CONDUCTANCES BY EXCITATORY AMINO ACIDS IS MEDIATED BY A SUBTYPE OF QUISQUALATE RECEPTOR

S. Charpak*, T. Knöpfel, S. Thompson and B.H. Gähwiler. Brain Research Institute, University of Zürich, CH-8029 Zürich (Switzerland)

Recently, we reported that cysteine could block the slow spike afterhyperpolarization (AHP) of hippocampal CA3 pyramidal neurones (Charpak et al. Soc. Neurosci. abstr. 374.13. 1989). In the present work, we characterized the endogenous agonists, receptor type and membrane currents involved in this effect.

Organotypic cultures of rat hippocampus were prepared as described previously. After 2-5 weeks in vitro, the cultures were superfused with a balanced salt solution containing 1 uM TTX and single-electrode voltage-clamp techniques were used to record currents from CA3 pyramidal cells.

Glutamate, aspartate, cysteine and homocysteate (0.5-1 mM) blocked a calcium-dependent potassium current underlying the AHP and the time- and voltage-dependent current I_M, despite pharmacological blockade (2 mM kynurenate) of ionotropic excitatory amino acid receptors. These effects could be reproduced by low concentrations (0.02-1 uM) of quisqualate and by agonists of the quisqualate metabotropic receptor such as Trans-1-amino-cyclopentyl-1,3-dicarboxylate. Combined intracellular and fura-2 recordings indicated that the quisqualate effect was not mediated through a change in cytosolic calcium, thus suggesting a direct blockade of potassium conductances.

ISOFLURANE DEPRESSION OF Ca-COMPONENT INVOLVED IN NMDA AND GLUTAMATE ACTIONS ON CORTICAL NEURONS.

H. El-Beheiry, E. Puil and K. G. Baimbridge. Depts. of Anaesthesia, Pharmacology & Therapeutics, and Physiology, Univ. of British Columbia, Vancouver, B. C., V6T 1W5, Canada.

A decrease in synaptic excitation has been suggested as a mechanism of action of general anaesthetics. The effects of isoflurane were studied using intracellular recording techniques and microspectrofluorimetric measurements of intracellular Ca^{2+} concentration ($[Ca^{2+}]_i$) with a Fura-2 probe in neocortical and cultured hippocampal neurons. In the presence of external Mg^{2+} (2 mM), isoflurane depressed, in a dose-dependent manner, the depolarizations and associated conductance changes evoked by iontophoretic applications of NMDA and glutamate (Glu). Anaesthetic administrations in the lower dose range (0.5-1.5MAC) had no effects on the passive membrane properties of the neocortical neurons. In higher doses, isoflurane induced slight hyperpolarization (3-5 mV) as well as increased input conductance (≈20%). In hippocampal neurons, isoflurane attenuated, in a dose-dependent manner, the increases in $[Ca^{2+}]_i$ evoked by bolus application of Glu or NMDA under conditions that favoured activation of the NMDA- and quisqualate-receptor subtypes. Verapamil perfusion reduced the presumed voltage-dependent increases of $[Ca^{2+}]_i$ induced by Glu application. The effects of isoflurane were additive with those of verapamil. It is suggested that isoflurane suppresses the depolarizations induced by NMDA and Glu by actions on receptor- and voltage-dependent Ca2+ influx or on processes for intracellular Ca2+ mobilization activated by Glu-receptor interactions.

ALLOSTERIC MODULATORS OF THE NMDA RECEPTOR AFFECT SYNAPTIC FUNCTION IN RAT HIPPOCAMPAL SLICES. S. Vicini, C.T. Livsey and G. Mereu. FGIN, Georgetown University, Washington, D.C. 20007.

Excitatory synaptic transmission in the dentate gyrus granular neurons and CA1 and CA3 pyramidal neurons of the rat hippocampus in a thin slice preparation (Edwards et al. Pfluger Arch. 414: 600, 1989) was studied by mean of the whole-cell tight-seal technique. We observed miniature spontaneous excitatory synaptic currents (mepcs) in most neurons investigated. Low frequency stimulation of the afferent input to these areas produced evoked excitatory synaptic currents (epsc). The synaptic currents of both mepcs and epcs presented in addition to a main fast decay a slower component (20-300 msec duration) relevant at holding potentials more depolarized than -55 mV, due to the relief of the Mg^{2+} blockade of NMDA-activated receptor-channels. Negative allosteric modulators for the glycine site located on the NMDA receptor domains such as 7-Cl-kynurenic acid abolished the slow component of the epsc. Tetanization of the excitatory input to dentate gyrus granular cells and CA1 pyramidal neurons produced in most cases long-lasting facilitation of the epscs and in some cases also of the mepscs if combined with depolarization of the postsynaptic neurons in the presence of picrotoxin. 7-Cl-kynurenic acid prevented the induction of this facilitation. These results demonstrate a role for the glycine regulatory site in the excitatory synaptic transmission in the hippocampus.

This work is supported by an NIH grant # PO1 NS-78130.

GLYCINE MODULATES EXCITATORY AMINO ACID-INDUCED EXCITATION OF RAT CEREBELLAR PURKINJE CELLS IN VIVO.

J.G. Netzeband, J.C. Strahlendorf and H.K. Strahlendorf. Departments of Physiology and Neurology, Texas Tech University Health Sciences Center, School of Medicine, Lubbock, TX 79430.

The action of glycine on excitatory amino acid-induced excitation of cerebellar Purkinje cells was investigated in urethane-anesthetized, adult, male rats using extracellular recording techniques and iontophoretic drug application. Glycine, alone, had little or no effect on the spontaneous firing rate of Purkinje cells, but it dose-dependently attenuated kainate-and quisqualate-induced excitations. Glycine's action on NMDA-induced excitation, however, was more complex and dependent on the initial firing rate of the cell. Slower firing cells responded with a dose-dependent attenuation, similar to that observed above. Faster firing cells, however, showed potentiation of NMDA-mediated excitation in the presence of a low dose of glycine (5 nA). In these cells, higher doses of glycine (10-40 nA) were less effective at potentiating NMDA, and in several cells, the effect was reversed to one of attenuation. These results suggest that glycine elicits a non-selective inhibitory modulation of excitatory inputs onto Purkinje cells, and that it also selectively potentiates responses to NMDA. This selective action on NMDA is in agreement with data from other areas of the nervous system which show that the NMDA-receptor has an allosteric glycine binding site and lends further support to the hypothesis that functional NMDA receptors exist on adult cerebellar Purkinje cells. INCREASED SENSITIVITY TO NMDA FOLLOWING CHRONIC LEAD EXPOSURE.

T.L. Petit, J.C. LeBoutillier*, and W.J. Brooks. Dept. of Psychology, Univ. of Toronto, Scarborough, Ont. Canada M1C 1A4

Exposure to lead (Pb) in children and developing animals inhibits neuronal development, adult plasticity, and learning and memory capacities. The NMDA receptor is critical in neural development, plasticity, and memory processes, and is known to be altered by divalent cations. The current research attempted to determine if there was an interaction between Pb and NMDA. Rat pups were exposed to high, moderate, and low levels of Pb during early development and injected with varying doses of NMDA at P15 or P25. Lead exposed rats were supersensitive to NMDA showing a more rapid onset and intense level of seizure activity that was relative to the degree of Pb exposure. Receptor binding autoradiography indicated an increase in NMDA receptors in the Pb exposed animals, particularly in the hippocampus. These effects are similar to those produced following chronic developmental administration of NMDA antagonists, and suggest that developmental Pb exposure chronically disrupts NMDA receptor function, resulting in a compensatory up-regulation of NMDA receptors.

490.19

SYNAPTOGENESIS AND ENHANCED SENSITIVITY TO NMDA FOLLOWING CHRONIC ADMINISTRATION OF PCP.
W.J. Brooks, T.L. Petit and J.C. LeBoutillier*
Dept. of Psychology, Univ. of Toronto, Scarborough, Ont, Canada, M1C 1A4.

Previous research in our laboratory has found that chronic administration of the NMDA antagonist phencyclidine (PCP) inhibits developmental synaptogenesis. The current research attempted to determine the effects of terminating chronic administration of PCP on subsequent sensitivity to NMDA and synaptogenesis. Five day old rat pups were administered daily subcutaneous injections of 10 mg/kg PCP for two weeks (the period of maximal neocortical synaptogenesis). The pups were sacrificed 1, 5, 15 and 25 days after the last injection of PCP and cortical sections processed for electron microscopy. Analysis of the molecular layer of occipital cortex revealed an initial (21) drop in total number of synapses followed by a period in which total synapses exceeded control values (P36). This period of synaptogenesis coincided with an enhanced sensitivity to NMDA induced seizure activity. These results provide further evidence of a relationship between NMDA sensitivity and the ongoing rate of synaptogenesis.

PHORBOL ESTER ENHANCES EXCITATORY AMINO ACID-INDUCED DOPAMINE RELEASE. I. Chaudieu, H. Mount, & P. Boksa. Douglas Hospital Research Center, Depts. Psychiat. and Pharmacol. & Therap., McGill University, Verdun, PQ., Canada.

Several neurotransmitter systems mediate cellular events via induction of phosphatidyl inositol breakdown leading to activation of protein kinase C (PKC). In support of this, phorbol esters, known to activate PKC, have been shown to enhance processes such as neurotransmitter release and features of long term potentiation. In fetal rat cultured mesencephalic cells, we show that the phorbol, 12-O-tetradecanoyl phorbol-13-acetate (TPA), at 100 nM, enhanced [^{3}H]dopamine ([^{3}H]DA) release evoked by NMDA, kainate, quisqualate or K^+ to 160%, 127%, 173% and 167% of control values, respectively. 100 nM TPA alone had no effect on [^{3}H]DA release. [^{3}H]DA release evoked by NMDA in the presence of TPA was completely inhibited by the non-competitive NMDA antagonist, MK-801, indicating that TPA enhancement of the NMDA response is mediated via activation of NMDA receptors. TPA enhanced NMDA-stimulated [^{3}H]DA release both in the presence and absence of 1.2 mM Mg^{2+}, indicating that TPA does not enhance the NMDA response by depolarizing DA neurons leading to reversal of a voltage-dependent Mg^{2+} blockade of the NMDA response. TPA also does not enhance the NMDA response in this preparation via release of glycine leading to glycine potentiation of the NMDA response, since in the presence of Mg^{2+}, glycine (1 or 10 uM) had no effect while 100 uM glycine inhibited NMDA-induced [^{3}H]DA release (Mount et al., this meeting). These results suggest that PKC activation may modulate excitatory amino acid-induced DA release from neurons originating in the ventral mesencephalon. *Supported by the FRSQ.*

PRESYNAPTIC GLUTAMATE RECEPTORS MODULATE NEUROTRANSMITTER RELEASE FROM SYNAPTOSOMES.
James K.T. Wang and Vijay Thukral*. Tufts University School of Medicine, Boston, MA 02111.

The existence of presynaptic glutamate receptors, and the question of which of the glutamate receptor subtypes regulates transmitter release, were addressed in this study. We labeled synaptosomes from adult rat olfactory bulbs with [^{3}H]norepinephrine, [^{3}H]dopamine, or [^{14}C]GABA, and assayed transmitter release in a superfusion apparatus. Glutamate (10 μM) increased the basal release of the two catecholamines by 50% within 1-2 min, and did not have any sigificant effect on the K^+-depolarization evoked release. The enhanced basal release was dependent on extracellular Ca^{2+}, and was blocked by the non-NMDA subtype selective antagonist CNQX (10 μM) but not by the NMDA subtype selective antagonist APV (10 μM). Quisqualate (10 μM) and AMPA (100 μM) had similar effects as glutamate, but kainate and NMDA did not. Glutamate also increased both the basal and the K^+-depolarization evoked efflux of [^{14}C]GABA. However, these effects were not blocked by either CNQX or APV, were not mimicked by AMPA, kainate or NMDA, and were not dependent on extracellular Ca^{2+}. These data suggest that in olfactory bulb synaptosomes there are presynaptic glutamate receptors, possibly of the non-NMDA quisqualate/AMPA subtype, that modulate catecholamine release. In contrast, the effects of glutamate on GABA efflux may not involve the Ca^{2+}-dependent, releasable pool of the transmitter.

CEREBRAL SYNTHESIS AND RELEASE OF KYNURENIC ACID
K.J. Swartz, M.J.During, A.Freese and M.F.Beal *Program in Neuroscience, Harvard Medical School, and Mass.General Hospital, Boston MA 02115.*

Kynurenic acid is an endogenous antagonist of excitatory amino acid (EAA) receptors and may therefore influence important physiologic and pathologic processes. The release of intracerebrally synthesized kynurenic acid into the extracellular fluid (ECF), where it may act at EAA receptors, has not been established *in vivo*. Furthermore, kynurenic acid synthesis from physiologically supplied precursors has not been demonstrate *in vivo* or *in vitro*. We studied the synthesis and release of kynurenic acid in rat striatum, using intracerebral microdialysis coupled with HPLC and fluorescence detection. The basal ECF concentration of kynurenic acid in the rat striatum was 17.1 ± 1.1 nM. Peripheral administration of the immediate precursor of kynurenic acid, L-kynurenine, resulted in marked dose dependent increases in striatal ECF concentrations of kynurenic acid, peaking at 2.5 hrs. The highest dose of L-kynurenine (100 mg kg^{-1}), administered peripherally, resulted in a 108 fold increase in plasma kynurenic acid levels and a 37 fold increase in cerebral ECF levels. Peripheral administration of kynurenic acid, at a dose that caused plasma levels to increase 430 fold, resulted in only 4 fold increases in striatal ECF concentrations. The precursor responsiveness of striatal ECF kynurenic acid to peripherally infused L-kynurenine was blocked by the central application (via the dialysis probe) of 1mM aminooxyacetic acid, an inhibitor of the immediate synthetic enzyme for kynurenic acid, kynurenine aminotransferase. Administration of L-tryptophan, was less effective than L-kynurenine in increasing ECF kynurenic acid concentrations, and did so at a considerably later time interval (6 hrs.). Infusion of L-kynurenine (100 µM), but not L-tryptophan (100 µM), through the dialysis probe, dramatically increased striatal ECF concentrations of kynurenic acid. The conclusions drawn from the present study are that: i) kynurenic acid is present in ECF within the central nervous system (CNS), ii) the CNS can synthesize kynurenic acid and release it into the ECF, iii) the majority of CNS kynurenic acid synthesis results from the transport of L-kynurenine across the blood brain barrier and iv) ECF concentrations of kynurenic acid can be dramatically increased by pharmacological manipulation of precursor levels.

491.2

APNEA PRODUCED BY MICROINJECTION OF KYNURENIC ACID INTO THE CAUDAL-SUBRETROFACIAL AREA OF THE VENTROLATERAL MEDULLA IN THE CAT IS DUE TO BLOCKADE OF BOTH NMDA AND NON-NMDA EXCITATORY AMINO ACID RECEPTORS.
R.A. Gillis*, P.J. Hornby and T.P. Abrahams, Dept. of Pharmacology, Georgetown University, Washington, D.C. 20007.

We recently reported that bilateral microinjection of kynurenic acid (KYN; 12.5nmol in 50nls) into the caudal-subretrofacial area produces apnea in chloralose anesthetized cats (Neurosci. Abstr. 15:100, 1989) The purpose of the present study was to determine which subtype(s) of excitatory amino acid (EAA) receptor is(are) responsible for maintaining a normal breathing pattern at this site. For this purpose, antagonists of NMDA (3-((RS)-Carboxypiperazin-4-yl-)-propyl-1-phosphonic acid (CPP))and non-NMDA (6-Cyano-7-nitroquinoxaline-2,3-dione (CNQX)) receptors were microinjected bilaterally (50nl; pH 7.4) into this site (approx. 3mm rostral to obex, 4mm lateral to midline and 1.5mm below the ventral surface) while monitoring arterial blood pressure (BP), heart rate (HR), tidal volume (Vt) and respiratory rate (f) in chloralose anesthetized cats. In the case of CPP three doses were studied (0.25nmol, n=3; 0.75nmol, n=3; 2.25nmol, n=2). All three doses produced similar decreases in Vt (-12±1, p<0.05; -10±1, p<0.05, and -16±5mls respectively), and increases in f (+14±2, p<0.05; -10±3, p<0.05, and -12±3breaths/min respectively). None of these animals exhibited apnea. In contrast, microinjection of CNQX (0.05nmol, N=3) resulted in only a small increase in f (+1.7±0.3breaths/min; p< 0.05) with no significant change in Vt. A combination of CPP and CNQX (N=5) resulted in a large decrease in Vt (-24±7mls; p< 0.05) and an increase in f (+18±4breaths/min; p< 0.05). Three of the five animals tested exhibited apnea. None of these drugs produced significant effects on BP or HR. These results indicate that the major EAA drive to respiratory neurons in the caudal-subretrofacial area involves activation of NMDA receptors but excitation of non-NMDA receptors may also play a crucial role in maintaining respiration. PHOSPHATE-ACTIVATED GLUTAMINASE (PAG) INHIBITORS ABOLISH GLUTAMATE-IMMUNOREACTIVITY IN THE RAT CEREBRAL CORTEX. F. Conti, M. Fabri, A. Minelli* and C. Sgattoni*. Institute of Human Physiology, University of Ancona School of Medicine, I-60131 Ancona (Italy).

Conversion of glutamine (Gln) to Glu catalised by phosphate-activated glutaminase (PAG) plays an important role in the formation of transmitter Glu. In the experiments reported here we have studied the effects of two PAG inhibitors -mersalyl acid (MA) and N-ethylmaleimide (NEM)- on the pattern of glutamate-immunoreactivity (IR) in the rat cerebral cortex.

MA (1mM) and NEM (1mM) were applied either intraparenchimally (0.2 µl) or topically (2 µl) to the parietal cortex. After 30 min. animals were perfused with 4% carbodiimide and the brain post-fixed for several days in 4% paraformaldehyde. Vibratome sections were then processed for Glu-immunocytochemistry (Conti et al. J. Neurosci., 7: 1887-1901, 1987). Controls included: sham injections, administration of physiological saline, and Nissl staining of adjacent sections to rule out aspecific effects, and MA and NEM applications into dorsal root ganglia (DRG) to verify whether the two compounds affected Substance P (SP) IR. Results can be summarized as follows: 1) both intraparenchimal and topical administration of MA and NEM results in a complete suppression of Glu-IR in the cerebral cortex; 2) this effect is not due to neuronal death, since Nissl staining of sections adjacent to those processed for Glu-immunocytochemistry reveals normal cortical architecture; 3) sham applications or injections of saline did not change the pattern of Glu-IR; 4) injections of both MA and NEM into DRG did not change the pattern of SP-IR.

Since PAG activity is involved in the formation of transmitter Glu, these results provide further evidence that Glu-IR observed in the cerebral cortex is related primarily to the transmitter pool of Glu.

Multiple lines of evidence implicate the excitatory amino acids, L-aspartate (L-Asp) and L-glutamate (L-Glu) as excitatory transmitters in the spinal cord. The specific objective of this study was to develop an experimental model to determine whether the EAA are released from primary afferents. Dorsal root ganglia (DRG) from 1 to 8-day-old rats were dissected and cultivated on chicken plasma-coated slides in Petri dishes for 7 to 10 days. After a 60 min equilibration period in Ringer's electrophysiological recording solution, the mean concentrations of EAA recovered during a 5 min interval were 1.24µM for L-Glu and 0.127µM for L-Asp. Stimulation of DRG organotypic cultures with either 25 or 50 mM potassium resulted in a concentration-dependent release of both L-Asp and L-Glu. Exposure of the cultures to 10µM capsaicin also caused release of both EAA. Peak increases of 84.14+12.75% (mean+SD) for L-Glu and 99.91+15.47% for L-Asp occurred within 10 min following exposure to high K^+. The stimulatory effect of K^+ was Ca^{2+}-dependent. Addition of high K^+ to cultures, from which DRG cell bodies, but not terminals were freshly removed, resulted in an increase of both EAA. High K^+, however, failed to increase the release of EAA from cultures where DRG cell bodies were removed 72 hours prior to release experiments. These results demonstrate that EAA are released from mammalian primary afferent fibers, and in particular, released from small diameter primary afferents. Work was supported by NIH grant NS27751, USDA grant PL95-113, NIDA grants DA 04190, DA 04090, DA00124.

ELECTRICAL-STIMULATION INDUCED RELEASE OF EXCITATORY AMINO ACIDS, INCLUDING SULPHUR-CONTAINING COMPOUNDS, FROM ACUTE HIPPOCAMPAL SLICES. J.M.Klancnik, M.Cuénod, B.H.Gähwiler and K.Q.Do Brain Research Inst., Univ. of Zürich, Switzerland.

Excitatory amino acids (EAAs) have been suggested as possible neurotransmitters in the hippocampus, and have been shown to be released by high-K^+ stimulation in a Ca^{2+}-dependent manner. To identify putative neurotransmitters released from specific synaptic locations, however, it is necessary to stimulate more selectively. The present study examined the release of amino acids from acute 400µm thick hippocampal slices prepared from adult SIV-50 rats upon electrical stimulation of Schaffer collaterals. In a submerged-type recording chamber, a 300µm diameter cannula was placed 50-60µm over the CA1 stratum radiatum, to collect 12 consecutive 1-min fractions of superfusate at a rate of 20µl/min. Electrical stimulation was applied via microelectrode for 4 min, at 50Hz, 100µsec pulse duration and an intensity which just evoked a population spike of maximal amplitude recorded in CA1 stratum pyramidale. Analysis was performed by reversed phase HPLC, following derivatization with o-phtalaldehyde, using a linear gradient of 0.03M acetate buffer (pH 7.0) and acetonitrile. Consistently, aspartate (Asp) levels were increased (from 0.05±0.03 to 1.55±0.71 pmol/fraction) upon stimulation, while levels of leucine, isoleucine, valine or phenylalanine showed no changes. An increase in glutamate levels was observed occasionally. In some experiments, low levels (approx. 0.2 pmol/fraction) of homocysteic acid (HCA) or cysteine sulfinic acid (CSA) were detected only during or following stimulation. Although high K^+-induced release of HCA and CSA from hippocampus has been shown previously, these results are the first to indicate a release of these sulphur-containing EAAs upon electrical stimulation. The present results suggest that Asp, HCA and CSA play a role in synaptic transmission in the Schaffer collaterals.

ARACHIDONIC ACID METABOLISM AND EXCITATORY AMINO ACID RELEASE. C.P. Duncan*, D. Martin and J.V. Nadler. Depts. Pharmacology and Neurobiology, Duke Univ. Med. Ctr., Durham, NC 27710.

It has been reported that metabolites of arachidonic acid are essential for catecholamine release from the adrenal medulla and stimulate glutamate release from synaptosomes. This study examined the effects of nordihydroguaiaretic acid (NDGA), an inhibitor of the lipoxygenase pathway, on the release of glutamate and aspartate from the Schaffer collateral-commissural-ipsilateral associational (SCCIA) pathway in area CA1 of the rat hippocampus. Transmitter release was evoked from superfused slices of the CA1 area (excluding stratum lacunosum-moleculare) by exposing the slices to 1-min pulses of 50 mM K^+. Under our conditions nearly all the release of glutamate and aspartate is Ca^{2+}-dependent and it originates predominantly from the SCCIA pathway.

Addition of 100 uM NDGA to the superfusion medium released endogenous glutamate and taurine from the slices. No aspartate release was detected. NDGA-evoked amino acid efflux was not Ca^{2+}-dependent. When the slices were depolarized with elevated K^+, NDGA depressed the evoked release of both glutamate and aspartate by about 80%. Indomethacin, an inhibitor of the cyclo-oxygenase pathway, did not affect glutamate or aspartate release.

These findings support a crucial role for lipoxygenase products of arachidonic acid metabolism in the synaptic release of excitatory amino acids. (Supported by NIH grant NS 16064.)

THE LOCALIZATION OF GLUTAMATE-METABOLIZING ENZYME mRNAs IN THE RAT CNS. K.M. Mearow, McMaster University, Hamilton, Ontario Canada

We have used in situ hybridization (ISH) to map the distribution of mRNAs coding for the glutamate-metabolizing enzymes, glutamine synthetase (GS), glutaminase (GA) and glutamate dehydrogenese (GDH) in the adult rat brain. ISH was carried out on frozen brain sections using synthetic 48-mer oligonucleotide probes directed against sequences coding for GS, GDH and GA.

GS mRNA was localized to glial cells in both white and grey matter. High density of labelling was associated with the Bergmann glial cell layer in the cerebellum, within the hippocampus and in certain cortical areas. GA mRNA was found to be enriched primarily in neurons. The location of labelled cells corresponded well with areas of known glutamatergic neurons - hippocampus, cerebellar granule layer, cortex (in particular, entorhinal cortex), pontine nuclei, olfactory bulb. GDH mRNA was found in both glial cells and neurons. The neuronal distribution of GDH was very similar to that of GA, while the glial distribution was similar to that of GS. The localization of the mRNAs corresponded well with the immunocytochemical distribution of cells labelled with antibodies against GS, GDH and GA.

ALTERATIONS IN REGIONAL KINETICS OF PHOSPHATE-ACTIVATED GLUTAMINASE WITH REGARDS TO AGE. D.R. Wallace and R. Dawson. University of Florida, Dept. Pharmacodynamics, Gainesville, FL. 32610.

Phosphate-activated glutaminase (PAG: L-glutamine amidohydrolase EC 3.5.1.2) hydrolyzes glutamine and thus forms both glutamate and ammonia. We have previously shown that a difference in regional ammonia inhibition exists between 8 month and 30 month old male Fischer-344 rats. The present study addresses the kinetics of PAG in the temporal cortex (TCX), striatum (STR), and hippocampus (HIPP) from 8 month and 30 month old F-344 rats. The basal activity (P2 fraction in the presence of 500uM glutamine and 10mM phosphate) was the highest in the TCX followed by the STR, and then the HIPP which had the lowest basal activity. Michaelis-Menten kinetics were done using substrate concentrations of 0.1-5.0mM glutamine in the presence of 10mM phosphate. The Km for PAG was unchanged in any of the regions from 8 month old rats. The values for Vmax displayed a similar trend as basal activity (TCX≥HIPP>STR). Vmax was significantly reduced approximately 15% in the STR with regards to age. In the HIPP, both Km and Vmax were significantly increased (approximately 30% and 25% respectively) with regards to age. There was no change in the kinetics of PAG in the TCX. The kinetic differences seen in this study and the changes seen in previous studies suggest that PAG is selectively altered in the aged brain, and that regional differences exist suggesting the existence of regional isozymes.

GLUTAMATE IMMUNOREACTIVITY IN TERMINALS OF CORTICAL EFFERENTS AND DORSAL ROOT AFFERENTS. R.J. Weinberg and A. Rustioni. Dept. of Cell Biology & Anatomy, University of North Carolina, Chapel Hill NC 27599.

Results obtained with techniques combining anterograde tracers with post-embedding electron microscopic immunocytochemistry will be illustrated using cortical efferents and primary afferents as models. Two days after injections of lectin-conjugated HRP in cortex, peripheral nerves, or dorsal root ganglia, rats were sacrificed by intraaortic perfusion with 2.5% glutaraldehyde, 0.5% para-formaldehyde, and 0.2% picric acid in phosphate buffer (pH 7.2). Peroxidase was demonstrated in 50 μm Vibratome sections of medulla and spinal cord, using a tungstate modification of the standard TMB histochemistry. DAB-stabilized sections were embedded in Epon-Spurr; thin sections on nickel grids were processed for post-embedding immunocytochemistry for glutamate and GABA using two different sizes of gold particles. Substantial numbers of glutamate- and GABA-labeled terminals were observed in both brain stem and spinal cord. Gold particles were concentrated over synaptic vesicles and mitochondria. Density of gold particles over anterogradely labeled terminals differed in terminals of different origins. The combination of these techniques with the retrograde tracer WGAapoHRP-Au, allows a fine-grain analysis of the chemical anatomy of neuronal microcircuitry.

GLUTAMATE AND ACETYLCHOLINE ARE CO-LOCALIZED IN THE LATERODORSAL TEGMENTAL AND PEDUNCULOPONTINE NUCLEI. J.R. Clements and S.J. Grant, School of Life and Health Sciences, Dept. Psychology and Prog. in Neuroscience, Univ. Delaware, Newark, DE. 19716.

Studies of the pedunculopontine (PPT) and laterodorsal tegmental (LDT) nuclei in the mesopontine tegmentum have emphasized the organization and projections of cholinergic neurons. Few studies have focused on the role of excitatory amino acids in these regions. Therefore, we decided to examine the distribution of glutamate-like immunoreactivity (GLI) in the rat mesopontine tegmentum.

GLI neurons were found extensively distributed throughout the mesopontine tegmentum. GLI neurons were intercalated among cholinergic neurons in the LDT and PPT, as well as in adjacent non-cholinergic areas. GLI neurons in the LDT and PPT were similar in morphological type and size to cholinergic neurons in these nuclei. Double labeling studies revealed a subpopulation of neurons in both the LDT and PPT which exhibited co-localization of GLI and ChA-T immunoreactivity. This suggests that some LDT and PPT neurons may contain two classical transmitters as well as previously described peptide co-transmitters.

These data raise the possibility that PPT and LDT target sites receive combined excitatory amino acid and cholinergic inputs and that excitatory amino acids contribute to the functions of the LDT and PPT, including behavioral state control, locomotion and activation of midbrain dopamine neurons.

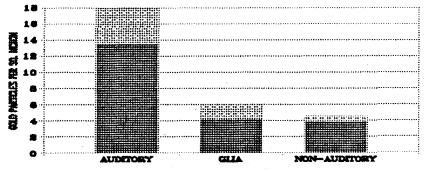
INCREASED LEVELS OF GLUTAMATE IMMUNOREACTIVITY IN THE AUDITORY NERVE ENDINGS OF THE DORSAL COCHLEAR NUCLEUS. J.M. Juiz, R.H. Helfert, R.J. Wenthold and R.A. Altschuler. Kresge Hearing Research Inst., Univ. Michigan, Ann Arbor, MI 48109 & LMO, NIDCD, NIH.

Increased levels of glutamate are likely to be associated with excitatory amino acid terminals, either as a transmitter or part of the transmitter pool. Quantitative evaluation of immunogold labeling provides a sensitive technique to determine glutamate levels in synaptic terminals. We have used this technique with glutamate antiserum in the cochlear nucleus, where auditory nerve terminals are believed to use an excitatory amino acid as their transmitter. The number of colloidal gold particles in auditory nerve terminals compared to other terminals and glial elements in the dorsal cochlear nucleus is seen see below:



The increased immunoreactive labeling for glutamate in auditory nerve terminals suggests that such labeling may serve as a useful marker for excitatory amino acid terminals.

491.12

IMMUNOCYTOCHEMICAL LOCALIZATION OF N-ACETYLATED ALPHA-LINKED ACIDIC DIPEPTIDASE (NAALADase). B.Stauch Slusher, G. Tsai, and J.T. Coyle. Departments of Pharmacology and Neuroscience, The Johns Hopkins School of Medicine, Baltimore, MD 21205.

N-Acetylated alpha-linked acidic dipeptidase (NAALADase) is a membrane-bound metallopeptidase that cleaves glutamate from the endogenous neuropeptide N-acetyl-aspartyl-glutamate (NAAG). We have purified rat brain NAALADase activity to apparent homogeneity, and have raised specific anti-NAALADase antibodies in guinea pig (Stauch et al., *submitted*). Immunocytochemical studies show intense NAALADase-immunoreactivity (NAALADase-IR) in several structures previously reported to contain NAAG-immunoreactivity (NAAG-IR) including: the globus pallidus, entopeduncular nucleus, substantia nigra, hippocampus, reticular thalamic nuclei, medial and lateral geniculate, lateral habenular nucleus, periaqueductal gray, molecular and granular cell layers of the cerebellum, spinal trigeminal nucleus, substantia gelatinosa, lateral cervical nuclei, and intermediolateral cell column. Within these structures, immunoreactivity was distributed throughout the neuropil; no cell bodies were stained, even after colchicine treatment. The only exception was a subpopulation of cerebellar granule cells whose cell soma stained intensely. In addition, NAALADase-IR was observed in several fiber tracts, including the stria terminalis, fornix, solitary tract, and corpus callosum; these fiber tracts also contain NAAG-IR. The co-localization of NAALADase-IR and NAAG-IR within the same neural structures supports the hypothesis that NAALADase is responsible for the catabolism of NAAG *in vivo*.

Monoclonal Antibodies to N-Acetyl-Aspartate. M.L. Simmons*, C. Frondoza*, and J.T. Coyle. Dept. of Neuroscience, The Johns Hopkins University School of Medicine, Balto., MD 21205.

N-acetyl-aspartate (NAA) is found in high concentrations in all areas of the brain, but is undetectable in non-nervous tissue [Tallan, et al. 1956]. NAA and glutamate are produced as a result of the enzymatic degradation of N-acetyl-aspartyl-glutamate (NAAG), a putative neurotransmitter/neuromodulator [Robinson, et al. 1987]. However, current information suggests that NAA may have functions unrelated to NAAG. For instance, analysis by HPLC has shown that NAA is present at nearly ten times the concentration of NAAG, and is more homogeneously distributed than NAAG [Koller, et al. 1984]. Monoclonal antibodies to NAA were produced to further study its role in the brain.

Spleen lymphocytes from a mouse immunized with NAA conjugated to thyroglobulin by carbodiimide were fused with P3/x63-Ag8 mouse myeloma cells. Clones were produced which secrete IgG2a(K) antibodies specific for conjugated NAA. Seven percent cross-reactivity with conjugated NAAG was observed only at high antibody concentrations; no cross-reactivity was observed with conjugated N-acetyl-glutamate or aspartate. Preincubation of the antibody with 0.5 mg/ml conjugated NAA blocked immunoreactivity 97%, while preincubation with conjugated NAAG and free NAA had no effect. Preliminary immunocytochemistry has shown that NAA-immunoreactivity is localized in neurons and widely distributed throughout the brain. This monoclonal antibody exhibits a high degree of specificity for conjugated NAA and will be useful in elucidating the function of NAA in the brain.

491.14

ABNORMAL EXCITATORY NEUROTRANSMITTERS IN HUMAN AND CANINE DEGENERATIVE MOTO-NEURON DISEASES G. Tsai, L.C. Cork*, J.C. Hedreen, B. Stauch Slusher, L. Passani, J.D. Rothstein, and J.T. Coyle. Depts. Neuroscience, Psychiatry and Neurology, The Johns Hopkins School of Medicine, Balto., MD, 21205.

There is increasing evidence that excitatory neurotransmitters may be involved in the pathogenesis of degenerative motoneuron disease (DMD). Accordingly, we have measured aspartate (Asp), glutamate (Glu), N-acetylaspartate (NAA), and N-acetylaspartylglutamate (NAAG) in pathologically confirmed amyotrophic lateral sclerosis (ALS) and hereditary canine spinal muscular atrophy (HCMD). In punch samples of human ALS cervical cord (ALS n=8, control n=6), only the ventral horn exhibited significant decreases in Asp (-21%) and Glu (-17%). However, both NAA and NAAG were reduced substantially in ventral horn, dorsal horn, and ventral root (-40%, -44%, -50%; and -60%, -43%, -36% respectively). In motor cortex, Asp and NAAG decreased significantly in deep gray matter (-32% and -29% respectively). Asp (-48%) and Glu (-46%) were also decreased in the white matter. In the HCMD, Asp, Glu, NAA, and NAAG in the thoracic cord all decreased significantly (-53%, -55%, -23%, and -24% respectively), whereas NAA and NAAG were unchanged in the motor cortex. The motor cortex of the dogs is devoid of pathology which is limited to the lower motoneurons in the spinal cord. These findings support the excitotoxic hypothesis of DMD and are consistent with previous report of the elevated NAA and NAAG in human ALS CSF. Since NAA and NAAG are highly concentrated in motoneurons, they may play a role in the pathogenesis of DMD.

491.15

IMMUNOCYTOCHEMICAL CO-LOCALIZATION OF N-ACETYL-ASPARTATE AND N-ACETYLASPARTYLGLUTAMATE IN MONKEY. L. Passani, G. Tsai, B. Stauch Slusher, M. Simmons, J.T. Coyle. Depts. Neurosci. and Psychiat., Johns Hopkins Med. Sch., Balto, MD, 21205.

N-acetylaspartate (NAA) and N-acetylaspartylglutamate (NAAG), a putative neurotransmitter/modulator, are enriched in neuronal tissue. NAA has been suggested as a precursor and/or metabolite of NAAG. The development of affinity-purified antisera against conjugated NAAG has permitted the immunocytochemical investigation of its cellular localization in rodent nervous tissue. Now highly specific monoclonal antibodies against conjugated NAA has been successfully produced (see abstract, M. Simmons et al.). To further understand the neuroanatomical relationship between NAA and NAAG in primate, we have exploited a double-staining immunocytochemistry technique for visualizing these two antigens in the same sections of monkey brain. Six *Macaca mulatta* were perfused with a combination of paraformaldehyde and carbodiimide. Immunocytochemical specificity of the antibodies was demonstrated by their differential blocking by conjugated NAAG and NAA. Preliminary results indicate NAA and NAAG are co-localized in different structures of the monkey brains. Thus, neurons in motor and cingulate cortex, the nucleus of the diaganol band, septal nucleus, hippocampus, globus pallidus, substantia nigra, subthalamic nucleus, lateral geniculate, deep cerebellar nuclei, brain stem and spinal cord motor nuclei all contain NAAG and NAA immunoreactivity. However, NAA immunoreactivity was more widely distributed than that of NAAG. These results are consistent with previous findings on regional concentrations of NAA and NAAG. Also, they support a functional relationship between NAA and NAAG.

491.16

ISCHEMIC CHANGES OF EXCITATORY NEUROTRANSMITTERS IN RAT HIPPOCAMPUS. J.K. Deshpande, G. Tsai, L. Passani*, and B. Stauch. Dept. of Anesthesiology & Neurosciences, The Johns Hopkins Medical Institutions, Baltimore, MD 21205

Using in vivo microdialysis, we have previously demonstrated that aspartate (ASP), glutamate (GLU), and N-acetylaspartatylglutamate (NAAG) are released from rat hippocampus after global ischemia. To further understand the changes in the metabolism of excitatory neuromodulators after ischemia, we have determined the tissue content of ASP, GLU, and/or metabolic N-acetylaspartate (NAA), a precursor of NAAG and N-acetylated alpha-linked acidic dipeptidase (NAALDase), which changes NAAG to NAA and GLU immediately after global ischemic and then after 96 hr of recovery. Immunocytochemical staining with monoclonal antibodies specific for NAA and affinity-purified antisera for NAAG was performed in rats subject to transient ischemia and after 48, 72, and 96 hr of recovery. In this model, frank neuronal necrosis is evident only after 72 hr. Implications of these results in elucidating the role of NAAG in ischemic neuronal damage are discussed.

491.17

PREFERENTIAL ASTROGLIAL LOCALIZATION OF KYNURENINE AMINOTRANSFERASE IN THE RAT HIPPOCAMPUS. R. Schwarcz, F. Du, W. Schmidt and E. Okuno. Maryland Psychiatric Research Center, Baltimore, MD 21228.

Kynurenine aminotransferase (KAT), the biosynthetic enzyme of kynurenic acid, was recently purified to homogeneity from rat kidney, and its identity with brain KAT was established (Okuno et al., submitted). Using rabbit anti-rat KAT antibodies, we have now studied KAT immunohistochemically in the normal rat hippocampus.

Control experiments, including absorption of antibodies with pure enzyme, showed no immunoreactivity. KAT-immunoreactivity(-i) was predominantly observed in glial cells. In general, these cells had 4-6 primary processes radiating from the cell bodies. They were present in all hippocampal subfields along the rostrocaudal axis. The hilus contained a higher density of KAT-i glial cells than CA1-3 regions, whereas the granule cell layer and the adjacent portion of the molecular layer of the dentate gyrus harbored only a few KAT-i glial cells. As demonstrated by double-labeling with glial fibrillary acidic protein, the vast majority of KAT-i cells appeared to be astrocytes. In addition, sporadic neurons containing KAT-i were also detected, mainly in strata oriens and pyramidale. These neurons probably belong to a subpopulation of interneurons.

The organization of cellular elements containing KAT might be of relevance for the function of kynurenic acid in the hippocampus. (Supported by USPHS grant NS 16102).

491.18

IMMUNOHISTOCHEMICAL LOCALIZATION OF QUINOLINIC ACID PHOSPHORIBOSYLTRANSFERASE IN THE HUMAN NEOSTRIATUM. C.Köhler, F. Du[1], E. Okuno[1], W.O. Whetsell, Jr.[2], and R. Schwarcz[1]. ASTRA Research Center, Södertälje, Sweden, [1]Md. Psych. Res. Ctr., Baltimore, MD 21228, and [2]Dept. Pathology, Vanderbilt Univ., Nashville, TN 37232.

The localization of quinolinic acid phosphoribosyltransferase (QPRT), the degradative enzyme of the endogenous excitotoxin quinolinic acid, was studied in the human neostriatum by immunohistochemistry. In 8 neurologically normal human brains, QPRT-immunoreactivity (QPRT-i) was detected in both glial cells and neurons. Glial cells containing QPRT-i had numerous processes radiating from the cell bodies. In Nissl-counterstained sections, most QPRT-i glial cells showed morphological features of astrocytes. Neurons containing QPRT-i had different sizes and shapes and were tentatively classified into three subpopulations. Most were medium-sized cells with ovoid or elongated perikarya. Small QPRT-i neurons, often spheroid in shape, were particularly noted in a zone of the caudate nucleus adjacent to the lateral ventricle. A few large QPRT-positive neurons were also observed. The somatic and dendritic morphology of QPRT-i neurons resembled that of aspiny neurons seen in Golgi preparations.

The localization of QPRT in distinct populations of neostriatal cells suggests specific functional correlates, and may be relevant for the pathogenesis of basal ganglia disorders. (Supported by USPHS grant NS 28236).

491.19

ANALYSIS OF THE DISTRIBUTION OF A PUTATIVE KAINIC ACID RECEPTOR IN MAMMALIAN BRAIN USING AN ANTI-KAINIC ACID RECEPTOR MONOCLONAL ANTIBODY. J.W. Goh[3], X.-P. Huang*[1], A. Auyeung*[1], C.J. Dechesne[2], R.J. Wenthold[2], M.D. Oberdorfer[2]and D.R. Hampson[1]. [1]Faculty of Pharmacy, University of Toronto, Toronto, Ontario, M5S 2S2; Laboratory of Molecular Otology, National Institutes of Health, Bethesda, MD 20892; [3]Dept. of Pharmacology & Toxicology, Queen's University, Kingston, Ontario, K7L 3N6.

Kainic acid and AMPA receptors mediate fast excitatory synaptic transmission in the CNS. Although the distribution of kainic acid receptors has been studied in a number of species using receptor autoradiography, very little is known about their cellular and subcellular distribution. We have produced a monoclonal antibody against a kainate protein purified from frog brain. This antibody recognizes a protein in rat and mouse that is brain-specific and has a Mr = 99,000. Immunoblot analysis of mouse brain revealed that the Mr = 99,000 protein was not detectable in the hippocampus until postnatal day 7; in the cerebellum, immunoreactivity was not observed at postnatal day 7 but was very intense in adult tissue. The subcellular distribution of this protein was examined by immunoblot analysis of purified subcellular fractions prepared from rat forebrain. The protein was not present in the soluble or myelin fraction but was present in mitochondrial and microsomal membranes and was highly concentrated in synaptic membranes and synaptic junctional fractions. Lesion studies in which domoic acid was microinjected into the amygdala resulted in a decrease in immunostaining in the hippocampus 30 days after injection. These results indicate that this monoclonal antibody recognizes a kainic acid receptor with a Mr = 99,000 and that this receptor is located postsynaptically on nerve cell membranes. Immunocytochemistry at the EM level confirmed these results.

Supported by NSERC and MRC (Canada).

ONTOGENY OF EXCITATORY AMINO ACID RECEPTORS IN RAT BRAIN. R.L. Makowiec, S.Y. Sakurai, J.B. Penney, and A.B. Young. Dept. of Neurology and Neuroscience Program, University of Michigan, Ann Arbor, MI, 48109.

The ontogenetic profile and regional distribution of excitatory amino acid (EAA) receptors were examined using quantitative autoradiography. We measured binding in the outer cortex, striatum, globus pallidus (GP), CA1, CA3, and dentate gyrus (DG) in 1-, 4-, 7-, 10-, and 14-day-old male rat pups. The NMDA receptor complex was labelled using [^{3}H]MK-801, [^{3}H]glycine and NMDA-sensitive [^{3}H]glutamate binding. Ionotropic and metabotropic quisqualate receptors were examined using [^{3}H]AMPA and AMPA-insensitive, quisqualate-sensitive [^{3}H]glutamate binding (AiQsGB), respectively.

From postnatal day (PND) 1 to PND 14 [^{3}H]MK-801 and [^{3}H]glycine binding increased in CA1, outer cortex and striatum while in GP binding remained at low levels. NMDA-sensitive [^{3}H]glutamate binding exhibited a different profile. In striatum, CA1 and CA3 binding peaked at PND 7 and remained constant to PND 14. Binding in GP decreased from PND 1 to PND 14. These data suggest that the various components of the NMDA receptor may be differentially expressed during development.

[^{3}H]AMPA binding increased from PND 1 to PND 14 in all regions examined except in CA3 where binding peaked at PND 7 and remained constant. Metabotropic binding (AiQsGB) peaked at PND 10 in striatum and outer cortex and then decreased at PND 14. In CA1 and DG, metabotropic binding increased during the first two weeks. In CA3, however, binding peaked at PND 7 and then decreased over the next week. Interestingly, in GP the relative amount of metabotropic binding was high at PND 1 and remained at this level through PND 14. These results suggest EAA receptors have unique ontogenetic profiles and may be involved in a variety of developmental CNS processes. Supported by USPHS Grant NS 19613.

EXCITATORY AND INHIBITORY AMINO ACID RECEPTORS IN HUMAN STRIATE CORTEX. W.F. Maragos, R.L. Albin, S.Y. Sakurai, R.L. Makowiec, D.S. Higgins, A. B. Young and J.B. Penney. Dept. of Neurology and Neuroscience Program, University of Michigan, Ann Arbor, MI. 48104.

Quantitative receptor autoradiography was used to determine the distribution of excitatory amino acid and inhibitory amino acid receptors in four human striate cortex specimens. Cytoarchitecture was determined by Nissl and cytochrome oxidase staining. $GABA_A$ receptors were densest in Layers 2-3 and 4C, intermediate in 4B, and lowest in Layers 1 and 5-6. $GABA_B$ receptors had a much lower density in Layers 1-3, intermediate in 4C-6 and lowest in 4B. NMDA receptors were densest in Layers 2-3 and 4C, intermediate in 1 and 4B and lowest in 5-6. Kainate receptors were densest in Layers 1 and 5-6. AMPA receptors were densest in Layers 1-3, intermediate in 5-6 and lowest in 4B-4C. Metabotropic receptors were densest in Layers 1-4A, intermediate in 4B and 5-6 and lowest in 4C. Distinct differences in receptor distribution were noted between areas 17 and 18. Supported by USPHS Grant NS 01300 and AG 06155.

DECREASED QUISQUALATE-SENSITIVE GLUTAMATE BINDING IN THE CEREBELLAR CORTEX OF THE DYSTONIC RAT. M.W. O'Brien, G.A. Oltmans, and J.F. Lorden. Dept. of Pharm. and Mol. Biol., Chicago Med. Sch., N. Chicago, IL 60064 and Dept. of Psych., Univ. of Alabama, Birmingham, AL 35294.

The genetically dystonic rat (*dt*) exhibits a complex and progressive movement disorder initially detectable on post-natal days 9 or 10. No detectable morphologic defects of the nervous system are apparent. The mutant is also insensitive to the tremorogenic effects of the drug harmaline. Recording studies suggest this insensitivity is linked to a defect in the olivo-cerebellar pathway, since few Purkinje cells of the *dt* rat show the typical increase in complex spike activity following harmaline. Recent studies indicate the failure to elicit harmaline-tremor is not due to a failure to activate olivary neurons. Thus the defect in the olivo-cerebellar pathway may, in part, be due to faulty climbing fiber - Purkinje cell (CF-PC) interaction. This study was designed to determine if an abnormality in cerebellar excitatory amino acid (EAA) receptors might contribute to the failure to elicit harmaline tremor.

Serial cerebellar slices from 16-d old *dt* rats were incubated in [3H]glutamate with or without competitors in the presence or absence of 2.5 mM $CaCl_2$. Two-way Analysis of Variance revealed a significant decrease in $CaCl_2$-independent total glutamate binding and quisqualate-sensitive glutamate binding in the cerebellar cortex ($p < 0.05$). Alterations in $CaCl_2$-dependant total and quisqualate-sensitive binding were not statistically significant ($p = 0.12$ and $p = 0.08$ respectively). Neither N-methyl-D-aspartate- nor kainate-sensitive binding appeared to be altered. These data suggest that altered cerebellar quisqualate receptors may contribute to an abnormality in CF-PC communication in the *dt* rat. (Supported in part by the Dystonia Medical Research Found.)

BEHAVIORAL PHARMACOLOGY: OPIATES, NMDA AND OTHERS

492.1

ANALYSIS OF THE DISCRIMINATIVE STIMULUS EFFECTS OF 3,4-METHYLENEDIOXYMETHAMPHETAMINE (MDMA). J. Broadbent, C. A. Metosh, * E. E. Riddle * and J. B. Appel. *Behavioral Pharmacology Laboratory, Department of Psychology, University of South Carolina, Columbia, SC 29208.*

It has been shown that the (+) and (-) isomers of 3,4-methylenedioxamphetamine (MDA) have discriminably different behavioral effects; e. g., (-) MDA is more similar to hallucinogens such as (+) lysergic acid diethylamide (LSD) and (±) 2,5-dimethoxy-4-methylamphetamine (DOM) and is probably more serotonergic than (+) MDA. The extent to which similar effects occur with the isomers of MDMA ("ecstasy"), the n-methyl derivative of MDA, has not yet been clearly established. Rats were therefore trained to discriminate either (+) MDMA (1.25 mg/kg), (+) MDA (1.25 mg/kg), (-) MDA (1.25 mg/kg), (+) amphetamine (1 mg/kg), or LSD (0.16 mg/kg) from saline and were tested with both isomers of MDMA and several related drugs of abuse. Neither (+) nor (-) MDMA resembled (+) amphetamine, cocaine, LSD, DOM or mescaline, independent of the training compound. The 5-HT antagonist pirenpirone did not significantly affect the stimulus properties of (+) MDMA. However, the isomers of MDA and MDMA cross-generalized and, in each instance, the (-) enantiomer was less potent than the (+) enantiomer. These data suggest that the subjective effects of (+) and (-) MDMA are unlike those of stimulants and hallucinogens but do resemble those of MDA.

BEHAVIORAL EFFECTS OF SIGMA LIGANDS: CORRELATION WITH SIGMA AND PCP RECEPTOR AFFINITY. J.G. Wettstein, F.J. Roman* and J.L. Junien*. Institut de Recherche Jouveinal, 3-9 Rue de la Loge, 94265 Fresnes, France.

Drugs thought to have affinity for sigma sites were studied for their effects under a fixed-ratio schedule of food reinforcement in rats. Dose-related decreases in FR responding were observed with each drug. Rimcazole, +PPP and haloperidol were studied for their effects as antagonists of the rate-decreasing effects of JO 1784 (+N-cyclopropylmethyl-N-methyl-1,4-diphenyl-1-ethylbut-3-en-1-ylamine), DTG and +NANM: haloperidol did not attenuate the rate-decreasing effects of JO 1784, DTG and +NANM; rimcazole attenuated the effects of +NANM but not JO 1784; and +PPP attenuated the effects of +NANM but not JO 1784 and DTG. Moreover, BMY 14802 did not antagonize the rate-decreasing effects of +PPP. Drugs were then examined for their capacity to inhibit (3H)DTG, (3H)+PPP, (3H)+NANM and (3H)TCP receptor binding in rat whole brain membrane preparations. For all drugs, the binding IC50's for the 4 radioligands were compared with the doses required to decrease FR responding to 50% of the control rate. These results indicate that in spite of weak correlation coefficients the potencies of the drugs in decreasing FR rate correlated better with their affinities for (3H)DTG and (3H)+PPP sites than for (3H)+NANM and (3H)TCP sites, however, it was difficult to distinguish between purported sigma agonists and antagonists using FR behavior in rats.

492.4

INFLUENCE OF SIGMA LIGANDS ON APOMORPHINE-INDUCED CLIMBING IN MICE. L.R. Moser*, M.A. Krizek*, D.J. McGinness Grimes*, N.L. Katz and R.F. Schlemmer, Jr. Dept. of Pharmacodynamics, University of Illinois at Chicago, Chicago, IL 60612.

The role of sigma sites in the CNS in the mediation of behavior has not been clearly elucidated. One interesting observation is that the sigma ligands BMY14802 (BMY) and rimcazole (RIM) antagonize apomorphine (APO)-induced climbing in mice (Taylor et al, Soc Neurosci Abstr 11:114, 1985; Ferris et al., J Pharm Pharmacol 34:388, 1982), a dopamine-mediated behavior. The purpose of the present study was to test the effect of four sigma ligands that do not bind to dopamine receptors - ditolylguanidine (DTG),(+)3-(3-hydroxylphenyl)-N-(1-propyl)piperidine([+]3-PPP), RIM and BMY - on APO-induced climbing in mice. Male Swiss albino mice (23-38 g) were treated with DTG (1-10 mg/kg) s.c. and APO (0.3-2 mg/kg) s.c. to observe dose-dependent changes for each drug. The effect of DTG (3 mg/kg) was also tested on the dose-dependent changes induced by APO (0.3-2 mg/kg). RIM (1-50 mg/kg), (+)3-PPP (1-30 mg/kg) and BMY (3-30 mg/kg) were given s.c. 30 min. prior to APO (1 mg/kg) s.c. In each experiment, mice were observed every 2 min. for the presence or absence of climbing for 30 min. after APO treatment. APO-induced dose-dependent increases in climbing, but DTG did not. Moreover, DTG did not alter APO-induced changes in climbing. BMY significantly decreased APO-induced climbing in a dose-dependent manner. RIM inhibited APO climbing; however, at effective doses (≥20 mg/kg) tremors and seizures were noted. (+)3-PPP did not alter APO-induced climbing. This study replicated previous data for BMY but failed to extend these findings to two additional sigma ligands (+)3-PPP and DTG. Although RIM antagonized APO climbing, it is not possible to clearly determine if this effect was specific or due to the presence of movement abnormalities. The results do not provide conclusive evidence for a role for sigma mediation of APO-induced climbing behavior in mice.

492.5

MU AND DELTA OPIOID AGONISTS QUIET ISOLATION-INDUCED VOCALIZATIONS IN RAT PUPS. **Susan E. Carden, Gordon A. Barr, Myron A. Hofer. Columbia University, Physicians and Surgeons.**

During the first three weeks of life, rat pups react to separation from the homecage, dam, and littermates by emitting ultrasonic vocalizations. In 10-day olds, these characteristic distress cries are diminished if either a social companion or morphine (0.125mg/kg) are provided. The opioid antagonist naltrexone reverses the quieting effects of a littermate or dam, as well as blocking morphine effects, suggesting a role for opioids in the modulation of early isolation distress.

Isolated 10-day old rat pups received intracisternal injections of agonists specific to the mu, delta, or kappa opioid recectors, (DAGO (0.001ug - 0.0625ug), DPDPE (0.3ug - 3.0ug) and U50-488 (1.0ug - 100ug). The rate of vocalization was monitored for 6 minutes. Pups were evaluated for sedation and each injection site was verified. Mu and delta agonists DAGO and DPDPE decreased the number of distress cries in non-sedated animals, while the kappa agonist U50-488 left vocalization rates unchanged.

492.6

ENHANCED SENSITIVITY TO NALTREXONE IN RATS: EFFECTS ON SALIVATION AND OPIOID RECEPTOR BINDING. C.W. Schindler, X.-Z. Wu*, T.-P. Su, E.B. Thorndike*, S.R. Goldberg* and J.L. Katz. NIDA Addiction Research Center, Baltimore, MD 21224.

Previous research (JPET 252: 8-14) showed that rats develop enhanced sensitivity to the effects of naltrexone (NAL) on operant responding when it is given in a cumulative dosing manner once per week. Enhanced sensitivity was also observed to the salivation produced by NAL. The purpose of the present experiment was to determine if the enhanced sensitivity observed for salivation would also occur independent of operant responding, and to determine whether any changes in opioid receptor binding would be observed following the regimen of NAL treatment. Rats were treated with NAL once weekly in a cumulative dosing procedure. The rats were initially given an i.p. injection of 1 mg/kg NAL followed 13 min later by a 2 mg/kg injection and so on until five injections had been given (1, 2, 7, 20 and 70 mg/kg) for total cumulative doses of 1, 3, 10, 30 and 100 mg/kg. Salivation was scored on a 3 point scale. Initially, no salivation was observed at any dose; however, over the course of an 8-week period, increasing amounts of salivation were observed at the 10, 30 and 100 mg/kg doses. This effect was long-lasting. After a period of 10 weeks during which no NAL was given, NAL produced similar degrees of salivation as after week 8. Animals injected with saline for 8 weeks showed no salivation and saline given to the animals which had received NAL had no effect. As with the enhanced sensitivity observed on operant responding, the salivation appeared to extinguish to lower doses when the higher doses of NAL were omitted. A separate group of 6 rats was treated with NAL for 8 weeks as above. One week following the last NAL treatment, their brains were removed and assayed for opioid receptors. In comparison to animals that were treated with saline for 8 weeks, mu receptors were unchanged in all brain areas assayed. Kappa and delta receptors were increased in an area containing primarily cortex, and delta receptors were decreased in midbrain. These results indicate that enhanced sensitivity to NAL can develop independently of operant responding and is correlated with some changes in opioid receptors.

492.7

DIPRENORPHINE DRUG DISCRIMINATION: ASSESSMENT OF NALTREXONE AND NALOXONE SUBSTITUTION. S. Smurthwaite and A.L. Riley. The American University, Washington, D.C. 20016.

DeRossett and Holtzman (J. Pharmac. Exp. Ther., 237: 437-444, 1986) have recently reported that monkeys were able to discriminate between the opiate antagonist diprenorphine HCl and its vehicle. However, other opiate antagonists failed to substitute for the diprenorphine cue. Paradoxically, opiate agonists did substitute for diprenorphine. Because Geter and her colleagues (Neurosci. Abst., 15:248, 1989) have recently demonstrated generalization between diprenorphine and naloxone in naloxone-trained subjects within a taste aversion procedure, the present experiment reexamined drug discrimination learning with diprenorphine within this design. Specifically, every fourth day for 13 conditioning trials rats were administered diprenorphine (3.2 mg/kg) 15 min prior to a saccharin-LiCl pairing. On intervening days, they received the diprenorphine vehicle 15 min prior to saccharin alone. Following acquisition of the discrimination, both naltrexone (0.18 to 10 mg/kg) and naloxone (0.32 to 32 mg/kg) substituted for diprenorphine, while the opiate agonist morphine (3.2 to 10 mg/kg) did not. The present data are consistent with other work within the taste aversion design demonstrating generalization between the opiate antagonists.

492.8

CHARACTERIZATION OF A NOVEL CLASS OF POTENT AND SELECTIVE SIGMA LIGANDS. P. C. Contreras, M. Bremer, L. Christine *, S. Iyengar, V. Dilworth, B. Cheng* and N. M. Gray*. CNSDR, G. D. Searle & Co., St. Louis, MO 63198.

Much less is known about sigma than phencyclidine (PCP) receptors because there are very few selective sigma ligands. The purpose of this study was to characterize the biological activity of a novel class of sigma ligands, 9,10-ethanoanthracene-like compounds and related analogs, which interacted selectively with sigma, but not PCP receptors. SC-48960 and SC-49574, two of the more potent sigma ligands in this series, had very weak affinity for $alpha_1$-, $alpha_2$-, $beta_2$-adrenergic or $dopamine_1$ receptors. SC-48960 had moderate affinity for muscarinic, $serotonin_2$ and $dopamine_2$ receptors, but SC-49574 had no affinity for these receptors. SC-48960 and SC-49574 did not produce any stereotyped behavior or ataxia in rats, but antagonized (+)SKF-10,047-induced stereotyped behavior and ataxia. These results indicate that SC-48960 and SC-49574 are potent and selective sigma ligands capable of antagonizing some of the behavioral effects of sigma ligands.

492.9

CENTRAL ADMINISTRATION OF ß-CASOMORPHINS AFFECT ANTINOCICEPTIVE BEHAVIOR IN NEONATAL RATS. J.M.C. Blom*, E.M. Blass and S. Hulse. Dept. of Psychology, Johns Hopkins University, Baltimore, MD 21218.

ß-casomorphins (ß-CMs) represent a group of opioid peptides derived from the enzymatic digests of a milk protein (ß-casein). ß-CMs are an interesting class of substances because they provide a means through which mother's milk may affect infants, possibly through an opioid pathway. A number of experiments in adult rats have demonstrated antinociception after central administration of ß-CM.

In the present studies (Exp. 1) we evaluated in day 10 rats the antinociceptive potencies of ß-CM injected intracerebroventricularly (ICV). In Exp. 2, by centrally injecting naloxone, we evaluated whether the antinociceptive effects of ß-CM were opioid mediated.

In Exp. 1, 10-day-old rat pups were injected ICV either with .25 Ug ß-casomorphin-5 (TYR-PRO-PHE-PRO-GLY), .25 Ug morphine (for comparison) or isotonic saline, in a volume of 1 Ul. Pain responsivity was assessed 20, 40 and 60 min. post injection by placing the rats left forepaw on a hotplate (48°C). Paw lift latency (PLL) increased significantly for pups injected with ß-CM and morphine when compared with saline injected pups. Increased PLL lasted for at least 60 min. In Exp. 2 pups received an ICV injection of either .25 Ug naloxone or isotonic saline, followed immediatly by an IP injection of either .5 mg/kg ß-CM-5, .1 mg/kg morphine or isotonic saline. ICV pretreatment with naloxone blocked the decrease in heat nociception caused by ß-CM-5 to a level comparable to that of saline.

These results demonstrate that ß-CM can influence antinociceptive behavior in infant rats through a central mechanism that seems to be opioid mediated.

492.10

DRUG-DRUG DISCRIMINATION WITH THE OPIATE ANTAGONISTS NALOXONE AND DIPRENORPHINE. M.A. Kautz and A.L. Riley. The American University, D.C. 20016.

Recently, it has been reported that diprenorphine substitutes for naloxone in subjects trained to discriminate naloxone from distilled water (Geter et al., Neurosci. Abstr., 15:248, 1989), suggesting that there are similarities between the stimulus properties of the two drugs. Given that the two drugs have differential affinities for the various subtypes of the opiate receptor and that animals can differentiate between opiate agonists that differ in this regard, the present study attempted to train animals to discriminate between naloxone and diprenorphine. Specifically, rats with a history of discriminating naloxone from distilled water in a conditioned taste aversion/drug discrimination procedure were given naloxone prior to a saccharin-LiCl pairing and diprenorphine prior to saccharin alone. Although diprenorphine initially substituted for naloxone, with repeated training subjects acquired the discrimination. In subsequent generalization tests, the substitution was selective with naltrexone generalizing to naloxone and nalorphine generalizing to diprenorphine. The discrimination and the subsequent substitution profiles are consistent with their differential receptor activity.

492.11

THE ANTAGONISM OF THE MORPHINE STIMULUS IN DRUG DISCRIMINATION LEARNING: AN ASSESSMENT WITHIN THE TASTE AVERSION DESIGN. S. Pournaghash, G. Stevenson* and A. L. Riley. The American University, Washington, D. C. 20016.

Putative antagonists can be given concurrent with the training drug in a drug discrimination learning procedure (DDL) to assess the ability of the antagonist to block the stimulus properties of the compound. That DDL within the taste aversion design is so rapidly acquired and robust may preclude this antagonism. This possible limitation was addressed in the present experiment. Following the establishment of a morphine discrimination (5.6 mg/kg), naloxone (1 mg/kg) was given either 10, 30, 60 or 180 min prior to the administration of morphine. When naloxone preceded morphine administration by 10 and 30 min, it completely antagonized the discriminative effects of morphine. By 60 min, naloxone no longer antagonized the discriminative effects. That naloxone blocked the discriminative effects of morphine at these intervals is consistent with other work on the interaction of naloxone and morphine in more traditional DDL designs and indicates that the rapid acquisition of DDL within the taste aversion procedure does not necessarily preclude its utility in assessing drug antagonism.

492.12

BEHAVIORAL EFFECTS OF THE NON-COMPETITIVE NMDA ANTAGONIST MK801 IN INFANT AND PREWEANLING RAT PUPS. L. Rajachandran, G. Goodwin and L.P. Spear, Dept. of Psychology and Center for Developmental Psychobiology, SUNY Binghamton, NY 13901.

Neonatal (3-4 day old) and preweanling (17-18 day old) Sprague Dawley rat pups were tested following the administration of (0) saline, .01, .05, .5, .1 and 1mg/kg MK801 s.c. Pups were observed in a premilk/milk test situation 30 and 60 minutes post injection. Behaviors were sampled for 5 seconds every 20 sec. for 5 minutes in each condition. In neonatal rat pups, reductions in a number of behaviors (forward locomotion, mouthing) were seen at the higher (.5 and 1mg/kg) doses. In contrast, evidence of behavioral stimulation was seen at a lower dose (.1mg/kg) in forward locomotion at 30 min. post injection. In preweanling rat pups, marked sedative effects of MK801 were seen at higher doses (decreases in forward locomotion, headlift and sniff) with signs of behavioral stimulation (increases in forward locomotion and mouthing) evident at low doses. Thus, as in adults, low doses of MK801 are behaviorally stimulatory and higher doses inhibitory to both neonatal and preweanling pups, although these effects are somewhat more pronounced in preweanling than neonatal rat pups. Investigation of the behavioral consequences of NMDA antagonists such as MK801 is important, given the possible therapeutic potential of these substances for use in young organisms.

492.13

ANTIPUNISHMENT EFFECTS OF NPC 12626 DURING ACUTE AND REPEATED DOSING IN RATS. **J.L. Wiley, J.H. Porter, A.D. Compton, and R.L. Balster. Depts. of Psych. and Pharm./Tox., VA Commonwealth Univ., Richmond, VA 23284.**

Rats were tested in a modified Geller-Seifter (1960) conflict test (MULT FI 60-sec FR 1) to determine if the competitive NMDA antagonist, 2-amino-4,5-(1,2-cyclohexyl)-7-phosphonoheptanoic acid (NPC 12626), would produce an increase in punished responding during acute and repeated dosing. Chlordiazepoxide (CDP) and phencyclidine (PCP) also were tested.

During separate acute dose determinations, NPC 12626 (30 and 56 mg/kg), CDP (10 mg/kg), and PCP (4 mg/kg) produced selective increases in punished responding relative to vehicle. During a six day repeated dosing procedure, the 30 mg/kg dose of NPC 12626 produced a selective increase in punished responding during 5 of the 6 days. PCP (2 mg/kg) produced a selective increase in punished responding on 3 of the 6 days; whereas, the 5 mg/kg dose of CDP produced significant increases in both punished and unpunished responding on 3 of the 6 days. These results demonstrate that the competitive NMDA antagonist NPC 12626 has selective antipunishment effects in an antianxiety animal model.

492.14

CHRONIC TREATMENT WITH MK801 PRODUCES TOLERANCE TO THE BEHAVIORAL EFFECTS. L.M. Ford, P.R. Sanberg, S.R. King*, and A.B. Norman. Division of Neuroscience, Departments of Psychiatry and Neurology, University of Cincinnati College of Medicine, Cincinnati, OH 45267.

Acute systemic injection of MK801, a non-competitive N-methyl-D-aspartate (NMDA) receptor antagonist induces locomotor hyperactivity, decreased rearing behavior and increased stereotypy (Ford et al., Physiol. and Behav. 46:755-758, 1989). Following chronic treatment with a number of receptor antagonists a tolerance to the behavioral effects is observed. We therefore compared the topography of MK801-induced locomotor activity after acute and chronic treatment to evaluate the possibility of tolerance or sensitization. Rats (n=8) received 0.5 mg/kg i.p. once daily for 21 days; locomotor activity was measured after the 1st (acute) and 21st (chronic) injection using the Digiscan Animal Activity Monitor. The increased ambulation (horizontal activity) was not significantly different between acute and chronic MK801 treatments. Rearing behavior was reduced following acute MK801 treatment compared to saline treated controls ($p<0.05$). However, following 21 days of treatment these MK801-induced reductions in rearing behavior were reversed and in some cases were elevated above control values. Thigmotaxis (wall hugging behavior), decreased with chronic treatment ($p<0.05$). Thus, chronic treatment with MK801 produced adaptations in the topography of locomotor activity of rats representative of tolerance to the behavioral actions of MK801. It is possible that neurochemical adaptations may underlie these adaptations in behavior. Supported by University of Cincinnati Research Council, Childrens Hospital (Cincinnati) and NINDS.

492.15

USE OF THE PIGEON CONFLICT PROCEDURE TO CHARACTERIZE ANXIOLYTIC DRUG ACTIVITY: EVALUATION OF N-METHYL-D-ASPARTATE ANTAGONISTS. W. Koek*, M.J. Brocco*, J.C.R. Randle and F.C. Colpaert*. FONDAX - Groupe de Recherche SERVIER, 7 rue Ampère, 92800 Puteaux, FRANCE.

The antipunishment effects of the clinically effective anxiolytics chlordiazepoxide (CDP), buspirone and ritanserin were evaluated using conflict procedures in rats (Vogel, Geller-Seifter) and in pigeons (Barrett). In rats, only CDP was found to have significant antipunishment activity. In pigeons, however, antipunishment effects were produced not only by CDP, but also by buspirone and ritanserin.

Because of its apparent effectiveness in detecting non-benzodiazepine anxiolytic agents, the pigeon conflict procedure was used to evaluate possible antipunishment activity of various N-methyl-d-aspartate antagonists. Punished responding was significantly increased by competitive NMDA antagonists (i.e., CPP and CGS 19755), but not by non-competitive NMDA antagonists acting at the NMDA receptor-associated ion channel (i.e., phencyclidine, ketamine and MK-801). In preliminary experiments, non-competitive NMDA antagonists thought to act at the NMDA receptor-associated glycine site (e.g., kynurenic acid, 7-chloro-kynurenic acid) failed to show significant antipunishment effects.

492.16

INDOMETHACIN ATTENUATION OF RADIATION-INDUCED HYPERTHERMIA DOES NOT AFFECT RADIATION-INDUCED HYPOACTIVITY. J.L. Ferguson, S.B. Kandasamy, A.H. Harris, M.R. Landauer and H.D. Davis. Dept of Behavioral Science, AFRRI, Bethesda, MD 20814-5145.

Exposure of rats to 5-10 Gy of high-energy electrons produces hyperthermia and reduces motor activity. Previous studies using a 60Co source suggest that radiation-induced hyperthermia results from a relatively direct action on the brain and is mediated by prostaglandins. To test the hypothesis that hypoactivity may be, in part, a thermoregulatory response to this elevation in body temperature, adult male rats were given indomethacin (0.0, 0.5, 1.0, 3.0 mg/kg, I.P.) and either irradiated (LINAC 18.6 MeV high-energy electrons, 10 Gy at 10 Gy/min, 2.8 usec pulses at 2 Hz) or sham-irradiated. The activity of all rats was then measured for 60 min in a photocell monitor for distance travelled and number of vertical movements. Rectal temperatures of irradiated rats given only vehicle were elevated by 0.9-1.1°C at both the beginning and end of the activity session. Indomethacin, at any dose, attenuated radiation-induced hyperthermia. Irradiated rats showed less motor activity than sham-irradiated rats. The decreased motor activity of the irradiated rats was not affected by any dose of indomethacin. These results suggest that the increased body temperature following irradiation is probably not a cause for the decreased motor activity.

492.17

GENETIC DIFFERENCES IN CONDITIONED TASTE AVERSION. N. E. Colley[1] and A. C. Collins [1,2]. [1]Psychology Department and [2]Institute for Behavioral Genetics, University of Colorado, Boulder, CO 80309.

Variability exists in the acquisition of illness-induced consumatory aversions. In an attempt to ascertain if genetic factors contribute to this variability, male mice from 6 inbred strains (A/J/Ibg, C3H/2Ibg, C57BL/6J/Ibg, DBA/2J/Ibg, BUB/BnJ, ST/bJ) were tested for differences in the propensity to develop conditioned taste aversion. Mice were injected with either nicotine (2 mg/kg) or cyclophosphamide (15 mg/kg) after an ingestion of a novel saccharin solution. Preference testing between water and saccharin was conducted over a 36 day time period. Dose response curves (0-2 mg/kg for nicotine and 0-25 mg/kg for cyclophosphamide) were constructed for 3 of the 6 inbred strains of mice (C3H/2Ibg, C57BL/6J/Ibg, DBA/2J/Ibg). Evidence suggests that there is genetic differences in the acquisition and extinction of conditioned taste aversion and that these differences appear to be dose dependent.

DIFFERENTIAL EFFECTS OF A1 AND A2 ADENOSINE RECEPTOR ANTAGONISTS ON PLACE CONDITIONING AND MOTOR ACTIVITY IN RATS. N.T. Brockwell and R.J. Beninger. Dept. Psychology, Queen's University, Kingston, K7L 3N6, Canada.

The recent development of potent antagonists which are relatively selective for A1 and A2 adenosine receptors has made it possible to assess the role of each receptor subtype in modulating behavior. The present study utilized newly developed apparatus which is capable of simultaneously measuring spontaneous motor activity and place conditioning, the most commonly used behavioral measure of drug reward. The experimental design consisted of 3 phases conducted over 12 successive days. During 3 preconditioning sessions, undrugged male Wistar rats received access to two distinctive chambers connected by a small tunnel. During the 8-session conditioning phase, groups were administered either the A1 antagonist CPX or the A2 antagonist CGS 15943 and confined to one of the chambers. On alternate sessions rats were injected with the vehicle and confined to the opposite chamber. On the test session, undrugged animals were again allowed access to both chambers. Results indicate that both 0.1 and 1.0 mg/kg IP CGS 15943 produced significant hyperactivity; 1.0 mg/kg IP CGS 15943 also produced a significant place preference. CPX (0.1 and 1.0 mg/kg IP) failed to significantly alter activity or induce place conditioning. Using an identical procedure, (+)-amphetamine (2.0 mg/kg IP) produced both significant hyperactivity and a place preference as expected. These results suggest the positive behavioral effects previously found with the non-specific adenosine antagonist caffeine (Brockwell, Eikelboom, & Beninger, Neurosci. Abstr., 1988) may be mediated by the A2 receptor subtype. (Funded by NSERC)

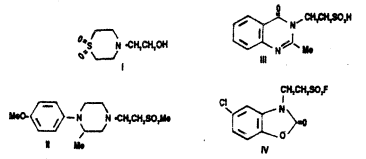
EFFECT OF SYNTHETIC ANALOGS OF TAURINE ON AUDIOGENIC SEIZURES, ETHANOL-INDUCED SLEEPING TIMES AND SYNAPTOSOMAL CALCIUM BINDING. R.J. Huxtable, R. Gupta*, R. Bowers* and K. Izumi**). Department of Pharmacology, University of Arizona, College of Medicine, Tucson, Arizona 85724; *)Department of Pharmacology, Faculty of Medicine, Kagoshima University, Kagoshima 890, Japan.

Taurine occurs in mM concentration in the brain. In vitro, taurine (25 mM) stimulates the high affinity binding of 6 μM Ca^{2+} to brain synaptosomes in a manner which is antagonized by the taurine antagonist, TAG (*Pharmacologist 30, A86, 1988*). Analogs of various structural types have now been synthesized which also produce a TAG-antagonized stimulation of Ca^{2+} binding. This **I** (10 mM) increases the binding of Ca^{2+} by 18%. Additionally, other compounds inhibit the binding of Ca^{2+} to brain synaptosomes in a manner antagonized by taurine itself. Thus, **II** (25 mM) produces a 34% decrease in Ca^{2+} binding. Taurine significantly reduces ethanol-induced sleeping time in mice without affecting blood ethanol concentration. A number of analogs mimic this action. For example, **III** (0.43 mMol/kg i.p.) significantly reduced sleeping time from 82 min to 66 min. Certain analogs also offered protection against sound-induced seizures in rats. Thus, **IV** (0.3 mMol/kg^{-1} i.p.) prevented seizures in 3 of 6 rats of the minimal seizure strain and 3 of 4 rats of the maximal seizure strain.



CELLULAR BIOLOGY OF 5HT RECEPTORS

493.1

FUNCTIONAL EVALUATION OF SEROTONIN 1C AGONISTS AND ANTAGONISTS BY INTRACELLULAR CALCIUM RELEASE AND PHOSPOINOSITIDE HYDROLYSIS IN A CELL LINE EXPRESSING A RECOMBINANT SEROTONIN 1C RECEPTOR. M. Baez, P. A. Hyslop* J. E. Audia, P. Q. Mooney* and L. Yu+. Lilly Research Laboratories, Lilly Corporate Center, Indianapolis, IN 46285; +Dept. of Medical Genetics, Indiana University School of Medicine, Indianapolis, IN 46223 USA.

AV12 cells were stably transformed with an expression vector, pHD, containing a full length clone of the mouse serotonin (5HT) 1C receptor. RNA hybridization and ligand binding studies confirmed the expression of the 5HT1C receptor in the recombinant cell line A1C-19. Stimulation of the A1C-19 cells with 5HT and known 5HT1C agonists resulted in release of intracellular calcium which was detected by dye fluorescence. This response was blocked by known 5HT1C receptor antagonists. The functional coupling of the 5HT1C receptor to phospholipase C in A1C-19 cells was further demonstrated by increased phosphoinositide hydrolysis in response to 5HT. These studies indicate that the A1C-19 cell line will be useful in evaluating novel 5HT1C receptor agonists and antagonists.

REGULATION BY GUANINE NUCLEOTIDES OF MEMBRANE BOUND AND SOLUBILIZED MELATONIN RECEPTORS FROM CHICKEN BRAIN. K.C. Chung and M.L. Dubocovich. Dept. Pharmacology, Northwestern Univ. Med. Sch., Chicago, IL 60611.

In this study we examined the effect of guanine nucleotides on the binding of the melatonin agonist 2-[^{125}I]-iodomelatonin (2-IMEL) in P_2 membranes and (0.5 %) digitonin-solubilized fractions of chicken brain (5 weeks old). These fractions were prepared in 50 mM Tris-HCl buffer (20 % glycerol, 1 mM EDTA, 1 mM PMSF, 1 mM mercaptoethanol, 10 mM Mg_2Cl, pH 7.4). The affinity (Ki) of 6-chloromelatonin for 2-IMEL was lower in solubilized fractions before (12 nM) or after (16.6 nM) elution through a G-100 column, than in membrane fractions (Ki = 214 pM). Guanine nucleotides inhibit 2-IMEL binding in membranes [GTPγS (Ki = 900 nM) < GTP << GMP], but not in the soluble fraction. GTPγS (0.1 mM) decreased the Bmax from 14.2 to 6.1 fmol/mg protein with no change in the K_D (234 pM) in membranes, but not in the soluble fraction (K_D = 44.5 ± 17 pM, Bmax = 4.1 ± 1.6 fmol/mg protein, n=3). Following reconstitution of CHAPS solubilized fractions with asolectin the GTPγS sensitivity for 2-IMEL binding was restored. We conclude that decoupling of melatonin receptors from G-proteins may account for the reduced affinity of 2-IMEL in solubilized fractions. Supported by USPHS grants MH 42922 (MLD) and NS 01740 (KCC).

SEROTONIN POTENTIATES ADENOSINE RECEPTOR-MEDIATED INCREASES OF cAMP IN MICROVASCULAR SMOOTH MUSCLE CELLS IN CULTURE. K.A. Berg[1], C.A. Diglio[2] and S. Maayani[1,3]. Depts. of Anesthesiology[1] and Pharmacology[3], Mount Sinai School of Medicine, CUNY, NY, NY 10029, and Dept. of Pathology[2], Wayne State University School of Medicine, Detroit, MI 48201.

Cerebral blood flow is modulated by alteration of blood vessel tone. This alteration can be achieved by simultaneous activation of multiple receptor-linked signal transduction pathways. We have chosen, as a model system, to study the effect of 5-hydroxytryptamine (5-HT, serotonin) on adenosine receptor-mediated cAMP production in vascular smooth muscle cells derived from rat cerebrocortical resistance vessels. Incubation (15 minutes) with 5'-N-ethylcarboxamidoadenosine (NECA, adenosine A_2 agonist; EC_{50}= 2 μM) increased cAMP production a maximum of 4-5 fold. 5-HT (10 μM) alone produced only a small increase in cAMP levels, however, it increased (2-fold) the maximal cAMP produced by NECA and shifted the NECA concentration response curve to the left (2-3 fold). The EC_{50} for 5-HT was approximately 1 μM. In addition, forskolin (1 μM)-stimulated cAMP levels were also enhanced by 5-HT. The potentiation of NECA-induced cAMP production by 5-HT was antagonized by the presence of the 5-HT_2 antagonists, ketanserin and spiperone, and mimicked by the selective 5-HT_2 agonist, 1-(2,5-dimethoxy-4-iodophenyl)-2-aminopropane (DOI). Incubation with the active phorbol ester, phorbol 12-myristate 13-acetate (PMA, 1 μM), but not the inactive phorbol ester, 4α-12,13-didecanoate (PDD, 1 μM), enhanced the cAMP response to NECA in a fashion comparable to that of 5-HT. Furthermore, protein kinase C (PKC) activity was increased (approximately 60%) following incubation with 5-HT for 15 minutes. These data suggest that the potentiation of NECA- and forskolin-induced cAMP production in resistance vessel smooth muscle cells by 5-HT is mediated via 5-HT_2 receptor activation of PKC. 5HT RECEPTORS ON CARCINOID TUMOR CELLS IN CULTURE
Haber, B., Lakoski*, J., Black*, E., Karp*, G., Parekh*, D., Townsend*, C., Thompson*, J. C., and Ishizuka*, J. Marine Biomed. Inst., Depts. of Pharmacol., Surgery, and Human Biol. Chem. and Genet., Univ. of Texas Med. Branch, Galveston, TX 77550

Cultured BON cells of carcinoid tumor origin contain high basal levels of 5HTP, 5HT, and 5HIAA as well as chromogranin, calcitonin, neurotensin, and pancreastatin (PS). 5HT and PS are released from BON cells by Ach (blocked by atropine) and by isoproterenol. 10^{-8} M 5HT. BON cells release PS in vitro upon stimulation with The presence of binding sites for a 5HT autoreceptor on cultured BON cells was assessed using [^{3}H]8-OH-DPAT (8-hydroxy-2(di-n-propylamino)tetralin selective agonist for $5HT_{1A}$ binding site. Scatchard analysis was done on a P2 tissue suspension prepared in Tris buffer (pH 7.4). Data shows significant numbers of $5HT_{1A}$ binding sites on BON cells (B_{max} +41.7+13.7 fmol/mg prot.) with a K_d of 3.0+1.8nM. Additional controls included analysis of hippocampal tissue with expected K_d(9.1nM) and B_{max}(445 fmol/mg prot.). Taken together, these data suggest that the release of 5HT from BON cells in vitro and carcinoid tumors in vivo may regulate the release of PS and other peptides via $5HT_{1A}$ autoreceptors.

Supported by ACS PDT-220, a grant from Sigma Tau and AG00450.

493.5

DOWN-REGULATION OF THE $5HT_{1B}$ RECEPTOR IN OPOSSUM KIDNEY (OK) CELL MEMBRANES R.C. Pleus and D.B. Bylund, Dept of Pharmacol, Univ of Neb Med Ctr, Omaha, NE, 68198.

We are investigating the regulation of the $5HT_{1B}$ receptor using membrane binding studies and functional assays. We observe a 40% decrease in $5HT_{1B}$ receptors in OK cell membranes when cells are pretreated for 16 hr with 10 μM 5HT and in the absence of fetal bovine serum (-FBS) using ^{125}I-cyanopindolol (1 to 124 pM) as the radioligand. OK cells were plated at $6x10^6$ cells per 150 mm culture dish and grown for 3 or 7 days. Cells harvested on day 7 yielded higher B_{max} values (~ 2x). FBS has an effect in these experiments. When cells are exposed to 5HT in the presence (+) of FBS, B_{max} values are not different, however, control -FBS have higher B_{max} values than +FBS.

		Day Harvested	K_D (pM)	B_{max} fmol/mg protein	n
Control	- FBS	7	48 ± 4	71 ± 14	3
	+ FBS	7	54 ± 4	49 ± 6	2
	+ FBS	3	40 ± 3	26 ± 2	4
5HT	- FBS	7	68 ± 12	43 ± 10	3
	+ FBS	7	76 ± 29	34 ± 8	2
	+ FBS	3	40 ± 12	22 ± 3	4

(*control -FBS vs 5HT -FBS, B_{max} p = 0.03, K_D p = 0.1115; control +FBS vs 5HT +FBS, B_{max} p = 0.095, K_D p = 0.479, one-tailed paired t-test)

In a functional assay (5HT inhibition of parathyroid hormone (PTH) stimulated cAMP) using intact OK cell cultures under -FBS conditions (as above), 5HT inhibits PTH-stimulated cAMP in a dose-response manner. When 0.1 to 10% of FBS is added to the assay, FBS in the presence of PTH inhibits cAMP production in a dose-dependent manner and is attenuated by 2 μM methiothepin. These studies demonstrate 1) down-regulation of the $5HT_{1B}$ receptor and 2) an FBS-related effect, which should be considered when undertaking such studies. (NIH grant GM37664)

493.6

REGULATION OF 5-HT_2 RECEPTORS ON P11 CELLS BY SEROTONIN. K.J. Ivins and P.B. Molinoff. Department of Pharmacology, University of Pennsylvania, Philadelphia, PA 19104.

P11 cells express a high density of 5-HT_2 receptors coupled to phosphoinositide (PI) hydrolysis. The effect of exposure to serotonin (5-HT) on the expression and function of 5-HT_2 receptors in P11 cells was investigated. In these experiments, PI hydrolysis was measured by the accumulation of ^{3}H-inositol phosphates in the presence of LiCl and drugs. The ability of 5-HT to stimulate PI hydrolysis was greatly reduced or absent following exposure of P11 cells to 10 μM 5-HT for 8 hr. The desensitization of 5-HT_2 mediated PI hydrolysis by 5-HT was time- and concentration-dependent. Exposure of P11 cells to 10 μM 5-HT for as short a time as 20 min led to a decrease in the ability of 5-HT to stimulate PI hydrolysis. With longer periods of exposure, concentrations of 5-HT as low as 100 nM caused desensitization of PI hydrolysis. Stimulation of PI hydrolysis by the α_1-adrenergic agonist 6-fluoronorepinephrine was not affected by prior exposure of cells to 5-HT, suggesting that the desensitization was selective for 5-HT_2 mediated PI hydrolysis. The density of 5-HT_2 receptors in membranes prepared from P11 cells was measured using ^{125}I-LSD. Exposure of P11 cells to 5-HT resulted in a decrease in the density of 5-HT_2 receptors with no change in the affinity of the receptors for ^{125}I-LSD. The decrease in the density of receptors was rapid and pronounced. A decrease in receptor density was observed following exposure to 10 μM 5-HT for 1 hr; after 24 hrs the density of 5-HT_2 receptors was approximately 20% of the original value. A decrease in the density of 5-HT_2 receptors after exposure of P11 cells to 5-HT may be involved in desensitization of 5-HT_2 mediated PI hydrolysis. (Supported by USPHS NS18591).

GENERATION OF A DNA PROBE FOR THE $5HT_{1b}$ RECEPTOR IN THE OK CELL, AN OPOSSUM KIDNEY CELL LINE. D.R. Cerutis and D.B. Bylund. Department of Pharmacology, University of Nebraska Medical Center, Omaha, NE 68198-6260.

Previous studies from our laboratory (Murphy, T.J., and Bylund, D.B., Mol. Pharmacol. 34:1-7, 1988) have demonstrated the presence of the serotonin $5HT_{1b}$ receptor in the OK cell line, an established renal proximal tubule epithelial cell line. In order to generate a probe for this receptor, the published sequences of G-21, $5HT_{1c}$ and 5HT-2 were used to design degenerate primers directed at the highly conserved sequences in the third and sixth transmembrane domains. OK cell RNA was isolated using an Applied Biosystems nucleic acid extractor. Approximately 2μg of this RNA was reverse transcribed using Moloney Murine Leukemia Virus reverse transcriptase and the resulting cDNAs subjected to 30 cycles of PCR with the above primers. The resulting product of about 0.7 kb is consistent with the calculated size of this region from the published sequences of other serotonin receptors. This 0.7 kb fragment also hybridizes with an oligonucleotide directed towards the fifth transmembrane region of the other published serotonin receptors. This 0.7 kb product is currently being used to screen a lambda gt11 OK cell cDNA library. (supported by NIH grant GM 40784)

493.8

PHARMACOLOGICAL CHARACTERIZATION OF A CLONED HUMAN 5-HT_{1D} RECEPTOR. J. M. Zgombick, R.L. Weinshank', M. Macchi', P. Hartig, and T.A. Branchek. Neurogenetic Corporation, Paramus N.J. 07652

We have recently isolated a DNA sequence encoding a human 5-HT_{1D} receptor. This new serotonergic receptor gene encodes a protein whose amino acid sequence displays relatively low transmembrane homology to other human G protein-coupled receptors: 5-HT_{1A} (56%), 5-HT_2 (43%), dopamine D_2 (46%), and α_{2A} (45%). Murine fibroblast Ltk' cells were stably transfected with the DNA encoding this newly derived human receptor gene, membranes were harvested, and radioligand studies were conducted. Occupancy studies demonstrated that [^{3}H]-5HT bound with high affinity (K_d=3.9±0.9 nM) and in a saturable manner (B_{max}=4.4±1.0 pmol/mg prot.). Competition studies revealed a pharmacological profile with rank order of potency: 5CT ≥ 5HT >> TFMPP > DPAT > DOI > Pindolol > ICS 205-930. The coupling of this receptor to G protein(s) was assessed in binding studies using the non-hydrolyzable guanine nucleotide analog, 5'-guanylylimidodiphosphate (Gpp(NH)p). Gpp(NH)p decreased specific [^{3}H]-5HT binding by 25±3 % in a concentration-dependent manner with an IC_{50} of 4.1±1.1 μM. These properties are consistent with the identification of this new clone as a human 5-HT_{1D} receptor. The existence of multiple subtypes of 5-HT_{1D} receptor has been suggested previously (Xiong and Nelson, Life Sci. 45:1433, 1989). The present clone will provide a useful tool to explore this possibility in the human genome. Further, it has been shown that closely related receptors of the same subfamily (e.g. α_{2A}, α_{2B}, α_{2C}) generally display approximately 75% transmembrane homology; in contrast, receptors from different subfamilies (e.g. 5-HT_{1A} vs. 5-HT_2) exhibit only 45-50% transmembrane homology. Therefore, we propose that the cloned human 5-HT_{1D} receptor constitutes the first member of a new subfamily of serotonin receptors.

493.9

DENSITY-DEPENDENT REGULATION OF AFFINITY STATES OF THE CLONED HUMAN 5-HT_2 RECEPTOR. N. Adham*, M. Macchi*, H-T. Kao*, P. Hartig, and T. Branchek. Neurogenetic Corporation, Paramus, N.J. 07652

We have recently reported that the cloned human 5-HT_2 receptor binds both ^{3}H-DOB and ^{3}H-ketanserin, supporting the hypothesis that the DOB binding site represents the agonist high affinity state of the 5-HT_2 receptor. (Hartig et al, ACNP 1989; Branchek et al, 2nd IUPHAR Serotonin Satellite, 1990). However, we noted that the data obtained in our laboratory displayed a markedly higher proportion of high affinity sites than reported by others and that this ratio could be experimentally manipulated. In order to address possible factors regulating the expression of multiple affinity states of the 5-HT_2 receptor, we made use of the high specific activity radioligand ^{125}I-DOI (Dupont-NEN). Specific binding of ^{125}I-DOI to the stable transfectants (Ltk$^-$) displayed high affinity (K_d=0.22nM) and saturability (B_{max}=124 fmol/mg prot). The density of ^{125}I-DOI binding sites in these cells was approximately half of the total ^{3}H-ketanserin binding sites (B_{max}= 234 fmoles/mg prot). The GTP derivatives GTP-γ-S and GppNHp potently inhibited the binding of ^{125}I-DOI (K_i= 39nM; 256nM, respectively) and produced an effect comparable to that observed in our control rat cortical membranes (K_i= 183 nM; GppNHp). Approximately 50% of the ^{125}I-DOI binding sites were sensitive to guanyl nucleotides. In order to determine the effect of receptor density on the proportion of receptors in the high and low affinity states, we used increasing amounts of DNA encoding the 5-HT_2 receptor in transient transfections (Cos 7). As the DNA was increased (in 5 steps, from 1-10 µg DNA/10^6 cells), we detected an increase in both the ^{125}I-DOI and ^{3}H-ketanserin binding; however, the ratio of ^{125}I-DOI/^{3}H-ketanserin bound (fmol/mg protein) decreased from 1.8-0.15. Furthermore, we noted a similar decrease in the proportion of high affinity states as a function of confluence. Although the number of receptors in the high affinity state did not change, the density of ^{3}H-ketanserin binding sites increased dramatically as confluence increased, thus decreasing the ratio of high/low affinity states. These data indicate that the pool of endogenous G-protein(s) may be rate-limiting in these expression systems such that the proportion of receptors in the high affinity state (presumably coupled to G-proteins) decreases as the receptor density increases.

493.10

BENZAZEPINE FUNCTION AT 5-HT_{1c} RECEPTORS EXPRESSED IN XENOPUS OOCYTES. C.A. Briggs, N.J. Pollock, D.E. Frail, R.F. Rakowski*, and J.W. Kebabian. Depts. Neuroscience & Corp. Molecular Biology, Abbott Labs, and Dept. Physiology, Chicago Medical School, North Chicago, IL.

Xenopus laevis oocytes were prepared and injected using standard techniques; two-electrode voltage clamp was used to record the Ca^{2+}-dependent Cl^- current response to 5-HT and other agonists. After injection with **rat brain RNA**, oocytes responded to 5-HT with an EC_{50} of about 30 nM, consistent with a selective expression of 5-HT_{1c} receptors (Lubbert et al. (1987), *J. Neurosci.* 7:1159). SCH 23390 (10^{-7}-10^{-5} M) blocked the response to 5-HT (10^{-7} M) in a stereo-selective and dose-dependent manner. There was no apparent agonist activity with SCH 23390. After injection with **clonal 5-HT_{1c} RNA**, oocytes responded to 5-HT with an EC_{50} of 10-30 nM. SCH 23390 (10^{-8}-10^{-4} M) was a stereo-selective partial agonist (EC_{50} about 4 uM, *cf.* Hoyer et al.(1989) *N.-S. Arch. Pharmac.* 339: 252). SKF 38393 and dopamine (10^{-6}-10^{-4} M) also acted as agonists. Benzazepines selective for the D1 dopamine receptor also bind and function at the 5-HT_{1c} receptor. Oocytes can be used to study such functions with normal and mutagenized RNAs.

493.11

MAMMALIAN CELLS TRANSFECTED WITH A RAT 5HT_2 RECEPTOR cDNA: EVIDENCE FOR MULTIPLE STATES AND NOT MULTIPLE 5HT2 RECEPTOR SUBTYPES. S. Leonhardt, E. Weisberg, B.J. Hoffman*, and M. Teitler. Dept. of Pharmacology and Toxicology, Albany Medical College, Albany, N.Y., 12208; *Lab. of Cell Biology, NIMH, Bethesda, Maryland 20892

Evidence has accumulated that the 5HT_2 receptor exists in two different states. The agonist high affinity state is coupled to a G-protein and can be labelled with the radioactive hallucinogens ^{3}H-DOB, ^{125}I-DOI and the antagonist ^{3}H-Ketanserin. The agonist low affinity state consists of the free receptor and is labelled by ^{3}H-Ketanserin. Recently, an alternative hypothesis has been put forward proposing that the radioactive hallucinogens are labelling a 5HT_2 receptor sub-type distinct from the receptor labelled by ^{3}H-ketanserin and other antagonist radioligands. To show which of these hyoptheses is correct, the rat 5HT_2 receptor gene was transfected into NIH-3T3 (murine fibroblast) and COS (green monkey kidney) cells. Neither non-transfected cell line expresses the 5HT_2 receptor. The transfected cells expressed high affinity binding sites for both ^{125}I-DOI and ^{3}H-ketanserin. Agonist affinities were significantly higher for ^{125}I-DOI labelled receptors than for ^{3}H-ketanserin labelled receptors in both cell types. Under the same experimental conditions the affinity of agonists and antagonists for the binding sites were essentially identical to the affinities of these sites in mammalian brain homogenates. The ^{125}I-DOI binding was guanyl-nucleotide sensitive, indicating coupling to a GTP- binding protein. These data indicate that the 5HT_2 receptor gene encodes for the agonist high affinity state and the agonist low affinity state of the 5HT_2 receptor. These results strongly support the two state receptor hypothesis and do not support the multiple 5HT_2 receptor sub-type hypothesis.

493.12

5-HT1A RECEPTORS REGULATE ADENYLATE CYCLASE MEDIATED RESPONSES IN THE HIPPOCAMPUS. Rodrigo Andrade, Dept. of Pharmacology, St. Louis Univ. School of Med. St. Louis, MO 63104

Although electrophysiological studies have shown that 5-HT1A receptors in the CA1 region of the hippocampus elicit a hyperpolarization mediated by an increase in potassium conductance through a mechanism that is independent of cAMP, biochemical experiments have reported that these receptors can also regulate adenylate cyclase. These results suggested that 5-HT1A receptors might be able to regulate responses signalled through cAMP generation. To test this possibility I examined the effects of the 5-HT1 agonist 5-carboxyamidotryptamine (5-CT) on β-adrenergic responses using intracellular recordings in *in vitro* hippocampal slices.

Consistent with previous reports, the predominant effect of norepinephrine (NE) in this region was to reduce the calcium activated afterhyperpolarization (AHP) by acting on a β-adrenergic receptor (Madison and Nicoll, 1982). Bath administration of 5-CT (0.3µM) elicited a hyperpolarization and a decrease in the amplitude of the AHP which appeared by in large secondary to the increase in membrane conduce. Moreover, in the presence of 5-CT, NE was proportionally more effective in reducing the AHP than either under control conditions or following the removal of the 5-CT from the bath (mean enhancement of NE: 27%, range 16%-49%, $p<0.01$). Similar effects were also observed in response to baclofen, a GABA-B agonist that has been previously shown to also inhibit adenylate cyclase and to converge upon a the same transmembrane signalling mechanism as 5-HT1A receptors to open potassium channels in these cells (mean enhancement= 23%, range 8%-40%, $p<0.05$).

These results indicate that activation of 5-HT1A and GABA-B receptors fail to block responses signalled by activation of adenylate cyclase and indeed results in an enhancement of these responses. These results are consistent with the biochemical observation that at least some receptors coupled to Gi can enhance the effects of β-adrenergic stimulation of adenylate cyclase and suggest a possible physiological role for such an enhancement. Supported by grant MH 43985 and the Alfred P. Sloan Foundation

NEURAL-IMMUNE INTERACTIONS: STRESS AND BEHAVIOR

494.1

MECHANISMS OF SUPPRESSED ANTIBODY PRODUCTION IN HANDLED MICE. J.M. Dopp, S.G. Schmidt*, N. Cohen*, and J.A. Moynihan*. Depts. of Microbiology and Immunology, and of Psychiatry, University of Rochester School of Medicine and Dentistry, Rochester, NY, 14642.

Handled mice show behavioral and physiological responses indicative of arousal, with presumed neuroendocrine and sympathetic nervous system concomitants. Thus, handling has been used as a rodent model of human stress. Mice handled before immunization show decreased primary IgG antibody levels and mitogen-induced T cell proliferation, but unchanged numbers of total spleen cells and percentages of splenic B cells, T cells, and T cell subsets (Moynihan, et al., Life Sci., in press). To determine the mechanism(s) through which handling suppresses antibody production, we have analyzed some of the known components of the immune response to keyhole limpet hemocyanin (KLH).

Group-housed female BALB/c mice were held individually 2 min/day for 2 weeks, while controls remained in their cages. 24 hr later, mice were either sacrificed (Group 1) or injected i.p. with 100 µg KLH (Group 2) and sacrificed 3 or 6 days later Compared to controls, handled mice in Group 1 had fewer Ig-secreting B cells (CELISA) and decreased levels of spontaneously-produced IgM (ELISA), but unchanged T-cell secretion of Con A-induced interleukin-2 (IL-2) and/or IL-4 (CTLL assay). Handled mice in Group 2 showed diminished KLH-induced proliferation (^{3}H-TdR incorporation) of unfractionated spleen and mesenteric lymph node cells.

The results indicate that neuroendocrine and/or sympathetic responses which accompany handling can alter specific immune function as measured by antibody production. Dimished antibody production does not appear to be caused by a decrease in IL-2/4, known to play a role in B cell differentiation. Future studies will focus on levels of T-cell help and on other relevant lymphokines and CNS-derived products that might directly affect immune responses.

494.2

SURGICAL STRESS INCREASES THE NUMBER OF BREAST CANCER METASTASES IN RATS G.G. Page, S. Ben-Eliyahu, R. Yirmiya, & J.C. Liebeskind Dept. of Psychology, UCLA, Los Angeles, CA 90024.

The acute stress of surgery is known to suppress natural killer (NK) cell cytotoxicity and increase the metastasis of solid tumors. Using a tumor model for breast cancer in rats, MADB106 adenocarcinoma, we recently demonstrated that forced swim stress increases metastases by suppressing NK activity against this tumor. This same malignant cell line, MADB106, syngeneic to Fischer 344 rats was used for this study. Thirty-eight rats were divided into 3 groups, subjected to a standard abdominal surgery under halothane anesthesia, to anesthesia only, or to no treatment. Three to five hours after completion of surgery/anesthesia, all animals were injected with $3x10^5$ MADB106 cells in .5ml PBS. Twenty-one days later, lungs were taken and surface metastases counted. Surgical stress significantly increased metastatic growth in the surgery group compared to either the anesthesia only or control groups. Taken together with the established role of NK cells in controlling MADB106 metastases, and with our recent evidence for a causal relationship between the effect of swim stress on NK activity and on metastases, the present finding suggests that surgical stress increases metastases by suppressing NK activity. This hypothesis is now being tested directly in our laboratory. Supported by the UCLA Psychoneuroimmunology Program (S.B-E. & R.Y.), and NIH grant NS 07628.

OPIATE-INDUCED INCREASE IN TUMOR METASTASES IS CAUSED BY SUPPRESSION OF NK ACTIVITY AND IS NOT MEDIATED BY GLUCOCORTICOIDS. R. Yirmiya, S. Ben-Eliyahu, Y. Shavit, R. P. Gale, A. N. Taylor, H. Weiner, G. Page, N. Lee*, and J. C. Liebeskind. University of California, Los Angeles, CA 90024, and the Hebrew University of Jerusalem, Israel.

The effects of two opiate drugs, morphine and fentanyl, on metastatic tumor growth, were tested using the MADB106 mammary adenocarcinoma cell line, previously shown to be controlled by natural killer (NK) cells. Additionally, the cytotoxic activity of NK cells against this tumor, which is syngeneic to Fischer 344 rats, was measured *in vitro*. Fischer 344 rats were injected either with naltrexone (10 mg/kg) or saline, and 20 min later, were injected with either morphine (50 mg/kg), fentanyl (35 µg/kg) or saline. One hour after the second injection, animals were either injected intravenously with 10^5 MADB106 cells and two weeks later lungs were removed and surface metastases counted, or sacrificed and NK activity determined in a standard ^{51}chromium-release assay. Administration of morphine or fentanyl produced a 5-8 fold increase in number of MADB106 metastases *in vivo*, and markedly decreased NK cytotoxicity *in vitro*. Naltrexone completely blocked these effects. In another experiment we found that administration of the glucocorticoid antagonist RU38486 (25 mg/kg, one hour before morphine administration) did not attenuate morphine-induced increase in lung metastases, indicating that the effects of morphine are not mediated by glucocorticoids. These findings suggest a casual relationship between the immune suppressive and tumor enhancing effects of opiates. Supported by the UCLA Psychoneuroimmunology Program (R.Y. and S.B.-E.), and grants NS 07628 (J.C.L.), AA 06744 and VA Medical Research Service (A.N.T).

SYMPATHETIC INVOLVEMENT IN THE STRESS-INDUCED INCREASE OF METASTATIC SPREAD: STUDIES OF A NATURAL KILLER-SENSITIVE TUMOR S. Ben-Eliyahu, R. Yirmiya, G. Page, S. A. Boun, A. N. Taylor, R. P. Gale, H. Weiner, and J. C. Liebeskind Dept. of Psychology, UCLA, Los Angeles, CA 90024

Stress can suppress natural killer (NK) cell activity and increase tumor growth. We have recently provided evidence for a causal relationship between immunosuppressive and tumorigenic effects of stress in an animal model of breast cancer. Using the MADB106 tumor cell line, which is syngeneic to the Fischer 344 rats used in these studies and is known to be controlled by NK cells, we previously showed that stress suppressed NK activity against this tumor in vitro and increased the number of metastases in rats inoculated with this tumor. In the present study, rats were either subjected to intermittent forced swimming stress or were not stressed. In the first experiment each group was injected with the ganglionic blocker, chlorisondamine (3 mg/kg i.p.), or with saline. In the second experiment each group was either injected with the selective ß-2 adrenergic antagonist, butoxamine (25 mg/kg i.p.), or with saline. One hour after stress rats were injected i.v. with $2x10^5$ MADB106 cells, and 12 days later surface lung metastases were counted. Stress significantly increased number of metastases in both experiments; clorisondamine markedly decreased this elevation, and butoxamine completely blocked it. Neither drug affected number of metastases in nonstressed groups. These findings suggest that ß-2 adrenergic receptor activation by the sympathetic nervous system is important in mediating the effects of stress on metastatic growth. Supported by the UCLA Psychoneuroimmunology Program (S. B.- E. and R.Y.) and grants NS 07628 (J.C.L.), AA 06744 and VA Medical Research Service (A.N.T)

EFFECTS OF EXERCISE ON IMMUNE FUNCTIONS OF UNDERNOURISHED MICE. S. Filteau*†, M.P. O'Grady†, R.A. Menzies*†, T. Kaido*†, J.B. Gelderd^, C. Edwards≠, and N.R.S. Hall†. Dept. of Physiology≠, and Dept. of Psychiatry†, Univ. of South Florida College of Med., Tampa, FL 33613, and Dept. of Anatomy^, Texas A&M Univ., College Station, TX 77843-1114.

Anorexia nervosa patients generally have normal immune function and viral disease resistance in spite of their severe undernutrition. Possibly the intense exercise commonly performed by these patients helps prevent undernutrition-induced immunodepression. To test this hypothesis, mice were fed either *ad libitum* or in restricted quantities to induce 25% loss of initial weight over 3 weeks. Half the animals from each dietary group were run on a treadmill for 30 min/day, 5 days/week. Exercise had no effect on several measures of nutritional status. One third of the restricted non-exercised mice, but no mice from any other group, exhibited intestinal pathology. Spleen weight and blastogenic response to lipopolysaccharide were significantly increased by exercise in undernourished mice. *In vivo* antibody response to sheep red blood cells, *in vitro* splenic responses to Concanavalin A and phytohemagglutinin, and production of tumor necrosis factor were not significantly affected by exercise. Serum corticosterone level was increased by food restriction and significantly decreased by exercise in the undernourished mice. These values are being correlated with changes in brain levels of biogenic amines. Regular exercise may help prevent undernutrition-induced immunodepression by altering the response of animals to stress. Supported in part by NIMH (MH45646) and the Med. Res. Council of Canada.

494.6

THE EFFECTS OF ISOLATION-INDUCED AGGRESSION ON IMMUNE PARAMETERS IN MICE. M.P. O'Grady and N.R. Hall. Div. of Psychoimmunology, Dept. of Psychiatry, Univ. of South Florida College of Medicine, Tampa, FL 33613

Isolation-induced aggression (IIA) was used as a model to assess the effects of a behavioral manipulation on measures of immunity. In addition, we evaluated the ability of thymosin fraction 5 (TF5), a thymic extract, to modulate IIA. TF5 stimulates ACTH release which, in turn, has been found to reduce IIA.

Pretreatment with TF5 altered neither the number of fights nor the latency to attack. However, the fighters and the intruders differed in the response of their lymphocytes to mitogens. Compared to intruders, the fighters were suppressed in their response to Con A ($p<.02$) and Pokeweed ($p=.001$) with no change in response to PHA. We then investigated the effect of housing and intensity of fighting on thymus weight. The intensity of the fights was determined by the housing conditions of the participants. Animals who fought submissive intruders as well as those who fought other aggressive mice had reduced thymus weights compared to the isolated controls ($p<.04$). Interestingly, there was a difference between the two groups of fighters as a function of intensity of fights. The group who fought aggressive mice had smaller thymuses than those animals who fought submissive intruders ($p=.006$). Thus, thymus weights reflected these intensity differences in what could be construed as a behavioral "dose-response curve". Research was supported in part by NS 21210.

BRAIN C-FOS IMMUNOREACTIVITY INDUCED BY CONDITIONED AND UNCONDITIONED AVERSIVE STIMULI.
M.O. Fraser*, G.E. Hoffman, D.T. Lysle, J.E. Cunnick, M.A. Pezzone, B.J. Kucinski and B.S. Rabin Departments of Pathology and Physiology, University of Pittsburgh, Pittsburgh, PA, 15216.

A variety of stressors can decrease immune function, and the hypothalamus is implicated in this response. In an attempt to define areas of the brain that influence immune function and respond to stressors, c-fos induction was examined following two stress paradigms. Adult male Lewis rats (2-4 per group) either underwent conditioning to foot shock (unconditioned stimulus, US) using auditory clicks as the conditioned stimulus (CS) or were exposed to the CS alone, and 12 days following the conditioning trials were either exposed to the CS for 1 hour or were taken directly from their cages. Other animals were either exposed to the US alone or remained naive. Animals were prepared for c-fos staining, as a marker for stimulated activity, as previously described (Hoffman et al., Endocrinology 126: 1736, 1990). C-fos was strongly expressed in cells of the paraventricular nuclei, some of which contain CRF, and other hypothalamic areas directly associated with autonomic function, the septal nuclei, and the corticomedial amygdala in animals exposed to a conditioned or unconditioned stress. Midline thalamic, amygdaloid and basal ganglia activation were greatest in the animals exposed to US alone. Control animals exhibited very little c-fos in the diencephalon. C-fos containing brain nuclei common to both stressors can now be targeted for further study aimed at elucidating their role in stress induced immune suppression.

STRESSOR-INDUCED MODULATION OF IMMUNE FUNCTION: EVIDENCE FOR A CONTEXT DEPENDENT HABITUATION PROCESS.
Donald T. Lysle, Ph.D., Dept. of Psychology, University of North Carolina, at Chapel Hill and Joan E. Cunnick, Ph.D., Dept. of Pathology, University of Pittsburgh.

Our prior work using male Lewis rats has shown that presentation of a stressor induces suppression of the mitogenic responsiveness of splenic lymphocytes, and repeated exposure to the stressor will result in attenuation of the suppressive effect. The present study evaluated whether presentations of a stressor (administration of 5.0 mg/kg of Amphetamine) would attenuate the suppressive effect induced by a different stressor (16 presentations of a 5-sec, 1.6 mA electric foot-shock). The results showed that the attenuation or habituation effect was specific to the repeatedly presented stressor, and did not attenuate the suppressive effect of a different stressor. Moreover, subsequent experiments showed that the habituation effect was specific to the environment or context in which the stressor was presented, as presentation of the same stressor in a different context resulted in a renewal of the suppressive property of the stressor. These findings indicate that the habituation process is dependent upon the presence of conditioned stimuli that predict the occurrence of the stressor. Our interpretation suggests that conditioned stimuli produce a compensatory response that opposes the suppressive effect of a stressor.

STRESS-INDUCED SUPPRESSION OF THE CELLULAR IMMUNE RESPONSE TO HERPES SIMPLEX VIRUS (HSV) AND THE EFFECT ON THE ESTABLISHMENT OF ACUTE AND LATENT INFECTION. R. H. Bonneau*, J. F. Sheridan*, N. Feng*, F. L. Jordan and R. Glaser*. Department of Medical Microbiology and Immunology, College of Medicine; Section of Oral Biology, College of Dentistry. The Ohio State University, Columbus, OH 43210.

It has been well documented that acute or repeated stressful events are able to suppress a broad spectrum of both humoral and cellular immunological responses; however, the effect of stress on the development of specific antiviral immune responses has yet to be reported. We have utilized an established murine model of local and systemic Herpes simplex virus type 1 (HSV-1) infection to study the effect of restraint stress on the generation of HSV-specific cytotoxic and helper T lymphocytes (CTL and HTL) as well as natural killer (NK) cell activity. These studies were extended to examine the effect of stress on the development and restimulation of the HSV-specific memory component of the cellular immune response. In addition, the effect of stress on the establishment of acute and latent HSV infection was investigated. Overall, restraint stress was shown to depress the generation of HSV-specific CTL and NK cell activity following local infection as well as increasing the level of infectious HSV at the site of local infection. Restraint stress was also demonstrated to inhibit the ability to restimulate HSV-specific memory CTL to the lytic phenotype following antigenic challenge. These findings provide evidence that physiological changes associated with restraint stress can influence the ability to generate an immune response to a specific viral infection, thus contributing to the understanding of some of the basic mechanisms underlying stress-associated immune regulation.

BEHAVIORAL, NEUROENDOCRINE AND IMMUNE SYSTEM STUDIES OF HIGH- AND LOW-AVOIDANCE ROMAN RAT LINES. P. Mormède*, N. Castanon*, *C. Sandi**, S. Vitiello*, J. Dulluc*, M. Le Moal and P.J. Neveu* Lab. Psychobiologie Comportements Adaptatifs INSERM. U259-INRA, Univ. Bordeaux II. Domaine de Carreire 33077 Bordeaux Cedex-France. *Psychobiology Lab., Istituto Cajal, Madrid, Espana.*

Roman strains of Wistar rats have been selected on the basis of their performance in two-way active avoidance behavior and differ also in several other behavioral responses, such as their locomotor activity in a novel environment, the high-avoidance strain (RHA) being more active than the low-avoidance animals (RLA). Despite these marked behavioral differences we could not find any between-strain variation in basal levels of corticosterone and ACTH, in their responses to different protocols of novel environment stress, or after CRF challenge. These results suggest that the differences previously described are not necessarily related to the behavioral trait and may be the consequence of a genetic drift or of local environmental conditions. On the other hand the prolactin response to stress was higher in the low-avoidance line.

The reactivity of spleen lymphocytes was studied *in vitro*. Natural killer activity against YAC-1 tumoral cells as well as the mitogenic response to concanavalin A were much higher in the low-avoidance strain.

The genetic link of neuroendocrine variation and immune function differences with behavioral characteristics is currently under study. The available data suggest that the Roman lines of rats are an interesting model for psychoneuroimmune studies.

INNATE AND ADAPTIVE IMMUNE RESPONSES IN A SOCIAL CONFLICT PARADIGM M. Lyte[1], S. Nelson[1]* and M.L. Thompson[2]. [1]Biological Sciences, Mankato State University, Mankato, MN 56002 and [2]Biochemistry, Tufts Univ. Sch. of Medicine, Boston, MA 02111.

Innate and adaptive immunity was examined at an *in vitro* and *in vivo* level in three strains of mice subjected to social conflict. C57BL/6, DBA/2 and B6AF1 strains were selected on the basis of known differences in neuroendocrine response to social conflict stress. Generation of primary IgM antibody responses to the T dependent antigen KLH was suppressed following chronic (>1 day) stress periods while IgM response to the T-independent antigen PVP was not affected. *In vitro* proliferative responses of splenocytes to the T cell mitogen Con A and B cell mitogen LPS were unaffected. Acute stress dramatically increased splenocyte phagocytosis while mitogen responses remained unaffected. DBA averaged a 269% increase in phagocytosis as compared to a 412% increase in C57. These findings indicate that alterations in innate immunity in addition to adaptive immunity should also be considered when evaluating neuroendocrine and immune interactions in response to stress and emphasize the importance of using a biologically relevant stressor such as social conflict.

494.12

IMMUNOSUPPRESSION INDUCED BY A MILD STRESSOR OR STRESSOR-RELATED ODORS. S. Zalcman, L. Kerr* and H. Anisman. Dept. of Psychology, Carleton University, Ottawa, Ontario K1S 5B6, Canada.

Paralleling the effects of inescapable footshock, exposure to a mild stressor (165 presentations of a weak light stimulus over a 96 min period) applied 72 hr after sheep red blood cell (SRBC) inoculation resulted in a marked suppression of the plaque forming cell (PFC) response in CD-1 mice. This treatment also reduced antibody titers, but over the course of several experiments this outcome occurred less reliably. A more pronounced and reliable immunosuppression was noted when the stressor was presented to mice in their home cages. Finally, exposing mice to an environment containing odors of mice that had previously been stressed likewise resulted in an immunosuppression. No such effect was evident if mice were exposed to odors of nonstressed mice. It seems that the PFC and antibody responses are exquisitely sensitive to apparently mild stressors, and raises the possibility that a light stimulus might be inappropriate as a CS for certain conditioned immunological studies.

494.13

NEONATAL HANDLING AFFECTS IMMUNE FUNCTION AND BEHAVIOR IN PORSOLT'S SWIM TEST. E. Fride, L.A. Hilakivi, and P.K. Arora*. Lab. of Neuroscience, NIDDK and Lab. of Clinical Studies, NIAAA, National Institutes of Health, Bethesda, MD 20892.

A greater resistance to stress and depression has been associated with increased immunocompetence. Evidence indicates that daily handling of neonatal rats results in an increased ability to cope with stress and in delayed development of both ulcers and tumor growth. In the present study, male and female Wistar rats were handled or left undisturbed during postnatal days 5-20. At 55 days, the time spent immobile in Porsolt's swim test (a putative model of depression) was measured. At 6 months of age, several immune parameters were assessed including natural killer (NK) cell activity and the numbers of splenic B, T, helper/inducer T (CD4+), and suppressor/cytotoxic T (CD8+) cells. The latter measures were assessed with fluorescent monoclonal antibodies against cell surface markers for B (αIgG), T (αThy1.2), CD4+ (αL3T4) and CD8+ (αLyt2) cells.

The duration of immobility in the water was significantly shorter in handled than in control rats ($F(1,36) = 33.5$, $p < 0.0001$). NK cell activity was 40% higher in handled rats ($F(1,26) = 12.7$, $p < 0.02$). Handled rats had fewer T- ($p < 0.001$) and CD8+ ($p < 0.02$) cells than control rats, resulting in a higher CD4/CD8 ratio ($p < 0.05$). The number of B- and CD4+ cells did not differ between treatment groups. These results indicate that early postnatal handling increased both performance in an animal model of depression and certain aspects of immunocompetence.

494.14

I. COMPARTMENT SPECIFIC CELL TRAFFICKING: POTENTIAL MECHANISM FOR STRESS-INDUCED IMMUNOMODULATION. M. Fleshner, L. R. Watkins, L. L. Lockwood, D. Bellgrau*, M. L. Laudenslager & S. F. Maier. DEPT. Psych., U. CO., Boulder, CO 80303

Stressors can alter immune function by many mechanisms. One hypothesis for stress-induced immunomodulation [SII] is changes in cell populations via lymphocyte trafficking. Since immune responses require cooperation of different cell types, stress-induced shifts in cell populations may affect an organism's ability to mount an immune response. We sought to determine if stress could alter lymphocyte trafficking & if so, whether this could be a mechanism for SII. To test for stress-induced lymphocyte trafficking, male rats either remained undisturbed in their home cages or were exposed to 100 1.6 mA inescapable tail shocks. Lymphocytes from peripheral blood, spleen, cervical lymph nodes and superior mesenteric lymph nodes (MLN) were collected and identified as positive for the cell surface markers: CD5, CD8, Ig, & CD4. Flow cytometry revealed a significantly increased $CD4^+/CD8^+$ ratio in MLN of shocked vs. control rats ($p<.001$). In contrast, peripheral blood, spleen, & cervical lymph node cell populations were not measurably altered. If this change in cell populations underlies SII, then immunomodulation should occur only if antigen is processed in the altered MLN. We thus compared the effect of shock on *in vivo* anti-KLH Ig levels after MLN exposure to KLH (by intraperitoneal injection) or spleen (by intravenous injection). Shock induced reductions in serum IgM & IgG levels (ELISA) were indeed observed only following IP KLH. Additional experimentation revealed that: 1) an intact spleen is necessary for stress-induced cell trafficking and Ig reduction, 2) the $CD4^+/CD8^+$ increase is seen in MLN 1 hr. but not 24 hrs. post stress, and 3) SII is not found when IP KLH is given by 48 hrs. post stress. In sum, these data suggest that SII of *in vivo* antibody production occurs due to cell trafficking. Shock seems to selectively mobilize splenic $CD4^+$ cells to move into MLN and $CD8^+$ lymphocytes to move out of MLN, thus altering the immune response to antigen processed at this site. ONR00014-85K0211, BNS-8808840 & MH37373.

494.15

II. COMPARTMENT SPECIFIC CELL TRAFFICKING: NEUROENDOCRINE BASES. L. R. Watkins, M. Fleshner L. L. Lockwood, D. Bellgrau*, M. L. Laudenslager & S. F. Maier. D. Psych., U.CO. Boulder, 80303

Stress can induce changes in immune function. The mechanism(s) for these changes remain unclear. One hypothesis for stress-induced immunomodulation [SII] for which we have evidence (Fleshner, et al., this vol) is changes in lymphocyte populations via cell trafficking. Since immune responses require cooperation of different cell types, stress-induced shifts in cell populations render an organism less able to mount an immune response. We next sought to investigate possible mediators of SI cell trafficking. We focused on 2 systems, the hypothalamic-pituitary-adrenal axis (HPA) and sympathetic outflow. These systems are activated during stress and can influence lymphocytes and lymphoid compartments. Specifically, we sought to determine if adrenal medullary hormones, corticosterone or splenic sympathetic innervation were necessary for stress-induced changes in cell trafficking. Rats were either adrenal demedullated (ADM), treated with intracerbroventricular (ICV) dexamethasone (Fleshner, et al. NS abst, 1989), or sympathectomized. Animals either remained undisturbed in their home cages or were exposed to inescapable tailshock. Blood samples were collected before (BL) and immediately after (100 sk) stress. ACTH and corticosterone levels were determined (RIA) to verify that 1) the adrenal cortex was still functioning in the ADM rats and 2) ICV Dex blocked HPA activation. Lymphocytes from superior mesenteric lymph nodes (MLN) and cervical lymph nodes were collected and identified as positive for the cell surface markers, CD4 & CD8. BL and 100 sk steroid and ACTH levels in ADM shocked rats did not differ from sham operated shocked rats. Shocked rats treated with ICV Dex had lower 100 sk steroid (not different from BL) and ACTH levels than vehicle treated shocked rats. Flow cytometry revealed a significant increase in $CD4^+/CD8^+$ ratio in MLN in ADM but not in ICV Dex treated rats. Thus, HPA activation but not medullary hormones seems necessary for SI changes in cell trafficking. The role of sympathetic outflow is currently being investigated. ONR00014-85K0211, BNS-8808840 & MH37373.

494.16

III. STRESS-INDUCED IMMUNOMODULATION: A STRAIN COMPARISON. L. L. Lockwood, M. Fleshner, L. R. Watkins, M. L. Laudenslager & S. F. Maier. Dept. of Psych., U. CO., CO Boulder, 80303

Stress can induce changes immune function. Since rat strains are known to differ with respect to their responsiveness to stressors, it is possible that stress may have varying immunologic impact on different rat strains. Exposure to inescapable tail shocks produces decreased KLH specific Ig levels and increased $CD4^+/CD8^+$ ratios in Sprague Dawley Holtzman rats (Fleshner et al., this vol). This reduction in Ig levels was seen only when KLH was given immediately prior to shock and not when KLH was given 48, 72, or 96 hrs prior to shock. We thus sought to determine if these changes could also be seen in Fischer 344 rats. Specifically, we investigated if in Fischer 344 rats 1) shock immediately post immunization reduces KLH specific Igs 2) shock produces a compartment specific increase in $CD4^+/CD8^+$ ratio and 3) shock has no effect on anti-KLH Igs when KLH is given 48, 72, or 96 hrs prior to stress. Fischer 344 strain male rats were immunized intraperitoneally with KLH and exposed immediately to 100 1.6 mA tail shocks. Blood samples were collected 3, 5, 7, 9, 14 & 21 days post immunization. Serum levels of KLH specific IgM and IgG were determined using ELISA. As seen in Sprague Dawley Holtzman rats, Fischer 344 strain rats show a profound decrease in both IgM and IgG anti-KLH Igs. To determine if shock induces changes in CD4 and CD8, Fischer 344 rats were sacrificed immediately following shock. Superior mesenteric and cervical lymph nodes were collected and lymphocytes were identified as positive for the cell surface markers CD4 and CD8. Flow cytometry revealed a significant increase in $CD4^+/CD8^+$ ratio specific to mesenteric lymph nodes. Thus, the stress-induced changes reported here seem to be consistant across strains. We are currently investigating whether shock has any effect on Fischer 344 antibody levels when KLH is given prior to shock. ONR00014-85K0211, BNS-8808840 & MH37373.

SOMNOGENIC IMPACT OF TRYPANOSOMIASIS IN RABBITS. L.A. Toth and J.M. Krueger. University of Tennessee, Memphis, TN 38163.

Trypanosomes cause the disease known as sleeping sickness in humans and induce a chronic wasting disease in rabbits. We examined the somnogenic impact of subcutaneous inoculation of rabbits with trypanosomes. Organisms were first detected in blood 7 days after challenge. Parasitemia correlated to the onset of fever, decreased food intake and elevated fibrinogen levels. The amount of slow wave sleep (SWS) was not markedly altered at this time, but rapid eye movement sleep (REMS) was reduced.

On days 7-17 after inoculation, fluctuations in blood parasite numbers and other physiologic parameters were observed. Daily SWS time gradually decreased below control values, as did delta wave amplitude (DWA) during SWS. The reduction in SWS first developed during the dark period, but eventually occurred throughout the day. However, a circadian pattern of sleep persisted, as did REMS suppression. These reductions in SWS, DWA and REMS reflect major disruptions in sleep architecture that are likely to be related to reduced quality of sleep.

THE SUPPRESSANT EFFECTS OF INTERFERON ON ACTIVITY AND FOOD INTAKE ARE NOT PROSTAGLANDIN MEDIATED M.A. Segall and L.S. Crnic, Univ Colorado School of Medicine, Denver, CO 80262

When used to treat cancer, interferon-α (IFN-α) produces fatigue, anorexia, and impaired cognition. A 1600 U/gm, i.p. injection of mouse IFN-α caused a decrease in locomotion and food pellets delivered that lasted 23 hrs after injection (Beh. Neuroscience, in Press). One possible mechanism for the decreased activity and consumption is the release of prostaglandins induced by IFN-α. This was tested by blocking prostaglandin synthesis with indomethacin. DBA/2J male mice (n=32) were placed for 2 days in a chamber with a photobeam activity monitor and automated food pellet delivery. Locomotion and number of food pellets delivered were recorded 24 hr/day. On the 2nd day the mice were given one of four i.p. injections: buffer, indomethacin (5 mg/kg), mouse IFN-α (1600 U/gm), or indomethacin (5 mg/kg) + mouse IFN-α (1600 U/gm). Ifn-α significantly suppressed locomotion and food pellets obtained in the 6 hour period after injection, as previously described, however only the effect on food pellet delivery was significant over the 23 hour period. There was no significant indomethacin main effect on any variable, nor IFN by indomethacin interaction. Indomethacin did not reverse the effects of IFN. The lack of effect of indomethacin suggests that prostaglandins do not mediate the suppressant effects of IFN-α on activity and food intake. Supported by MH09718 & MH00621.

IMMUNODEFICIENCY AND ACTIVITY-BASED ANOREXIA. P.F. Aravich, L.E. Doerries*, E. Farrar*, S. Downing*, A.H. Elhady*, A. Metcalf* & A.M. Johnson*. Dept. Anat./Neurobiol., Eastern Virginia Med. Sch., Norfolk, VA 23510; Vet. Affairs Med. Ctr., Hampton, VA 23667; Dept. Psych., Christopher Newport Coll., Newport News, VA 23606.

Anorexia nervosa is correlated with various abnormalities including excessive exercise and immunodeficiency. We have been exploring the phenomenon of activity-based anorexia (ABA) in the rat, produced by superimposing voluntary wheel-running exercise on a restricted-feeding schedule, and have found specific opioid abnormalities that are not a secondary consequence of weight loss. These abnormalities could potentially affect immune function, which is reduced in ABA. This experiment determined if ABA immunodeficiency can be distinguished from weight-loss immunodeficiency. Adolescent male rats were subjected to a delayed-type hypersensitivity skin test and sacrificed following a 26% weight loss. Control groups consisted of a weight-loss matched group and an ad lib fed group. Compared to normal rats, ABA and weight-loss matched rats had comparable reductions in induration size, leukocyte number and relative thymus and spleen weights, and comparable increases in relative adrenal weight. We conclude that, on these measures, ABA immunodeficiency is a secondary consequence of weight loss and that ABA-specific opioid abnormalities do not account for the deficits.

MURAMYL DIPEPTIDE (MDP)-INDUCED PRODUCTION OF TUMOR NECROSIS FACTOR (TNF) BY HUMAN GLIOBLASTOMA CELLS EXPRESSING HLA$_{DR}$. L. Hong*, A.E. Postlethwaite*, L. Johannsen and J.M. Krueger. Univ. of TN, Memphis, TN 38163

In humans, the major histocompatibility complex (MHC) class II molecule HLA$_{DR2}$ is associated with the narcolepsy (1). Astrocytes express HLA$_{DR}$ in response to IFN gamma. These cells also bind MDP and produce TNF; both substances are somnogenic. We investigated if prior treatment with IFN gamma alters the ability of a human glioblastoma cell line, HTB16, to produce TNF in response to MDP stimulation. HTB16 cells were grown with or without IFN gamma. On the 5th day, IFN gamma was removed and the cells were treated with MDP (0.01 - 1 μg/ml) for 2 d. Expression of HLA$_{DR}$ was quantified by ELISA. TNF in culture supernatants from cells was measured using an L cell cytotoxicity assay. IFN gamma-induced expression of HLA$_{DR}$ in these cells was dose- and time-dependent. MDP (0.01, 0.1 ug/ml) enhanced production of TNF in HLA$_{DR}^+$ cells, but not in HLA$_{DR}^-$ cells. The results suggest that the responsiveness of glial cells to MDP depends on prior exposure to IFN gamma. We are now exploring the possibility that enhanced TNF production in HTB16 cells is HLA$_{DR}$ dependent; the TNF gene is located within the region of the MHC suggesting that it is involved in the pathology of HLA-associated diseases.

FAILURE OF ESTRADIOL (E2) TO INDUCE AN LH SURGE IN OVARIECTOMIZED (OVX) RATS EXPOSED TO CONSTANT LIGHT (LL): EFFECTS OF NALOXONE (NX) TREATMENT. I. R. Cohen and M. R. Sterner, Lilly Research Laboratories, Eli Lilly & Co., Greenfield, IN 46140.

Cyclic release of LH is dependent on the presence of an estrogen stimulus and normal circadian rhythms. While estrous cyclicity is maintained in intact rats following short term exposure to LL, long term exposure leads to a loss of spontaneous LH surges. In addition, the opiate system appears to be involved in modulating LH secretion via effects on neurotransmitter activity. Thus, the effects of short term exposure to LL on the E2-induced LH surge in OVX rats and the role of the opiate system in mediating these effects were examined.

Fischer 344 rats (12 L: 12D photoperiod) were OVX and half were placed into LL (Day 0). Rats received a Silastic implant of E2 on Day 7 and the right atrium was cannulated on Day 8. On Day 9 rats were bled hourly (1200-2000h: 0.5ml). A second group was treated as described but on Day 9 one third of the rats in LL and LD received NX (10 mg/kg BW) at 0915h, NX at 1215h or saline at 0915h and were bled hourly (0900-1700h). LH was determined by RIA.

E2 failed to induce an LH surge in OVX-LL rats. An LH surge was evident in LD E2-treated rats by 1500h and peaked between 1700-1800h. NX at 0915 or 1215h enhanced and advanced the LH surge in LD rats. Also NX at 0915 elevated basal levels of LH at 1000 and 1100h. NX treatment in LL-E2 rats failed to elicit an LH surge. LL rats responded to NX treatment with only a brief elevation in basal LH levels.

These data indicate that: (1) the inhibitory effect of LL on the LH surge is enhanced following OVX and (2) the opiate system does not appear involved in mediating the inhibitory effect of LL on the LH surge mechanism.

495.2

FAILURE OF ESTRADIOL (E2) TO INDUCE AN LH SURGE IN OVARIECTOMIZED (OVX) CONSTANT LIGHT (LL) RATS: EFFECTS OF PROGESTERONE TREATMENT. M.R. Sterner and I.R. Cohen. Lilly Research Laboratories, Eli Lilly & Co., Greenfield, IN 46140.

It has recently been demonstrated that E2 treatment fails to elicit an LH surge in OVX rats housed short-term in LL. Since progesterone (P) exposure has been shown to enhance the magnitude of the E2-induced LH surge in OVX rats, the ability of combined E2+P treatment to restore the LH surge in OVX rats housed in LL was examined.

Fischer 344 rats were bilaterally OVX and housed in 12L:12D (LD) or LL (Day 0). On Day 7 rats received a Silastic capsule (s.c.) containing E2, followed 24h later (Day 8) by right atrial cannulation. On Day 9 blood samples were taken hourly (0.5ml;1200-2000h). Rats in the LL groups received an injection of oil or P (5mg P/0.25ml oil) at 1220h. Serum was assayed for LH and PRL levels by RIA.

E2 treatment alone failed to induce an LH surge in the LL rats. Moreover, combined E2-P treatment also failed to elicit an LH surge in the LL rats. E2 exposure of control LD rats resulted in an LH surge. PRL levels were unaltered in E2-treated LL rats. In contrast to the LH results, E2+P treatment did affect PRL release in LL rats. Combined E2+P treatment of LL rats resulted in a significant increase in PRL from 1600-2000h. E2-treated control LD rats exhibited a PRL surge which peaked at 1500h.

This study demonstrates that : (1) E2 treatment alone is inadequate to alter basal levels of LH or PRL in OVX-LL rats and (2) E2+P is insufficient to induce an LH surge in OVX-LL rats but does result in an increase in afternoon PRL levels. The neurochemical mechanisms mediating these photoperiod effects are currently under investigation.

COLOCALIZATION OF ESTROGEN RECEPTOR AND GALANIN IMMUNOREACTIVITY IN THE RAT PREOPTIC AREA. K.L. Cashon and R.E. Watson, Jr. Dept. Anatomy and Neurobiology, Univ. of Kentucky Medical Center, Lexington, KY 40536-0084.

Galanin (GAL) immunoreactive (ir) neurons are abundant in the preoptic area and hypothalamus. Bloch, et al. (Soc. Neurosci. Abstr. 15: 577, 1989) have shown that GAL-ir neurons are especially plentiful in important sexually differentiated components of the preoptic area and that many of these neurons concentrate radiolabeled estrogen. This study was conducted to determine if GAL-ir neurons in these sexually differentiated regions express estrogen receptor (ER) immunoreactivity. Intact and gonadectomized female Sprague-Dawley rats were treated with colchicine intracerebroventricularly and perfused with Zamboni's fixative. Frozen sections (25 µm) were incubated in monoclonal antibody H222 (Abbott Laboratories; 10 µg/ml) and reacted using nickel ammonium sulfate-intensified DAB which yielded a blue-black reaction product that was largely restricted to nuclei of immunopositive cells. Sections were then incubated in rabbit primary antiserum to GAL (Peninsula Labs) and reacted with DAB, producing the typical reddish-brown reaction product in the cytoplasm of immunopositive cells. Double-labeled cells, characterized by a blue-black nucleus (ER-ir) surrounded by reddish-brown cytoplasm (GAL-ir) were present in the anterior medial preoptic nucleus (Paxinos and Watson atlas, 1986; corresponding to the anteroventral periventricular nucleus (Simerly and Swanson, Brain Res. 400:11, 1987)), periventricular preoptic area, and the medial preoptic nucleus, especially its central part. Numerous double labeled cells were present in both intact and gonadectomized females. Thus, these results lend further support to the notion that GAL-ir neurons in sexually differentiated components of the preoptic area may serve as targets for estrogen action and contribute to expression of hormonally mediated function. {Supported by the University of Kentucky Medical Center Research Fund.}

FURTHER EVIDENCE THAT LHRH NEURONS ARE NOT DIRECTLY ESTROGEN RESPONSIVE: LHRH AND ESTROGEN RECEPTOR IMMUNOREACTIVITY IN THE GUINEA PIG BRAIN. R. E. Watson, Jr., M.C. Langub, Jr., and J. W. Landis*. Dept. Anatomy and Neurobiology, Univ. of Kentucky Medical Center, Lexington, KY 40536-0084.

Evidence obtained from steroid autoradiography (Shivers, et al., 1983; in rat) and estrogen receptor (ER) immunocytochemistry (Karsch and Lehman, Soc. Neurosci. Abstr. 14: 1069, 1988; in sheep), has indicated that the LHRH system is not directly estrogen responsive. The present study was conducted in the guinea pig brain to examine the relationship of LHRH- and ER-immunoreactive (ir) cells using a double label immunoperoxidase method. Intact male and female guinea pigs (Hartley strain, young adult, 4 of each sex) were perfused with Zamboni's fixative and 25 µm frozen sections were processed for the sequential localization of ER-ir (H222, Abbott Laboratories) and LHRH-ir (LR-1, Dr. R. Benoit). ER-ir was demonstrated with nickel ammonium sulfate-enhanced DAB as the chromogen which produced a bluish-black reaction product that was largely confined to cell nuclei. LHRH-ir was demonstrated with DAB which produced the typical reddish-brown reaction product in neuronal cytoplasm. The distribution of LHRH- and ER-ir cells overlapped extensively; abundant LHRH-ir neurons and ER-ir cells were located in the medial preoptic area, anterior hypothalamus, area of the tuber cinereum, infundibular nucl., and ventrolateral nucl. (nomenclature from the atlas of Bleier, 1983). However, in the 8 analyzed brains, only a few LHRH cells have been found to also be immunopositive to ER. Frequently, LHRH-ir neurons were located in immediate proximity to many ER-ir cells, which often were arranged in clumps or aggregates. Interestingly, at the most anterior aspect of the preoptic area, abundant varicose LHRH-ir fibers streamed directly past many ER-ir cells, suggesting the possibility of synaptic interactions between them (see Langub, et al., this volume). These results indicate that in the guinea pig the primary estrogenic control of the LHRH system is imparted by estrogen receptor-positive interneurons. {Supported by the University of Kentucky Medical Center Research Fund.}

495.5

SYNAPTIC INTERACTIONS OF LHRH-IMMUNOREACTIVE TERMINALS WITH ESTROGEN RECEPTOR-IMMUNOREACTIVE NEURONS IN THE GUINEA PIG PREOPTIC AREA. M.C. Langub, Jr., B.E. Maley, and R. E. Watson, Jr. Dept. Anatomy and Neurobiology, Univ. of Kentucky Medical Center, Lexington, KY 40536-0084.

During an examination of the relationship of LHRH and estrogen receptor (ER) immunoreactivity (ir) in the guinea pig brain (Watson, et al., this volume), it was noted that LHRH-ir varicosities were frequently in close apposition to ER-ir cells. This study was conducted to examine ultrastructurally the relationship of LHRH-ir terminals and ER-ir cells. Female guinea pigs (Hartley strain) were perfused with buffered 4% paraformaldehyde and 0.1% glutaraldehyde and 50 µm brain sections were processed for the sequential localization of ER- and LHRH-ir. ER-ir was demonstrated with monoclonal antibody H222 (Abbott Labs) using TMB as the chromogen (Norgren and Lehman, 1989). Sections were then incubated in anti-LHRH (LR-1; Dr. R. Benoit) and reacted using DAB as the chromogen. These two chromogens produce reaction products that are readily distinguishable at the ultrastructural level. Thin sections at the rostral pole of the preoptic area at the medial preoptic nucleus (MP; nomenclature from the atlas of Bleier, 1983) and immediately adjacent to it, revealed abundant ER-ir cells that were identified by the presence of crystalline TMB product within nuclei. DAB labeled LHRH-ir processes and terminals were frequently seen in apposition to ER-ir cells. Less frequently, LHRH-ir synaptic terminals contacted ER-ir perikarya. A large number of chemically-uncharacterized synapses were also present on ER-ir perikarya. These results indicate that LHRH neurons can provide input to ER-ir neurons. In light of the fact that LHRH neurons themselves do not express ERs (Watson, et al., this volume, and others) it is likely that ER-ir systems in the preoptic area and hypothalamus regulate the activity of LHRH neurons. The present finding of LHRH synaptic input to ER-ir neurons suggests the existence of a feedback loop in which the activity of ER-positive neurons can in turn be regulated by LHRH - ir neurons. {Supported by the University of Kentucky Medical Center Research Fund.}

EFFECT OF GONADECTOMY ON GNRH CELLS IN THE NERVUS TERMINALIS AND PREOPTIC AREA IN MALE AFRICAN CICHLIDS, HAPLOCHROMIS BURTONI. **R.C. Francis, R.D. Fernald* and B. Jacobson. Institute of Neuroscience, University of Oregon, Eugene, OR 94703.**

Magnocellular neurons in the preoptic area (POA) that are immunoreactive to GnRH (irGnRH) control the rate of maturation in males of Haplochromis burtoni. The size of these neurons is influenced by the social environment, such that dominant individuals exhibit large soma sizes and subordinate individuals relatively small soma sizes. Here I sought to determine whether androgen feedback is required to maintain the large cells in dominant fish. Subjects were either gonadectomized or sham-operated. After four weeks all fish were sacrificed. Gonadectomized fish were examined for residual testes. Their brains were then removed, sectioned on a cryostat and stained with an antibody to salmon GnRH. Gonadectomized fish showed no reduction in soma size relative to controls, nor any difference in the intensity of the antibody stain. In addition, there was no reduction in aggression in gonadectomized males compared to sham-operated fish. These results suggest that circulating androgens do not modulate soma size in GnRH-secreting neurons of adult males, and that aggressiveness too, is relatively independent of androgen levels.

495.7

SIMULTANEOUS *IN VIVO* MEASUREMENT OF LH AND LHRH FROM THE SAME ANTERIOR PITUITARY PUSH-PULL PERFUSION SAMPLE IN INTACT AND CASTRATED MALE RATS. R.L. Pickle and V.D. Ramirez. Dept. of Physiology and Biophysics, University of Illinois, Urbana, Illinois 61801.

The utility of push-pull perfusion (PPP) for neuroendocrine investigation in conscious animals has recently been expanded in our laboratory with the ability to contemporaneously measure LHRH and LH from the same anterior pituitary perfusion sample. Young adult male rats were stereotaxically implanted with a push-pull cannula in the anterior pituitary 14d prior to experimental use. The animals were perfused with a modified KRP containing 0.1 mM bacitracin at a flow rate of 20 µl/min. Perfusions lasted 4-6h and were continuous for the duration of the experiment with fractions being collected on ice at 10 min intervals. Samples were immediately partitioned for separate LH and LHRH radioimmunoassays, snap frozen on dry ice, and stored at -20°C until time of assay.

Intact (n=3) and 14d castrated (n=3) animals exhibited clearly pulsatile release profiles for LHRH as well as for LH. Detailed analysis of the release profiles for both hormones was performed using the PC Pulsar program. As demonstrated previously, mean LHRH release approximately doubled for castrate animals compared to intact animals, with no significant difference observed in pulse frequency or amplitude between intact or castrate animals. Intact animals exhibited a mean pulse frequency of 1 pulse every 32.5 ± 4.5 min with castrated animals exhibiting 1 LHRH pulse every 28.8 ± 1.1 min. However, LH pulse frequencies did differ ($p<0.01$) between these groups, with observed frequencies of 1 pulse every 53.3 ± 9.6 min and 1 pulse every 32.5 ± 0.9 min for intact and castrated animals, respectively. The disparity between LH and LHRH pulse frequencies within each group, reflects the substantially higher number of silent LHRH pulses (those not temporally associated with a LH pulse) shown by intact animals.

These observations are in agreement with a number of previous reports addressing this issue by sampling circulating levels of LH, and further agree with the notion that the pituitary of intact animals is less responsive to hypothalamic LHRH as a result of testosterone's effect on the gonadotrophs.

DISTRIBUTION OF ESTROGEN RECEPTOR (ER) CONTAINING AND GnRH NEURONS IN THE RHESUS MACAQUE. K.A. Sullivan, A. J. Silverman, J. W. Witkin and M. Ferin, Depts. Anat. & Cell Biol., & OB/GYN, Columbia Univ. N.Y., N.Y. 10032

Gonadal steroids are known to regulate the synthesis and secretion of GnRH. Colocalization studies using autoradiography for 3H estradiol and immunocytochemistry for GnRH (Nature 304:345,'83) identified very few GnRH cells that contained ER. The present study was undertaken to re-examine this issue using a rat monoclonal antibody (H222, Abbott Labs) to ER and a rabbit polyclonal antibody to GnRH (LR1, Benoit) in the ovariectomized rhesus macaque. Animals were perfused with 4% paraformaldehyde, the brain was fixed overnight and 50um sections through the preoptic area (POA), anterior hypothalamus (AHA) and medial basal hypothalamus (MBH) cut. ER was visualized with a nickel-DAB and GnRH with FITC. Cells immunoreactive for ER were observed within the medial preoptic area as well as periventricular, ventromedial and infundibular nuclei. ER immunoreactivity was mainly confined to nuclei of cells but was also present in the cytoplasm of a few neurons. GnRH neurons were observed in the preoptic area as well as in hypothalamic nuclei. (JCN, 211:309,'82). Many of these neurons were fusiform in shape and extended long dendrites, while a few were multipolar. The distributions of GnRH neurons and ER cells did not overlap and were rarely found close together. Of the 293 GnRH neurons counted to date, none contained ER. Experiments are currently underway to determine the neurotransmitter phenotype of the ER-containing cells and how they might relate synaptically to GnRH neurons.DK 42323

GABA RECEPTOR ANTAGONISTS INCREASE LHRH NEURONAL RESPONSIVENESS TO NOREPINEPHRINE (NE). R.Hartman, J. He* and C.A.Barraclough,Dept of Physiol, Sch. Medicine, Univ. of Maryland, Baltimore, MD 21201.

These studies examined whether the limited responsiveness of LHRH neurons to norepinephrine (NE) we observed in previous studies was due to the endogenous secretion of GABA from local hypothalamic interneurons. The icv or medial preoptic area (MPOA) infusions of either bicuculline (BIC; GABA-A antagonist) or phaclofen (PHAC; GABA-B antagonist) into chloral hydrate anesthetized, ovariectomized, estrogen-treated rats did not affect basal LH levels (95 ± 8.5 ng/ml). When NE was infused icv, it produced a modest rise in plasma LH which peaked within 15 min (240 ± 25 ng/ml). In contrast, if BIC (2 ng/2 µl) or PHAC (20 ng/2 µl) was given icv and NE (45 ug/2 µl) was infused 15 min later, plasma LH was markedly increased to peak levels of 723 ± 98 and 844 ± 126 ng/ml, respectively, within 15 min after icv NE. Similarly, when either BIC (0.5 ng/0.5 µl) or PHAC (10 ng/0.5 µl) was infused into the MPOA and NE was given 15 min later (icv) peak LH levels of 726 ± 105 and 844 ± 126 ng/ml, respectively, were obtained.

Seemingly, LHRH neurons, in their normal resting state (e.g. when plasma LH levels are low), are relatively unresponsive to NE and this may be due to the endogenous secretion of GABA from local inhibitory interneurons located within the MPOA. NIH Grant HD-02138.

IN-VITRO RELEASE OF LHRH AND 5-HIAA/5-HT FROM THE MEDIAL-BASAL-PREOPTIC HYPOTHALAMUS (MBH) OF OVARIECTOMIZED (OVX) E_2 TREATED AND PROESTROUS RATS: EFFECT OF GABA STIMULATION. R.C. McRee* and D.C. Meyer, Dept. of Physiology, Eastern Va. Med. School, Norfolk, VA 23501.

Studies on female rats suggest that 5-HT modulates LH release through LHRH systems while a GABA-A receptor-mediated mechanism can increase LHRH release in male rats. Since GABA is a major neurotransmitter in the CNS the following experiments utilized an in-vitro superfusion system (Krebs-Ringer-Phosphate) to measure the effect of GABA on LHRH and 5-HIAA/5-HT (index of 5-HT activity) release from the MBH of proestrous and OVX E_2 treated rats. MBH tissue was removed at 1000 Hours (0500 - 1900 H. light), and 500 µl. fractions were collected (50 µl/min.) and assayed for 5-HT and 5-HIAA by HPLC-EC and LHRH by RIA. The release of LHRH was significantly decreased ($P<.05$) following GABA superfusion (1×10^{-4} M) in OVX E_2 treated rats, however GABA had no significant effect in proestrous rats. GABA had no significant effect on the 5-HIAA/5-HT ratio in the OVX E_2 treated rat but significantly decreased the 5-HIAA/5-HT ratio on proestrus ($P<.05$). Collectively these data suggest that both 5-HT and GABA may play a role in LHRH release and that GABA's actions are dependent on the level of E_2 and may not utilize 5-HT systems.

LUTEINIZING HORMONE (LH) PULSE FREQUENCY, BUT NOT AMPLITUDE IS REDUCED FOLLOWING INHIBITION OF DOPAMINE-β-HYDROXYLASE (DBH). S.J. Legan*, J.H. Urban, S.S. Mehta*, L.A. Conaghan*, J.E. Levine. Dept. Neurobiol & Physiol, Northwestern Univ., Evanston, IL 60208; *Dept. Physiol & Biophysics, Univ. of Kentucky, Lexington, KY 40536.

We recently demonstrated that α_1-adrenergic receptor blockade reduces frequency but not amplitude of pulsatile LH secretion. This study examined the effects of reduced catecholaminergic (CA) neurotransmission on LH pulse frequency and amplitude. 6d castrate or 14d ovariectomized rats were bled through atrial catheters at 5min intervals for 2h. Rats received an i.v. injection of the DBH inhibitor FLA-63 (25mg/kg) or vehicle (50% propylene glycol). Sampling was resumed 2-4h following injections. Treatment with FLA-63 decreased LH pulse frequency in male (3.6±0.1 to 0 pulses/h,n=3) and female rats (3.3±0.5 to 0.8±0.3 pulses/h,n=6; $p<.02$). Mean pulse amplitude in the females was unchanged (2.46±0.21 ng/ml versus 2.60±0.47 ng/ml). Pulse parameters were unaffected by vehicle treatment. These data demonstrate that suppression of noradrenergic/adrenergic transmission reduces the activity of the LHRH pulse generator without affecting LH pulse amplitude. Our observations suggest that CA facilitation of LH secretion is exerted on the pulse generating mechanism only and not on other cellular processes modifying LHRH secretion. Moreover, the FLA-63-treated rat provides a pharmacological model in which pulse generator activity is selectively suppressed for a prolonged period, thereby allowing for detailed analyses of pulse generator regulatory mechanisms. (NIH HD20677, HD21921, HD00879, JEL; HDo7304, SJL).

OVARIAN HORMONES INCREASE DOPAMINE RECEPTOR CONCENTRATION IN THE HYPOTHALAMUS AND STRIATUM OF THE RAT. J. F. Rodriguez-Sierra and L. C. Murrin. Departments of Anatomy and Pharmacology, University of Nebraska Medical Center, Omaha, NE 68198

Prepuberal rats (25-days of age) were treated with either estradiol benzoate (EB, 10 µg, sc) or sesame oil vehicle at 1200h. Forty four hours later some of the animals were treated with progesterone (PROG, 1 mg, sc) or with sesame oil vehicle. Animals were sacrificed either at 900h or at 1600h at 27 days of age. The brains were removed and 1 mm thick sections were made using the Jacobowitz brain blocker. The striatum and the arcuate-median eminence regions were microdissected and frozen in dry ice. We pooled three animals for each point in the assay. Tissue was weighed and processed for binding to D1 and D2 receptors as described previously. We used as ligands ^{3}H-SCH-23390 and ^{3}H-spiperone (+ 50 nM ketanserin) for the D1 and D2 receptors, respectively. We found no significant differences between male and female hypothalami in the morning or afternoon at 27 days of age. Administration of EB alone did not alter the concentration of D1 receptors in either sex, but animals administered progesterone after EB showed a significant increase of D1 receptor binding in both male and female rats. The striatal D1 receptors showed a decrease in binding during the afternoon in the female rats. The males did not show this effect in D1 striatal receptors. There was no effect of EB treatment on either sex in the D1 striatal receptor, but the animals administered PROG after EB showed a dramatic increase in binding. We found a significant increase of binding to the D2 receptor in the afternoon for the female, but not the male, rat. The increase in D2 receptor binding in the hypothalamus was augmented by EB treatment and amplified further by PROG administration in the female rat. The male rat did not show the effect of EB, but PROG had a dramatic effect in increasing D2 binding to the D2 receptors in the hypothalamus. The D2 receptor binding in the striatum did not show the afternoon increase in the female rats, but did show a significant increase in binding to the administration of EB and of EB and PROG. The male rats showed an increase of striatal D2 binding after EB and PROG. Our results suggest that ovarian hormones act not only in the tuberoinfundibular hypothalamic area, but also in the striatum to modulate dopamine neurotransmission. We believe that the modulation of the tuberoinfundibular receptors by the ovarian steroids is related to the effects of dopamine on prolactin. The striking effect of progesterone in the female rat striatum might be related to the sterotypic behavior displayed by the female in estrus: such as the head tremor (sometimes called ear-wiggling) and the hopping behavior exhibited when the female is pursued by the male. (This work was supported by grants from the NIH HD-13219 to J.F. R.-S. and NS-23975 to L.C. M.)

HYPOTHALAMIC POMC mRNA LEVELS DURING RECOVERY FROM CHRONIC ESTRADIOL: DOPAMINERGIC MECHANISM? D.D. Rasmussen, M. Jakubowski, D.L. Allen, J.L. Roberts. Dept Repro Med, UCSD, La Jolla, CA 92093, and Fishberg Res Ctr for Neurobiol, Mt Sinai Sch Med, New York, NY 10029.

Dopamine (DA) appears to regulate hypothalamic POMC-containing neurons. To investigate this regulation we used a model in which rat mediobasohypothalamus (MBH) dopaminergic, but apparently not noradrenergic, activity has been demonstrated to be suppressed by chronic high estradiol (E_2) and then rebound in the weeks following removal of the E_2, surpassing pre-suppression levels. Under at least some steroidal conditions MBH dopaminergic activity is higher in the morning than afternoon, so we also addressed possible diurnal modulation. Rats were ovariectomized (OVX), OVX with 3 d low (18 pg/ml) E_2 , OVX with 20 d high (99 pg/ml) E_2, or OVX with 20 d high E_2 followed by removal of the E_2 for 10 or 20 d. 6 rats/trtmnt were sacrificed at 0900 h and 1500 h and hypothalamic *cytoplasmic* and *nuclear* POMC mRNA were quantified in solution hybridization/-nuclease protection assays. 0900 h levels of *cytoplasmic* mRNA were suppressed 21% (relative to OVX) by chronic high E_2 trtmnt but rebounded 52% by 10 d post-E_2 to a level greater than OVX. 1500 h levels were suppressed 31% by chronic E_2 and then gradually increased 68% to a level greater than OVX by 20 d post-E_2. 0900 h *nuclear* mRNA levels were also suppressed 22% by chronic E_2 and then rebounded 33% 10 d post-E_2, whereas 1500 h levels were increased only after 20 d. At 10 d post-E_2 both *cytoplasmic* and *nuclear* POMC mRNA levels were greater at 0900 h than at 1500 h. The currently demonstrated suppression and subsequent rebound and "overshoot" in POMC mRNA content in response to administration and removal of chronic high E_2 parallels the changes previously demonstrated in MBH dopaminergic activity. We are further investigating this correlation between MBH dopaminergic and POMC/endorphinergic activity by evaluating changes in tyrosine hydroxylase mRNA content in these same samples.

ESTRADIOL MODULATES THE ACTIVITY AND QUANTITY OF TYROSINE HYDROXYLASE IN THE MEDIAN EMINENCE. C. Pasqualini*, B. Guibert*, N. Faucon-Biguet *, B. Kerdelhué°° and V. Leviel*. L.P.N.- °N.B.C.M. CNRS, 91198 Gif-sur-Yvette, °°Lab. Neurobiol. Reprod. CNRS-INRA 78350 Jouy-en-Josas (France).

The nature and mechanism of estradiol (E2) effects on tuberoinfundibular dopaminergic (TIDA) neurons are still controversial. In the present study, we investigated the effects of an acute E2 treatment in parallel on the activity of tyrosine hydroxylase (TH) in the median eminence (ME) and on serum prolactin (PRL) release. Twelve-days ovariectomized rats were injected with 17βE2 (25µg s.c.) at 11.00h and sacrified hourly from 12.00 to 19.00h. TH activity was quantified by measuring the amount of exogenous tyrosine converted to L-DOPA in vitro by ME homogenates and serum PRL by RIA. A bimodal response to treatment was observed : an immediate decrease in TH activity occurred -preceeding and accompanying a rise in serum PRL- followed by an increase beyond control levels, one hour after the maximal release of PRL. This secondary increase in TH activity was no longer observed when rats were previously treated with a specific rat PRL antiserum, suggesting it was not due to E2 per se , but rather mediated by the E2-induced PRL elevation. To pinpoint the process underlying the E2-induced decrease in TH activity, we also evaluated the kinetic parameters of TH in the ME as well as its quantity (by "Western blot" analysis). The decrease in TH activity after E2 treatment nicely paralleled an immediate decrease in the affinity of TH for its cofactor (6-MPH4), while Vmax was unchanged. A decrease in the amount of TH was also observed but its latency precluded its major involvement in the immediate decline of TH activity. Therefore, when observed independently from those of PRL, E2 effects on TH in TIDA neurons are clearly inhibitory. They consist in a desactivation of the enzyme together with a reduction of its synthesis.

EVIDENCE FOR INDEPENDENT α_1 ADRENERGIC AND OPIOIDERGIC REGULATION OF PULSATILE LUTEINIZING HORMONE (LH) SECRETION. K. M. Vogelsong and J. E. Levine. Dept of Neurobiology and Physiology, Northwestern University, Evanston, IL 60208

A prevalent hypothesis holds that catecholaminergic (CA) neurons mediate opioidergic inhibition of LHRH release. To test this theory, we analyzed effects of opiate and α_1 adrenergic blockade on pulsatile LH secretion in intact and ovariectomized (OVX) rats. Effects of separate or combined treatments with the opiate receptor antagonist, naloxone (NAL), and the α_1 adrenergic antagonist, prazosin (PRA) were examined to determine (i) which parameters of LH secretion are altered by each drug, and (ii) if α_1 adrenergic blockade eliminates opioid inhibitory tone. Metestrous (MET) or OVX rats with atrial catheters were bled every 5min for 4h. After 1h, rats received PRA (1mg/kg ip) or vehicle, followed by NAL (5mg/kg iv) or vehicle. Frequency, but not amplitude, of LH pulses was suppressed ($p<.05$) by PRA in OVX animals, while the drug was without effect in MET rats. By contrast, NAL increased ($p<.05$) mean LH release in both MET and OVX rats. PRA pretreatment did not block NAL effects in MET rats. In PRA-treated OVX rats, NAL appeared to augment LH secretion in many cases where pulses occurred within 1h following NAL. These data suggest that opioid effects are not mediated exclusively by NA pathways. Instead, it is proposed that opioid inhibitory tone is exerted independently from α_1 adrenergic facilitation of the LHRH pulse generator. (NIH RO1-HD20677, KO4-HD00897, PO1-HD21921).

SIMULTANEOUS ESTIMATION OF ADRENALINE AND NORADRENALINE TURNOVER IN THE PREOPTIC AREA AND MEDIAN EMINENCE OF PRO-OESTROUS AND DIOESTROUS RATS. J. Opacka-Juffry* and C.W. Coen. Division of Biomedical Sciences, King's College, London, UK.

The present study was designed to assess the simultaneous rates of turnover of noradrenaline and adrenaline in the preoptic region containing the luteinizing hormone releasing hormone (LHRH) cell bodies and in the median eminence, the site of the LHRH terminals. Rats were maintained with lights on from 06.00 to 20.00h. The turnover rates were assessed by catecholamine decline 2 hours after dopamine β-hydroxylase inhibition with 10mg FLA 63/kg given ip at 12.00 or 17.00h on dioestrus and 12.00, 15.00 or 17.00h on pro-oestrus. Samples were micropunched from 300µm cryostat sections which were subsequently fixed, stained and assessed. Although no significant change was found in adrenaline turnover in the preoptic area or median eminence within diestrus, there was a significant increase on pro-oestrus in both sites by the latter sampling point; this time corresponds to that of the LH surge in our colony. Noradrenaline turnover in the same material failed to demonstrate significant changes in the preoptic area within either of the days, but at 12-14.00h on pro-oestrus it was significantly higher than at the same time on dioestrus. While recognizing the limitations of assessing turnover by amine depletion, these results on histologically verified samples suggest that the occurrence of the LH surge is associated with increased adrenaline turnover in the region of the LHRH-containing perikarya and terminals.

DIFFERENTIAL LH AND FSH RESPONSES TO N-METHYL-D-ASPARTATE IN INTACT AND CASTRATE MALE RATS. F.J. Strobl, U. Luderer*, N.B. Schwartz, and J.E. Levine. Dept. of Neurobiology and Physiology, Northwestern Univ., Evanston, IL 60208.

The excitatory amino acid agonist N-methyl-D-aspartate (NMDA) stimulates LH secretion by evoking an acute increase in LH-releasing hormone (LHRH) secretion. These studies were conducted to determine (i) whether FSH secretion is also stimulated by NMDA treatment, (ii) if any NMDA effects on FSH are mediated by LHRH, and (iii) if LH and FSH responses to NMDA are affected by changes in endocrine status. Castrate (n=10) and sham-castrate (n=11) male rats received 100ug LHRH antagonist or oil vehicle at 2100h and on the next day were bled at 10min intervals through atrial catheters from 0900-1200h. Animals received 5 mg NMDA after 1h and 500ng LHRH after 2h. Plasma LH and FSH were determined by RIA. In oil-treated sham-castrates LH levels were increased by 110% ($p<.01$), while FSH levels were unchanged following administration of NMDA. LH responses to NMDA were attenuated in castrates compared to sham-castrates. FSH levels were also unchanged following NMDA in castrates. LHRH antagonist pretreatment blocked LH responses to NMDA, as well as LH and FSH responses to LHRH. Our data indicate that the amount of LHRH released during the stimulation of an LH pulse is an inadequate stimulus for pulse-like stimulation of FSH secretion. While pulsatile LHRH stimulation may support basal FSH secretion, pulse-like increments in FSH secretion may either be constitutive endocrine events or be driven by a separate FSH-RH. Attenuation of NMDA-induced LH secretion in castrates may reflect a diminishment of the releasable LHRH pool following removal of gonadal negative feedback. Supported by NIH P01-HD21921 and R01-HD20677.

DIFFERENTIAL GONADOTROPIN RESPONSES TO N-METHYL-D-ASPARTATE (NMDA) IN PROESTROUS (PRO), METESTROUS (MET) AND OVARIECTOMIZED (OVX) RATS. U. Luderer*, F.J. Strobl, J.E. Levine, N.B. Schwartz. Dept of Neurobiology and Physiology, Northwestern Univ, Evanston, IL 60208.

NMDA, an analog of the excitatory amino acid aspartate, elicits luteinizing hormone (LH) and prolactin (PRL) release in rats. These experiments were carried out to i) verify that NMDA-stimulated LH secretion is mediated by LH releasing hormone (LHRH), ii) assess the degree to which NMDA stimulates follicle stimulating hormone (FSH) in a LHRH-dependent manner and iii) analyze the relationship between endocrine status and responsiveness to NMDA. Estrous, diestrous or 8-day OVX rats were fitted with atrial catheters and injected with 100 ug LHRH-Antagonist (Antag) or vehicle at 2100h. Starting at 0900h the next day blood was withdrawn every 10 min for 3h. Each animal received 5 mg NMDA after the first, and 500 ng LHRH after the second, hour. NMDA significantly increased LH in MET and PRO females. Antag reduced the increases. In OVX females LH paradoxically decreased after NMDA. FSH was not affected by NMDA and was slightly suppressed by Antag. PRL increased after NMDA in all groups. LHRH caused surge-like LH and small FSH increases in vehicle groups. These results demonstrate that LHRH mediates the LH response to NMDA in rats; lack of FSH responses to NMDA suggests that physiological increments in endogenous LHRH secretion are insufficient to stimulate pulse-like FSH release. Comparison of NMDA responses also suggests that the releasable pool of LHRH is not increased before the preovulatory LH surge. (Funded by NIH HD07504).

COMPARISON OF LH AND PROLACTIN RESPONSES TO KAINATE AND NMA IN LACTATING AND CYCLING RATS. R. Abbud* and M.S. Smith. Department of Physiology, University of Pittsburgh School of Medicine, Pittsburgh, PA 15261.

We have reported that in cycling rats, NMA (20-40 mg/kg, iv) stimulates both LH and prolactin (PRL) release (Endocrinology 124: 1905, 1989). In lactating rats, GnRH neurons are refractory to NMA, but NMA inhibits suckling-induced PRL secretion. NMA's effects on PRL, whether stimulation of PRF's or DA predominate, appear to depend on the reproductive state of the animal. Recent autoradiographic studies suggest that kainate receptors may be more abundant than NMDA receptors in the hypothalamus. Thus, we have examined LH and PRL responses to kainate (1.5-2.5 mg/kg iv). Three pulses of kainate were infused 2 hrs apart and serial blood samples were collected at 10 min intervals. Lactating rats suckling 8 pups (day 10 postpartum) were primed for 24 hrs with GnRH pulses (5 ng iv every 50 min) to restore pituitary GnRH receptors before administration of kainate.

In diestrous and estrous rats, kainate induced larger LH responses than did NMA. Surprisingly, PRL secretion did not increase in response to kainate. In the lactating rats, kainate had similar effects as those of NMA, that is, it was unable to overcome the lactation-induced suppresion of LH release, but it did inhibit suckling-induced PRL secretion. By 24 hrs after pup removal, both kainate and NMA induced small increases in LH secretion but only NMA stimulated PRL release.

These data demonstrate that the suckling stimulus induces GnRH neuronal refractoriness to exogenous stimuli such as excitatory amino acids. Also, kainate and NMDA receptors appear to have different distributions on neurons that affect PRL secretion. (NIH grant HD 14643)

REGULATION OF AUTONOMIC FUNCTION: TEMPERATURE REGULATION AND NEURAL-IMMUNE SYSTEM INTERACTIONS

BROWN ADIPOSE TISSUE RESPONSES OF CONSCIOUS AND ANESTHETIZED RATS FOLLOWING VMH ELECTRICAL OR INTRAVENOUS NOREPINEPHRINE STIMULATION. J.A. Thornhill and I. Halvorson. Dept. of Physiology, Univ. of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0.

Thermoregulatory experiments were conducted in conscious and urethane anesthesized male Sprague-Dawley rats previously acclimated for 3 weeks at 4°C or 21°C to determine if VMH electrical stimulation or intravenous (iv) norepinephrine infusion could activate interscapular brown adipose tissue (BAT) thermogenesis, as indicated by significant increases in IBAT temperature (T_{IBAT}) above core, as measured colonically (T_C). Experiments were conducted twice when the animal was conscious but restrained (trained to Plexiglass holder beforehand) and lastly when anesthetized with urethane (1.5 g/kg ip). T_C, T_{IBAT} and tail (T_t) temperatures and blood pressure (from indwelling femoral arterial catheter) were monitored before and for 20 min after bipolar electrical stimulation (0.5 msec pulses of 100 μA at 50 Hz for 30 sec) of the ventromedial hypothalamic nucleus (VMH) or after intravenous infusion (100 μl/min) of sterile saline and norepinephrine HCl (NE, 20 μg/ml). Conscious or anesthetized rats acclimated to 4°C evoke significant increases in T_{IBAT} above T_C after VMH electrical or iv NE stimulation.

Supported by the Medical Research Council of Canada.

VENTROMEDIAL HYPOTHALAMIC STIMULATION OF BROWN ADIPOSE TISSUE THERMOGENESIS. L. Kelly* and C. Bielajew, Dept. of Psychology, University of Ottawa, Ottawa, Canada, K1N 6N5.

The ventromedial hypothalamus (VMH) is implicated in the central regulation of brown adipose tissue (BAT) facultative thermogenesis, although inconsistencies exist in the reported observations of effective areas. In this study, VMH stimulation of BAT thermogenesis was mapped with moveable electrodes, lowered in 0.16mm increments. Seven male hooded rats were implanted in the VMH region, with interscapular BAT and core temperatures monitored continuously. Each train of 25 (100μsec) square wave cathodal pulses was delivered at 300μA, 500msec on/500msec off, for a trial duration of 60sec. A mid-VMH descent yielded two active sites, both with a typical BAT temperature change of 0.4-0.6°C, in contrast to the temperature profiles found at the single active site in each of two mid-anterior VMH, and one dorsal medial hypothalmic (DMH) placements. These profiles showed larger temperature changes of 1.1-3.3°C, and slower returns to baseline (70-180min). Non-responsive placements included the anterior and posterior VMH, and two descents immediately lateral to the VMH. A regulatory connection of the VMH to BAT thermogenesis is demonstrated, with the possibility that several different substrates stimulate BAT activity. These could be related to the known differences between cold and dietary signals which both act on BAT through the VMH. Supported by NSERC grant #U0514 to C.B.

PROSTAGLANDIN-E_2 STIMULATION OF BROWN ADIPOSE TISSUE (BAT) THERMOGENESIS IN SPONTANEOUSLY HYPERTENSIVE (SHR) AND WKY RATS. S.Bhatnagar, M.J.Meaney and S.Amir. Ctr. for Studies in Behav. Neurobiol.,Dept. of Psych., Concordia Univ.,Douglas Hospital Res. Ctr., McGill Univ., Montreal, Canada.

SHRs exhibit diminished ability to maintain body temperature in the cold, but the pathophysiological mechanism responsible for this deficiency is unknown. We studied the possibility that failure of SHRs to defend body temperature in the cold is related to a reduced ability to centrally activate adaptive thermogenesis in BAT. In the present study, injection of PGE_2 (50-200ng) into the POAH had a differential effect on intrascapular BAT temperature (IBATt) of adult, urethane-anesthetized SHRs and normotensive WKYs. The 50ng dose produced an increase of 0.72 ± 0.17°C in IBATt in SHRs compared to a larger increase of 1.65±0.15°C in WKYs ($p<0.01$). 100ng of PGE_2 produced an increase of 1.22±0.26°C in SHRs and an increase of 1.90±0.08°C in WKYs ($p< 0.05$). 200ng of PGE_2 increased IBATt by 1.45±0.23°C and 1.97±0.16°C in SHRs and WKYs, respectivley. It has been shown that injection of PGE_2 into the POAH mimics the effect of cold in stimulating BAT thermogenesis. The finding that SHRs exhibit reduced sensitivity to the central effects of PGE suggests that the diminished ability of these animals to defend body temperature in the cold may be related, at least in part, to a defect in central mechanisms mediating the effect of cold on nonshivering thermogenesis in BAT.

496.4

THE INFLUENCE OF ONE-KIDNEY RENOVASCULAR HYPERTENSION ON THE HYPERTHERMIC RESPONSE TO CENTRAL PGE_1 IN THE RAT. D.M.Fyda, W.L.Veale & Q.J.Pittman, Department of Medical Physiology, University of Calgary, Calgary, Alberta, Canada T2N 4N1.

There is evidence for high circulating levels of arginine vasopressin (AVP) during development of one-kidney/one-clip (1K1C) hypertension. Arginine vasopressin is also known to act centrally as an endogenous antipyretic against a prostaglandin E_1 (PGE_1) fever. As peripheral and central release of AVP has been correlated, this study assessed whether 1K1C hypertension (left nephrectomy followed by the application of a 0.2 mm diameter clip to the right renal artery) influenced the hyperthermia evoked by an intracerebroventricular injection of 150 ng PGE_1 (in 5.0 μl). Remote monitoring of core temperature (Tc) occurred prior to clipping and on days 4, 8 and 12 post-clipping for a 60 min baseline and a 120 min post-PGE_1 injection period. Prior to clipping, PGE_1 evoked a 1.4°C rise in Tc relative to baseline values ($p<.0001$) in all 16 rats. Post-clip, nephrectomized-only controls remained normotensive and continued to show similar rises in Tc following PGE_1. On days 4 and 8 post-clip, the blood pressure of the 1K1C rats steadily increased (as monitored by tail plethysmography) but the PGE_1-evoked rise in Tc was essentially abolished relative to pre-clip levels ($p<.0001$). Blood pressure of the 1K1C rats stabilized on day 12 post-clip at 185 ± 5 mmHg and Tc now rose by 0.84°C ($p<.0001$) following PGE_1. To establish if the suppression of fevers observed during the development of hypertension was due to the central release of AVP, other 1K1C rats received an AVP receptor type 1 antagonist (Manning Compound, 200 pmol in 1 μl bilaterally into the ventral septal area) 15 min prior to PGE_1. Under these conditions the typical hyperthermia was reinstated. These data suggest that during the development of this model of hypertension there may be an increase in the central activity of AVP which contributes to the inability of the animals to obtain a fever. When the hypertension stabilized, the animals were able to obtain a fever, suggesting that central AVP activity had returned towards normal levels. Supported by the MRC (Canada), Heart Foundation (Canada), & AHFMR (Alberta).

HIGH DENSITY OF PROSTAGLANDIN E_2 BINDING SITES IN THE ANTERIOR WALL OF THE THIRD VENTRICLE (A3V). K. Matsumura[1], Y. Watanabe[*2], H. Onoe[*2], Y. Watanabe[*2], O. Hayaishi[*2]. [1]Dept. of Physiol., Osaka Univ. Med. Sch., Kita-ku, Osaka 530, [2]Dept. of Neuroscience, Osaka Bioscience Institute, Suita, Osaka 565, JPN.

Prostaglandin E_2 (PGE_2) exerts potent hyperthermic action when injected into the preoptic-hypothalmic region (POHA). To determine the exact functional sites of PGE_2, we used in vitro autoradiography of ^{3}H-PGE_2 binding sites in the rat POHA. Frozen sections of rat brain were cut in a cryostat and mounted on glass slides. They were preincubated in Tris-HCL buffer and then incubated with 20 nM ^{3}H-PGE_2 solution for 30 min. Non-specific binding was obtained using consecutive sections by the addition of 100 uM unlabeled PGE_2 to the incubation mixture. They were dried and juxtaposed to ^{3}H-sensitive films. After 4-5 weeks, the films were developed and the optic density was measured. The highest density of ^{3}H-PGE_2 binding was found in the A3V. Within A3V, the density was especially high in regions closest to the third ventricle or surrounding the organum vasculosum laminae terminalis (OVLT) but was relatively low in the OVLT itself and the medial preoptic area/ anterior hypothalmic area. A3V seems to be involved in PGE_2 induced hyperthermia.

SENSITIVITY OF RAT MEDIAN PREOPTIC NEURONS TO TEMPERATURE, ANGIOTENSIN II AND NOREPINEPHRINE. K.A. Travis and A.K. Johnson. Depts. of Psychology and Pharmacology and the Cardiovascular Center, Univ. of Iowa, Iowa City, IA 52242.

The median preoptic (MnPO) nucleus receives angiotensinergic projections from the subfornical organ, noradrenergic projections from the brainstem and has reciprocal connections with the medial preoptic nucleus of the hypothalamus. The present study sought to determine the specificity of MnPO neuronal responses to angiotensin II (AII) (10^{-4} or 10^{-5}M), norepinephrine (NEpi) (10^{-4} or 10^{-5}M) and changes in temperature (32-42°C).

In-vitro neuronal activity was recorded from MnPO neurons in sagittal tissue slices (350-450 um) of male Sprague-Dawley rats. Single units were evaluated for responses to changes in perfusate temperature and perfusion by AII, NEpi or both AII and NEpi.

Of the neurons tested for sensitivity to changes in temperature (n=40), 75% were thermo-insensitive and 25% were warm sensitive. Of the neurons tested for responses to the drug challenges (n=31), 42% responded to at least one treatment. Most neurons which responded to the drug challenges did so with increased activity (86%). In addition, some neurons showed an additive or synergistic response to AII and NEpi applied together. Drug treatment rarely (1/15) affected the thermosensitivity of the neurons.

ALTERED BRAIN [^{3}H]IDAZOXAN BINDING IN RABBITS DURING FEVER. L.K. Vaughn. Marquette Univ. Sch. of Dentistry, Milwaukee, WI 53233.

The neuronal mechanisms responsible for fever are incompletely understood and the possible role of changes in the number and/or affinity of brain receptors to thermoregulatory neurotransmitters during fever is unknown. We investigated whether fever is associated with changes in α-2 adrenergic receptors (α-2 AR) since norepinephrine has been implicated as a neurotransmitter involved in fever and α-2 AR are altered by microwave-induced hyperthermia (Gandhi and Ross, Radiat. Res. 109:90,1987). Rabbits were sacrificed 0.5 hr to 4 hr after injection with 0.25 μg/kg Salmonella abortus equi endotoxin (n=5 at each time point) or saline (n=10) and binding of [^{3}H]idazoxan, an α-2 AR antagonist, in tissue homogenates of various brain regions was performed using the method of Reader et al. (Neurochem. Res. 11:9, 1986). Maximal changes in binding occured 2 hr after injection. Further experiments at 2 hr (n=7 saline, n=7 endotoxin) revealed an increase in Bmax in the posterior hypothalamus (PH)(19%) and striatum (STR)(62%). There was also a significant increase in Kd (PH, 25%; STR, 97%). There were no significant changes in the anterior hypothalamus, medulla or cortex. The increased receptor number and decreased receptor affinity might indicate that two populations of α-2 AR are undergoing changes. The observed changes in α-2 AR number and affinity may serve to enhance or modulate regulatory mechanisms involved in fever.

496.8

PERFUSION OF ARGININE VASOPRESSIN WITHIN THE MEDIAL AMYGDALOID NUCLEUS ATTENUATES PROSTAGLANDIN HYPERTHERMIA IN THE URETHANE-ANAESTHETIZED RAT. P. Federico, T.J. Malkinson*, Q.J. Pittman and W.L. Veale. Neuroscience Research Group, The University of Calgary, Alberta, Canada T2N 4N1.

The neuropeptide arginine vasopressin (AVP) has been shown to act within the ventral septal area (VSA) in conscious animals as an endogenous antipyretic. AVP content in amygdalar nerve terminals has recently been found by other investigators to change in febrile or pyrogen tolerant animals, suggesting that AVP may also act in association with fever in this site. Thus, experiments were undertaken to determine whether AVP push-pull perfusion within the medial amygdaloid nucleus (meA) or VSA would attenuate prostaglandin (PGE) hyperthermia in the urethane-anaesthetized rat. The meA was chosen as the novel target for AVP perfusion due to its strong vasopressinergic input as well as its extensive reciprocal connections with brain loci important in fever and antipyresis. Guide cannulae bilaterally directed toward the lateral cerebral ventricles as well as the meA or the VSA were stereotaxically implanted in 66 male Wistar rats (270 -330 g) under urethane anaesthesia (1.5 g/kg). After surgery, the rats were allowed a 30 minute settling period during which colonic temperature, recorded by a thermistor probe, was maintained at a baseline of 37.17 ± 0.05°C. Following this, aCSF or AVP (6.5 μM in aCSF) was bilaterally push-pull perfused within the meA or VSA for 120 minutes prior to an i.c.v. injection of PGE_1 and for an additional 120 minutes after injection. Perfusion of AVP (6.5 μM) within the meA significantly attenuated the hyperthermic response to i.c.v. PGE_1 compared to similar perfusion of aCSF (aCSF = 1.37 ± 0.25 °C, AVP = 0.67 ± 0.15 °C; $p < 0.05$). Perfusion of AVP within the VSA resulted in a more significant suppression of PGE_1 hyperthermia compared to similar perfusion of aCSF (aCSF = 1.34 ± 0.16 °C, AVP = 0.32 ± 0.25 °C; $p < 0.01$). These results suggest that AVP perfused within the meA or VSA suppresses PGE_1 hyperthermia in the urethane-anaesthetized rat. However, AVP perfused within the meA suppresses PGE_1 hyperthermia less efficaciously than AVP perfused within the VSA.

496.9

THERMOREGULATORY CONSEQUENCES OF HIPPOCAMPAL TRANSECTIONS AND SEPTAL LESIONS IN HAMSTERS: DELAYED RESPONSES TO EXOGENOUS PYROGEN AND DELAYED DROP IN NOCTURNAL TEMPERATURE. P.Johnson and K.T.Borer, Dept. Kinesiology, Univ.of Michigan, Ann Arbor, MI 48109.

To characterize the thermoregulatory consequences of rostromedial septal lesions (SEP) and hippocampal transections (HIPPO), mature female golden hamsters were implanted with temperature telemetry devices for monitoring of core temperature (t_c, Minimitter Co.) one week prior to SEP (n=8), HIPPO (n=6), and control (CON, n=6) neurosurgery. On days 10,12, and 14 postsurgery, responsiveness of lesioned hamsters to the lipopolysaccharide (LPS) pyrogen was checked by injecting each animal ip with saline or two doses of LPS (10 and 20 ug/kg). Lesions resulted in: (1) a 5h (SEP) to 9h (HIPPO) delay in the decline of nocturnal t_c, and in response to injected LPS, (2) a reduced early phase in t_c rise, and (3) a 3 to 5 h delay in the second phase of t_c rise. Hippocampus, and to a lesser extent the rostromedial septum in hamsters play a role in nocturnal tc decline and in pyrogenic response to LPS.

496.10

EFFECT OF INTERLEUKIN-1α ON RADIATION-INDUCED HYPERTHERMIA IN RATS. S. B. Kandasamy, K. S. Kumar*, A. H. Harris*, and J. F. Weiss*. Behavioral Sciences and Radiation Biochemistry Departments, Armed Forces Radiobiology Research Institute, Bethesda, MD 20814-5145.

Exposure of rats to 10 Gy of high-energy electrons (18.6 MeV) produces hyperthermia and decreased hypothalamic levels of the antioxidant enzymes superoxide dismutase (SOD) and glutathione peroxidase. Intracerebroventricular administration of 1-5 μg of SOD or 1-5 units of glutathione peroxidase attenuated radiation-induced hyperthermia. Recombinant human interleukin-1α (IL-1α) administered 24-hr before radiation exposure increased the levels of antioxidant enzymes and prostaglandin E_2 (PGE_2) and reduced the hyperthermic response. These effects were blocked by the cyclooxygenase inhibitor indomethacin and also did not occur when IL-1α was administered 1-hr before radiation exposure. The results suggest that the attenuation of radiation-induced hyperthermia by IL-1α may involve PGE_2 synthesis and the stimulation of antioxidant enzymes.

496.11

RESPONSES OF PREOPTIC NEURONS TO HUMAN RECOMBINANT INTERLEUKIN-6 (IL6) IN TISSUE SLICES. L. Xin* and C.M. Blatteis. Univ. of Tennessee, Memphis, TN 38163.

It has been suggested that IL6 may be another endogenous pyrogen (EP) because, like other such agents, its i.v. injection induces monophasic fevers, albeit at much higher doses than the others. We recently showed that its site of action in guinea pigs is the preoptic area (PO); this is also the locus of the pyrogenic action of the other EPs. This brain region contains cold- (C) and warm- (W) sensitive neurons that generally are excited and depressed, respectively, during the febrile rises other EPs induce, while thermally insensitive neurons are affected unpredictably. This study was undertaken to determine whether the neuronal action of IL6 is analogous to that of the other EPs. Extracellular single-unit activities of warm-sensitive and thermoinsensitive neurons were recorded in 350 μm-thick slices of guinea pig PO perfused with oxygenated artificial cerebrospinal fluid. Thermosensitivity was assessed by firing rate changes over the perfusate temperature range 32-42°C; no C units were identified. IL6, added directly to the perfusate at 1 μg/10 μl, depressed the activities of all the W units recorded. The decrease in firing rate was (means ± SD) 2.9 ± 2.2 imp/s, with an onset latency of 6.0 ± 1.3 min and a duration of 34.2 ± 17.7 min. These findings indicate that the effects of IL6 on preoptic thermosensitive neurons are similar to those of other putative EPs, but last longer. All the thermoinsensitive neurons in the PO were also affected by IL6, responding with either an increase (67%) or a decrease (33%) in activity. (Supported by NIH NS 22716 and BRSG RR05423).

496.12

FOOD INTAKE AND BODY TEMPERATURE RESPONSES OF RATS TO RECOMBINANT HUMAN INTERLEUKIN 1-B (IL-1B) AND IL-1B ANTAGONIST (IL-1B ANTAG). C.L. McLaughlin, G.J. Rogan and C.A Baile. Animal Sciences Division, Monsanto Company, St. Louis, Mo 63198.

The cytokine Il-1B, produced by activated macrophages, may mediate the cachexia associated with cancer. Food intake (FI) is decreased by acute but not chronic administration of IL-1B in rats. Il-1B also induces analgesia and this effect was blocked by Lys-D-Pro-Thr, an IL-1B antag (Ferriera, S.H., et al., Nature 334:698, 1988). In the present experiment the ability of this IL-1B antag to block the FI and body temperature (BT) responses to IL-1B were tested in male Sprague-Dawley rats. IP administration of 1.25, 1.88 and 2.50 μg IL-1B decreased FI 13, 20 and 19% 4-22 hours after treatment (25.2, 21.9, 20.2 and 20.3 g, respectively, $p<.05$). Cumulative 22-hr FI was decreased for the 2 higher doses only. In experiment two the decreased FI intake 4 hr after 1.25 μg IL-1B (3.0 vs 5.5 g, $p<.01$) was blocked by coadministration of 5 mg/rat Il-1B antag (4.0 vs 5.5 g, NS) but not 1 mg or less (300 or 600 μg). However, 22-hr FI was decreased similarly by 1.25 μg IL-1B alone and in combination with 1 or 5 mg IL-1B antag (25.0, 25.0 and 26.0 vs 32.0 g, respectively). The IL-1B antag alone (2.5, 5.0 and 10.0 mg/rat) did not affect cumulative 22-hr FI (31.1, 31.3, 29.5 and 31.6 g, respectively). Increased BT 4 hrs after 1.25 μg/rat IL-1B (.9 C vs control, -1. C, $p<.01$) was blocked by 5 and 25 mg IL-1B (.3 and .2 C, respectively, NS). BT 22 hrs later was not affected. It is concluded that IL-1B antag can block FI and BT responses to IL-1B in addition to the analgesic responses demonstrated previously.

496.13

DISTRIBUTION OF CYCLOOXYGENASE (PGH2 SYNTHASE)-LIKE IMMUNOREACTIVITY IN THE OVINE CENTRAL NERVOUS SYSTEM. C.D.Breder and C.B. Saper. Depts. of Pharm. & Physiol. Sci. and Neurology, Univ. of Chicago, Chicago IL 60637

Cyclooxygenase (COX) is the rate limiting enzyme in the conversion of arachidonic acid to prostaglandins. These lipid mediators have been implicated in numerous central nervous system activities including generation of the febrile response, modulation of peptidergic neurotransmission in the cerebral cortex and depolarization of sensory afferent neurons. We mapped in detail the distribution of COX-like immunoreactive (ir) structures in the ovine central nervous system with two polyclonal antisera raised against the purified enzyme. COX-ir neurons were observed throughout the cerebral cortex in a distinct laminar pattern that varied in different areas. COX-ir neurons were particularly numerous in the basal forebrain, particularly in the tubero- mammillary and dorsomedial hypothalamic nuclei, the basal amygdala and the bed nucleus of the stria terminalis. In the brainstem they were found in somatic sensory cell groups including the dorsal column nuclei and the spinal trigeminal nucleus as well as visceral sensory regions such as the nucleus of the solitary tract and parabrachial nucleus. COX-ir non-neuronal structures were observed in association with the circumventricular organs of the third and fourth ventricle. We propose that COX may be present within the CNS particulary in neuronal pathways involved in sensory and autonomic function.

EFFECTS OF TEMPORARY LIDOCAINE LESIONS IN THE VSA OF THE BRAIN OF THE ENDOTOXIN-TOLERANT RAT ON BLOOD PRESSURE AND HEART RATE. M.R.H. McCashin,* C. Shaw, and N.W. Kasting, Dept. Physiology, University of British Columbia, Vancouver, B.C. Canada V6T 1W5

There exists a close correlation between blood pressure and body temperature in rats with first time endotoxin fevers. AVP released into the VSA, reduces body temperature during fever. Blood pressure sensitive neurons have been located in the VSA, therefore neuronal connections within the VSA may play an important role in modulation of body temperature by blood pressure during fever in the rat. Telemetry was used to measure MABP and HR from unrestrained rats. Brain and rectal thermistors were used to measure body temperature (Tb). Rats were rendered tolerant by injections of endotoxin every 3 days. The VSA was infused for the length of the experiment with 5% lidocaine or vehicle (1 ml/hr). Linear regression analysis of vehicle-treated tolerant rats showed no relationship between Tb and MABP whereas lidocaine-infused tolerant rats had a good correlation (re=0.74). These results lead us to conclude that the VSA mediates some of the pathways between Tb and MABP in the tolerant rat.

NEURAL-IMMUNE INTERACTIONS II

PRENATAL EXPOSURE TO DIETHYSTILBESTEROL AND CHANGES IN THE IMMUNE SYSTEM. N.R.S. Hall and M.P. O'Grady. Psychoimmunology Div., Dept. of Psychiatry, Univ. of South Florida College of Med., Tampa, FL 33613.

We have previously shown that thymosin peptides can modulate reproductive neuroendocrine circuits and that activation of the immune system during ontogeny can modulate the adult reproductive axis. In this study, we evaluated the effects of early exposure to a synthetic estrogenic compound, diethylstilbesterol (DES). Pregnant SW mice were injected with 1 μg of DES either between days 11-15 or days 17-20 of gestation. Control mice received the same volume of oil vehicle or remained uninjected. Overall, early exposure to DES was found to enhance mixed lymphocyte responsiveness, and blastogenesis in response to Con-A, PHA and LPS in the 4-6 week old male and female offspring. Control females had increased thymus weight and spleen cell blastogenic responsiveness compared with control males while DES exposure increased the male measures toward those of the untreated female offspring. These results suggest that exposure to estrogenic compounds during fetal development can alter the immunologic status of the adult. Supported in part by a grant from the NIH (NS21210).

IMMUNOLOGIC DISPARITY IN THE HYPOPITUITARY DWARF MOUSE. RJ Cross; LE Boyarsky and TL Roszman. College of Medicine, University of Kentucky, Lexington, KY 40536-0084.

The DW/J dwarf mouse, a homozygous recessive mutation lacks growth hormone (GH) and prolactin and can be characterized by extremely stunted growth. Reports by several laboratories indicate that these mice are also compromised immunologically implicating a role for neuroendocrine hormones in the development thymus and spleen and are deficient in both humoral and cell-mediated immunity. These immunological abnormalities can be corrected by supplemental treatment with GH and thyroxine or GH alone. However, more recent data show that these mice are not impaired immunologically and have a normal percentage of T-cell and B-cells in the spleen and cell-mediated immunity to oxalazone, a skin sensitizing agent. Observations by this laboratory indicates an immunological disparity exists in this strain of mice. Although all mice are small in size, some have a normal percentage of T-cells, B-cells and T-cell subsets in the spleen, while others show an abnormal predominance of T-cells over B-cells. The thymus is also not normal in that th population of $CD4^+$, mature T-helper cells predominate with very few immature CD4/CD8 cells, the cell type normally found in highest frequency. (Supported in part by USPHS grant NS22512).

EFFECTS OF THYMOSIN α_1 ON PITUITARY HORMONE RELEASE. L.Milenkovic* and S.M.McCann. Dept. Physiol., UT Southwestern Medical Center, Dallas, Texas 75235-9040.

We have studied the effects of thymosin α_1 ($T\alpha_1$) on TSH, ACTH, Prl and GH release. To evaluate its effect in vivo we injected the peptide into the third ventricle (3V) of conscious male rats, and measured the concentration of the pituitary hormones in plasma at different times after injection. Following 3V injection of $T\alpha_1$, there was a significant, dose-related decrease of plasma TSH and ACTH concentrations on comparison to control groups. Also, a significant decrease of plasma Prl was observed. There were no significant changes in plasma GH. To examine the effect of $T\alpha_1$ at the pituitary level we incubated hemipituitaries in vitro with different concentrations of the peptide. In this system $T\alpha_1$ evoked a dose-dependent release of TSH and ACTH, while there was no effect on the release of Prl and GH. The results indicate a hypothalamic effect of $T\alpha_1$ to decrease release of TSH, ACTH and Prl. Acting directly at the pituitary level, the peptide stimulates release of TSH as well as ACTH. Both hypothalamic and pituitary sites of action might be of importance for the interaction between central nervous, endocrine and immune system.

CHOLINE O-ACETYLTRANSFERASE (ChAT) ACTIVITY IN THE ADULT MOUSE THYMUS. M. Badamchian, J. Hausman, T. Radojcic* and K. Bulloch Dept. of Biochem, Mol. Bio. George Washington Univ. Washington, D.C. 20037; Dept of Psychiatry Univ. of Cal. San Diego, La Jolla, CA 92093.

Acetylcholinesterase and muscarinic acetylcholine receptors have been identified in the adult mouse thymus. However, specific ChAT has only been identified within thymic nerves via immunocytochemistry. In this study, we have evaluated the thymuses and brains of fourteen adult male and female BALB/c mice, five to six weeks of age for specific ChAT activity as described by Badamchian and Carroll, J. Neurosci.,5:1955,1985. Our results show that ChAT activity for whole brain was 9.9 +/-0.76 µmol/min/mg protein and 2.51 +/-0.72 µmol/min/mg protein for the thymus. Higher levels of ChAT activity would be expected for tissue such as the brain (which includes both cholinergic neuronal cell bodies and fibers) than for thymus (which contains only cholinergic neuronal fibers). Future studies will determine if the activity of this enzyme in the thymus is influenced by development, circadian rhythms or hormonal stimulation. Supported by ONR grant #N00014-89-J-1256.

LUTEINIZING HORMONE-RELEASING HORMONE GENE EXPRESSION IN THE THYMUS. B. Marchetti, C.C. Maier*, R.D. LeBoeuf*, and J.E. Blalock*. Dept. of Pharmacology, Univ. of Catania, Italy and Dept. of Physiology and Biophysics, Univ. of Alabama at Birmingham, Birmingham, 35294 U.S.A.

The luteinizing hormone-releasing hormone (LHRH) gene is expressed in hypothalamic and extra-hypothalamic brain regions, as well as in mammary gland, gonads, and placenta. These results suggest that LHRH plays an important functional role in the control of reproductive functions. Recent evidence (Marchetti, B. et al., Endocrinology 125:1025, 1989) indicates that LHRH is able to directly influence lymphocyte function both in vivo and in vitro via specific LHRH receptors. In this report, we show that LHRH is expressed by immune cells. Poly A$^+$ mRNA from murine thymocytes and splenocytes was used as a template for selective RNA-PCR. Amplification primers were designed to yield a 330 bp cDNA product. PCR products from thymocyte and splenocyte mRNA preparations using a LHRH-specific ^{32}P-labelled oligodeoxynucleotide probe showed that the coding sequence for LHRH was present. These LHRH cDNAs from lymphocytes will be sequenced and compared to the sequence of hypothalamic LHRH. The results of this study provide the first characterization at the molecular level of LHRH gene expression by cells of the immune system and identifies another potential regulatory circuit between the neuroendocrine and immune systems.

ACCELERATED DEVELOPMENT OF MONOAMINERGIC INNERVATION OF KIDNEY, SPLEEN AND THYMUS IN SPONTANEOUSLY HYPERTENSIVE RATS (SHR). Vincent H. Gattone II, and Edwin S. Purcell*. Department of Anatomy and Cell Biology, The University of Kansas Medical Center, Kansas City, Kansas.

The SHR has several pathologic traits which accompany the elevated blood pressure, including increased actuivity of renal sympathetic nerves, renal damage and immune deficiency compared to the normotensive Wistar Kyoto rat (WKY). The augmented sympathetic nerve activity is thought to contribute to the pathogenesis of hypertension as well as the vascular abnormalities in SHR. We propose that augmented or early sympathetic innervation might contribute to renal changes and immune deficiency in the SHR. The development of monoaminergic nerves in kidney, spleen and thymus of SHR and WKY rats (newborn, 1, 2, 3 and 12 weeks of age) was examined using the glyoxylic acid histofluorescence method. Coded specimens were examined using epifluorescence microscopy and evaluated for extent and intensity of fluorescence from monoaminergic nerves. The innervation was scored (0-5) for thymus and spleen. Norepinephrine levels were determined for kidney. Development of sympathetic innervation was accelerated in SHR in all three organs. The kidney and thymus exhibited a sustained increase in innervation while the spleen exhibited only a transient increase. In conclusion, kidney, thymus and spleen are innervated precociously in the SHR as compared to the WKY. Renal innervation may predispose the kidney to hypertensive damage while thymic and splenic innervation may contribute to the immune deficiency of the SHR. Supported by PHS grant #MH46511.

CORTICOSTERONE REGULATION OF ADRENAL STEROID RECEPTOR LEVEL IN BRAIN AND IMMUNE TISSUE. R.L. Spencer, A.H. Miller* and B.S. McEwen. Lab. of Neuroendocrinology, Rockefeller Univ., New York, NY 10021.

We have compared the extent of adrenal steroid (AS) receptor up- and down-regulation that occurs between different tissues in response to removal of endogenous adrenal steroids (via adrenalectomy; ADX) and replacement with exogenous corticosterone (CORT; via subcutaneous pellets). Male S.-D. rats (300-350 g) were ADX and some were given replacement doses of CORT for 5 days producing plasma CORT levels ranging from low to high physiological values. All CORT pellets were removed 24 h before sacrifice and RIA of trunk blood from each individual animal indicated that there was no residual CORT at the time of death. An additional short-term ADX (24 h) group served as the reference for the number of AS receptors present in the non up- or down-regulated state. The type I AS receptor did not up-regulate with 6 days of ADX, but was down-regulated significantly in the hippocampus by both the medium and the high dose of CORT replacement, and in the spleen by the high dose of CORT. The type II AS receptor was significantly up-regulated in all brain areas examined and in the spleen after 6 days of ADX. The high dose of CORT replacement significantly down-regulated type II receptors in a variety of brain areas (hippocampus, cortex, septum/basal forebrain, and cerebellum) and in immune tissues (thymus, spleen, and peripheral blood mononuclear cells), but not in the pituitary. These data indicate that the extent of AS receptor up- and down-regulation varies between different tissues and may have relevance for tissue differences in the functional responsiveness to chronic glucocorticoid treatment. (Supported by MH 41256)

IMMUNOSUPPRESSION BY CHLORPROMAZINE IS NOT RELATED TO ITS DOPAMINE ANTAGONIST PROPERTIES. H.U. Bryant, P.L. Berry*, R.E. Roudebush*, N.K. Layman*, R.L. Cain* and L.D. Butler*. Dept. Immunology, Eli Lilly and Co., Indianapolis, IN 46285.

A number of neurologically active substances affect the immune system via either direct or indirect mechanisms. For example, immunomodulatory effects have been attributed to the neuroleptic phenothiazine, chlorpromazine (CPZ). CPZ possesses a complex pharmacology; a particular interest to us was its ability to act as a dopamine receptor antagonist. Therefore, a series of experiments were conducted to evaluate the effects of dopaminergic antagonists on a battery of immunologic parameters. Mitogen elicited mouse spleen cell proliferation *in vitro* was inhibited by CPZ, trifluoperazine (TFP), sulpiride (SUL) and haloperidol (HAL; IC_{50} values of 50, 5, 1.4 and 1 µM, respectively). Metoclopramide (METO) had no effect. *In vivo* lymphocyte proliferation in mice (uptake of iododeoxyuridine [IUDR]) was markedly suppressed (85%) by relatively high doses of CPZ (10 to 15 mg/kg) which also produced sedation (inverted screen test). TFP and HAL at 10 mg/kg produced mild reductions of IUDR uptake, while SUL and METO had no effect. A murine graft verses host response was unaffected by HAL, SUL and METO, and was modestly inhibited by TFP (45% at 30 mg/kg) and CPZ (30% at 15 mg/kg). No suppression was observed in a picryl chloride induced delayed type hpersensitivity response. These studies indicate that more specific dopamine antagonists (e.g. SUL and HAL) do not share the immunomodulatory profile of CPZ, suggesting these effects of CPZ are not related to its dopamine antagonistic properties and are due to another activity of the phenothiazine.

THYMIC OXYTOCIN RECEPTORS: STEROID EFFECTS AND DEVELOPMENTAL CHANGES. Caldwell, J.D., Walker, C.H., Pedersen, C.A., Peterson, G., Noonan, L. R., and Mason, G.A.; Dept. of Psychiatry and BDRC, Univ. of North Carolina, Chapel Hill, NC. 27599-7250

The presence of oxytocin (OXT) immunoreactivity and expression in the thymus gland led to the discovery of OXT receptors in thymocytes. Using the OXT specific analogue ornithine-vasotocin, we studied OXT receptors in membrane fractions from the thymus of neonatal and adult rats. In adult ovariectomized rats given one of four different steroids (5 ug daily for three days) we found several changes in OXT receptors. Testosterone (T) and estradiol (E) both increased OXT receptor affinity (K_D = 0.2 nM for oil, and 0.12 for both E and T) while decreasing receptor densities (B_{max} = 10.1 fmol/mg protein for oil vehicle, vs. 5.5 and 6.4 for E and T). Corticosterone and progesterone (P) reduced receptor densities (B_{max} = 7.5 for both) without affecting receptor affinity. Giving 500 ug P 5 hours before decapitation to animals treated with 5 ug E resulted in an increase in the density of thymic OXT receptors (B_{max} = 6.0 versus 8.8 fmol/mg protein for E only versus E & P). We found thymic OXT receptors in pups as early as day 4 after birth. The density of thymic OXT receptors increased from day 4 to day 22 of development (from B_{max} = 0.266 $\pm$ .08 to 0.621 $\pm$ .05 fmol/mg protein). Oxytocin release in infants may be an important factor in establishing immune competence.

CALCIUM ENHANCES cAMP PRODUCTION IN T LYMPHOCYTES STIMULATED THROUGH THE ß-ADRENERGIC RECEPTOR. S.L. Carlson and T.L. Roszman*, Dept. of Microbiology and Immunology, Univ. of Kentucky Medical Center, Lexington, KY 40536-0084

Lymphocytes express functional ß-adrenergic receptors that are linked to the cAMP second messenger system. Stimulation of these receptors has been shown to alter lymphocyte activation and function. To understand the mechanism of ß-adrenergic effects on T cells, we have investigated the intracellular signals generated in human T cells in response to stimulation with a ß-adrenergic agonist (isoproterenol, ISO) and a mitogen (phytohemagglutinin, PHA). Dual stimulation of T cells with ISO and PHA results in a synergistic rise in cAMP production (J. Neuroimmunol. 24:155, 1989). PHA alone does not stimulate significant cAMP, but rather signals the cell via the PI cycle resulting in increased intracellular calcium ($[Ca^{2+}]_i$) and activation of protein kinase C.

Increased Ca^{2+} is one possible mechanism by which PHA stimulation could enhance ß-adrenergic-linked cAMP production. To examine the effect of increased Ca^{2+}, two agents were used that increased $[Ca^{2+}]_i$ by different mechanisms. Ionomycin acts at the level of the plasma membrane to carry Ca^{2+} ions across the membrane from the extracellular medium. Thapsigargin, (gift from Dr. Michael Hanley, Univ. Cambridge) acts at the level of the endoplasmic reticulum to inhibit the Ca-ATPase pump, resulting in increased $[Ca^{2+}]_i$. Neither agent had an effect on cAMP levels in T cells when used alone, but when paired with stimulation of the ß-adrenergic receptor caused a synergistic increase in cAMP. These results suggest that the Ca^{2+} fluxes that result from mitogen stimulation of T cells are involved in the synergy of cAMP production in ISO-stimulated T cells. The stimulation of T cells by PHA and ISO in Ca^{2+}-free medium resulted in enhanced cAMP production, presumably because of the release of Ca^{2+} from intracellular stores. Collectively these results indicate that Ca^{2+} has a role in modulating cAMP production in T cells. (Supported by NS-17423 and F32-NS08591)

FETAL ALCOHOL EXPOSURE (FAE) ALTERS DEVELOPMENT OF GLUCOCORTICOID CYTOSOLIC RECEPTOR (GCCR) NUMBER IN RAT THYMOCYTES. C.M.K. Wong*, B.J. Branch*, L. Nguyen*, F. Chiappelli and A.N. Taylor. Sch. of Dentistry, Lab. of Neuroendocrinol., Br. Res. Inst., & Psychoneuroimmunol. Prog., UCLA, & West L.A. VAMC/Brentwood, Los Angeles, CA 90024.

We have shown that FAE in the last 15 days of gestation (5% w/v ethanol) in Sprague Dawley rats is associated with long-lasting alterations in the regulation of hypothalamo-pituitary-adrenal (HPA) function and of cell-mediated immunity (CMI). In the context of HPA-CMI interactions, we tested FAE outcome on the development of the number of GCCR sites/cell in thymocytes from 16-72 day-old male rats. Preliminary data suggest a "U"-shaped pattern in normal rats (day 16:5540 sites/cell±294 [SEM, n=2]; day 30:3921±859[3]; day 44: 6823 ±481[3]; day 72:9312±754[4]). FAE rat thymocytes had more GCCR than normal rats at earlier (day 16:107%; day 30: 116%; day 44: 110%), but not later ages (day 72:86%). The control pair-feeding procedure also altered GCCR number compared to normals (day 16: 82%; day 30:119%; day 44:86%; day 72: 67%). Our data indicate that the normal development of GCCR in rat thymocytes mirrors that of the proliferative response of thymocytes to concanavalin A (ConA) but that the effects of FAE on thymocyte GCCR number and ConA response development are not perfectly correlated, suggesting that the complex effects of FAE on HPA-CMI circuitry may be mediated only in part by GCCR. (VA Medical Research & Bettingen Fdn.)

ADRENAL STEROID RECEPTOR ACTIVATION IN VIVO HIGHLY CORRELATES WITH IMMUNE FUNCTION AS MEASURED IN VITRO Miller AH*, Spencer RL, Kim C*, Trestman R*, McEwen BS and Stein M, Mt Sinai School of Med, NY, NY 10029

The relationship between estimates of adrenal steroid (AS) receptor activation in vivo and immune function in vitro was determined in SD rats (n=6) exposed to high (10µg/ml), medium (0.8µg/ml) and low (0.3µg/ml) doses of dexamethasone (DEX) in the drinking water overnight (16 hrs). The following day, spleens were removed for Type I and II AS receptor binding and measurement of Con A induced splenocyte proliferation. DEX administration was associated with a stepwise decrease in Type II AS binding while Type I AS binding was unchanged. In addition, DEX was associated with a stepwise decrease in splenocyte proliferation. A highly significant correlation between Type II binding and the Con A proliferative response was observed (r=.89, p<.0001), indicating that as Type II receptor binding decreases (reflecting receptor activation) so does immune function. No correlation was found between Type I binding and mitogen proliferation. These data support the notion that in order for adrenal steroid hormones to alter immune function, evidence of receptor activation is an important prerequisite. Supported by NIMH MH00680-02 (AHM) and MH46504-01 (AHM).

NORADRENERGIC INFLUENCES ON NATURAL KILLER CELL ACTIVITY. J. Irwin, L.F. Kuehner* & K.A. Zito. Psychology Dept., Queen's University at Kingston, Ontario, Canada K7L 3N6

Studies of acute stress, as well as pharmacological investigations have implicated norepinephrine (NE) as an agent of immunological modulation. The present study assessed the effects of *in vivo* manipulations of noradrenergic activity on the cytotoxicity of Natural Killer (NK) cells.

Depletions of norepinephrine were induced in male CD-1 mice by administration of 250 mg/kg of alpha-methyl-para-tyrosine (AMPT), an inhibitor of tyrosine hydroxylase. Mice were then sacrificed for determination of NK cytotoxicity against YAC-1 target tumor cells in a 6 hr chromium release assay. There was a reduction in NK activity 3 hr following AMPT administration. However, 24 hr following AMPT administration, NK activity was no longer inhibited. In separate experiments CD-1 mice received I.P. injections of NE or the beta-adrenergic agonist isoproterenol. Surprisingly, NE administration again resulted in a dose-dependent suppression of NK activity. In contrast, administration of the beta agonist enhanced NK cytotoxicity in a dose-dependent fashion. The data suggest that modification of sympathetic nervous system activity, which occurs under conditions of acute stress, may disrupt natural killer cell function.

497.14

CENTRAL MU AND NOT KAPPA OPIOID RECEPTORS MEDIATE SUPPRESSION OF NATURAL KILLER CELL ACTIVITY. L.C. Band[1], Agu Pert[2], B.R. de Costa[1*], K.C. Rice[1*], and R.J. Weber[1]. [1]Laboratory of Medicinal Chemistry, NIDDK, NIH and [2]Biological Psychiatry Branch, NIMH, Bethesda, MD, 20892.

Opiates have well-documented immunosuppressive properties. Clinical use of these compounds may promote tumor growth or metastases, or increase the likelihood of postoperative complications. Furthermore, the increased susceptibiltity of opiate addicts to infection suggests that abuse of these agents may carry the additonal risk of depressed immune function. It has been demonstrated that both peripheral and intracranial injection of morphine depresses natural killer cell (NK) proliferation; the periaqueductal grey has been shown to be involved in the mediation of this effect (Weber & Pert, *Science*, 245, 1989). The following studies were conducted in order to determine the opioid receptor subtype mediating opiate-induced immunosuppression. The selective mu agonist [D-Ala^2, NMe-Phe^4, Gly-ol]-Enkephalin (DAGO) and the selective kappa agonist (S,S)-U50,488 were microinjected into the lateral ventricle in Fisher 344N male rats. Three hours after microinjection spleens were removed and assayed for NK activity. DAGO (6-60 nmol) reduced NK activity while (S,S)-U50,488 (20-200 nmol) had no effect. Preliminary data indicate that the high affinity delta receptor agonist [D-Pen^{2,5}]-Enkephalin (DPDPE) does not suppress NK activity. These findings suggest that opiate-induced immunosuppression is mediated primarily through mu-receptors. Further specification of receptors involved in immunosuppression should provide direction for the design of medicinal compounds which do not compromise immune competence.

497.15

FLOW CYTOMETRIC ANALYSIS OF EXCITABILITY TO PROGESTERONE IN PURIFIED HUMAN NATURAL KILLER CELLS. R.N. Mandler, M.D. Domalewski*, L.C. Seamer*, D. Whitlinger*, R. Doshi*, H. Faris* and A.D. Bankhurst*. Departments of Neurology, Rheumatology and Flow Cytometric Lab, The University of New Mexico School of Medicine, Albuquerque, NM 87131.

Natural killer (NK) cell function depends on a myriad of molecules that interact with membrane receptors and ion channels. Steroid-like Na^+ channel agonists such as veratridine and batrachotoxin depolarized human NK cells in a tetrodotoxin (TTX)-sensitive fashion that suggested presence of Na^+ channels (Mandler, R.N., et al., J. Immunol. 144:2365-2370, 1990). This discovery prompted a study of purified human NK cell excitability to a variety of human steroids using flow cytometry and voltage-sensitive dyes. Highly-purified human NK cells (CD16=95 ± 1%) were prepared using a negative panning technique. Progesterone (10-200 uM) depolarized NK cells in a concentration-, time- and temperature-dependent fashion. Neither cortisol, cholesterol, testosterone, 21-HO cortisone, pregnenolone, nor aldosterone modified NK cell excitability. Progesterone but not the other steroids produced marked effects in NK cell cytotoxicity against K562 tumor target cells. Progesterone effects on purified human NK cell excitability and cytotoxic function might represent one of a number of mechanisms of neuroendocrine modulation of the immune response.

REPEATED INTRACEREBROVENTRICULAR (ICV) INJECTIONS OF CONJUGATED DOPAMINE (DA-G-BSA) PRODUCE PERIPHERAL ANTIBODIES. O. MRABET*, C. MESSIER, N. MONS*, C. DESTRADE and M. GEFFARD. URA CNRS n°339, U. Bordeaux I, 33405 Talence and Immunol. and Pathol. Lab. CJF 88-13 INSERM, U. Bordeaux II, 3300 Bordeaux Cédex, FRANCE.

Repeated ICV injections of an anti-conjugated dopamine antibody (ACDA) appear to produce CNS lesions particularly in the caudate nucleus (Neurosci. Abstr. 13, 501, 1987). We measured the effect of repeated ICV injections of DA-G-BSA on the peripheral production of ACDA. Mice with an ICV cannula were injected once a week for 5 weeks with either DA-G-BSA, the protein carrier BSA or pre-immune immunoglobulins (IgG); blood samples were collected before each injection. ELISA tests revealed a high sera concentration of ACDA after the third (and following) injection of DA-G-BSA (in 8 out of 9 animals) but not after the injection of either BSA or IgG. Booster ICV injection of DA-G-BSA further increased the sera concentration of ACDA. In another experiment, the same quantity of DA-G-BSA previously injected ICV was injected in the tail vein once a week for 5 weeks. ELISA tests showed only moderate sera concentration of ACDA (in 3 out of 6 animals). We found the CNS immune response to DA-g-BSA to be very strong even though the doses of DA-g-BSA injected were very small and that no immunostimulant was given. The comparison of the results obtained by central and peripheral injections suggest that the peripheral response may be mediated by the combined T and B responses while the central response would depend mainly on the B response.

REJECTION OF MESENCEPHALIC RETINAL XENOGRAFTS IN THE RAT INDUCED BY SYSTEMIC ADMINISTRATION OF RECOMBINANT GAMMA INTERFERON. T. Subramanian, I.F. Pollack and R.D. Lund. Depts of Neurobiology, Anatomy and Cell Science, and Neurosurgery, Univ. of Pittsburgh School of Medicine, Pittsburgh, PA 15261.

Previous studies have shown that well integrated mesencephalic retinal xenografts can be induced to reject by various systemic and local manipulations (Pollack et al., Neurosci. Abs., 15:11, 1989). In each of these rejection paradigms the development of major histocompatibility complex (MHC) antigen expression on cells in and around the graft coincided with the onset of overt rejection. To determine whether induction of MHC antigen expression was in itself a sufficient stimulus to provoke a rejection response, we examined the effect of systemic administration of rat recombinant gamma interferon (a strong inducer of MHC antigen expression) on xenograft viability.

Post-natal day 1 Sprague-Dawley rats received mesencephalic grafts of embryonic day 13 CD-1 mouse retina. Starting at 21 days of age, one half of these animals received 2 x 10^4 units of rat recombinant gamma interferon intraperitoneally for 6 to 9 days while the other half served as litter matched controls. All the rats were sacrificed 30 days after the final injection and 30 µm thick coronal sections were made through the mesencephalon. Adjacent sections were stained with cresyl violet and antibodies against rat MHC class I (OX-18) and class II (OX-6) antigens, microglia (OX-42), astrocytes (GFAP) and lymphocytes (anti-lym).

Each of the animals that received gamma interferon showed a strong rejection response characterized by perivascular cuffing with mononuclear cells in and around the graft, infiltration of the graft and the surrounding host tissue by lymphocytes and MHC class I- and class II- antigen positive cells resembling reactive microglia. The rejection rate in this group was significantly higher than the control group (Fisher's exact test, p=0.002). These results suggest that gamma interferon is a lymphokine mediator of the initiation and/or subsequent maintenance of the rejection response to cross-species transplants. DIFFERENTIAL AND SEX SPECIFIC EFFECTS OF KAINIC ACID (KA) AND DOMOIC ACID (DA) LESIONS IN THE LATERAL SEPTAL AREA (LSA) ON BODY WEIGHT (BWt) AND THE HUMORAL IMMUNE SYSTEM. L. Wetmore*, J. Burns* and D.M. Nance. Depts. of Pathology and Physiology, Univ. of Manitoba, Winnipeg, MB, Canada, R3E 0W3.

KA lesions in the LSA of female rats increases BWt and decreases the humoral immune response, relative to controls. DA is a more selective and potent kainate agonist than KA. We tested the effects of LSA lesions produced by DA (0.15 µg in 0.5 µl) on the immune response of female and male rats immunized with ovalbumin. Similar to KA, DA produced an increase in BWt gain of female rats, but reduced BWt gain in male rats. DA produced greater cell loss in the LSA of male rats than in females. Unlike KA, DA lesions had no effect on the immune response of female rats nor was the immune response of male rats altered by the lesions. We reexamined the effects of KA (0.375 µg in 0.25 µl) in the LSA on BWt and the immune response of male and female rats. In females, KA lesions produced an increase in BWt gain and reduced humoral immunity. Similar lesions in male rats had no effect on BWt or immune response. To test if the absence of an effect of DA lesions on the immune system of female rats was due the the small lesions noted in the first study, we tested the effects of more concentrated DA (0.15 µg in 0.25 µl) on the immune response of female rats. This dose produced substantial cell loss in the LSA and a large increase in BWt gain, but the immune response of the DA lesioned females was similar to controls. Thus, both KA and DA lesions in the LSA produce an increase in BWt gain of female rats, but only KA lesions reduce humoral immunity. BWt regulation and immune function were unaltered by DA or KA lesions in the LSA of male rats. Supported by Medical Research Council of Canada.

BETA ENDORPHIN MODULATES CALCIUM CHANNEL FLUX IN HUMAN NEUTROPHILS. D.B. MILLAR*, D.L. MAZOROW* AND John Thomas. NIMH Neuroscience Center at St. Elizabeths, Washington, DC 20032, and Naval Medical Research Institute, Bethesda, MD 20814. We report here that Beta Endorphin (Bend) also significantly influences n-formyl-methionyl-leucyl- phenyalanine (FMLP) stimulated Ca^{++} entry into human neutrophils. Ca^{++} flux was analysed using the Fura-2 fluorescent technique and the equations described by Mazorow and Millar (FASEB J. 4, #4, A1209 (1990)). 10^{-6} M FMLP induces a Ca^{++} flux in neurotrophils comprising a sharp initial rise and fall followed by a broader rise and fall. Experiments with Prostaglandin d2, dibutyrl cyclic AMP and EGTA showed that the second Ca^{++} peak was reduced in amplitude by the first two compounds and obliterated by the last. In 2.5 x 10^{-5} M nifedipine there is also no second peak. We conclude that the second peak is due to influx of Ca^{++} into the cell via a Ca^{++} channel. Neutrophils incubated for 1 1/2 h at 37° with Bend (10^{-12} to 10^{-6} M) show major changes in the shape and height (f_m) of the second peak in a dose and donor dependent manner. In some donors, f_m is reduced by about 50% as compared to control. In others f_m is increased to values close to that of the initial peak (usually the first peak height is ~2x the height of the second peak). Finally, experiments with naloxone, an opioid antagonist, have not yet satisfactorily shown the reactive site for Bend to be an opiate receptor.

COMPARISON OF SERUM ANTIBODY RESPONSES TO CNS AND SYSTEMICALLY ADMINISTERED OVALBUMIN (OVA). L.B.Gordon*, M.Kahn*, H.F.Cserr and P.M.Knopf. Physiology and Biophysics, Brown Univ., Providence, RI 02912.

Mechanisms underlying the immunologic privilege of the CNS are poorly understood. We have compared serum antibody responses to OVA, administered either into CNS or systemically in Sprague-Dawley rats, to determine if reduced activity of the afferent limb of the humoral immune response contributes to this phenomenon. 90 μg of OVA was infused either into: the caudate nuclei or lateral ventricle CSF, through cannulas implanted 7 days previously; the nasal mucosa; or the hind footpads. Caudate nuclei-injected animals were challenged 6 weeks later with systemic OVA plus Freund's complete adjuvant. Serum titers of anti-OVA were measured weekly using an ELISA for up to 14 weeks. The fraction of rats with detectable serum titers was 4/9 for caudate nuclei injections (range of all titers: <50 - 2,000), 4/4 for CSF (200-1,500), 0/9 for nasal mucosa (<50), and 0/3 for hind footpads (<50). Caudate nuclei-injected animals with undetectable titers (N=4) responded more rapidly and with higher titers than naive controls to systemic challenge, indicating the presence of memory cells. Results indicate that the afferent limb of the humoral immune response to intracerebral OVA is as active, or more active, than to systemic antigen. Supported by NIH grant NS-11050.

LYMPHOCYTIC CHORIOMENINGITIS VIRUS (LCMV)-INFUSED RATS EXHIBIT ELEVATED CEREBROSPINAL FLUID (CSF) IMMUNOGLOBULIN A (IgA). A.H.Woo, P.M.Knopf, and H.F.Cserr. Program in Molec. Bio., Cell Bio., and Biochem. and Section of Physio. and Biophys., Brown Univ., Providence RI 02912.

We have developed a nonpathologic, nontraumatic rat model in which to study the humoral immune reponse to virus in the central nervous system (CNS). Fisher rats were microinfused with UV-inactivated LCMV through a lateral ventricle cannula implanted 7 days previously. At 21 days, CSF and serum immunoglobulin (Ig) titers and concentrations of IgA and albumin were determined by enzyme-linked immunosorbent assays. Rats infused with cell culture supernatant or saline and sham-operated rats were used as negative controls. An Ig titer index and IgA index were used to evaluate total CSF Ig and IgA with respect to blood-brain barrier (BBB) integrity where Index = [CSF Ig titer or IgA/serum Ig titer or IgA] / [CSF Alb/serum Alb]. Of 6 LCMV-infused rats, 3 exhibited an elevated total Ig titer index and 2 exhibited an elevated IgA index (> log mean + 2 SD of controls, n=11). We are investigating whether this specific appearance of IgA within an intact BBB is due to a secretory transport mechanism analogous to that found in mucosal tissues outside the CNS.

STUDIES ON THE FUNCTION OF N-ACETYL MURAMYL DIPEPTIDE IN THE INDUCTION OF AUTOIMMUNE DISEASE. F.C.Westall and Ali Mohammadi. Institute for Disease Research, P.O.Box 1293, Alta Loma, CA and California State Polytechnic University, Pomona, CA 91768.

Acetyl muramyl dipeptide (MDP) derived from gut bacteria, is found throughout the human body. As an adjuvant, it has been used to induce autoimmune diseases, eg. experimental allergic encephalomyelitis (EAE) and artifical castration. For induction of either disease, the association of MDP with the autoantigen is quite important. We have examined whether MDP functions by suppressing the proteolytic digestion of the antigen. If potential antigens are digested too rapidly they would not be available for immunoprocessing. MDP does suppress the digestion of these antigens. However, since both antigens themselves show remarkable stability against the proteases utilized, it would seem unlikely that this is a function of MDP. More probably the MDP-complex is immunoprocessed as a unit. Finally it would appear that digestibility of potential immunogens plays a more important part in determining what is immunogenic.

PRAZOSIN TREATMENT ATTENUATES MONOAMINERGIC AXONAL DAMAGE DURING DEVELOPMENT OF EAE IN RATS. S.R.White, G.Samathanam*, P.Black* and K.Owada*. Dept. of VCAPP, Washington State Univ., Pullman, WA 99164.

Our laboratory has found that extensive damage occurs to descending monoamine- and peptide-containing axons during development of the CNS autoimmune disease experimental allergic encephalomyelitis (EAE). This damage is usually found near perivascular and submeningeal inflammatory foci. The α-adrenergic antagonist, prazosin, suppresses the clinical signs of EAE and delays the inflammatory response in the spinal cord (Brosnan et al., Proc. Natl. Acad. Sci. 82:5915, 1985). The present study used immunohistochemical techniques to determine whether prazosin also prevents axonal damage in rats that have been inoculated for EAE.

Lewis rats were inoculated for EAE with Lewis rat spinal cord homogenate. Prazosin injections began on day 7 postinoculation (2 mg, i.p., twice per day) and continued until sacrifice day (day 15). The control group received equivalent injections of the saline vehicle. The prazosin treatment markedly attenuated clinical signs (hindlimb ataxia was observed in only 1/7 rats, whereas 6/7 control rats developed severe to complete hindlimb paralysis). Inflammation in the spinal cord was attenuated, but not prevented, by prazosin (17.3 ± 1.7 versus 30.2 ± 0.6 foci per 6 mm long section). Prazosin also attenuated, but did not prevent, axonal damage (2.6 ± 0.2 versus 6.8 ± 0.6 5HT axonal damage foci per 6 mm long section). The close correlation between degree of inflammation and severity of axonal damage provides additional evidence that these axons become damaged as they encounter inflammatory foci in the spinal cord.

ANTIGEN PRESENTATION BY GLIAL CELLS FROM EAE RESISTANT AND SUSCEPTIBLE STRAIN OF MICE.
G. Birnbaum, L. Albrecht* and G. Eichhorn*. Dept. of Neurology, Univ. of Minnesota Sch. of Med., Minneapolis, MN 55455

We studied the antigen presenting properties of glial cells derived from strains of mice resistant (B10.S) or susceptible (SJL/J) to experimental allergic encephalomyelitis (EAE). Indicators were T cell lines sensitized to myelin basic protein (MBP) that were Class II identical with the glial cells.

Monolayers of glial cells from newborn murine cerebral hemispheres were exposed to a mixture of lymphokines from activated T cells to induce Class II MHC expression on glial surfaces. Glia were irradiated and varying amounts of MBP (0.25, 2.5, or 25 μg/ml) were placed onto the cultures along with 1 X 10^5 MPB sensitized T cells. After 48 hours the proliferative responses of the T cells were measured using a ^{3}H-thymidine incorporation assay.

At high antigen concentrations (25 μg/ml) B10.S and SJL/J glia functioned equivalently in inducing MBP sensitized T cells to proliferate. At lower antigen concentrations (2.5 μg/ml) glia derived from the EAE susceptible strain, SJL/J, were more efficient at presenting antigen as measured by an increased ability to induce T cell proliferation (multiplicities of 2.9±1.1 for SJL glia vs.1.7±1.1 for B10.S glia). Spleen cells from both mouse strains were identical in their abilities to present MBP indicating differences in presentation were tissue specific.

One factor in determining susceptibility to an organ specific autoimmune disease may be the antigen presenting capabilities of the target organ, in this case the brain.

IMMUNE RESPONSE TO CSF-INFUSED MYELIN BASIC PROTEIN (MBP) IN THE LEWIS RAT. C.J.Harling-Berg, P.M.Knopf, H.F.Cserr. Physiology and Biophysics, Brown Univ., Providence RI 02912.

Our previous work showed that CSF-infused albumin induced a significant systemic antibody response in the Sprague-Dawley rat. Present studies are aimed at evaluating the immune response to a CNS antigen, guinea pig MBP, infused into the CSF of the Lewis rat, a strain susceptible to the CNS demyelinating disease experimental allergic encephalomyelitis (EAE). The immune response was evaluated by studying serum antibodies and EAE expression. As a positive control, the immune response to CSF-infused chick ovalbumin (COA) was studied in a separate group. Antigen (90 or 900μg) in saline (10 or 20μl) was infused (0.5μl/min) through a cannula implanted into a cerebral ventricle. Serum antibodies titers were measured using an ELISA, 14-16 days post CSF-infusion. Rats receiving MBP were scored (0-4) for clinical signs of EAE. Serum anti-COA antibodies were detected in most rats (8/11) and titers ranged from 20 to 2,000. In contrast, serum anti-MBP antibodies were detected in only a few rats (3/15) and these were low (titer 20). Preliminary studies indicate that rats (N=3) receiving a CSF-infusion of MBP prior to an EAE-inducing challenge demonstrate a delay in EAE onset (Day 12 v 16) and less severe symptoms (score 1 v 3) compared to naive rats (N=7). Supported by Natl. MS Soc. and NIH NS 11050.

IMMUNOLOGIC CHANGES ASSOCIATED WITH SPINAL CORD TRANSECTION IN RATS. J.B. Gelderd^, N.R.S. Hall†, R.A. Menzies*†, M.P. O'Grady†, M. Wiranowska*• and S. Filteau*†. Dept. of Anatomy^, Texas A&M Univ., College Station, TX 77843-1114, and Depts. of Neurology• & Psychiatry†, Div. of Psychoimmunology, Univ. of South Florida College of Med., Tampa, FL 33613.

The study was designed to determine whether reactive astrocytes in the spinal cord are capable of secreting monokines and lymphokines. Male, Sprague Dawley rats ranging in age from 40 to 50 days were anesthetized and a dorsal midline incision was made in the mid-thoracic region. A laminectomy was performed at the T5-T6 vertebral level, and the spinal cord was transected with a scalpel. Sham animals were subjected to the same surgery, but omitting the transection step. A group of unhandled control rats was also included. Four 2mm sections of spinal cord were dissected from each rat at either 24 hours, 72 hours, 7 days or 14 days. The spinal cord segments included adjacent and distal sections both rostral and caudal to the site of transection. Detectable levels of interferon alpha have not been found in these sections at either 24 or 72 hours, although more sensitive assays of interferon activity are currently being assessed along with the later time points. Decreases in thymus and spleen weight were detected at both the 24 and 72 hour time points and these are being correlated with lymphocyte blastogenesis and cytokine production. Since cytokines act upon and are secreted by astrocytes, we are hypothesizing that they are produced and play a physiological role within the neuropil adjacent to the spinal injury. These studies were supported in part by a grant from the NIH, DA05723.

BRAIN REACTIVE AUTOANTIBODIES IN THE SERA OF RA PATIENTS. C.Madsen* and S.A.Hoffman. Dept. of Microbiology, ASU, Tempe, AZ 85287.

Recent studies have focused on the effects of psychosocial influences on the immune system in chronic immunologic diseases. Relatively little attention has been paid, however, to the potential influence of altered immune system functioning on psychological profiles. Autoantibodies to brain have been demonstrated in patients with various autoimmune diseases. It has been hypothesized that such brain reactive autoantibodies play a role in mediating some of the CNS manifestations seen in these diseases. Rheumatoid arthritis (RA) is an autoimmune disease in which patients exhibit profound depression, although other psychological involvement or CNS manifestations are rarely reported. This study reports the occurence of autoantibodies in the sera of RA patients against integral brain membrane proteins isolated from normal mouse brain and localized regions of human brain. Membrane antigens were extracted by phase separation with Triton X-114. They were separated by SDS-PAGE, blotted onto nitrocellulose membrane and probed with RA sera. Numerous antoantibodies were found to react against whole mouse brain. A smaller number of antibodies were also found to react to human brain. Implications of these findings for the significance of these antibodies with respect to stress and immunity, their genesis, and relation to neuropsychiatric manifestations will be discussed.

SYMPATHECTOMY OF LYMPH NODES EXACERBATES THE EXPRESSION OF EXPERIMENTAL ARTHRITIS. D. Lorton, D.L. Bellinger, M Duclos, S.Y. Felten, and D.L. Felten. Dept. of Neurobiol. and Anat., Univ. of Rochester Sch. of Med., Rochester, NY 14642.

Adjuvant arthritis (AA) was examined in adult male Lewis rats following local sympathetomy (SYMP) of draining lymph nodes (LN). Rats received bilateral local LN injections of 6-hydroxydopamine (6-OHDA) or vehicle (VEH), then half of the rats from 6-OHDA and VEH groups received injection of Freund's complete adjuvant (FCA) at the base of the tail. The remaining rats from each group received the same volume of mineral oil, resulting in four treatment groups: 6-OHDA/FCA,VEH/FCA, 6-OHDA/oil and VEH/oil. Following these treatments, AA was assessed by changes in body weight, dorsoplantar swelling, arthrogram scoring and radiographic analysis for day (D) 27. SYMP of draining LNs accelerated the onset and exacerbated the inflammation and osteopathic changes associated with AA. Body weights did not differ significantly in any treatment group. Limbs of rats who received VEH/FCA demonstrated bilateral inflammation at D17 post-FCA injection; bilateral inflammation of limbs of rats from the 6-OHDAA/FCA group was apparent by D15 following FCA injection. Dorsoplantar swelling AA groups was increased significantly by D17 compared to the 6-OHDA/VEH groups. Significant differences in dorsoplantar swelling in rats who received VEH/oil compared with either AA group was not observed until D23. At D27, a significant increase in dorsoplantar width was observed for the VEH/FCA group compared to the 6-OHDA/FCA group and both control groups. Analysis of X-rays taken of ankle joints on D27, revealed destructive joint changes in both AA groups compared to both control groups. As was observed with dorsoplantar width at D27 , more extensive joint damage was apparent in analysis in 6-OHDA treated arthritic rats compared to VEH treated AA rats. These finding suggest that the noradrenergic (NA) innervation of draining LN play a regulatory role in processing of a relevant antigen for the initiation of AA changes, and that absence of these NA fibers results in exacerbation of the severity and acceleration of the time of onset of AA.

SUBSTANCE P (SP) DENERVATION OF LYMPH NODES ATTENUATES THE EXPRESSION OF ADJUVANT INDUCED ARTHRITIS. D.L. Felten, D. Lorton, D.L. Bellinger, M. Duclos and S.Y. Felten. Dept. of Neurobiol. and Anat., Univ. of Rochester Sch. of Med., Rochester, NY 14642.

Adjuvant arthritis (AA) was examined in adult male Lewis rats following local SP denervation of draining lymph nodes (LN). AA was induced by intradermal injection of Freund's complete adjuvant (FCA) in mineral oil into the subplantar area of the right hind paw. One day after injection of FCA or mineral oil, half of the rats from FCA group and mineral oil groups received injections of capsaicin (CAPS) into the right draining LN. The remaining rats from each group were administered the same volume of vehicle, resulting in four treatment groups: FCA/CAPS, FCA/vehicle, oil/CAPS and oil/vehicle. Following these treatments, arthritis was assessed by changes in body weight and dorsoplantar swelling for 20 days. Body weights of AA rats, were significantly decreased by 14 days following FCA injection compared to non-AA rats; however, AA rats did maintain body weight from day 1 of the experiment through the expression of AA 20 days later. Bilateral inflammation of hindlimbs was apparent by day 20 post-footpad injection in the FCA/vehicle group. No inflammation was observed in any limb in non-FCA treated rats. No significant difference in dorsoplantar widths of any treatment group was observed compared to controls from day 0 to day 14. Right dorsoplantar width of AA rats were significantly increased compared to both control groups by day 20. At day 20, a significant increase in left dorsoplantar width was observed only in nondenervated, arthritic group (FCA/vehicle) compared to either control group. At day 20, left dorsoplantar widths of the FCA/CAPS group did not differ from either control group. Further studies are required to determine if this difference represents a delayed onset of AA contralateral to the devervated side or an inability of these limbs to develop the inflammation characteristic of arthritis. These findings indicate a dual role of SP innervation in AA through modulation of both inflammation in the joint, and immune responses in lymphoid organs.

498.11

AGE-RELATED ALTERATIONS IN NOREPINEPHRINE UPTAKE IN THE RAT SPLEEN. D.L. Bellinger, D. Lorton, S.Y. Felten, and D.L. Felten. Department of Neurobiology & Anatomy, University of Rochester School of Medicine, Rochester, NY 14642.

Sympathetic noradrenergic (NA) innervation of the spleen is reduced significantly in aged Fischer 344 rats compared with young adult rats (S.Y. Felten et al., Neurobiol. Aging 8: 159-165, 1987). Norepinephrine (NE) concentration and the number of noradrenergic (NA) terminals in spleen decline by greater than 50% and 80%, respectively, with age. In the present study, we examined the high-affinity uptake of NE in spleens from 3 and 21 month old F344 rats using an *in vitro* spleen slice model coupled with morphometric analysis of NA nerve terminal using fluorescence histochemistry for catecholamines. In spleen slices from 3 and 21 month old rats, uptake of ^{3}H-NE from the external incubation medium into nerve terminals was saturable, sodium-dependent, blocked (approximately 62% inhibition) by μM concentrations of desipramine (a competitive NA uptake inhibitor), and followed Michaelis-Menten kinetics, with an apparent Km of 1-2 μM, characteristic of NE high-affinity uptake in other systems. In spleen slices from 21 month old rats, a 70% decrease in total uptake of NE was observed compared with 3 month old rats. Morphometric analysis confirmed the loss of NA nerve terminals in alternate slice of spleens from 21 month old rats. Estimates of ^{3}H-NE uptake per terminal in 21 month old animals demonstrated an approximate increase in uptake of 70% compared with young adult controls. These findings demonstrate that the loss of NA nerve fibers in spleens from aged rats is accompanied by a significant decline in the total uptake of NE. Further, the efficiency of uptake per NA terminal is enhanced in spleens from aged rats, suggesting an increase in the density of high-affinity uptake binding sites for NE in NA nerve terminals, probably as a compensatory mechanism resulting from the decline in NE concentration and/or loss of NA nerve terminals that occur with aging.

TUMOR NECROSIS FACTOR alpha AND INTERLEUKIN-1 alpha INCREASE PAIN THRESHOLDS IN THE RAT

A.E.Panerai,P.Sacerdote, P.Ricciardi, M.Bianchi*
Dept.Pharmacology, Schoolof Medicine, Univ. Milano, Milano Italy

Recent evidences show that TNF and IL-1 synthesis is not confined only to cells of the immune system, but it is present also in brain. We investigated whether TNF was able to modify pain thresholds in the rat and since TNF induces IL1 production, we considered this cytokine also. In the hot plate test intracerebroventricolar(icv) injection of TNF at the dose of 1 and 2.5 ng /rat induces a significant increase in pain thresholds at 3 and 5 min: higher and lower doses are ineffective. 5 and 10 ng of icv IL-1 also increase pain thresholds with a time course similar to TNF. The administration of a m-Ab against IL-1 blocks TNF induced analgesia suggesting the involvement of IL-1 in the TNF effect. Anti sera against the endogenous opioids(B-endorphin, dynorfin met-enk) are ineffective on both cytokines. From receptor binding studies it appears that TNF does not bind the opioid receptor. The cyclooxygenase inhibitor indomethacin does not block the effect of either cytokines.
Our data are a further example of the links existing between the nervous and immune system.

498.13

PLASMA β-ENDORPHIN (β-E) AND NATURAL KILLER (NK) CELLS IN CONGENITAL INDIFFERENCE TO PAIN (CIP). R. Bernardini, G. Mauceri*, A. Tine', M.C. Nazzarino*, G. Malaponte*, A. Nicosia* and L. Pavone'. Inst. of Pharmacology, 'Pediatric Clinic, and *General Pathology, Univ. of Catania Sch. Med., I-95125 Catania, Italy.

CIP is a rare inherited syndrome characterized by unresponsiveness to painful stimuli. We have evaluated plasma β-E levels and immune function in two patients affected by CIP. Peripheral blood lymphocytes (PBL) were incubated with graded concentrations of phytoemoagglutinin (PHA), with or without addition of β-E. Incorporation of ^{3}H-thymidine was measured 72 h later. We have also studied NK membrane phenotype expression, by incubating PBL with specific anti-Leu 7 and 9 fluorescent monoclonal antibodies. Finally, we have measured plasma levels of β-E, ACTH, and cortisol. PBL proliferation rate was normal, either after incubation with PHA, β-E alone, or in association. Among the surface antigens studied, NK Leu 7 of patients was decreased significantly ($p<0.01$, t test). Plasma β-E levels of patients were higher ($p<0.01$, t test) than controls. No change occurred in plasma ACTH and cortisol levels.

Results indicate that in CIP high plasma β-E levels are associated to NK cell decrease.

498.14

INHIBITION OF SYMPATHETIC OUTPUT ATTENUATES SHOCK-INDUCED SUPPRESSION OF MITOGENIC ACTIVITY. J. E. Cunnick, D. T. Lysle, M. O. Fraser, M. A. Pezzone, and B. S. Rabin. Center for Brain, Behavior, and Immunity, Dept. of Pathology, University of Pittsburgh School of Medicine, Pittsburgh, PA 15213-2582.

Our laboratory has previously demonstrated that the presentation of 16 electric foot-shocks (5 sec, 1.6 mAmp) to male, Lewis rats can induce suppression of the mitogenic response of whole blood and whole spleen lymphocytes to concanavalin A and phytohemagglutinin. The suppression of the splenic mitogen response can be attenuated by the IP administration of ß-adrenergic receptor antagonists, propranolol and nadolol. These drugs do not attenuate the suppression of the blood mitogen response.

Stimulation of the α2-receptors on sympathetic neurons is known to decrease the release of norepinephrine (NE) from the nerve terminals. Our current study examined the ability of α2-receptor agonists to attenuate the shock-induced immune suppression. The α2-receptor agonist, clonidine, but not midodrine is able to cross the blood brain barrier. We administered the α2-agonists or vehicle, IP, 30 min prior to a stress session. The administration of each drug was able to attenuate the shock-induced suppression of the splenic mitogen response to a significant degree at the highest doses administered (50 & 100 μg/kg clonidine and 5 & 10 mg/kg midodrine). However, neither drug attenuated the shock-induced suppression of the blood mitogen response.

This data supports our earlier finding of two distinct mechanisms mediating the suppression of blood and splenic mitogenic responses. Furthermore, modulation of NE release can significantly attenuate the suppressive effects of stress on splenic, but not blood, mitogenic responses. This data indicates that the peripheral release of NE, in vivo, is responsible for the suppression of the spleen mitogenic response.

NEURAL-IMMUNE INTERACTIONS: INTERLEUKINS

499.1

NOREPINEPHRINE AND PROSTAGLANDIN E2: EFFECTS ON SINGLE UNIT ACTIVITY RECORDED FROM THE RAT HYPOTHALAMUS IN VIVO. W. McVaugh and N. Dafny. Dept. Neurobiology and Anatomy, University Texas Medical School at Houston, TX 77225.

Both prostaglandins and activation of the central noradrenergic system have been associated with IL-1's induction of corticotropin releasing factor (CRF) from the PVN into the portal circulation. The goal of this study is to examine the effects of locally applied norepinephrine (NE) and prostaglandin E2 (PGE2) on the electrical activity of single neurons recorded from the anterior hypothalamus/paraventricular area in the anesthetized rat. Male Sprague Dawley rats (280-320g) were anesthetized with urethane (1.2g/kg bw ip) and placed in a stereotaxic instrument. The skull was bared, a 5mm hole drilled in the cranium and the dura reflected. Norepinephrine and PGE2 were iontophoresed onto individual neurons by means of a multibarrel micropipette assembly with a recording barrel attached. Preliminary results indicate that the percentage of neurons responding to NE with a change from baseline activity increased with dose (20,40,80nA - 41,59,65% respectively) and that all doses resulted in excitation. Little change was seen in the overall number of cells responding to 3 doses of PGE2 (20,40 and 80nA - 50,44 and 54% respectively). The two lower doses resulted primarily in excitation while the highest dose produced inhibition in the majority of responders. Previously we demonstrated that IL-1 itself was capable of exciting these neurons as well. These results suggest that: 1) IL-1's activation of the NE input to the PVN may stimulate CRF release and 2) PGE2 induced by IL-1 may also stimulate PVN CRF neurons.

499.2

Cytokine-Associated Axonal Changes Coincide Temporally With Circulating Tumor Necrosis Factor After RIL-2 Infusion. M.D. Ellison* and C.W. Christman, Dept. of Anatomy, Medical College of Virginia, Richmond, VA 23298

In brains of rIL-2-infused rats, we have recently reported alterations of axonal ultrastructure reminiscent of those described in murine spinal cord slices treated with tumor necrosis factor (TNF). These axonal changes were accompanied by other neuronal and glial abnormalities similar to those previously reported in various inflammatory demyelinating conditions and recently linked, by other investigators, to cytokines. In our laboratory, such alterations were seen as early as 4 hours after a single rIL-2 infusion and were also observed after 3 and 5 days of rIL-2 infusions, administered 3 times daily. The present study was undertaken to determine whether rIL-2-related brain parenchymal alterations in rats are accompanied temporally by elevations of circulating TNF. Adult male rats were infused once (N=6) or thrice daily for 3 days (N=7) with rIL-2, IV (6×10^5 IU/kg, Cetus Corp.). Controls (N=15) were comparably infused with rIL-2 vehicle. Venous blood samples were drawn prior to infusion in 16 additional animals and at 2,4, and 8 hours after the final infusion in rIL-2/vehicle recipients. Serum TNF activity was determined by L929 fibroblast bioassay (kindly performed by Cetus Corp.). In 14 of 16 samples drawn prior to infusion and in all serum samples from animals infused with rIL-2 vehicle, TNF acfivity was below the assay level of detection. Serum samples from rats infused once with rIL-2 ranged in TNF activity from 34 to 430 ng/ml. Animals receiving rIL-2 over 3 days exhibited serum TNF activity ranging across animals from 0.31 to 56 ng/ml, except for 1 8-hr. sample (430 ng/ml). TNF levels in the multiple rIL-2 infusion group were statistically lower than those measured in the single infusion group. Although TNF activities varied across animals in each group, activities for each animal generally remained constant across sample times. We concluded from these data that, after systemic rIL-2 administration, elevations of circulating TNF are temporally coincident with the presence, in brain, of axonal changes similar to those previously associated with TNF, in vitro. Whether circulating TNF and cytokine-linked morphological CNS abnormalities are causally related remains to be determined and merits further investigation. (Supported by NS 25871).

DIFFERENTIAL STAINING FOR NEUROIMMUNE SUBSTANCES IN BRAINS OF ETHANOL (ETOH) ADMINISTERED RATS. I. Sterzl and G.P. Kozlowski. Department of Physiology, University of Texas Southwestern Medical Center, Dallas, TX 75235-9040.

The ABC Elite kit (Vector Labs) was used to test if ETOH may alter immunoreactive CNS antigens to six antisera: rab & sheep anti-rat IgG, rab anti-rat albumin (Arnel Inc), mAb 11B11 rat anti-mouse Il-4 (Ohara & Paul) & CD4 (Vitetta GK1.5), and mAb1403 mouse anti-rat homologue of human CD4 (Chemicon Int). As previously described (Neurosci Abstr 15,416), male rats were simultaneously pair-fed either an ETOH or control liquid diet for 30 days or Lab Chow and water *ad lib*. There was considerable hypothalamic and hippocampal staining for IgG, Il-4, and CD4. MAb GK1.5 stained equivalent structures to mAb1403 but was less immunoreactive. In general, the ETOH animals had more neurons stained for IgG, Il-4 and CD4 but not albumin when compared to controls. The ETOH animals had twice the IgG-containing neurons in the arcuate nuc and subfornical organ but the staining was diffuse rather than punctate as found for all other areas and antisera. In controls, Il-4 and CD4 staining was greater in supraoptic nuc (SON) than paraventricular nuc (PVN) but ETOH treatment reversed this pattern by enhancing PVN and reducing SON staining. Supported by AA-06014.

IMMUNE SYSTEM ACTIVATION INCREASES GFAP ICC IN HYPOTHALAMUS. X. Ou, M.N. Gordon and D.G. Morgan. Andrus Gerontology Center, U Southern Cal, L.A., CA 90089-0191

This study is a preliminary report of our attempts to determine the nature of immune system modulation of CNS function. Normal immune activity is regulated by multicomponent feedback loops between the immune system and the nervous system. IL-1 is suggested to be one substance that conveys information from the immune system to nervous system. Our initial attempt was to measure the IL-1 level in CNS following immune system activation using immunohistochemical procedures, but this has not been successful due to lack of antibodies reacting with the rat IL-1 variant. Since IL-1 has been reported to activate astrocytes, we measured GFAP levels immunohistochemically as a potential indicator of IL-1 activity in CNS. In this study, male Sprague Dawley rats were injected with 10% sheep red blood cells in physiological saline (4ml/kg body weight, i.p.) to activate the immune system. Control rats were similarly injected but with saline. Vibratome sections were prepared from animals killed 2 hours, 1 day and 7 days post-injection, and stained immunohistochemically for GFAP. There was no significant change in hypothalamic GFAP staining 2 hours after the injection. However, at both 1 and 7 days after the rbc injections there were increases in GFAP staining (about 3-fold). At no time was cortical GFAP staining altered by the injections. This result suggests that astrocytes may participate in neuroimmunological interactions. EFFECT OF INTERLEUKIN 6 ON PROLACTIN SECRETION, cAMP AND INOSITOL PHOSPHATE PRODUCTION IN RAT PITUITARY CELLS. M.Grimaldi*,E.Landolfi*,T.Florio,O.Meucci* and G.Schettini. Dept. of Pharmacolgy, II School of Medicine, University of Naples, Via S. Pansini 5, 80131 Naples, ITALY.

Interleukin 6 (IL6) is a cytokine having many physiological activities. It has been reported that IL6 is released from rat Hypothalamus, suggesting a role for this cytokine in the regulation of pituitary hormone release. We analyzed the direct effects of IL6 on Prolactin (PRL) secretion on single lactotrophes, by means of reverse hemolytic plaque assay technique. IL6 (200-2000 U/ml) inhibited basal, VIP (-24%) and TRH (-20%) stimulated PRL secretion. Rat anterior pituitary cells pre-exposed to IL6 (500 U/ml) for 20 min showed a reduction of VIP and forskolin-stimulated adenylate cyclase activity (-15%), while the basal production of cAMP was not affected. Conversely when the cytokine was added directly to the cells membranes derived from pituitary no IL6 effect was detectable. Moreover pituitary cells pre-exposed to IL6 (5-500 U/ml) for 20 min showed a dose-dependent reduction of the TRH stimulated inositol posphate production (-25%). Our data suggest that IL6 modulates PRL secretion and affects the formation of both cAMP and inositol phosphate at pituitari level.

499.6

THE STIMULATORY EFFECT OF INTERLEUKIN-6 ON CORTICOTROPIN-RELEASING FACTOR AND THYROTROPIN RELEASING HORMONE SECRETION IN VITRO. K.Lyson, L.Milenkovic* and S.M.McCann. Department of Physiology, Neuropeptide Division, U.T. Southwestern Medical Center, Dallas, Tx 75235-9040.

Since we reported a stimulatory effect of intraventricularly injected interleukin-6 (IL-6) on ACTH release and an inhibitory influence on TSH secretion in vivo, we decided to determine the hypothalamic action of IL-6. After 30 min. preincubation rat medial basal hypothalamus (MBH) was incubated for 30 min.with IL-6 in Krebs-Ringer bicarbonate buffer, and corticotropin-releasing factor(CRF) and thyrotropin-releasing hormone (TRH) release into the incubation medium were measured by RIA. IL-6 (10^{-15}-10^{-9}) evoked a bell-shaped dose-dependent increased CRF secretion with a maximal effective dose of 10^{-13} M of IL-6 (Mean±SEM: 0.57±0.07, vs. control: 0.27±0.02, pg/mg/0.2ml, $p<0.005$), while TRH release was significantly stimulated only by a 10^{-11} M concentration of IL-6 (0.77±0.11 vs. control: 0.48±0.04, $p<0.025$). The results support a role of IL-6 at the hypothalamic level to stimulate CRF and to a lesser extent TRH release. (Supported by NIH grants DK 10073 and DK 40994.)

CENTRAL LIPOPOLYSACCHARIDE INFUSION INDUCES INTERLEUKIN-1 PRODUCTION IN THE ADULT RAT BRAIN IN VIVO. S.H. Lisanby, L.D. Rokoske, J.C. Ritchie, S.K. Sundar, and J.M. Weiss.

Interleukin-1 (IL1) is elevated in the cerebrospinal fluid during slow wave sleep, endotoxin-induced fever, and animal models of multiple sclerosis; however, it is not known whether IL1 enters the brain from the periphery (via the organum vasculosum laminae terminalis) or whether it is synthesized and released centrally. Previous studies have shown that neonatal astrocytes in vitro and injured brain biopsies release IL1; also, intraperitoneal (ip) lipopolysaccharide (LPS) has been reported to elevate brain and plasma IL1 and induce fever in the mouse. The objectives of this study were to determine whether endogenous IL1 production may be induced in the adult rat brain in vivo with LPS, and to investigate the role of central IL1 production in fever, steroidogenesis (SG), and immunosuppression (IS). LPS was infused into the lateral ventricles or ip, brain extracts were ultrafiltered and then fractionated to separate IL1 inhibitors. Ten and 100 ng LPS infused intracerebroventricularly (icv) significantly elevated IL1 bioactivity (17kd fraction) of glial lysates and brain interstitial fluid at 90 mins ($p<.05,.025$). After 24 hrs, brain IL1 was no longer elevated, coinciding with the reported time course for recovery from central LPS-induced fever. Plasma IL1 was not elevated after icv LPS. When given ip, 2.5 mg/kg LPS did not elevate brain IL1 at 5 hrs, but did elevate plasma IL1 and corticosterone ($p<.025$), results which suggest that SG reported after ip LPS may not result from elevated brain IL1. Interestingly, 1 hr of electric tail shock significantly elevated colonic temperature and plasma IL1, and pilot studies found no significant change in brain IL1 post shock; thus, findings after tail shock resemble effects observed after ip LPS injection. In conclusion, these results show icv LPS induces IL1 production in the adult rat brain in vivo with a time course paralleling that reported for central LPS-induced fever, suggesting LPS mediates fever via IL1. In that IS occurs 90 mins after 10 ng LPS icv, and icv LPS elevates brain IL1, the findings are consistent with the hypothesis that central IL1 production mediates IS following LPS in brain.

LOCALIZATION OF INTERLEUKIN-1 SYNTHESIS IN DIENCEPHALON REGION OF RATS CENTRALLY INFUSED WITH LIPOPOLYSACCHARIDE. S.K.Sundar, M.A. Cierpial, S.Long, J.C.Ritchie & J.M. Weiss
Dept. of Psychiatry, Duke Medical Center, Durham, NC 27710

Intracerebroventricular infusion of Interleukin-1 (IL1), a potent modulator of the hypothalamic pituitary adrenal axis, has been shown to produce rapid peripheral immunosuppression. Similar immunosuppression was also detected when de novo synthesis of IL1 was induced by central infusion of lipopolysaccharide (LPS) (Sundar et al 1989, PNAS 86:6398, 1989). It is of interest to determine which area(s) of brain produce IL1. Ninety minutes after central infusion of LPS, virus-antibody free Charles River rats were sacrificed and brains disected into four regions: cortex, cerebellum, diencephalon and brain stems of 3 rats were pooled together, and 3 whole brains were pooled. Astroglial cells were isolated, lysed by sonication, and the clarified supernatant was fractionated on Sephadex G-50 columns under aseptic conditions. Fractions were analyzed for IL1 by thymocyte proliferation test.

IL1 bioactivity corresponding to 17,000 kD was detected in extracts of whole brains and in diencephalon only; but not in the remaining brain regions. Thus LPS-induced IL1 was found in a region of brain that actively regulates HPA axis; consistant with this, plasma corticosterone was elevated in LPS-infused rats. These observations combined with the detection of IL1 mRNA will elucidate whether IL1 is synthesized locally or transported as a neurotransmitter.

INTERLEUKIN-1 (IL-1) INHIBITS ACETYLCHOLINE BIOSYNTHESIS IN CULTURED BASAL FOREBRAIN NEURONS. **L. Ni, R.P. Hart, and G. M. Jonakait. Dept. Biological Sciences, Rutgers University, Newark, NJ 07102**

Since brain levels of IL-1 are elevated in Alzheimer disease (Griffin et al.,*PNAS* 86, 7611, 1989), we sought to determine the possible influence of IL-1 on cholinergic neurons in both the basal forebrain (BF) and neostriatum (NS). Organ cultures of embryonic rat BF or NS (E16) were grown with and without human recombinant IL-1 for 8-10 days and choline acetyltransferase (ChAT) activity was measured as an index of cholinergic development. IL-1 (20 U/ml; Cistron) lowered ChAT activity in both brain regions by as much as 70%. In the BF, IL-1 did not affect levels of mRNA coding for neuron-specific enolase, suggesting that the effect of IL-1 was not a generalized toxic action on neurons in the cultures. Moreover, IL-1 had no effect on levels of message coding for glutamic acid decarboxylase, suggesting that GABAergic neurons were spared the effects of IL-1 and that the action on cholinergic neurons was somewhat specific. Cholinergic neurons, though compromised, survived a relatively brief (5-day) exposure to IL-1 since ChAT activity recovered to control levels following removal of IL-1. The addition of nerve growth factor following IL-1 removal stimulated ChAT activity still higher. These data suggest that IL-1 specifically and significantly compromises cholinergic biosynthesis in cultured BF and NS.

INTERLEUKIN-1 (IL-1) STIMULATES PREPROTACHYKININ GENE EXPRESSION IN CULTURED SYMPATHETIC GANGLIA. G. M. Jonakait and R. P. Hart, Dept. of Biological Sciences, Rutgers University, Newark, NJ 07102

Recent studies from our laboratory have shown that IL-1 dramatically increases substance P (SP) peptide in cultures of neonatal rat superior cervical (sympathetic) ganglia (SCG; Jonakait and Schotland, *J. Neurosci. Res.* 26:24-30, 1990). Northern blot analysis of RNA obtained from cultured ganglia show that mRNA coding for the prohormone precursor, preprotachykinin (PPT), is also increased 4-5-fold by treatment with IL-1, suggesting that increases in mRNA levels mediate the rise in peptide.

Since ganglia increase SP in response to deafferentation, we investigated the role played by depolarizing stimuli in the IL-1-induced increase in SP. Growth of SCG cultures in 40 mM KCl prevented IL-1-induced increases in either SP peptide or PPT mRNA, suggesting that deafferentation is required for immune responsiveness.

Glucocorticoid hormones suppress immune responsiveness in many systems. In this system, too, dexamethasone inhibited the ability of IL-1 to increase both SP peptide and PPT mRNA (K_i=5nM).

Indomethacin (1uM), included in the cultures to block IL-1-induced increases in prostaglandins, depressed the IL-1-induced increase in SP only slightly (21%), suggesting that prostaglandins are not primary mediators of this action of IL-1.

ENDOTOXIN OR INTERLEUKIN-1 ADMINISTRATION ELEVATES PLASMA CORTICOSTERONE, AND BRAIN MHPG AND TRYPTOPHAN. A.J. Dunn. Department of Pharmacology, Louisiana State University Medical Center, Shreveport, LA 71130-3932.

In previous experiments, administration of antigens or infection of mice elicited stress-like elevations of plasma corticosterone, and brain tryptophan, and increases in cerebral norepinephrine (NE) metabolism. Similar results were obtained following IP administration of various preparations of interleukin-1 (IL-1 human α or β, or murine α). We have now studied the endocrine and neurochemical responses to ICV IL-1, and IP or ICV endotoxin administration. ICV human IL-1α produced dose-dependent elevations of plasma corticosterone, and brain concentrations of tryptophan and the NE catabolite, MHPG. The effective dose range was not markedly different from that obtained with IP injections. This could imply that the effect of IP IL-1 is not due to penetration of the brain by IL-1. Two different preparations of E. coli lipopolysaccharide (LPS: Sigma L3129 and L3755) administered IP produced dose-dependent elevations of plasma corticosterone. Although responses were somewhat variable, doses > 0.10 μg were always effective, and L3755 was somewhat more potent than L3129. Accompanying the endocrine changes, were elevations of brain MHPG, the serotonin catabolite, 5-HIAA, and tryptophan. There were smaller elevations of the dopamine catabolite, DOPAC. ICV administration of LPS (0.1 to 5 μg) also elevated plasma corticosterone, and brain MHPG, but was less effective in elevating brain tryptophan. These results suggest that endotoxin, like foreign antigens and IL-1, can produce stress-like endocrine and neurochemical changes. This most likely occurs by LPS-stimulated macrophage secretion of IL-1.

INTERLEUKIN-2 (IL-2) INHIBITS ACETYLCHOLINE RELEASE FROM RAT HIPPOCAMPAL SLICES BY ALTERING OPIOID PEPTIDE RELEASE D. M. Araujo, P. A. Lapchak, A. Beaudet, and R. Quirion. Douglas Hosp. Res. Ctr., Neuroanat. Lab., MNI, & McGill Univ., Montreal, Quebec, Canada.

Recently, we have shown that the lymphokine IL-2 decreases the K+-evoked release of acetylcholine (ACh) from rat hippocampal slices (Araujo et al., Brain Res. 498: 257, 1989). In the present study, we demonstrate that this effect is indirect and may be mediated by an interaction with opioid peptides, which are known to reduce ACh release in this tissue (Lapchak et al., Neurosci. 31: 313, 1989). First, inhibition of ACh release (by 31.5+4.2%) by IL-2 (10 nM) was prevented by tetrodotoxin (1 μM), suggesting that the effect of IL-2 is distal to the cholinergic terminals. Second, the effect of IL-2 appears to involve opiate receptors, since it was antagonized by naloxone (10 μM) and potentiated by B-endorphin (1 μM). Moreover, mu- opiate receptors are implicated, since neither kappa- nor delta- selective drugs alter ACh release in this tissue. However, a direct interaction of IL-2 with opiate receptors seems unlikely since naloxone (10 μM) did not alter the binding of IL-2 to its receptor sites in the hippocampus. Furthermore, IL-2 increased (by 24-44%) the release of endogenous opioid peptides (met-enkephalin and leu-enkephalin) from slices. Thus, it appears that in the hippocampus IL-2 inhibits ACh release indirectly, by enhancing the release of endogenous opioid peptides. (MRC & FRSQ, Canada)

IMMUNOAUTORADIOGRAPHIC LOCALIZATION OF INTERLEUKIN-2 RECEPTORS (Tac ANTIGEN) IN RAT AND HUMAN BRAIN. A. Beaudet, D.M. Araujo, R. Quirion and P.A. Lapchak. Neuroanatomy Lab., Montreal Neurological Institute and McGill University, Montreal, Quebec, H3A 2B4, Canada.

Recent evidence suggests that the lymphokine interleukin-2 (IL-2) may be involved in the regulation of CNS function. In the present study, we determined the localization of IL-2 receptor immunoreactivity (IR) in sections of rat and human brain using the monoclonal antibody anti-Tac. In rat brain, Tac IR was observed in a limited number of regions including the hippocampal formation, median eminence-arcuate nucleus complex, cerebral cortex (lamina IV), lateral septum, neostriatum and cerebellum. This distribution was comparable to that of IL-2-like IR, suggesting that IL-2 may be synthesized and/or stored in the vicinity of interaction with its receptor. In sections from human hippocampal formation, Tac IR was detected throughout the hippocampus and dentate gyrus. Moreover, brains from patients with Alzheimer's disease exhibited qualitatively higher immunostaining of the dentate gyrus than those of controls. In summary, our results demonstrate that IL-2 receptors are present in both normal and diseased mammalian brain. These results suggest that IL-2 may be involved in immune responses during neurodegenerative processes, in addition to playing a role in the regulation of neuronal function in the CNS. IMMUNOHISTOCHEMICAL DETECTION OF INTERLEUKIN-2 IN NORMAL MOUSE BRAIN. F. Villemain, J.M. Girard*, T. Owens* and A. Beaudet. Neuroanatomy Lab., Montreal Neurological Institute, Montreal, Quebec, H3A 2B4, Canada.

Previous studies have suggested that interleukin-2 (IL-2), a lymphokine produced by activated T cells and playing a central role in immune cooperation mechanisms, may be present in mammalian brain. In the present study, endogenous IL-2 was detected by immunohistochemistry in the brain of normal CD-1 mice. Labeling was performed on frozen sections using a rat IgG2a anti-murine IL-2 (S4B6) as primary antibody and either peroxidase anti-peroxidase or immunoautoradiography as detection procedures. In brains fixed by intracardiac perfusion of a 4% paraformaldehyde solution, dense Il-2 immunoreactivity was detected within the arcuate nucleus-median eminence complex of the hypothalamus as well as over capillary walls throughout the brain. Animals perfused with a mixture of 4% paraformaldehyde and 0.2% or 0.5% glutaraldehyde exhibited even stronger labeling of the arcuate nucleus-median eminence complex but were virtualy devoid of vascular staining. Lymph nodes from the same animals exhibited positive IL-2 immunostaining within a selective population of T cells at the periphery of secondary follicles, irrespective of the fixation conditions. These studies provide the first demonstration of the presence of IL-2 immunoreactivity in adult mouse brain and indicate that most of the lymphokine is concentrated within the arcuate nucleus-median eminence complex of the hypothalamus. Supported by MRC.

IDENTIFICATION OF INTERLEUKIN-1 RECEPTOR mRNA IN MURINE HIPPOCAMPUS. E. Wada*, E.T. Cunningham, Jr., Wm. M. Mitchell, D.B. Carter*, D.E. Tracey*, J.F. Battey, and E.B. De Souza. Neurobiology Laboratory, NIDA Addiction Research Center, Baltimore, MD 21224 (E.T.C. Jr., W.M.M., E.B.D.S.); Laboratory of Neurochemistry, NINDS, Bethesda, MD 20892 (E.W., J.F.B.) and The Upjohn Company, Kalamazoo, MI 49007 (D.B.C, D.E.T.).

The cytokine interleukin-1 (IL-1) has been reported to have a number of effects in brain including induction of fever, alteration of slow-wave sleep and neuroendocrine effects such as activation of the hypothalamic-pituitary-adrenal axis and inhibition of the hypothalamic-pituitary-gonadal axis. In this study, we sought to identify the brain areas that might mediate some of these effects of IL-1 by using in situ hybridization of ^{35}S-labeled anti-sense cRNA probes derived from a full-length murine T-cell IL-1 receptor cDNA to investigate the distribution of IL-1 receptor (IL-1-R) mRNA in the mouse brain. In general, the level of IL-1-R mRNA signal was very low, with the molecular layer of the dentate gyrus of the hippocampus providing the only prominent signal in brain. Notably, the signal in the hippocampus was much higher than that found in the hypothalamus, a brain area implicated in the effects of IL-1 on neuroendocrine function. Control sections hybridized with sense cRNA probes displayed no signal above background. The pattern of distribution of IL-1-R mRNA in brain was similar to the autoradiographic distribution of ^{125}I-IL-1α-labeled IL-1 receptors. These results suggest that IL-1 may alter neuroendocrine activity to a large extent through actions in the hippocampus in a manner similar to glucocorticoid regulation of hypothalamic hormone secretion.

499.16

INTERLEUKIN-1 RECEPTORS IN MOUSE BRAIN: CHARACTERIZATION AND AUTORADIOGRAPHIC LOCALIZATION. T. Takao, D.E. Tracey*, W.M. Mitchell and E. B. De Souza. NIDA, Baltimore, MD 21224; The Upjohn Co., Kalamazoo, MI 49007.

The cytokine interleukin-1 (IL-1) has a variety of effects in brain including induction of fever, alteration of slow-wave sleep and alteration of neuroendocrine activity. The potential sites of action of IL-1 in brain were examined using ^{125}I-recombinant human interleukin-1α (^{125}I-IL-1α) to characterize IL-1 receptors in homogenates of mouse (C57BL/6) hippocampus and to localize IL-1 binding sites using autoradiography. The binding of ^{125}I-IL-1α was linear over a broad range of membrane protein concentrations, saturable, reversible, and of high affinity (K_D: 114±35 pM; B_{max}: 2.5±0.4 fmol/mg protein). In competition studies, recombinant human IL-1α, recombinant human IL-1β and a weak IL-1β analog IL-1β^+ inhibited ^{125}I-IL-1α binding to mouse hippocampus in parallel with their relative bioactivities in the T cell comitogenesis assay with K_i values of 55±18, 76±20 and 2940±742 pM, respectively; rat/ human corticotropin-releasing factor and human tumor necrosis factor showed no effect on ^{125}I-IL-1α binding. Autoradiographic localization studies revealed very low densities of ^{125}I-IL-1α binding sites throughout the brain, with highest densities present in the molecular and granular layers of the dentate gyrus of the hippocampus and in the choroid plexus. The identification of IL-1 receptors in brain with characteristics similar to IL-1 receptors in immune and neuroendocrine tissues provides further support for a physiological role for IL-1 to regulate central nervous system activity.

LAMINAR DISTRIBUTION OF ZINC IN THE RAT SmI BARREL CORTEX. N. D. Akhtar and P. W. Land. Dept. of Neurobiology, Anatomy and Cell Science, Univ. of Pittsburgh, Sch. of Med., Pittsburgh, PA 15261.

We used the selenium method of Danscher (Histochemistry (1982) 76:281-293) to localize zinc storage granules in the rat somatosensory (SmI) barrel cortex. The distribution of selenide-precipitated zinc was compared with staining for cytochrome oxidase activity. There is a heterogeneous distribution of zinc staining in rat SmI cortex. The darkest staining is in lamina V which stains non-uniformly for zinc. Lamina V contains dark patches of zinc staining that tend to fall below the septae between barrels in lamina IV. Lamina IV itself is organized into lightly stained patches, each of which is centered upon a barrel. Intervening septal regions are more darkly stained. A band of light staining is present at the lamina V/VI border. Lower lamina VI and laminae II/III have moderate levels of staining, whereas lamina I is only lightly stained. Several studies suggest that zinc is released at excitatory cortical synapses. In addition, it is thought that zinc modulates neurotransmission at glutamate receptors. Thus the pattern of zinc staining in the barrel cortex may reflect functional differences in excitatory input to different regions within SmI. (Supported by NIMH grant MH09773 and NIH grant NS 23047).

METABOLIC CORRELATES OF SENSORY DISUSE AND RECOVERY DURING AGING. J. Metzler and P.J. Hand. Dept. of Animal Biol., Univ. of Penn. Sch. Vet. Med., Phila., PA 19104.

Effects of chronically altered sensory input on the aging CNS and the time course of any changes examined. The rat vibrissal SI cortical barrel system model was used. Effects of disuse and subsequent recovery of single vibrissa C3, on C3 and adjacent vibrissae B3, C2, C4, and D3 functional representations in lam. IV of SI was examined using the (^{14}C)-deoxyglucose (2DG) method. Twenty four young adult (YA;90-da old) and 6 aged (AG; 1.5-2 yr old) rats were studied. Two groups of 12 YA had C3 clipped (disuse) unilaterally for 30 or 90 da. Control side C3 was clipped or not during this time. In 6 animals in each YA group, C3 regrew (recovery) for 30 da. Surrounding B3, C2, C4 and D3 vibrissae were spared and stimulated or not following 2DG injection. Of 6 AG rats examined, C3 was clipped unilaterally--4 for 30 and 2 for 90 da; 3 rats had B3, C2, C4, and D3 stimulated during the 2DG procedure. Analyses indicated that in YA and AG animals 1) B3, C2, C4, D3 vibrissae activation produces increased labeling in the "disused" C3 representation as compared to control side; 2) 30 and 90 da disuse effects are similar; 3) labeling was similar in control and "recovered" C3 representations; and 4) compensatory changes are greatest in YA. In conclusion, while the YA CNS is capable of greater functional responses to sensory disuse and recovery, the AG CNS also exhibits plasticity. (Supported by U. PA. Res. Found. Grant & USPHS Grant NS-22283.)

VIBRISSA DENERVATION EFFECTS ON CORTICAL REPRESENTATION OF SUPRAORBITAL (SOG) AND INFRAORBITAL (IOG) GUARD HAIRS IN RAT. P.J. Hand, S-C.Sheu, and F-J Lai *. Dept. of Animal Biol., Sch. of Vet. Med., Univ. of Penna., and Dept. of Anat., Natl. Yang-Ming Med.Col., R.O.C.

Does peripheral denervation alter the principal cortical target (PCT) of a spared sensory receptor organ, which expanded its representation into denervated territory, but is at a distance from the surgical field? Six 2-day old rats received unilateral vibrissa denervation. 90 days post-denervation, 14C-deoxyglucose (2DG) was injected and either SOG (n=3) or IOG (n=3) stimulated bilaterally. SOG and IOG activation on the non-denervated side served as a control. 2DG labeling [cerebral glucose utilization rates (CGU) and areal extent] was analyzed within lam.IV of SI posteromedial barrel subfield (PMBSF) and adjacent SOG-IOG PCTs. Results (in comparison to control side) were as follows: (1) SOG and IOG activation produced a 29.5% increase in CGU in caudal-half of PMBSF overlying rows B-E and associated "straddlers" [mean areal increase of labeling beyond their PCT was 45% (SOG) and 119% (IOG); (2) SOG and IOG labeling in register with the PCTs exhibited no LCGU differences ($p>.05$); and (3) mean areal extent of labeling associated with PCTs were altered- 40% decrease (SOG) and 44% increase (IOG). Thus a peripheral receptor organ's PCT representation can be effected (e.g., areal extent altered) by a "distant" peripheral denervation and may significantly influence the recovery process. (Supported by USPHS grant NS-22283 and R.O.C. Natl. Sci. Council grant)

DEVELOPMENT OF LAYER IV IN RAT SOMATOSENSORY CORTEX L. Zhang and N. G. F. Cooper. Dept. of Anatomy and Neurobiology, Univ. of Tenn., Memphis, TN 38163

Layer IV of the somatosensory cortex of rodents contains a characteristic pattern of neuronal aggregates called barrel subfields. The objective of this study is to relate patterns of thalamocortical afferents to barrel subfield patterns during development. We have investigated the development of the rat somatosensory barrel field cortex with cresyl violet and carbocyanine dye DiI as follows:(1) Cresyl violet staining of tangential sections of SmI cortex on postnatal day 2(P2) through P11. (2) Thalamocortical mapping with DiI in postmortem fixed tissue from P1(day of birth) to P9. We found that granule cells in layer IV of SmI cortex appear as a continuous sheet prior to P3. On P4 separations in this sheet allowed visualization of cortical subfields representing face, forelimb, hindlimb and trunk. Nissl stained barrels were detected on P4 in the face area. Barrels representing forelimb and hindlimb were visible between P5-P6. DiI labeled thalamocortical axons reached the marginal zone on P1 and appeared to be sorted in layer IV of the cortical-face region by P3. Thus, the pattern of thalamocortical afferents from VPM appears before the corresponding cortical barrels representing the face. Further studies are required to determine if this sequence is repeated for forelimbs and hindlimbs. The segregation of thalamocortical axons appears to be concurrent with the appearance of glial patterns, but not with neuronal patterns. Supported by NIH:NEI EY02708.

THALAMIC AFFERENT SEGREGATION PRECEDES BARREL FORMATION IN THE RAT SI CORTEX. R.S.ERZURUMLU AND S.JHAVERI Dept. Brain & Cognitive Sci., M.I.T., Cambridge, MA 02139.

The formation of periphery-related patterns by somatosensory thalamocortical afferents was examined in paraformaldehyde-fixed embryonic and neonatal rat pups. Axons from the ventro-basal (VB) nucleus to somatosensory SI cortex were labeled with the fluorescent tracer DiI.

VB afferents are present in the cortical plate (CP) by E19. On PND 0 (=E22), layers V and VI have differentiated from the CP, and VB axons form a dense plexus within these layers; a few thalamic axons traverse the CP and extend into the marginal zone. By PND1, VB axons define their projection zone in the lower part of the CP. However, no patchy distribution of thalamic afferents is evident at this time. On PND 2, a vibrissa row-related pattern with occasional patches emerges within the presumptive layer IV. This pattern sharpens over the course of the next 24 hours and by PND 3, individual vibrissa-related patches can be clearly distinguished.

Thus, a vibrissa-related punctate organization in SI cortex is established by VB axons prior to differentiation of layer IV cells into barrels. However, maturation of this pattern may not be independent of other cortical elements (see Blue et al., *Soc. Neurosci. Abstr.*, 1990). Supported by NIH grant NS 27678.

500.6

NEONATAL P-CHLOROAMPHETAMINE (PCA) TREATMENT DELAYS PATCH FORMATION BY THALAMOCORTICAL AXONS IN RAT BARREL CORTEX. M.E. Blue, R.S. Erzurumlu, S. Jhaveri and M.V. Johnston. The Kennedy Institute and Johns Hopkins Medical Institutions, Baltimore, MD 21205 and Massachusetts Institute of Technology, Cambridge MA, 02139.

During early postnatal development, dense patches of serotonergic (5-HT) axons from the raphé nuclei form a vibrissa-related pattern in barrel field cortex. Afferents from the ventrobasal (VB) nucleus display a similar pattern which develops just prior (12-24 hrs.) to that of 5-HT axons. The present study examines a possible interaction between the two cortical projections. Rats were administered the 5-HT neurotoxin, p-chloroamphetamine, (PCA; 10 mg/kg, s.c.) on postnatal days P0, P1, P2 and P3; control littermates received saline. Pups were sacrificed on P2.5 and 3.5. Thalamocortical axons were labeled with the fluorescent tracer, dil and their distribution examined in flattened cortex preparations.

Normally, the vibrissa-related pattern of VB afferents emerges on P2. In PCA-treated rats, the development of this pattern lags one day behind controls. The density of 5-HT axons in the VB is low in both groups, indicating that the effect is mediated at a cortical level. These results along with previous findings of a delay in the formation of barrel cytoarchitecture after PCA-treatment suggest a trophic influence by serotonin on maturing VB afferents and on the layer IV cells that comprise the barrels.

Supported by NIH grants NS27678 and NS28208.

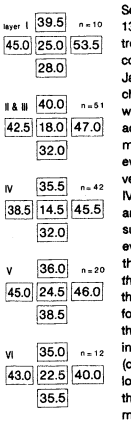
Physiological aspects of the barrel cortex of the mouse: a single unit laminar latency analysis.

E. Welker*, M. Armstrong-James+, H. Van der Loos*.

* Institute of Anatomy, University of Lausanne, Rue du Bugnon 9, 1005 Lausanne, Switzerland.
+ Dept. Physiology, London Hospital Medical College, London E1 2AD, U.K..



Serving as a baseline for plasticity studies, we have been recording from 135 single units in the barrel cortex of normal mice. Carbon fiber electrodes were lowered perpendicular to the pial surface into barrel columns B2, B3, C1, C2, C3 and D2 (for technical details see Armstrong-James and Fox, 1987, J Comp Neurol 263:265-281). The response characteristics of units in layer IV were used to determine the principal whisker (PW) for a given penetration. Units were pooled, and classified according to cortical layer. The numbers in the figurines indicate the median latencies for responses of the PW (central blocks) and of those evoked by stimulation of surrounding whiskers (rows displayed vertically; arcs, horizontally). The shortest latency was observed in layer IV upon stimulation of PWs. Responses to surround whiskers in the row arrive earlier than to stimulation of surround whiskers in the arc. In supragranular layers the rostral surround whisker in the row (lower block) evoked shorter latency responses than the caudal whisker in the row; for these layers a similar anisotropy is observed within an arc: signals from the more lateral surround whisker (left block) reach the cortex faster than those from the whisker medial to PW. In the infragranular layers these forms of anisotropy do not seem to exist. Comparing these data with those obtained in rat (article quoted above), we conclude that information from surrounding whiskers elicits in the mouse much later (ca. 2x) cortical responses than in the rat. The mechanism behind this longer period of "reflection" can be of subcortical or intracortical nature; this difference can be considered as a new piece of evidence that a mouse is not a rat. Support: Swiss NSF 3100.009468.

Intra-columnar and interlaminar relay of vibrissal inormation in barrelfield cortex.

By *M. Armstrong-James and **K. Fox. *London Hospital Medical College, Turner St., London E1 2AD, U.K. and **Center for Neural Science, Brown University, R.I. 02912.

Our previous studies have shown that surround receptive fields of barrel cells in rat S1 cortex appear to be constructed intracortically. We now report that the centre receptive vibrissa (CRV) data is relayed vertically in a column of neurons prior to relay to adjacent columns. Extracellular recordings were made in identified layers of rat barrel cortex and latency differences of neurons to stimulation of centre and surround receptive vibrissae (CRV and SRV) measured. Latency differences for pairs of cells in the same penetration to stimulation of the CRV were also collected. To the CRV, Layers IV and Vb neurons discharged earliest, and layers II and III on average 2-3 ms later. The data suggests that serial relay from layers IV to III to II is the most common event. No significant differences were found for latency or magnitude of response of layer Va cells to stimulation of centre and immediate SRVs. *Temporal summation of responses to several* simultaneously stimulated vibrissae is therefore ideal in layer Va. Layer II, III, IV and Va cells showed no statistical difference in latency of discharge to SRVs, suggesting parallel column-column relay for construction of surround receptive fields. The mean transmission velocities were calculated at about 0.08 m/s for column-column information transfer and 0.18 m/s for intracolumn (layers IV-II-II) transfer (assuming major relay from layer IV).

ECTOPIC LOCATION OF HEAVILY 2DG-LABELED NEURONS IN BARREL CORTEX OF THE BEHAVING HAMSTER

J.S. McCasland, R.W. Rhoades, and T.A. Woolsey. Division of Experimental Neurology and Neurosurgery and McDonnell Center for Studies of Higher Brain Function, Washington University. School of Medicine, St. Louis, MO 63110, and Department of Anatomy, Medical College of Ohio, Toledo, OH 43699

We used a high-resolution 2-deoxyglucose (2DG) technique in material double-labeled for cytochrome oxidase (CO) to study stimulus-dependent patterns of label in barrel cortex of the behaving hamster. We compared the distribution of 2DG label in cortices of normal behaving animals with those in which all large whiskers except left C3 and right A1 and E4 were trimmed one day before the experiment. In normals, all barrel columns were heavily 2DG labeled. The whisker-trimmed animals showed increased labeling mainly in the barrel columns appropriate to the spared whiskers in both cortices as well as in the brainstem and thalamic representations of those whiskers. A small subset of cortical neurons, scattered through lower layer IV and upper layer V and with characteristics of nonpyramidal GABAergic neurons, showed strikingly heavy labeling. Interestingly, in whisker-trimmed subjects many heavily labeled neurons were found "ectopic" to the principal columns of the stimulated whiskers. The locations and numbers of these cells were highly variable from case to case, but in each case examined to date showed a rough correspondence in spatial distribution to the principal whisker columns. The zone of heavy 2DG labeling invariably corresponded precisely to heavily CO-stained somata. Studies are under way to determine whether these cells are indeed GABAergic. The ectopic locations of many heavily-labeled neurons, in contrast to the homotopic labeling seen in brainstem and thalamus, suggests that these neurons function as a neural network involved in regulation of intracortical activity. Supported by NIH grant NS17663.

PRENATAL CENTRAL VIBRISSAL PATHWAYS LABELED WITH DiI AND DiA

S. L. Senft. *Department of Neurology and Neurosurgery, Washington University School of Medicine, Saint Louis, Mo. 63110.*

Earlier work focused on postnatal elaboration of mouse thalamocortical axons (Senft, 1987). This pathway (and also the cortico- and trigemino- thalamic projections) is now being studied in prenatal mice. Fluorescent lipophilic dyes, the red-orange "DiI" and the yellow-green "DiA" (Molecular Probes), are applied to fixed cortex, thalamus and brainstem, and the tissue is stored at 37-60 C° for 4-14 days.

The Ventro-Basal (VB) nucleus is retrogradely labeled from cortex as early as E17 (E0 indicates conception; ~E19 the day of birth), when fibers from the brainstem trigeminal complex are within the diencephalon.

Several technical items are notable: (1) Perfusion is with unbuffered 8% paraformaldehyde (pH 10), producing hardened tissue that sections uniformly and contains very crisp dye labeling. (2) For cytoarchitecture, 0.05% bisBenzimide (Molecular Probes) is added to the perfusion fixative, staining the brain uniformly *en bloc* and obviating any extra manipulations that might damage sections. (3) DiI and DiA are solubilized with dichloromethane (Aldrich) and pressure-ejected from micropipettes. (4) Cells and fibers remain distinct for weeks to months, at room temperature, mounted in a 1:1 solution of 100% glycerol and 8% paraformaldehyde (pH 8-10). (At lower pH labeled membranes become fuzzy shortly after sectioning and clearing.) (5) Vibratome sections cut in this solution are already cleared and can be mounted directly. Supported by NIH grants NS 17763 and NS 07057.

EFFECTS OF EARLY WHISKER REMOVAL ON THE DEVELOPMENT OF THE PROJECTIONS FROM ZONA INCERTA TO THE NEOCORTEX.

M.A.L. Nicolelis, C-S.Lin and J.K. Chapin. Hahnemann Univ., Phila., PA 19102.

Recently we described a major GABAergic projection from zona incerta (ZI) to the entire neocortex of rats that is remarkably expanded in young animals. In the present study we examined the development of this projection and its alteration by early postnatal (PN) whisker removal. Long-Evans rats (n = 50) ranging in age from PN day 1 to adulthood received small injections (0.1 to 0.5 µl) of either *rhodamine coated microspheres (RCM) or Fluoro-gold (FG) in the primary* somatosensory (SI) and/or primary visual cortex. The projection from ZI to SI was first detected in normal animals injected at PN day 1 and perfused at PN day 3. It reached its maximal expansion at PN week 1, remained stable until PN week 2 and started to decline after PN week 3 until it reached its adult pattern. Another group of animals (n = 17) was subjected to monolateral whisker removal at PN day 1. After reaching adulthood these animals received small injections of fluorescent tracers in the SI cortex (barrel fields). These injections were found to label as high a proportion of neurons in the ZI of these whisker deprived adults as in normal young rats (1 to 2 weeks old). In addition, projections from the magnocellular subdivision of the medial geniculate body to the SI (previously identified only in young rats, but not in normal adults) were also observed in these deprived animals. Neurophysiological mapping of somatosensory responses in the ventral posteromedial (VPM) thalamus were also carried out in neonatally deprived adult animals anesthetized with pentobarbital. Unlike normal adults, neurons in the *VPM of these deprived rats were found to respond preferably to ipsilateral* manipulation of the whiskers and secondarily to other receptive fields located in the contralateral face. Overall, these results indicate that early postnatal whisker removal can produce a stabilization of otherwise transient thalamocortical and incertocortical projections. *Supported by grants NS26722, AAO6965, KO2-AA00089, AFOSR 90-0266 and FAPESP 88/4044-9.*

TOPOGRAPHIC MAPPING OF EVOKED SOMATOSENSORY POTENTIALS IN RAT: SPATIAL AND TEMPORAL ANALYSIS.

SHI DI and DANIEL S. BARTH *Departments of Neurology and Psychology, Univ.of California, Los Angeles, (U.S.A)*

Surface mapping of evoked potentials in vibrissa/barrel cortex has been studied in rat (Woolsey, 1948; Axelrad,1976). The present study reexamined the topographic vibrissal representation in rat SmI using an 8x8 multichannel *microelectrode array to simultaneously record* epicortical field potentials. The potential complex evoked by vibrissal displacement began with a positive-negative fast wave followed by a positive-negative slow wave, which were defined sequentially as P1, N1, P2, and N2 components. The P1 and N1 components, with latencies of ~8 and ~15 ms respectively, were spatially restricted within a 1 mm² cortical area and demonstrated a vibrissal dependent topology similar to previous cortical recordings, corresponding to the spatial arrangement of layer IV barrels. In contrast, the P2 (~30 ms) and N2 (~90 ms) were widely distributed over 2-3 mm² recording areas, and had a vibrissa dependent topology that only approximated that of the P1 and N1. These data indicate that the fast activation (P1 and N1) spreads from the corresponding barrel focus over a short period and obscures the clear somatotopic map seen at earlier latencies. *Our results suggest that the evoked response complex consists of* individual temporal components with distinct spatial distributions. Spatial and temporal analysis of the surface response complex, particularly if combined with selective laminar potential measurements, may provide a useful approach for studying vibrissal information processing at the neural network level.

NUCLEUS BASALIS NEURONS PROJECTING TO PRIMARY SOMATOSENSORY CORTEX BARRELS. M.A. Howard,D.J. Simons,E.W. Rubel. Depts. Neurosurg. and Otolaryngol., U.Wash., Seattle WA 98195 and Dept. of Physiol., U. Pittsburgh, Pittsburgh, PA 15261

Retrograde tracing experiments were conducted to localize Nucleus Basalis Magnocellularis (NBM) neurons projecting to somatosensory cortex barrels. Barrels were mapped under physiologic control using a tungsten microelectrode. Rhodamine dextran was injected into one barrel per rat. Rats were sacrificed 3 to 6 days later. Cytochrome oxidase staining confirmed barrel field injection sites encompassing no more than 2 barrels. Thalamic ventrobasal complex (VB) cells labeled intensely in all rats. Labeling of NBM neurons was less intense and improved with longer post-injection survival times. Labeled neurons consistently occupied a region of anterior ventral NBM extending caudally approximately 1.5 mm from the anterior commissure. Labeled cells within each coronal section were located within the ventral portion of NBM, 1.5 to 3.0 mm from the midline. The maximum number of labeled cells per coronal section was 7 and 28 for NBM and thalamic neurons respectively. Total number of labeled NBM neurons was variable (range 1-44) despite consistent labeling of BV neurons.

Barrelfield projecting neurons of NBM are located within a discrete region of the nucleus and may be selectively manipulated with a stereotaxic probe. (Supported by NIH Grant NS08438-01).

SENSORY SYSTEMS—RETINA: RETINAL GANGLION CELLS

501.1

THE DISTRIBUTION OF RETINAL GANGLION CELLS IN NORMAL (CD-1) AND TRANSGENIC MICROPHTHALMIC MICE. S.D. Schlussman and S.C. Sharma. Depts. Cell Biol. and Anatomy and Ophthalmology, New York Medical College, Valhalla, NY 10595.

Genetic ablation of gamma-2 crystalline expressing cells leads to reduction in lens size and these transgenic animals have a microphthalmic phenotype (Breitman et al, Science 238:1987). In order to evaluate the effects of microphthalmia on the number and distribution pattern of retinal ganglion cell layer (GCL) neurons, cell counts and isodensity maps were made from flat-mounted retinae of control (CD-1) and transgenic microphthalmic mice. Isodensity maps revealed a centroperipheral gradient with the highest cell density just temporal to the optic disk and the lowest in the far periphery. The cell density was lower in microphthalmic mice than controls at all retinal eccentricities. Estimates of the total number of neurons in the GCL revealed that there were 70% fewer neurons in the microphthalmic GCL compared to control (33,000 vs. 113,000). We demonstrated earlier that transgenic microphthalmic mice contained 70% fewer optic axons than controls (8,500 vs 52,500). Comparison of these studies suggests that a high proportion of the neurons in the GCL of transgenic animals may be displaced amacrine cells.

LUCIFER YELLOW, FLUORESCENT RETROGRADE TRACERS AND FRACTAL ANALYSIS CHARACTERISE FERRET RETINAL GANGLION CELLS. R.J.T.Wingate*, T.FitzGibbon*, E.I.Webb* and I.D.Thompson*. (SPON: Brain Research Association). University Laboratory of Physiology, Parks Road, Oxford OX1 3PT, United Kingdom.

We have used an in vitro method to study the morphology of adult ferret retinal ganglion cells. Fluorescent retrograde tracers were injected into the lateral geniculate nucleus and/or the superior colliculus, some days prior to the light perfusion fixation and isolation of the retina. Labelled cell bodies were identified and intracellularly injected with lucifer yellow under a fixed stage compound microscope equipped with epifluorescence. By selective use of different coloured tracers, the branching pattern of the retinofugal axons could also be assessed. Lucifer yellow fills were drawn from serial photographs. Drawings were digitised on a 256 by 256 pixel array (Seescan Imaging Limited, Cambridge, U.K.) and the dendritic branching pattern analysed. Ganglion cell morphology resembled the alpha, beta and gamma classes, confirming the tracer studies of Vitek et al, 1985 (J.Comp.Neurol.,**241**,1-11). Quantitative comparisons of dendritic morphology were undertaken using automated Sholl ring counts, supplemented by a routine enabling the fractal dimension (df) of the arbors to be estimated (Caserta et al, 1990, Phys.Rev.Lett.,**64**,95-98). Gamma-like cells are found to have a substantially lower fractal dimension to both alpha and beta-like types. Alpha, beta and gamma cells have characteristicly differing central projections.

MORPHOLOGICAL CHARACTERISTICS OF NEOTENOUS TIGER SALAMANDER GANGLION CELLS. C.B.Toris, F.F. Risinger* and R.F. Miller. Dept. Physiol. Univ. of MN, Mpls, MN 55455.

Tiger salamander retinal ganglion cells were examined morphologically by injection of horseradish peroxidase (HRP) into the optic nerve sheath, followed by computer aided neuron reconstruction of the HRP filled cells. Based on cell size, placement and dendritic complexity, four broad types were identified to date (small-simple, SS; small-complex, SC; large-simple, LS; and large-complex, LC). Cells having an area of influence of less than 30,000 μm^2 were considered small. Cells with less than 35 terminal dendritic branches and/or short dendritic segment lengths (less than 15 μm) were considered simple. LC cells had a circular dendritic branching pattern extending throughout the inner plexiform layer (IPL). The dendrites of LS cells branched in a polar pattern and arborized in either sublamina a and/or b of the IPL. SC cells had dendrites arborizing in the IPL in sublamina a and/or b. SS cells differed from SC cells by having smaller total dendritic fiber length and a smaller average number of terminal dendritic branches (18 vs 45, respectively). The density of ganglion cells was estimated at approximately 300 cells/mm^2. Soma density and size were independent of eccentricity. Displaced ganglion cells were rare (2 of 58). These findings show that the ganglion cells of the tiger salamander differ dramatically from those of the mudpuppy retina. Detailed structure/function correlations will be necessary to further characterize ganglion cells in these animals. (R01EY07376)

PEPTIDERGIC DISPLACED GANGLION CELLS IN THE PIGEON RETINA. D.E. Hamassaki* and L.R.G. Britto. Dept. Physiol. Biophys., Inst. Biomed. Sci., São Paulo State Univ., 05508 São Paulo, SP, Brazil.

Displaced ganglion cells (DGCs) represent the sole source of retinal axons entering the nucleus of the basal optic root (nBOR) of the avian accessory optic system. In this study we investigated chemically-specific DGCs projecting to nBOR. Retrograde labeling of DGCs was obtained with rhodamine beads injected into nBOR of pigeons anesthetized with ketamine and xylazine. The indirect fluorescence and avidin-biotin methods were used to detect immunoreactivity to antibodies against substance P (SP, Sera Lab) and cholecystokinin (CCK, Immunonuclear). Following rhodamine beads injections into nBOR, approximately 4,700 DGCs were retrogradely labeled in the contralateral retina. About 25% of these DGCs were also labeled with the antibody against SP. A different population of about 15% of the DGCs projecting to nBOR showed CCK immunoreactivity. Both types of DGCs were mainly found in peripheral retinal regions and their sizes ranged from 12-24 µm (SP) and 18-29 µm (CCK). Together with previous data on catecholaminergic DGCs, the present results indicate that retinal inputs to nBOR are chemically heterogeneous.

GABAERGIC GANGLION CELLS IN CAT RETINA L. Shelton*, S.B. Tieman and K.R. Fry. Neurobiology Research Ctr, SUNY, Albany NY 12222 and Ctr for Biotechnology, Baylor College of Medicine, The Woodlands TX 77381.

Until recently, little was known about the neurotransmitters used by the ganglion cells of the vertebrate retina. We have recently shown that whereas most retinal ganglion cells (RGCs) contain N-acetylaspartyl-glutamate (NAAG), 5-10% do not. Gamma-aminobutyric acid (GABA) has previously been localized in a small percentage of RGCs in the rat and the rabbit. To determine whether any RGCs in the cat contain GABA, we have attempted to double-label these cells with antisera to GABA and with AB5, a monoclonal antibody specific for RGCs. Six cats were deeply anesthetized and perfused with a mixture of 4% paraformaldehyde and 4% carbodiimide. Retinal sections or whole-mounts were incubated in a mixture of the primary antibodies (guinea pig anti-GABA (Chemicon) at 1:1800; AB5 at 1:7500), followed by rhodamine-labeled goat anti-guinea pig and fluorescein-labeled goat anti-mouse (Jackson; each at 1:100). As previously reported, AB5 labeled many cell bodies in the ganglion cell layer (presumably RGCs) and their processes in the inner plexiform and optic nerve fiber layers, while the GABA antibody labeled numerous small cells in the inner nuclear and ganglion cell layers (presumably amacrine cells) as well as a few larger cells in the ganglion cell layer. The great majority of labeled cells contained only one label. However, in every cat tested so far, a few cells (up to 5% of the AB5-positive cells) contained both labels, suggesting that in cat, as in rat and rabbit, some RGCs are GABAergic. 501.6

NMDA-evoked responses in retinal ganglion cells of the larval tiger salamander. **J. Gottesman & R.F. Miller Dept. Physiology & Graduate Program in Neuroscience, Univ. of Minnesota, Mpls. MN 55455.**

We measured *N*-methyl-D-aspartate (NMDA) evoked currents via whole cell recordings made in a retinal slice preparation using the larval tiger salamander. We recorded ganglion cell responses to bath applications of agonists and antagonists in both current- and voltage-clamp. All cells displayed an inward current to NMDA when in normal (1 mM) external Mg^{2+} and held at -60 to -70 mV. This current reversed near 0 mV and had a negative slope conductance region beginning at potentials around -30 to -40 mV. Reducing external Mg^{2+} linearizes the current-voltage relation and increases both baseline current noise and NMDA-evoked currents while increasing external Mg^{2+} reduces noise and blocks NMDA currents.

Application of D-2-amino-7-phosphonoheptonoate (D-AP7), 7-chlorokynurenate, zinc or MK-801 had two effects: 1) Responses to NMDA were blocked and 2) Baseline current noise (especially in Mg^{2+}-free ringer) was reduced in amplitude. Responses to kainate were not affected by any of these agents.

Our results suggest that the external concentration of Mg^{2+} may play a role in controlling the extent to which NMDA receptors contribute to light-evoked responses in ganglion cells, especially near threshold.

Our data suggest that the NMDA receptor of the tiger salamander retinal ganglion cell possesses: a voltage-dependent Mg^{2+} block of the channel, a strychnine-insensitive glycine site, a zinc site and a phencyclidine/MK-801 site making these amphibian NMDA receptors similar to those in mammalian CNS neurons. (EY03014)

501.7

NEURAL CODING OF E-VECTOR AND COLOR IN GANGLION CELLS OF SALMONID FISHES. Craig W. Hawryshyn. Department of Biology, University of Victoria, P.O. Box 1700, Victoria, B.C., CANADA V8W 2Y2.

Studies have shown that fish can discriminate E-vector and orient to polarized light fields. However, these studies were conducted when little was known about ultraviolet (UV) sensitivity. Our recent studies have shown that UV-sensitive cones in addition to green- and red-sensitive cones play a major role in polarization sensitivity. The UV cones show a preference for vertical E-vector while the green and red cones both prefer the horizontal E-vector. This condition is necessary for discriminations on the basis of E-vector. Since the optic media of fish transmits UV radiation, a linearly polarized UV stimulus can stimulate all the cone mechanisms that overlap in the UV spectrum. Single-unit recordings have shown that UV/red opponent ganglion cells exhibit orthogonal polarization sensitivity. In one case, a UV-on/red-off unit was examined. When the UV polarized light stimulus was used under conditions of parallel sensitivity in the UV and red cones, a vertical E-vector orientation resulted in an on response, a horizontal orientation resulted in an off response and an oblique orientation resulted in an on-off response. Supported by NSERC(URF0043984).

501.8

HOW GANGLION CELLS SUMMATE EPSPS IN THE RECEPTIVE FIELD CENTER: PHYSIOLOGY, BIOPHYSICS AND COMPUTER SIMULATIONS. R.F. Miller, P.A. Coleman and S. Jayaram. Dept. of Physiology, Univ. of Minn., Minneapolis, MN 55455.

We studied the mechanisms by which ganglion cell dendrites summate EPSPs in the receptive field center of sustained On-ganglion cells in the mudpuppy retina. Our analysis was based on comparisons of whole-cell recording data (from the intact, perfused retina-eyecup), with computer simulations, using compartmental models derived from identified morphologies. Both linear and non-linear membrane were simulated for these studies, using our own software (NMA), combined with a commercially available analog simulator (Saber, Analogy Software). Bipolar cell inputs were simulated through conductance changes, whose time course was based on exponential (alpha) functions. Experimentally, we studied spatio-temporal summation in the receptive field center, using displaced spots and slits of light, whose intensity ranged from near threshold to well above threshold levels. We will present detailed models which account for the spatio-temporal summation properties of ganglion cell dendrites, for both large vs small signals and center vs distal inputs, to show that high values of membrane resistance (70,000 ohms cm^2) are required to adequately account for the physiology. Supported by NEI Grant EY-07376.

501.9

THE ROLE OF GANGLION CELL DENDRITIC ARCHITECTURE IN INCREASING THE SPATIAL BANDWIDTH OF CAT RETINAL W-CELLS. M.H. Rowe and J.F. Cox, Neurobiology Program, Ohio Univ., Athens, OH 45701.

The contrast sensitivity profiles of many cat retinal W-cells include a significant high frequency shoulder which makes it impossible for them to be fitted with a single gaussian function, and which indicates that the receptive field center mechanism itself is not gaussian in shape. We have used a model of the spatial sampling characteristics of ganglion cell dendrites to show that incomplete sampling of the underlying bipolar array by the ganglion cell could provide one possible explanation for this phenomenon. Given reasonable values for the size and spacing of bipolar cell receptive fields, it can be shown that incomplete sampling of the bipolar array within the domain of a ganglion cell dendritic tree will result in a sensitivity profile for the receptive field center which contains significant irregularities, i.e. a bumpy gaussian. The fourier transform of such a sensitivity profile produces a contrast sensitivity function which contains a high frequency shoulder very similar to those observed experimentally in W-cells, and this is true even when the irregularities are confined to the periphery of the dendritic tree. When applied to camera lucida drawings of HRP filled W-cells, the model produces 2 dimensional receptive field profiles which also contain significant irregularities, and whose fourier transforms include high frequency shoulders at some orientations. Thus, one consequence of incomplete sampling of the bipolar array is to extend the spatial bandwidth of the ganglion cell to frequencies about 30% higher than would be predicted from the overall dimensions of the receptive field. Supported by grants EY06013 and EY08038 from the National Eye Institute.

501.10

OSCILLATIONS IN CAT RETINAL GANGLION CELL RESPONSES TO LIGHT FLASHES. A.W. Przybyszewski, Dept. of Physiology, Freie Universität Berlin, Arnimallee 22, 1 Berlin 33, BDR.

The action potentials of ganglion cell (GC) responses to diffuse light flashes were convoluted with the second derivative of the Gauss function (Mexican hat) to obtain wavelet transformation. The width of the Mexican hat function was varied in 640 (OFF-center GCs) or 512 (ON-center GCs) steps (from 0.6 to 384 or 307ms), which gives different narrow band pass filters. This kind of analysis demonstrates a "mathematical" microscope, whereby the degree of magnification was varied. Some parts of the wavelet transformation were extended and analysed in the frequency domain to explore oscillatory components of the impulse pattern. The amount of different oscillations was richer in class I (Y) than class II (X) and in OFF- than in ON-center GCs. The range of analysed oscillations was between about 1000 and several Hz. Increase of the diffuse flash light intensity in the photopic range (0.5 to 100 cd m^{-2}) caused a shift in the frequency of some oscillations, e.g. in the primary activity period of ON-center GCs frequency increase proportionally to intensity. The change of the light intensity evoked new oscillations and changed the length of the old one. This method, by which the "local" (in time after stimulus) character of the different frequency components is preserved, could give insight into an interpretation of the neural circuity (our other abstract this Meeting).

501.11

AN ANALYSIS OF CAT GANGLION CELLS OSCILLATIONS BEFORE AND AFTER INTRAVITREOUS INJECTION OF AMINO-PHOSHONOBUTYRIC ACID (APB).

T.H. Chung*, O.-J. Grüsser and A.W. Przybyszewski. Dept. of Physiology, Freie Universität Berlin, Arnimallee 22, 1 Berlin 33, BDR (supported by ENA).

We compared the effects of APB injected (0.5-3mg pro eye) into the vitreous body on ganglion cell activity evoked by diffuse short (10ms) or longer (1s) light stimuli or eyeball deformation. The experiments were performed in pentobarbital anaesthetized cats. Single ganglion cell activity was recorded by means of microelectrodes from optic tract axon.

In on-center GC light-induced responses were completely inhibited one to two hours after APB injection. GC response to eyeball deformation was at first reduced and later completely disappeared significantly faster then the responses to light. This could be explained by the fact that APB also acts on synapses between horizontal and bipolar cells (Soc. Neurosci. Abstr.,15,part 1, p.925,1989). We used wavelet transformation (see our abstract this Meeting) to find oscillations in the response of GC to diffuse light flashes before and after APB injection. In some experiments the primary phase (maximum frequency of discharges) was strongly reduced in frequency after APB injection (from 1000-800Hz to 600-200Hz in 20-30min after APB injection). This reduction was not always synchronized with a disappearence of the GC's response to deformation. This supports the hypothesis that APB also acts on other synapses than photoreceptors - on bipolar cells as in lower vertebrates (Slaughter & Miller 81,86, Shiells & *al.*,81, Nawy & Copenhagen, 87).

501.12

COMPARING A RETINAL MOTION DETECTOR ALGORITHM TO CLASSICAL APPROACHES.

F.H. Eeckman, M.E. Colvin*, J.L. Teeters*, and T.S. Axelrod*. Lawrence Livermore Natl. Laboratory, Livermore, CA 94550.

Last year we presented a three-dimensional simulation of the motion detector circuitry in the vertebrate retina (Neurosci. Abstr. 366.23). The model consists of five layers of cells in a closely packed hexagonal array. All cells are modeled as single compartment, leaky-integrator neurons. The model-input consists of series of images of size 512 x 512.

We compare the performance of this model to some classical tracking approaches used to track dim targets against cluttered backgrounds. The test set consists of several 2d Gaussian blobs imbedded in independent and identically distributed Gaussian noise. The targets have a fixed signal to noise ratio with respect to the background and they move with different constant speeds. The algorithms we used for comparison are: adaptive thresholding and multi-stage hypothesis testing. Adaptive thresholding is computationally the simplest technique. Thresholding only works under conditions of constant contrast without contrast reversals, yet it is the most commonly used track detection method. Thresholding performance establishes a minimum performance limit against which all other algorithms can be judged. Multi-stage hypothesis (MHT) testing is the most complex technique. It starts a track at every pixel, in every direction, in every frame. It then uses statistical tests to weed out false tracks and to continue only those that are promising. In the Gaussian noise environment, MHT represents the upper limit of theoretically best possible performance. We found that the retinal algorithm is a powerful technique for target-extraction and we will discuss the importance of the various features of the biological algorithm in the realization of that performance.

SENSORY SYSTEMS—VISUAL CORTEX: RESPONSE PROPERTIES

502.1

RECEPTIVE FIELDS IN THE VISUAL CORTEX OF THE GRAY SQUIRREL:A DESCRIPTIVE STUDY.

F.W.GRASSO.UNIV. OF MASS.NEUROSCIENCE & BEHAVIOR PROGRAM,AMHERST,MA. 01003.

To broaden understanding of the comparative functions of visual-cortical neurons and move toward an ecologically inspired understanding of the neurophysiology of vision, maps were made of the receptive fields (RFs) of single units (n=55) in V1 of five Gray Squirrels(Scurius carolinensis). RF maps were made with an on-line computer system that presented a flashed or moving disc stimulus and collected responses in a manner previously used to map units in cats,monkeys and hamsters. The RFs could be classified by gross response properties as simple(65%),complex(22%), or unclassified(13%). They could also be classified by their spatial structure as Disc(40%),Bar (11%),Composite(22%),Diffuse(20%) or unclassified (8%). RFs classed Diffuse were always complex, Bar and Disc were always simple,while Composites were either complex or simple. The details of the spatial structure of the composite class vary across species. It is suggested that this class of RFs reflects species adaption to environmental niche. The maps will be compared to those made in other species.

502.2

SINGLE-UNIT ACTIVITY CORRESPONDING TO POPULATION BURSTS IN LAYER III OF RAT PRIMARY VISUAL CORTEX *IN VITRO*.

R. B. Langdon and M. Sur. Dept. of Brain and Cognitive Sciences, Massachusetts Institute of Technology, Cambridge, MA 02139.

In the rat primary visual cortex, single-shock stimulation to the base of a cortical column results in a brief burst of glutamatergically driven field potential spikes in layer III (Langdon and Sur, Soc. Neurosci. Abst., 1988, 1989, and *J. Neurophys.*, in press). We have proposed that these spikes represent synchronous firing of layer III output neurons linked by recurrent excitatory projections. We have now examined the relationship between single-unit recordings and these population events. Recording primarily from layer III, we have observed units that fire in brief bursts (2 to 6 spikes) in response to single-shock stimulations. As with the population bursts, spikes occurred 2.5 to 3.5 msec apart and amplitudes decayed rapidly. Post-stimulus latency histograms revealed individual spikes which matched the latencies of the "S1" (antidromic) and "S2" (synaptically driven) field potential spikes. Short latency spikes were more tightly phase-locked than later ones. Spikes occuring after 5 msec were prevented by 10 μM CNQX or low-Ca^{++} medium. In contrast, D-APV (50 μM) did not prevent short-latency (5 to 15 msec) spikes, but tended to reduce burst durations. In sum, layer III may contain a network of neurons that fire in bursts driven primarily by transmission through kainate/quisqualate glutamatergic receptors.

Supported by EY07023.

502.3

SPATIAL AND TEMPORAL PROPERTIES OF CELLS IN THE RABBIT'S STRIATE CORTEX.

Casanova C.[1], Molotchnikoff S., McKinley P.A.[1], Morin C.*, Nault B.*, Michaud Y. [1]School of Physical and Occupational Therapy, McGill University, and University of Montreal, Montreal, Canada.

Bars and spots have been primarily used to determine the visual properties of cells in the rabbit's visual cortex. To our knowledge, drifting sinusoidal gratings have never been utilized to study the properties of single cortical cells despite the fact that gratings have been commonly presented to rabbits in discrimination tests (e.g. Van Hof et al., 1983). Tungsten-in-glass microelectrodes were used to record visual responses of cells in the striate cortex to drifting sinusoidal gratings of 80% contrast in New Zealand rabbits. A total of 35 cells were recorded in the visual cortex. Out of these, 26 units responded to drifting gratings, mostly with modulated discharges. More than half of the units were tuned to low spatial frequencies (SF) [mean= 0.16 c/deg; bandwidth < 2 octaves]. The remaining cells shown no attenuation of their responses to very low SF (low-pass cells). Out of these low-pass cells, two units were more responsive to a full-screen flicker rather than to the drift of a sine-wave grating. Almost half of the cells were tuned for a wide range of temporal frequencies (mean=3.6 +/- 2.6 Hz; bandwidth around 2.5 octaves), and the remaining cells were low or high-pass (6 and 2 units, respectively). Attempts have been made to record from all part of the visual field. So far, no differences have been noted between the cells' properties with respect to receptive field location (optic axis or binocular area of the visual field).

EVIDENCE OF LAGGED-TYPE GENICULATE INPUT TO VISUAL CORTEX.

A.B. Saul and A.L. Humphrey. Dept. of Neurobiology, Anatomy and Cell Science, U. of Pittsburgh, Pittsburgh PA 15261.

We previously characterized the response properties of lagged and non-lagged X and Y cells in the cat lateral geniculate nucleus (J. Neurophysiol., July 1990). Here, we are investigating their possible influence on visual cortex. Cortical simple cells were tested with narrow bars whose luminance was modulated sinusoidally at several temporal frequencies. First harmonic amplitude and phase were measured at a series of positions across the receptive field. Also, gratings were drifted in each direction at various spatial and temporal frequencies to characterize cells' directional tuning.

Lagged and non-lagged geniculate cells differ in response phase: lagged cells have a quarter-cycle phase lag and latencies 70ms longer on average. Cortical receptive field subzones similarly fall into groups separated by a quarter cycle phase lag and a 70ms latency increase. The phase difference between these two types of subzones is not as clear as that between lagged and non-lagged geniculate cells, but most simple cell subzones can be classified as lagged or non-lagged type according to their response phase. Some cells show purely lagged or non-lagged type subzones; other cells show both types of subzones.

The geniculate data suggested that lagged and non-lagged inputs to cortex might converge to produce direction-selective cells. From simulations, such cells would be expected to show direction selectivity only at low temporal frequencies, typically below 4Hz, because the inputs would lose their quarter-cycle phase difference beyond 4Hz and the non-lagged input would dominate at high temporal frequencies. Area 17 neurons often satisfy these predictions. The loss of direction selectivity at higher temporal frequencies can generally be predicted from the arrangement of response phase across the receptive field, as can the cell's spatial frequency tuning.

We conclude that lagged input from the LGN may be physiologically demonstrable in visual cortex and may contribute to direction selectivity, and spatial and temporal frequency tuning.

EFFECTS OF NOREPINEPHRINE ON VELOCITY TUNING AND DIRECTION SELECTIVITY OF CAT VISUAL CORTICAL NEURONS. J. McLean, C-S. Lin, B.D. Waterhouse. Dept. Physiol. and Biophys., Hahnemann Univ., Phila., PA 19102

The effect of norepinephrine (NE) on the responses of striate cortical neurons to moving bars was studied using microiontophoretic techniques in anesthetized, paralyzed cats. Unit responses to optimally oriented bright and dark bars moving back and forth across the receptive field were measured at seven different speeds. Velocity tuning curves were then computed by taking the average maximum response for each speed, direction and bar contrast. A mean direction index was also calculated for responses to bright and dark bars. In the presence of NE (5-20nA) many of the cells examined demonstrated a shift in their velocity tuning curve such that the cell's preferred velocity was changed, while the shape of the velocity tuning curve was unaltered. In some cases the shape of the tuning curve was also modified during NE application such that the type of velocity response was changed, e.g. "velocity broad band" converted to "velocity low pass". In the majority of cells studied, the mean direction index increased in the presence of NE. For other cells, the velocity tuning and direction selectivity were unaffected by NE administration. Additional experiments on the same population of neurons revealed no obvious changes in orientation tuning. These results demonstrate that the spatiotemporal properties of striate cortical neurons are, at least, partially subject to modification by NE. In a broader context, these findings add a new dimension of specificity to the potential modulatory influence of the noradrenergic system on central processing of sensory signals. INTRACELLULAR RECORDING STUDY OF STIMULUS SPECIFIC RESPONSE PROPERTIES IN THE CAT VISUAL CORTEX. SATO, H.[1], DAW, N.W.[2] and FOX, K.[2] [1]Dept. Neurophysiol., Biomed. Res. Ctr., Osaka Univ. Sch. Med., Kitaku, Osaka, 530 JAPAN, [2]Dept. Cell Biol. & Physiol., Washington Univ. Sch. Med., St. Louis, MO 63110, USA

Stimulus specific response properties were studied intracellularly in cells recorded from cat primary visual cortex. Animals were anesthetized with a gas mixture of 70 % N_2O and 30 % O_2 containing 0.5-0.7 % halothane and were paralyzed. In all five direction selective complex cells recorded, visually evoked EPSPs were tuned to one direction of stimulus motion (preferred direction), that is, EPSPs to the opposite direction were smaller than those to the preferred direction. Visually evoked IPSPs were also tuned to the preferred direction. These results suggest directionally tuned EPSPs make a major contribution to direction selectivity in complex cells. In an orientation selective simple cell, both EPSPs and IPSPs were tuned to an optimally oriented stimulus. A stimulus oriented diagonally to the optimal orientation evoked IPSPs but they were substantially smaller than those to an optimally oriented stimulus. We suggest the possibility that in the cat primary visual cortex excitatory inputs are tuned to optimal stimuli to produce direction/orientation specific responses and IPSPs evoked by non-optimal stimuli contribute to sharpening the direction/orientation tuning.

RESPONSIVENESS OF CELLS IN AREA 17 AFTER LOCAL INTERCEPTION OF THE DESCENDING PATH FROM AREA 18. B. Nault, Y. Michaud, C. Morin, C. Casanova, S. Molotchnikoff. Dept. Sciences biologiques, Université de Montréal, C.P. 6128, Succ. A, Montréal (Québec) Canada H3C 3J7.

There is no doubt that there exist massive reciprocal connections between visual cortical areas (17, 18, 19...). Thus, in addition to the predominant input from LGN, area 17 receives afferents which originate in area 18 and 19. In the present experiments, we have investigated the feedback path from area 18 to area 17. The strategy is to see the effect of local reversible inactivation of area 18, in the same retinotopic register as the site of the recording electrode in anesthetized cats.

To date 36 cells were fully tested. Data may be summarized in the following way: 63% of the cells were affected by the blockade and most cells saw their activity diminished. Interestingly some properties were more susceptible to the lack of input from area 18 than others. The average decrease in activity is 24% and we never observed a total loss of evoked discharges. It appears that the directionality is particularly sensitive to area 18 blockade.

In contrast to the feedforward influences (17 → 18), the present data suggest that area 18 has a modularoty effect on cells of area 17 by re-enforcing the input from the LGN.

THREE KINDS OF FUNCTIONAL COUPLING BETWEEN CAT AREAS A17 AND A18 REVEALED BY CROSS-CORRELATION.

J. I. Nelson[1], J. Bullier[2], P. A. Salin*[2], M.H.J. Munk*[1].
[1]Biophysics, Philipps University, Marburg, W. Germany 3550; [2]Exptl. Neuropsychology Lab, INSERM 94, Bron, France 69500.

Anatomical studies (Salin, Bullier, Kennedy JCN 1989, 283: 486) demonstrate that the connections between Areas 17 & 18 do not link only retinotopically corresponding regions. We have characterized these connections functionally by cross-correlating activity from pairs of microelectrodes in A17 & 18.

Sorted by width, the cross-correlograms (CCHs) fall into 3 non-overlapping populations (238 runs, 12 cats, 2 labs): towers (T, 2-9ms wide), castles (C, 10-70ms) & hills (H, 200-1000ms). T-, C- & H-couplings are independent; they occur separately or combined. Ts occur at 0 +/-1ms, suggesting common drive. Cs were also centered, but in a range of 5-15ms (1 area fires 1st); so offset Cs may arise from direct A17/A18 connections.

Ts are found only when receptive fields (RFs) have overlap (and usually similar orientations too); Cs are found equally often out of overlap (limit: 8 deg between RF centers). Without RF overlap, Cs occur only when preferred orientations match.

This functional coupling is sensitive to RF separation and orientation preference. Cs and esp. Hs possess the spatial and temporal spread needed to account for modulatory influences from outside the RF (Nelson & Frost, BR 1978, 139: 359; ExBR 1985, 61:54). Nevertheless, functional coupling without RF overlap, or matched orientations, or temporal delay requires the extension of current concepts of visual cortical organization.

CHANGES IN RECEPTIVE FIELD (RF) SIZE OF SINGLE CELLS IN PRIMATE V1 AS A CORRELATE OF PERCEPTUAL COMPLETION. M. Fiorani Jr.*, R. Gattass, M.G.P. Rosa* and C.E. G.Rocha-Miranda*. Instituto de Biofisica, UFRJ, BRAZIL.

Dynamics of RF size of single cells in Cebus monkey V1 was studied in anesthetized and paralyzed preparations. Presentation of long bars revealed "RFs" driven by the contralateral eye, located within the projection of the blind spot (BS). Short bars within the BS elicit no response. Recording sites marked by electrolytic lesions were located within the representation of the BS revealed by CO histochemistry after monocular enucleation. This indicates that cells in V1 are capable of interpolating stimulation on the surround of a naturally blind region. To access the generality of this phenomenon we used opaque masks subtending 2 to 15 degrees to generate scotoma-like regions centered at eccentricities ranging from 5 to 20 degrees. Under masking conditions we observed three groups of cells: The first with no response; the second with extremely large RFs; the third had small RFs in the unmasked condition and continue to respond to large bars in the same location in spite of the use of masks. Thus, these cells respond at the "hidden RF" by interpolating over a large distance. The interpolated response were found at all tested eccentricities and present the same orientation and directional selectivity of those in the non masking condition. LOCALIZATION OF UNITS IN V1 OF THE AWAKE MACAQUE *RESPONDING TO DIFFUSE ILLUMINATION*. T.M. Wengenack and S.J. Bolanowski, Dept. of Neurosurgery, Univ. of Rochester Med. Sch., Rochester, NY 14642 and Inst. for Sensory Research, Syracuse Univ., Syracuse, NY, 13244

We have found that approximately 51% of units (n= 736) recorded from V1 of the awake macaque respond to full-field (Ganzfeld) illumination (Wengenack, et al., SN Abst., 14, 1988). The response types fall into three categories: transient (18%), slowly adapting (13%), and sustained (i.e. luxotonic, 69%). Of those giving a sustained response, 72% could be binocularly activated and displayed one of four prominent response profiles: averaging (38%), inhibition (16%), summation (27%), and suppression (5%).

As determined on the anesthetized macaque, neurons in the cytochrome oxidase (CO) patches, as opposed to inter-patch regions, are typically non-orientation selective and may also respond to diffuse illumination. These two facts make it likely that the Ganzfeld-driven units described above reside within the CO patches. In an effort to verify this, we have electrolytically marked (elgiloy electrodes, Prussian Blue reaction) the various response types and compared their location to the CO patches. Surprisingly, there appears to be no relation between units responding to Ganzfeld illumination and the CO pattern. The units were found to occur both within CO patches and non-patch regions and they occurred in several different cortical layers. The results suggests that units responding to Ganzfeld stimulation for the awake animal can be orientation as well as non-orientation selective, and that anesthesia may affect the response properties of units in V1.

OSCILLATIONS OF ON-GOING AND EVOKED ACTIVITY IN NEURONAL ASSEMBLIES REVEALED BY REAL-TIME OPTICAL IMAGING IN CAT VISUAL CORTEX. A. Arieli, D. Shoham, R. Hildesheim* and A. Grinvald, The Weizmann Inst., Israel, IBM Res. Div. & Lab. of Neurobiol. The Rockefeller Univ.

In order to detect recurring patterns of activity in neuronal assemblies, we recorded, both optically and electrically, the spatio-temporal patterns of on-going and evoked activity of the same cortex. The visual cortices (areas 17 & 18) of anesthetized cats were stained with the dye RH-795. Cortical activity was evoked with stimuli consisting of drifting gratings. Optical signals (from 124 sites), Electroencephalogram (EEG), Local-Field-Potential (LFP) and spike activity (from two isolated neurons), were recorded simultaneously. Activity was recorded for 70 seconds in each trial.

We define "neuronal assembly" as a group of neurons that **cooperate** to perform a specific computational task. The activity of neurons in an assembly is **time-locked** (coherent). However, neurons belonging to different assemblies might not be spatially segregated. To separate the signals from different assemblies we used the fact that the activity of neurons in each assembly is coherent. Each spike was used as a trigger for averaging the optical signals. With sufficient averaging, activity of neuronal assemblies not containing the reference neuron was averaged out, enabling the **selective visualization** of the reference neuron's assembly.

This analysis revealed complex coherent patterns which "scanned" the cortex at several frequencies in the range of 3-50 Hz. Oscillations were detected at several frequencies mostly around 3 and 25 Hz. Surprisingly, analysis of the spatial patterns at different temporal frequencies revealed striking frequency dependent spatial structures of the neuronal activity. The spatial patterns of both on-going and evoked oscillations did not show a clear correspondence to the orientation columns. Interestingly we found that several recurring spatio-temporal patterns were very similar during both on-going and evoked activity. These results suggest that intrinsic on-going oscillations in neuronal assemblies play an important role in shaping spatio temporal patterns evoked by sensory stimuli.

COLOR FACILITATES MOTION CORRESPONDENCE IN VISUAL AREA MT K.R. Dobkins and T.D. Albright, The Salk Institute, La Jolla, CA 92037

A wealth of anatomical and physiological data suggests that motion and color are processed in separate channels in the primate visual system. While psychophysical data on this subject have been more equivocal, recent experiments have shown that color disambiguates motion correspondence in an apparent motion display (Green, Perc. and Psychophys., 45:15, 1989; Papathomas et al., ARVO Abs., 1989). We have used a similar paradigm to investigate the neural basis of chromatically facilitated motion perception. Our stimulus consists of alternating rows of isoluminant red and green dots (gaussian blurred) that are displaced by half of the inter-dot distance at 15Hz. Direction can only be disambiguated through color. Our human psychophysical data confirm that color facilitates motion and, furthermore, demonstrate that degree of facilitation varies with size of spatial displacement.

Neurons in cortical visual area MT are highly selective for direction of motion yet unselective for color. We recorded from single MT neurons in alert rhesus monkeys. An isoluminant red/green pair was found for each cell by the minimal response elicited by a drifting green bar varying in luminance on a red background. The apparent motion stimulus was then placed in the cell's receptive field. Responses to chromatic correspondence were compared in the preferred and null directions. Although direction selectivity was commonly weaker than that elicited by luminance correspondence, significant color-facilitated motion correspondence was seen for the majority of cells. Degree of facilitation varied as a function of spatial displacement.

These results confirm the presence of a functional chromatic input to the magno pathway and imply true chromatic "gating" of directional selectivity. Psychophysical experiments suggest that color may be but one of many low-level cues (e.g. orientation) that facilitate motion correspondence. It remains to be seen whether cue facilitation is a general phenomenon underlying direction selectivity in MT.

ANALYSIS OF RELATIVE MOVEMENT BETWEEN AN OBJECT AND ITS BACKGROUND IN THE MACAQUE VENTRAL MST AREA.
Y. Sugita and K.Tanaka Lab. for Neural Information Processing, RIKEN, Wako, Saitama 351-01, Japan.

Cells in the ventral MST area responded to a small-field movement with directional selectivity. They did not respond to a wide-field movement, but when a stationary object was placed in front of the moving background, about 40% of them responded in the direction opposite to their preference for the small-field movement. We examined the properties of this reversed response to the background movement as well as the mechanisms of the response, by using anesthetized (N_2O) and immobilized (gallamine triethiodide) monkeys (M. fuscata). These responses are not specifically related to pursuit eye movements, because (1)their preferred speed for the object movement roughly corresponded to that for the background movement, and (2)the reversed response was evoked as long as the object was placed within the receptive field, and, furthermore, the receptive field did not necessarily include the fovea. Instead, they are likely to be involved in the general analysis of the object motion relative to its background. The reversed response was considerably reduced by decreasing the background diameter from 80 to 40 deg. The response was abolished by blurring the border of the object, whereas a slight change in object size did not decrease the response. We conclude that not only movement of the wide-field background but also phenomena at the border of the object are necessary to evoke the response.

502.14

DISTRIBUTION OF RESPONSE PROPERTIES ACROSS TOPOGRAPHIC SUBDIVISIONS OF MACAQUE PRELUNATE GYRUS. M. Youakim* and J.S. Baizer Dept. of Physiology, University at Buffalo, Schl. Med., Buffalo, NY 14226.

We have studied response properties and topographic organization of the prelunate gyrus in four hemispheres of two awake, behaving, pigtail macaque monkeys. Topography in the pigtail macaque is similar to that reported for the rhesus (Maguire and Baizer, 1984). A vertical meridian representation (VM) ran diagonally across the gyrus, 10-13 mm lateral to the junction of the lunate and intraparietal sulci. Anterior and lateral to the VM was V4 (Area AL of Maguire and Baizer). Posterior and medial to it was Area PM. We compared single cells in V4 and PM for sensitivity to several stimulus dimensions, including orientation, color, size, and effect of background stimuli. Two response properties, orientation sensitivity and background modulation, distinguished PM from V4. Area PM contained a significantly greater proportion of orientation sensitive cells (73%, 47/64) than V4 (35%, 30/86, $p<.001$). In V4, however, a greater proportion of cells (37%, 15/41) showed dramatically enhanced responses to a visual stimulus in the presence of a background pattern than in PM (5%, 1/20, $p<.05$). Supported by MH42130 and the Whitehall Foundation.

502.15

STIMULUS SELECTIVITY OF INFEROTEMPORAL CORTEX NEURONS: SIMULTANEOUS RECORDING FROM ADJACENT CELLS. I. Fujita, K. Cheng* and K. Tanaka. Lab. for Neural Information Processing, RIKEN, Wako, Saitama 351-01, Japan.

The anterior part of the inferotemporal cortex (AIT) of the monkey contains cells which selectively respond to particular visual patterns. An essential step towards understanding how visual pattern information is processed in AIT is to learn how cells with different selectivities are spatially arranged. This study addressed the question of whether neighboring AIT cells have similar selectivity for visual pattern stimuli.

A monkey (*Macaca fuscata*) was anesthetized with a mixture of N_2O and O_2 and was immobilized with gallamine triethiodide during the experiments. We recorded simultaneously from several adjacent AIT cells with a single electrode. The electrode position was adjusted so that activity of one cell could be reliably isolated from multiple unit activity with a threshold discriminator. Responses of the isolated cell were tested with a set of stimuli including tens of 3-D objects. With the aid of a computer graphics system we then determined what aspects of the effective stimuli were essential to activate the cell. Throughout these procedures, peristimulus time histograms were generated for the isolated cell and for nearby cells, which were selected by a second window discriminator.

Adjacent cells showed similar or related selectivity in most cases. They were selective to limited and overlapped ranges of the stimulus feature spectrum, although the degree of selectivity or the optimal features were slightly different among adjacent cells. For instance, one cell responded to a "reversed T" pattern (⊥), but not to a "reversed Y" (人) or an arrow (↓), and a cell simultaneously recorded responded to all 3 stimuli. Neither cell responded to other stimuli including a "T", an "L", a "mirrored L" (⅃) and bars (_ or |). Crosscorrelograms of simultaneously recorded cells showed either symmetrical or asymmetrical peaks indicating that the cells were functionally connected. Clustering of cells with similar selectivity and functional connections suggests that local interactions among neighboring AIT cells contribute to selectivity to visual pattern stimuli.

502.16

DERIVATION OF POPULATION VECTORS FROM THE RESPONSE SPECIFICITIES OF VISUAL CORTICAL CELLS.
M.P. Young* and K. Tanaka. Lab. for Neural Information Processing, RIKEN, Wako-shi, Saitama, Japan.

It has often been suggested that the cell population may be a useful level at which to analyse activity in neural systems. Population vectors have been derived for motor cortical cells by assuming that cell preferences may be defined in the vector space in which movements are made (Georgopoulos A.P., et al, Science, 233:1416-9, 1986). Population vectors could also be derived for visual cells with simple stimulus specificities by an analogous assumption about the dimensions of the relevant space. Many visual cells, however, have more complex 'trigger' features. The first step in the derivation of population vectors for these more complex cells is to find a Euclidean space in which the response properties of each cell may be represented. This can be accomplished by applying multidimensional scaling (Shepard, R.N., Science, 210:390-398, 1980) to a table of the responses of cells to a number of stimuli. The stimulus preference of each cell may then be represented in the derived space as a vector, or, to preserve information about the cell's breadth of tuning, as a statistical distribution. Population vectors or population distributions can then be derived by summation after weighting the cell vectors by response magnitude.

This approach can be applied to the responses of local populations of anterior inferotemporal (AIT) cells which respond to a narrow range of complex stimuli. A feature of these local populations is that neighbouring cells have similar stimulus specificities (see Fujita, I., et al., this meeting). This populational analysis can be used to determine what stimulus feature is signalled by a particular local population of cells. Population distributions, derived in this way, allow comparison between the properties of cell populations and psychophysical representations of the discriminability of stimuli, when these are given in terms of signal detection theory.

502.17

VISUAL AND OCULOMOTOR PROPERTIES OF SINGLE NEURONS IN POSTERIOR CINGULATE CORTEX OF RHESUS MONKEY. S. Y. Musil, C. R. Olson, and M. E. Goldberg. Laboratory of Sensorimotor Research, National Eye Institute, Bethesda, MD 20892, and Dept. of Psychology, George Mason University, Fairfax, VA 22030.

The posterior cingulate cortex (CGp) of the rhesus monkey is widely regarded as a paralimbic area with functions related to emotion and motivation. However, it is linked by a strong reciprocal pathway to parietal Area 7a which participates in visual, attentional and oculomotor processes. To see if CGp is involved in these processes we recorded from single neurons in CGp in a rhesus monkey trained to perform a variety of visually guided oculomotor tasks.

Neuronal activity was modulated in relation to task performance in roughly half of the neurons forming our sample. The factors most strongly influencing the level of activation were the orbital position of the eye and the amplitude and direction of saccades. Neurons influenced by orbital position characteristically discharged tonically when the eye was in an extreme position and exhibited a graded decrease of excitation as the eye deviated from this position. Neurons influenced by saccades changed their firing level at or shortly after saccade onset. They were broadly tuned for direction and fired most strongly during and after large saccades. Although initial and final orbital position affected the response of these postsaccadic neurons, they did not discharge when a seemingly effective locus was acquired by an ineffective direction or amplitude of saccade. These neurons did not respond to small (1^0) spots of light, but because even saccade-related activity was often modulated by background illumination they must be visually responsive.

These results suggest that CGp neurons participate in visuomotor or visuospatial functions depending upon accurate knowledge of eye position and recent eye movements. They do not support a uniquely emotional or motivational function for CGp.

502.18

MODALITY SPECIFICITY OF NEURONAL RESPONSES IN THE ANTERIOR ECTOSYLVIAN CORTEX (AEC) OF CATS. H. Jiang*, F. Lepore, M. Ptito and J.-P. Guillemot. Groupe de Rech. en Neuropsy. Exp., Université de Montréal and Université du Québec, Montreal, Qué., Can. H3C 3J7.

In order to establish the modality specificity of the AEC and to determine whether it is a polysensory area, extracellular recordings were carried out along the banks of the Anterior Ectosylvian Sulcus (AES) in anesthetized-curarized cats. Three types of stimuli were used: visual stimuli consisted of light or black bars presented at optimal speed and orientation; air puffs and light touches applied to different body regions made up the somatosensory stimuli; auditory stimuli were presented through a speaker positioned either in front or on either side of the interaural line on the horizontal plane. Results showed that unimodal, bimodal (visual-auditory, visual-somatosensory, auditory-somatosensory), and trimodal units were distributed about equally in the AES, with a slight predominance of the latter type of units. Thus, approximately 2/3 of the units responded to at least two modalities. The receptive fields (RFs) of cells with visual or/and somatosensory modalities were almost always large and bilateral. The somatosensory RFs covered either the face, whiskers, head, or/and neck, the trunk or/and limbs and the tail. The response to stimulation in one modality in a multimodal unit was not always equal to that evoked in the same unit to stimulation of a different modality. There were no significant differences in the modality distribution along both the ventral and dorsal surfaces of the sulcus. The high proportion of multimodal units suggests that AEC is a polymodal area which is probably involved in integrating sensory input with action.

502.19

RETINOTOPIC ORGANIZATION AND RECEPTIVE FIELD CHARACTERISTICS OF NEURONS IN THE VISUAL WULST OF THE PIGEON. E. Sproule* and B.J. Frost. Department of Psychology, Queen's University, Kingston, Ontario, K7L 3N6, Canada.

In the avian visual system, a significant number of retinofugal fibres project to the dorsal thalamic nucleus complex (n. opticus principalis thalami, or OPT). The main ascending target of the OPT is a laminated structure on the dorsal surface of the telencephalon known as the Wulst.

Although there are reports in the literature which indicate the presence of retinotopicity in the pigeon Wulst, the retinotopic organization of this structure has not been systematically investigated. We used standard electrophysiological techniques to record from single units in the Wulst, and mapped their receptive field positions. In addition, we measured the sharpness of tuning of units selective for the orientation of bar stimuli.

We mapped the contralateral visual field within the Wulst, and observed a heavy overrepresentation of the region of binocular overlap. Thirty-four percent of the isolated units were orientation-selective and appeared to be more broadly tuned than neurons in mammalian striate cortex. The data are consistent with previous suggestions that the visual Wulst may be functionally analagous to mammalian striate cortex.

NEURONES IN PRIMATE TONGUE MOTOR CORTEX ALTER THEIR FIRING RATES DURING SWALLOWING. G.M Murray+ and B.J. Sessle. Faculties of Dentistry, Univ. of Toronto, Canada M5G 1G6, and +Univ. of Sydney, Australia 2006.

Our recent studies have shown that many neurones in tongue motor cortex (tongue MI) alter their firing rates during a tongue-protrusion task performed by a monkey. This study's aim was to see if tongue MI neurones also alter their firing rates during semi-automatic orofacial movements such as swallowing. Extracellular single neurone recordings were made from tongue MI (defined by intracortical microstimulation; $\leq$20 μA) in an awake monkey (M. fascicularis) swallowing the fruit juice reward associated with successful performance of tongue-protrusion task trials; EMG recordings were also made from the genioglossus muscle. For each of 76 tongue MI neurones, the firing rates during the task and during the period of genioglossus EMG activation associated with the swallow were compared statistically (ANOVA) with that during a preceding control period. The neurones were found to be (i) swallow-related only (14%, 11/76), i.e., each neurone exhibited significant changes (vs. control) in firing rate during swallowing only, (ii) both swallow- and task-related (33%, 25/76), or (iii) unrelated to swallowing and the task (20%, 15/76). These data suggest that tongue MI may be involved in the execution of orofacial movements associated with swallowing.

SOMATOSENSORY AND MOTOR CORTICAL REPRESENTATIONS OF THE TONGUE AND THEIR CORTICOFUGAL MODULATION OF THE JAW-OPENING REFLEX (JOR) IN RATS. C.Y. Chiang, J.O. Dostrovsky and B.J. Sessle. Dept. of Physiology, Fac. of Medicine, and Fac. of Dentistry, Univ. of Toronto, Toronto, Ont. M5S 1A8, Canada.

The aim of this study was to compare the effects of stimulation of tongue somatosensory and motor cortices on the JOR. Cortical evoked potentials (EPs) produced by lingual nerve (Lg) stimulation were recorded in chloralose/ketamine-anaesthetized rats and were located in a sagittally oriented strip of cortex (2x4 mm) approximately 6 mm lateral to Bregma. The largest EPs (2-2.5mV; latency 5.2$\pm$0.2ms, n=11) were recorded near the rostral end of this strip (A2-2.5, L6-7 with respect to Bregma). The tongue motor area (1.5x2.5mm) was mapped with intracortical microstimulation (ICMS;<60uA, 10ms train of 0.2ms, 300Hz pulses); lowest threshold ICMS sites (mean 30.7$\pm$4.2 uA, n=13) were located at A1-2, L6-7. Although the tongue motor area overlapped extensively with the somatosensory area (as defined by EPs) an effective ICMS site could be found where there was no clear Lg-induced EP. Conditioning stimulation (10ms train, 50uA) at this motor area site produced a pronounced facilitation of the JOR induced by Lg test stimuli (>200% of control JOR at 11-15ms) followed by a 200ms inhibitory phase that was maximal (25% of control) at a conditioning-test interval of 50ms. In contrast, similar conditioning stimulation at the somatosensory site of maximal Lg-induced EPs produced similar but smaller facilitatory (130%) and inhibitory (40%) effects on the Lg-induced JOR. These findings indicate that tongue sensori-motor cortex has both facilitatory and inhibitory actions on the JOR and that the tongue motor cortex may exert more powerful modulatory influences than tongue somatosensory area on the Lg-induced JOR.

503.3

MODULATION OF RESPONSES OF PRIMATE FACE SOMATOSENSORY CORTEX SI NEURONES TO PERIPHERAL STIMULI DURING TRAINED MOTOR TASKS. L.-D. Lin, G.M. Murray, and B.J. Sessle
Fac. Dentistry, Univ. of Toronto, Toronto, Ont., M5G 1G6

Modulation of somatosensory transmission in limb SI neurones has been implicated in limb motor control. This study's aim was to see if somatosensory transmission in face SI neurones is modulated in relation to orofacial movements. Extracellular single neurone recordings were made in 2 awake monkeys (M. fascicularis) trained in tongue protrusion and biting tasks. Mechanical (200 ms) or electrical (100 μs) stimuli were applied to the mechanoreceptive field (RF) of single neurones with a perioral RF, or the lingual nerve was electrically stimulated for neurones with a tongue RF. Evoked responses of neurones were tested during, and for 1-s prior to, the movement associated with each task. Depression of evoked activity occurred in only 10 of 19 neurones tested during the biting task but was noted in all 16 neurones tested during the tongue task; modulation of the evoked activity often occurred 50-100 ms before the onset of tongue EMG activity associated with the tongue task. No modulation was noted prior to or during the tasks for 3 neurones tested in limb SI that had a RF on the hand. These data suggest that somatosensory transmission in SI neurones may be modulated prior to and during voluntary orofacial movements; the presence of modulation may depend on RF location and the nature of the task. DISTRIBUTION AND PROPERTY OF THE ORO-FACIAL SI NEURONS IN RELATION TO MASTICATION IN AWAKE CATS. H. Hiraba, T. Yoshida*, C. Tsujimoto* and R. Sumino*. Dept. of Physiol., Sch. of Dent., Nihon Univ., 1-8-13 Kanda Surugadai, Chiyoda-ku, Tokyo 101, JAPAN.

Single neuronal activities were recorded in the oro-facial area of the first somatosensory cortex (the oro-facial SI) of 8 awake cats, to investigate the functional role of sensory information during mastication. Fifty-nine percent of the recorded oro-facial SI neurons (365/620) showed a rhythmical burst firing in relation to the movements of the jaw and the tongue during mastication. Approximately 75% of the mastication related (MR) neurons were found in the perioral and the tongue projection areas of the oro-facial SI. These MR neurons had receptive fields in the perioral region, tongue and teeth which were easy to be stimulated during mastication. However, distinction between MR and non-MR neurons with the same receptive field depended on differences in the direction-sensitivity and threshold value to stimulation during mastication.

These results suggest that the MR neurons would supply sensory informations required the performance of mastication.

We investigated the neuronal activity in the motor cortex (MI) in relation to mastication. We will also discuss to be different in the neuronal activity between the SI and the MI.

MULTIPLE CONTROL OF CEREBRAL CORTEX IN EYE MOVEMENTS. Y. TAMAI and A. KIMURA, Dept. of Physiology, Wakayama Medical College, Wakayama 640, Japan

Neuron discharges in the eye movement-evoking cortices (EMECs) were studied in relation to visually or auditory guided saccades of the cat. Experiments were carried out using nonanesthetized cats with chronic microelectrodes implanted simultaneously in the EMECs: the medial wall of the hemisphere under the cruciate sulcus, the medial and lateral bank of the presylvian sulcus, the fundus of the coronal sulcus and the ventral bank of the anterior ectosylvian sulcus. The cat was sitting in the box and moving her eyes according to the light or sound signals. There were two types of neuron in the EMECs, the one was locked to the sensory signal and the other was locked to the eye movement. The movement-locked neurons, however, were not always active in an specific EMEC but discharged simultaneously or alternatively between the EMECs. These results suggest that the eye movement may be controlled by many cortices located in the different portion of the corebral cortex.

DISTRIBUTION OF MOVEMENT RELATED POTENTIALS (MRP) IN A MONKEY: EFFECTS OF A UNILATERAL LESION OF THE SUPPLEMENTARY MOTOR CORTEX. N.S. Nicholson and J.C. Arezzo, Albert Einstein College of Medicine, Bronx, New York 10461

Identification of the neural generators of MRPs requires topographic mapping of individual components. For this purpose a macaque was implanted with 104 epidural electrodes extending bilaterally from the principal to the lunate sulci. The animal was trained to perform self-paced, right wrist movements; EMG was used to trigger MRP averaging (1 s epoch with 500 ms pre-movement). Five MRP components were identified; 3 were mapped in detail. N2A and N2B are phasic negativities which each begin less than 325 ms before the EMG burst and peak at approximately 70 ms prior to, and coincident with, the EMG, respectively. P2B is a large positivity which follows EMG onset. The N2A component is maximal overlying the contralateral motor (MI) and supplementary motor areas (SMA), with a significant distribution overlying equivalent ipsilateral regions. N2B is also distributed bilaterally, centered over MI although less prominent ipsilaterally. P2B is characterized by a broad contralateral distribution centered over the somatosensory region.

Following initial mapping, the animal suffered an accidental punctate lesion of the left SMA, portions of the basal ganglia and the anterior commissure were also involved. Clinical sequelae included focal motor seizures followed by temporary right upper extremity paralysis. After functional recovery the contralateral EMG was indistinguishable from pre-lesion studies. N2A, however, was significantly reduced in amplitude ($P<0.01$) and its distribution was restricted to the posterior contralateral MI. N2B showed similar but less severe changes (approximately 65% decrease contralaterally). P2B showed little overall change in amplitude or distribution.

These findings suggest that SMA participates bilaterally in the initiation of movement as represented by the phasic negativities seen immediately prior to and coincident with the EMG burst. Furthermore, they confirm the sensitivity of surface MRPs to subclinical cortical motor dysfunction.

DEFICIT IN UNIMODAL (TACTILE) AND CROSSMODAL DELAYED MATCHING FROM COOLING PREFRONTAL CORTEX. J.M. Fuster, B.V. DiMattia*, K.A. Posley* and W.W. Shindy*. Department of Psychiatry and Brain Research Institute, UCLA School of Medicine, Los Angeles, CA 90024.

The purpose of this research was twofold: (A) to acquire normative data on the ability of monkeys to learn a haptic (tactile) memory task (delayed matching-to-sample); and (B) to examine the effects of reversible cryogenic lesions of dorsolateral prefrontal cortex on performance of the task. A task-trial essentially consisted of the following sequence: (1) palpation or visualization of a stereometric object (the sample); (2) delay (5-60 sec); and (3) presentation of two objects for a haptic or visual choice--rewarded if correct (i.e., if the chosen object matched the sample object). Three monkeys were trained to perform the task with several pairs of objects differing in shape, size, or texture. Learning rate and efficiency varied among animals. One animal did not learn to make haptic choices. The other two learned to perform the task faster and to a higher level in the visual-haptic mode (visual sample, haptic choice) than in the other two modes (haptic-visual and haptic-haptic). In all three animals, learning rate and final level of performance depended on the object pair and the delay. Performance decreased as a function of delay. After training, cooling probes were implanted--under general anesthesia--on dorsolateral prefrontal cortex and posterior parietal cortex in the two animals that learned the task in all three modes (visual-haptic, haptic-visual, and haptic-haptic). Bilateral prefrontal cooling to 15° C induced a reversible performance deficit in all three modes. No significant performance deficit was induced by bilateral parietal cooling (15° C) on haptic-haptic performance. The results indicate a deficit in tactual as well as visual short-term memory from functional depression of dorsolateral prefrontal cortex. This deficit obtains for the three modes of cross-temporal integration performed by the animals in these experiments.

PREFRONTAL AND POSTERIOR PARIETAL UNITS IN CROSS-TEMPORAL VISUO-MOTOR (COLOR-DIRECTION) ASSOCIATION. J. Quintana and J.M. Fuster. Department of Psychiatry and Brain Research Institute, UCLA School of Medicine, Los Angeles, CA 90024.

The extracellular activity of 152 posterior parietal units was recorded and compared with that of 204 dorsolateral prefrontal units in a monkey performing a visuo-motor task. The stimuli and responses were dissociated in space and time. A central color stimulus (1) was followed by a 12-sec delay and by a second stimulus (2)--a pair of color or white lights--prompting a manual response to either the right or the left side, according to the following contingencies:

Stimulus 1	Delay	Stimulus 2	Response direction
Yellow or Green	12 s	White lights	Right
Blue or Red	12 s	White lights	Left
Red or Green	12 s	Red and Green	Matching color (random side)

Units were classified according to their differentiation of stimulus color and/or response direction. Color-coupled units were about equally numerous in both cortices (10.3% in prefrontal; 12.5% in parietal). On the average, the per bin ratio postcue/baseline of the activity of those units in trials with the preferred color decreased during the delay. Direction-coupled units were more common in parietal than prefrontal cortex (27.6% vs 18.1%). Of these, units that showed direction related activity anticipating the correct response position throughout the delay were twice more common in prefrontal cortex (7.8% vs 3.9%). Such units showed, on the average, a gradual increase of delay activity after the cue. The slope of this increase seemed to be a function of the probability of the future response direction associated with each color. Units with direction related activity restricted to the choice period showed larger reactions in parietal than prefrontal cortex. Some units in both cortices showed activity related to the predictability (i.e., certainty or uncertainty) of the response direction. These results suggest that neurons in dorsolateral prefrontal and posterior parietal cortices may be part of distributed cortical networks for visuomotor cognitive processing. Prefrontal units seem especially involved in the preparatory aspects of the impending action and posterior parietal units in the spatial aspects of the action at the time of its occurrence.

THE PREFRONTAL CORTEX AND SENSORIMOTOR BEHAVJOR: EFFECTS OF HORMONAL AND CIRCADIAN CYCLES. A.G.C. Bergqvist, M.C. Kennedy and S.S. Smith, Dept. of Anatomy, Hahnemann Univ., Philadelphia, PA 19102.

Neurons from the rat dorsomedial prefrontal cortex (PFC), the frontal pole and mediodorsal (DM) thalamus were recorded simultaneously using chronically implanted arrays of 5-7 microwires (0.001" dia). Implanted animals were trained to locomote on a computer- controlled treadmill device (alternately on-off, at 10 s intervals) for a period of 1-2 hs daily during neuronal recording. Cross-correlated activity was recorded from the PFC and its DM thalamic afferents in order to define a functional connectivity and establish the CNS site within this network relevant to behavioral and hormonal effects on the system. In addition, in order to investigate possible learning effects related to PFC activity and hormonal states, a randomly generated tone-signalled treadmill onset was implemented in the behavioral paradigms. PFC activity was found to be correlated to a greater degree with locomotion (tread on) compared with non- movement (tread off) when neurons in this area were recorded from rats on diestrus 1 or 2 (D), a period of relatively low estradiol levels, during the light segment of the light:dark cycle. The tread off- correlated discharge was markedly augmented by three- fold on estrus (E), following the cyclic increase in circulating, endogenous estradiol, relative to values obtained on D. In many cases, cells exhibiting tread on-correlated maximal activity were transformed to tread- off-correlated cells. When tested during the dark part of the cycle, tread-off correlated discharge was higher on E when compared with similar values during the light. Furthermore, increasing treadmill speed (from 4 to 11 cm/s) produced greater alterations in neuronal-correlated discharge when tested on D compared to E. Both estrous cycle and circadian effects on neuronal responses to tone-signalled treadmill onset were also observed. Thus, the present results suggest that hormonal as well as light-dark fluctuations produce alterations in the response of PFC neurons to pre-movement conditions. These results are also consistent with the hypothesis that the PFC may play a role in spatial memory through processing of temporal information. In addition, the PFC may be a relevant CNS locus for the reported effects of estradiol on sensorimotor activity and certain visuospatial learning tasks. *Supported by NS 25809 to SSS.*

TOPOGRAPHIC REPRESENTATION OF MEMORY IN THE PREFRONTAL CORTEX OF MONKEYS REVEALED BY LOCAL APPLICATION OF BICUCULLINE. T. Sawaguchi and P.S. Goldman-Rakic. Sec. of Neuroanatomy, Yale Univ. Sch. of Med., New Haven, CT 06510.

To examine the functional organization of the prefrontal cortex for spatial working memory, bicuculline was locally injected into the dorsolateral prefrontal cortex while monkeys performed an oculomotor delayed response task. The monkeys fixated a central spot and made memory-guided saccades to a visuospatial target which had been presented prior to a brief (usually 5 sec) delay period. In each trial the target was presented at one of several (> 22) peripheral locations with different eccentricities and/or directions. The local injection of bicuculline (1-10 ug/ul) induced deficits in the memory-guided saccade to a few specific target locations that varied by the injection site but usually contralateral to it. The deficit was characterized by increases in the variability and discrepancy between target and memory-guided saccades made to it. The deficit was sensitive to the duration of delay, and longer delays were associated with larger deficits. Furthermore, the relationship between the affected location of the target and injection sites showed a topographic manner: more peripheral locations were affected by injections into more lateral regions, and upper locations were affected by injections into more caudal regions of the dorsal prefrontal cortex. No deficits appeared in a control task given in the same session which required only sensory-guided saccades. The results suggest that memory modules for specific visuospatial representations are topographically represented on the prefrontal cortex.

503.11

DELAY- PERIOD ACTIVITY OF PREFRONTAL NEURONS IN DELAYED SACCADE AND ANTI-SACCADE TASKS. S. Funahashi and P.S. Goldman-Rakic, Sect. of Neuroanatomy, Yale Univ. Sch. of Med., New Haven, CT 06510.

The directional delay-period activity of prefrontal neurons is thought to reflect a mnemonic event, holding "on line" information that will guide the correct response at the end of the delay. In the present study we hoped to learn more about the nature of the mnemonic code; specifically, whether it reflects information about the coordinates of the sensory cue or the direction of the impending response. To examine this issue, we compared neuronal activity under two task conditions: a delayed saccade task (DS), in which the correct saccade was always to the same direction signaled by the cue, and a delayed anti-saccade task (DAS), in which the required saccade was to the direction opposite that signaled by the cue.

A total of 44 neurons with directional delay-period activity in the DS task was examined in the DAS task. The majority (n=30) showed the same directional delay-period activity, i.e., responded only when the cue was presented at the same location in both tasks, regardless of the direction of the saccade performed. The specificity for cue direction in these neurons was further illustrated by their pattern of activity on DAS trials in which the monkey failed to inhibit the prepotent response tendency. On these trials, which are identical to correct trials in the DS task, the neuron also discharged in accord with the location of the cue. Ten additional neurons showed delay-period activity which depended on the direction of the forthcoming saccade and the remaining 4 neurons exhibited directional delay-period activity only in the DS task.

The present results with respect to oculomotor responses are in accord with data originally obtained for manual delayed-response tasks by Niki and Watanabe (Brain Res,105:79,'76). Both studies indicate that independent prefrontal neurons code cue and response direction and that each is a distinct component of the circuitry involved in memory-guided responding. We speculate that the smaller proportion of neurons that code saccade direction are closely linked to structures which generate saccades, whereas the larger fraction of neurons that maintain a representation of sensory events could supply directional information to be read out by any of several motor centers. The independence of sensory-coded and response-coded memoranda provides a mechanism for flexible response choice. Supported by MH44866, MH38546.

COMPUTER STUDIES OF THE ROLE OF NMDA RECEPTORS AND POSITIVE FEEDBACK LOOPS IN THE GENERATION OF DESCENDING MOTOR COMMANDS. L. N. Eisenman, J. Keifer and J. C. Houk. Dept. of Physiology, Northwestern Univ. Medical Center, Chicago, IL 60611.

Positive feedback in recurrent loops between the cerebellum, red nucleus and motor cortex is thought to be important in the generation of central motor commands (J.C. Houk *In*, Models of Brain Function, p. 309, 1989). A computer simulation of cerebellorubral elements has been implemented to test this theory. Positive feedback between reciprocally connected neurons was triggered by a transient sensory input and regulated by preset levels of inhibitory input from cerebellar Purkinje cells.

The activation function for a neuron was motivated by physiological data derived from the *in vitro* turtle preparation, which suggests that motor commands in the red nucleus are produced by recurrent excitation from the cerebellorubral circuit mediated by combined NMDA and non-NMDA dependent synaptic transmission. The voltage dependency of the NMDA-associated channels was modeled as a threshold-like discontinuity in the activation function assumed for the model neurons. When a pair of cells with these properties were reciprocally connected, two stable regions resulted. There was an off state and an on state that had a wide range of stable operating points. The intensity of activity in the on state could be modulated by inhibitory input representing the effect of Purkinje cells. In contrast, when activation functions without discontinuities were used, the on state of the network was much less controllable.

Twelve reciprocally connected two-cell pairs were interconnected to model divergence in linkages between the motor cortex and the interpositus nucleus of the cerebellum. Each of the 12 elements is considered to have a preferred direction sensitivity. With this network several observations of Georgopoulos and colleagues regarding population vectors in motor cortex were reproduced. The values of the inhibitory input determined the final state of the network which reproduced activity patterns that resembled population vectors. It was further possible to simulate rotations of population vectors similar to those which have been related to mental rotation of images (Georgopoulos et al., Science 243: 234, 1989).

503.13

NETWORK MODEL OF THE CEREBELLUM AND MOTOR CORTEX THAT LEARNS TO CONTROL PLANAR LIMB MOVEMENTS. A.G. Barto, N.E. Berthier, S.P. Singh* and J.C. Houk, Dept. of Computer and Information Sciences, Univ. of Mass., Amherst, MA 01003. Recently we proposed a new model that treats the cerebellum as an array of modules that function as adjustable pattern generators (Houk et al, *Neural Networks for Control*, Miller, Sutton & Werbos, 1990). Here we report on the capabilities of small arrays of these modules for learning to control two-dimensional movements. The present modules are inspired by interconnections between the cerebellum and the motor cortex and the goal was to control a set of planar limb movements in a task analogous to the one used by Georgopoulos and coworkers to study populations of motor cortical neurons. The synapses between parallel fibers and Purkinje cells (PCs) were adjusted using training signals transmitted by climbing fiber inputs and a training rule inspired by the biochemistry of intracellular messengers regulating LTD at parallel fiber synapses. Climbing fibers were assumed to fire during corrective movements with a probability that was broadly tuned to the direction of the correction. Retrieval of a motor program from memory was controlled by a preselection process that turned PCs off and on in a bistable manner. The motor program was then initiated by a trigger signal and continued until the summed proprioceptive and target inputs caused PC transitions to their on-states, whereupon strong inhibition terminated the program. The movement trajectories were qualitatively similar to those observed experimentally. (Supported by ONR N00014-88-K-0339.)

Computer Animation of Electrophysiological Responses. SA Reid, RA Palovcik, JC Principe and A Albuquerque Jr. Univ. of Florida, Depts. of Neurosurgery and Electrical Engineering and V A Medical Center. Gainesville, FL.

New methods for displaying data from multiple channel recordings plot a dependent variable on a third axis over spatial extent of tissue. The resulting computer-generated surfaces are animated over time to reveal simultaneous patterns of correlated activity over the entire slice.

This method was implemented for displaying evoked potential data recorded from multiple sites in rat hippocampus and human cortex. The animation revealed important dynamic differences between the propagation of evoked activity in hippocampal vs. cortical slices despite the fact that many individual traces from each appeared similar. Our animations instantly communicate complex spatial patterns in data. This allows intuitive comprehension of the dynamics of brain slice neuronal circuitry at a level impossible to achieve with traditional voltage-time plots. The results of our animation provide a new conceptual framework for analyzing multisite evoked and spontaneous activity.

503.15

TEMPORAL PATTERNS IN A CAM. H. Stowell. ERBP Lab., 120 Nature Creek, Milledgeville GA 31061 USA.

How does a Content Addressable Memory (CAM) store and recall the timing of sensory stimuli? Continuing EEG data from humans [1] imply that quasi-limit-cyclic activity in the 'theta-alpha' range (5-15 Hz) is critical to working memory of timing. Five naive subjects, trained to minimize extracranial artifacts, show phase constraints and phase ordering at above-chance level in scalp-conducted, vertex-to-earlobes EEG when attending to novel sequences of auditory transients; this phase ordering appears in both stimulated and silent trials, for small averages and single epochs ($1 \leq N \leq 10$) when subjects have a knowable and self-paced time-frame, but only at chance level within an unknowable time-frame. Momentary drowsing, with failure to recall a wakefully suprathreshold and always detectable acoustic pattern, shows abrupt EEG center-frequency slowing from ~ 10 to ~ 5 Hz before the stimulus time-window and a much larger and later 'vertex evoked potential'. The wakeful effects tend to disappear with subjective familiarity over weekly sessions of 1½-2½ hrs.

A MICROELECTRONIC DEVICE FOR MULTICHANNEL STIMULATION OF AND RECORDING FROM NEURONS. E.G. Bylander*[1], R.D. Entreken*[1], H. Moradi*[2], W.M. Gosney*[2], and D.J. Woodward[3]. Bylander Associates[1], Southern Methodist Univ.[2], UT-Southwestern Med. Ctr.[3], Dallas, TX 75235.

An IC chip has been designed and fabricated by MOSIS for alternatively recording from or stimulating each of 16 electrodes placed in the CNS. The chip is based on previous work "VLSI-Circuit Control of Recording and Stimulation in Cultured Neuronal Network Study" by P.V. Vithalani, N.A. Buzaid, R. Balasekaran, W.M. Gosney, L.L. Howard and G.W. Gross (submitted IEEE Transections on Neural Networks). A write-only memory register is included on the chip to select one or more of 16 sensor wires for stimulation, or all inputs can be employed as high impedance sensors. As presently configured, the chip is mounted in a 1 inch square by 1 mm thick leadless chip carrier (LCC) which in turn is wired to a small LCC socket. It is then wired to five 12-pin, 2 mm thick Microtech connectors which allow the unit to be mounted directly to a female Microtech headstage. A testing program has demonstrated successful recording from typical neurons detected by multiple 25 micron microwires implanted in neostriatum of awake behaving rats. The stimulation circuitry also has been successfully tested. The practical dynamic range of biphasic stimuli is +1.2V to -3.8V but may be extended. These results are in use for the design and development of the next generation chip which will include 32 I/O channels, but with reduced I/O lines by means of multiplexing and serial control. Target installations will include embedding of the chip in configurations employing multichannel silicon probes with microcable interconnections. The latter are under development with Dr. S. Ang at U. Arkansas. *Supported by the Communities Foundation of Dallas, MH44337, AFOSR 90-0146, DA02338, and the Biological Humanics Foundation.*

DYNAMIC CONVERGENCE IN NEURAL ASSEMBLIES. P.H. Bedenbaugh[1], G.L. Gerstein[1], A.M.H.J. Aertsen[2]*, [1] *Departments of Physiology and Bioengineering, University of Pennsylvania, Philadelphia,* [2] *MPI for Biological Cybernetics, Tübingen, FRG*

When interpreting the simultaneously recorded activity of several neurons one must remember that the neurons are embedded in a large, densely interconnected network. The firing of the observed neurons is partly determined by the activity of the many unobserved neurons. For any two observed neurons, the presynaptic network can be subdivided into a shared pool that projects to both cells and pools that project only to one cell. Let us call the influence that a presynaptic pool, shared or unshared, exerts on an observed target neuron the 'dynamic convergence'. In contrast to the static, anatomical notion of a converging projection, dynamic convergence is a physiologic measure that reflects rapid shifts in the active and inactive parts of neural structures. Recent theoretical work has shown that the properties of this dynamic convergence, both its magnitude and its internal correlation structure, dramatically effect the strength of correlation between the activities of the observed postsynaptic neurons.

It is infeasible to directly measure the activities and relative influences of the various presynaptic pools. We can learn something about the unobserved presynaptic pools, and hence the dynamic convergence by studying the joint statistics of the observed spike trains. We are investigating a dynamic generalization of the coherence function. The coherence function is the the cross spectrum of two processes, normalized by the product of the square roots of their individual autospectra. Coherence is widely used in geophysics and EEG-analysis to discern the extent to which two spatially distinct observations are driven by the same underlying process. For linear systems, coherence varies between zero and one and provides a static measure of shared input.

This type of quantitative measure is relevant for evaluating contrasting ideas of neuronal assembly organization. Each neuron in a Hebbian assembly participates in several loosely coupled networks. Input activity imposes a particular organization by igniting one such network. Other models are built on tightly coupled and essentially disjoint groups of neurons whose organization would appear invariant with stimulus conditions. Dynamic convergence would be highly stimulus related in the first case, and not so in the second.

INVERTEBRATE MOTOR FUNCTION

504.1

THE ROLE OF THE BRAIN IN LOCOMOTORY BEHAVIOR OF A PARASITIC FLATWORM. M.V.K. SUKHDEO. Dept. of Animal Sciences, Rutgers University, New Brunswick, NJ 08903.

The flatworms (phylum Platyhelminthes) are the first phylogenetic group to evolve "true brains" and thus, are appropriate models for the study of the original functions of the brain. *Hymenolepis diminuta*, a parasitic flatworm, is capable of coordinated locomotory activity that is not affected by the removal of its brain. This parasite uses a complex adaptive behavior, consisting of retrograde peristaltic-like waveforms (PL), to maintain its position in the small intestine. In addition, it also uses this behavior to migrate anteriorly in the intestine (in response to cues elaborated during host feeding) to position its strobila in the regions of highest nutrient concentrations. PL frequency varies along the strobila in a coordinated manner, occurring at a rate of 25.3 ± 1.1 Hz in the cephalic region and decreasing linearly to a rate of 5.8 ± 1.3 Hz in the caudal regions. The form and frequency of this complex behavior along the strobila is not significantly altered by decerebration. In addition, when placed on a thermal gradient (20-32°C), intact worms use PL waves to migrate uphill to a preferred temperature of ~30°C (thermo-orthokinesis). Decerebrate worms also move similarly up the gradient, but there are some qualitative differences in the behavior. Although worm survival in the host requires the brain, it is concluded that the elaboration of PL waves and the coordination of these movements along the body is under the control of the peripheral system.

504.2

TEMPERATURE DEPENDENCY OF WING-BEAT FREQUENCY IN INTACT AND DEAFFERENTED LOCUSTS. J.A. Foster and R.M. Robertson. Department of Biology, Queen's University, Kingston, Ontario, K7L 3N6, Canada.

Locusts do not regulate thoracic temperature during flight. As a result the thoracic temperature of a flying locust can exceed ambient by as much as 8-10°C. Elevated thoracic temperatures have been shown to affect wing-beat frequency in intact *Locusta migratoria*. This study investigated the temperature dependency of wing-beat frequency in intact and deafferented *Locusta*.

Intact tethered locusts were flown in a wind tunnel at different ambient temperatures for up to 3 hours while wing-beat frequency and thoracic temperature were monitored. EMG recordings were made in a deafferented locust perfused with different temperature salines. Wing-beat frequency was shown to vary with thoracic temperature in both the intact and the deafferented situation. The slope of the rise in wing-beat frequency with experimental increases in thoracic temperature was similar in intact and deafferented animals.

Thus these experiments demonstrate that a central effect of temperature on wing-beat frequency exists. Further intracellular experiments are necessary to investigate the neural basis of these temperature effects.

504.3

EFFECTS OF TEMPERATURE ON PROPERTIES AND INTERACTIONS OF FLIGHT NEURONS IN THE LOCUST. R.M. Robertson and J.A. Foster. Department of Biology, Queen's University, Kingston, Ontario, K7L 3N6, Canada.

An increase in the thoracic temperature of intact Locusta migratoria tethered flight results in an increase in wingbeat frequency. Similarly, increasing the temperature of the thoracic ganglia in a deafferented preparation results in an increase in the frequency of the centrally generated flight rhythm.

We investigated the neural basis for these changes using a deafferented preparation of Locusta migratoria. Intracellular recordings were made from the neuropile segments of identified flight neurons using standard techniques. The temperature of the ganglia was altered by superfusing them with warmed saline (25-40°C).

To date we have found the following effects which are consistent with previous studies of temperature effects in insect ganglia. The duration and amplitude of action potentials were decreased. The latency of direct synaptic connections was approximately halved by a 10°C rise in temperature. In contrast with previous reports of an increase in the amplitude of excitatory post synaptic potentials (psps) we found that the amplitude of inhibitory psps was decreased. Preliminary evidence indicates that this reduction may be due to membrane hyperpolarization brought on by increased temperature.

504.4

PLASTICITY IN THE FLIGHT SYSTEM OF THE LOCUST. A.Büschges and K.G.Pearson, Dept. of Physiology, University of Alberta, Edmonton, Canada.

The initial depolarization in elevator motoneurons in intact flying locusts is induced by the phasic activity of the hindwing tegulae during the downstroke of the wings. Previous studies have shown that removal of the tegulae results in a decrease in the rate of depolarization in elevators, an increase in the interval between the onset of depressor and elevator activity (the D-E interval), and a reduction in the wing beat frequency. We have now quantified these effects and found that they are not permanent. The average wing beat frequency (WBF) of the intact flying locusts was about 20 Hz and the average D-E intervals were about 20 ms for the forewing and 25 ms for the hindwing. Removal of the wing tegulae induced a drop in WBF to 73% of the initial value and caused an increase of the D-E intervals (average increase D-E interval forewing: 12 ms; average increase D-E interval hindwing: 17 ms). The initial fast and rapid depolarization in the elevator motoneurons disappeared. Over a period of about 2 weeks following the removal to the tegulae there was a progressive increase in the WBF (to about 90% of its intact value) and a progressive reduction in the D-E intervals. 14 days after the removal of the tegulae the &average D-E interval for the forewing was about 20 ms and the average D-E interval for the hindwing was about 28 ms. Intracellular recordings from the elevator motoneurons in recovered animals during flight showed that the initial depolarization was comparable to that occurring in normal intact animals. The neural mechanisms underlying the recovery of the flight pattern following tegula removal are now being investigated. Preliminary data have indicated that there are changes in the characteristics of the central rhythm generating network as well as alterations in the influence from other wing proprioceptors in establishing the motor pattern.

NEURONES WITH BILATERAL AXONS IN THE LOCUST CENTRAL NERVOUS SYSTEM. H.-J.Pflüger[1], P.Stevenson[1], M.Ferber[1] and M.Eckert[2]. Freie Universität Berlin, Institut für Neurobiologie, Königin-Luise Str. 28-30,D-1000 Berlin 33,FRG[1]) and Univ. Jena,WB Tierphysiologie, Erbertstr.1, DDR-6900 Jena, GDR[2]).

In the thoracic and abdominal ganglia of the locust central nervous system several populations of midline cells with bilateral axons exist, that release neuromodulatory substances. In the abdominal ganglia some of the cells could be identified with respect to their target organs and transmitters. Among the cells with bilaterally symmetrical axons are two "classical" DUM-(dorsal unpaired median) cells that innervate all skeletal muscles of the abdomen and stain with an Octopamine antibody (M.Eckert,Jena). Two other cells with bilateral symmetrical axons, also resembling DUM-cells, run exclusively to the insect heart. One of the two cells stains with an FMRFamide-like antibody. Neurones with bilaterally asymmetrical axons exclusively run to the heart and do not stain with either an Octopamine or FMRFamide-like antibody.

MEMBRANE PROPERTIES OF LOCUST NONSPIKING LOCAL INTERNEURONES. G. Laurent. California Institute of Technology, Biology Division, 156-29, Pasadena CA 91125.

The electrotonic and active membrane properties of nonspiking local interneurones were studied, using the switched current- and voltage-clamp techniques in neuropilar recordings. The average transmembrane potential (V_r) of the interneurones was 58±6mV (n=85) and the input resistance (in the linear region of the I-V curve) was 16.5±8MΩ (n=19, range 8 to 32MΩ). The charging curves evoked by low density hyperpolarizing current pulse injection yielded 2 time constants (τ_m and τ_l) whose average values were 33.2±9ms and 3.3±1ms (n=18) respectively. The mean specific membrane resistance of the nonspiking interneurones is thus about 33kΩ.cm^2. An outward rectification was consistently observed upon depolarization. This rectification was generally activated from potentials more negative than V_r, and was accompanied by a decrease in input resistance and membrane time constant. The resting membrane, for example had a time constant of 26.4±8ms (n=31). This outward rectification was due to at least 2 conductances with different inactivation kinetics, similar to the A- and delayed rectifier conductances. No inward rectification was observed upon injection of hyperpolarising current. In about 60% of the recordings, an active and TTX-resistant depolarizing process could be evoked by rapid depolarization around V_r. The voltage-dependent properties of the membrane of the nonspiking interneurones had dramatic effects on the time course of natural or evoked unitary PSPs. The half width of EPSPs, for example, decreased by a factor of 7.5 if the membrane potential was shifted from -90 to -50mV. *Supported by The Royal Society, SERC (UK), and the Hasselblad Foundation.*

DISTRIBUTION OF SYNAPTIC INPUT OF WING STRETCH RECEPTORS IN DENDRITES OF LOCUST FLIGHT MOTONEURONS. H. Schneider, Universitaet Konstanz, Biologie, 7750 Konstanz, FRG.

To study the integrative properties of identified motoneurons (MNs) synaptic input was compared in various cellular stuctures using double intracellular recordings. Overlap of the arborizations of the pre- and postsynaptic neurons was demonstrated by differential intracellular staining (DIS) with Lucifer Yellow and Texas Red.

The morphology of the 2 subalar MNs (SAMNs, wing depressor) in the mesothorax of the locust Locusta migratoria is characterized by 6 primary dendrites (PD) which originate laterally and medially from a neuropilar segment (NPS). In both SAMNs, EPSPs are directly elicited by activity of forewing (msSR) and hindwing stretch receptors (mtSR). These EPSPs were recorded with no latency shift and with similar time course in the PDs and the NPS. Amplitude and time to peak indicate that msSR-EPSPs originate in all recorded PDs; mtSR-EPSPs, however, appear to originate mainly in the medial PDs and spread electrotonically into the lateral PDs. DIS of SRs and SAMNs support these interpretations. The msSR overlap with all recorded PDs; the mtSR, however, mainly with the medial PDs.

These results suggest that a functional differentiation of PDs of SAMNs with regard to synaptic input from SRs does not exist due to the anatomical organization of direct physiological connections and the electrotonic spread of EPSPs. Supported by DFG (Ku 240/14-1,2).

IN FLIES, MOTOR NEURONS SUPPLYING INDIRECT (POWER) AND DIRECT (STEERING) FLIGHT MUSCLES OCCUPY DISCRETE NEUROPILS SUPPLIED BY CHARACTERISTIC MOTION-SENSITIVE DESCENDING NEURONS. Nicholas J. Strausfeld and Carol Arakaki*. Arizona Research Labs, Division of Neurobiology, Univ. of Arizona, Tucson AZ 85721

Specific flight muscles [nomenclature: Wisser A, Nachtigall W (1983) Zoomorphology 104:188-195] have been impaled with cobalt-filled electrodes to retrogradely fill motor neurons supplying them. Silver-intensified neurons were reconstructed, and related to specific depths and regions within thoracic ganglia. Two sets of fibrillar muscles (DLMs and DVMs) and one set of non-fibrillar muscles [hg1, 2, pro- and supinators. Functions: Wisser and Nachtigall (1983); Heide G (1968) Z Vergl Physiol 59:456-460] are supplied by superficial pterothoracic motor neurons whose bilaterallay symmetrical dendrites are visited by bilateral terminals of descending neurons (DNs) responding to symmetrical front-to-back visual flowfield motion [see Gronenberg and Strausfeld (1990) Neurosci Abstr 16]. At deeper levels in the meso- or metathoracic ganglia, large unilateral, or bilaterally asymmetric motor neurons supply antagonistic basalar muscles involved in steering. These neurons are visited by terminals of DNs that respond to asymmetrical shifts of the visual panorama, or to small-field motion. Laterally and ventrally, unilateral motor neurons [examples: I_1, III_2, Tp) include those involved in tension and wing-vault control. Certain steering motor neurons (B1-3, III_1) show cobalt-coupling to specific functionally identified DNs and to primary sensory afferents from the wings and halteres, thus providing evidence for the convergent role of synergistic mechanosensory and visual inputs in flight maneuvers. **Supported by NIH Grant No. R01 EYO 7151-01 and NSF Biological Centers Grant DIR 82-20082**

504.9

IN FLIES, FLIGHT VELOCITY AND STEERING MANOEUVRES RELATE TO TWO DIFFERENT SETS OF DESCENDING NEURONS.
Wulfila Gronenberg and Nicholas J. Strausfeld. Arizona Research Labs, Division of Neurobiology, Univ. of Arizona, Tucson AZ 85721

Neuroanatomical studies of Diptera show that descending neurons (DNs) originating from dorsal brain neuropil connect to the flight motor neuropil in the thoracic ganglia. A variety of staining techniques reveal that these dorsal DN are postsynaptic to 1) "giant" motion sensitive lobula plate tangential (VS and HS cells); 2) "small" lobula plate tangentials; 3) retinotopic neurons; 4) mechanosensory afferents. The DN dendrites are organized in 4 groups (dorsal DN clusters) each of which receives input from a different set of lobula plate interneurons. The terminals of certain dorsal DNs arborize bilaterally in the dorsalmost meso- and metathoracic neuropil which contains bilateral motor neurons of the indirect flight power muscles providing thrust. Most dorsal DNs terminate unilaterally in dorsolateral neuropil of all three thoracic neuromeres. These contain motor neuron dendrites of the neck muscles and of the direct flight steering muscles. Intracellular recordings reveal that DNs with bilateral terminals respond best to symmetric visual flowfields such as encountered during straight flight. DNs that terminate in the neck- and flight steering motor neuropil prefer directional stimuli such as downward or horizontal motion or non-symmetric visual flowfields. The same stimuli trigger muscle activity in steering muscles, as recorded electromyographically, and induce behavioral optomotor responses (pitch, yaw, and roll). We conclude that DNs extract specific features from the common pool of input information and process this information with respect to its relevance to the control of a particular flight manoeuvre. **Supported by NIH Grant No. R01 EYO 7151-01**

PROJECTION NEURONS FROM THE THIRD OPTIC NEUROPIL OF FLIES SEGREGATE ONTO DISCRETE CLUSTERS OF RELAY NEURONS DESCENDING TO THE THORACIC MOTOR NEUROPIL
Cole Gilbert and Nicholas J. Strausfeld. Center for Insect Science and ARL-Div. Neurobiology, Univ. Arizona, Tucson, AZ, 85721.

In Diptera the third optic neuropil is divided into a ventral lobula and a dorsal lobula plate. Neuroanatomical studies using Golgi impregnation or cobalt backfilling show that uniquely identifiable neurons or assemblies of neurons from the two regions project to the lateral deutocerebrum to separate target areas which are associated with discrete clusters of descending neurons (DNs). These integrate afferent visual, as well as olfactory and mechanosensory, information and project to thoracic motor neuropil. Intracellular recording and lucifer yellow dye injection has been used to characterize physiologically and identify anatomically visual neurons projecting to DN clusters. The dorsal clusters receive input from small- and wide-field neurons arising in the ipsilateral lobula plate. Most, but not all, afferents are maximally excited by specific directions of moving stimuli. The ventral clusters receive input from wide- and small-field neurons arising in the ipsilateral lobula, and in males but not females, from a sex-specific neuron projecting from the contralateral lobula. These afferents are also of several physiological classes, with some being directionally-selective, but many being more sensitive to light ON and OFF than to motion. The physiologically determined receptive fields of afferents from the lobula or lobula plate are approximately congruent with the dendritic spreads in the retinotopic projection of visual space into the neuropil. The differences in response properties of afferents apparently relate to the destination of specific DNs to their thoracic target areas. **Supported by a Center for Insect Science Postdoctoral Traineeship to CG (NSF DIR 82-20082) and an NIH Grant R01 EY07151 to NJS**

MUTATIONS AFFECTING K AND Na CURRENTS IN *DROSOPHILA* ALTER PHYSIOLOGICAL PROPERTIES AND PRODUCE ABNORMAL SPONTANEOUS ACTIVITY IN THE GIANT FIBER PATHWAY.
J. E. Engel and C.-F. Wu. Dept. of Biology, University of Iowa, Iowa City, IA 52242.

The neural circuitry controlling the escape reflex in flies has been well characterized. We examined the physiological and behavioral effects of perturbing this pathway with the mutations *Shaker* (*Sh*), *Hyperkinetic* (*Hk*), and *ether-á-go-go* (*eag*), which reduce K currents, and *no action potential* (*nap*), which reduces Na current. By recording from the dorsal longitudinal (DLM) flight muscles and the tergotrochanteral (TTM) leg extensor muscle, we monitored spike activity underlying a jump-and-flight escape response to electric stimulation mediated by the giant fiber pathway.

The mutants *Sh*, *Hk*, *eag Sh*, and *Hk eag*, which affect K currents, have a longer refractory period for both DLM and TTM response, with latency unchanged. In contrast, *nap* flies show lengthened latency and refractory period, but only in the TTM . Apparently the TTM pathway is preferentially affected because of differential expression of the *nap* gene or a higher sensitivity due to a lower safety margin in a component of the pathway.

Double mutant *eag Sh* flies show abnormal spontaneous rhythmic spiking in DLM muscles. This is not associated with wing beating, nor does it respond to tactile stimuli that turn flight on and off. The non-flight spikes are not seen in *eag* or *Sh* alone and are suppressed by *nap* in *eag Sh; nap* triple mutants. Simultaneous recordings from pairs of DLM muscle fibers innervated by the same or separate giant fibers indicate that the spontaneous activity is neurogenic and may involve the flight pattern generator or an interneuron mediating the giant fiber response. In *Hk eag*, rhythmic spiking is seen in the TTM in addition to the DLM, implicating the giant fiber , which innervates both muscles.

CHANGES IN PROPRIOCEPTIVE CIRCUITS DURING INSECT METAMORPHOSIS.
D.A.Tamarkin and R.B.Levine. ARL Div. Neurobiology, Univ. Arizona, Tucson, AZ 85721.

During insect metamorphosis there are dramatic changes in behavior that require alterations in neural circuits. Toward understanding this reorganization, we have characterized the interactions between the bilaterally-paired abdominal stretch receptors (SRs) and identified motoneurons (MNs) in the larval and adult stages of Manduca. The SR was left attached to the isolated nervous system, and stimulated electrically. MNs were monitored intracellularly and identified by lucifer-yellow injection. Our initial studies have focused on the intersegmental muscle (ISM) MNs which persist through adult emergence and show relatively little dendritic alteration.

In both the larva and pharate adult, ISM MNs with **bilateral** dendrites receive excitatory input from ipsi. and contra. SRs in the same segment as the target muscle. Signal averaging and treatment with high-divalent saline suggest that these connections have a direct component. ISM MNs with **unilateral** dendrites receive direct excitatory input from only the ipsi. SRs in both stages. The input to these unilateral MNs from the contra. SR is polysynaptic in both stages, but is inhibitory in the larva and changes to excitatory during adult development. Similar, but weaker and more variable, connections were observed for MNs innervating the next posterior segment. All of these connections are consistent with opportunities for the SR terminals and the MN dendrites to overlap at the light level. Interneurons which receive direct input from the SR have been identified. These may be involved in the polysynaptic connections described.

Thus, significant changes in the proprioceptive information supplied to the ISM MNs occur during metamorphosis. These changes may be related to the changes in abdominal posture and movements seen during this period.

MODELLING THE CONTROL OF INSECT SKELETAL MUSCLE.
Jim H. Belanger. Dept. of Zoology, Univ. of Toronto, Toronto, Canada M5S 1A1.

Vertebrates and invertebrates use fundamentally different strategies for muscular control. Vertebrates use many motor units, with very little modulation of individual units, while invertebrates use very few units (often only one or two) combined with extensive peripheral modulation. This renders much of the existing modelling work on vertebrate muscle inappropriate for application to insects. I have attempted to develop a relatively low-level model which takes into account the extensive modulatory input to insect skeletal muscle.

The model is a numerical simulation written in C and run on an IRIS workstation. The essence of the model is the production of graded contraction via the progressive recruitment of radially-arrayed Ca^{++} release sites. Potential changes at the surface of the model fibre passively propagate inward along the invaginated tubules, triggering localized release of Ca^{++} whenever the excitation-contraction threshold is reached. Several sites within the model are suitable loci for modulation. The most powerful effect is produced by lowering the excitation-contraction coupling threshold, which can produce contraction in the absence of depolarization (as is seen, for instance in the action of the peptide cotransmitter proctolin in many systems (Orchard, Belanger and Lange, *J. Neurobiol. 20*, 1989)). Other available modulatory mechanisms are ligand-gated calcium channels in the sarcoplasmic reticulum (SR), which are in parallel with the voltage-gated channels, and the Ca^{++}-uptake system of the SR.

By varying the nature of the synaptic input, this model allows an examination of the nonlinear interactions between the conventional (excitatory and inhibitory) transmitters and the unconventional cotransmitters. In addition, it allows quantitative examination of the hypothesis that cotransmitters are used for energy efficiency in motor control.

GABAERGIC PRESYNAPTIC INHIBITION AS MODULATOR OF MONOSYNAPTIC REFLEX IN CRUSTACEA.
A. EL MANIRA*, D. CATTAERT* & F. CLARAC. CNRS LNF2, 31 Chemin Joseph Aiguier BP 71, 13402 MARSEILLE CEDEX 9 FRANCE.

In the thoracic crayfish *in vitro* preparation, it is possible to record intracellularly sensory terminals from a complex leg proprioceptor (the chordotonal CB) and motoneurons (MNs) controlling the joint where this receptor is inserted. Mechanical as electrical stimulation applied on the CB receptor induces monosynaptic resistance reflex in MNs. By recording from CB terminals, we have demonstrated the presence of primary afferent depolarizations (PADs). In tonic preparation PADs occur continuously, by contrast during fictive locomotion they occur at fixed time in the locomotor cycle. Spontaneous PADs were supressed by bath application of GABA antagonists (Picrotoxin and Bicuculline). This result suggests that GABA receptors exist in the presynaptic CB terminals. This hypothesis was verified since small quantities of GABA or Muscimol applied near the recording site over the ganglion elicit a transient depolarisation of the impaled sensory terminal; they were coincident with a reduction of input resistance. The inhibitory role of GABA on the monosynaptic reflex has been confirmed since all MNs showed a marked and reversible reduction in compound EPSP amplitude when the CB nerve was stimulated during GABA application.

COMPONENTS OF REFLEX STIFFNESS IN HERMIT CRAB ABDOMINAL MUSCLE. W. D. Chapple. Dept. of Physiology and Neurobiology, University of Connecticut, Storrs, CT 06269.

Control of shell position in the hermit crab is mediated in part by a stretch reflex in the abdominal ventral superficial muscles (VSM). By stretching the muscle with band-pass limited (25 Hz) Gaussian noise and sampling muscle force and membrane potential, the input-output properties of the reflex can be determined by parametric identification techniques. After a transient increase in stiffness and 4th segment motoneuron frequency at stimulus onset, mechanical impedance decays to a steady-state level after 10 seconds and can be approximated by a third order model. Cutting the abdominal connectives at different segments produce changes in the impedance that suggest that there is a low frequency component (0.1 Hz) possibly due to interneuron activation and a higher frequency component (1.0 Hz) that may be due to a direct sensory pathway. The changes at low frequencies are consistent with an involvement of both excitatory and inhibitory pathways in controlling impedance.

SEROTONIN (5-HT) POTENTIATES CONTRACTION OF DISSOCIATED FIBERS OF APLYSIA BUCCAL MUSCLE. F. Zhang and J.L. Ram, Dept. of Physiology, Wayne State Univ., Detroit, MI 48201

Buccal muscles of *Aplysia* are innervated by cholinergic and serotonergic neurons. Serotonergic input underlies, in part, increased contractility during feeding arousal. With isolated muscles, acetylcholine (ACh) causes contraction, whereas 5-HT potentiates contraction. To study cellular mechanisms underlying these responses, muscle fibers were dissociated with collagenase (2-4 hr at 30 °C). Fibers average 270 ± 10 μm in length (n=37) and 10.8 ± .7 μm in diameter (n=19; max. diameter averages 13.6 ± .9 μm). High K (100 mM superfusion for 2 s) causes contraction, e.g. shortening a typical field of 10 fibers from 311 ± 20 μm to 262 ± 17 μm ($p<.05$, paired t). 1 μM nifedipine blocks High K contraction. 5-HT (10^{-6} M, 1 min) potentiates contraction (resting length, 285 ± 35 μm; 3 s high K, 190 ± 30 μm; 3 s high K after 5-HT, 140 ± 20 μm; n=5, $p<.05$, paired t). ACh also elicits contractions which are potentiated by 5-HT: resting length, 264 ± 20 μm; 3 s ACh, 194 ± 15 μm; 3 s ACh after 5-HT, 156 ± 13 μm; n=6, $p<.05$, paired t. Contraction is also elicited by depolarization via patch electrode. Whole cell currents elicited by depolarization and agonists are described in another abstract. Experiments are in progress to determine whether contractions elicited by patch electrode can be potentiated by 5-HT. Supported by MDA and NIH RR 08167.

504.17

INDIVIDUAL BUCCAL MOTONEURONS OF *APLYSIA CALIFORNICA* INNERVATE MULTIPLE BUCCAL MUSCLES AND DISPLAY UNIQUE NEUROMUSCULAR SYNAPTIC PLASTICITIES. K. P. Cohen* and M. D. Kirk. Div. Biol. Sci., Univ. Missouri-Columbia, Columbia, MO 65211.

Several buccal motoneurons of *Aplysia californica* and their target muscles of the buccal mass have been previously identified. For instance, B15 and B16 were shown (Cohen et al., 1978) to innervate the Accessory Radular Closer (ARC) Muscle also known as muscle I5 (Howells, 1942). However, using a semi-intact preparation consisting of the buccal ganglia attached to the buccal mass (muscles I1-I6 exposed) via nerves n4 and n5, we have shown that several of these large ventral cluster motoneurons innervate more than one nonhomologous buccal muscle. In addition to innervating I5, B15 innervates I4 and B16 innervates I1/I3, I4 and I6. Furthermore, B6 and B9 innervate I1/I3, I4 and I6, B11 innervates I1/I3, I4, I5 and I6 while B10 innervates only the bilaterally homologous I1/I3 muscles. At 10 Hz stimulation to individual motoneurons, neuromuscular synaptic potentials exhibited facilitation and depression with amplitudes and time courses unique to particular motoneurons. From these results it is clear that to understand the behavioral significance of firing in particular motoneurons, the co-activation of nonhomologous as well as bilaterally homologous buccal muscles by individual motoneurons must be considered. Supported by NIH grant NS24662.

504.18

IDENTIFICATION AND CHARACTERIZATION OF BUCCAL MOTONEURONS EXPRESSING FMRFAMIDE-LIKE IMMUNOREACTIVITY IN *APLYSIA CALIFORNICA*. T. L. Ross and M. D. Kirk. Div. Biol. Sci., Univ. Missouri-Columbia, Columbia, MO 65211.

In *Aplysia californica* the peptide FMRFa is synthetized by several buccal neurons (Lloyd et al., 1987) and has physiological actions in the feeding system. However, the identities and targets of neurons synthesizing FMRFa are unknown. We are using intracellular lucifer yellow injections combined with immunocytochemistry to uniquely identify buccal motoneurons expressing FMRFa-like immunoreactivity (FMRFa-LI).

Large ventral cluster cells of the buccal ganglia from 150 to 300 gram animals were identified based on cell body size and position, axonal projections, and muscle innervation. Following ionophoretic injection of these cells with lucifer yellow, the ganglia were prepared as either 10 micron paraffin sections or whole mounts. Preliminary double-label experiments show that the motoneuron B3 expresses FMRFa-LI and projects to the ipsilateral buccal muscle I1/I3. Future experiments will identify the remaining motoneurons expressing FMRFa-LI and test the properties of their neuromuscular synapses. Supported by NIH grant NS24662.

NEURONAL CONTROL OF COORDINATED LIP MOVEMENTS DURING FEEDING IN *APLYSIA*. S. C. Rosen, E. L. Halvorsen*, E. C. Cropper, M. W. Miller, K. R. Weiss, and I. Kupfermann. Cntr. Neurobiol. & Behav., Columbia Univ. & NYS Psychiatric Inst., New York , NY 10032.

Ingestive behaviors involve coordinated head, lip, and buccal mass movements. Buccal movements are controlled by motor neurons and a central pattern generator (CPG) in the buccal ganglion. In order to study the integration of lip and head movements, we identified lip motor neurons (C11 and C12) that have somata in the cerebral ganglion M clusters and axons in the ipsilateral lower lip (LLAB) nerves. The cells receive direct synaptic inputs from C2 and C3, histaminergic mechanoafferents with receptive fields adjacent to the lips, and B19, a buccal to cerebral interneuron (BCI). C12, but not C11, showed remarkably diverse immunocytochemical staining for neuropeptides found in various buccal motor neurons including, SCPb, buccalin, and myomodulin. The firing of C11 produced circumferential contraction of the inner lips. Firing C12 produced radial contraction that extended to the neck. LLAB lesions produced deficits in inner lip movements during feeding by free-moving animals, whereas upper lip nerve lesions did not. Chronic nerve recordings showed that C11 fired during lip closure, prior to radula protraction, and C12 fired during lip opening and radula retraction. When feeding programs were driven by stimulating cerebral command element CBI-2, C11 and C12 fired antiphasically at rates sufficient to elicit feeding movements. The buccal programs incorporated activity of cerebral motor neurons for extrinsic buccal muscles, but had no effect on cerebral B cluster lip motor neurons. When synaptic transmission in the buccal ganglion was blocked by divalent cations, or when the cerebral-buccal connectives were cut, CBI-2 no longer phasically activated C11 or C12, although it produced weak tonic activation of C11. The findings suggest that coordinated lip movements for feeding are produced by cerebral motor neurons that are driven by a buccal CPG network via BCIs. Moreover, expression of the motor program may be modulated by local cerebral circuitry.

504.20

COMPARISON OF THE BEHAVIORAL EFFECTS OF ENDOGENOUS PEPTIDES ON VISCERAL MOTOR CIRCUITS IN APLYSIA. JLM Morgan, SH Ligman, PH Brownell. Dept of Zoology, Oregon St Univ, Corvallis, OR 97331

In *Aplysia*, the behavioral functions of neuropeptides can be studied in the context of simple motor circuits that control discrete components of visceral motor behavior. Of particular importance as a model is the neuroendocrine bag cell system that triggers egg-laying behavior. Peptides released by the bag cells affect many neurons in the abdominal ganglion, but the connection between neuronal and behavioral effects has not been systematically examined. We have used a semi-intact preparation of branchial and cardiovascular organs to investigate this relationship: By 1) evoking bag cell discharges, and 2) infusing the bag cell peptides, egg-laying hormone (ELH) and α-bag cell peptide (α-BCP) into the abdominal ganglion artery, we have quantified this relationship for four motor circuits. These motor circuits vary in complexity from a single motor neuron regulating tonic muscle tension (pericardial membrane) to several neurons (interneurons and motor neurons) regulating complex patterned movements (vascular, gill, and siphon motor systems). In the simplest circuit, α-BCP and ELH caused changes in spike rate of the motor neuron (LC_P) that were closely correlated with motor output (pericardial tension). In the more complicated gill and siphon circuits, the bag cell peptides affected most of the motor neurons involved, but not in a manner that accounted for the observed behavior. For example, α-BCP inhibited nearly all gill and siphon motor neurons, but failed to relax branchial muscle tension. In some preparations vascular infusions of α-BCP reduced the magnitude and or frequency of respiratory pumping. Similarly, vasomotor neurons (LB_{VCa}) were strongly inhibited by α-BCP without relaxation of vasomotor tension. We conclude that the central effects of peptides on motor neurons can be directly correlated with behavior in simple circuits. However, in larger circuits, the responses of a more complicated system are increasingly influenced by interneurons that integrate activities of these cells. (NIH NS18681, OR Heart Assoc. 80-962, Sigma Xi)

PERIPHERAL MODULATION OF SWIMMING SPEED IN A PTEROPOD MOLLUSC. R. A. Satterlie. Deparment of Zoology, Arizona State University, Tempe, AZ 85287-1501.

Three swimming speeds have been described for the pteropod mollusc Clione limacina: slow, fast and escape. The change from slow to fast swimming can be attributed to changes in the configuration of the pattern generator, and the recruitment of fast-twitch motor units, as opposed to the activation of only slow-twitch motor units during slow swimming. Escape swimming is apparently superimposed on fast swimming since additional changes in pattern generator and swim motor neuron activity have not been noted. Escape swimming appears to involve activity in two sets of neurons that modify the activity of the swim musculature. In both sets of neurons, electrical activity is independent of pattern generator activity. One set of neurons monosynaptically excites both slow- and fast-twitch muscle cells and produces strong wing contractions. The other neurons show serotonin-immunoreactivity and produce a short-term excitatory modulation of muscle contractility. The time courses of activity in these two groups of neurons suggest that the motor neurons may be used for the initiation of escape swimming (startle response) while the modulatory neurons may be used for maintenance of escape swimming.

HUMAN CAUDATE AND PUTAMEN CHEMOARCHITECTURE N. Selden, C. Geula, and M-M. Mesulam, Harvard U., Boston, MA

Human striatal neurons containing the peptides choline acetyltransferase (ChAT), somatostatin (SOM) and calcium-binding protein (calbindin D_{28k}) were visualized immunohistochemically using specific antibodies (generously provided by L. Hersh, R. Benoit and M. Celio, respectively).

Each peptide was associated with a different neuronal population. ChAT-positive neurons were relatively large (diameter: 25-35u), multipolar in shape, intensely stained and exhibited no major variations in density between various components of the striatum. SOM-positive neurons were also darkly stained, but were smaller (15-20u) and variable in perikaryal morphology. The density of SOM neurons was higher in the caudate nucleus than in the putamen. Two populations of calbindin-positive neurons were observed: (1) a large population of lightly stained, small neurons (10-15u), distributed throughout the striatum, with the greatest density over the dorso-medial caudate nucleus, 2) a small population of larger (10-20u), darkly stained neurons, most frequently encountered in the lateral putamen. Approximately half of the latter neurons also stained positively for NADPH-diaphorase, an enzyme which is co-localized with somatostatin in striatal neurons. There may thus be an overlap between some of the somatostatin-positive and larger calbindin-positive neurons in the putamen.

These chemoarchitectonic differences may be related to well-known differences of connectivity and behavioral affiliation between the caudate nucleus and putamen.

505.2

IMMUNOSTAINING FOR PROTEIN 10 CALCIUM-BINDING PROTEIN FORMS STRIOSOME-RELATED PATCHWORK IN THE RAT STRIATUM. B. Quinn, A.M. Graybiel, L. Winsky, and D.M. Jacobowitz. Dept. of Brain & Cognitive Sciences, Massachusetts Institute of Technology, Cambridge, MA 02139, and Lab. of Clinical Science, NIMH, Bethesda, MD 20892.

Protein 10 (Pr10) is a newly described calcium-binding protein that is distinct from calbindin 28kD and that may be the mammalian homologue of calretinin (Winsky et al., PNAS 86:10139, 1989). We have studied the distribution of Pr10 immunostaining in the striatum of adult rats, and have compared patterns of Pr10 immunoreactivity to those of calbindin 28kD (CaBP)-like immunoreactivity, a known marker for a large fraction of the small-to-medium-sized neurons of the striatal matrix (Gerfen et al., PNAS 82:8780, 1985). Cellular Pr10 immunostaining appeared in scattered striatal neurons. Neuropil immunostaining for Pr10 was concentrated in patches (ca. 100 um wide) with angular profiles scattered through the caudoputamen, and in the caudoputamen's dorsolateral rim. The most darkly stained Pr10-positive patches were in the dorsolateral part of the striatum, where CaBP immunostaining is minimal. Elsewhere, scattered Pr10-immunoreactive patches appeared to correspond to CaBP-poor zones (patches, striosomes). There was no clear relationship between the locations of the Pr10-positive patches and the Pr10-positive neurons. Heterogeneous distributions of Pr10-positive neuropil also appeared in the nucleus accumbens-ventral striatum. These findings indicate that Pr10 calcium binding protein and calbindin 28kD have different and at least partly complementary distributions within the striosomes and matrix of the striatum. We thank the National Parkinson Foundation & NIH NS 25529, and P.C. Emson for anti-CaBP antiserum.

EFFECTS OF PRENATAL METHYLAZOXYMETHANOL (MAM) ADMINISTRATION ON STRIATAL PATCH FORMATION. A.M. Snyder-Keller. Wadsworth Center for Laboratories and Research, New York State Dept. Health, Albany, NY 12201.

The formation of striatal patches, consisting of clusters of neurons and overlapping patches of nigrostriatal dopamine (DA) afferents, occurs prenatally. Persistence of the cellular patches after the prenatal removal of DA innervation (Snyder-Keller, Neurosci. Abstr. 15:906, 1989), suggests that intrinsic factors guide the association of patch neurons. Striatal patch neurons are born earlier (E13-15 in rat) than neurons of the matrix (E15-birth) (van der Kooy & Fishell, Brain Res. 401:155, 1987), and this fact was used to selectively delete striatal patch neurons. The antimitotic agent MAM, delivered as a single dose (20-30 mg/kg) or two doses (total $\leq$45 mg/kg) on embryonic days 12-14, resulted in a reduction in forebrain mass and distortion of the striatum. Striatal cellular patches, characterized as substance P-dense and calbindin-poor, were still apparent, but consisted of a smaller number of relatively larger patches. These same neuronal patches could be selectively labelled by an injection of Fluoro-Gold into the neonatal striatum. The DA innervation appeared less distinctively patchy during the first postnatal week, but AChE-positve neuropil assumed a fairly normal distribution. Thus, patches form despite the deletion of a large number of striatal patch precursors, but the birthdate of the neurons remaining in patches remains to be determined. VITAMIN D-DEPENDENT CALCIUM-BINDING PROTEIN (CALBINDIN-D-28K) IMMUNOREACTIVE NEURONS IN THE MONKEY AND THE RAT BASAL FOREBRAIN. H.T. Chang, H. Kuo and Q. Tian* Department of Anatomy and Neurobiology, The University of Tennessee, Memphis, College of Medicine, Memphis, TN 38163

A recent study has shown that many cholinergic neurons in the human nucleus basalis of Meynert (NBM) are immunoreactive for calbindin-D-28k (CBP), a Vitamin D-dependent calcium binding protein (Ichimiya et al., Brain Res. 1989, 499:402-406). However, the relationship of the CBP immunoreactive neurons with the cholinergic NBM neurons in other species has remained unclear. In this study, a mouse monoclonal antibody raised against CBP (a gift from Dr. M.R. Celio) and a rabbit antiserum raised against human placental choline acetyltransferase (ChAT) (Chemicon Inc.) were used in double-labeling immunofluorescence reactions to compare the distribution of CBP neurons with that of the ChAT neurons. In the Rhesus monkey (Macaca mulatta) NBM, virtually all of the CBP neurons contain ChAT, whereas about 70 to 80% of the ChAT neurons contain CBP. On the other hand, CBP does not co-localize with ChAT in the rat (Sprague-Dawley) NBM. The rat CBP neurons are fewer in number and smaller in size than the ChAT neurons. The difference in the expression of CBP immunoreactivity in the rat and monkey NBM neurons suggests that Vitamin D-dependent calcium homeostasis may have different roles in the primate and the rodent basal forebrain functions.

SEROTONERGIC INNERVATION OF THE RAT BASAL FOREBRAIN: A LIGHT AND ELECTRON MICROSCOPIC IMMUNOCYTOCHEMICAL STUDY. H. Kuo and H.T. Chang, Department of Anatomy and Neurobiology, The University of Tennessee, Memphis, College of Medicine, 875 Monroe Ave., Memphis, TN 38163

In the basal forebrain, non-cholinergic elements may play an important role in regulating the normal activity of cholinergic neuron. However, the distribution patterns and the synaptic connections of many non-cholinergic elements are not known. In this study, the distribution of serotonin (5-Hydroxytryptamine, 5HT) immunoreactive (5HT+) axons in the rat basal forebrain was examined. At least two types of 5HT+ axons could be distinguished in this region: One type consisted of relatively thin fibers endowed with small varicosities, and was found densely distributed throughout the substantia innominata (SI), ventral pallidum (VP), and ventral striatum (VS) without apparent differential distribution. The other type consisted of thicker fibers with larger varicosities, and was found mainly within SI and a junctional area between VP and VS. Electron microscopic analysis revealed that 5HT+ boutons formed asymmetrical synapses with mainly dendrites, and occasionally with somata of SI, VP and VS neurons. Present results suggest that the basal forebrain is innervated by at least two types of 5HT+ axons and that these 5HT+ axons may form excitatory synapses with basal forebrain neurons.

CALBINDIN-D28K AND PARVALBUMIN IN PRIMATE BASAL GANGLIA. P.-Y. Côté, A.F. Sadikot and A. Parent. Lab. of Neurobiol., Fac. of Med., Laval Univ., Québec, Canada.

The distribution of cell bodies expressing either calbindin-D28k (CB) or parvalbumin (PV) immunoreactivity (IR) in basal ganglia of squirrel monkeys (*Saimiri sciureus*) was studied on contiguous sections incubated with monoclonal antibodies against CB or PV (M.R. Celio). In the striatum, medium-sized CB-IR cells occurred in very large number and appeared strictly confined to the extrastriosomal matrix, as identified by its intense acetylcholinesterase staining on adjacent sections. Less numerous medium-sized PV-IR neurons were also distributed in a patch-like manner in the striatum, but the correspondence with the striosomal organization was not clear. The CB-IR neurons in the dorsal portion of the striatum were less intensely stained than those in the ventral portion, whereas the inverse occurred for neurons expressing PV. At the pallidal level, neurons in both segments were devoid of CB-IR but displayed very strong PV-IR. The neurons of the subthalamic nucleus were also markedly enriched with PV but displayed only very light CB staining. In the substantia nigra (SN)-ventral tegmental area (VTA) complex, CB-IR cells abounded in the VTA and in the dorsal tier of the pars compacta of SN, but were absent in the ventral tier of the pars compacta and in the entire pars reticulata of SN. In contrast, numerous PV-IR neurons occurred in pars reticulata and pars lateralis of SN, but none were found in the pars compacta and VTA. These findings reveal that the patterns of CB and PV distribution in primate basal ganglia are strikingly complementary, suggesting a synergic role for these two calcium binding proteins in basal ganglia function. [Supported by grants from MRC and FRSQ].

LIMBIC SYSTEM ASSOCIATED MEMBRANE PROTEIN (LAMP) IN PRIMATE BASAL GANGLIA. A.F. Sadikot, A. Parent and P. Levitt. Lab. of Neurobiol., Fac. of Med., Laval Univ., Québec, Canada and Dept. Anat., Med. Coll. Pennsylvania, Philadelphia, PA

A monoclonal antibody raised against LAMP was used to study the distribution of this glycoprotein in basal ganglia of 2 squirrel monkeys (*Saimiri sciureus*) and 1 cynomolgus monkey (*Macaca fascicularis*). In both species a similar heterogeneous distribution of LAMP immunoreactivity (IR) was seen. In striatum, areas of intense IR included the ventral striatum, rostral and ventral portions of putamen and most of caudate nucleus. The striosomes, as identified on adjacent sections stained for acetylcholinesterase or calbindin-28kD, were much more intensely stained than the extrastriosomal matrix. The external pallidum showed dense IR in its rostral pole and in dorsal and ventral thirds of its more posterior portion. The internal pallidum was virtually devoid of IR, except for a dense zone at its interface with the lateral hypothalamus. The ventral pallidum displayed moderate IR surrounding the more lightly stained subcommissural pallidum. In the subthalamic nucleus LAMP-IR was light laterally but increased significantly medially. In the brainstem, moderate LAMP-IR occurred mainly within the substantia nigra (SN), the ventral tegmental area, the retrorubral field and the pedunculopontine area. The SN pars reticulata displayed rostrocaudal and mediolateral gradients of decreasing IR. The SN pars compacta showed moderate IR in its dorsal tier but only light staining in its ventral tier, whereas the SN pars lateralis was largely devoid of IR. Thus, LAMP-IR is intense in limbic areas, light to moderate in associative territories, and virtually absent in sensorimotor regions of primate basal ganglia.

RECIPROCAL CONNECTION BETWEEN THE TWO PALLIDAL SEGMENTS IN PRIMATES. L-N. Hazrati and A. Parent. Lab. of Neurobiol., Fac. of Med., Laval Univ., Québec, Canada.

Studies with the lectin *Phaseolus vulgaris*-leucoagglutinin (PHA-L) revealed the existence of interconnections between the external (GPe) and internal (GPi) segments of the pallidum in the squirrel monkey (*Saimiri sciureus*). Small iontophoretic injections of PHA-L in the dorsomedial half of GPe produced significant anterograde fiber labeling in GPi. Both coarse and smooth labeled fibers arose from the injection site, traversed the internal medullary lamina and invaded the dorsomedial half of GPi. The coarse fibers passed through GPi to terminate within the subthalamic nucleus and the substantia nigra. In contrast, the smooth fibers consisting of thin and nonvaricose axons terminated directly within GPi. They were poorly branched and arborized in a pericellular, basket-like pattern around the somata and proximal dendrites of GPi neurons. Typically, one perikaryon was innervated by a single axon displaying numerous rather large varicosities reminiscent of terminal boutons. Conversely, PHA-L injection in the central core of GPi led to significant anterograde fiber labeling in the dorsomedial half of GPe. These fibers displayed long intervaricose segments proximally, and branched rather frequently distally making contact *en passant* with several GPe cells. Hence, the GPi-GPe projection appears rather diffuse in comparison to the more direct cell-to-cell relationship displayed by the GPe-GPi projection. Current electron microscopic studies should reveal more about the type of contact established by this short pallidopallidal interconnection system, which could play a crucial role in the functional organization of the basal ganglia. [Supported by grants from the MRC and FRSQ].

505.9

THE EXISTENCE OF A MARGINAL DIVISION IN THE MONKEY STRIATUM. S.Y.Shu and X.Bao. Dept.of Neurobiology,Inst.of Neuroscience,Xian, China.

In the rat, a band of densely packed medium sized fusiform cells has been found at the caudal border of the striatum and named marginal division.(Shu,et al. J Chemical Neuroanatomy,1988). The marginal division has special morphology, immunohistochemistry and projection patterns, distinguishable from the rest of the striatum.

The present study is to investigate whether a marginal division is in the monkey striatum. A part of monkey(Macaca mulatta) brain including putamen and globus pallidus was sectioned and the sections were processed immunohistochemistry of L-enkephalin(L-ENK), Neurotensin(NT), and Cholecystokinin(CCK). L-ENK, CCK and NT immunoreactive fibers and terminals were more densely accumulated in the caudo-medial border of the putamen than in the rest of the putamen. The neuronal somata are mostly fusiform in this region and some of them are L-ENK and NT immunoreactive. Based on the morphology, immunohistochemistry, and position of this region, it is very possible that a special marginal division, similar to the marginal division of the rat,also exists in the caudo-medial border of the putamen adjacent to the globus pallidus in monkeys.

EM STUDY OF SP+ STRIATAL NEURONS AND THEIR INPUT FROM NIGRAL DA+ NEURONS. E.J. Karle, K.D. Anderson and A. Reiner. Dept. of Anatomy & Neurobiology, Univ. of Tennessee, Memphis, TN 38163.

Considerable information is available regarding the synaptic inputs to medium spiny striatal neurons in general. However, little is specifically known regarding the inputs to substance P-containing (SP+) spiny striatal neurons, since these neurons label poorly immunohistochemically in mammals. To overcome this limitation, we have used immunohistochemistry to investigate this issue in pigeons, in which SP+ striatal neurons and their dendrites can be readily labeled.

EM double-labeling techniques were employed, using immunogold labeling for dopaminergic (DA+) terminals (labeled with anti-tyrosine hydroxylase) and PAP/DAB labeling for SP+ neurons. Consistent with the observed abundance of SP+ striatal neurons at the LM level, SP+ cell bodies and their dendrites were abundant at the EM level. The distal portions of these dendrites were spine-laden. These spines typically received asymmetric synaptic contacts at their tips from unlabeled terminals (presumably of cortical or thalamic origin). DA+ nigral terminals also made synaptic contacts and appositions with the SP+ neurons. The SP+ neurons also received synaptic input from SP+ terminals and from numerous unlabeled terminals whose origin is uncertain. In addition, SP+ terminals made synaptic contact with numerous unlabeled neuronal targets, including "pallidal" type dendrites that were densely coated with terminals.

These results provide direct evidence that the same major qualitative types of synaptic input to striatal medium spiny neurons are also received by SP+ striatal neurons. Supported by NS-19620, 3P01NS-26473 (A.R.) & Univ. of Tenn. Neurosci. Ctr. of Excellence (K.D.A.)

SELECTIVE DISTRIBUTION OF TYROSINE HYDROXYLASE IMMUNOREACTIVE AFFERENTS RELATIVE TO MEDIUM SPINY NEURONS IN CAUDATE PUTAMEN AND NUCLEUS ACCUMBENS OF THE RAT: A GOLGI EM STUDY. D.S. Zahm. Dept. of Anat. and Neurobiol., St. Louis Univ. Sch. Med., St. Louis, MO 63104.

Since tyrosine hydroxylase (TH) immunoreactive (IR) axospinous contacts are significantly more prevalent in the caudate-putamen and accumbal core than in the accumbal shell (Zahm and Haycock, Soc. Neurosci. Abst. 15:905), we have now addressed whether striatal medium spiny neurons in the nucleus accumbens are contacted by fewer numbers of TH-IR boutons than their counterparts in the caudate-putamen. Following immunoperoxidase demonstration of TH-IR boutons in 50μm vibratome sections, a section Golgi protocol was used to impregnate medium densely spined neurons. The positions of impregnated neurons relative to the boundaries of caudate-putamen, accumbal core or accumbal shell were established by comparison with adjacent sections processed to display substance P or 28kD calcium binding protein immunoreactivities. The numbers of immunolabeled profiles contacting profiles of identified, impregnated dendrites were expressed as a function of the summed lengths of the limiting membranes of such dendrites appearing within the zone of antibody penetration. While the word contact as used here implies only membrane apposition, punctate symmetrical synaptic specializations were occasionally observed. The analysis, which disregarded patch/matrix distinctions, revealed that medium spiny neurons in the accumbal shell are contacted over 50% less frequently by TH-IR boutons than are those in the caudate putamen and accumbal core, although the density of immunolabeled boutons was about the same in the three structures. Supported by USPHS grant NIH-23809.

MORPHOLOGICAL DIVERSITY OF TACHYKININ - PRODUCING NEURONS IN ADULT FELINE NEOSTRIATUM. M.K. Boylan and R.S. Fisher. Mental Retardation Research Center and Department of Anatomy & Cell Biology, UCLA, Los Angeles, CA 90024.

Neurons in the neostriatum produce and distribute tachykinin peptides (TKs) to all areas of the basal ganglia. However, the morphological identity of these TK-producing neurons remains controversial. In order to directly test the hypothesis that a morphologically diverse population of cells are the source of TKs in the adult neostriatum, we double labeled individual neurons with combined TK immunohistochemistry and a single slice Golgi/gold-toning procedure (to reveal somatodendritic morphology).

The majority of resulting double labeled neurons were of the medium spiny type I class, with spine-free cell bodies/proximal dendrites, densely spiny dendrites and an axon emerging from the cell body. Less frequently, medium spiny type II neurons were observed to be TK-positive. These cells had somatic and/or proximal dendritic spines, an axon emerging from dendritic origins and spiny dendrites. They were observed in all areas of the neostriatum. On occasion, medium and large sparsely spiny and aspiny cells were double labeled.

These results are the first direct demonstration that medium spiny type II and large and medium aspiny neurons are a subset of TK-producing cells in the adult neostriatum. The diversity of cell classes that produce TKs and other neurotransmitters, such as GABA, in the adult neostriatum indicates that neurotransmitter identity is not strictly associated with or limited by neuronal morphology. Supported by USPHS Grants NS 24596 and HD 05958.

REGULATION OF GAP JUNCTION PROTEINS IN NEOSTRIATUM: EXPRESSION OF CONNEXIN-32 AFTER SUBSTANTIA NIGRA DESTRUCTION. R. Fisher, M.S. Levine, N.A. Buchwald, P. Micevych and G. Zampighi. Departments of Psychiatry and Anatomy, Mental Retardation Research Center and Brain Research Institute, UCLA School of Medicine, Los Angeles, CA 90024 U.S.A.

Substantia nigra lesions augment dye-coupling between neurons in neostriatum. Our object was to determine if persistent accumulations of gap junction proteins and their encoding mRNAs contribute to this effect. Unilateral electrolytic lesions of substantia nigra in adult rats caused dopamine depletion after 14 days(decreased tyrosine hydroxylase content in neostriatum ipsilateral to lesions). As shown by in situ hybridization, mRNA encoding connexin 32 (C-32), the 32 kD hepatocyte-specific gap junctional protein, increased in neurons of dopamine-depleted neostriatum. As shown by immunohistochemistry, C-32 protein also increased in neurons of dopamine-depleted neostriatum. Both markers occurred at low levels in "intact" neostriatum of lesioned cases (5) and normal cases (3). We conclude that: 1) Dopamine may regulate gap junctions in neostriatum since loss of nigrostriatal input leads to supranormal accumulations of C-32 mRNA and protein in association with enhanced neuronal dye-coupling. 2) Gap junctions occur at low levels in intact neostriatum because C-32 protein and mRNA are detectable but barely apparent in association with low incidence of neuronal dye-coupling. Significant and progressive up-regulation of neostriatal neuronal coupling is predicted during the course of nigrostriatal dopaminergic denervation in Parkinson's disease. Supported by USPHS NS24596 and HD05958.

505.14

EXTRASTRIATAL GABAERGIC AND CHOLINERGIC INPUTS TO THE NEOSTRIATUM. T. Duong and R.S. Fisher. UCLA Mental Retardation Research Center and Department of Anatomy, Los Angeles, CA 90024.

It is widely believed that sources of GABAergic and cholinergic innervation of the neostriatum are local circuit neurons. In this study, the hypothesis that GABAergic and cholinergic neostriatal inputs originate, in part, from extrastriatal sites in the basal ganglia has been examined. We used double labeling means for detecting connectivity and transmitter molecular markers. Adult cats were injected unilaterally in the head of the caudate nucleus with the retrograde tracer wheat germ agglutinin bound to inactivated horseradish peroxidase and combined to colloidal gold. Brain sections were processed for simultaneous demonstration of the retrograde tracer and immunohistochemical labeling of choline acetyltransferase (ChAt) and glutamic acid decarboxylase (GAD). Results reveal that unilateral ChAt-immunoreactive (ChAt-ir) neurons located dorsal to the globus pallidus provide an afferent input to the head of the caudate nucleus. These ChAt-ir neurons (about 100-150 cells / case) are fusiform to multipolar and distributed at the level of and rostral to the anterior commissure. A smaller number (about 50-100) of GAD-ir neurons from this peripallidal region and from the globus pallidus itself also contibute to the pallidostriatal input. These pallidal and peripallidal projections are undecussated. In the mesencephalon, unilateral GAD-ir neurons located in the reticulate zone and in the medial portion of the compact zone of the substantia nigra form a small component of the nigrostriatal pathway. The number of contralateral GAD-ir neurons retrogradely labeled was few, if any. **These results provide morphological evidence of extrastriatal accessory GABAergic and cholinergic afferents ascending from basal ganglia regions.** This represents a first clear demonstration of transmitter diversity in these connections and may suggest transmitter variation of internal basal ganglia feedback circuits. Supported by HD07032, HDO5958 and NS24596.

DIFFERENTIAL ORGANIZATION OF INPUTS TO NEOSTRIATUM FROM PAIRED PRE- AND POST-CENTRAL CORTICAL AREAS. M. FOTUHI, V.E. KOLIATSOS, G.E. ALEXANDER, M.R. DELONG. Depts. Neurology and Neuroscience, Johns Hopkins Univ. Sch. Med.,Baltimore,MD 21205.

We have previously shown that pre- and post-central arm areas of the primary motor cortex (M1) and somatosensory cortex (S1) project to overlapping regions of putamen (Fotuhi et al. SN Abst. 15:285, 1989). In the present double anterograde study in green monkeys (using WGA-HRP and tritiated amino acids), we examined the relationship of terminal fields from the arm regions of another pair of interconnected cortical areas, the supplementary motor area (SMA) and area 5.

SMA terminals overlapped with the area 5 injection site, and vice versa. Striatal terminal fields of both areas extended over a long rostrocaudal domain of the caudate and putamen, with SMA terminals covering the more medial regions. In contrast to overlapping terminal domains of M1 and S1 projections, SMA terminal fields were segregated from, and complementary to those of area 5.

These results suggest a more complex and varied organization of corticostriatal projections from interconnected pre- and post-central areas than was predicted by our initial study.

505.16

ORGANIZATION OF MEDIAL PREFRONTAL CORTICAL PROJECTIONS TO THE VENTRAL STRIATUM. M. C. Lee and A. Y. Deutch. Departments of Psychiatry and Pharmacology, Yale University School of Medicine, New Haven, CT 06510.

Neurons in the medial prefrontal cortex (PFC) project to both the dorsal striatum (DS) and ventral striatum (VS). We have examined the organization of mPFC projections to the VS.

Anterograde tracer studies revealed that ventral mPFC sectors most heavily contribute to VS projections. PHA-L deposits into the infralimbic cortex resulted in the most selective VS labelling (without concomitant extensive labeling of fibers in the medial aspects of the DS). Ventral prelimbic cortex PHA-L injections also labeled the VS. More rostral injections of the medial orbital cortex did not result in significant VS labeling. PHA-L fibers ventromedial to the nucleus accumbens interdigitated with clusters of dense substance P-like immunoreactive fibers, i.e., typically avoided ventral pallidal sectors.

Consistent with the anterograde data, dual retrograde tracer deposits into the VS and DS revealed that the majority of mPFC neurons did not collateralize to innervate both the VS and DS, but originated from different neurons, typically in different mPFC sectors. DS projecting neurons typically were seen in the superficial aspects of layer V, whereas VS efferents originated from deep layer V.

These findings provide an anatomical substrate for recent biochemical data from our laboratory which indicate that removal of corticofugal projection neurons from tonic dopaminergic inhibition selectively enhances the responsiveness of the VS (but not the DS) dopaminergic innervations to pharmacological and environmental challenges.

DUAL-TRACER COMPARISON OF THE CORTICOSTRIATAL PROJECTIONS OF THE FRONTAL EYE FIELD AND THE SUPPLEMENTARY EYE FIELD IN THE PRIMATE. H.B. Parthasarathy[1], J.D. Schall[2], A.M. Graybiel[1]. [1]Dept. of Brain and Cognitive Sciences, M.I.T., Cambridge, MA 02139. [2]Dept. of Psychology, Vanderbilt Univ., Nashville, TN 37240.

The supplementary eye field (SEF) and the frontal eye field (FEF) are two regionally distinct but interconnected areas of the frontal lobe involved in the control of saccadic eye movements. Microstimulation of FEF elicts vector-coded saccades, whereas evidence links SEF to saccades whose amplitude and direction are eye-position dependent. Both of these cortical eye fields send projections to the striatum, another region known to process visual and oculomotor information. In the experiments described here, we asked whether the SEF and FEF convey their oculomotor representations to the same or to different striatal sites.

We compared the corticostriatal projections of the two eye fields in 5 cynomolgous monkeys. Guided by responses to cortical microstimulation, we placed either of the two anterograde tracers, [^{35}S]-methionine or horseradish peroxidase - wheat germ agglutinin (HRP-WGA), into each field. Serial-section analysis of the striatum demostrated a patchy projection to the striatal matrix from each of these areas that is restricted primarily to the body of the caudate nucleus and the cell bridges between the caudate nucleus and putamen. The projections were often interdigitated, but they were largely non-overlapping.

The striatum exerts critical effects on the nigrotectal control system that modulates activity in the superior colliculus. Our results indicate that there may be separate corticostriatal circuits subserving this control in the basal ganglia. Supported by NIH grant EY02866.

PROPRIOCEPTION AND THE STRIATUM: PRIMATE SOMATOSENSORY CORTICAL AREA 3A PROJECTS MORE BROADLY TO THE STRIATUM THAN DO AREAS 3B OR 1. A. W. Flaherty, A. M. Graybiel. Dept. of Brain and Cognitive Sciences, M.I.T., Cambridge, MA 02139.

To quantify the relative contributions of projections from somatosensory cortical areas to the striatum, we have calculated how relative corticostriatal magnification factor varies with cortical area and body part representation.

In 15 squirrel monkeys we made 25 injections of anterograde tracers ([^{35}S]-methionine or HRP-WGA) into the mouth (n=8), hand (n=10), and foot (n=7) representations of area 3a (n=6), area 3b (n=13), and area 1 (n=6). Injection sites were guided by multiunit recording of somatosensory receptive fields. Cross-sectional areas of labeled tissue were measured on a computer image analyzer from 40 um sections taken 480 um apart. We defined the corticostriatal magnification factor (M) for a cortical site as the ratio of the volume of labeled striatum to the volume of the injection site in cortical layers III through V.

Three-way analysis of variance showed that neither the body part representation injected nor the tracer had a significant effect on M, whereas the cortical area injected had a very significant effect ($p<0.005$). The projection from area 3a to the striatum ($M=6.30\pm0.93$) was about twice as broad as those from area 3b ($M=3.17\pm0.34$) and area 1 ($M=2.19\pm0.27$). (All values are means ± SEM.)

This result is of interest because area 3a represents primarily deep (muscle spindle) receptors, and may be more important for position sense than are areas 3b and 1, which represent primarily cutaneous sensation. The greater corticostriatal magnification of area 3a thus supports the view that the striatum is more concerned with posture and movement control than with fine touch.

FUNCTIONAL MAPPING OF RAT STRIATUM WITH ^{14}C DEOXYGLUCOSE: SOMATOTOPY, SENSORY-MOTOR INTEGRATION, AND EVIDENCE FOR RIGHT/LEFT SEGREGATION OF INFORMATION. Lucy L. Brown, Manuel F. Gonzalez, and Frank R. Sharp. Albert Einstein College of Medicine, Bronx NY 10464.

^{14}C deoxyglucose autoradiography was used with electrical stimulation of the cortex to map corticostriate fields of activation. Awake animals (n=23) were stimulated in forelimb MI cortex, vibrissae MI, vibrissae SI and hindlimb sensorimotor cortex. Cortical and striatal activation extended several mm anterior-posterior. Image analysis was used to define and localize activated striatal regions. Segregation of forelimb, vibrissae and hindlimb activated regions was significant in striatum. However, vibrissae sensory and motor cortex stimulation resulted in extensive overlap of activation in ipsilateral striatum, suggesting extensive sensorimotor integration. Of potential great interest is that activation contralateral to the stimulation side was .4 mm ventral to the ipsilateral activation, suggesting a place code for ipsilateral and contralateral (left/right) information in the striatum. The results confirm a definite somatotopy in striatum, but with widespread fields, especially vibrissae.

DISTRIBUTION OF BASIC FIBROBLAST GROWTH FACTOR IN THE ADULT RAT STRIATUM. Rosalinda C. Roberts, Cornelio G. Caday, Seth P. Finklestein and Marian DiFiglia. Massachusetts General Hospital, Boston MA. 02114

In neostriatal cultures, basic fibroblast growth factor (bFGF) enhances neuron survival and protects striatal neurons from glutamate toxicity (Freese et al., this meeting). Although bFGF has been localized to a number of CNS areas in adult brain little is known about its distribution in the neostriatum. In the present study, bFGF immunoreactivity was localized in the adult rat striatum. bFGF positive neurons were abundant throughout the striatum, with only small pockets of tissue lacking labeled cells. Many medium and large neurons were labeled, however not all cells in each subcategory were positive. At the EM level immunoreactivity, visualized with both DAB and colloidal gold, was deposited in patches throughout the cytoplasm of somata and dendrites. Reaction product was most often associated with neurofilaments and microtubules. Little or no label was found in glia or axon terminals, however bFGF positive axon initial segments were occasionally seen. Thus, bFGF may be an intra-neuronal growth factor in the mature striatum; its subcellular distribution suggests that it is not actively secreted from striatal neurons. NIH grant NS16367 to MD.

EFFECTS OF CORTICAL LESION BY THERMOCOAGULATION ON STRIATAL GENE EXPRESSION IN THE RAT : II SOMATOSTATINERGIC INTERNEURONS. P.Salin and M-F. Chesselet Dept. of Pharmacology U. of Pennsylvania Philadelphia, PA.

The cerebral cortex projects massively to the dorso-lateral part of caudate putamen (striatum), a structure primarily involved in the control of movement and cognition. A subset of cortico-striatal excitatory inputs has been shown to terminate upon a category of medium-sized aspiny interneurons expressing both neuropeptide Y (NPY) and somatostatin (SOM). Previous immunohistochemical studies have shown that the number of neurons stained for NPY and SOM increase after unilateral cortical lesion in the rat (Kerkerian et al, Eur. J .Neurosci. 2, 1990 ; Salin et al Brain Res. in press). Our goal was to determine whether striatal NPY and SOM gene expression was affected after cortical deafferentation. Fronto-parietal cortex was lesioned in rat by superficial thermocoagulation. Lesioned and control rats were sacrificed 5 or 21 days after lesion. The brains were cut on a cryostat, (10um-thick coronal sections) and processed for in situ hybridization histochemistry using a 35S radiolabeled cRNA probe. The number of labeled cells per striatal area and the intensity of labeling per individual neuron (number of pixels occupied by silver grains) were measured with an image analysis system (Morphon). In lesioned rats, the number of cells containing NPY and SOM mRNA and the intensity of labeling per individual neuron were significantly increased in the dorso-lateral striatum of both hemispheres. The parallel increase of the mRNA and peptide levels suggest that the lesion of the cerebral cortex by thermocoagulation result in an activation of NPY/SOM striatal interneurons. Supported by BNS 86-16841.

EFFECTS OF CORTICAL LESION ON STRIATAL GENE EXPRESSION IN THE RAT: I. EFFERENT NEURONS. M-F Chesselet and P. Salin. Dept. of Pharmacol. U. of Penn. Philadelphia,

Previous studies (Uhl et al. J.Neurosci.'88) have shown a decrease in striatal enkephalin (Enk) mRNA levels after cortical lesions in rats. We have further investigated the effect of cortical lesions on the levels of mRNA encoding glutamic acid decarboxylase (GAD), Enk and substance P (SP), and the corresponding peptides in the basal ganglia. Fronto-parietal cortex was lesioned unilaterally in rats by thermocoagulation and the animals were sacrificed 5, 21 and 90 days after the lesion. Cryostat-cut sections (10um) were processed either for immunohistochemistry with 125I labeled secondary antibodies or for in situ hybridization histochemistry with 35S radiolabeled cRNA probes. Sections were exposed to X ray film and the optical density of the autoradiographic signal measured. No striatal atrophy was observed at any time after the lesion. SP and Enk immunoreactivity increased in the internal (entopeduncular nucleus) and external (globus pallidus) pallidum respectively. This correlates with data on human cortical diseases or injuries (Bouras et al Neurosci. Abst. 15 861 '89). Enk and GAD mRNA levels increased in the striatum at all survival times but SP mRNA increased only at 5 days post-lesion. The results suggest a paradoxical increase in the synthesis of striatal efferent neurotransmitters after disruption of excitatory cortical pathways The discrepancy observed between ours results (by thermocoagulation lesion) and data of Uhl et al. (by aspiration lesion) could be explain by differential involvement of compensatory post-lesional processes. The prolonged and marked effects observed on Enk containing-neurons suggest that they may be a preferential target of cortico-striatal inputs. Sup by BNS 86-16841.

EFFECTS OF CLOZAPINE AND HALOPERIDOL ON STRIATO-PALLIDAL NEURONS AS REVEALED BY IN SITU HYBRIDIZATION HISTOCHEMISTRY (ISHH) IN THE RAT. M. Mercugliano and M-F. Chesselet, Dept. of Pharmacology, Univ. of Pennsylvania, Philadelphia, PA.19104

We have shown that clozapine and haloperidol have differential effects on the mRNA encoding glutamic acid decarboxylase (GAD) in the globus pallidus (GP) and entopeduncular nucleus (EP) of the rat. Clozapine's unique ability to increase GAD in the GP is likely related to its lack of motor side effects[1]. The GP and EP receive separate inputs from the striatum which contain enkephalin (ENK) and substance P (SP) respectively. We have measured the mRNAs for these peptides with ISHH in the striata of rats treated for 28 days with either haloperidol (1mg/kg/day), clozapine (20 mg/kg/day), or vehicle in order to assess the role of the striatal-GP pathway on clozapine's effect in the GP. ISHH was performed on cryostat-cut sections, with cRNA probes for ENK (S. Sabol, NIMH) and SP (H-U. Affolter, Lofstrand). Differences in labelling intensity were quantified with optical density measurements of film autoradiographs. While both drugs decreased labelling for SP mRNA.in the striatum, clozapine, but not haloperidol, decreased labelling for ENK mRNA in this area. The results show that, under these conditions, the two drugs similarly affect SP gene expression in striato-EP neurons, whereas only clozapine affects ENK gene expression in striato-GP neurons. This suggests that the increase in GAD mRNA in the GP after clozapine treatment is due to decreased activity of striato-GP neurons. Supp. by MH44894, ICI America, Inc. and MH14654 (M.M.)

EFFECT OF 6-HYDROXYDOPAMINE (6-OHDA) LESIONS OF THE SUBSTANTIA NIGRA ON THE LEVELS OF GLUTAMIC ACID DECARBOXYLASE (GAD) AND PREPROSOMATOSTATIN (SOM) mRNAs IN THE RAT PALLIDUM. Soghomonian J-J and Chesselet M-F, Dept . of Pharmacology, U. of Pennsylvania, Philadelphia, PA

...The role of the dopaminergic nigro-striatal pathway in the regulation of GAD and SOM mRNAs in neurons of the pallidum was investigated by in situ hybridization histochemistry (ISHH). Adult rats received an unilateral injection of 6-OHDA (6 µg in 2 µl) in the substantia nigra. After 7 days, animals were tested for contralateral turning with a single injection of apomorphine and sacrified two weeks later. The brains were frozen and cryostat-cut (10µm-thick). Sections were processed for ISHH with a 35S-radiolabeled cRNA for GAD (A. Tobin) or SOM (G. Goldman). In the globus pallidus of 6-OHDA-treated rats, the number of labeled cells was higher (29 ± 2.9 cells per mm^2) on the side ipsilateral to the lesion as compared to the contralateral side (14 ± 2.8) and to controls (20 ± 2.8). The intensity of labeling per cell was also higher in the globus pallidus ipsilateral to the lesion. In the entopeduncular nucleus of 6-OHDA-treated rats, the number of GAD-labeled cells was higher on the side ipsilateral to the lesion (17.5 ± 2.2) whereas the contralateral side had a number of labeled cells similar to controls (9.9 ± 1.5). By contrast, there was a massive increase (3-4 time) in the number of SOM-labeled cells, and intensity of labeling per cell, on the entopeduncular nucleus ipsilateral to the lesion (as compared to contralateral or control). These results suggest that removal of the dopaminergic neurons of the substantia nigra increases the expression of GAD mRNA in both pallidal segments in the rat and affects dramatically the expression of SOM mRNA in the entopeduncular nucleus. Supp by BNS 86-16841 and MH44894 and the PMAF (JJS).

506.6

REGULATION OF NEUROPEPTIDE EXPRESSION IN THE NUCLEUS ACCUMBENS OF THE RAT.

P.Voorn, C.R.Gerfen, Lab of Cell Biology, NIMH, Bethesda, MD 20892. Dept. Anatomy, Vrije Universiteit, Amsterdam, the Netherlands.

Enkephalin (ENK)- and substance P (SP)-immunoreactivity (IR) patterns in the nucleus accumbens (NA) are heterogeneous, showing areas of heavy, moderate or light immunostaining. Combined immunocytochemistry (ICC) and in situ hybridization histochemistry (ISHH) of ENK- and SP-mRNA with oligodeoxynucleotides showed that the heterogeneous IR-patterns in the shell region, but not in the core region of the NA can be recognized also in the distribution of ENK- and SP-mRNA. In the caudate-putamen decreased dopaminergic neurotransmission or lesion of neocortical inputs are known to cause dramatic alterations in peptide- and mRNA levels for ENK and SP. The present study focusses on possible regulation of ENK- and SP synthesis in the NA by dopaminergic and/or allocortical inputs from the hippocampus. Quantitative ISH and ICC were used to examine changes in the levels of ENK- and SP-mRNA after unilateral lesions of the dopaminergic fibers in the medial forebrain bundle with 6-OHDA and/or transsection of the fornix. Results show that 10-14 days after 6-OHDA-lesion the level of expression of ENK is increased and that of SP is decreased on the lesioned side compared to respective levels on the non-lesioned side. Dopaminergic regulation may act through direct inputs to the ENK- or SP-containing cells, but may also be relayed through cholinergic interneurons. A dopamine-acetylcholine interaction was studied at the morphological level by employing ISHH for the D2 receptor (Bunzow et al., Nature 336, 1988) and ICC for choline-acetyltransferase. Results show that cholinergic neurons in the caudate-putamen express the D2 receptor, whereas in the NA not all cholinergic neurons appear to express the D2 receptor.

COCAINE AND AMPHETAMINE INDUCE THE IMMEDIATE-EARLY GENE C-FOS IN STRIOSOME AND MATRIX COMPARTMENTS OF THE STRIATUM. A.M. Graybiel[1], R. Moratalla[1], H.A. Robertson[2] and M.R. Peterson.[2] [1]Dept. of Brain and Cognitive Sciences, M.I.T., Cambridge MA 02139 &[2]Dept of Pharmacology, Dalhousie Univ., Halifax, Nova Scotia.

Cocaine and amphetamine are psychomotor stimulant drugs that produce dramatic long-term changes in behavior. Many of these effects are thought to be mediated by dopaminergic mesostriatal systems. Here we tested the possibility that these drugs activate immediate early genes (IEGs) in the striatum. Adult rats were treated with intraperitoneal amphetamine (5 mg/kg), cocaine (25 mg/kg), or saline, and were perfused after 45 min- 6 hr. Sections through the striatum were stained for fos-like immunoreactivity and for calbindin$_{28k}$-like immunoreactivity to demonstrate striosome/matrix architecture.

Amphetamine and cocaine, but not saline, induced highly specific patterns of c-fos expression in dorsal and ventral striatum. Immunoreactivity appeared in nuclei of medium-sized striatal neurons by 45 min-1 hr, and declined by 6 hr. Cocaine induced c-fos both in striosomes and in matrix. By contrast, amphetamine induced a striking striosome-predominant pattern in the rostral caudoputamen, with more generalized induction farther caudally. In situ hybridization with oligonucleotide probes established that the induction involved c-fos transcription. Induction of c-fos-like immunoreactivity by each drug was blocked by pretreatment with the D1 dopamine antagonist SCH233390 (0.5 mg/kg), but only cocaine-elicited induction was blocked by reserpine (10 mg/kg).

We conclude that some of the physiological and behavioral effects of psychomotor stimulant drugs may depend on selective patterns of gene transcription in striosomes and matrix. Supported by The Seaver Institute, NIH NS 25529, The United Parkinson Foundation, NARSAD and MRC of Canada.

506.8

ACTIVATION OF RAT STRIATAL c-FOS BY DIRECT INFUSION OF DOPAMINERGIC AGONISTS AND FORSKOLIN. H.A Robertson[1], A.M. Graybiel[2] and M.L. Paul[1]. [1]Dept. of Pharmacology, Faculty of Medicine, Dalhousie University, Halifax, N.S., Canada B3H 4H7 and [2]Dept. Brain & Cog. Sci., MIT, Cambridge, MA 02139, U.S.A.

Recently we demonstrated that systemic injections of D1-selective dopamine agonists activate the immediate-early gene c-fos in the caudate-putamen and nucleus accumbens ipsilateral to a 6-OHDA lesion (Robertson, H.A. et al, Brain Res. 503:346, 1989). To characterize further this response, we have now investigated the effects of direct infusion of agents into the striatum in naive rats, in rats with unilateral 6-OHDA lesions and in rats pretreated with the biogenic amine-depleting drug reserpine. Drugs were slowly infused under pentobarbital anesthesia, and two hours later, rats were perfused for immunohistochemical localization of c-fos protein.

The D1-selective agonists SKF-38393 and CY-208243 produced marked c-fos activation in 6-OHDA and reserpine-treated rats but had no effect in naive rats. This response was attenuated by the D1 antagonist SCH-23390 (0.5 mg/kg, i.p.). Forskolin produced c-fos activation in both naive and treated animals, and this was unaffected by SCH-23390. In all animals, c-fos immunoreactivity was confined to the striatum.

In agreement with our earlier studies, the D2-selective agonist LY-171555 did not induce c-fos activation when infused directly into the striatum. These results suggest that the effect of the D1 agonists is direct and may be mediated by dopamine-sensitive adenylate cyclase.

THE EFFECTS OF ACUTE ANTIPSYCHOTIC DRUG TREATMENT ON MONOAMINE SYSTEMS IN THE NUCLEUS ACCUMBENS CORE AND SHELL. D. A. Cameron and A. Y. Deutch. Departments of Psychiatry and Pharmacology, Yale University School of Medicine, New Haven, CT 06510.

Recent anatomical studies indicate that the nucleus accumbens (NAS) can be differentiated into core (NAS_C) and shell (NAS_S) regions. The NAS_C and NAS_S have distinct afferents and efferents, and may subserve different functions. We have examined the consequences of acute antipsychotic drug (1.0 mg/kg haloperidol and 12.5 mg/kg clozapine) treatment on NAS monoamine systems.

Basal dopamine (DA) content and turnover in the two NAS regions did not significantly differ. However, serotonin (5-HT) concentration was lower, and 5-HIAA concentration and 5-HT turnover higher, in the NAS core than in the shell.

Haloperidol and clozapine increased DA turnover in both the NAS_C and NAS_S; haloperidol augmented dopamine turnover to a significantly greater degree than did clozapine. DA turnover was not differentially augmented between the two NAS regions. In contrast, 5-HT turnover was enhanced by both haloperidol and clozapine in the NAS shell only; serotonin turnover was not increased in the NAS_C. Haloperidol and clozapine augmented NAS_S 5-HT turnover by the same magnitude.

These data indicate that the NAS core and NAS shell can be pharmacologically dissociated. These data thus complement anatomical data differentiating the core and shell regions of the NAS, and suggest that functional differences may soon be uncovered.

Excitatory Amino Acid Receptors in Rat Basal Ganglia. RL Albin, RL Makowiec, Z Hollingsworth, LS Dure, JB Penney, AB Young. Dept. of Neurol., Univ. of Michigan, Ann Arbor, MI 48109

Excitatory amino acids (EAAs) are the neurotransmitters of numerous basal ganglia afferents and circuits. Quantitative receptor autoradiography was used to determine the distribution of EAA receptors in rat basal ganglia. NMDA, AMPA, KA, and metabotropic (MET) receptors, and the non-NMDA-KA-Quisqualate glutamate binding site (NNKQG) were densest in striatal regions. AMPA, MET, and NMDA receptors were denser in ventral than dorsal striatum. KA and NNKQG were uniformly dense in both ventral and dorsal striatum. All receptors had lower density in GP, VP, EP, STN, SN, and VTA. Receptor density was invariably higher in VP than GP with VP having relatively high density of AMPA, NNKQG, and KA binding. AMPA and MET receptors were relatively dense in STN. NNKQG binding was relatively high in SN. Inhomogeneous EAA receptor distribution indicates heterogeneous behavior of EAA neurotransmission within the basal ganglia. Supported by NS01300, NS19613.

NMDA RECEPTOR ACTIVATION IN THE NEOSTRIATUM INCREASES FOS SELECTIVELY IN MEDIUM SIZED NEURONS BUT NOT LARGE CELLS. N. Aronin and M. DiFiglia, Dept. of Medicine, Univ. of Mass. Med. Sch., Worcester, MA 02160, and Dept. of Neurology, Mass. General Hosp., Boston, MA 02114.

We sought to identify which neostriatal cells are responsive to NMDA receptor activation. The NMDA agonist quinolinic acid (QA, 10ug in 0.5ul) was injected into the rat caudate (n=10); 2h later immunohistochemistry was performed using affinity-purified antisera against the 127-154 fragment of Fos, a candidate effector of gene transcription. Results: QA injection increased nuclear labeling of Fos throughout the neostriatum; CSF infused into the contralateral caudate produced sparse labeling of nuclei only at the site of injection. Co-injection of QA with the NMDA receptor antagonist APV prevented Fos expression. Fos was localized predominately to medium sized neurons, including cells reactive for NADPH diaphorase; most large neurons were devoid of nuclear labeling. Ultrastructural examination verified that Fos was confined to the nuclei of medium sized neurons with unindented and indented nuclei; reaction product was distributed unevenly in the karyoplasm and notably in patches along the inner face of the nuclear membrane. Implications: Medium sized spiny and aspiny neurons have a high density of NMDA receptors and activation of NMDA receptors in these neurons contributes to the regulation of c-fos gene expression. Supported by the NSF and NIH.

Muscarinic Receptors Modulate Apomorphine Induction of Dynorphin in Striatal Patch Neurons J.B.Daunais and J.F. McGinty Department of Anatomy and Cell Biology East Carolina University School of Medicine, Greenville N.C. 27858

Previous studies have shown that repeated injections of the dopamine (DA) agonist, apomorphine (APO), increase dynorphin immunoreactivity (DYNir) and mRNA in striatal patch neurons (Li et al. JPET 246:403, Gerfen, C.R., McGinty, J.F. and Young, S.W. submitted). Stimulation of DA receptors also leads to decreased acetylcholine (Ach) turnover in striatal neurons. This study was conducted to investigate whether cholinergic tone affects the APO-induced DYN increase in striatonigral neurons.

The muscarinic agonist, oxotremorine 0.46 mg/kg (OXO), or muscarinic antagonist, scopolamine 10.0 mg/kg (SCOP) was administered s.c. 30 min. prior to 5.0 mg/kg, s.c. APO or saline twice daily for seven days. Eighteen hours after the final injection, the rats were perfused with 4% buffered paraformaldehyde for immunocytochemistry (ICC). ICC analysis using an antibody to DYN 1-8 (J.S.Hong, NIEHS) demonstrated increased DYNir in striatal patches with no appreciable difference between the control group and the SCOP alone or OXO alone groups. OXO decreased, whereas SCOP augmented, the APO-induced DYNir in cells and fibers of striatal patches. These data support the conclusion that a decrease in cholinergic interneuronal activity mediates the APO-induced increase in DYN synthesis in striatal patches. Supported by DA 03982 and Sigma Xi.

DISCHARGES OF SUBSTANTIA NIGRA RETICULATA (SNR) NEURONS DURING SLEEP-WAKING STATES. S. Datta, R. Curró Dossi, D. Paré, G. Oakson* and M. Steriade, Lab. Neurophysiol., Sch. Med., Univ. Laval, Quebec, Canada.

We have recently described several categories of mesopontine cholinergic neurons related to the genesis and brainstem-thalamic transfer of ponto-geniculo-occipital (PGO) waves (Steriade et al., 1990, J. Neurosci., in press). As one of these cellular types discharged stereotyped spike bursts over a background of decreased firing rate during REM sleep, we hypothesized that these PGO-on bursts are generated by low-threshold spikes deinactivated by membrane hyperpolarization and further suggested that GABAergic SNR cells represent one of the possible sources of hyperpolarization in peribrachial (PB) neurons.

To test this hypothesis, we recorded single SNR cells in chronically-implanted, naturally sleeping cats. SNR cells were antidromically identified from the PB area and ventromedial thalamic nucleus. Quantitative data were obtained from a sample of 16 SNR cells recorded during waking (W), EEG-synchronized sleep (S), and REM sleep. Rates of spontaneous discharges were similar in W (26.3 Hz) and S (28.8 Hz), but increased significantly during REM sleep (42.8 Hz). In all states, SNR neurons discharged tonically, with absence of high-frequency bursts and quite symmetrical interspike interval histograms. Out of 16 identified SNR cells, 7 increased their tonic firing 70-100 ms prior to the thalamic PGO wave. These data suggest that a population of SNR cells may exert tonic and/or phasic inhibitory actions upon a class of PB neurons that fire PGO-on bursts crowning the low-threshold spike. Supported by MRC grant MT-3689.

SEROTONIN (5-HT) INHIBITS MESOPONTINE CHOLINERGIC NEURONS *IN VITRO*. C.S. Leonard and R. Llinás, Center for Neural Science, NYU 6 Wash. Pl. NY, NY 10003 and Dept. Physiol. & Biophys., NYU Med. Ctr. 550 First Ave. NY, NY 10016.

The effect of 5-HT on neurons of the pedunculopontine (PPT) and laterodorsal tegmental (LDT) nucleus was studied with intracellular recording methods in brain slice preparations from guinea pig and rat. Cholinergic neurons were identified physiologically and morphologically by combined intracellular injection of lucifer yellow or biocytin and histochemical staining for NADPH-diaphorase (Leonard and Llinás, '88, Soc. Neurosci. Abst. 14: 297), which selectively labels mesopontine cholinergic neurons (Vincent et al., '83, Neurosci. Letts. 43: 31-36). Focal application of 5-HT on physiologically identified cholinergic neurons (type II cells, Leonard and Llinás, '90, In: Brain Cholinergic Systems, Steriade and Biesold, Eds.) produced a transient suppression of firing and membrane hyperpolarization. Bath application of 5-HT produced a maintained hyperpolarization whose magnitude varied with 5-HT concentration (3-30μM). The hyperpolarization was unaffected by Ringer containing TTX and low Ca/ 2mM Co, indicating a direct action of 5-HT on mesopontine neurons. The hyperpolarization reversed near the potassium equilibrium potential and was accompanied by a large decrease in membrane resistance suggesting the activation of a potassium current. These results imply that mesopontine cholinergic neurons are directly inhibited by their serotonergic afferents and suggest that they become disinhibited during REM sleep when serotonergic neurons exhibit greatly reduced discharge rates. Supported by NINCDS13742 and a grant from the American Parkinson Disease Association.

507.3

LATERAL HYPOTHALAMIC PROJECTIONS TO THE PEDUNCULOPONTINE TEGMENTAL NUCLEUS AND ADJACENT MIDBRAIN TEGMENTUM IN THE RAT. T.L. Steininger and B.H. Wainer. Dept. of Pharm. and Phys. Science, Univ. of Chicago, Chicago IL 60637.

The cholinergic neurons of the pedunculopontine tegmental nucleus (PPT) are thought to modulate behavioral arousal through its widespread projections to the thalamus and brainstem reticular formation. Retrograde tracing studies suggest that this nucleus receives information from a variety of sources, including the posterior lateral hypothalamic area (LHAp). To further evaluate these putative afferents to the PPT, anterograde tracing with *phaseolus vulgaris* leukoagglutinin (PHA-L) was combined with immunocytochemical localization of choline acetyltransferase (ChAT).

Iontophoretic injections of 2.5% PHA-L were placed into the LHAp. The tissue was processed for the sequential immunolocalization of PHA-L with diaminobenzidine as the chromagen and of ChAT with benzedine dihydorchloride. Few PHA-L immunoreactive varicose fibers were seen in proximity to ChAT immunoreactive neurons in the PPT and laterodorsal tegmental nucleus (LDT). However, moderate to dense labeling was seen in the retrorubral field adjacent to the rostral PPT, in the central tegmental field adjacent to mid and caudal levels of the PPT, and in the medial parabrachial subnucleus situated caudally adjacent to the PPT. Descending projections from the LHAp may terminate mainly on noncholinergic neurons in the midbrain tegmentum. (NS 17661, MH09919, and GM 07839)

507.4

THE CLASSIFICATION OF AXON TERMINALS FROM BRAINSTEM STRUCTURES TO THE MEDIODORSAL THALAMIC NUCLEUS (MD) IN THE RAT. M.Kuroda and J.L.Price, Dept. Anat. & Neurobiol., Washington Univ. Sch. of Med., St.Louis, MO 63110.

Presynaptic terminals from the brainstem to MD were studied with the electron microscope in the rat, by means of anterograde transport of WGA-HRP. Labeled axons were seen mainly in the lateral part of MD after the injections of 1% WGA-HRP (50 nl) into the substantia nigra (SN), superior colliculus (SC), and dorsolateral tegmentum (DLT). The boutons arising from SC were small (<1 μm in diameter), formed asymmetrical synaptic contacts with small dendrites, and contained round synaptic vesicles. The axon terminals from DLT relatively large boutons (2-4 μm) with asymmetric synaptic contacts and round vesicles. The pre- and postsynaptic elements were surrounded by glial lamellae, to form glomeruli. These ultrastructural features are almost identical to the previously described boutons in the medial and central segments of MD that originate from the basal amygdaloid nucleus and the piriform cortex. In contrast, the nigral afferent terminals were medium to large in size (2-3 μm), made symmetrical synaptic junctions with dendritic shafts and occasionally with somata, and contained pleomorphic vesicles. These terminals are similar to the ventral pallidal afferents to the medial part of MD. Moreover, a combined study with GAD-immunohistochemistry and WGA-HRP labeling revealed that the terminals of nigral origin were immunoreactive for GAD.

These results suggest that the afferents from SC and DLT are excitatory, while nigral projections are inhibitory and GABAergic.

Supported by NIH research grant DC00093.

LDT-PPT CHOLINERGIC NEURONS COLLATERALIZE TO TWO THALAMIC TARGETS. P. Shiromani, J. Velazquez-Moctezuma, and C. Floyd.* San Diego VAMC and UCSD, La Jolla, CA 92093.

Cholinergic neurons in the lateral dorsal tegmental (LDT) and pedunculo-pontine tegmental (PPT) nuclei have been shown to heavily innervate the thalamus. In order to determine whether single LDT-PPT cholinergic neurons simultaneously project to two thalamic targets, in rats, unilateral microinjections (0.1 ul) of rhodamine-conjugated microbeads were made into the central-lateral (CL) thalamic nucleus, and FITC-conjugated microbeads (0.1 ul) were injected into the lateral geniculate nucleus (LGN). Pontine sections were processed for immunohistochemical localization of choline acetyltransferase (ChAT). As previously shown by others, we found a heavier projection to the CL compared to the LGN and more neurons were labelled ipsilateral to the injection site. About 5% of LDT-PPT ChAT positive somata were found to contain both rhodamine and FITC beads indicating that some LDT-PPT cholinergic neurons project to both the CL and the LGN. Some LDT-PPT somata were non-cholinergic but projected to the two thalamic targets. Such a collateralization might be useful in the production of events related REM sleep. LDT-PPT cholinergic neurons are implicated in producing EEG desynchrony via intralaminar thalamo-cortical neurons. LDT-PPT cholinergic neurons are also implicated in producing PGO wave activity recorded in the LGN. We postulate that by projecting to two thalamic targets, a minority of the LDT-PPT cholinergic neurons influence two thalamic targets and thereby might coordinate the simultaneous occurrence of cortical desynchrony and PGO waves during REM sleep.

RAPHE-RAPHE INTERCONNECTIONS IN THE RAT DEMONSTRATED BY ANTEROGRADE LABELING WITH PHASEOLUS VULGARIS LEUCOAGGLUTININ. M.R. Park. Dept. Anatomy & Neurobiology, Univ. Tennessee, Memphis, The Health Science Center, Memphis, TN 38163.

Interconnections between raphe nuclei have long been implicated from retrograde axon tracing studies. In the present study, injections of the lectin phaseolus vulgaris leucoagglutinin (PHA-L) into various midline brainstem and mesencephalic targets produce networks of anterogradely labeled varicose axons in the dorsal raphe nucleus. This is true for structures that are immediately ventral to the dorsal raphe nucleus: median raphe, rostral linear raphe, caudal linear raphe, and a dorsal portion of the interpeduncular nucleus in which serotonin immunoreactive cell bodies are found. These structures lie along the caudal portion of an axis, extending caudally and dorsally from the medial forebrain bundle, of raphe-projecting nuclei. This is also the axis along which a major portions of afferent and efferent axons to and from the dorsal raphe nucleus, respectively, travel. Distant from this axis, PHA-L injections in raphe pontis also produce labeled terminal axonal fields in the dorsal and median raphe nuclei. Reconstruction of these axon pathways confirm the idea that reticular formation nuclei are richly interconnected.

The nature of the numerous axon varicosities remains unclarified. In common with other afferents to the dorsal raphe nucleus, such as the lateral hypothalamic area and ventral tegmental area, varicosities are often not in close apposition to 5-HT immunoreactive neurons, in double labeled material. This suggests that either the varicosities seen in PHA-L material do not all correspond to presynaptic boutons or that the predominate target for some dorsal raphe afferents is not the population of serotonergic neurons.

EFFERENT PROJECTIONS FROM THE DORSAL RAPHE NUCLEUS. L.J. Sim and S.A. Joseph, Neuroendocrine Unit, University of Rochester, Rochester, N.Y. 14642.

The dorsal raphe nucleus (DRN) and ventrolateral periaqueductal gray (PAG) have been identified as part of a descending pain modulating pathway. Neurons in this region have also been shown to influence cardiovascular and homeostatic function and behavior, such as the expression of fear. The dorsal raphe complex contains serotonergic, catecholaminergic and peptidergic systems. In this study, we have injected the anterograde tracer phaseolus vulgaris leucoagglutinin (PHA-L) into various subdivisions and surrounding nuclei of the dorsal raphe complex to define the trajectory of fibers emanating from this region. PHA-L was iontophoresed into specific areas throughout the rostral-caudal extent of the DRN. Animals were sacrificed 10-15 days later and PHA-L was identified using nickel enhanced immunocytochemistry. PHA-L immunoreactive (-ir) fibers and terminals are identified in numerous forebrain nuclei including the nucleus accumbens, bed nucleus of the stria terminalis, septum and amygdala. PHA-L-ir fibers are also identified in diencephalic and brainstem nuclei including the paraventricular and medial thalamus, paraventricular nucleus, periventricular gray, lateral habenula, locus coeruleus, parabrachial nucleus, nucleus of the solitary tract and throughout the DRN and PAG. PHA-L-ir fibers are also found in the dorsal horn and central gray of the spinal cord. This anatomical data substantiates behavioral studies in which the DRN has been shown to modulate descending pain pathways as well as ascending autonomic and behavioral function. SINGLE UNIT ACTIVITY IN THE PARABRACHIAL REGION (PB) DURING STIMULATION OF THE AMYGDALOID CENTRAL NUCLEUS (ACE) AND PAVLOVIAN CONDITIONING IN RABBITS. J.P.Pascoe & B.S.Kapp. Dept. Psychology, Univ. Vermont, Burlington, VT 05405

The ACE is an essential part of a forebrain system that contributes to the autonomic features of emotion. The PB has reciprocal connections with the ACE and may be a relay in ascending and descending pathways between the ACE and various sensory and visceral motor areas. We have examined activity in PB neurons during stimulation of the ACE and during the Pavlovian conditioned bradycardic response.

Of 133 PB neurons, 35 were activated antidromically from the ACE (6-26 ms, $\bar{X}$=13 ms) and were located medial (14) or just lateral (21) to the brachium conjunctivum (BC). Activity in these neurons was infrequent, was decreased or not altered during conditioning, and was unaffected by pinna shock. Of 38 neurons activated orthodromically from the ACE (4-45 ms, $\bar{X}$=7 ms), 3 were located medial and 16 just lateral to the BC, and 19 were located dorsally within the mesencephalic area between the BC and the inferior colliculus. In many of these neurons a short latency (<15 ms) increase in activity occurred to presentations of both tone and pinna shock during conditioning. A respiratory rhythm was evident in the ongoing activity of 14 neurons located near the ventrolateral tip of the BC. These data suggest a convergence of sensory input and ACE output at the level of the PB, but the role of PB input to the ACE during conditioning remains to be identified. BRAINSTEM PROJECTIONS FROM THE NUCLEUS OF THE SOLITARY TRACT IN THE RAT. E.T.Cunningham, Jr. and P.E. Sawchenko. The Salk Institute for Biological Studies, La Jolla, CA 92037.

Anterograde transport, retrograde transport, and immunohistochemical techniques were used to characterize the organization of brainstem projections from the nucleus of the solitary tract (NTS) in the rat. The results are as follows: 1) Nearly all subregions of the NTS give rise to an extensive set of intrinsic projections that almost invariably involve "associational" and "commissural" projections within that subregion on the ipsilateral and contralateral sides. In addition, the rostral part of the NTS gives rise to a strong input to the ventral and ventrolateral parts of the nucleus. The central subnucleus, in contrast to all other parts of the NTS, gives rise to, and receives, only sparse intrinsic inputs. 2) The ventral and ventrolateral parts of the NTS project to the ventromedial division of the trigeminal motor nucleus, to the intermediate subdivision of the facial nucleus, to the caudal ventral parts of the hypoglossal nucleus, and to the region of the nucleus ambiguus. 3) The central subnucleus gives rise to a dense, primarily ipsilateral, projection to the rostral, or compact, part of the nucleus ambiguus. 4) Most parts of the caudal, medial half of the NTS, including the commissural portion, project heavily to the dorsal motor nucleus of the vagus nerve (DMX). 5) The central gray (CG) receives projections principally from those parts of the medial and commissural NTS known to contain the A2 and C2 catecholamine cell groups. 6) The A1 and C1 catecholamine cell groups in the ventrolateral medulla receive their heaviest and most directed input from the commissural part of the NTS. 7) The parabrachial nucleus receives a dense input from virtually all parts of the NTS, with the exception of the central subnucleus. Together, these results provide evidence for topographically discrete pathways from the NTS to a number of motor and relay nuclei important in autonomic, neuroendocrine and orofacial function.

IN VITRO RAT BRAINSTEM SLICES REVEAL GUSTATORY NEURON TYPES. R.M. Bradley and R.D. Sweazey. School of Dentistry, University of Michigan, Ann Arbor, MI 48109-1078.

Using intracellular recordings and biocytin injections we are defining the intrinsic membrane properties of neurons in the gustatory zone of the solitary tract nucleus (NTS). Three neuron types were separated using current injection pulse paradigms in rat brainstem *in vitro* slice preparations. Injections of depolarizing current produced a low frequency, regular pattern of response in Type I neurons; a high frequency, regular response in Type II neurons; and a high frequency, burst-like pattern of response in Type III neurons. Furthermore, in both Type I and III neurons, preceding the depolarizing current pulse by a hyperpolarizing prepulse produced a delay in the initiation of the first spike. This delay was dependent on both the magnitude and duration of the prepulse. Preliminary reconstructions of biocytin-filled neurons indicate that these physiologically defined neuron groups also have different morphological characteristics. The presence of neuron types in the gustatory NTS suggests that these groups have different roles in processing gustatory information.

ELECTROPHYSIOLOGY AND MORPHOLOGY OF CO2-SENSITIVE NEURONS IN THE DORSAL VAGAL COMPLEX STUDIED IN VITRO. J.B. Dean, E.A. Gallman, and D.E. Millhorn. Dept. of Physiology, Univ. of North Carolina, Chapel Hill, NC 27599.

We reported previously (*Exp. Brain Res.*, 76:656, 1989; *Neurosci.*, in press) that certain neurons in the nucleus tractus solitarii (NTS) and dorsal motor nucleus are depolarized inherently by hypercapnia. Additional work, reported here, using the *in vitro* slice preparation (rat) shows that CO_2-induced changes in excitability are associated with one or more of the following: decreased amplitude & duration of afterhyperpolarization, depolarization of the membrane, & decreased conductance. In one NTS neuron with slow oscillations of membrane potential, hypercapnia increased the magnitude and rate of oscillation. CO_2-induced depolarization was unaffected by 1μM tetrodotoxin, but prevented by pretreatment with 2 mM 4-aminopyridine. Lucifer Yellow filled somata of CO_2-sensitive cells were either pyramidal, oval, or fusiform as viewed transversely and produced 3-5 primary processes. Somata ranged from 28-50μm in their longest diameter. Most processes appeared to radiate towards the dorsal surface, fourth ventricle, or central canal, sometimes coming to within 20μm of these structures. Experiments are underway to determine the efferent projection of CO_2-sensitive neurons using rhodamine microspheres. (NRSA HL07398, NIH HL33831, AHA 881108, ALA)

IN VITRO STUDIES OF HYPOXIC MODULATION OF MEMBRANE PROPERTIES IN THE DORSAL VAGAL COMPLEX E.A. Gallman, J.B. Dean and D.E. Millhorn, UNC, Chapel Hill, NC 27599

The present study was undertaken to determine the direct effects of hypoxia on neurons of the dorsal vagal complex (nuc. solitary tract, dorsal motor nuc. of the vagus). Since this region is known to have diverse function (*e.g.* respiratory, cardiovascular control), we wondered if cells in this region might also exhibit diverse responses to hypoxia. Intrinsic hypoxic responses of these neurons have a direct bearing on their functioning in homeostatic control. Intracellular recordings were made in rat brain slices in a perfusion-interface chamber at 35-37°C while exposed to 95% O_2/5% CO_2. Cells were tested in hypoxia (95%N_2/5%CO_2) for 2-3 min. Some neurons tested were hyperpolarized by hypoxia with a decrease in R_N, suggesting an increased gK^+. Such neurons decreased firing rate during hypoxia. Other neurons tested were depolarized with a large decrease in R_N and decreased firing rate, suggesting a depolarizing block. Still other neurons were excited by hypoxia, depolarizing slightly and increased firing rate with little change in R_N. There were also cells which were not responsive to this brief hypoxic challenge. Thus cells within the DVC exhibit a number of responses to hypoxia which may reflect the diverse functions of this region. (USPHS Grant HL-33831)

CONNECTIONS OF THE DORSAL VAGAL COMPLEX IN THE FERRET [Mustela putorius furo]. N.L. Strominger, A.P. Knox and D.O. Carpenter. Department of Anatomy, Cell Biology and Neurobiology, Albany Medical College, Albany, NY 12208.

The connectivity of the ferret dorsal vagal complex was studied with HRP or WGA-HRP delivered via micropipette. Animals were perfused transcardially with buffered saline followed by 2.5% gluteraldehyde in 0.1 M phosphate buffer after 24-48 hours. Tissues were cut at 50um on a freezing microtome and reacted with tetramethyl benzidine. In different animals, injections were restricted to the AP, were immediately adjacent to the AP centered in the solitary nuclear complex, or involved the AP together with the adjacent tegmentum. In cases with injections limited to the AP, labeled fibers could be traced only into the adjacent solitary complex, specifically the medial and subgelatinosus subnuclei. These nuclei also contained labeled perikarya. After injections centered in the solitary complex, labeled perikarya occurred in the AP, parabrachial nucleus, paraventricular nucleus of the hypothalamus and in the substantia innominata. Efferently labeled fibers were followed to the paraventricular nucleus. We conclude that in ferrets ascending brainstem pathways from the AP relay in the solitary complex.

507.14

DISTRIBUTION OF NEUROPEPTIDES AND 5-HT IN THE FERRET BRAINSTEM. I. THE DORSAL VAGAL COMPLEX. G.E. Lucier, R. Egizii, F.M. Boissonade and K.A. Sharkey. Dept. Medical Physiology, University of Calgary, Calgary, Alberta T2N 4N1 Canada

The ferret is becoming increasingly important in neurophysiological studies. Since we are using this animal for studies of G.I. tract function, it was necessary to examine the central distribution of various neurochemicals in nucleus tractus solitarius (nTS), area postrema (AP) and dorsal motor nucleus of the vagus (DMV), [the dorsal vagal complex (DVC)]. In order to help define the boundaries of these nuclei in the ferret, the location of the DMV and hypoglossal (XII) nuclei were confirmed using retrograde tracing with HRP applied to the cervical vagus or XII nerve respectively. Frozen 40μm serial brainstem sections were cut, incubated with antibodies against substance P (SP), calcitonin gene-related peptide (CGRP), enkephalin (ENK) and serotonin (5-HT), and processed using the PAP procedure. All immunoreactivity (IR) appeared in fibers and/or terminals. In the nTS, SP-, and to a lesser extent, CGRP-IR were present in discrete areas, suggesting localization within subnuclei. Dense SP- and CGRP-IR were also found in the AP and the DMV. In contrast, ENK-IR was evenly distributed, whereas 5-HT-IR was sparse and scattered, but both were found throughout the DVC. The only IR cell bodies seen were those containing 5-HT in the DMV. Vagal nerve fibers entering the brainstem (approx. 2.0 mm rostral to obex) contained primarily CGRP-IR, to a lesser extent 5-HT-IR and occasionally SP-IR. (Supported by Canadian MRC and Alberta Heritage Foundation for Medical Research).

507.15

DISTRIBUTION OF NEUROPEPTIDES AND 5-HT IN THE FERRET BRAINSTEM. II. THE TRIGEMINAL COMPLEX. F.M. Boissonade, K.A. Sharkey, R. Egizii and G.E. Lucier. Dept. Medical Physiology, University of Calgary, Calgary, Alberta T2N 4N1 Canada.

As a basis for future neurophysiological studies in the ferret, it was necessary to examine the central distribution of various neurochemicals in the trigeminal complex: main sensory nucleus (MSN) and spinal trigeminal nucleus (spV), divided into caudalis, interpolaris and oralis. Frozen 40μm serial brainstem sections were cut, incubated with antibodies against substance P (SP), calcitonin gene-related peptide (CGRP), enkephalin (ENK) and serotonin (5-HT), and processed using the PAP procedure. In caudalis, dense SP-, CGRP- and ENK-immunoreactive fibers and terminals (IR) were present as a single band in laminae I and II, and less densely in lamina V. At ~ 800 μm caudal to obex, the central portion of the SP- and CGRP-IR band in laminae I and II disappeared and an additional band appeared along the dorsomedial border of laminae IV and V. In contrast, 5-HT-IR was present over the entire sub-nucleus with the most dense IR in laminae I and II. In caudal interpolaris, SP-, CGRP- and ENK-IR was restricted to the dorsolateral border and a ventromedial portion of the nucleus. This IR disappeared in rostral interpolaris. Sparse 5-HT-IR was present throughout interpolaris and most dense in a band along the medial border. In oralis, all substances were found in IR fibers crossing the trigeminal tract and as terminals and fibers scattered around the periphery of the nucleus, especially along the dorsomedial border. In MSN, SP-, CGRP- and ENK-IR was localized in the dorsomedial part of the nucleus and 5-HT-IR was evenly distributed throughout. (Supported by Canadian MRC and Alberta Heritage Foundation for Medical Research).

LEARNING AND MEMORY—PHARMACOLOGY: MONOAMINES

508.1

OLFACTORY BULB NOREPINEPHRINE MAY BE REQUIRED FOR EARLY OLFACTORY LEARNING. Weiquan Lin, D.A. Wilson, and R.M. Sullivan. Developmental Psychobiology Laboratory, Dept. Psychology, University of Oklahoma, Norman, OK

Norepinephrine (NE) is known to be critically involved in a variety of olfactory learning paradigms for acquisition of conditioned neurobehavioral responses. For example, in rat pups, systemic injections of NE β-receptor antagonists can block olfactory preference conditioning and its neural correlates (Sullivan et al., 1989). The present study limited NE blockade to the olfactory bulb during training, to determine the role of bulb NE in early learning.

On PN5, under cold anesthesia, pups had a cannula (30 ga) chronically implanted into one bulb and had the contralateral naris occluded. Pups were returned to the litter until PN6, when olfactory conditioning occurred. Pups were trained in one of 3 groups, PAIRED - odor paired with tactile stimulation, RANDOM, or ODOR ONLY. During a 10 min habituation period and the 10 min training session, pups had either saline or 100 μM propranolol infused into the bulb (0.1 μL/min). On PN7, pups were given a behavioral odor preference test or injected with [14C] 2-DG and exposed to the conditioned odor. Preliminary results suggest that NE antagonists limited to the bulb block acquisition of a learned behavioral odor preference. Neural correlates of this response are being examined.

DSP-4, SOCIAL HOUSING CONDITIONS AND OLFACTORY EXPERIENCE INFLUENCE NOVELTY-INDUCED ANXIETY IN RATS. C.A. Cornwell-Jones, T. Palfai*, D. Krasenbaum*, E. Eyer Jr.*, B. Clark* and K. Kinnard*. Department of Psychology, Syracuse University, Syracuse, NY 13244.

Three experiments tested the hypothesis that housing control and DSP-4 treated rats together is stressful and increases anxiety. Rats were injected s.c. with water or the norepinephrine (NE) neurotoxin DSP-4 on the day of birth, placed at weaning in bedding with either a familiar or novel odor, and observed in three different situations 11-13 days later. Rats housed in the familiar odor in mixed groups (DSP-4 and water) showed abnormally low levels of rearing in the open field, and social interaction with strange rats, indicators of anxiety. These effects were not seen in rats from mixed groups housed in the novel odor. The data suggest that exposure to a novel odor can reduce anxiety. Mixed housing in either odor elevated rats' exploratory behavior in the home cage, and also depressed frontal cortex NE levels for DSP-4-treated rats. These data suggest that mixed housing is stressful, particularly for DSP-4 treated rats.

508.3

THE EFFECTS OF ALPHA-2 ADRENERGIC DRUGS ON CORTICAL AND HIPPOCAMPAL ELECTRICAL ACTIVITY AND LEARNING/MEMORY IN RATS WITH COGNITIVE DYSFUNCTION. J. Sirviö, P. Riekkinen Jr.*, A. Valjakka*, T. Halonen* and P.J. Riekkinen. Dept. of Neurology, University of Kuopio, Finland

The present set of experiments were undertaken in order to study whether alpha-2 adrenergic agonist (guanfacine) or antagonist (atipamezole) would improve age-associated cognitive dysfunctions. We studied the effects of different doses of those drugs on cortical electrical activity (spectral electroencephalogram (EEG) the amount of high voltage spindles (HVS)) and hippocampal electrical activity as well as acquisition and retention of passive avoidance (PA) and water maze (WM) tasks. The models used were aged (24-months old) rats, fimbria-fornix (FF)- and nucleus basalis (NB)-lesioned rats. Surgery of animals (implantation of electrodes and lesions) were done under deep anesthesia. Guanfacine (Sandoz Ltd, Switzerland) was injected intraperitoneally (4 ml/kg), and atipamezole (Farmos Ltd, Finland) was injected subcutenously (0.5 ml/kg). Vehicle treated rats received saline. The most significant findings were:
1) atipamezole (3 mg/kg) decreased the number of HVS and improved the performance in PA test (testing latency) of aged rats 2) atipamezole (3 mg/kg) decreased the delta and theta power of nb-lesioned rats
3) guanfacine (0.004-0.1 mg/kg) increased the number of HVS (which were blocked by atipamezole) and theta power both in young and aged rats
4) guanfacine (0.001 mg/kg) impaired the performance of young and aged rats in WM task 5) atipamezole (1 and 3 mg/kg) increased immobility-related power of 4-8 Hz (theta) band of hippocampal EEG in both FF-lesioned and sham-operated rats
These results suggest that a selective alpha-2 antagonist may improve cognitive dysfunctions related to aging.

508.4

INVOLVEMENT OF PERIPHERAL AND CENTRAL β-NORADRENERGIC RECEPTORS IN MEMORY STORAGE. **I. B. Introini-Collison, D. Saghafi* and J.L. McGaugh. Ctr. Neurobio . Learning/Memory and Dept. Psychobiology. U.C. Irvine.**

Peripheral administration of epinephrine modulates memory in a time- and dose-dependent manner. Since epinephrine does not readily cross the blood-brain barrier, it is not likely that it exerts its effects directly in the central nervous system. The present experiments compared the effects of epinephrine and dipivefrin (DPE) on retention of an inhibitory avoidance task and a reversal visual discrimination task in mice. The most effective dose of epinephrine for inducing memory facilitation was 0.1 mg/kg. DPE, a less polar analogue of epinephrine which has a higher tendency to cross membranes, also significantly facilitated memory for both tasks when administered posttraining. The dose-response curve also followed an inverted-U shape with 0.01 mg/kg most effective. The enhancing effects of DPE on memory appear to be mediated by central β-adrenoceptors: the centrally-acting β-noradrenergic antagonist propranolol, but not the peripherally-acting β-adrenergic antagonist sotalol, blocked DPE-induced enhancement of memory. However, sotalol did prevent the effects of epinephrine on memory, suggesting a peripheral site of action for epinephrine. α-Adrenoceptors do not appear to be involved in the facilitatory effects of either DPE or epinephrine on memory: the peripherally-acting α-adrenergic blocker phentolamine did not prevent epinephrine-induced enhancement of memory, while neither phentolamine nor the centrally acting α-adrenergic blockers prazosin or yohimbine blocked the facilitatory effects of DPE on memory. These results support the view that epinephrine initiates its facilitatory effects on memory through the activation of peripheral β-noradrenergic mechanisms, while DPE exerts its effects directly in the brain.

MEMORY IMPAIRMENTS WITH MEDIAL SEPTAL MORPHINE INJECTIONS: ATTENUATION WITH PERIPHERAL GLUCOSE INJECTIONS. M.E. RAGOZZINO, M.E. PARKER AND P.E. GOLD. Dept. Psychol., U. Virginia, Charlottesville, VA 22903.

ß-endorphin injected into the medial septum impairs spatial memory (Bostock et al., *Behav. Neurosci., 102*, 643). Peripheral glucose injections attenuate amnesias produced by several treatments, including opiate agonists. Here, we determined whether morphine injected into medial septum impairs memory in spontaneous alternation and inhibitory avoidance tasks and whether peripheral glucose administration attenuates the deficits. Rats received morphine sulfate (3 μg in 1 μl) into the medial septum 30 min prior to testing for spontaneous alternation performance. Morphine-treated rats had significantly lower alternation scores than did CSF-injected controls. Glucose (100 mg/kg, IP), administered at the time of morphine injection, blocked the impairment. With treatments as above, rats were subsequently trained in an inhibitory avoidance task and tested for retention 24 hr later. Morphine-treated rats had significantly lower retention scores than did controls and this impairment was reversed by glucose. Thus, morphine injected into medial septum impaired two measures of memory and both deficits were reversed by concomitant peripheral glucose administration. These findings are consistent with the view that circulating glucose levels, directly or indirectly, inhibit opiate functions in the medial septum. (Supported by ONR N0001489-J-1216 and NIA AG 07648).

PARALLEL EFFECTS OF THE NMDA ANTAGONIST NPC 12626 ON SLEEP AND MEMORY: REVERSAL OF THE MEMORY DEFICIT WITH NON-NMDA AGENTS. D.L. WALKER, W.S. STONE and P.E. GOLD. Neuroscience Program & Dept. Psychology, University of Virginia, Charlottesville VA 22903.

We previously demonstrated that NPC 12626 impairs spontaneous alternation (SA) and inhibitory avoidance performance as well as long-term potentiation. In the present study we characterized this drug's effects on sleep patterns. Rats were injected with NPC 12626 30 min prior to a 3-hr recording session. Sleep stages were defined by EEG, EMG, and activity measures. 10 but not 1 mg/kg significantly decreased total sleep (TS), paradoxical sleep (PS) bout duration and the PS/TS ratio. 10 but not 1 mg/kg also impaired the SA performance of these animals. The parallel effects of this drug on sleep and memory may reflect a more general impairment of arousal mechanisms important to both.

We previously found that glucose, naloxone, and physostigmine attenuate SA deficits produced by a variety of treatments. In this study we similarly attempted to reverse NPC 12626 - induced deficits. Mice were injected with NPC 12626 (35 mg/kg) 50 min prior to SA testing, and glucose (250 mg/kg), physostigmine (0.01 mg/kg), or naloxone (1 mg/kg) 30 min prior to testing. Each drug reversed the effects of NPC 12626 without having any effect when administered alone. Thus, some effects of NMDA antagonists can be ameliorated by non-NMDA treatments. We are currently assessing the effects of these treatments on NPC 12626 - induced sleep deficits. (Supported by AG 07648 and ONR N0001489-J-1216; NPC 12626 generously provided by NOVA Pharmaceuticals).

508.7

GLUCOSE ENHANCEMENT OF MEMORY IN ELDERLY HUMANS: C.A. MANNING, M.W. PARSONS and P.E. GOLD. Dept. Psychology, U. Virginia, Charlottesville VA 22903.

Glucose improves performance on secondary memory tasks in elderly humans. To dissociate glucose effects on storage from acquisition, we examined the effects of posttraining glucose on memory in elderly humans. In addition, a preliminary dose-response curve of glucose effects on memory was carried out.

Subjects aged 60-81 (n=23) heard a narrative passage and were given immediate posttraining or pretraining glucose, or saccharin. Recall, tested 24 hours later, was significantly better in both glucose conditions than in the saccharin condition. Next, adults aged 60-82 (n=10) were given beverages with 10g, 25g or 50g glucose and 50.6 mg saccharin. After ingestion, subjects took memory tests previously enhanced by glucose. The 25g glucose dose significantly improved performance relative to saccharin with a trend for improvement at the 10g dose.

These studies further define the effects of glucose on human memory. The finding that posttraining glucose enhances memory suggests that the treatment acts on memory storage processes. Glucose enhancement of memory outlasts the increase in blood glucose levels, as seen in the 24-hour recall enhancement with both pre- and posttraining glucose. Finally, the selective enhancement at 25g suggests that, as in animal studies, glucose effects on memory are characterized by an inverted-U dose-response curve. (Supported by AG 07648 and ONR N0001489).

THE MEMORY RETRIEVAL EFFECTS OF IDAZOXAN DEPEND ON THE DEGREE OF FORGETTING. M. Bunsey, J. Horne* and B.J. Strupp. Division of Nutritional Sciences and Department of Psychology, Cornell University, Ithaca, NY 14853.

We previously observed that the effect of AVP4-9 on memory retrieval is critically dependent on the accessibility of the memory at the time of injection. A single dose of the peptide enhanced memory at long retention intervals when memory was weak in control rats and impaired memory at short retention intervals, when memory was strong in controls. This pattern of results suggests that the injected peptide was interacting with endogenous changes corresponding to the strength of the memory. Using the same protocol and memory test (social learning paradigm), the present study was designed to determine if this same pattern of results would be produced by pretest administration of a drug that increases norepinephrine (NE) release, the α_2 antagonist idazoxan (IDA). This hypothesis was based on the evidence that: (1) the mnemonic effects of VP are mediated, in part, by catecholamines, (2) changes in central NE metabolism at retrieval have been shown to correlate to recall, and (3) retrieval has been shown to be facilitated by IDA. Pretest IDA (2 mg/kg) produced the same pattern of results as previously observed with AVP4-9, suggesting that endogenous NE activity at the time of recall varies with accessibility of the memory.

508.9

THE EFFECTS OF ESSENTIAL ELEMENTS ON LEARNING AND MEMORY IN MICE. Q.S. Deng and Y. Yin*. Dept. of Pharmacology, Nanjing Tie Dao Medical College, Nanjing, China 210009

Previous studies showed that essential elements are universally required for survival (Frieden E. Biochemistry of the essential ultratrace elements. Plenum Press, 1984). We have examined the hypotheses that learning and memory are closely related to some essential elements. Studies were conducted by testing of mice in an Y-maze. Male mice (25-32 g) were divided into 10 groups (N=15 in each group). Animals were fed with standard food but different water containing various essential elements. The Choice accuracy which was the number of correct choice in 10 trials was determined after 3 weeks. Those elements: Na (5.4×10^{-2} M), Mg (1×10^{-1} M), Cu (1.6×10^{-4} M), and Fe (2.7×10^{-5} M), increased the choice accuracy significantly. However, others (Cl, Mn, Zn, Al, K and tap water) did not affect choice accuracy. The results of the present study suggest that some essential elements (Na, Mg, Cu and Fe) have positive effects on leaning and memory in mice. (supported by Natural Science Foundation of China #0389001).

SCOPOLAMINE INTERACTIONS WITH SELECTIVE D1 AND D2 AGONISTS AND PERFORMANCE IN THE RADIAL-ARM MAZE. E. D. Levin and J. E. Rose. Department of Psychiatry, Duke University Medical Center, Durham, NC 27710.

There is evidence for a reciprocal interaction of dopaminergic (DA) mechanisms with muscarinic systems in terms of cognitive function. The adverse effect of scopolamine in the radial-arm maze (RAM) choice accuracy can be counteracted by DA blockade. This study examined the interactions of D1 and D2 agonists with scopolamine effects on RAM choice accuracy. Eleven adult female Sprague-Dawley strain rats were injected (SQ) 20 minutes before testing with normal saline, scopolamine (0.15 mg/kg), the D1 agonist SKF 38393 (2 and 4 mg/kg), the D2 agonist quinpirole (0.04 and 0.08 mg/kg) and each of the D1 and D2 agonist doses with scopolamine. None of the doses of the D1 and D2 agonists by themselves showed signs of reducing choice accuracy. The D2 but not the D1 agonist slowed the rate of responding. Scopolamine by itself caused both a decline in choice accuracy and an increase in choice latency. These effects were not counteracted by either the D1 or D2 agonist. In fact, the D2 agonist showed greater than additive effects in slowing the rate of arm entries. There was an indication that the D2 agonist in combination with scopolamine caused a further decline in choice accuracy. This effect of exacerbating the effect of scopolamine-induced choice accuracy impairment contrasts with the D2 agonist reversal of the RAM choice accuracy impairment caused by the nicotinic antagonist mecamylamine. AMPHETAMINE EFFECTS ON JUMP-UP AVOIDANCE AND CAUDATE DOPAMINE METABOLISM AS MEASURED BY HPLC IN VIVO DIALYSIS P.H. Janak, S. Shibanoki*, K. Ishikawa* and J.L. Martinez, Jr. Dept. of Psychology, Univ. of California, Berkeley CA & *Dept. of Pharmacology, School of Medicine, Nihon Univ., Tokyo, JAPAN

Each day for 2 days rats received 1 avoidance trial using a 290uA footshock delivered to the floor of an automated shelf-jump box 10 s after placement in the chamber. Rats were allowed to escape shock delivery by jumping onto a raised shelf. Immediately after each training trial, animals received AMPH or saline, IP. Retention was tested by training to a criterion 24 hr later. AMPH (1 mg/kg) facilitated acquisition of the jump-up response ($F(1,7)=10.53$ $p<.02$). In separate animals implanted with cannulas, caudate dopamine (DA), DOPAC and HVA levels were measured following IP injection of AMPH. Dialysate samples were collected at 20 min intervals for 3 hr after injection and assayed with HPLC-ECD. A 1 mg/kg dose increased striatal DA levels 20-40 min after injection to 518+71.85% of baseline. DOPAC and HVA decreased 40-80 min postinjection by 39+2.67% and 66+3.83%, respectively. Supported by DA06192 DA04795 and DA05375.

D-AMPHETAMINE INCREASES STRENGTH BUT DOES NOT DECREASE LATENCY OF SPINAL FIXATION IN RATS. M.J. Bartelt, A.G. Hutchins*, L.E. Kerns*, J.M. Guidetti*, and M.M. Patterson Department of Psychology and College of Osteopathic Medicine, Ohio Univ. Athens Ohio, 45701

It has been demonstrated that lasting hindlimb flexion (spinal fixation) may be induced by external stimulation to the upper right hindlimb in spinalized rats (Steinmetz *et. al., J.C.P.P.,* 95:4, 548-555, 1981). Temporal parameters of spinal fixation were examined by Steinmetz, *et. al.,* (*J.C.P.P.,* 96:2, 325-327, 1982). In 1989, Bartelt *et.al.* (*Neurosci. Abst.*,15:467, 1989) found d-amphetamine to significantly increase the amount of hindlimb asymmetry. The present study was done to establish the temporal parameters of spinal fixation under d-amphetamine.

In the present study, 70 rats were anesthetized with Nembutal (50 mg/kg i.p.) and randomly assigned to one of seven groups of 10, 20, 25, 30, 40,45, and 50 minutes stimulation time. Animals were administered d-amphetamine (2mg/kg i.p.) 15 minutes prior to stimulation and then spinalized at T7. Immediately following upper hindlimb stimulation (3-4mA, 100-pps, 7msec, repetitive dc pulses), fixation was measured as the amount of weight needed to remove hindlimb asymmetry.

Results show a generalized increase in the asymmetry for all time groups when compared to results of Steinmetz, *et.al.,* 1982. with a noted plateau of asymmetry occurring between stimulation times of 30 and 45 minutes. The asymmetry strengthening effect of the d-amphetamine increased with increases in time of stimulation. This work supports earlier work by Bartelt *et.al.* ,1989, which suggested catacholamine involvement in the fixation. Further work will include a dose-response evaluation of d-amphetamine.

508.13

FACILITATION OF LEARNING AND MEMORY FOLLOWING ADMINISTRATION OF THE 5-HT3 RECEPTOR ANTAGONISTS ZACOPRIDE AND DAZOPRIDE IN MICE. H. J. Altman[1] and R. F. Berman[2], [1]Department of Psychiatry, Wayne State University School of Medicine, Detroit, MI 48207, [2]Department of Psychology, Wayne State University, Detroit, MI 48202.

Recent evidence points to the existence of multiple serotonin (5-HT) receptor subtypes within the CNS. Presently, three major subtypes of 5-HT receptors have been identified - designated 5-HT1, 5-HT2 and 5-HT3. Over the past several years this laboratory has been systematically investigating the role(s) each of these purported 5-HT receptor subtypes may play in the mediation of the processes underlying learning and memory. The purpose of the present series of studies was to examine the effects of acute pre-training and/or pretesting blockade of 5-HT3 receptors on learning and memory in mice trained in a shock-motivated Y-maze visual discrimination task and a one-trial inhibitory avoid ance task. Significant improvements in learning and/or memory were seen in both tasks, thus providing evidence for a possible role for 5-HT3 receptors in the mediation of the processes underlying learning and memory in mice trained in these two tasks.

508.14

EFFECTS OF COMBINED CHOLINESTERASE INHIBITION AND SEROTONERGIC RECEPTOR BLOCKADE ON AGE-RELATED INHIBITORY-AVOIDANCE RETENTION DEFICITS IN RATS. H.J. Normile and H.J. Altman. Dept. of Psychiatry, Wayne State Univ. Sch. of Med., Detroit MI 48207

We recently reported that post-train administration of serotonergic receptor antagonists attenuated avoidance retention deficits normally exhibited by aged rats. In the present study, we determined whether subeffective doses of one such antagonist, ketanserin, would augment the facilitative effects produced by the cholinesterase inhibitor, physostigmine, on memory in aged rats using the same task. The drugs were injected ip alone, or in combination, immediately following training. Retention testing occurred 24 hrs following training. A dose-dependent enhancement of memory was demonstrated as a result of the three treatment conditions (i.e., ketanserin, physostigmine, ketanserin + physostigmine). The facilitation of memory produced by the combined treatment was observed at doses well below those required to produce a similar effect when each drug was administered alone. The results provide additional evidence for an interaction between the cholinergic and serotonergic neurotransmitter systems in learning and/or memory, and may have important implications in the treatment of geriatric-related cognitive disorders. (Supported by NIA grant #AG07069 and ADRDA grant #RG87087).

p-CHLOROAMPHETAMINE'S MEMORY IMPAIRING EFFECTS IN RATS ARE DUE TO SEROTONERGIC RELEASE NOT DEPLETION. A.C. Santucci, R. Gluck*, J. Bangston*, M. Gerard* and V. Haroutunian. Bronx VAMC & Mt. Sinai School of Medicine, New York, NY 10468.

The present investigation examined whether the memory impairing effects of p-chloroamphetamine (PCA) are due to the drug's serotonergic release or depletion consequences. In Expt. 1, rats received PCA or saline at various intervals before passive avoidance training and were then tested 24 hr later. Results indicated that PCA (2.5 mg/kg) impaired retention relative to saline-injected controls only when the drug was given shortly (15 min - 2 hr) before training (ps < .05). In Expt. 2, animals were prepared with 5,7 DHT (30 μg/2 μl, DMI pretreatment) or sham lesions of the nucleus basalis of Meynert (nbM). Two weeks postoperatively subjects were administered 2.5 mg/kg PCA or saline 30 min prior to passive avoidance training and were then tested 72 hr later. Retention deficits were observed only in rats treated with PCA irrespective of the animal's lesion status (ps < .05). However, both the PCA treatment and the 5,7 DHT lesion procedure produced stern serotonergic depletions in the frontal cortex (44% - 66%) and in the nbM (50% - 85%) (ps < .05). It is concluded that the memory deficits following PCA administration are due to the drug's serotonergic release effects at sites other than the frontal cortex or the nbM.

RIPLEY'S "BELIEVE IT OR NOT!": AN HISTORICAL REPRESENTATION OF NEUROSCIENCE FACTS AND ARTEFACTS IN THE POPULAR PRESS. R.A. Johnson. Behavioral Neuroscience Program, Department of Psychology, UCLA, Los Angeles, CA 90024.

In 1918, New York sports cartoonist Robert Ripley published the first of what would prove to be untold thousands of facts and factoids, under the rubric "Believe It or Not!" (BION). In his worldwide pursuit of truth that was stranger, or at least more interesting, than fiction, Ripley could not help but encounter and advertise some of Neuroscience's more intriguing anecdotes and artefacts. He and his successors presented these in over 300 newspapers in 17 languages, to a circulation reaching at one point 80 million, in the same stylized black and white illustrations and exclamation-pointed statements as his other claims.

Ripley's biographers have noted that "his was a mind uncluttered by culture", and that he had "the curiosity of the unlearned". He was interested in the fascinating, the curious, and the bizarre, with often-reprinted neuroscience oddities such as Phineas Gage and trephined skulls falling among the steady stream of topics teasing the public's seemingly insatiable appetite for anecdotes and minutiae. The popular impact of BION is undeniable; BION was a national institution, a forerunner of modern tabloids in the appreciation of the *facts* of science without consideration of the scientific *process*, but with a reputation for scrupulous documentation of its claims.

This poster is the beginning of a project examining the popular representation and perception of Neuroscience. Neuroscience-themed BION panels will be presented, compared with their original sources, and examined with respect to salience of interpretation and accuracy of content. Attendees of the Annual Meeting will be invited to recollect and discuss encounters with BION and other popular sources, especially as the popular accounts sparked personal interest in the neurosciences.

THE HERRICKS AS NEUROSCIENTISTS. II. CHARLES JUDSON HERRICK 1868-1960. L. H. Marshall and H. W. Magoun, Brain Research Institute, UCLA, Los Angeles, CA 90024.

The youngest of four brothers who were reared on a frontier midwestern farm that provided the major subsistence for the Baptist minister's family, Charles Judson Herrick assimilated nature, a Christian attitude, and intellectual expectations. He followed his ten-years-older brother, Clarence, to Denison University and the University of Cincinnati and returned to Denison to be associated with him in a new graduate biology program. Charles Judson received his Ph.D. from Columbia University in 1900. After he returned to Denison, he continued a commitment made in 1894 that was of greatest importance to the progress of neuroscience: managing editorship of the Journal of Comparative Neurology, when Clarence became desperately ill. For 30 years he was the journal, setting type when necessary. Called to the University of Chicago in 1907, Herrick began teaching medical students. He also organized a graduate course that attracted students and faculty from many disciplines. Herrick's writings became prominent after he retired in 1934, the happiest and most fruitful years of his career. His most important publication was The Brain of the Tiger Salamander (1948). Not content solely with descriptive research in elegant detail, Herrick explained and amplified his ideas in psychobiology, to "... find out what these animals do with the organs they have and what they do it for.... "

509.3

THE HERRICKS AS NEUROSCIENTISTS I. CLARENCE LUTHER HERRICK 1858-1904. H. W. Magoun and L. H. Marshall, Brain Research Institute, UCLA, Los Angeles, CA 90024.

Clarence Luther Herrick was born near the thriving frontier village of Minneapolis, Minnesota. His interest in nature and intellectual precocity led him, with three adolescent friends, to form the Young Naturalists Society, with serious papers delivered at regular meetings throughout their high school period. By graduation from the University of Minnesota, he had published five articles on natural history topics in scientific journals. During a year's postgraduate study in Leipzig, Herrick translated Rudolf Hermann Lotze's booklet, Outlines of Psychology (1881). As professor of natural history at Denison College Granville, Ohio, he formalized in his teaching and writing his concepts of psychobiology, and realized the productiveness of the ontogenous and phylogenous approach to the brain-mind problem. Three years in Cincinnati saw the peak of his research career and the launching of the Journal of Comparative Neurology in 1891. An aborted appointment at the new University of Chicago held great hopes that Herrick would be able to form a department integrating interdisciplinary studies in neuroscience. The University president, William Rainey Harper, reneged on several promises, however, and Herrick felt he could only resign. When tuberculosis struck, he went to New Mexico and became briefly the first president of its university. He died there at 46 years of age.

PRESERVED PRIMING OF NOVEL STIMULI IN AMNESIA: EVIDENCE FOR MULTIPLE MEMORY SYSTEMS. M.E. Smith (1,2) & M. Oscar-Berman (2). 1. Psychology, Texas A&M University, College Station, TX, 77843; 2. Boston Univ. School of Medicine.

Repetition priming of items with pre-existing codes in memory (e.g. words) might be mediated either by activation of those codes, or by new learning. In contrast, priming of novel stimuli (e.g. pseudowords) probably requires new learning. Consistent with the activation view, studies of perceptual identification (Cermak et al., 1985, Neuropsychologia) and stem-completion (Diamond & Rozin, 1984, J. Abnml. Psychol.) have found spared priming of words in amnesia, but impaired priming of pseudwords. In the present study we measured repetition priming of words and pseudowords in a lexical decision task, comparing data from 8 Korsakoff amnesic patients and matched control subjects. We also found normal priming of words and no priming of pseudowords in amnesia, but only for RT data. The amnesics patients also demonstrated an enhanced tendency to misclassify repeated pseudowords as words. This indicates a preserved ability to acquire novel information in amnesia, and is consistent with multiple memory-system theories (e.g. Tulving & Schacter, 1990, Science).

HUNTINGTON'S PATIENTS LEARN MOTOR ASSOCIATIONS, BUT NOT MOTOR SEQUENCES. D. B. Willingham and W. Koroshetz. Dept. of Psychology and Dept. of Neurology, Harvard U. and Mass. Gen. Hosp., Cambridge, MA 02138.

The striatum is implicated in motor learning (Heindel, et al, 1989). The present work tested motor learning in Huntington's Disease (HD) to test whether the striatum subserves learning all motor skills or only a subset.

In Experiment 1 one of four lights appeared, and subjects pushed a button below the light. Subjects were not told that the sequence of lights repeated. Control subjects were unaware of the sequence, yet showed sequence-specific learning by response times that decreased, then increased when switched to random lights. HD patients did not show sequence-specific learning.

Experiment 2 eliminated the repeating sequence and made the stimulus-response mapping incompatible. Under these conditions HD patients learned the task normally.

Striatal damage affects tasks requiring association of visual cues and motor responses, but not tasks based on sequences of responses. This dissociation suggests independent subsystems of motor learning. We hypothesize that the striatum sets up rapid, open-loop sequences of movements, possibly through connections with supplementary motor cortex. Somatosensation, not vision or kinesthesia, guides these movements. The association of visual cues and motor responses operates independently of the striatum, possibly in premotor cortex (Passingham, 1985).

VISUAL RECOGNITION MEMORY IN 8- AND 12-MONTH OLD HUMAN INFANTS. M.H. Kates and M. Moscovitch, Dept. of Psychol. U. of Toronto, Erindale Campus, Mississauga, Ont., Canada L5L 1C6

A direct reinforcement version of a delayed non-matching-to-sample task (DNMS) was used to assess visual recognition memory in 48 8- and 80 12-month old human infants. The task involved allowing infants to become familiar with a toy, and then recording whether an infant reached for the novel or familiar toy in a pair. Each session included 12 or 18 trials with no delay and either 40, 80, or 200 sec. between familiarization and test. In addition, the delay period was either unfilled or filled with interference caused by presenting other toys for later testing. When the delay period was unfilled, both groups successfully chose the novel toy at the 80 sec. delay interval. However, when interference was interpolated during the delay, the 8-month olds performed at chance at the 80 and 200 sec. delays, whereas the 12-month olds performed well above chance, although some forgetting was noted. The performance of infant humans on DNMS is compared to that of normal infant monkeys and adult monkeys with hippocampal lesions. It is suggested that by 12 months of age, but not by 8 months, the human hippocampus is sufficiently developed to mediate performance across long delay intervals filled with interference.

FURTHER CHARACTERIZATION OF THE VISUAL PROCESSING DEFICIT IN NEPHROPATHIC CYSTINOSIS. S.N.Nichols*,A.O.Ballantyne*, B.L.Hodge* and D.A.Trauner. Dept. of Neurosciences, Univ. of California, La Jolla, CA 92103

Previous studies have demonstrated an isolated deficit in visual processing in children with infantile nephropathic cystinosis, a hereditary lysosomal storage disorder. Children with this disorder appear to have difficulty both with visual memory and with manipulation of mental images. In order to further characterize the problem, 11 children with cystinosis and 11 matched controls were studied using a visual memory task, the Benton Visual Retention Test (VRT).

Cystinotic subjects made significantly more errors involving reproduction of internal details of figures on the VRT than did controls (1.9±1.6 vs. 0.9±1.1, p=.02). The 2 groups did not differ significantly in their tendency to distort the overall shape of the figures. Preliminary analyses of 2 other tasks, Gollin Incomplete Figures and Closure Speed, suggest that cystinotics may perform more poorly on tests involving identification of incomplete figures, a skill requiring integration of detail.

These data suggest that children with cystinosis may be impaired in their ability to maintain details of an image in memory or to form an accurate mental image when incomplete visual information is presented.

509.8

PROCESSING OF SPATIAL RELATIONS WITHIN AND BETWEEN THE DISCONNECTED CEREBRAL HEMISPHERES. J. Sergent. Montreal Neurological Institute, McGill University, Montreal, Canada.

This study examined 3 issues related to the processing of spatial relations by commissurotomized subjects. (1) The respective competence of the disconnected hemispheres at performing judgments of relative position and distance between two objects was tested. The results showed that the two hemispheres were equally competent at representing and operating on these spatial-relation representations. (2) The capacity of the disconnected hemispheres to operate conjointly was then examined. The two disconnected hemispheres were simultaneously stimulated with the same information and had to produce a single response based on this information. Compared to unilateral stimulations, bilateral stimulations resulted in enhanced response accuracy and, depending on the type of decision, in patterns of response latency and accuracy different from the patterns of either unilateral condition. These results suggest that the two disconnected hemispheres can operate simultaneously and are able to join the outcomes of their respective operations before the production of a single response. (3) Interhemispheric communication of visuospatial information was studied. Unlike pattern information that is typically confined to the hemisphere that receives it in the commissurotomized brain, visuospatial information could be subjected to interhemispheric comparison as a function of its categorical and metric properties, although the patients had only implicit knowledge of part of the transferred information.

NORMAL ORGANIZATION OF CATEGORY KNOWLEDGE IN ALZHEIMER'S DISEASE. A. Cronin-Golomb, A. Kokodis*, S. Corkin, J.H. Growdon. Dept. of Brain and Cognitive Sciences, MIT, Cambridge MA 02139, Dept. of Psychology, Boston University, Boston MA 02215, and Dept. of Neurology, Massachusetts General Hospital, Boston MA 02114.

Deficits in category knowledge in Alzheimer's disease (AD) may be attributable to a disruption in underlying organization, or to impaired retrieval of correctly organized information. We addressed these alternative possibilities with 3 tasks: (1) category decision (Is __ a member of [category]?), (2) ranking of category exemplars by typicality (e.g., airplane>tractor>sled as 'typical' types of vehicles), and (3) fluency (name as many members of [category] as possible in 1 minute). Comparisons of 18 patients with AD, who varied in dementia severity, and 14 age-matched control subjects (CS) revealed highly similar patterns of performance. Certain of the 10 categories proved more difficult than others in all 3 tasks. The correlation between AD and CS performance was 0.83 for Task 1, 0.88 for Task 2, and 0.98 for Task 3. The pattern similarity existed despite other group differences, e.g., slower reaction times for AD than CS in Task 1, and production of fewer items by AD than CS for Task 3. The results suggest that, although retrieval of category information is impaired in AD, the underlying organization of category knowledge is normal.

COGNITIVE ABILITIES IN LESBIANS. C.M. McCormick and S.F. Witelson, Departments of Psychology and Psychiatry, McMaster University, Hamilton, Canada.

We previously reported an increased prevalence of non right-hand preference in homosexual women and interpreted the result as evidence that atypical cerebral asymmetry is a factor in homosexuality (McCormick et al., 1987, 1990). In the present study, we compared homosexual females to heterosexual females and males (n = 31 per group), matched for hand preference, on cognitive tests that typically reveal differences between males and females (spatial ability, fluency). Previous results with homosexual males (Witelson & McCormick, 1989) indicated lower spatial ability and higher fluency in homosexual males than in heterosexual males. In contrast, no cognitive differences were found overall between homosexual and heterosexual females. However, among non right-handed subjects, homosexual females scored lower on cognitive tests than did heterosexual females. These results are examined with reference to neuropsychological studies of women exposed to atypical levels of prenatal hormones.

A COGNITIVE BEHAVIOURAL DEFICIT ASSOCIATED WITH HIV-SEROPOSITIVITY. B.D. Fantie§†, A.F. Mirsky†, and R.T. Bowes*, §Neuropsychology Laboratory, Department of Psychology, The American University, Washington, D.C. 20016-8062, and †Laboratory of Psychology and Psychopathology, National Institute of Mental Health - Intramural Research Program, Bethesda, MD 20892.

Although there is clear evidence that the brain is a primary site of human immunodeficiency virus (HIV) infection, controversy exists concerning whether the early presence of HIV is associated with any concomitant cognitive or behavioural dysfunction detectable through standard neuropsychological assessment. In this preliminary report we present three cases of such a deficit, manifesting as an alteration in the ability to perform the Wisconsin Card Sorting Task (WCST), in a population of young adults likely to be particularly vulnerable to central nervous system compromise. In contrast to 14 seronegative controls, 3 HIV+ patients showed a decline in performance on certain components of the LPP-Attention Battery during a 3-6 month follow-up session. Specifically, they completed fewer categories and made more 'Failure to Maintain Set' errors on the WCST in comparison to both controls and their own initial performance. Their scores on other tasks either remained stable or improved across sessions, indicating that the decline on the WCST was unlikely to be the result of some general motivational effect. There is great practical importance in the early detection of cognitive/behavioural dysfunction associated with HIV seropositivity.

LAUGHTER: SOCIAL CONTEXT, STRUCTURE, AND CONTAGION. R. R. Provine. Dept. of Psychology, Univ. of Maryland Baltimore County, Baltimore, MD 21228.

Laughter is an ubiquitous, species-typical human signal and motor act. Laughter is almost exclusively social, even more so than smiling and talking; it occurs 30 times more frequently in social than in solitary settings. Laughter is characterized by stereotyped laugh note duration ("ha") and inter-note-interval ("ha-ha-ha...."). This stereotypy contributes to the acoustic signature of laughter and is the stimulus for laugh-induced ("contagious") laughter. Although the contagiousness of laughter is widely known and has even spawned the technology of the "laugh track" on broadcast comedy shows, the ramifications of this extraordinary behavior for human brain function have not been appreciated. The potent contagious laughter effect suggests that humans have evolved a neurological acoustic feature detector that evokes laughter when triggered by a stimulus having the unique stimulus properties of laughter. The stereotypy of laughter as an acoustic stimulus and motor act and the presence of the contagious laughing effect suggests that modular mechanisms are involved in both laugh production and reception. These data provide insights into the curious behavior of laughter, the evolution of language, and a variety of issues in cognitive neuroscience.

DOSE EQUIVALENCY: A HUMAN BEHAVIORAL BIOASSAY TECHNIQUE. R. S. Kennedy, J. E. Fowlkes*, W. P. Dunlap,* and Janet J. Turnage*. Essex Corporation, Orlando, FL 32803.

It is a well-known fact that human performance is impaired by drugs, toxic elements, environmental stress, illness, emotional strain, and nutritional deficits. Scientific study of how these factors influence performance in the workplace is hindered by the lack of suitable metrics. In a series of experiments, various treatments (e.g., halon, hyoscine, hypoxia, alcohol) and holistic measures of mental acuity (WAIS, ASVAB, Wonderlic, ACT) were given to various groups of subjects. An Automated Performance Test System (APTS) battery of repeated-measures cognitive, perceptual, information-processing, and motor tests was also administered in standardized format in all the studies. Using APTS scores as predictors, regression equations were calculated to determine performance impairment as a function of alcohol dosage (the criterion) in one carefully graded experiment. Performance decrement was correlated with blood alcohol level (r = .88) using a composite APTS score. Regression equations were then calculated for these same tests using the holistic intelligence measures. Then the dozen sensitivity studies, using various drugs, were translated into the effects that those agents had on mental activity using as a transform the performance test battery regression equations. The ability to use such a dose equivalency method to conduct human performance bioassays is discussed as it relates to neuroscience research and for practical workplace decisions.

DECOUPLING OF PET MEASURED LEFT CAUDATE AND CORTICAL METABOLISM IN ADULT DYSLEXIA. P. Tallal, F. Wood*, M. Buchsbaum*, L. Flowers*, I. Brown and W. Katz*. Center for Molecular and Behavioral Neuroscience, Rutgers Univ., Newark, N.J. 07102.

Positron Emission Tomography (PET) was used to investigate neural mechanisms underlying speech processing disorders in reading impaired (dyslexic) subjects. Ten adult dyslexics, as defined by childhood reading and IQ scores, and ten controls were compared on glucose utilization values obtained from PET reflecting brain activation during a continuous auditory syllable detection and discrimination task. In controls, the glucose utilization values in either caudate were highly correlated with values in all cortical regions, especially those in frontal and temporal areas. In dyslexics, however, correlations were significantly attenuated, and most correlations between left caudate and other cortical regions were near zero. The differences between the correlations in the dyslexics and in the controls were significant at p less than .05.

The results are interpreted in light of our previous report from an MRI study of smaller caudate volumes in language impaired children (Jernigan, T., Tallal, P., and Hesselink, J., Am. Acad. of Neurol., 1989), and in light of theoretical implications for the role of caudate activity in language processing.

ELECTROCORTICOGRAM COHERENCE AND CORRELATION OF AMPLITUDE MODULATION BETWEEN ELECTRODES BOTH DECLINE IN MILLIMETERS IN HUMAN AS WELL AS IN RABBIT BRAINS. T.H.Bullock, V.J. Iragui* and J.F. Alksne*, Dept. of Neurosciences, U.C.S.D., La Jolla, CA 92093.

Coherence is not typically widespread over the cortex; it may have a significant microstructure. Metal disc electrodes 5-10 mm apart, embedded in plastic strips, inserted under the dura over frontal, parietal and temporal lobes of epilepsy patients recorded electrocorticogram (ECoG) during sleep, wakefulness and seizures. We computed coherence (Coh) for frequencies (F) 1-80 Hz between all 120 pairs among 16 electrodes and plotted Coh vs distance (D) between electrodes, pooling lobes but not states or patients. Averaging over many sec, Coh declines monotonically with increasing D, for all Fs. Coh vs F shows no consistent pattern; differences in Coh with F are commonly slight. Though widely different among subjects and electrode sites, a roughly median value of 5-15 mm for Coh=0.5 in humans compares with 2.5-5 mm reported for rabbits (T.H. Bullock & M.C. McClune EEG Clin. Neurophysiol. 73:479-498, 1989). This is probably the best measure of the degree of synchronization in domains of cortex. Between slow-wave sleep and alert states differences in these values are slight. Another dynamic feature, quite distinct from Coh, is the correlation between electrode loci of the amplitude modulation (AM) of narrow ECoG bands. For 6 bands, 1-4, 4-8, 8-13, 13-19, 19-30, 30-45 Hz, we computed AM envelopes, low-passed these to 4 Hz, correlated (AMCor) each pair of electrodes, and plotted this value vs D. AMCor declines with D; at 10 mm mean values are usually 0.4-0.6 for all Fs, slightly more for the lowest; at 20 mm <0.1-0.4; at 30 mm some correlations are just significantly negative. It remains to learn whether these two aspects of cooperativity covary with state or region.

509.16

CURRENT-DENSITY IMAGING AS A METHOD OF VISUALIZING NEURONAL ACTIVITY OF THE BRAIN. Y. C. Okada, J.-C. Huang*. VA/LANL/UNM Center for Magnetoencephalography, VA Medical Center and Dept. Neurology, Univ. New Mexico Sch. of Med., Albuquerque, NM 87108

In magnetoencephalography (MEG) the neuronal generator giving rise to the magnetic field outside the head is commonly represented by a current dipole. In contrast we have investigated the application of MEG as a method for obtaining an image of current densities as a functional map of neuronal activity in the brain. Here we describe a hierarchical deconvolution algorithm for current imaging. As in the linear estimation procedure this method starts with the solution of the linear matrix equation of the form: B=AJ, where B is the vector containing the component of the magnetic field data normal to a field plane, J is a vector of current densities lying tangentially on the source plane and A is the lead-field matrix. In the initial step, the source plane is divided into coarse grids. The solution for J is found from the generalized inverse of A equal to $(A'A)^{-1}A'$, where A' is the transpose of A. The magnitudes of J determines the grid pattern of the source plane to be used in the next step. Those grids containing large magnitudes are subdivided, whereas the rest is left undivided. Using this new grid pattern, the linear equation is solved again. The procedure is repeated iteratively until the minimum grid size becomes less than the spatial resolution of this method determined by the distance between the field and source planes. Simulations showed that this method requires 5-10 times less number of free parameters and faster than the straight-forward single-step, linear estimation technique. The solution is more stable with the former method in the presence of noise in the B field.

ANATOMICAL CONSTRAINTS FOR NEUROMAGNETIC SOURCE MODELS. **C.C.Wood, J.S. George, P.S. Lewis*, D.M. Ranken*, and L. Heller***. Neuromagnetism Lab., MS M715, Los Alamos National Lab., Los Alamos NM 87545.

The goal of neuromagnetic recording techniques is high resolution mapping of human brain activity. This goal requires the solution of an ill-posed inverse problem; namely, the determination of the number, location, spatial configuration, strength, and timecourse of the neuronal currents that give rise to the magnetic field distribution at the head surface. To help resolve ambiguities in the source modeling process, we are using a system for anatomical segmentation and volumetric reconstruction based on MR images (George et al., *Soc. Neurosci. Abs.*, 1989, 15:730) to investigate alternative strategies for constraining the locations of allowable sources. One strategy uses proximity to the local cortical surface to generate an error term that is incorporated into a standard least-squares minimization algorithm. Another strategy makes use of the fact that surface magnetic fields are a nonlinear function of location but a linear function of source orientation and current strength. Field distributions may therefore be expressed as linear combinations over a basis matrix including field amplitudes at each sensor location for unit current vectors in x, y, and z dimensions. A constrained basis matrix formulation can be combined with pseudo-inverse procedures such as the minimum norm lead field expansion to increase the anatomical realism of mathematical reconstruction procedures.

509.18

MULTI-SOURCE MODELING OF NEUROMAGNETIC DATA: SIMULATION AND EMPIRICAL STUDIES. **S. Supek* and C. J. Aine**. Physics and Life Sciences Divisions, MS M715, Los Alamos National Laboratory, Los Alamos, NM, 87545

A critical step in attempting to model the surface magnetic fields generated by the human brain is determining the number of sources (i.e., the "order" of the model). To address this question we conducted extensive simulation studies using point current dipole sources in a homogeneous spherical conductive medium in which the number, spatial configuration and strength of sources and amount of noise added were systematically varied.

Three approaches to the identification of model order from the simulated instantaneous magnetic field distributions were evaluated: (1) visual inspection of isofield contour maps; (2) comparison of percent of variance accounted for by single- versus multi-source models; and (3) examination of the reduced chi-square values (chi-square/degrees-of-freedom) for alternative models. When the true noise level is known, the reduced chi-square approach provides the most sensitive and valid means for determining model order. However this method is sensitive to both the accuracy of noise estimates (for empirical data) and the magnitude of the noise. For example, when the noise level is high, a chi-square test may indicate that a single source configuration could have generated a field pattern actually produced by multiple dipoles.

This approach has been applied to empirical neuromagnetic data elicited by the simultaneous and separate presentation of visual stimuli.

510.1

EFFECTS OF FOREBRAIN LESIONS ON DRINKING AND SALT APPETITE AFTER DOCA OR YOHIMBINE. D.A. Fitts. Dept. of Psychology, Univ. of Washington, Seattle, WA 98195.

Lesions of the ventral part of the ventral median preoptic nucleus (VVMnPO) enhanced daily salt appetite induced by sc injections of 0.5 to 5 mg/kg/day deoxycorticosterone acetate (DOCA), but had no effect on acute salt appetite or water intake after one sc injection of 5 mg/kg yohimbine (yohimbine method: Johnson, et al., Soc. Neur. Abs., 15, 964, 1989.) Lesions of the subfornical organ (SFO) had no effect on daily saline or water intakes during 3 mg/kg/day DOCA, but significantly reduced acute water intake after yohimbine. Pretreatment with a large dose of 100 mg/kg captopril ip did not significantly reduce either the water or saline intakes after yohimbine injections in normal rats, so these behaviors do not appear to depend on peripheral angiotensin synthesis. The findings demonstrate that the enhanced DOCA-induced saline intake in VVMnPO-lesioned rats is specific to lesions of the ventral lamina terminalis. By contrast, the VVMnPO lesion reduces salt appetite after angiotensin-related treatments such as captopril or sodium depletion, and has not been found to affect stimulated water intake (Fitts, et al., Behav. Neurosci., in press). SFO lesions do not affect salt appetite in daily intake tests, but do reduce acute or chronic water intake after treatments such as angiotensin, captopril or yohimbine. Supported by NS22274.

HEPATIC VAGOTOMY DOES NOT REDUCE THE SATIATING EFFECT OF A NaCl PRELOAD ON DEPLETION-INDUCED NaCl INTAKE. S.P. Frankmann, C.J. O'Connor* and G.P. Smith. Bourne Lab., Dept. of Psychiatry, New York Hospital-Cornell Univ. Med. Coll., White Plains, NY 10065.

The hepatic branch of the vagus nerve has been suggested to be necessary for the normal satiation of depletion-induced NaCl appetite (Tordoff et al., 1986, 1987). If this is true, removal of the hepatic vagus should result in 1) an increase in NaCl intake and 2) less decrease in NaCl intake when given a preload of NaCl. To test this, depletion naive, male, Long-Evans rats were given either sham (S, n=12) or hepatic (H, n=12) vagotomies. Following recovery, all rats were sodium depleted by Lasix (furosemide, 10 mg, sc) and overnight sodium-deficient diet and water. At 18 h later, half of each surgical group received no load (NL) or a load (L) of 7.5 ml of 0.5 M NaCl into the stomach. Ninety min later, the rats were offered 0.3 M NaCl and water in a 1-hr, NaCl-appetite test.

At the end of the first 15 min, the hepatic vagotomized group showed a normal NaCl intake (H/NL = 5.6±1.0 ml; S/NL = 5.9±0.9 ml) and a normal supression of NaCl intake to the preload of NaCl (H/L = 3.3±1.0 ml; vs S/L = 3.3±0.9). The preload produced a significant suppression of NaCl intake ($F(1,20)=7.96$, $p<0.01$), but there was no effect of surgical group ($F(1,20) = 0.29$, $p = 0.60$). At 60 min, there were still no significant differences between the H/L (4.0±1.2 ml) and S/L (3.3±0.9 ml) groups. The H/NL (6.5±0.85 ml) and S/NL (8.9±0.9 ml) groups were not significantly different ($F(1,10) = 3.18$, $p = 0.11$), although the intake from 15-60 min was 46.4% less for the H/NL group.

If the hepatic vagotomized rats had a more rapid emptying of the NaCl preload, this could obscure a satiety deficit. To test this, the rats were sodium depleted again and 90 min after the NaCl preload (1.48 mEq), they were anesthetized and their stomachs were removed. The stomach content volumes were measured and the sodium concentrations were determined by flame photometry. There were no differences in the residual stomach sodium content (mEq) between the two groups (S = 0.117 ± 0.043; H = 0.096 ± 0.042). Thus, under our conditions, the hepatic vagus was not necessary for a normal satiation of NaCl appetite.

SODIUM SENSITIVITY AND ORIGINS OF THE PRIMARY POLYDIPSIA OF THE INBRED MICE. K. Koizumi, K. Inenaga*, N. Akamatsu* and H. Yamashita. Depts. of Physiology, SUNY Health Science Center at Brooklyn and University of Occupational and Environmental Health, Kitakyushu, Japan.

The excessive drinking (5-8 times that of normal) of the inbred mice, STR/N, which is not due to lack of vasopressin nor renal dysfunction, was reduced to 35% of control level by low Na^+ diet (10% of regular food). Reduction in water intake began on Day-1 and continued for 9 days after the end of low Na^+ diet which was given for 18 days. In non-polydipsic S/W mice, water intake was reduced to 60% of the control from Day-10 to Day-18 only. Food intake was not much affected in both strains. Since osmolarity and Na^+ concentration of plasma are similar in both strains, the results suggest that the STR/N mice possess an abnormal set-point for Na^+ related to water intake. To test this hypothesis, in brain slice preparations responses of the AV3V-OVLT neurons to changes in osmolarity and Na^+ concentration of the bathing medium were studied using extracellular recordings. No significant differences in their responses were found between the STR/N and S/W. In both groups the neurons were inhibited by hypertonic and excited by hypotonic saline. Replacing Na^+ with mannitol or sucrose did not alter these responses, indicating that no difference existed in sensitivity of the neurons of both strains to Na^+. Our findings suggest that neurons located in the CNS other than in the AV3V may be involved in altered Na^+ sensitivity, or that other mechanisms play a role in the observed attenuation of the polydipsia by low Na^+ diet. (Supported in part by a grant from USPHS, NS-00847).

SODIUM APPETITE IN RATS AFTER DIETARY SODIUM DEPRIVATION: INHIBITION BY ESTROGEN. E.M. Stricker, E. Thiels and J.G. Verbalis. Depts. of Behavioral Neuroscience and Medicine, University of Pittsburgh, Pittsburgh, PA 15260.

Little sodium appetite is observed when rats are deprived of dietary Na for 4 days, presumably because aldosterone secretion minimizes renal Na losses. When Na deprivation is extended to 8 days, however, a spontaneous sodium appetite results in adult male rats that far exceeds their urinary Na losses during the deprivation period; they ingested 19 ± 2 ml of 0.5 M NaCl solution in 7 hr, which is as much NaCl as rats have ever been reported to drink rapidly. In contrast, female rats drank much less saline after 8 days of Na deprivation (8 ± 1 ml in 7 hr). Because of this sexual dimorphism in sodium appetite, we also studied NaCl intake in gonadectomized rats after 8 days of Na deprivation. Both male and female animals drank comparable amounts of saline as intact males but reverted to the low intakes of intact females when replaced with physiologic amounts of estrogen. These results indicate that a robust sodium appetite can be produced in rats by extended dietary Na deprivation, and that estrogen has a marked inhibitory effect on the induced sodium appetite under these conditions.

DEPENDENCE OF ANGIOTENSIN-INDUCED NACL INTAKE ON THE ANTEROVENTRAL WALL OF THE THIRD VENTRICLE, "AV3V". L.A. De Luca Jr.*, O. Galaverna*, J. Schulkin*, E. Stellar and A.N. Epstein. Depts. of Biology and Anatomy and Mahoney Inst. Neurol. Sci., Philadelphia, PA 19104.

The structures of the AV3V are rich in angiotensin (ANG) binding sites and may therefore be important for the participation of cerebral ANG in the ANG/aldosterone (ALDO) synergy that underlies increased salt intake in the rat. Sham operated (n=12) and AV3V (n=11, showing deficient dipsogenic response to pulse intracerebroventricular (pICV) ANG II and to s.c. 2 M NaCl) damaged rats were therefore evaluated for the natriorexigenic effects of 1) activation of brain ANG with 100 ng of pICV renin that increased 5 h 3 % NaCl and water intake in shams (8.0 ± 1.9 and 68 ± 13.0 ml, n=6) but not in AV3V (0.3 ± 0.3 and 10.0 ± 4.3 ml, n=6), 2) systemic deoxycorticosterone, DOCA, at 2.5 and 5.0 mg/day, for 3 days. AV3V animals responded to DOCA, but drank less NaCl (376 % vs 580 %) and, unlike shams, did not increase their water intake, and 3) sodium depletion (furosemide and removal of ambient Na for 24 h). Both groups expressed a Na appetite after Na depletion, but shams restored their deficit sooner and drank more water. Tissue in the AV3V and the medial amygdala (MAMY) (Schulkin et al., Behav. Neurosc. 103:1989) may be essential parts of the neural circuit for the ANG/ALDO synergy : AV3V for ANG action and MAMY for the action of ALDO. Supported by MH 43787 & NS 03469.

THE REVERSAL OF THE SODIUM CHLORIDE AVERSION OF FISCHER-344 RATS BY CHORDA TYMPANI NERVE TRANSECTION. S.I.Sollars* & I.L.Bernstein. Dept of Psychology, University of Washington, Seattle, WA 98195.

Fischer-344 (F-344) rats are atypical in their lack of a preference for any concentration of NaCl solution and their avoidance of NaCl solutions preferred by other rat strains. Whole nerve recordings from the chorda tympani (CT) indicate greater responsiveness of the CT to NaCl stimulation in F-344 rats than in other strains, such as Wistars. Moreover, the exaggerated CT response appears to be associated with greater sensitivity to the sodium channel blocker amiloride. This suggests that when F-344 rats drink NaCl solutions amplified signals from the CT may contribute importantly to their NaCl aversion. The present study examined whether the F-344 rat's NaCl aversion persists after bilateral transection of the CT nerve. In adult male F-344 rats the chorda tympani was sectioned bilaterally (CTX) or was exposed but not sectioned (SHAM). Two bottle preference tests were given to CTX and SHAM rats beginning two weeks after surgery. Concentrations of NaCl (0.6%; 0.8%; 1.0%) maximally preferred by other strains yet avoided by intact F-344 rats were used as the test simuli. At all concentrations tested, CTX animals preferred NaCl solutions to water. This preference differed dramatically from the avoidance of these solutions by SHAM animals. CT cuts in other rat strains have generally failed to significantly affect NaCl preference. That CTX animals preferred NaCl solutions, rather than just failed to avoid them, indicates that they continue to detect the taste of NaCl after CT transection. These findings are consistent with the hypothesis that the F-344 rat's aversion to the taste of NaCl solutions stems from input provided by the CT nerve, particular that component of the CT response which is sensitive to amiloride.

BILATERAL LESIONS OF THE CENTRAL NUCLEUS OF THE AMYGDALA: EFFECT ON SODIUM INTAKE. Q. Galaverna*, L.A. De Luca Jr*, J. Schulkin*, A. Epstein, University of Pennsylvania; E. E. Coons, New York University.

The central nucleus of the amygdala is the end-station in the ventral forebrain for taste visceral afferents and it is rich in angiotensin-containing terminals. It, therefore, may be an important structure in the neural network that mediates the angiotensin/ aldosterone synergy that underlies increased NaCl intake in the rat. Accordingly, the 3%NaCl and water ingestive behaviors of rats with bilateral ablation of the central nucleus of the amygdala were studied. After uneventful postoperative recovery of food and water intake: 1) daily need-free NaCl intake disappeared both in rats with no prior history of sodium depletion and in those whose intake had been enhanced by several depletions, 2) they did not drink NaCl, but did drink water, in response to SC mineralocorticoid (Mcort), (5mg/day of DOCA), 3) they drank water but did not drink NaCl after activation of brain angiotensin (Ang) with pulse intra-cerebroventricular injection of 100ng of renin, and 4) their NaCl intake after sodium depletion (lasix + removal of ambiant Na+) was blunted. Although its role in salt intake behavior is not yet clear, this work shows that NaCl, but not water intake, depends on intact central nucleus of the amygdala. In their absence, all forms of NaCl intake (need free, Ang-, Mcort-, and depletion-induced) are absent or markedly deficient.

CENTRAL ANGIOTENSIN II (ANG II)-RECEPTOR BLOCKADE REDUCES YOHIMBINE-INDUCED SALT APPETITE. R.L. Thunhorst, K.M. Riggins & A.K. Johnson, Univ. of Iowa, Iowa City, IA 52242.

Subcutaneous (s.c.) injection of the alpha-2 adrenergic antagonist yohimbine (YOH) rapidly produces salt appetite in sodium-replete rats. This effect survives nephrectomy, thus showing independence from the peripheral renin-angiotensin system. We tested for a role of central ANG II receptors by using central ANG II-receptor blockade with sar^1ile^8-ANG II (n=10) or sar^1thr^8-ANG II (n=10) in YOH-treated rats. Rats received lateral ventricular infusions of blocker (15 ug/hr) or vehicle. YOH (3.0 mg/kg) was injected s.c. after 1 hr, and central infusions continued for another 3 hr. Water and 0.3 M NaCl were present throughout. Tests were repeated, alternating the central treatment. Both ANG II-receptor blockers reduced saline, but not water, intakes to s.c. YOH (*p<.05).

	Cum 3 hr intakes after YOH				%
	Water	Saline	Total		Saline
Vehicle	6.1	4.3	13.1	ml	47
Sar^1Ile^8	11.6	1.5*	10.4	ml	15*
Vehicle	8.2	2.6	10.8	ml	22
Sar^1Thr^8	7.6	1.1*	8.7	ml	11*

Thus, central ANG II receptors are importantly involved in salt appetite after YOH treatment.

AGE-DEPENDENT TASTE PREFERENCES IN RABBITS FOR A SODIUM SACCHARIN SOLUTION. L.J. Dreshfield, L. Fabrigar* and S.D. Berry. Dept. of Psychology, Miami U., Oxford, Ohio 45056.

Preferences for water versus a .22% sodium saccharin solution were obtained for 12 young (4-6 mos., $\bar{X}$=4.7) and 12 old (31-69 mos., $\bar{X}$=53.4) New Zealand white rabbits. Both solutions were offered ad lib in the home cage, and positions were counterbalanced each day for four days. Data were collected an additional six days from many of the subjects to confirm stability of preference. Overall solution intake was not different between groups; older animals consumed an average of 371 ml per day, and younger animals consumed about 487 ml per day ($p < .127^3$). A subpopulation of both young and old animals exhibited a bottle position preference, so data from these animals were excluded from taste preference analysis. Young animals demonstrated a significant preference for water ($\bar{X}$ saccharin consumption 31.5% per day, N=7), while older animals strongly preferred the saccharin solution ($\bar{X}$ intake 78% per day, N=9, $p < .007$). These results suggest that aging increases preference for .22% saccharin solution in rabbits, and may have been responsible for mixed findings in previous taste preference studies. Therefore, we conclude that age is a variable that may affect the incentive value of rewarding stimuli and must be taken into account in studies of learning and motivational processes.

ANGIOTENSIN 1-7 POTENTIATES ANGIOTENSIN-INDUCED DRINKING. M.J.Sullivan, T.G. Beltz and A.K. Johnson. Ottawa Civic Hospital Research Institute Neuroscience Unit, Ottawa, Ontario, Canada, K1Y 4E9, and Departments of Psychology and Pharmacology and the Cardiovascular Center, Iowa City, Iowa 52242

Aminopeptidase inhibitors potentiate the pressor and dipsogenic effects of angiotensins, probably by inhibiting the degradation of the peptides. In this study we examined the ability of a fragment of angiotensin II (ANG II), angiotensin 1-7 (ANG 1-7), to increase the drinking responses to ANG II. Recent data suggests that ANG 1-7 may effect release of vasopressin (Schiavone et al., 1988) and that ANG 1-7-like immunoreactivity has been localized in rat forebrain (Block et al., 1988). Therefore, we re-examined the dipsogenic effect of the peptides and investigated the effects on fluid and Na balance. Rats were prepared with lateral ventricular cannulae. A dose-response curve to 0, 0.1, 1, and 10 nmol ANG 1-7 was generated. Other groups of rats received icv injections of ANG II with and without a 100-fold higher dose of ANG 1-7. A final group of animals was implanted with osmotic minipumps. Lateral ventricular infusions of artificial cerebrospinal fluid or 2 nmol/ul/hr ANG 1-7 were made and Na and water balance monitored. ANG 1-7 potentiated drinking responses to icv ANG II. As previously reported, ANG 1-7 was not dipsogenic at any of the doses tested nor did it induce salt appetite or affect Na or water balance. We conclude that ANG 1-7 potentiates the actions of ANG II by competing for degradation sites.

SURGICAL TRANSECTIONS OF POSTERIOR HYPOTHALAMIC CONNECTIONS: EFFECTS ON WATER INTAKE AND RENAL FUNCTION. K.M. Andrews*, M.K. McGowan, G.L. Robertson* & S.P. Grossman. Comm. on Biopsychology, Univ. of Chicago, Chi. IL

Transection of fibers in the posterior hypothalamus produces severe polydipsia which appears to result from disinhibition of a thirst regulatory mechanism. Rats subjected to coronal knife cuts (KC) drank 100-300% more than baseline and sham-lesion (SL) controls. Urinary output increased commensurately. Water intake was reduced similarly by nephrectomy and sham nephrectomy in KC rats, but was still higher than in SL rats. Food deprivation also decreased water intake in KC rats to the level of SL controls, even though food intake remained unaltered by the knife cuts. Water intake and urine output was significantly increased by hypertonic saline i.p. at 0.5, 1 and 8h post-injection. Despite marked differences in input and output, KC and SL rats demonstrated similar basal plasma vasopressin. However, when KC and SL rats were given hypertonic saline i.p., plasma vasopressin rose in SL rats only. Histological analysis confirmed that the knife cuts did not involve the supraoptic nuclei or the neurohypophysis. These preliminary findings suggest that the polydipsia and polyuria in KC rats may be due to a complex mechanism that involves not only decreased secretion and action of vasopressin but an abnormal response to thirst stimuli.

REGIONAL CEREBRAL BLOOD FLOW FOLLOWING ICV ANGIOTENSIN II IN THE RAT. D.A. Czech[1] and E.A.Stein[2]. Marquette University Dept of Psychology[1] and Medical College of Wisconsin, Dept of Psychiatry[2], Milwaukee, WI 53233.

Angiotensin II (AII) is a potent dipsogen when administered both peripherally & centrally. As its sites of action are not well understood, we attempted to map brain regions affected by ICV AII, and which might be linked to its dipsogenic effects. We utilized the method of Sakurada et al. to measure regional cerebral blood flow (rCBF) in conscious rats. Male rats were fitted with a single ICV cannula, adapted to mild restraint over several weeks, and assigned to one of three groups: (Veh)-vehicle injection, H_2O available; (W+)-AII (100ng in 2 µl), H_2O available; (W-)-AII, H_2O available from injection to first lick only. Resulting rCBF data fell basically into 3 groupings: Gp 1) Relative to Veh, both W+ and W- exhibited significant increases in rCBF. This putative generalized drug effect was seen in such regions as the median preoptic, lateral and medial preoptic areas and cingulate cx; Gp 2) Increases in W- over both W+ and Veh, perhaps reflecting AII's action as a dipsogen. These areas included the organum vasculosum lamina terminalis, subfornical organ and paraventricular hypothalamus; Gp 3) A sequential increase in W+ and W- This group included the lateral and anterior hypothalamus and zona incerta. No decreases in rCBF were ever observed in any region or after any treatment. These data indicate that rCBF may be a sensitive measure for the detection of the central sites of action of AII as a dipsogenic agent, and may reveal distinctions between regions associated with drinking initiation and those reflecting motivation circuitry. (Supported in part by a grant from Marquette University graduate school dean).

510.13

SHAM-DRINKING BEHAVIOR IN RATS VARIES OVER THE DIURNAL LIGHT/DARK CYCLE. D. S. Dracos and F. W. Flynn. Dept. of Psychology and Neuroscience Program, University of Wyoming, Laramie, 82071.

Rats' intakes and 2-bottle preferences for sucrose and QHCl vary over the 12:12 LD cycle (Dracos & Flynn, 1989). Sham drinking tests were run to separate the role of oral from postoral effects on diurnal preference differences. Rats were entrained to a 12:12 LD cycle and fitted with gastric fistulae. At the onset of either the light (Light Group, n=5) or dark cycle (Dark Group, n=4), rats were presented with 4 ascending concentrations of sucrose, NaCl, HCl, and QHCl, and allowed to sham drink for 30 min or 1 h. The Dark Group sham drank significantly more 0.3 M sucrose (87.3 $\pm$ 12.4 ml) and 1.0 M sucrose (78.8 $\pm$ 7.0 ml) in 1 h than did rats in the Light Group (40.4 $\pm$ 5.9 ml and 41.6 $\pm$ 11.0 ml respectively), p's <0.05. In comparison to the Light Group, the Dark Group sham drank significantly more 0.01 M NaCl but significantly less of 0.03 M, 0.1 M, and 0.3 M NaCl, p's <0.05. There were no group differences in response to HCl. The Dark Group drank more 3 x 10-3 M QHCl than the Light Group, $p<0.05$. These results demonstrate that rats' sham intakes are influenced by the changes in physiology that accompany the 12:12 LD cycle and suggest that taste processing could be affected by the diurnal cycle. (Supported by NS-24879 awarded to F. W. Flynn.)

DIPSOGENIC STIMULI PAIRED WITH EATING SUPPORT CONDITIONED INITIATION OF DRINKING WITHOUT CONDITIONED WATER INTAKE IN RATS. F. S. Kraly and K. A. Spiess*. Dept. of Psychology, Colgate University, Hamilton, NY 13346.

The claim (Fitzsimons & LeMagnen, JCPP 67:273, 1969) that rats learn to associate orosensory properties of food with postprandial dehydrational consequences remains unexamined. We have done experiments in which an ingested food conditioned stimulus (CS) is paired with one of various dipsogenic unconditional stimuli (UCS; i.p. 0.5% BW 1M NaCl, s.c. 0.25 mg/kg angiotensin II (ANG), 5 mg/kg histamine or 0.9% NaCl as a control) known to be putative signals for drinking elicited by eating. The CS-UCS pairings on 2, 6 or 9 trials were followed by an extinction trial (i.e., CS without UCS) to examine for conditioned drinking. With a 30-min CS-UCS interval, the ANG UCS supported a conditioned aversion ($p<.001$) to a liquid food CS without evidence ($p>.10$) for conditioned drinking; the histamine UCS supported neither conditioned aversion nor water intake ($ps>.20$). With a 10-min CS-UCS interval, the 1M NaCl and histamine UCSs each supported conditioned initiation of drinking, measured by shorter ($ps<.05$) latency to initiate drinking upon presentation of CS on the extinction trial (vs. baseline) without supporting conditioned water intake ($ps>.10$). These results show that (a) two putative signals for food-related drinking, cell dehydration and histamine, serve as UCSs for conditioned initiation of drinking in response to a food CS; (b) conditioned water intake may be difficult to demonstrate.

510.15

DEHYDRATION- AND DEPRIVATION-INDUCED CHANGES IN NEURAL METABOLIC ACTIVITY IN THE HINDBRAIN OF 6-DAY-OLD RAT PUPS: IMAGE AVERAGING AND IMAGE DIFFERENCING OF 2-DG AUTORADIOGRAMS. S.E. Swithers and W.G. Hall. Department of Psychology, Duke University, Durham, NC 27706.

In 6-day-old rat pups, both dehydration and overnight deprivation enhance ingestion. The modulatory effects of dehydration and deprivation may have similar neural bases, or may be accomplished by different neural mechanisms. To examine these possibilities, the topography of neural metabolic activity during a 1 hour [14-C] 2-deoxyglucose (30 uCi/100g BW, s.c.) incorporation period was compared in 6-day-old rat pups that were cellularly dehydrated by injection of hypertonic saline or that were 24 hours deprived. Autoradiographic images corresponding to sections of the neural axis at several levels of the hindbrain were selected for each experimental group and analyzed. Difference images were then generated by subtracting average images from one another.

Relative to 24 hour deprived pups, cellularly dehydrated pups showed increased metabolic activity in parabrachial nuclei, nucleus of the mesencephalic trigeminal nerve, oral regions of the nucleus of the spinal trigeminal nerve, nucleus ambiguus, and areas between sensory and motor trigeminal nuclei. Cellularly dehydrated pups had decreased activity in the oral region of the nucleus of the solitary tract as well as in medullary and pontine reticular areas.

510.16

SHORT TERM FOOD DEPRIVATION CAUSES PICA PROPORTIONATE TO THE AMOUNT OF FOOD WITHHELD. D. Mitchell. Psychology Dept., Univ. of Southern California, L.A., CA 90089-1061.

Geophagy (clay consumption) is a common form of pica (consumption of nonnutritive substances) during famines. Rats will frequently engage in appreciable amounts of pica during brief periods (23 hr) of food deprivation. Previous experiments employing emetic toxins, motion sickness, and conditioned illness indicate that pica relieves the subjective symptoms of gastrointestinal malaise. Assuming that over short deprivation periods the more food withheld, the more severe or prolonged the unpleasant gastrointestinal sensations, the present experiment determined if pica shows a systematic relationship to the amount of food withheld. Accordingly, rats maintained with water and clay (kaolin) continuously available were subject to periodic episodes of food restriction in a counterbalanced Latin Square design. Thirty animals that had consumed at least 15.0 g of kaolin on a 23 hr food-deprivation screening test were matched and randomly assigned to six groups. Each group was tested in a unique sequence of conditions spaced six days apart during which they were permitted 23 hr access to 0, 5, 10, 15 20 g or ad lib food. They consumed 19.9, 10.1, 7.6, 5.3, 3.2, and 0.2 g of kaolin respectively. These results indicate that pica induced by food deprivation is similar to other causes of pica and that it is mediated by subjective visceral sensations.

510.17

HUMAN SATIETIN (h-SAT) PURIFIED ON HPLC INFUSED INTRACEREBROVENTRICULARLY (ICV) DOES NOT PRODUCE CONDITIONED TASTE AVERSION IN RATS. L.L. Bellinger and V.E. Mendel. Depts. Physiol. Baylor Coll. Dent., Dallas, TX 75246 and Animal Physiol. Univ. Calif., Davis 95616.

Previously (Pharm Biochem & Behav 23:559, 1985) we found semi-purified (sp) h-SAT produced taste aversion in a two bottle test when infused ICV. In the present study sph-SAT was purified on HPLC, which yielded two peaks (P-A, 10.7%; P-B, 89.3% by wt.) Male Sprague Dawley rats (327-404g) were fitted with chronic third ventricle cannulas. The rats (LD 12:12, light out at 1130h) were given access to water in calibrated bottles, for 1 h/day (1030-1130h) and food ad libitum for 4 weeks. The rats were then divided into three groups (GRP): GRP 1, control (n=8); GRP 2, P-A (n=11); GRP 3, P-B (n=10). On day 1 all groups were ICV infused (10 μl) with artificial-cerebrospinal fluid (a-CSF) at 1000 h. At 1030 h, the control group was given almond flavored (0.5% extract) water (AFW) and the experimental groups banana flavored water (BFW). One hour and 24 h food intake (FI) and 1 h fluid intake were measured and found to be similar in all groups. On the next day the groups were ICV infused with: GRP 1, a-CSF and given BFW; GRP 2, P-A, 11 μg/rat and GRP 3, P-B, 90 μg/rat; both groups were given AFW. Fluid intake was similar in all groups, however, 1 h and 24 h FI were both suppressed ($P<0.05$) in GRP 3 (1.4$\pm$0.3g, 11.2$\pm$0.8g) compared to GRP 1 (2.6$\pm$0.5g, 16.0$\pm$1.0g) and GRP 2 (3.0$\pm$0.3g, 14.8$\pm$1.2g). On day 4 the groups were given a two-bottle choice test of AFW vs BFW, GRP 1, 7.1$\pm$2.1 vs 11.0$\pm$1.4 mls; GRP 2, 6.9$\pm$0.9 vs 6.9$\pm$1.3 mls; GRP 3, 9.2$\pm$1.7 vs 6.9$\pm$1.8 mls, all N.S.). These data suggest HPLC purified P-B can suppress FI without producing taste aversion and thus may be a physiological satiety agent.

CONDITIONED FOOD AVERSIONS INDUCED BY CHRONIC LITHIUM CHLORIDE INFUSIONS IN RATS: EFFECTS OF AREA POSTREMA LESIONS. L.A.Eckel* and K.-P. Ossenkopp. Dept. Psychology, Univ. Western Ontario, London, Ontario, CANADA N6A 5C2.

Lithium has been shown to be a highly effective agent in inducing conditioned food aversions (CFA). The effects of chronic LiCl infusion on food intake and diet preference in rats with area postrema lesions (APX) or sham lesions (APS) were examined. Osmotic minipumps, filled with a saturated aqueous solution of LiCl, were implanted into the peritoneal cavity of APX and APS rats. Similarly, nonfunctional pumps were implanted in two other groups of APX and APS rats. The LiCl infusion or sham drug phases were paired with free access to a novel diet during a 7 day conditioning phase. Food intake was measured during the conditioning phase and preferences for the novel diet vs. a familiar diet were assessed a week after the conditioning phase. During the conditioning phase the APS group infused with LiCl exhibited a significant reduction in food intake relative to the sham drug APS group ($p < .01$). No significant differences in food consumption were found between the two APX groups. Group APS given LiCl also showed a marked aversion to the novel diet, whereas group APX given LiCl did not. These results indicate that CFAs induced with chronic LiCl infusions are mediated by the area postrema. (Supported by a NSERC grant to KPO).

510.19

EFFECTS OF ZACOPRIDE AND 8-OH-DPAT ON BODY ROTATION-INDUCED CONDITIONED TASTE AVERSIONS IN RATS. L.A.Ruttan and K.-P. Ossenkopp. Dept. Psychology, Univ. Western Ontario, London, Ontario, CANADA N6A 5C2.

The 5HT-3 antagonist zacopride and the 5HT-1a agonist 8-OH-DPAT have both been shown to possess anticmetic properties. Two separate experiments examined the effects of zacopride and 8-OH-DPAT on body rotation-induced conditioned taste aversions (CTA) in male hooded rats. The rats were adjusted to a 23.5 h/day water deprivation schedule. On 3 conditioning days 30 min access to a 0.1% sodium saccharin solution was followed by subcutaneous administration of either zacopride (0.1 mg/kg), 8-OH-DPAT (0.1 mg/kg), or isotonic saline. Fifteen minutes following drug administration the animals were exposed to the body rotation procedure which consisted of 30 min rotation at 70 rpm on a schedule of 60 s on - 60 s off. The animals were again given access to water (30 min) on each of the next 4 days and were then tested for saccharin preference (two-bottle tests) over the next 12 days. The results indicated that administration of 8-OH-DPAT significantly enhanced the body rotation-induced CTA ($p < .01$), whereas zacopride significantly attenuated the induced CTA ($p < .05$). (Supported by a grant from NSERC to KPO).

IBOTENIC ACID LESIONS OF THE LATERAL HYPOTHALAMUS BLUNT AFFECT BUT DO NOT INDUCE TASTE AVERSION. K.C. Berridge, The University of Michigan, Department of Psychology, Ann Arbor, MI, 49109.

Aphagia and increased aversive taste reactivity (gapes, etc.) occur after electrolytic lateral hypothalamic lesions (Teitelbaum & Epstein, '62; Schallert & Whishaw, '78; Stellar et al., '79; Fluharty & Grill, '81) and after excitotoxic striatopallidal lesions (Berridge & Cromwell, in press). Aversion is not enhanced, in contrast, after nigrostriatal 6-OHDA lesions that produce aphagia (Berridge et al, '89). Do *excitotoxic* lesions of the lateral hypothalamus that produce aphagia increase aversion to tastes? Thirty-two male rats received bilateral injections of ibotenic acid (0.8 ul, 1.2 M) into the lateral hypothalamus (A-2.0,L±1.9,V-8.0). Ten rats showed aphagia that lasted at least 8 days after the lesion. Nine control rats received vehicle injections. Taste reactivity to 1 ml oral infusions of sucrose, NaCl, citric acid, and quinine solutions (delivered via chronic oral cannulae) was videotaped and assessed frame-by-frame.

Aphagic rats showed reduced levels of aversive *and* hedonic reactions (tongue protrusions, etc) to tastes, compared to control rats or to rats that were not aphagic after lesions. Although a reduction of sensorimotor arousal might explain this result, sensorimotor deficits have been argued *not* to be produced by excitotoxic hypothalamic lesions (Dunnett, et al, '85). An alternative explanation is that a global *blunting* of hedonic and aversive affect is produced by the loss of intrinsic neurons from the lateral hypothalamus. Enhancement of aversion by electrolytic lesions may require a synergistic destruction of multiple hypothalamic elements. Alternatively, enhanced aversion may require destruction of neurons from bordering regions that are outside of the hypothalamus itself.

TASTE AVERSION LEARNING IN THE FERRET: LIMITS ON CONDITIONED AND UNCONDITIONED STIMULI. B. M. Rabin and W. A. Hunt*. Armed Forces Radiobiology Research Institute, Bethesda, MD 20814, and University of Maryland Baltimore County, Baltimore, MD 21228.

Previous research has shown that treatment with toxic stimuli that produces vomiting also produces conditioned taste aversion (CTA) learning at a lower dose. To further evaluate the relationship between emesis and CTA learning, ferrets were allowed to drink a 10% sucrose solution immediately prior to injection of lithium chloride (LiCl) or exposure to ionizing radiation. Treatment with neither unconditioned stimulus resulted in the acquisition of a CTA, even when vomiting was produced by the toxin. In contrast, when canned cat food was used as the conditioned stimulus, a CTA was produced by injection of LiCl (3.0 mEq/kg), but not by exposure to radiation (200 cGy). These results, in relation to those of other studies, indicate that the association between the CTA and emetic effects of exposure to toxins may be species specific, depending upon the nature of both conditioned and unconditioned stimuli.

LEARNING AND MEMORY: SPATIAL

511.1

A NEW METHOD FOR ESTIMATING SPATIAL LOCALIZATION IN RATS. A. Speakman* & J. O'Keefe*. (SPON: Brain Research Association) Anatomy Dept, University College, London WC1E 6BT UK

A widely used apparatus for estimating spatial localization in studies of hippocampal function is the 'water maze' (Morris, R.G.M., Learn. Motiv., 1981, 12:239). We describe a task which is similar in principle, but which has the advantage that the rat is not immersed in water. Instead the rat is motivated by appetite to approach a goal defined only by its spatial relationship to distal cues.

A small skull-mounted post is chronically implanted in a rat. During training an apparatus is attached with a nozzle which sits in front of the animal's mouth during free behavioural movement across a circular arena (1.18m diameter). A length of plastic tubing connects the dispensing apparatus to a distant solenoid valve and pressurised liquid reservoir. Operation of the solenoid valve results in a squirt of saccharine solution directly into the animal's mouth. Typically a volume of 0.1ml saccharine at a concentration of 0.4% is dispensed over 100ms. A computer is used to track the animal's position and to administer the reward at particular places (goals).

We have shown that rats will learn to approach goals defined in this manner. In addition, by rotating controlled cues from trial to trial, we have shown that distal cues can control spatial localization of this type. Two methods have been used to gauge the accuracy of spatial localization in relation to the cues. In a 'titration' method, rats received reward over a particular spatial area which gradually shrank/expanded as the rat demonstrated it could/could not find the goal. In the 'radial reward' method, the probability density of reward varied as an inverse function of the distance from the goal.

511.2

DISCRETE EXCITOTOXIC LESIONS OF THALAMUS DO NOT DISRUPT PERFORMANCE OF RATS ON A SPATIAL DELAYED NON-MATCHING TO SAMPLE (DNMTS) TASK. J.K. Robinson, S. Koger, D.M. Lacourse*, and R.G. Mair. Dept. Psychol., Univ. New Hampshire, Durham, NH 03824.

To study the role of thalamic lesions in DNMTS deficits caused by pyrithiamine treatment (NSci Abst 15:304, 1989), 48 rats were pretrained on DNMTS and given one of four treatments: midline thalamic lesion, (N=16) bilateral thalamic lesion (±1mm from midline) (N=16), sham lesion of hippocampus overlying the bilateral site (N=8), and sham surgery (N=8). The injections of 5µl of 1 mM NMDA destroyed tissue within a radius of .45 mm of the cannula. None of the lesioned animals were impaired on measures of response accuracy or speed at any of the memory delays tested. These data contrast with those of more extensive RF lesions of thalamus (cf Mair, et al, this meeting).

511.3

DIENCEPHALIC ANTEROGRADE AMNESIA FOR SPATIAL INFORMATION IN THE RAT. R. J. Sutherland, H. N. Rice* and J. M. Hoesing. Dept. of Psychology, The Univ. of Lethbridge, Lethbridge, AB, Canada, T1K 3M4.

The necessary subcortical damage for "diencephalic" amnesia is not established. We sought to determine: 1. if prelesion training on the "procedural" aspects of the Morris water task would ameliorate the deficit in new place learning associated with thalamic or mammillary damage and 2. the relative magnitude of impairment associated with damage to anterior thalamic (AT), mediodorsal thalamic (MD), and/or mammillary bodies (MB).

All rats were trained preoperatively to swim to a hidden platform in the Morris water task. Each day the platform was positioned in a new location in the pool. They were divided into 5 groups receiving electrolytic lesions to MD, AT, MB, MD+MB, or sham lesions. All rats were retested in the moving platform version of the Morris water task. Neither MD nor MB damage alone reliably impaired performance. Rats with AT or MD+MB damage showed an inability to learn the hidden platform location throughout postoperative testing. The results provide support for the idea that combined damage to circuitry involving MD and MB is necessary to produce a severe diencephalic anterograde amnesia. Interestingly, performance in this task is not sensitive to amygdala damage.

511.4

MEDIAL SEPTAL LESIONS DISRUPT SPATIAL, BUT NOT NONSPATIAL, WORKING MEMORY IN RATS. John E. Kelsey and Hannah Vargas*, Dept. Psychology, Bates College, Lewiston, ME 04240

Damage to the projection from the medial septal nucleus (MS) to the hippocampus has been hypothesized to disrupt spatial working memory more than it disrupts nonspatial working memory (Aggleton, Hunt, & Rawlins, 1986). To further test this hypothesis, rats with MS lesions were first trained on a spatial delayed nonmatching to sample (DNMTS) task in a Y-maze and then on a nonspatial DNMTS task in the same Y-maze. The spatial task required the rats to enter the arm opposite that which they were forced to enter on the preceding run in order to obtain .5 cc of 8% sugar water. As anticipated, rats with small MS lesions were less accurate in selecting the opposite arm during acquisition when the retention interval was 10 sec. Moreover, in subsequent tests when the retention interval was varied between .5, 1, and 2 min, the deficit increased as the retention interval increased. The nonspatial task required the rats to enter the arm containing the object not encountered in the straight alley on the preceding forced run. In contrast to the spatial task, MS lesions did not disrupt accuracy of choice during acquisition or during subsequent tests when the retention interval was varied. Although it is possible that the difference in the effects of the lesions on these two tasks could be due to differences in task difficulty or to recovery of function, these possibilities seem unlikely. Thus, these results suggest that rats with small MS lesions have more difficulty remembering where they have been than they do remembering what object they have just seen.

511.5

IMPAIRED SPATIAL MEMORY FOLLOWING VENTROMEDIAL THALAMIC LESIONS IN RATS. J. D. Butler and D. B. Neill. Dept. of Psychology, Emory University, Atlanta, GA 30322.

Neuroanatomical and electrophysiological experiments indicate that the ventromedial nucleus of the thalamus (VMT) may have a nonspecific arousal regulatory effect on neocortex. Observations from past experiments in our laboratory lead us to believe that the VMT may participate in memory processes. We have found that rats bearing electrolytic lesions of VMT are impaired in the acquisition, but not the retention, of a number of conditioned responses. In the present experiment, we evaluated the ability of VMT rats to perform in a commonly-used test of "working" memory, the radial arm maze. Ten naive, male Sprague-Dawley rats were trained to retrieve food from the arms of a 8-arm radial maze. Each daily test consisted of a study phase in which four arms of the maze were blocked. The rats retrieved food from the non-blocked arms and were then removed from the maze for 45 sec. During this interval the remaining arms of the maze were opened. Upon reintroduction to the maze (retention phase), the task was to retrieve food from the previously unvisited closed arms. Errors were defined as entrances to arms visited previously in either the study or retention phases. Upon reaching criterion, the rats were then divided into two groups of 5 animals each. The VMT group received anodal electrolytic lesions (1 microamps for 10 sec) in the VMT. In the sham operated group the electrode was lowered but no current was passed. The memory test was then administered once daily for 9 days. VMT lesioned animals displayed significantly more errors than did sham operated rats.

511.6

HIPPOCAMPAL LESIONS IN RATS PRODUCE A TEMPORALLY-GRADED RETROGRADE AMNESIA ON A SPATIAL MEMORY TASK. J.L. Kubie, S. Dayyani, R.U. Muller, B. Cohen, E. Major and R.J. Sutherland. S.U.N.Y. Health Sci Center, Brooklyn NY and Univerisity of Lethbridge, Alberta, CAN

A temporally-graded retrograde amnesia is a characteristic of the human amnestic syndrome. A recent water-maze study by Sutherland *et al* suggests a parallel in rats: Animals trained 14 weeks before hippocampal lesions were able to reacquire efficient behavior while those trained immediately before surgery were seriously impaired on reacquisition (Neurosci Abstr **13**:1066, 1987).

In a study reported last year we attempted to further investigate this phenomenon with another spatial task -- an appetitive task run in a dry, cylindrical enclosure (Kubie *et al*, Neurosci Absrt **15**:609, 1989). We found that rats trained 14 weeks before surgery had no retrograde loss -- they rapidly reaquired the spatial task. In contrast, the same rats exhibited an anterograde amnesia in that, after hippocampal lesions, they could not learn to navigate towards a second, novel location. The current study is an extension of our previous work and asks two questions: Is there evidence of temporally graded retrograde amnesia? and, if so, is the retrograde amnesia specific to spatial memories?

In the first experiment, using procedures identical to the earlier study, rats were trained on the spatial task within a two week interval, and were then immediately subjected to hippocampal (n=5) or sham (n=6) lesions. After sufgery rats with hippocampal lesions were severely impaired, and 4 never reacquired spatial abilities on the spatial task. This is in contrast to previous data where rats with a 14 week interval between training and surgery were relatively unimpaired. Thus, there is support for a temporal gradient in the retrograde amnesia.

In the second experiment, rats were trained in an object discrimination task where each rat was rewarded for digging below one out of 12 objects in an open camber. Following a 2-week acquisition period rats were given hippocampal (n=3) or sham (n=1) lesions. After recovery, all rats showed perfect retention of the preoperative habit. Thus, the retrograde amnesia seen in rats appears to be at least somewhat specific to spatial memory. (supported by NIH grant RO1-NS20686)

511.7

SPATIAL AND CUED DISCRIMINATIONS: ROLE OF THE HIPPOCAMPUS AND PROTEIN KINASE C S.Golski, D.S. Olton, M.Mishkin, J.L.Olds, and D.L.Alkon. Dept. of Psychology, Johns Hopkins University, Baltimore, MD 21218.

The role of the hippocampus in spatial and cued discrimination learning was examined in two experiments in a modified, cue-controlled water maze: (1) the effects of hippocampal lesions on performance, (2) the effects of performance on protein kinase C (PKC) in the hippocampus. The spatial discrimination (SD) and cued discrimination (CD) were equivalent in terms of the sensory and motor components, but differed in the stimuli that were relevant and irrelevant to the discrimination. Hippocampal lesions (HPC) impaired performance relative to controls (CON) in the SD, but not the CD. Mean response time (and standard error) to reach the submerged platform on the final block of trials was: SD-CON=5.4(0.6), SD-HPC=12.6(1.6), CD-CON =3.2(0.3), CD-HPC=5.1(1.1)(N=8, each group). Alterations in PKC were determined by autoradiography in separate groups of rats after 2 or 9 sessions of training (8 trials per session) in either discrimination.

511.8

DIFFERENTIAL EFFECTS OF MEDIAL SEPTAL LESIONS ON ACQUISITION IN TWO SPATIAL MEMORY TASKS. M.W. Decker, R. J. Radek* and M. A. Pelleymounter, Neuroscience Research, Abbott Labs, Abbott Park, IL 60064.

Medial septal lesions disrupt cholinergic input to the hippocampus and produce behavioral deficits similar to those observed following hippocampal lesions. In the current study, however, medial septal lesions differentially affected acquisition of two spatial memory tasks generally regarded as being sensitive to hippocampal damage--the radial arm maze and the Morris water maze.

Radiofrequency lesions of the medial septum (MS) were made in male, Long-Evans rats. These rats and nonoperated controls were then trained in a Morris water maze to find a camoulflaged escape platform located in a fixed position across trials. Escape latencies for MS-lesioned and control rats were not significantly different, and anlaysis of search patterns during a probe trials conducted in the absence of an escape platform revealed no differences between groups. When these rats were later trained on the radial arm maze, however, the MS-lesioned rats displayed marked impairments that persisted throughout a 13-day training experience ($p<.001$). Thus, these MS lesions impaired spatial learning in the radial arm maze, but not in the water maze.

Experiments with a different set of rats revealed MS lesion-induced impairment of short term, within session habituation of locomotor activity in an open field, but no effect on habituation of activity observed across days. This finding may be related to the differences observed between the effects of these lesions on the radial maze and the water maze since information regarding the platform location in the water maze is typically maintained over longer periods than is information regarding arms visited in the radial maze. The distinction, however, does not appear to be related to arbitrary, experimenter-imposed working /reference memory manipulations, as further work revealed no lesion effect on the performance of a "working memory" version of the water maze in which a new platform location was used each day.

511.9

ROLE OF THE HIPPOCAMPUS AND POSTERIOR PARIETAL CORTEX IN EXPLORATION AND RESPONSE TO A SPATIAL CHANGE IN RATS. C. Thinus-Blanc, B. Poucet, E. Save* and M.C. Buhot*. Lab. Functional Neurosci., C.N.R.S., 31 chemin Joseph-Aiguier, 13402 Marseille, France.

This study was aimed at dissociating the role of the posterior parietal cortex (PPC) and hippocampus (HPC) in exploration and in reaction to spatial novelty. In two experiments, rats were first allowed to explore an open field containing one or several objects (habituation phase). Then a change was brought to the initial situation either by removing the object (Experiment 1) or displacing two objects among five (Experiment 2). Both changes could be detected on the basis of the spatial array only. The behavioral reaction to the change was measured by the time spent exploring.

Rats with PPC lesions or HPC lesions were tested. We also investigated the effect of reversible short-lasting inactivation of the hipppocampus in rats chronically equipped with cannulae implanted into the ventral hippocampus and injected with lidocaine. By comparison with control rats who spent more time at the location of the disappeared stimulus (Experiment 1) or who reexplored selectively the displaced objects (Experiment 2), the hippocampally damaged rats did not display any reaction to change in either experiment. As hippocampal rats, animals with PPC lesions did not react to the change in Experiment 1. In contrast, in Experiment 2, rats with PPC lesions reexplored the whole set of objects. Therefore, the role of PPC appears to be more subtle than that of HPC. PPC may have a particularly important role in discriminating spatial environmental changes that result from the absence of familiar visual cues.

511.10

EFFECTS OF A SHORT-LASTING REVERSIBLE INACTIVATION OF THE HIPPOCAMPUS AND SEPTUM ON SPATIAL LEARNING IN RATS. B. Poucet, M.C. Buhot* and C. Thinus-Blanc. Lab. Functional Neurosci., C.N.R.S., 31 chemin Joseph-Aiguier, 13402 Marseille, France.

The present study was aimed at testing the effects of a reversible inactivation of either the hippocampus or the septum on long-term and short-term spatial learning in the rat. In a circular platform with 18 holes on the periphery, rats chronically equipped with cannulas into the ventral hippocampus or the septum were trained to locate the unique hole leading to a hidden shelter in order to avoid a bright light. In Exp.1, the task emphasized long-term acquisition of spatial information (1 trial/day for 16 days, 24 hrs ITI). The location of the hole was changed on the 17th day and rats were injected with lidocaine just before each of the further 8 daily trials. Both lidocaine-injected and sham-injected rats relearned the new location at a similar rate. In Exp.2 which emphasized short-term acquisition of spatial information (3 trials/day, 1min ITI), rats were sham-injected or lidocaine-injected on alternate days and had to learn a new hole location each day. While sham-injected rats improved in orientational accuracy over successive trials, lidocaine-injected rats did not. These results confirm the role of the septum and hippocampus in spatial learning. However, rats were impaired only when septo-hippocampal activity was neutralized over the whole course of spatial processing (Exp.2). In contrast, inactivation of the septo-hippocampus during restricted periods of a longer-term process did not seem to prevent normal function in spatial learning (Exp.1). It is hypothesized that the septo-hippocampal formation could process information "off-line" in the delay between two learning trials.

511.11

FIMBRIA-FORNIX TRANSECTIONS DISRUPT THE ONTOGENY OF DELAYED ALTERNATION BUT NOT POSITION DISCRIMINATION IN THE RAT. M.E. Stanton and J.H. Freeman Jr. Neurotox. Div., U.S. EPA, Research Triangle Park, NC 27711 and Dept. of Psychology, UNC-Chapel Hill, Chapel Hill, NC 27514.

Three experiments examined the effects of fimbria-fornix transections on the ontogeny of discrete-trials delayed alternation (DA) and position discrimination (PD) in a T-maze (for procedures see Green & Stanton, Behavioral Neuroscience, 1989, 103, 98-105). In Experiment 1, 23-day-old rat pups given lesions on postnatal day 10 (PND10) acquired PD, but not DA after 60 training trials. Experiment 2 showed that this same lesion prevented the developmental emergence of DA between PND19 and PND27. Experiment 3 showed that 23-day-old pups with these lesions begin to show acquisition of DA, if given 72 additional training trials. Lesions were verified by histological examination of the fornix and AChE staining in the hippocampus.

The septohippocampal projection appears to be necessary for the ontogeny of DA but not PD in the rat. The lack of effect on PD suggests the lesion selectively impairs memory processes subserving DA. These findings suggest a role for septohippocampal maturation in the ontogeny of these memory processes.

511.12

NEONATAL MEDIAL PREFRONTAL CORTEX LESIONS AND SPATIAL DELAYED ALTERNATION IN THE DEVELOPING RAT: RECOVERY OR SPARING? J.H. Freeman Jr. and M.E. Stanton. Dept. of Psychology, UNC-Chapel Hill, Chapel Hill, NC 27514 and Neurotox. Div., U.S. EPA, Research Triangle Park, NC 27711

Two experiments examined the effects of medial prefrontal cortex aspiration lesions on acquisition of T-maze delayed alternation (DA) and position discrimination (PD) in infant rats (see Green & Stanton, Behavioral Neuroscience, 1989, 103, 98-105, for procedural details). In Experiment 1, rat pups given lesions on postnatal day 10 (PND10) and trained on PND23, acquired PD, but not DA after 60 training trials. Experiment 2 showed that this lesion-induced impairment was no longer evident in animals trained on PND33. Lesions were verified by histological examination of cresyl-violet stained brain sections.

The medial prefrontal cortex appears to be involved in DA but not PD during early development in the rat. The differential effect on these two tasks suggests a selective impairment of the memory processes subserving DA. The failure of this early lesion to impair DA learning in adult rats therefore appears to reflect recovery rather than sparing of function (Kolb & Nonneman, Brain Res., 1978, 151, p. 144). This recovery may occur between 23 and 33 days of age in the rat.

511.13

CEREBRAL ^{14}C-GLUCOSE UPTAKE PATTERNS INDUCED IN MICE BY SPATIAL DISCRIMINATION TESTING IN AN EIGHT ARM RADIAL MAZE.
B. Bontempi*, J. Sif*, C. Messier, R. Jaffard and C. Destrade. Lab. Psycho- physiol. URA CNRS 339, Univ. Bordeaux I, 33405 Talence France and (J.S.) Biol. Dept, BP 20 El Jadida Univ. Marocco.

Regional mapping of ^{14}C-glucose (GLU) uptake was analyzed in mice at different time intervals both the first (Day 1) and last (Day 9) daily sessions of a spatial discrimination testing procedure in an eight-arm radial maze. BALB/c mice with a jugular catheter were randomly divided into four groups: two experimental groups, respectively trained for 1 day and 9 days in the spatial discrimination task and two (quiet and active) control groups. Each experimental group was divided into three subgroups injected with GLU at different post-training (PT) intervals (30 s, 1 hr and 3 hr); the animals were sacrificed 5 min later and the brain processed for autoradiography. The mapping of GLU was analyzed using the relative glucose uptake method. On Day 1, a progressive increase of labelling was found in trained animals for the medial septum and the mediodorsal thalamic nucleus (5 min PT), the hippocampal formation (1 hr-PT) and the subiculum and the frontal cortex (3 hr-PT). In contrast, on Day 9, increased labelling was found 5 min-PT in all previously mentioned regions. However, 1hr and 3 hr-PT, no significant labelling was found in these structures.

These results suggest that the sequential nature of the activation observed on Day 1 represents the time-dependent progressive organization of memory.

Supported by CNRS and DRET grants.

511.14

DIFFERENTIAL EFFECTS OF MEDIODORSAL THALAMIC OR MAMMILLARY BODIES IBOTENIC ACID LESIONS ON SPATIAL SHORT-TERM MEMORY IN MICE.
F. Alaoui-Bouarraqui *, D. Béracochéa and R. Jaffard. Lab. Psychophysiologie, URA CNRS 339, Univ. Bordeaux I, 33405 Talence Cedex France.

Some of the deficits observed in the human Korsakoff syndrome (impairments of temporal order judgements, exagerated vulnerability to interference) have been attributed to a frontal lobe dysfunction even though direct damage to the frontal cortex of these subjects is not systematic. Given the constant presence of diencephalic damage in Korsakoff subjects, it remains possible that these diencephalic damage are involved in frontal-related deficits. In the present experiments, we have studied the effects of lesionning either the mediodorsal thalamic nucleus (MD) or the mammillary bodies (MB) on memory tasks known to reveal impairments resulting from frontal lesions.

The tasks were run in an automated 8-arms radial maze. In the **"recognition task"**, the basic procedure relied on a forced visit (target-visit) followed immediately by a test-phase during which the subject had to choose between the target-visit and a new , non-visited arm (win-shift strategy). The difficulty of the task was increased by including interfering forced visits (from 1 to 5 i.e. study-phase) between the target-visit and the test-phase. This task was designed to study the vulnerability to interference. In the **"serial-order task"**, all arms were visited during the study-phase; the position of the target-visit was varied, from the 1st to the 6th one. During the test-phase, the subject had to choose in all cases between a given target-visit and the last visited arm of the study-phase. Thus, the difficulty of the recognition increased as a function of the recency of the target-visit. Results showed that MD lesions induced a marked deficit in the serial order task but not in the recognition one, whereas the opposite was observed following MB lesions.

These results provide evidence for a differential involvement of subcortical damage in frontal-related deficits.

511.15

SEX-SPECIFIC PATTERNS OF SPATIAL BEHAVIOR PREDICT HIPPOCAMPAL SIZE IN WILD RODENTS. L.F.Jacobs*S.J.C.Gaulin*,D.F.Sherry and G.E.Hoffman. Dept. of Anthropology,Univ.Pittsburgh,Pittsburgh,PA 15260.

In polygamous vole species males range more widely than females in the field and perform better on laboratory measures of spatial ability; both differences are absent in monogamous vole species. Such cognitive differences, predicted by theories of sexual selection, should be reflected in the size of the hippocampus, a structure known to mediate spatial learning and whose size, in inbred mouse strains, correlates positively with maze performance.

Ten females and males were taken from wild populations of two vole species. The volume of the hippocampus, relative to the entire brain, was determined from serial brain sections. Males of the polygamous species, Microtus pennsylvanicus,had significantly larger hippocampi than did females, whereas there was no sex difference in hippocampal size in the monogamous species, M. pinetorum. Our result suggests that the structure of functional subunits in the brain can be shaped by evolutionary processes to meet particular cognitive demands. In Microtus, the pressures of sexual selection may have produced adaptive sex differences in brain structure and behavior.

511.16

THE ONTOGENY OF PLACE MEMORY IN THE RAT AND INFLUENCES OF REARING IN AN ENRICHED ENVIRONMENT. J. R. Keith, J. W. Rudy* and J. P. Terrones. Dept. of Psych., Univ. of Colorado, Boulder, CO 80309.

Rats are capable of place learning by the third postnatal week (Rudy et al., Behav Neurosci, 101, 1987). Yet place learning and memory are dependent upon several cortical structures that continue to mature after the third postnatal week. So, one might expect further improvement in some of the processes that mediate place learning after Day 21. This hypothesis was evaluated by determining if there are changes during the postweaning period in rats' ability to retain place information.

Young animals (21 days old) were impaired, relative to older animals (40 days old) at learning the hidden-platform version of the Morris navigation task when a training schedule was used which required animals to retain and build upon information provided over long intervals. Young animals also forgot a well-learned hidden-platform problem more rapidly than older animals. Yet young animals retained a proximal cue-based version of the task for up to 120 h suggesting that their failure to retain the hidden--platform task reflected a selective inability to retain distal-cue-based place information.

Rearing animals in an enriched environment accelerated the maturation of the animals' ability to retain place information but had no effect on acquisition of place information.

511.17

AMPA- AND IBOTENATE-INDUCED LESIONS OF THE BASAL FOREBRAIN: DISSOCIABLE EFFECTS ON WATER MAZE ACQUISITION AND PASSIVE AVOIDANCE RETENTION. K.J. Page*[1], H.M. Marston*[2], L.S. Wilkinson*[2], T.W. Robbins[2] and B.J. Everitt[1]. Depts. of Anatomy[1] and Experimental Psychology[2], Univ. Cambridge, CB2 3DY, England.

Ibotenic acid or AMPA (α-amino-3-hydroxy-5-methyl-4-isoxazole propionate) was infused into the region of the nucleus basalis of Meynert (nbM) of rats. Acquisition and performance of a water maze over a 10-day period (2 trials/day) were unaffected by AMPA-induced lesions which caused an 80% decrease in cortical choline acetyltransferase (ChAT) activity. However acquisition, but not performance, was significantly impaired by ibotenate lesions, which caused a 60% reduction in cortical ChAT activity. Ibotenate-lesioned rats swam further in the training quadrant during a probe trial, when the platform was removed, than either AMPA-lesioned or control rats, suggesting a perseverative search strategy. Neither ibotenate, nor AMPA, lesions affected step-through passive avoidance (PA) acquisition. However, rats with AMPA, but not ibotenate, lesions were significantly impaired in a 96hr retention test. Histological analysis revealed that AMPA infusions destroyed more nbM ChAT-immunoreactive neurons than did ibotenate infusions but, unlike ibotenate infusions, spared the overlying globus pallidus and many parvocellular neurons of the ventral pallidum. The ibotenate-induced impairment in the water maze appears to be related to pallidal, not nbM, damage. The AMPA-induced impairment in PA retention appears to be more directly related to destruction of magnocellular cholinergic nbM neurons.

511.18

EFFECTS OF MEDIAL SEPTAL LESIONS ON ACTIVITY AND WATER MAZE PERFORMANCE. John J. Boitano, Carl P. J. Dokla, Sean Parker, Kristina Stalzer*, Nanci Norelli*, Melissa Fiorini*. Depts. of Psychology, Fairfield University, Fairfield, CT 06430, & St. Anselm College, Manchester, NH 03102.

The effects of electrolytic lesions of the medial septal area (MSA) in F-344 rats was examined using 2 activity measures and reversal learning in the Morris water task. In the circular open field, the number of areas entered by control and lesioned A's were contrasted over 8 days (5 min/day). In a closed field situation, all A's were given forced confinement in an empty goal box (40 mins over 4 days), and were then placed in the field for 5 daily sessions. Latency to head-poke into the goal box plus the areas traversed were converted to a velocity index. Both locomotion and velocity were significantly reduced in the MSA rats ($ps < .01$). Acquisition in the water maze over 16 days revealed insignificant group differences. In a test of reversal learning, one month later, MSA rats took significantly longer to locate the hidden platform (4 days, 2 trials/day; $p < .0003$). While the findings support previous research concerning hypoactivity in MSA A's, they raise unanswered questions about possible neuroanatomical changes taking place after acquisition.

511.19

BEHAVIORAL EFFECTS OF COMBINED CHOLINERGIC AND NORADRENERGIC LESIONS. D.J. Connor, P.J. Langlais and L.J. Thal San Diego VAMC and Dept. of Neuroscience, UCSD, La Jolla, CA.

To examine the behavioral effects of combined lesions of the cholinergic and noradrenergic systems, we lesioned the nucleus basalis magnocellularis (nBM) and dorsal noradrenergic bundle (DNB) of adult F-344 rats (280-300g) with ibotenic acid and 6-OHDA respectively. ChAT activity was significantly decreased from controls in both the nBM and nBM/DNB groups (depletion %ant./%post. = 40.5/20.2 and 33.6/15.2 respectively) and was nonsignificantly increased by the DNB lesion alone (5.6/4.3). NE levels were depleted by >90% by the DNB lesion with no effect of the nBM lesion on NE levels. Acquisition of the Morris water maze showed an impairment of performance by the nBM lesion and an independent enhancement of performance by the DNB lesion. Reversal of the task revealed a similar pattern with the DNB lesion decreasing the behavioral effects of the nBM lesion. A water-motivated T-maze using a nonmatch-to-sample paradigm showed impaired acquisition of the task by all lesioned groups. An open field maze showed no significant differences in horizontal activity between groups. These results suggest independent effects of the two lesions, and that NE depletion is able to reverse the cholinergic deficit in some tasks.

511.20

MOUSE STRAIN DIFFERENCES IN MORRIS WATER TASK PERFORMANCE. B.F. Petrie and N.M Standish. Department of Psychology, Red Deer College, Red Deer, Alberta, Canada, T4N 5H5.

Pigmented and Albino mice were swum for 30 days, to test for spatial learning ability, in the Morris water task. Albino animals were unable to reliably find the platform, while the time taken by Pigmented mice in escaping the pool declined rapidly, reaching asymptote within 7 days. Results are discussed in the context of genetic differences in the appropriate selection of strategy, that may have correlative anatomical and neurochemical underpinnings. Implications for memory augmentation and deficit are also analyzed.

512.1

INTERSPRCIES VARIATION IN THE VOLUME OF HVC, A SONG-RELATED AVIAN NUCLEUS. T.J.DeVoogd, J.R.Krebs* and S.D.Healy*. Dept. of Zoology, Oxford University, Oxford and Dept. Psychology, Cornell Univ., Ithaca, NY 14853

The avian song system is an interconnected group of brain nuclei that are believed to be responsible for song production in songbirds (Nottebohm et al., 1976). The telencephalic nucleus most directly implicated in song production is Hvc (higher vocal control). There is considerable variation in the volume of HVc in males, both within and between species. This variation is correlated with syllable repertoire size in canaries (Nottebohm et al., 1981), but not in red-winged blackbirds (Kirn et al., 1988). In two populations of marsh wrens, Hvc is larger in birds from the one with large syllable repertoires (Canady et al., 1984). These studies suggest that HVc volume is somehow related to song capacity but the nature of the relation is unclear. In the present study, the volumes of Hvc, the telencephalon and the parahippocampus were calculated for 26 species of songbird. In this sample, Hvc (L+R) varied in volume from .212 mm^3 (chiff chaff) to 5.728 mm^3 (magpie). Telencephalon and Hvc volume are positively correlated (r = .41). Telencephalon and parahippocampus volume are more closely related (r = .88). Thus, most of the variation in the volume of the parahippocampus can be accounted for by allometric relations; most of the variation in Hvc volume cannot. The residual Hvc volume was then compared to indices of species-typical song duration and variety (Hamilton and Zuk, 1982; Read and Weary, 1990) Preliminary analyses suggest that the remaining variation in Hvc volume is not related to song duration or the number of different syllables in a bird's repertoire, but is related to the number of different songs that a bird is able to produce.

LOSS OF SPECIES-SPECIFIC SONG RESPONSES AFTER LESION OF A FOREBRAIN NUCLEUS IN FEMALE CANARIES. E. A.Brenowitz. Depts. of Psych. & Zool., Univ. of Washington, Seattle WA 98195.

Song production in male birds is regulated by a network of forebrain nuclei. Why do females that do not normally sing have these same nuclei, albeit in reduced form? One hypothesis is that these regions act in song perception, as shown for males (Margoliash '83; Williams '85). I tested this by examining the behavioral responses of female canaries to song before and after lesions of the caudal nucleus of the ventral hyperstriatum (HVc). Estradiol-implanted females were exposed to male canary song and to white-crowned sparrow song, and the number of copulatory solicitation displays performedwas recorded. No bird gave > 1 display to sparrow song. When females gave ≥ 5 displays to canary song, they received either sham or electrolytic lesions to HVc. I then tested post-lesion responses to canary and to sparrow song. When the caudal medial portion of HVc was destroyed, birds responded equally strongly to canary and sparrow song. Shams and lesioned birds with intact caudal medial HVc continued to respond only to canary song. Thus, lesions of caudal medial HVc seem to eliminate conspecific song recognition without disrupting song responsiveness, supporting the hypothesis that HVc acts in song perception in non-singing female birds. (Supported by NIH DC00487 & Sloan Fellowship)

512.3

BILATERAL LMAN LESIONS IN ADULT MALE CANARIES AFFECT SONG IN DIFFERENT WAYS WITH DIFFERENT LATENCIES. R.Suter, A.Tolles, M.Nottebohm and F.Nottebohm. Rockefeller Univ. Field Research Center, Millbrook, NY 12545.

The lateral magnocellular nucleus of the neostriatum (LMAN) was bilaterally lesioned in 6 adult (17-months old) male canaries in mid-September, when their song was very variable. The song of these birds was recorded during the following 6 months; the birds were then killed and their brains prepared for histology. Immediately after the lesion song became extremely stereotyped -- more so than in canaries in breeding condition -- successive repetitions of a same syllable being virtual carbon copies. However, within 2-3 weeks syllable diversity plummeted and birds started to produce uncommonly long tirades of just a few syllable types. These few syllable types were often delivered in a stammering fashion. We infer that in adult canaries in end-of-summer plastic song the recursive circuit to which LMAN belongs is necessary for song plasticity and for the acquisition, production and sequencing of complex learned repertoires.

512.4

DEAFENING AFFECTS CELL RECRUITMENT IN THE HVC OF ADULT FEMALE CANARIES. F.Nottebohm, B.Simpson and B.O'Loughlin.Rockefeller Univ. Field Research Center, Millbrook, NY 12545.

Six adult female canaries were deafened, 7 served as controls; 2 weeks later both groups got E2 implants and were placed facing cages with singing males. All females received 10 injections of 3H-thymidine (50uCi per inj. at 12h intervals) starting three days later. Their brains were processed for autoradiography six weeks after the last injection. The boundaries of the high vocal center (HVC) were defined using cresyl violet. The HVC of deaf and hearing birds did not differ in volume, number of neurons, glia and endothelial cells, area of overlying ventricular zone (VZ) and % of labeled neurons. However, the % of labeled VZ cells overlying HVC and the % of labeled HVC glia and endothelial cells were higher in the deaf than in the hearing birds (R+L sides combined). Interestingly, the effect on glia and endothelial cells was significant only on the right side. Mean nuclear diameters of labeled HVC neurons were larger on the left than on the right side of hearing birds. Deafness affected turnover and differentiation of HVC cells, particularly on the right side.

512.5

NEURONAL CLUSTERS: INCORPORATION SITES FOR NEURONS BORN IN ADULT CANARY FOREBRAIN. J. R. Kirn and F. Nottebohm, The Rockefeller University, Field Research Center, Tyrrel Road, Millbrook, NY 12545.

Neurons generated in the adult canary telencephalon are incorporated into vocal control nucleus HVC (Higher Vocal Center), where half or more become long-projection neurons within the efferent pathway controlling learned song (Alvarez-Buylla & Nottebohm Soc. Neurosci. Abst. 383.10, 1989; Kirn & Nottebohm, Soc. Neurosci. Abst. 383.9, 1989). Some new neurons also make direct soma-soma contacts with other neurons intrinsic to HVC, forming neuronal "clusters" (Burd & Nottebohm, JCN, 240:143-152, 1985). In the present work, we quantify this phenomenon and identify neuron types found in clusters. Each of 9 adult male canaries (17 month) received a total of 14 injections of ^{3}H-thymidine (6.7 Ci/mmole, 2.5 uCi/gm bwt., two injections/day over 7 days). Birds were sacrificed 30 days later and 6μ brain sections were processed for autoradiography and counterstained with cresyl violet. Roughly 40% of ^{3}H-labelled HVC neurons (x=38%; range=30-52%) were in clusters containing 2-4 unlabelled neurons. This value is probably an underestimate due to cell/cluster splitting during tissue sectioning. The projection patterns of clustered neurons were explored in additional male canaries (n=4) who received stereotaxic injections of the retrograde tracers Di-I or Fast Blue into Area X and Fluoro-gold into RA (Robustus Archistriatalis), the two targets for HVC projection neurons. A common cluster arrangement of a single Area X-projecting neuron, surrounded by 2-3 RA-projecting cells was observed. Thus, the major projection patterns of HVC are reflected in smaller neuronal assemblies. Neuron clustering is associated with synchronized activity in other systems (Theodosis et al., Nature 332: 738-40, 1986). In HVC, the activity of newly formed neurons may be constrained by that of preexisting neurons within clusters--a potential mechanism for the preservation and amplification of information in a system which undergoes turnover of some of its elements. It is also possible that newly formed neurons alter cluster response properties.

512.6

EFFECT OF UNILATERAL DENERVATION ON THE ACOUSTIC OUTPUT FROM EACH SIDE OF THE SYRINX IN SINGING MIMIC THRUSHES. R. A. Suthers and R. S. Hartley*. Sch. of Med. and Dept. of Biology, Indiana Univ., Bloomington, IN 47405.

Microbead thermistors implanted in each primary bronchus of adult male catbirds (Dumetella carolinensis) and brown thrashers (Toxostoma rufum) were used to record the acoustic contribution from each side of the syrinx before and after unilateral denervation of the syringeal muscles. Thermistors responded to air movement produced by the vibrating syringeal membranes. In these birds, paralysis of the muscles on either side of the syrinx resulted in an abnormal song, but the effect was usually slightly greater after the left side was paralyzed. Denervation of either the left or right side of the syrinx increased the number of syllables to which that side contributed sound. Few or no syllables were produced by the intact side alone and most post-operative syllables contained simultaneous contributions from both sides of the syrinx. The sound generated on the denervated side usually consisted of a fundamental with an abnormally low frequency and multiple harmonics. The frequency of this fundamental typically paralleled changes in the rate of airflow on that side of the syrinx, which in turn followed changes in the driving subsyringeal pressure. Sound from the intact side was essentially normal. The abnormal post-operative song in these birds is primarily due to their inability to regulate resistance or membrane tension on the operated side of the syrinx. We postulate that since the denervated side can no longer be silenced by adduction, its relaxed medial tympaniform membrane vibrates at a frequency determined by the rate of airflow across it. (Supported by grant BNS 87-20192 from N.S.F.).

512.7

GABAERGIC INHIBITION CONTRIBUTES TO NON-LINEAR SUMMATION AMONG MULTIPLE FREQUENCY CHANNELS IN THE BARN OWL'S INFERIOR COLLICULUS.

K. Mori[1*], I. Fujita[1,2] and M. Konishi[1].
[1]Div. of Biology, Caltech, Pasadena, CA 91125 and [2]Lab. for Neural Information Processing, RIKEN, Wako, Saitama 351-01 Japan.

Interaural time difference (ITD) is the primary azimuthal sound localization cue for the barn owl. Since ITD is processed in separate frequency channels in the brainstem pathway, neurons therein cannot distinguish ITD from interaural phase difference. Instead, they respond to multiple ITD's that give rise to the same phase difference ('phase ambiguity'). However, cells in the external nucleus and some cells in the lateral shell of the central nucleus (ICL type 2 cells of Fujita & Konishi, *Soc.Neurosci.Abstr.*, **15**:114, 1989) of the inferior colliculus solve the ambiguity by gathering inputs from different frequency channels. We investigated the interaction among frequency channels in those cells, and examined the role of $GABA_A$ inhibition in the process by iontophoretic application of its specific antagonist, bicuculline methiodide (BMI). Single units in the inferior colliculus of anesthetized barn owls were isolated with a multibarrel microelectrode. Two tones of different frequencies were presented binaurally. ITD vs. response curves for simultaneous presentation of two tones were compared with those for separate presentation of the same tones. Three types of interaction were noted; linear summation, non-linear facilitation, and non-linear suppression. Some cells changed type of interaction depending on the frequency-pair used. Iontophoretic application of 5mM BMI converted non-linear responses to a linear type to a varying degree. These results demonstrate the complex nature of the non-linear interaction across frequency channels in the inferior colliculus of the barn owl, as well as the involvement of GABAergic inhibition in this process. Focusing in Owls and Raptors Measured by Photorefraction

H. Howland, M. Howland & J. D. Pettigrew, Division of Biological Sciences, Cornell University, Ithaca, N.Y. ,14853 & Vision Touch and Hearing Research Centre, Department of Physiology, University of Queensland, St. Lucia, Qld. 4067

Previous work on a number of species of owls has shown that these birds exhibit a very great range of accommodative abilities which are roughly correlated with their size. Large owls exhibit small accommodative ranges while small owls generally exhibit large ones. An exception to this rule is the (medium sized) barn owl, Tyto alba, which showed a greater than 10 diopter accommodative range (1). We have initiated an investigation of the focusing abilities of Australian owls and raptors including three species of tytonid owls, the boobook, and a sparrow hawk, hobby falcon and black kite. We have employed both orthogonal photorefraction and photo-retinoscopy, using for the latter both infra red and visible light. We have found that the speed and range of accommodation of the raptors exceeds that of the Australian Tytonidae. We obtained a clear neutralizing photoretinoscopic refraction of the sparrowhawk (Accipiter cirrhocephalus) showing that it accommodated through 10 diopters. Particularly interesting was the fact that the peripheral fields of the hobby falcon (Falco longipennis) and the sparrow hawk exhibited considerable astigmatism. The implications of the focusing abilities of these birds and the optical qualities of their eyes for their visual capacities will be discussed. Facilites permitting, several of the optical refractive techniques will be demonstrated. Supported in part by NIH grant EY-02994 & a Fogarty fellowship to HCH and a grant from the ARC to JDP.

ACOUSTICALLY RESPONSIVE UNITS IN THALAMIC REGIONS AFFERENT TO THE AVIAN BASAL GANGLIA

S.E. Durand,*J.M. Tepper & M.-F. Cheng, Institute of Animal Behavior and Center for Molecular and Behavioral Neuroscience, Rutgers University, Newark, NJ 07102

Recently, Area X, a region within the oscine parolfactory lobe (LPO) that is a component of vocal pathways, has been implicated in song acquisition in vocal learners. In the Ring dove (*Streptopelia risoria*), a non-vocal learner, caudolateral LPO has not been demonstrated to exhibit a specialized subdivision associated with vocal pathways. However, in the dove, caudal LPO apparently receives auditory input from the thalamic nucleus ovoidalis (Ov). Additionally, a thalamic region, caudal to the thalamic projection of Area X in songbirds, contains acoustically responsive units and is retrogradely labeled from caudal LPO. The possibility that caudal LPO is a region of the basal ganglia involved in acoustic and motor integration, with reciprocal connections.to the thalamus, is a question deserving further investigation across avian species.

The projection from Ov to caudal LPO and the medial paleostriatum augmentatum (PA), initially revealed by the anterograde tracer *Phaseolus vulgaris* leucoagglutinin (PHA-L), was confirmed with the retrograde fluorescent dye, fluorogold. An injection encompassing caudal LPO and anteromedial PA also heavily labeled cells in the caudolateral region of the dorsomedial nucleus of the posterior thalamus (DMP), as well as in the area ventralis of Tsai. Injections that encompassed anterior LPO, but spared its caudal regions, failed to label neurons in Ov or DMP.

During our study of the acoustic responses of Ov neurons, 4 acoustically responsive units in the DMP/DIP border region were recorded in urethane anesthetized subjects. In the absence of acoustic stimulation, these units exhibited low levels of activity, ranging from 0.2 to 0.5 spikes/s and exhibited long latency responses (>25ms) to 500 ms noise bursts. Tone pulses of 200Hz elicited bursts of activity from 2 of these units; one also responded robustly to 500Hz tones. A more dorsally located unit showed only weak responsiveness to frequencies in the range of 2 kHz. A minor projection from Ov to caudal DMP was revealed previously with PHA-L, but it may not constitute the source of auditory input to these units.

HIPPOCAMPAL LESIONS IMPAIR NAVIGATIONAL MAP DEVELOPMENT IN HOMING PIGEONS.

V. P. Bingman, P. Iaolé*, G. Casini* and P. Bagnoli. Dept. Psychology, Bowling Green State Univ., Bowling Green, OH 43403.

The homing pigeon navigational map allows birds to determine their position and take up an approximate homeward bearing from distant, unfamiliar locations. The navigational map shares many characteristics with the "cognitive map" found in the psychological literature, and may be the best example of a naturally occurring cognitive mapping system. The hippocampus has been found to play a critical role for spatial navigation in laboratory rodents. Surprisingly, previous research has shown that hippocampal ablation has no discernible effect on the functioning of the pigeon navigational map in adult birds with homing experience. In contrast, the present study demonstrates that hippocampal ablation in young pigeons who have yet to acquire a navigational map strikingly impairs their latter ability to take up a homeward bearing from distant unfamiliar locations. The data suggest that the avian hippocampus plays a critical role in navigational map acquisition while playing no further necessary role once the map is formed. Alternative explanations will be explored.

512.11

VISUAL FOREBRAIN AND EATING IN THE PIGEON.

R. Jager*, U. Schall*, J.J.Arends, R. W. Allan* and H. P. Zeigler. Biopsychology Program, Hunter College, (CUNY), New York, NY 10021.

The role of forebrain visual structures in the sensorimotor control of eating in the pigeon was examined using a technique combining unilateral hemispherectomy with monocular occlusion to produce a reversible "visual decerebration". Given the hodology of the visual system (complete decussation of the visual pathways to the forebrain) input to the eye contralateral to the intact hemisphere will access, unilaterally, all components of the tectofugal and thalamofugal pathways. For the eye contralateral to the ablated hemisphere, the forebrain components of these pathways will be eliminated. By alternately occluding the eye contralateral to the intact and ablated hemisphere, subjects could be tested first as visually "normal" and then as visually "decerebrate".

When tested in the Binocular condition or using the eye contralateral to the intact hemisphere, subjects showed no impairment on measures of ingestive efficiency, discrimination of food from non-food items, peck localization and the amplitude scaling of gape (interbeak distance) during grasping. When using the eye contralateral to the ablated hemisphere, there were significant impairments in ingestive efficiency, peck localization and discrimination of food from non-food items but no effects upon grasping and amplitude scaling behaviors. The dissociation of localization and grasping deficits suggests that these two tasks are mediated by different neural substrates. *Supported by NSF Grant BNS 88-10722 and NIMH Grant MH-08366.*

AUTORADIOGRAPHIC LOCALIZATION OF MUSCARINIC CHOLINERGIC RECEPTORS IN THE BUDGERIGAR BRAIN

G.F. Ball Dept. of Psychology, Boston College, Chestnut Hill, MA 02167

Budgerigars (Melopsittacus undulatus) a member of the parrot order, possess a neural vocal control system that is possibly homologous, at least in part, to the complex of nuclei that control vocal behavior in the songbird order. A comparison of the transmitters present in the song control nuclei in these two distantly related avian groups may address the question of homology and clarify whether vocal behavior is regulated in a similar fashion in these two taxa. I therefore used in vitro quantitative autoradiography to map the distribution of muscarinic cholinergic receptors, a receptor known to be present in several song control nuclei in songbirds, in male and female budgerigars. Muscarinic receptors were labelled using (^{3}H) N-Methyl scopolamine (1 nM conc. ± 5 µM atropine). Slices were exposed to tritium sensitive film for 1 week. Autoradiograms were analyzed using an image analysis sytem. The highest levels of specific binding were detected in parts of the basal ganglia such as the parolfactory lobe and the paleostriatum augmentatum. Moderate binding was detected in the hypothalamus at the level of the paraventricular nucleus. Of the song control nuclei, the nucleus intercollicular (ICo) in the mid-brain was specifically labelled. No structure could be discerned that resembled the robust nucleus of the archistriatum (RA) homologue. At the level of the anterior commissure a lateral structure exhibiting high specific binding was detected that was near the putative homologue of the caudal part of the ventral hyperstriatum (HVc) in the budgerigar. However, it did not appear to correspond precisely to this nucleus. These data suggest potential differences in the regulation of vocal behavior in parrots and songbirds.

513.1

EFFECT OF DIETARY FAT SOURCE ON MACRONUTRIENT SELECTION B. J. Mullen and R. J. Martin, Dept. of Foods and Nutrition, Dawson Hall, Univ. of Georgia, Athens, GA 30602

We have previously reported that type and level of dietary fat can influence an animal's subsequent preference for carbohydrate (CHO) and protein (PRO). Rats fed a 34% tallow diet show a subsequent preference for a high PRO diet while those fed 34% corn oil show a preference for a high CHO diet. The present study was undertaken to determine if the factor(s) responsible for enhancing PRO consumption in the tallow fed animals is restricted adipose tissue. Hence, we tested the effect of another beef fat, butter, which is derived from secreted lipid rather than a constituent of adipose tissue. Male, Sprague-Dawley rats (75-99 g) were divided into 3 groups and fed diets containing either 34% corn oil, tallow or butter for 2 days. These diets were then replaced with 2 diets given simultaneously to test dietary selection: 1) 15% CHO/60% PRO and 2) 65% CHO/ 10% PRO. Animals previously fed corn oil selected more CHO and less PRO than did animals fed either tallow or butter. The amounts of PRO and CHO selected by animals fed tallow or butter were not significantly different. These results suggest that the factor(s) responsible for altering diet selection are present in both adipose tissue and milk fat.

513.2

ADRENALECTOMY AND CORTICOSTERONE REPLACEMENT: EFFECTS ON MACRONUTRIENT INTAKE. D.L. Tempel, M. Yamamoto*, T. Kim* and S.F. Leibowitz. Rockefeller Univ. N.Y. 10021.

Adrenalectomy (ADX) decreases food intake and body weight and prevents the development of various forms of obesity. The present experiments studied macronutrient intake patterns in rats with "complete" ADX (blood corticosterone [CORT] levels < 2 µg%), "incomplete" ADX (blood CORT levels >3 µg%), and after low vs. high doses of CORT replacement.

Results indicate that, in complete ADX rats, both 24hr carbohydrate intake (-25%; $p<0.05$) and 24hr fat intake (-35%; $p<0.05$) are decreased, whereas in incomplete ADX rats, only fat intake is suppressed (-40%; $p<0.05$). This suggests that low circulating CORT levels are sufficient to maintain 24hr carbohydrate but not fat ingestion. This suppression of carbohydrate feeding occurs almost exclusively during the first 2 hrs of the dark cycle, when endogenous CORT levels as well as natural carbohydrate feeding normally peak. In contrast, the decrease in 2hr fat intake is only a small portion (20%) of the total 24hr fat suppression seen in both complete and incomplete ADX rats, which appears to occur uniformly throughout the feeding cycle.

Consistent with the finding that carbohydrate feeding in the early dark is lost only in complete ADX rats with <2 µg% CORT, tests with CORT replacement show that low levels of administered CORT (0.05-0.5 mg/kg via s.c. injection, implants or orally), which raise blood hormone levels to between 1 and 5 µg%, are effective in restoring early dark carbohydrate feeding; however, only higher doses of CORT (>2.0 mg/kg), resulting in blood levels of >10µg%, effectively restore 24hr fat intake. These results indicate that nutrient intake is differentially affected by ADX at different times of the feeding cycle and that low levels of CORT are sufficient to maintain or restore carbohydrate intake, while higher levels are necessary to restore fat intake. It is suggested that different steroid receptors in the brain may underlie these effects.

513.3

VARIATIONS IN THE EFFECTIVENESS OF TYPE II RECEPTOR STIMULATION ON FEEDING AND WEIGHT GAIN IN RATS. L. Devenport*, C. Hicks, and R. Stith. Dept. Psychol., Univ. Oklahoma, Norman OK 73019 and Dept. Physiol., Univ. Oklahoma Hlth. Sci. Ctr., Oklahoma City OK 73069.

Of the numerous metabolic functions of corticosterone (Cort), virtually all can be assigned to the message derived from its type I receptor. This opens the question as to the role of the high density/low affinity type II receptor. The endogenous type II signal is relatively brief and is delivered against a background of type I saturation. The present study examined the relative effectiveness of this pattern of signalization. The type II agonists, dexamethasone (Dex) and RU28362 (RU) were chronically administered in the presence or absence of continuous type I stimulation. Dex and RU were delivered by continuous infusion or by single daily injections at 7 pm. Administered alone, RU and Dex reduced body weight gain, feeding efficiency, and food intake. Continuous infusion was considerably more suppressive than injection and produced wide fluctuations in daily body weight gain. The suppressive effects of Dex and (especially) RU were attenuated when type I receptors were occupied; the lowest dose of RU (5ug/kg/day) slightly augmented the strong anabolic effect of the type I agonist (Aldo). The outcome of type II receptor stimulation depends upon mode of administration and concurrent type I activity.

513.4

BODY WEIGHT GAIN IN RATS AFTER FOOD RESTRICTION AND ADRENALECTOMY (ADX) IS INCREASED BY INTRAVENTRICULAR (IVT) CORTICOSTERONE (CORT). P.K.Green, C.W.Wilkinson, S.C.Woods. Depts Psych and Psychiat and Behav Sci, Univ Wash, Seattle WA 98195 and VA Med Ctr, Tacoma WA 98493.

ADX gold thioglucose-treated mice reportedly increase food intake and body weight after a single IVT injection of CORT. To study the role of CORT on weight gain, Long-Evans rats were either allowed free access to chow (AD LIB group) or food restricted (RES) to half baseline daily food intake (18 g/day) for two weeks prior to ADX or sham operation. The next day rats received a single IVT injection of 100ug CORT in 2 ul propylene glycol vehicle, or 2 ul vehicle (VEH). This dose of CORT had no effect on body weight gain when administered subcutaneously. In both AD LIB and RES groups, ADX arrested or decreased weight gain over the six days following the injection (AD LIB: mean loss of 1.8g for ADX vs. gain of 14.9g for SHAM; RES: ADX gained 46.6g, SHAM 74.3g). In the AD LIB group, IVT CORT non-significantly reduced weight gain relative to their controls. In the RES group, IVT CORT significantly decreased body weight gain in SHAM rats (CORT: 68.4±7,4g, VEH: 82.6±4.4g), yet significantly increased body weight gain in ADX rats (CORT: 59.7 ±5.6g, VEH: 36.7±7.5g). It is concluded that centrally-acting CORT has a role in determining body weight regain after food restriction in non-obese rats.

513.5

RATS OVERFED AS NEONATES BECOME OBESE AND INSULIN RESISTANT AS ADULTS. J. Diaz, E. McGarvey, G. Watkins* and A. Scheurink*. Dept. of Psychology, University of Washington, Seattle, WA 98195

Animal models of the various aspects of non-insulin-dependent diabetes (NIDDM) have typically used mutant rat strains and or severe pharmacological insults such as streptozotocin lesions of the pancreas. This experiment precipitated aspects of NIDDM with environmental manipulations during development.

At four days rat pups were randomly assigned to one of three groups 1) mother reared in litters of ten (MR) 2) gastrostomy-fed for nine days (Days 5-14) to match the growth of the MR group (WM), and 3) gastrostomy-fed with excess formula to accelerate growth (OF). At Day 14, the gastrostomy-fed groups were returned to dams. All animals were weaned on Day 21. Females were bred at age 65 days. At 180 days females who had a successful pregnancy received IV glucose challenges via chronic jugular catheters.

Overfed animals became frankly obese after puberty. Only the less severely obese females were able to carry a pregnancy to term, and their pups were significantly smaller than the offspring of sibling controls. An exaggerated insulin response to the IV glucose challenge was seen.

These data demonstrate that nutritional manipulations early in life may produce an adult with some of the characteristics of NIDDM.

513.6

EFFECTS OF LESIONING THE AMYGDALA, PARABRACHIAL NUCLEUS AND THE HYPOTHALAMIC PARAVENTRICULAR NUCLEUS ON LIPOPRIVIC AND GLUCOPRIVIC FEEDING. N.Y. Calingasan, B.W. Hutton* and S. Ritter. Department of VCAPP, Washington State University, Pullman, WA 99164-6520.

Previous results have shown that feeding, stimulated by mercaptoacetate-induced blockade of fatty acid oxidation (lipoprivic feeding), is dependent on vagal sensory neurons innervating the abdominal viscera. Feeding elicited by 2-deoxy-D-glucose-induced blockade of glucose utilization (glucoprivic feeding) does not require peripheral vagal neurons, but is abolished by area postrema (AP)/NTS lesion. In this study, lesions were placed in the central nucleus of the amygdala, parabrachial nucleus and the hypothalamic paraventricular nucleus, areas known to receive visceral sensory projections from the AP/NTS region, in order to identify central neural substrates for these controls of feeding. After recovery from surgery, rats were placed on a medium fat diet for at least 2 wks and then tested for lipoprivic and glucoprivic feeding. Electrolytic lesions which included the central nucleus of the amygdala abolished lipoprivic, but not glucoprivic, feeding. Kainic acid lesions of the lateral parabrachial area did not impair either control. Relatively large hypothalamic lesions destroying the paraventricular nucleus disrupted both controls. Thus, areas containing projections from the AP/NTS region may be important for glucoprivic and lipoprivic feeding. The projections critical for each control may be distinct, although convergent at some sites.

ABLATION OF GLUTAMATE-SENSITIVE AREA POSTREMA NEURONS DOES NOT ABOLISH GLUCOPRIVIC FEEDING. M.G. Hulsey, D.K. Hartle and R.J. Martin. Depts. of Foods & Nutrition and Pharmacology. Univ. of Ga., Athens, Ga.

High plasma levels of monosodium glutamate (MSG, s.c.) cause a selective loss of glutamate-sensitive neurons (GSN) in the area postrema (AP). The neurochemical profile of most GSN in AP are tyrosine hydroxylase (TH) immunoreactive (IR) ① and/or 5HT IR ② (Phelix and Hartle, BRES ① in press, ② submitted for publication). Approximately 2500 neurons are killed in the AP while no pyknotic nuclei appear in the adjacent NTS or other circumventricular organ regions. Only subfractions of the total TH-IR and 5HT-IR AP cell populations are GSN. Remainder populations are glutamate-insensitive, even with a subsequent MSG treatment. AP/NTS has been implicated in the glucoprivic feeding response subsequent to 2-Deoxyglucose (2-DG) administration. We tested whether the GSN of AP are critical to this response. We treated eight 220 g male SD rats with 6 mg/g s.c. MSG. Five days later, 4 of the rats were given a glucoprivic challenge. In the 3rd h of the 12 h photoperiod, 400 mg/kg 2-DG or saline was administered i.p. in a randomized block design (N=4 each group). Intake of ground chow was computer-monitored at resolutions of .5 Hz and .01 g. An analogous second trial was performed using an MSG dose of 9 mg/g. Cumulative food intake values for the 3h post-injection period were subjected to 1-way ANOVA. In both MSG treatments, ablation of the GSN in AP failed to inhibit the glucoprivic feeding response to 2-DG ($p < .008$). We conclude the GSN of the AP are not involved in the glucoprivic feeding response. Support: HLBI 37705.

THE EFFECT OF INTRAVENOUS INSULIN ON CEREBROSPINAL FLUID (CSF) BIOGENIC AMINE CONCENTRATIONS IN ANESTHETIZED RATS. **Thomas W. Castonguay and Wayne J. Kuenzel University of Maryland, College Park, Maryland 20742**

Intact rats will self-administer insulin i.v. if the concentration of each injection is within 50-100 mIU. The purpose of the present experiment was to measure the effects of insulin on changes in serotonin and dopamine metabolite concentrations in CSF. Adult rats were anesthetized, fitted with jugular vein cannulae, and injected with 1 of 3 doses of insulin: 100, 200 or 300 mIU. CSF was collected at 0, 10 and 30 min. after injection. Analysis of CSF samples was performed using HPLC with electrochemical detection. Within 30 minutes 5-HIAA increased 13, 31 and 22 percent over baseline levels in the 100, 200 and 300 mIU groups respectively. CSF DOPAC increased 50% in response to 100 mIU insulin within 10 minutes of injection. Higher insulin concentrations resulted in an inverse relationship with DOPAC, with a 22% decrease observed at 30 min. These results suggest that insulin favors increased serotonin and dopamine metabolism. (Supported in part by a grant from the Whitehall Foundation).

HYPERINSULINEMIA AND REDUCED SODIUM EXCRETION IN DIETARY OBESE, WEIGHT-CYCLED RATS. R. J. Contreras. Department of Psychology, University of Alabama, Birmingham, AL 35294.

The aims of the present study were to: (1) replicate the findings of Ernsberger and Nelson (*Am. J. Physiol.*, 254: R47-R55, 1988) reporting the development of mild hypertension in dietary obese Sprague-Dawley (S-D) rats exposed to 4 cycles of food restriction-refeeding (weight cycling) on a sweet milk diet; and (2) determine whether the mild hypertension was associated with changes in sodium excretion, hyperinsulinemia, pressor responsiveness to angiotensin II, and heart rate response to pharmacological blockade of the autonomic nervous system. Twenty-five male S-D rats were divided among 3 groups: 8 rats were fed Agway pelleted chow (Pellet); 8 rats were fed pelleted chow plus sweetened condensed milk (Milk); and 9 rats were exposed to 4 cycles of a 4-d fast alternated with 2-wk of refeeding pelleted chow and sweetened condensed milk (Cycled).

Dietary obesity and weight cycling resulted in significant elevations in body weight and terminal brown fat pad and white fad pad weights, hyperinsulinemia, and reduced sodium excretion. In contrast to Ernsberger & Nelson, weight cycling superimposed on dietary obesity did not alter (1) blood pressure, or (2) heart responses to sympathetic blockade with metoprolol and parasympathetic blockade with methylscopolamine. The pressor responses to intravenous administration of angiotensin were also unaffected by obesity and weight cycling. The dietary obese, weight-cycled S-D rat may not be a good animal model for human obesity-related hypertension.

WHEN MAINTAINED ON A RESTRICTED DIET, RATS REARED IN ENRICHED ENVIRONMENTS DEFEND BODY WEIGHT BETTER THAN RATS REARED IN ISOLATION. **S.C. Fowler, J.M. Chase, M.J. Kallman, and P. Hopkins*. Depts. of Psychol. and Pharm., Univ. of Mississippi, University, MS 38677.**

Between the ages of 22 and 82 days rats were reared, under ad libitum food and water conditions, in either enriched environments (n=37) or in individual isolation cages (n=32). Then all rats were restricted to daily 1 hr feeding for the next 78 days. At this time enriched rats were significantly heavier than the isolates, $t(67)=3.275$, $p=0.002$. In addition, the difference between pre- and post-feeding body weights significantly favored the enriched rats by 4.63g, $t(67)=2.822$, $p=0.006$. These results suggest that superior defense of body weight by the enriched rats is behaviorally mediated via the enriched rats eating at a higher rate than the isolates. A second study replicated the first and further showed that (1) isolates are heavier than enriched rats when fed ad libitum and (2) limiting feeding to 1 hr/day does not abolish the brain-weight-increasing effects of enriched environment rearing. **Supported by DA 05310.**

DIET-INDUCED OBESITY (DIO) AND HIGH ENERGY DIET (HED) ADVERSELY AFFECT LOCAL CEREBRAL GLUCOSE METABOLISM (LCGU). B.E. Levin. Neurology Svc., VA Med. Ctr., E. Orange, NJ 07019, Dept. Neurosciences, NJ Med. Sch., Newark, NJ 07103.

Previous studies (Levin & Sullivan, 1989) showed that rats prone to develop DIO had defective activation of autonomic brain areas to food-related cues. Here, 24 adult male SD rats were fed an HED for 3mo; half became DIO, gaining 58% more weight, while the rest were diet resistant (DR), with the same weight gain as 12 chow-fed rats. Fasting rats were then trained to drink 1ml of 50% glucose in 1min associated with a tone cue. LCGU was then assessed in 20 brain areas, using [14C] 2-deoxyglucose (Sokoloff et al., 1977), with tone alone or with tone plus 0.15% saccharin in place of glucose. DR but not DIO rats increased LCGU 14% to saccharin intake in the n. tr. solitarius while overall LCGU was 14% lower in the central amygdalar n. of DIO rats. HED intake led to reduced inferior olive LCGU to saccharin and a 15% overall increase in medial amygdalar n. LCGU in DR and DIO vs. chow-fed rats. Thus, both DIO and HED intake adversely affect activation of brain autonomic areas to food related cues. This may play a role in development and perpetuation of DIO.

ESTRADIOL INCREASES SYMPATHETIC NERVOUS SYSTEM ACTIVITY IN RETROPERITONEAL ADIPOSE TISSUE. S.J. Lazzarini and G.N. Wade. Neuroscience and Behavior Program and Dept. of Psychology, Univ. of Massachusetts, Amherst MA 01003.

Estrogens have both central and peripheral effects on body weight in rats. Ovariectomy (OVX) results in body weight gain (primarily by increasing fat stores) and estradiol replacement therapy reverses these effects. The sympathetic nerves play a role in estradiol-induced fat pad weight losses in OVX rats. Denervation of retroperitoneal adipose tissue (RWAT) attenuates fat pad weight loss. This effect is not due to alterations in the concentration of cytosol estrogen receptors. We determined whether estradiol-induced fat pad weight losses are accompanied by increased RWAT norepinephrine (NE) turnover, an index of sympathetic activity. Rats were OVX and treated with estradiol benzoate (EB) or sesame oil vehicle. NE turnover was assessed by measuring the decline of tissue NE over time after injection of α-methyl-*p*-tyrosine, an inhibitor of tyrosine hydroxylase activity and thus NE biosynthesis. NE turnover in RWAT, but not heart, was significantly greater in animals treated with EB, suggesting that estradiol decreases fat pad weight in part by increasing sympathetic nervous system activity. It is possible that estradiol acts in the brain to regulate the activity of the sympathetic nerves. (Supported by NS 10873, DK 32976, and MH 00321.)

(-)*threo*-CHLOROCITRIC ACID DECREASES SHAM FEEDING OF SUCROSE IN RATS. S.C. Weatherford, W.B. Laughton, J. Salabarria* and D. Nelson*. Neurobiology and Obesity, Hoffmann-La Roche Inc., Nutley, NJ 07110.

It has been proposed that the novel anorectic agent, (-)-*threo*-chlorocitric acid (CA), decreases food intake through a reduction in gastric emptying (Pharm. Bio. Behav., 1981). If so, CA should not decrease sham feeding, a preparation where postingestive cues such as gastric distension are greatly minimized. Here we examine the effect of CA in rats sham feeding 20% sucrose relative to the appropriate "real" feeding condition.

RESULTS: Values are mean ± SEM % of baseline intake

	Real Feeding			Sham Feeding		
	Minutes of Feeding Tests					
Dose	0-15	0-60	0-120	0-15	0-60	0-120
100	75±5*	86±6	103±6	94±1	91±2	83±2
200	83±6	78±5*	92±6	105±3	84±2*	64±2*
400	52±9*	50±8*	42±6*	89±4	73±6*	49±7*

Tests were conducted in the a.m. after a 17 hr fast, N=8, doses are mg/kg, p.o. given 30 min before sucrose, * $p < .05$.

CONCLUSIONS: Since CA decreased sham feeding, its anorectic effect cannot be solely attributed to inhibition of gastric emptying. However, since CA was more potent in the real feeding condition relative to sham feeding and the time course of the response in the two feeding conditions was different, this suggests that part of CA's anorectic effect does depend on postingestive cues.

513.14

DUODENAL GLUCOSE INFUSION IN THE RABBIT. P.J. Geiselman, A. Acevedo-Cruz*, and D.S. Gray. Dept. Psychol., UCLA; Div. Diab., USC Sch. Med., Los Angeles, CA 90024.

Rapid duodenal glucose infusion (3 ml/min) increased chow intake in free-fed and meal-fed rabbits. Slow duodenal glucose infusion (1 ml/min) increased food intake in meal-fed rabbits but decreased food intake in free-fed rabbits, suggesting that daily pattern of meal-taking can determine whether glucose produces satiety or hunger.

To define further conditions under which glucose produces satiety or hunger, blood glucose and insulin were measured in free-fed rabbits. After fast duodenal glucose infusion, insulin increased sharply, followed by a precipitous decline in blood glucose. Slow duodenal glucose infusion increased insulin moderately, which failed to decrease glycemic levels significantly. Tests are being conducted to determine whether feeding responses vary across trials in free-fed rabbits (as found in meal-fed rabbits) and, if so, if changes in food intake are related to blood glucose and insulin responses.

CONDITIONED SATIETY DEPENDS ON GASTRIC AND POSTGASTRIC SIGNALS. J. Miesner*, G.P. Smith, J.D. Davis, and P. Olcese*, New York Hospital-Cornell Medical Center, White Plains, NY 10605 and University of Illinois, Chicago, IL 60680.

When rats are given consecutive sham feeding (SF) tests, intake increases progressively to a maximum in 4-5 tests. Interspersing 2 real feeding (RF) tests between SF tests prevents this progressive increase in intake (Davis & Smith, 1990). This result suggests that a learned association between the flavor of the test diet and its postingestional consequences under real feeding conditions inhibits sham intake (conditioned satiety). To determine if the postingestional factor is of gastric and/or postgastric origin, 10 rats equipped with a surgically implanted, inflatable, pyloric cuff and a gastric fistula were tested with a 0.8M sucrose diet on 6 cycles of 2 RF tests followed by 1 SF test. On all tests the pyloric cuff was inflated to prevent postgastric stimulation by the ingested fluid. Under these conditions sham intake increased with experience ($p<.01$), but not as much as when no RF tests intervened. Since no progressive increase in sham or real intake occurred when food emptied normally from the stomach during real feeding, we conclude that postgastric stimulation is a necessary component of postingestional stimulation for normal conditioned satiety. The results also reveal a significant effect of gastric stimulation because the increase in sham intake observed when the ingested food accumulated in the cuff-closed stomach during RF tests was significantly less than the progressive increase in sham intake when sequential SF tests were administered without interspersing 2 RF tests.

RUNNING WHEEL ACCESS AND EATING BEHAVIOR OF MALE RATS. R. Eikelboom. Dept. of Psychology, Wilfrid Laurier Univ., Waterloo, Ont N2L 3C5

Food consumption drops by about 30% when running wheels are made available (Looy & Eikelboom, Physiol Behav., 45:405, 1989). This study recorded only total daily food consumption and running. The nature of the change in feeding needs to be determined.

In the present study 8 male Sprague-Dawley rats (310-325g) where housed in individual cages (as weight controls n=4) or in special cages with pellet dispensers (45mg Rodent Chow Bio-Serv) providing ad lib food. For 9 days food and water consumption patterns were recorded in 5 sec bins. Then wheels were made available for 30 days and all three behaviors recorded. Wheels were closed and food and water consumption recorded for a further 30 days.

When rats had wheel access food consumption dropped by about 40%. By 30 days it had returned to about 80% of baseline. These changes were due to changes in meal number (from 18.8 to 10.7 meals a night when the wheel was opened to 13.6 after 30 days). There was no simultaneous change in the meal size. (Work sponsored by NSERC)

DAILY CYCLES IN SOME THERMOREGULATORY RESPONSES OF PIGEONS DURING FOOD DEPRIVATION AND RESTRICTED FEEDING.

D.L. Phillips*, M.E. Rashotte, and R.P. Henderson*. Psychobiology/Neuroscience Program, Department of Psychology R-54, Florida State University, Tallahassee, FL 32306-1051.

Core body temperature (Tb), whole-body thermal conductance (C), and whole-body heat loss (HL) were studied in pigeons during two conditions: **food deprivation** for several days, and **single daily feeding** to maintain body weight at 80% of ad libitum values for several months. Twenty-four hour measurements during the 12h:12h L:D cycle show: i) during **food deprivation**, C is reduced more rapidly than Tb; and, Tb develops a larger-amplitude cycle while the amplitude of the C cycle is reduced; ii) during **single daily feeding**, occasional variation in the amount of food presented markedly affects the amplitude of the Tb cycle, but not the C cycle; and, the time at which food is presented in the day alters the cyclic pattern of Tb and C, but does not affect total daily HL. In both conditions, C contributed more to the reduced HL than did Tb, indicating its predominance as an energy conservation mechanism.

GABA$_A$ AND BENZODIAZEPINE BINDING IN ADULT AND PERINATAL RODENT SUPRACHIASMATIC NUCLEUS. M. Li* and J. L. Fuchs. Univ. of North Texas, Dept. Biological Sciences, Denton, TX 76203.

GABA$_A$ and associated benzodiazepine binding sites have been implicated in the control of rodent circadian rhythms. Certain GABA$_A$ and benzodiazepine agonists or antagonists can produce or block phase shifts, or alter the free-running period. Interest in these systems led us to examine [^{3}H]muscimol (GABA$_A$) and [^{3}H]flunitrazepam (benzodiazepine) binding in rat and hamster suprachiasmatic nucleus (SCN), the primary circadian pacemaker. Receptor autoradiography was used to test for the presence of rhythms which might underlie the phase-dependency of the pharmacological effects. No diurnal differences in ligand binding were found, using 6 rats at each of 8 time points in LD 12:12. In addition, there were no differences in light versus dark at night.

[^{3}H]Muscimol and [^{3}H]flunitrazepam binding increased in the rat SCN from embryonic day 18 to near adult levels by E20. The increases probably do not depend upon synaptogenesis, as very few synapses are present in the fetal SCN. The rises occurred around E19, when the SCN [^{14}C]2-deoxyglucose rhythm is first entrained to the maternal rhythm, suggesting that GABA$_A$ and associated benzodiazepine binding sites might participate in fetal entrainment. Supported by MH41865.

ALLOXAZINE BLOCKS THE HYPNOTIC EFFECT OF TRIAZOLAM IN RATS. **S.D.O'Connor and M. Radulovacki, Dept. of Pharmacology, Univ. of IL., Chicago, IL 60612.**

Triazolam, a benzodiazapine (BDZ) hypnotic, appears to mediate several of its effects through receptors coupled to the GABAergic system. It has been hypothesized that central effects of BDZs are mediated in part through the adenosine (ADO) system (Phillis and O'Regan, TIPS 9: 5, 1988). Recent work from our lab has demonstrated the interaction between these two systems, since chronic i.c.v. administration of a specific ADO transport inhibitor, soluflazine, mimicked the effect of chronic administration of triazolam, by decreasing radioligand binding to ADO A2 receptors in the striatum. To further examine the role of ADO in the hypnotic effect of BDZs, we measured the effect of acute administration of an ADO A2 receptor antagonist, alloxazine (ALX) on sleep induced by triazolam. Sprague-Dawley rats given 0.1 mg/kg triazolam i.p. showed decreased waking (25%) and increased total sleep (10%) as compared to controls during a 6 hour recording period ($p<0.05$). Pre-treatment of rats with 5mg/kg ALX i.p., which had no effect on waking by itself, resulted in a return to control levels of sleep when given in combination with triazolam. These results indicate that at low doses, sleep induced by triazolam may be a function of increased ADO activity that can be blocked by ADO A2 receptor antagonists.

DOES THE PHASE-SHIFTING EFFECT OF AN ACUTE INCREASE IN ACTIVITY ON CIRCADIAN RHYTHMS OF HAMSTERS INVOLVE BENZODIAZEPINE RECEPTORS? C. Wickland and F. W. Turek, Dept. Neurobiol. & Physiol., Northwestern U., Evanston, IL.

Treatment of golden hamsters with the short-acting benzodiazepine, triazolam, is associated with acute increases in activity and phase-dependent shifts in the circadian rhythm of locomotor activity which can be prevented by prior treatment with the benzodiazepine antagonist, RO-15-1788. Since transfer to a new cage with a running wheel a few hours before the onset of activity also induces phase advances in the activity rhythm in hamsters normally housed without wheels, we conducted this study to examine the effects of administration of RO-15-1788 on the phase-shifting effect of this transfer. Hamsters housed without running wheels in constant light were treated 4 hours before activity onset with (1) transfer to a new cage with a wheel for 1 hour (RO+Wh), (2) 5 mg RO-15-1788 and transfer to a new cage with a wheel for 1 hour, or (3) 5 mg RO-15-1788 alone (RO). Phase advances induced by RO+Wh ($\bar{x}$=46±22 min.) were smaller than those induced by Wh ($\bar{x}$=132±48 min.) and larger than those induced by RO ($\bar{x}$=15±8 min.), but were not significantly different from either. The number of wheel revolutions in group RO+Wh was significantly less than those in group Wh ($p<.01$). Also, the increase in total locomotor activity during the hour of treatment for group RO+Wh was significantly less than the activity increase for group Wh ($p<.05$), and significantly greater than the activity increase for group RO ($p<.01$). These results suggest that treatment with RO-15-1788 attenuates the phase-shifting effect of an acute increase in activity on the circadian rhythm of activity in hamsters. These results also indicate that RO-15-1788 has an inhibitory effect on the amount of increased activity that normally occurs after transfer to a new cage with a running wheel.

514.4

NOCTURNAL ADMINISTRATION OF FENTANYL: THE POTENTIATION OF THE THERAPEUTIC EFFECT IN RATS. R.A.Del Vecchio*, A.V.Wing*, C.A.Taylor, C.Tsai and M.J.Benvenga. Anaquest/BOC Health Care, Murray Hill, New Jersey, 07974.

Modern chronopharmacology involves the study of the effect of biological timing on the affinity and response of an organism to chemical agents. The present study investigated the behavior following nocturnal (2000-2400 hrs) or diurnal (0900-1400 hrs) administration of fentanyl to rats.

Male rats (N=6/dose) were treated with fentanyl intravenously and assessed for loss of righting (LOR). The ED50 for nocturnal administration (0.005 mg/kg) was approximately 3 times more potent than when fentanyl was administered diurnally (ED50 = 0.0175 mg/kg). In addition, the duration of LOR at night (2.68 min) was over 3 times shorter than when given during the day (8.76 min). The recovery index, assessed with a rotarod, indicated that the nocturnal recovery (31.3) was faster than the recovery during the day (18.2). Preliminary biochemical analysis (night vs. day) has revealed a trend difference in kappa binding while mu and delta binding remains to be reconciled. These results may have implications in the clinical use of opiates.

514.5

EFFECTS OF MUSCARINIC ANTAGONISTS ON SLEEP. R.K. Zoltoski, J. Velazquez-Moctezuma, M. Shalauta*, S.L. Lucero*, C. Floyd*, J.C. Gillin, P.J. Shiromani. Dept. of Psychiatry, San Diego VAMC, and Univ. of CA, San Diego, San Diego, CA 92093.

It is well known that muscarinic receptors regulate the onset of REM sleep. Recent findings from our laboratory indicate that REM sleep in cats can be elicited by M2 muscarinic receptor stimulation in the medial pontine reticular formation. The present study was designed in rats to assess the participation of M1 receptors in the regulation of REM sleep. Sprague-Dawley rats that were chronically instrumented for sleep recordings were injected in a randomized fashion with five doses (0,0.5,1,2, and 4 mg/kg) of trihexyphenidyl, a selective M1 antagonist or scopolamine, a non-selective muscarinic antagonist. There was no significant change in sleep latency by either drug. Following all doses of scopolamine, a significant increase in REM latency, as defined from time of sleep onset, was observed. However, a significant increase in REM latency was observed following only the highest two doses of trihexyphenidyl. Additionally, the preliminary effects of biperiden (2,4, and 8 mg) in human subjects suggest that M1 receptors exert no influence on the regulation of REM sleep. These preliminary findings in conjunction with our cat data support our hypothesis that M1 receptors do not play a significant role in the onset of REM sleep.

514.6

OLFACTORY BULBECTOMY LENGTHENS TAU IN MALE SYRIAN HAMSTERS David R. Pieper, Melinda Thompson* and Catherine Lobocki*, Providence Hospital, Department of Physiology, Southfield, MI 48037

Olfactory bulbectomy (BX) increases gonadotropin secretion in male hamsters. BX also lengthens the free-running period of locomotor activity (tau) in rats and mice. It is possible that a longer tau could be causally related to the increase in gonadotropin release. The present study examined whether BX lengthens tau in hamsters.

Twenty-three day old hamsters were BX or sham BX (SH) and one half of each surgical group was placed in cages with exercise wheels (EX group) while the other half was housed in similar cages without wheels (SED). At this time all animals were on a 14L:10D photoperiod. Eight weeks later, all animals were transferred to an animal room on constant darkness (DD) in order to assess tau. Activity rhythms were monitored with an Esterline-Angus recorder.

While the animals were still on 14L:10D, BX delayed activity onset in relation to lights off from .15 ± .034 hr to .37 ± .025 hr ($p < 0.001$). When the animals were placed on DD, the mean tau was 24.08 ± 0.04 hr in the SH animals compared to 24.41 ± 0.03 hr in the BX group ($p < 0.001$).

In conclusion, the olfactory bulbs exert a tonic influence on the circadian clock of hamsters so that the period of the clock is longer. It remains to be determined by what mechanism or neural pathway this influence is mediated, and whether the longer tau is involved in the effect of BX to increase gonadotropin secretion.

INTRACELLULAR RECORDINGS FROM TUBEROMAMMILLARY NEURONES IN AN ISOLATED AND PERFUSED WHOLE BRAIN OF GUINEA-PIG IN VITRO.

A. KHATEB, M. SERAFIN AND M. MUHLETHALER, *Dept de Physiologie, CMU,1211 Genève 4, Switzerland*

Following extracellular recordings in behaving cats it has been suggested that histaminergic neurones from the tuberomammillary nucleus (TM), which have widespread projections in the brain, play an important rôle in the control of arousal (Lin et al., Brain Res., 1989, 479: 225-240). Recently rat TM neurones were shown to survive well in vitro in an explant of the basal hypothalamus (Haas and Reiner, J.Physiol., 1988, 399: 633-646) and to resemble in many respects other aminergic neurones. While this technique is useful for assessing the intrinsic properties of TM neurones (Green et al., J.Physiol., 1990, 420:149-163), it cannot resolve their synaptology, which is important in order to understand their rôle in the control of behavioral states. It was thus of interest to determine whether such TM neurones could survive in an isolated and perfused whole brain (IWB) of guinea-pig in vitro and in a first step to determine whether their properties would resemble those of TM neurones recorded in the rat explant. We recorded from 20 TM neurones in the IWB. As shown previously TM neurones were mainly characterized by their broad action potential and the presence of a transient rectification due to an A current. Their basic properties were (mean ± SEM): resting potential, -58.3 ± 1.23 mV (n=11); spike amplitude: 64.4 ± 2.04 mv (n=14); spike width 2.16 ± 0.079 ms (n=13). These neurones discharged spontaneously at a rate of 13.95 ± 1.76 spikes/s (n=11). It is concluded that TM cells survive well in the IWB and that this model can be usefully applied to their further study in vitro (supported by a Swiss NSF grant no. 31-26495.89)

514.8

NEUROTRANSMITTER MODULATION OF FIRING MODE IN THALAMIC INTRALAMINAR NEURONS AND ITS FUNCTIONAL IMPLICATIONS Anne Williamson and David A. McCormick Neuroanatomy Section, Yale Medical School.

The thalamic intralaminar nuclei collectively innervate wide regions of the neocortex and have been proposed to contol in part the excitability and pattern of activity generated in thalamocortical circuits. Indeed, neuronal activity in the intralaminar thalamic nuclei exhibits two distinct states: rhythmic burst firing during drowsiness and slow wave sleep, and single spike activity during periods of waking, attentiveness and REM sleep. The ascending modulatory neurotransmitter systems which release acetylcholine (ACh), histamine (HA), norepinephrine (NE) or serotonin (5-HT) determine which state these neurons exhibit. Here we investigate, using standard extracellular and intracellular electrophysiological techniques, the actions of these four neurotransmitters on thalamocortical relay neurons in the guinea pig centromedian and reuniens nuclei, maintained as thalamic slices *in vitro* .

Extracellular recordings revealed that at rest intralaminar neurons fire spontaneous high frequency (200-400 Hz) bursts of action potentials at a regular rate of 0.5-3.0 Hz. Local application of HA, NE, or ACh resulted in an abolition of rhythmic burst firing and the promotion of single spike activity. In contrast, application of 5-HT resulted in an abolition of rhythmic burst firing without the promotion of single spike activity. Intracellular recordings reveal that these changes in firing mode are mediated by three ionic actions: 1) a slow depolarization associated with a decrease in membrane conductance; 2) a decrease in response to large hyerpolarizing current pulses, possibly mediated by an enhancement of the hyperpolarization-activated cation current I_h; 3) an abolition of the slow Ca^{++}-activated K^+ current I_{AHP} in a subpopulation of neurons. Together, these ionic actions potently inhibit the generation of rhythmic oscillations and promote single spike activity by depolarizing the neuron out of the range in which slow oscillations can occur, by reducing responsiveness to large inhibitory inputs, and by abolishing the slow afterhyerpolarization and consequently, spike frequency adaptation. These changes in the firing mode of intralaminar neurons may then prepare the cortex to receive information arising from the primary sensory nuclei.

STUDY OF BEHAVIORALLY DEPENDENT PAIRED-PULSE FACILITATION AND INHIBITION IN THE HIPPOCAMPAL CA1 REGION. F. Cao and L.S. Leung. Depts. of Clin. Neurol. Sci. and Physiology, Univ. Western Ontario, London, Ontario, Canada, N6A 5A5.

It has previously been reported that excitatory postsynaptic potentials and population spike evoked by stimulatum of afferents to the basal dendrites and the apical dendrites of pyramidal cells in hippocampal CA1 region are dependent on behavioral state. To further study the modulation of neuronal transmission by behavioral state, double pulses of electrical stimulation with interpulse interval (IPI) at 20, 30, 50 and 100 msec were delivered to Shaffer collaterals in the chronically implanted rat preparation during each of four behavioral states: immobile awaking (IMM), voluntary walking (WLK), slow-wave sleep (SWS) and REM sleep (REM). The paired pulse index (PPI, ratio of the amplitude of second population spike to that of first one) was classified according to the amplitude of first population spike (P1). The results showed that in a certain range of P1 amplitude the population spike of second pulse was significantly greater than first one (PPI>1) during WLK and REM at an IPI of 30, 50 and sometimes 100 msec. On the contrary, PPI<1 was observed during IMM and SWS for the same IPIs. If the IPI was decreased to 20 ms, the second population spike would be smaller than first one in most cases no matter which of the four behavioral states the rat was in. These results indicate that facilitation is the dominant response during WLK and REM, but inhibition is the dominant response during IMM and SWS. Besides, The PPI increased significantly as IPI increased from 20 to 50 msec for a given averaged P1 value for each of four behavioral states, which suggests that the ratio of facilitation to inhibition became greater as IPI prolonged. (Supported by NS25383 and NSERC).

514.10

SHORT-TERM CHANGES IN EEG-DESYNCHRONIZED STATES AFTER IBOTENIC INJECTION INTO INTRALAMINAR THALAMIC NUCLEI. G.Marini*, I.Gritti & M.Mancia (SPON: European Neuroscience Association). Istituto Fisiologia Umana II and *C.N.R.-ITBA, via Mangiagalli 32-Milano (Italy)

In this study we have examined the short-term effects (2 days) on the behavioral states of bilateral injections of ibotenic acid into the intralaminar thalamic complex.Nine cats,implanted with sleep recording electrodes, were used. Under ketamine anesthesia the animals received the excitoxin (50µg/µl-1.8µl) stereotaxically in the rostral (centralis lateralis,CL) or caudal (centrum medianum,CM) nuclei.When recovering from anesthesia, both groups of animals overacted to sensory stimuli and displayed a highly aroused behavior, associated with saccades and fast desynchronized EEG patterns.This acute enhancement was followed by a decrease in the amount of both EEG-desynchronized states (wake and REM sleep) and REM saccades,even though the amount of REM sleep increased in CL-, while decreased in CM-lesioned cats. The results support evidence of the role of intralaminar complex in tonic processes of cortical activation as well as in gaze mechanisms, suggesting, however, different functions of CL and CM nuclei in REM sleep.

SLEEP/WAKE ACTIVITY OF VENTROBASAL COMPLEX NEURONS IN THE RAT. G.A. Marks and H.P. Roffwarg. Dept. Psychiatry U.T. Southwestern Med. Sch., Dallas, Tx 75235.

The paucity or absence of GABAergic interneurons (G-I cells) in the ventrobasal complex (VB) of rat constitutes a specialization in thalamic cytoarchitecture that can be useful for the study of the functional roles of different neuronal populations in thalamus. We now report on the preliminary analysis of spontaneous activity of extracellularly recorded neurons in the VB of freely moving, unanesthetized Long Evans Hooded rats and compare it to activity obtained in the lateral geniculate nucleus (LGN), a relay nucleus with G-I cells, and thalamic reticular nucleus (TRN), a nucleus providing GABAergic inhibition to relay nuclei. VB cells tend to discharge more slowly than LGN relay cells but express a similar proportional change across states with the highest mean rates of discharge occurring during waking and REM sleep and lowest during SW sleep. Both cell populations increase rate in SW sleep at the transition to REM sleep. State-related discharge patterns differ. LGN cells fire in a regular burst-pause pattern in SW sleep and tonically in REM and waking. VB cells express more single spike activity in SW and are more bursty in REM. Comparing the activity of VB cells to somatosensory receptive cells of the TRN, we find little to relate them reciprocally. As a group, TRN cells do not change mean discharge rate with state except for increased rate in SW sleep at the transition to REM sleep. All TRN cells express marked pattern changes with strong rhythmicity across states. VB cells discharge with poor rhythmicity and not in the frequencies exhibited by TRN cells.

We conclude that the absence or presence of G-I cells can have an effect upon the sleep/wake related activity of thalamic relay cells. Interneurons may play a role in the control of discharge pattern and rhythmicity. No evidence is found to support a role of TRN in mediating sleep/wake activity in thalamic relay nuclei.

FIRING OF POSSIBLY CHOLINERGIC NEURONS IN THE LATERODORSAL TEGMENTAL NUCLEUS OF THE RAT DURING WAKEFULNESS AND SLEEP Y. Kayama and M. Ohta* Dept. of Physiology, Fukushima Medical College, Fukushima 960-12, Japan

To examine a hypothesis that cholinergic neurons in the laterodorsal (LDT) and pedunculopontine tegmental nuclei play a key role in shift or maintenance of sleep-waking state, single neuronal activity was recorded in the LDT of rats whose head was fixed painlessly with a stereotaxic device for chronic preparation, sleep-deprived beforehand.

Our previous study in anesthetized rats (Kayama & Ogawa Neurosci.Lett. 77:277-282,1987) showed that, among neurons encountered in the LDT, those firing broad spikes must be cholinergic. We could record from the same broad-spike neurons in this study. Some of these neurons were very silent during wakefulness, increased their firing slightly when the animal fell asleep, and during paradoxical sleep they had slowly fluctuating, high-rate discharge (up to 30 spikes/sec on a phase of the highest rate). Others had regular tonic firing of ≤5 Hz during wakefulness, which decreased during slow wave sleep and almost stopped during paradoxical sleep. The changes in firing usually preceded (2-20 sec) the changes in EEG (syn- or desynchronization).

These results suggest that 1) the LDT is a collection of cholinergic neurons heterogenous in nature, and 2) the cholinergic neurons may play an important role in induction and maintenance of high activity level of the upper brain during wakefulness and paradoxical sleep.

DESIPRAMINE- INDUCED REM SLEEP SUPPRESSION: EVIDENCE FOR A CENTRAL ALPHA- 1 ADRENERGIC MECHANISM. R.J.Ross, P.J.Gresch*, W.A.Ball*, L.D.Sanford* and A.R.Morrison. Dept. V.A.M.C. and Depts. of Psychiatry and Animal Biology, Univ. of Penna. Schools of Med. and Vet. Med., Phila., PA 19104.

Acute norepinephrine (NE) uptake blockade by desipramine (DMI) suppresses REM sleep (REMS) in the cat and other species. To understand the underlying adrenergic receptor mechanism(s), the effect of co-administering the α-1 antagonist prazosin or the β antagonist propranolol was investigated. Four cats were implanted with EEG, EOG, EMG, and lateral geniculate electrodes. Six- hour polygraphic recordings at baseline (placebo capsule, 3cc i.p. saline), after 1 mg/kg p.o. DMI plus i.p. saline, and after DMI plus prazosin (0.01, 0.03, or 0.1 mg/kg i.p.) were compared. Study condition order was counterbalanced, and trials were separated by 1 week. REM percentage (REMS time/total sleep time) was reduced by DMI (26.1 vs. 3.1, $p<0.001$) and increased again with prazosin co-administration at successively higher dosages (3.5 vs. 10.9, $p<0.1$; 3.1 vs. 12.2, $p<0.05$; 3.1 vs. 14.0, $p<0.05$). Propranolol (5 mg/kg i.p.) had no significant antagonistic effect, nor did the peripherally- acting hypotensive agent hydralazine (0.5 mg/kg i.p.). Thus, a central α-1 mechanism partially explains DMI's REMS suppressant effect. The results are consistent with the finding in narcoleptic dogs that cataplexy, which may be comparable to REMS atonia, has α-1 inhibitory modulation (Mignot, E. et al., J. Clin. Invest., 82:885, 1988). Supported by D.V.A. Med. Res. Serv., MH42903 and MH18825.

EFFECTS OF p-CHLOROPHENYLALANINE ON THERMOREGULATION AND SLEEP IN RATS AT SEVERAL AMBIENT TEMPERATURES. H.Li* and E.Satinoff. Psychology Dept., Univ. of Illinois, Champaign, IL 61820

p-chlorophenylalanine (PCPA), a relatively specific serotonin depletor, has been reported to cause hyposomnia for several days when injected i.p. We studied the participation of serotonin in the relationship between thermoregulation and sleep/waking in a 12:12 light/dark photoperiod. Telemetered body temperature (Tb) and sleep were recorded in male rats for 7 days after i.p injection of saline (at lights-on of the second day) and PCPA (300 mg/kg, at lights-on of the third day) at three ambient temperatures (Ta): 20 (n=7), 30 (n=7), and 32°C (n=8). At Ta 20°C, Tb dropped 2.3°C in the first 6 hr post-PCPA, and the amplitude of the Tb rhythm was lower than normal for the next 3 days. At Ta 30°C, there was no initial drop in Tb and Tb amplitude was attenuated for 2 days. At Ta 32°C, there were only minor changes in Tb. The effects of PCPA on sleep were independent of both Ta and Tb. In the light, REM sleep was depressed immediately and remained lower than normal for 3 days. Slow-wave-sleep was depressed for 2 days beginning 24-hr post-PCPA. These results suggest that the mechanisms by which serotonin depletion affects Tb and sleep are different.

514.15

HYPOTHALAMUS AND SLEEP: TIME-COURSE OF SEROTONINERGIC CHANGES. M.G. De Simoni*°, L. Imeri*, R. Giglio*, A. Vezzani° and M. Mancia*. Inst. of Human Physiology, Milan I-20133 and °Inst. "Mario Negri", Milan I-20157, Italia.

Changes in serotonin (5HT) system in the anterior (MPA) and posterior (LH) hypothalamus have been studied in relation to sleep (S) and wakefulness (W). In vivo voltammetry and polygraphic recordings were performed simultaneously in freely moving rats by means of a telemetry system applied to voltammetric recordings.

The extracellular levels of the 5HT metabolite 5-hydroxyindolacetic acid (5HIAA) significantly increase with W (maximal increase: 15 ± 3.6 % in MPA and 15 ± 4.2 % in LH) and decrease with S (slow wave and paradoxical S; maximal decrease: -16 ± 3.7 % in MPA and -20 ± 3.1 % in LH). In both areas these changes begin some minutes before S or W are fully established. The changes related to S come significantly earlier in MPA than in LH and this difference is present only in the dark period. Bilateral lesions of MPA (0.5 ug/100 nl of kainic acid) induce a persistent increase of W during dark periods underlying the involvment of MPA in sleep control in relation to the light-dark cycle.

514.16

SENSITIVITY AND SELECTIVITY OF IN VITRO SEROTONERGIC RESETTING OF THE MAMMALIAN SUPRACHIASMATIC CIRCADIAN CLOCK. R.A. Prosser, J.D. Miller, and H.C. Heller*. Dept. Biological Sciences, Stanford University, Stanford CA 94305.

The suprachiasmatic nuclei (SCN) contain a circadian oscillator that produces a 24 hr rhythm of spontaneous electrical activity when isolated *in vitro*. We are using the SCN slice preparation to investigate the role of the serotonergic projection to the SCN from the raphe nuclei.

Brain slices containing the SCN were prepared from adult male Wistar rats housed in 12:12 LD. At a designated circadian time (CT), the slice perifusion medium was replaced for 1 hr with medium supplemented with the non-specific serotonin agonist quipazine or antagonist metergoline. The averaged electrical activity of single SCN neurons monitored on day 2 *in vitro* was compared to that of untreated slices (mean time-of-peak = CT 6.0±0.32 hr, N=5; CT 0 = lights-on) to determine whether the treatment shifted the SCN clock.

We determined that 1) quipazine permanently resets the SCN clock; 2) this effect depends on the CT of treatment, inducing 3-4 hr advances at CTs 6 and 9, 2-4 hr delays at CTs 15, 18 and 21, and little or no effect at CTs 0,3 and 12; 3) the ED_{50} for quipazine at CT 6 is 0.5 uM; 4) metergoline also resets the clock but at different CTs from quipazine; and 5) metergoline blocks phase-shifts induced by quipazine at CT 6. Together these results suggest that the SCN clock is directly sensitive to phase resetting by serotonergic ligands, and that this sensitivity is both dose- and time-specific.

514.17

EFFECT OF YOHIMBINE ON THE SLEEP-WAKE PATTERN OF LEAN AND OBESE ZUCKER RATS. **S. DeMesquita, K.A. Burgess* and E. Schoene*. Department of Physiology, Marshall Univ Sch of Med, Huntington, WV 25755-9340**

The sympathetic nervous system, which regulates not only feeding behavior but sleep, metabolism and energy balance, appears to be decreased or inhibited in the obese Zucker rat (Holt and York, Brain Res. 481:106-112,1989). Zucker rats were implanted with EEG and EMG electrodes and monitored for sleep-wake pattern before, during and after the infusion of the α_2-adrenoreceptor antagonist, yohimbine (YOH). YOH was infused continuously for 5 days (10mg/kg/day) s.c. in lean (N=5, 578g) and obese (N=6, 743g) Zucker rats, using miniosmotic pumps. Total sleep time % increased significantly (26%) in the obese rat during YOH and remained elevated following YOH withdrawal. Rapid Eye Movement (REM) sleep % was unchanged during YOH in both groups, however YOH withdrawal caused a 30% and 39% increase in REM% in lean and obese rats respectively, due to a 60% increase in REM period frequency. YOH and its withdrawal were associated with a significant rise in both Non-REM and REM sleep time in the obese rat, this effect was evident to a lesser extent only during YOH withdrawal in the lean rat.

THE D-1 DOPAMINE RECEPTOR MODULATES REM SLEEP IN THE RAT. M. Trampus , N. Ferri* and E. Ongini. Research Laboratories, Schering-Plough S.p.A., I-20060 Comazzo, Milan, Italy

The D-1 agonist SKF 38393 and the selective D-1 antagonist SCH 23390 were studied for their effects on sleep-waking cycle in the rat by using EEG techniques. SKF 38393 (0.1-10 mg/kg s.c.) dose-dependently reduced rapid eye movement (REM) sleep and enhanced wakefulness (W). The drug affected REM significantly over a low dose range (ED50 = 0.4 mg/kg) at which W remained unchanged and the characteristic grooming was not apparent. Effect on REM was characterized by a decreased number of episodes and no changes of latency to the first episode. SCH 23390 (0.0003-0.3 mg/kg s.c.) enhanced the amount of REM by increasing both number and average duration of episodes. There was also a moderate increase of non-REM sleep which was less marked than that occurring for REM. Given at 0.003 mg/kg, SCH 23390 fully prevented reduction of REM induced by SKF 38393 (0.3-3 mg/kg).
Considering the low dose range at which the D-1 agonist and the D-1 antagonist were effective on REM, it is suggested that D-1 receptors might have an important role in the regulation of REM sleep process.

514.19

RAPID GONADAL RECRUDESCENCE AND BODY AND LIPID MASS INCREASES WITH HYPOTHALAMIC LESIONS IN PHOTOREGRESSED SIBERIAN HAMSTERS. M. P. Maharaj*, T. G. Youngstrom and T. J. Bartness. Depts. of Psychology and Biology, Georgia State University, Atlanta, GA 30303.

We previously found that combined pinealectomized (PINX) and SCN lesioned (SCNx), photoregressed hamsters had recrudesced testes within 5 wks, but not intact or PINX-only controls. The purpose of the present experiment was to determine if this result was simply due to damage of retinal-pineal circuitry components. Photoregressed hamsters were PINX, SCNx, given paraventricular nucleus lesions (PVNx) or left intact. Blood was sampled weekly for 5 wks at which time testes and epididymal fat (EFAT) were harvested, circadian rhythms of wheel-running assessed and lesions histologically confirmed. Hamsters with PVNx hits and SCNx misses (mostly caudal and dorsal to the SCN) had increased testes, EFAT and body weights, increased food intake, normal activity patterns, and progressively increasing and marked serum PRL, but not FSH levels. In contrast, PINX, SCNx hits, PVNx misses and intact controls had typical short day values and SCNx hits had arrhythmic activity patterns. These results suggest an area caudal and dorsal to the SCN, and extending to and including the PVN, is involved with maintaining short day responses under these conditions and may also inhibit PRL release in long photoperiods based on preliminary lesion data.

514.20

COMPARISON OF EFFECTS ON SLEEP OF ADENOSINE AND ADENOSINE ANALOGS MICROINJECTED TO THE STRIATUM AND PREOPTIC AREA OF RATS. S.R. Ticho, M. Lekovic*, C. Vugrincic*, E. Dziennik*, and M. Radulovacki. Dept. of Pharmacology, University of Illinois, Chicago, IL 60612.

Adenosine A2 receptors are located in the olfactory tubercle, nucleus accumbens and striatum while adenosine A1 receptors show a heterogeneous distribution throughout the CNS. To localize adenosine's behavioral effects within different brain areas, we compared the effects on sleep of adenosine and adenosine analogs microinjected to the striatum and preoptic area of the rat. Polygraphic recordings were examined during a six hour period of the light cycle. Microinjections to the preoptic area were 0.5ul while injections to the striatum were 1.0μl. All three of the drug treatments, ADO (0.025M, n=10), a selective ADO A1 receptor agonist (CPA, 0.001M, n=5), and a nonselective ADO A1/A2 receptor agonist (NECA, 0.002M, n=7) microinjected to the preoptic area increased deep slow-wave sleep (SWS2) (27%, 27%, 48%) ($p<0.05$) respectively as compared to saline controls. Furthermore, ADO and NECA caused a significant increase in total sleep (13%, 16%) ($p<0.05$). In contrast, no changes in sleep parameters were observed when these drugs (ADO, n=6) (CPA, n=6) (NECA, n=6) were microinjected to the striatum. We observed a 20% increase SWS2 with NECA, this increase did not attain significance.

514.21

SOMNOGENIC AND PYROGENIC EFFECTS OF THE IMMUNOSTIMULANT FK-156. **K.A. Serpa and L.T. Meltzer, Dept. of Pharmacology, Parke-Davis Pharmaceutical Research Division, Warner-Lambert Co., Ann Arbor, MI 48105.**

Muramyl peptides (MP) enhance sleep in experimental animals. Muramyl dipeptide (MDP; N-acyl-muramyl-L-alanyl-D-isoglutamine), originally synthesized as an immunostimulant, is also somnogenic and pyrogenic. Additionally, a MP is the active component of Urinary Sleep Factor S. FK-156 (D-lactyl-L-alanyl-D-glutamyl-(L)-meso-diamino-pimelyl-glycine) and FR-40929 (L-alanyl-D-glutamyl-(L)-meso-diamino-pimelic acid) are MP analogs which lack a sugar moiety. FK-156 is a potent, while FR-40929 is a weak, immunostimulant. In order to better understand the structural requirements for different pharmacological activities we compared the somnogenic and pyrogenic effects of FK-156, FR 40929 and MDP in rabbits. MDP increased slow-wave-sleep (SWS) and body temperature (BT) at doses of 25-100 µg/kg s.c. FK-156, 100 µg/kg s.c., induced changes in SWS and BT that were comparable to 100 µg/kg of MDP. In contrast, FR-40929 was less potent than MDP and FK-156, with a threshold dose for increasing SWS and BT of 0.3 mg/kg s.c. These data indicate that a sugar moiety is not necessary for the somnogenic and pyrogenic effects of MP analogs.

NEUROTOXICITY: MPTP

515.1

METHAMPHETAMINE AND MPTP PRODUCE CHANGES IN PCP AND NMDA RECEPTOR BINDING IN MOUSE BRAIN. S.F. Ali, S.H. Lee*, J.F. Bowyer and W. Slikker, Jr.*. Div. of Reprod. & Develop. Tox., National Center for Toxicological Research, Jefferson, AR 72079.

In rodents and primates methamphetamine (METH) and 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) are known to be toxic to presynaptic dopamine (DA) terminals. This study was designed to evaluate the in vivo effects of toxic doses of METH and MPTP on monoamine levels and n-methyl-D-aspartate (NMDA) and phencyclidine (PCP) receptors in mouse brain. Adult male C57/B6N mice were injected four times with 0 or 10 mg/kg METH, i.p. at 2 hr intervals or single injections of 0 or 25 mg MPTP/kg, i.p. Animals were sacrificed 3 days later. NMDA (^{3}H-CGS-19577) and PCP (^{3}H-TCP) receptor binding were analyzed in cerebral membrane preparations using filtration techniques and monoamine concentrations in striatum by HPLC/EC. Dopamine levels in striatum were significantly decreased (40-50%) after METH or MPTP treatment. In vivo METH and MPTP significantly decreased PCP but not NMDA receptor binding. In vitro MPTP (1-1000uM) produced a concentration dependent decrease in PCP and NMDA receptor binding but METH produced a decrease in PCP binding only at high concentrations (500 and 1000 uM). These data demonstrate that neurotoxicity induced by METH or MPTP, as indicated by decreasing DA levels, results in reduced ligand binding to the PCP or NMDA receptor complex.

515.2

METHAMPHETAMINE- AND 1-METHYL-4-PHENYL-1,2,3,6-TETRAHYDROPYRIDINE-INDUCED DOPAMINERGIC NEUROTOXICITY: MODULATION BY VARIOUS PRETREATMENTS. M.S. Saporito, C. Konradi, L. Manzino, P.K. Sonsalla and R.E. Heikkila. UMDNJ-Robert Wood Johnson Medical School, Piscataway, N.J. 08854.

Methamphetamine is a potent dopaminergic neurotoxin in the nigrostriatal tract of mice. This neurotoxicity is dependent on dopamine synthesis and release and is blocked by dopamine receptor antagonists such as haloperidol and by the non-competitive NMDA receptor antagonist MK-801. It has previously been reported that methamphetamine pretreatment leads to partial protection against a subsequent challenge dose of methamphetamine. In the present study, we have evaluated the effect of various pretreatment regimens on methamphetamine- and 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)-induced dopaminergic neurotoxicity. Mice were pretreated with methamphetamine or cocaine for four days and challenged on the fifth day with either methamphetamine or MPTP. Dopaminergic neurotoxicity was evaluated several days later by quantifying neostriatal dopamine content and tyrosine hydroxylase activity. A low dose pretreatment regimen with methamphetamine led to a nearly complete protection against subsequent methamphetamine-induced neurotoxicity. In contrast, cocaine pretreatment potentiated both methamphetamine- and MPTP-induced neurotoxicity. Potential mechanisms for these observations will be discussed.

515.3

DOPAMINE DEPLETION BY INTRASTRIATAL INJECTION OF MPTP N-OXIDE. Y.S. Lau, Y.K. Fung, K.L. Trobough*, J.R. Cashman* and J.A. Wilson. Creighton Univ., Omaha, NE 68178, Univ. of Nebraska, Lincoln, NE 68583 and Univ. of Calif., San Francisco, CA 94143.

MPTP N-oxide is the major peripheral metabolite found in vivo following systemic injection of the dopaminergic neurotoxin, MPTP (Lau et al., Life Sci. 43:1459, 1988; Chiba et al., JPET 246:1108, 1988). Despite its presence and high concentration, the properties of this potentially neurotoxic metabolite have not been described. MPTP, MPTP N-oxide (15 μg/side) or saline was injected bilaterally to the caudate-putamen of male C57/BL mice. Five hours later, the striatal dopamine (DA) levels in mice treated with MPTP (8.6$\pm$1.5 ng/mg) and MPTP N-oxide (11.0$\pm$1.1 ng/mg) were significantly lower than in the control mice (15.9$\pm$0.6 ng/mg). In vitro incubation of striatal homogenates with MPTP or MPTP N-oxide (0.89 mM) for 5 hours revealed that there was a time-dependent conversion of MPTP to MPP^+, which could be blocked by pargyline (0.01 mM). MPTP N-oxide remained unchanged in a 5 hour incubation. The central DA depleting action of MPTP N-oxide was correlated with its ability to cause [^{3}H]DA release in striatal synaptosomes. MPTP N-oxide did not alter the electrophysiologically recorded field potential in nigro-striatal slices. Our data show that MPTP N-oxide can directly cause the chemical depletion of striatal DA without modifying the characteristics of synaptic transmission. Supported by the Health Future Foundation.

515.4

NEUROTOXICITY OF MPTP-3-OL, AN MPTP ANALOG, TOWARD MOUSE STRIATAL DOPAMINE NEURONS. S. K. Hemrick-Luecke*, D. W. Robertson, J. H. Krushinski, Jr.* and R. W. Fuller. Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, IN 46285.

In CFW mice, 1,2,3,6-tetrahydro-1-methyl-4-phenyl-3-pyridinol (MPTP-3-OL) caused a dose-dependent depletion of striatal dopamine and its metabolites 3,4-dihydroxyphenylacetic acid (DOPAC) and homovanillic acid (HVA) 1 week after the last of 4 daily s.c. doses. MPTP-3-OL injected at 80 mg/kg s.c. resulted in a 71% depletion of dopamine, a 70% depletion of DOPAC and a 51% depletion of HVA in striatum and 56% depletion of norepinephrine in the frontal cortex of mice. MPTP-3-OL, like 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), is converted to 1-methyl-4-phenylpyridinium (MPP+). One hour after 80 mg/kg MPTP-3-OL injected s.c., MPP+ concentrations in the brain of mice were 7.41 µg/gm. Deprenyl pretreatment antagonized the depletion of brain catecholamines after MPTP-3-OL injection and inhibited the formation of MPP+ in whole brain of mice. These data are similar to those observed after MPTP injection into mice. In vitro, MPTP-3-OL was a substrate for monoamine oxidase type B from mouse brain and liver, being oxidized at a slower rate than MPTP. Deprenyl (10 µM) inhibited both MPTP and MPTP-3-OL oxidation in vitro. These data indicate MPTP-3-OL is a neurotoxic analog of MPTP with a unique structure, having a hydroxy substituent on the 3-position of the tetrahydropyridine ring of MPTP.

DOSE-DEPENDENT EFFECTS OF 2'-CH_3-MPTP ON MONOAMINERGIC SYSTEMS IN MICE: TYROSINE HYDROXYLASE AND GFAP IMMUNOCYTOCHEMICAL STUDIES. L. Gordon, X.L. Chen and M. Gupta. Dept. of Anatomical Sci. & Neurobiology, Univ. Louisville Sch. Med., Louisville, KY 40292.

Previous studies from this laboratory have shown that 2'-CH_3-MPTP produces a significant decrease in the number of tyrosine hydroxylase (TH)-positive neurons in substantia nigra and the ventral tegmental area. The present studies were undertaken to investigate if additional monoaminergic nuclei including locus coeruleus and the dorsal raphe dopaminergic neurons are also affected and if these effects are dose-dependent. Young adult male C57BL/6 mice were given multiple injections of 2'-CH_3-MPTP (7.5 and 10mg/kg i.p.) over a two day period. Three days later, control and treated mice were anesthetized and perfused with the fixative. Adjacent 40µm thick serial sections through the brain were stained immunocytochemically for TH and GFAP. The number of TH-positive neurons were quantitated in the SN, VTA, A8, locus coeruleus and dorsal raphe as well as GFAP-immunoreactive astrocytes in the striatum. The results show that 2'-CH_3-MPTP produced a statistically significant and a dose-dependent decrease in the number of TH-immunoreactive neurons in the SN, VTA and A8 followed by extensive gliosis in the striatum compared to the controls. These data demonstrate that 2'-CH_3-MPTP is much more toxic than MPTP HCl and affects several monoaminergic nuclei in the brain. Quantitative analysis on gliosis in the striatum is currently in progress. Supported by USPHS grant R29 NS24291 to MG.

515.6

LONG-TERM SURVIVAL OF 2'-CH_3-MPTP-TREATED MICE: TYRINE HYDROXYLASE AND GFAP IMMUNOCYTOCHEMICAL STUDIES. M. Gupta and X.L. Chen. Dept. of Anatomical Sci. & Neurobiology, Univ. Louisville Sch. Med., Louisville, KY 40292.

Previous studies from this laboratory have shown that dopaminergic neurons in the substantia nigra, ventral tegmental area and the A8 cell group are reduced significantly after short-term survival following 2'-CH_3-MPTP treatment in mice. In the present studies, young adult male C57BL/6 mice were treated with 2'-CH_3-MPTP over a two day period (total dose 30mg/kg i.p.) and examined 2 weeks, 2 months and 6 month after treatment. At the appropriate survival times, control and 2'-CH-MPTP-treated mice were anesthetized and perfused intracardially with 4% paraformaldehyde and 1.5% sucrose in 0.1M PO_4 buffer. Serial 40µm thick sections were cut through the entire brain; adjacent section were stained immunocytochemically for tyrosine hydroxylase (TH) and Glial Fibrillary Acidic Protein (GFAP). The number of TH-positive neurons were quantitated in the SN, VTA and A8. The results show a significant reduction in the number of TH-immunoreactive neurons in the SN and VTA up to 6 months after treatment followed by extensive gliosis in the striatum. Quantitative analysis of the GFAP-stained astrocytes in the striatum is currently in progress. The following will be discussed: (a) regeneration and plasticity of the dopamine neurons in the SN, VTA and A8 after long-term survival follwing treatment with 2'-CH_3-MPTP and (b) astrocyte proliferation in the striatum with long-term survival. Supported by USPHS grant R29 NS24291 to MG.

515.7

MOBILIZATION OF MACROPHAGES IN DOPAMINERGIC AREAS OF THE BRAIN AFTER ADMINISTRATION OF MPTP. A. Hess, C. Desiderio* and W. G. McAuliffe*. Dept. Neuroscience and Cell Biology, UMDNJ, RW Johnson Med. Sch., Piscataway, NJ 08854.

Immunohistochemical staining with Mac-1 antisera reveals microglial cells. The cells are numerous and located in gray and white matter in all areas of the brain. Cell bodies are samll, processes are elongated and spiked and appear like microglial cells after silver carbonate staining. After MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine),(mice, 50mg/kg s.c., one per day for 2 days, 3 days after last injection), Mac-1 staining reveals very intensely stained cells accumulated in the nucleus accumbens and restricted in the substantia nigra to the pars compacta. These are locations of dopaminergic cells, fibers and terminals, and this can serve as an illustration of the specificity of action of MPTP as a dopaminergic neurotoxin. These cells appear to be macrophages and have intensely-stained cell bodies and numerous short processes radiating out from the cell body. Since both microglia and macrophages have the same antigen type, we suggest that resident microglia inherent in the brain become reactive microglia after degenerative effects of MPTP on dopaminergic neuronal elements, and hypertrophy, become round, shorten their processes and become macrophages. The mobilization of macrophages after MPTP adds an additional factor the etiology of the pathophysiology of MPTP-induced neurotoxicity.

515.8

VITAMIN E DEPLETION DOES NOT POTENTIATE MPTP TOXICITY IN C57 BLACK MICE. John S. Althaus, Michael A. Burian*, Chris J. Hudson* and Philip F. VonVoigtlander, CNS Diseases Research, The Upjohn Co., Kalamazoo, MI 49001.

The current study was designed to test the importance of endogenous antioxidants in MPTP toxicity. The approach taken was to deplete vitamin E in C57 Black mice using a vitamin E deficient diet. MPTP was then administered at 10 or 30 mg/kg i.p. once daily for 5 consecutive days. The results showed that dietary vitamin E manipulation did not affect MPTP toxicity. In mice fed basal or vitamin E deficient diets for two weeks or twelve weeks, catechol levels of the striatum and tegmentum were depleted to the same extent by MPTP. The results also show that MPTP did not affect vitamin E concentrations in the striatum or tegmentum. The depletion of vitamin E by dietary restriction was not enhanced by MPTP administration.

Because vitamin E is an antioxidant which functions primarily in membranes, we proposed that MPTP toxicity does not appear to directly involve lipid peroxidation in this model. That is not to say that MPTP toxicity does not involve the generation of free radicals or oxidative stress. It does suggest that if these processes are involved in MPTP toxicity, then peroxidative damage to membrane lipids is not a major mediator of the damage caused to dopamine neurons.

THE METABOLIC EFFECTS OF MPP+ IN CULTURED CEREBELLAR GRANULE CELLS A.M. Marini, T.S. Nowak Jr, J.P. Schwartz, and I.J. Kopin.
Clinical Neuroscience Branch, NINDS, NIH, Bethesda, Maryland 20892.

We have determined, in a homogeneous population of cerebellar granule cells in culture, intracellular metabolite levels of adenosine triphosphate (ATP), phosphocreatine (PCr) and creatine, as well as medium glucose and lactate levels, following exposure to 50 micromolar MPP+. MPP+ depleted PCr to 20% of control levels within 30 minutes and it remained at this level for up to one week. The decrease in PCr was accompanied by an equimolar *increase in creatine.* *No significant* change in ATP levels occurred within the first 48 hours, but 50% decreases were observed after this time. There was also a marked decrease in medium glucose, with enhanced lactate accumulation. Neurons remained viable for at least 9 days in culture. Although glucose was repleted every three days after day 7 in culture, neuronal death occured after day 12 in culture. These results suggest that the neurons are sustaining their ATP levels through anaerobic metabolism of glucose in the presence of MPP+.

MITOCHONDRIAL RESPONSE IN N2AB-1 NEUROBLASTOMA CELLS AFTER EXPOSURE TO MPP+. S.J. Simmons [1], J.T. Hansen [2] and M. F.D. Notter [2] [1]Environmental Health Science Center and [2]Department of Neurobiology and Anatomy, University of Rochester, Rochester, NY 14642.

The effect of MPP+ on the N2AB-1 mouse neuroblastoma cell line was examined by electron microscopy with morphometric analysis and by the metabolic parameters glucose consumption and lactate production. Previously, we demonstrated that differentiated N2AB-1 cells are less sensitive to MPP+ toxicity than mitotic N2AB-1 cells as assessed by morphology, cell number and protein incorporation.

Mitochondrial area, ratio of mitochondrial area to cytoplasmic area(Ma/Ca), and percent damaged mitochondria were measured morphometrically. The control mitotic and differentiated N2AB-1 cells were equivalent for all three parameters. After MPP+(100uM) exposure for 24hr, the Ma/Ca increased from 9% to 15%, the mitochondrial area tripled, and 85% of the mitochondria were damaged in both mitotic and differentiated cells. Mitochondria of both mitotic and differentiated cells *were equally effected by MPP+ exposure.*

Lactate production and glucose consumption were 300% of control after 24hr MPP+ exposure in both mitotic and differentiated cells. After 48hr exposure, total lactate production was 270% of control, while total glucose consumption was 240% of control in both phenotypes. A similar response was seen after exposure to the mitochondrial toxin Rotenone(2uM), indicating a loss of mitochondrial function and increased dependence on glycolysis for energy.

These data indicate that while mitotic N2AB-1 cells are more sensitive to MPP+ in whole cell response(cell death and decreased protein synthesis), the mitochondria of both mitotic and differentiated cells respond equally to the toxic insult, suggesting that total metabolic requirements of the cell play a role in the sensitivity to MPP+.

4'-ALKYLATED ANALOGS OF 1-METHYL-4-PHENYLPYRIDINIUM ION ARE POTENT INHIBITORS OF MITOCHONDRIAL RESPIRATION. R.E. Heikkila, S.K. Youngster, M.R. Gluck*, and W.J. Nicklas
Dept. of Neurology, UMDNJ-Robert Wood Johnson Medical School, Piscataway, NJ 08854

1-Methyl-4-phenylpyridinium ion (MPP^+), a major brain metabolite of the dopaminergic neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine, is an inhibitor of Complex I of the mitochondrial respiratory chain. We have synthesized several analogs of MPP^+ containing various alkyl groups in the 4' position of the phenyl ring and have determined their capacity to inhibit the oxidation of NADH-linked substrates by intact mouse liver mitochondria. These compounds are considerably more potent inhibitors of respiration than MPP^+ itself, with the potency increasing as the length of the alkyl chain increases. The most potent inhibitor, the 1-methyl-4-(4'heptylphenyl)pyridinium species (IC_{50}=0.5 μM), is about 200 times as effective as MPP^+ itself (IC_{50}=110 μM). In addition, tetraphenylboron (TPB), a lipophilic anion, is able to increase the potency of all these MPP^+ derivatives. However, the relative degree of potentiation appears to decrease as the length of the 4'-alkyl chain increases. Thus, all of the MPP^+ analogs are closer in inhibitory potency in the presence of TPB then in its absence. These observations suggest that the presence of an aliphatic 4'-alkyl group increases the accessibility of the compound to its inhibitory site. These analogs should prove to be useful tools for studying the nature of the process whereby MPP^+ and its pyridinium analogs interact with Complex I to inhibit mitochondrial respiration.

STUDIES ON THE MECHANISM OF MPP^+-INDUCED NEUROTOXICITY USING *IN VIVO* DIALYSIS
A. Giovanni, M.S. Saporito, S.K. Youngster and R.E. Heikkila. Dept. Neurology, UMDNJ-Robt. Wood Johnson Med. Sch., Piscataway, NJ 08854.

The dopaminergic neurotoxicity of MPTP and several of its analogs depends on 1) bioactivation of the tetrahydropyridine to a pyridinium species via MAO and 2) active accumulation of the pyridinium into dopaminergic neurons via the dopamine uptake system. Additionally, evidence exists which suggests that the inhibition of mitochondrial oxidation of NADH-linked substrates by these pyridinium species is an important feature of the neurotoxicity. In this study, several MPP^+ analogs were tested for their capacity to act as substrates for the dopamine carrier and for their ability to inhibit mitochondrial respiration. Compounds were subsequently chosen for *in vivo* neurotoxicity studies which demonstrated ranges in potency to serve as a substrate for the dopamine carrier and to inhibit mitochondrial respiration. The neurotoxicity of MPP^+ and its analogs was determined after the central administration of the compounds via an *in vivo* dialysis probe followed by the measurement of stimulated extracellular dopamine levels. Neurotoxic MPP^+ analogs, like MPP^+ itself, caused an irreversible depletion of DA as demonstrated by the lack of a stimulated increase in extracellular DA brought about by an infusion of MPP^+ 24 hours after an initial exposure to the analog. Data from the *in vivo* dialysis studies strongly support the theory that the neurotoxicity of these compounds depends not only upon their ability to act as substrates for the DA carrier but also upon their capacity to inhibit mitochondrial respiration.

515.13

MECHANISM OF ACCUMULATION OF 1-METHYL-4-PHENYLPYRIDINIUM ION (MPP^+) INTO MOUSE BRAIN SYNAPTOSOMES. D.A. Di Monte, K.P. Scotcher*, I. Irwin*, L.E. DeLanney, and J.W. Langston. California Parkinson's Foundation and California Institute for Medical Research, San Jose, CA 95128.

Incubation of mouse brain synaptosomes (essentially devoid of contamination by extrasynaptosomal mitochondria) in the presence of MPP^+ resulted in its time- and concentration-dependent accumulation. Intrasynaptosomal concentrations of 79 μM and 106 μM were reached 10 and 30 min, respectively, after addition of 50 μM MPP^+. The uptake of MPP^+ into synaptosomes was relatively unaffected by the catecholamine uptake blocker mazindol; in contrast, the rate of MPP^+ uptake was greatly increased by tetraphenylborate, a lipophilic anion that facilitates the transport of permeant cations across membranes via a Nernstian concentration gradient. Furthermore, MPP^+ accumulation was significantly increased (by substituting NaSCN and KSCN for NaCl and KCl in the incubation medium) or decreased (by ouabain, veratridine or KCl) as a consequence of enhancing or lowering, respectively, the plasma membrane potential of synaptosomes. Data indicate that (1) MPP^+ present at concentrations in the 10^{-5} M range may cross neuronal membranes despite its charged chemical structure and without the need of a specific uptake mechanism, and (2) polarization of neuronal membranes may facilitate the accumulation of this toxic cation into nerve terminals.

MPP^+-TYPE NEUROTOXICITY OF A PYRIDINIUM METABOLITE DERIVED FROM HALOPERIDOL. H. Rollema, B. Subramanyam*, N. Castagnoli Jr*. Dept. Medicinal Chemistry, University Groningen, 9713 AW The Netherlands and Dept. Chemistry, Virginia Polytechnic Institute, Blacksburg, VA 24061.

Neurotoxic properties of a recently described (Subramanyam, B. et. al., *BBRC*, 166:238, 1990) pyridinium metabolite ($HALP^+$) of the neuroleptic agent haloperidol, were compared with those of the dopaminergic neurotoxin MPP^+. A rat intrastriatal microdialysis assay was employed to assess the potential toxicity of $HALP^+$. The test compounds (2mM MPP^+ and 2mM $HALP^+$) were perfused intrastriatally via the dialysis membrane for various time periods and the output of the neurotransmitters and metabolites under investigation was monitored continuously. A challenge perfusion with MPP^+ 24 hours later was used to determine the extent of irreversible nerve terminal damage caused by the perfusion with the test compounds the previous day. $HALP^+$ lacks the acute potent dopamine (DA) releasing effect of MPP^+. However, a 7.5 hour lasting $HALP^+$ perfusion compromises dopaminergic nerve terminals as shown by a small DA release induced by the challenge MPP^+ perfusion. The effects of $HALP^+$ on lactate production were also measured by microdialysis. A 1 hour perfusion with HALP+ caused an increase in lactate levels to about 150% of basal values, indicating that $HALP^+$, like MPP^+, inhibits mitochondrial respiration in vivo. These results show that various other types of quaternary pyridinium compounds, not closely structurally related to MPP^+, can cause dopaminergic toxicity. They also suggest a potential role of $HALP^+$ as a cause of persistent tardive dyskinesia after chronic use of haloperidol.

TRANSGENIC MICE EXPRESSING THE HUMAN SOD GENE ARE RESISTANT TO MPTP-INDUCED TOXICITY.[1]S. Przedborski, [1]V. Kostic, [1]V. Jackson-Lewis,[2]E. Carlson*,[2]C.J. Epstein* [1]J.L. Cadet. [1]Columbia University, NY 10032 and[2]University of California, CA 94143.

MPTP causes significant depletion of striatal dopamine (DA) which is similar to that seen in Parkinson's disease (PD). Free radical (FR) toxicity has been suggested to be involved in the pathogenesis of both PD and MPTP toxicity. Superoxide dismutase (SOD) is a key enzyme of the antioxidant system that protects cells from the hazards of FR. In order to further evaluate the role of FR in MPTP-induced toxicity, we tested the possibility that transgenic (Tg) mice which express the human SOD gene (Epstein et al., PNAS 84:8044, 1987) might be protected against the toxic effect of MPTP. Young white adult SOD-Tg mice and their non-Tg littermate were injected with MPTP (30 mg/kg, i.p. for 3 days) while SOD-Tg and non-Tg control mice received saline injections. Five days after the last injections, the mice were sacrificed and striatal DA, serotonin (5-HT) and their metabolites (DOPAC, HVA and 5-HIAA) were determined. MPTP reduced DA level (-56%; $P<0.01$) in the non-Tg mice. DOPAC and HVA levels were also significantly decreased. In contrast, MPTP did not affect DA, DOPAC, or HVA levels in the SOD-Tg mice. In both MPTP-treated groups, 5-HT and 5-HIAA levels were not different from controls. These results indicate that increased SOD activity may prevent the toxicity of MPTP in mice presumably by scavenging FR formed after MPTP administration. NHCHHD HD-17001, PDF.

ACUTE MPTP INDUCES C-FOS GENE EXPRESSION IN MOUSE BRAIN. A.M. Duchemin, K.P.Gudehithlu, N.H. Neff and M. Hadjiconstantinou. Depts of Pharmacology and of Psychiatry, The Ohio State University College of Medicine, Columbus, OH 43210.

c-Fos protein acts as a transcriptional regulatory factor for a number of genes expressed in the brain. Its synthesis can be increased by various stimuli that modify neuronal function. In this report, we show that the neurotoxin, MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine), induces a transient expression of c-fos gene in the mouse brain.

MPTP was injected i.p. into mice and total RNA from several areas of the brain extracted at different time intervals following the injection. c-fos mRNA was assayed by Northern blot hybridization with a nick-translated XhoI-NcoI restriction fragment from the pc-fos (mouse)-3 gene obtained from ATCC. c-fos mRNA increases were detectable with doses of MPTP as low as 10 mg/kg and the changes increased with the dose of MPTP. The dose-related changes were similar for several brain regions. The time-course of the induction of c-fos mRNA was studied after a dose of 50 mg/kg MPTP. In the striatum, c-fos mRNA increased 20 min after injection, was maximal at 40 min and decreased to control values at 90 min. In the hippocampus, the increase of c-fos mRNA was delayed: the content was maximal at 50 min, remained elevated at 90 min and decreased to control levels at 2 hrs. The D1 and D2 dopaminergic receptor antagonists, haloperidol (10 mg/kg), sulpiride (150 mg/kg), and SCH 23390 (10 mg/kg), injected i.p. 30 min before MPTP, did not prevent the increase of c-fos mRNA. These results suggest that the response to MPTP is apparently unrelated to interaction with dopamine receptors.

EARLY-LIFE MPTP EXPOSURE SLOWS AGE-RELATED LOSS OF SUBSTANTIA NIGRA NEURONS. W.G. Tatton, C.E. Greenwood, N.A. Seniuk, P. Salo, D. Holland* and M.Kwan*. Departments of Physiology and Nutritional Sciences, University of Toronto, Toronto, Ontario, Canada. M5S 1A8.

We showed that four populations of immunocytochemically-identified monoaminergic neurons display different rates of age-related loss across the lifespan in C57Bl mice (Tatton et al, Soc. Neurosci.15:160,1989). Neuronal loss was exponential (% Loss= $e^{-A*Age\ in\ Wks + B)}$ with 99% confidence limits from ± 1 to 3%. Calne & Langston postulated that toxin-induced and age-related neuronal loss sum to determine the time course of disabilities found in some neurodegenerative diseases (Lancet 2:1457,1983). We tested this hypothesis by treating C57Bl mice with 60 or 150 mg/kg of MPTP or saline at 8 wks of age and examining substantia nigra compacta (SNc) neurons at 52 or 88 wks of age using immunocytochemistry for tyrosine hydroxylase (TH), neuron specific enolase and neurofilament proteins together with the retrograde transport of fluorogold. Measurement of the % area of TH+ tissue in the ipsilateral striatum normalized against the number of TH+ SNc somata (counted from alternate sections through the whole nuclei) was used as a measure of relative terminal axonal length. Comparison of the numbers of surviving TH+ SNc neurons in MPTP treated mice to summed values for the age-related loss plus the MPTP dose-dependent loss of TH+ SNc neurons at 20 days after MPTP exposure (Seniuk et al, Br. Res. 1990, in press) showed that MPTP treatment at 8 wks of age markedly slows the rate of loss of neurons surviving MPTP exposure (A constant = 0.0130 for saline but = 0.0068 for SNc neurons surviving early life MPTP, $p> .001$). Saline-treated and MPTP-treated aged SNc neurons showed average increases of somal crossectional area, estimated terminal axonal length/SNc neuron and TH immunodensity/unit area of soma relative to those in 8 wk old mice that are proportional to the combined loss of neurons by toxic exposure and aging. The slowed age-related loss of SNc neurons surviving early-life MPTP exposure will be considered relative to somal hypertrophy, terminal axonal sprouting and alterations in the synthesis of specific proteins in the neurons . A COMPARISON OF SPATIOTEMPORAL VOLTAGE DISTRIBUTIONS OF THE SECOND AND THIRD DIVISIONS OF THE TRIGEMINAL NERVE EVOKED POTENTIAL IN MAN. C. G. Widmer. Dental Research Center, Emory University School of Dentistry, Atlanta, GA 30322.

Mapping the initial cortical response to trigeminal nerve stimulation has been reported (Widmer, C. G., *J. Dent. Res.*, 66:117, 1987), but no study has examined spatiotemporal voltage distributions of different divisions within the same subject. Also, no study has mapped the muscle reflex potentials which may contaminate the evoked response. The purpose of this study was to map the evoked responses after stimulation of the greater palatine nerve (V_2) and mental nerve (V_3). Median nerve evoked potentials were used as a control.

Three subjects were stimulated with a 0.2 ms pulse at 1.2 Hz and averaged for 512 stimuli. Potentials from 28 scalp recording sites (modification of 10-20 International system) were amplified (bandpass 1-1000 Hz), acquired at 4000 Hz/channel, averaged by a computer acquisition system (BrainWave Systems) and stored on disk for subsequent mapping. Topographical activity maps were generated (BrainWave Systems) in the range of 14-30 ms for the median nerve and 4-20 ms for the trigeminal nerve and the initial cortical responses were identified and latencies were recorded.

Median nerve evoked responses occurred at 20.2 ± 1.4 ms with the greatest activity in the parietal region contralateral to the stimulation site. Both V_2 (12.1 ± 1.0) and V_3 (12.8 ± 1.1) distributions were highest in amplitude over the region of the somatosensory cortex (C5-T3, C6-T4) contralateral to the stimulation site. The V_2 distribution was located slightly superior to the V_3 initial cortical response consistent with known trigeminal topographical distribution in the somatosensory cortex. Muscle reflex potentials were identified *bilaterally* in the same region.

FRACTAL DIMENSION OF AN EVOKED POTENTIAL. W.D. McCall, Jr. and C.G. Widmer. SUNY Buffalo, NY 14214 and Emory Univ., Atlanta, GA 30322.

If the evoked potential is deterministic and chaotic, it should have a fractal dimension. Our purpose was to obtain the fractal dimension of an evoked potential.

The median nerve in one subject was stimulated at 1.2 Hz with 0.2 ms pulses at 3 times sensory threshold for 256 trials while recording each response from 28 sites simultaneously. The correlation dimension (Grassberger and Procaccia, Physica D 9:189, 1983) was calculated for the 30 ms potential using recording sites as embedding dimensions. Straight lines were fit to the log-log display of the cumulative distribution of distances by a least-square-error algorithm. An acceptable fit had five or more points and a correlation coefficient of 0.980 or greater.

The correlation dimension increased until the 12th embedding dimension where the correlation dimension was 6.4. Since the stroboscopic Poincare section reduced the original dimension by one, we interpret our result as suggesting that the fractal dimension of the evoked potential was about 7.4.

CHOLINERGIC EFFECTS ON HUMAN MIDLATENCY AUDITORY EVOKED RESPONSES. R.J.Strandburg, J.S.Buchwald, E.H.Rubenstein* and J.Schwafel*. Depts. of Psychiatry, Physiology & Anesthesiology, UCLA School of Medicine, Los Angeles, CA 90024

In contrast to the Pa component of the auditory middle latency evoked response (MLR), marked P1 abnormalities are observed in Alzheimer's disease, autism and schizophrenia. To further differentiate and characterize these two components, click elicited MLRs were recorded from 7 normal male volunteers receiving the cholinergic antagonist scopolamine followed by the agonist physostigmine. Pa (25-40 msec), Nb (40-50 msec) and P1 (50-65 msec) components obtained in these 2 conditions at a central scalp lead (CZ) were compared with immediately preceding control data recorded with click rates of 1, 5, 8 and 10/sec (P1 disappears at the faster rates while Pa is not affected).

Intravenous scopolamine eliminated the P1 and slightly increased Pa; subjects reported drowsiness but were awake with eyes open throughout the recordings. Subsequent injections of physostigmine resulted in a rapid reversal of the scopolamine effects: the subjects became alert, Pa decreased, and P1 returned to its control amplitude (and declined in response to rapid click rates). These data in conjunction with the results of related studies of MLRs in the cat suggest that the P1 generator system includes a cholinergic brainstem-thalamic component of the ascending reticular activating system.

DEPTH CORRELATES OF MIDLATENCY AUDITORY P1 IN THE CAT. J. Harrison, K. Tung* and J. Buchwald. Physiology Dept., Brain Res. Inst., and Mental Ret. Res. Ctr., UCLA, Los Angeles, CA 90024.

The "cat-P1", previously called by us "wave A", is a positive potential evoked by clicks, with a latency of 20-30 msec, recorded from the vertex. Like the human P1, it is absent with rapid click repetition rates (10/sec) and during slow-wave sleep but present during wakefulness and REM sleep. Both the P1 and cat-P1 are reversibly eliminated by scopolamine, a muscarinic cholinergic antagonist, and recover with physostigmine, a cholinesterase inhibitor. The human P1 is absent in a group of Alzheimer's disease patients, and the cat-P1 is abolished by bilateral lesions of the pedunculopontine tegmental nucleus (PPT) in the midbrain reticular formation. To test the hypothesis that the vertex-recorded cat-P1 is generated by PPT projections to the thalamus, we recorded from thalamic sites and tested midlatency click-evoked potentials with the effects of rapid repetition rates and cholinergic drugs. EEG was recorded from awake cats with clicks presented at a rate of 0.2/sec or 10/sec. Most of the depth-recorded potentials, many targeted for thalamic nucleus centrum medianum, were diminished or abolished by rapid click rates and scopolamine. Like the vertex cat-P1, the depth potentials sometimes recovered or were enhanced by physostigmine or carbachol. These data further support the hypothesis that the vertex cat-P1, and perhaps the similar human P1, reflect activity in a cholinergic system projecting from PPT to the thalamus. (Supported by USPHS HD05958 and NS25400.)

CORRELATION OF DICHOTIC LISTENING WITH CORTICAL AUDITORY EVOKED POTENTIALS IN PATIENTS WITH COMPLEX PARTIAL EPILEPSY. S.Khoshbin, B.J.Murawski*and C.S.Petrou*. Dept.of Neurology, Harvard Medical School, Boston, MA 02115.

Forty patients with history of partial complex seizures were studied using the dichotic listening test (Kimura, 1961), the Wechsler Adult Intelligence Scale, routine electroencephalography and cortical auditory evoked potentials. Correlation was found between these tests and information from neurological exams and radiographic studies. All patients with abnormal dichotic digits had abnormalities on cortical evoked potentials at N100, P200 or P300 components. The routine electroencephalogram was rarely informative. Abnormalities of dichotic digits correlated well with topographic mapping of evoked potentials with regard to dominant and non-dominant hemisphere findings. Good correlation was also found between discrepancies in verbal and performance scores on the Wechsler Adult Intelligence Scale and cortical auditory evoked potentials. Sample cases will be illustrated.

516.6

EFFECT OF DEXMEDETOMIDINE (D), ON VISUAL EVOKED POTENTIALS (VEPs) IN CHRONICALLY INSTRUMENTED CATS. K.A. Poterack* and W.T. Schmeling. Depts. of Anesthesiology and Pharmacology , Medical College of Wisconsin, Milwaukee, WI 53226

Inhalation anesthetics, including halothane (H), have been shown to modulate both the amplitude and latency of VEPs. D, an $alpha_2$-adrenergic agonist, produces profound sedative/anesthetic-like actions. The present study examined the effects of D (5, 10 µg/kg) and H (1-2%) on strobe flash VEPs of cats chronically instrumented with stainless steel electrodes to record from cortical (C) and lateral geniculate (LG) sites. A deep electrode was placed in the mesencephalic reticular formation (RF) for the production of cortical arousal. H produced an increased latency and decreased amplitude of the P1 peak recorded from C and LG. D administration, while producing clinical sedation and EEG slowing, resulted in preservation of the VEP waveform without significant change in amplitude or latency. RF stimulation after agent administration produced EEG changes consistent with arousal and return of VEP waveforms towards control. The receptor-specificity of the $alpha_2$ - agonists may produce sedation/unconsciousness without the global disruption of neural pathways produced by the inhalation agents. EFFECTIVE ANODE AND CATHODE ARE VERY CLOSE TOGETHER WHEN STIMULATING PERIPHERAL NERVE WITH THE MAGNETIC COIL. P.J. Maccabee, V.E. Amassian, R.Q. Cracco, L. Eberle*, A. P. Rudell, K.S. Lai*. Departments of Neurology and Physiology, SUNY, Health Science Center, Brooklyn, N.Y. 11203.

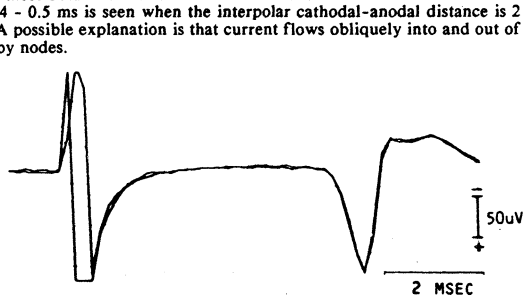
We stimulated distal median nerve at the wrist using monophasic magnetic coil (MC) pulses and a novel hardware switching device which reverses current in the round and figure of 8 MC (Cadwell Laboratories). Thus, no errors are introduced by physically rotating the round MC through 180° to reverse current flow. Thenar motor unit responses were elicited at threshold intensities. No shift in latency was detected when the current in the figure 8 MC was reversed (Fig. 1) confirming our previous observations when the round MC was rotated. These data differ markedly from those obtained with conventional electrical stimulation where a shift of 0.4 - 0.5 ms is seen when the interpolar cathodal-anodal distance is 2 cm. A possible explanation is that current flows obliquely into and out of nearby nodes.



516.8

HUMAN NEUROMAGNETIC AND NEUROELECTRIC ALPHA FREQUENCY ACTIVITY REACTIVITY AND EVOKED FIELDS. C.C. Gallen, S. Hampson*, T.T. Yang*, F. Bloom, W. Young. Dept. of Neuropharmacology, Res. Inst. of Scripps Clinic, La Jolla, CA 92037.

A " moving window" approach was used to estimate the rates and timing of stimulus-related reductions in magnetoencephalographic (MEG) and electroencephalographic (EEG) intrinsic alpha frequency power in five paired (MEG probe located directly over EEG electrode) occipital sites. Serial recordings of 120 epochs of cycling central visual stimulus on/off in eight normal subjects allowed isolation of the two-second periods preceding and following onset of visual stimulus in each epoch. Waveforms were rectified and the average amplitude of alpha in an initial 100 msec window was calculated and plotted. Subsequently the window was "moved" in small increments and the average amplitude serially recalculated and plotted. This process produced a smoothed line reflecting fluctuations in alpha amplitude over time. Modelling studies with square wave and linearly sloped data revealed potential distortion of latency estimates for onset and cessation of reactivity. But, when certain specified characteristics were present, this measure showed utility as both a comparative measure of rate of change and for estimation of the midpoint of signal decline. As used in this study, the "moving window" method indicated maximal alpha reactivity in the first few hundred msec following stimulus onset, a period which overlapped multiple visual evoked waves. With limitations, the moving window approach allows estimation of the rate of decline of rhythmic activity.

516.9

BEHAVIORAL STATE SPECIFIC CHANGES IN THETA ACTIVITY: SCALP EEG VS. HIPPOCAMPAL DEPTH ELECTRODE RECORDINGS. J.L. Thompson, K.J. Meador*, D.W. Loring*, G.P. Lee*, D.W. King*, B.B. Gallagher, A.M. Murro*, J.R. Smith* and H.F. Flanigin*. Departments of Neurology and Surgery, Medical College of Georgia, Augusta GA 30912.

We previously demonstrated differential effects of behavioral state on human hippocampal EEG activity. In this study, we compared the percentage of theta activity recorded from a scalp electrode (Cz) to that recorded from a hippocampal depth electrode contralateral to the seizure focus in 13 patients with unilateral temporal lobe epilepsy (7 left focus, 6 right focus). Behavioral conditions incuded: resting eyes closed (RC), resting eyes open (RO), eyes open with auditory word activation (AW), eyes open with visuospatial activation (AV). Theta activity decreased significantly at both sites during RO and AV compared to RC, and during AV compared to AW ($p<0.02$). In the RC state, theta activity predominated in the scalp record, while delta activity predominated in the depth record. Theta activity decreased during RO ($p<0.05$) compared to AW in the depth record alone. In contrast, theta decreased significantly during AW ($p<0.02$) compared to RC in only the scalp record. Generally, the state specific changes in theta activity compared to RC were accounted for by downshifts into the delta range at both sites. Furthermore, the scalp record during RC shows the expected relatively greater alpha activity, while AW shows significantly increased alpha activity ($p<0.02$) compared to RO in the depth record only. Differential theta activity recorded simultaneously at two different sites may offer some clues as to the functional changes that occur within specific brain regions according to behavioral state.

516.10

CROSS VALIDATION OF EVENT-RELATED POTENTIAL (ERP) MARKERS OF ADULT DYSLEXIA BY REGIONAL CEREBRAL BLOOD FLOW (rCBF). C.E. Naylor, M.R. Harter, F.B. Wood*, D.L. Flowers*, and I.S. Brown. Section of Neuropsychology, Bowman Gray School of Medicine, Wake Forest University, Winston-Salem, NC 27103 and University of North Carolina-Greensboro, Greensboro, NC 27412

Previous studies (Harter et al. and Naylor et al.) showed a left central P240 deficit in dyslexic children and a bilateral central P240 deficit in dyslexic adults, respectively, in a visual letter discrimination task. Flowers, et al., showed focal left temporo-parietal rCBF increases in dyslexic adults, compared to controls, in an auditory word length analysis task.

In a sample containing 13 dyslexic and 10 non-dyslexic adults, both defined by childhood reading scores, the abnormal left temporo-parietal flow increase was correlated ($p < .01$) with both left and right central P240 as well as with left and right frontal P240 amplitude reductions. While this suggests convergence on a common deficit, across modalities and across physiological methods, it raises an important question of ERP source localization which is discussed by reference to illustrative MRI findings from individual subjects.

516.11

HYPERTENSION AND BODY POSITION AFFECT CAROTID ARTERY BLOOD FLOW VELOCITY DURING THE VALSALVA MANEUVER. I.E. Holden, B. Cimprich, B.L. Metzger*, B. Therrien. The University of Michigan, Ann Arbor, MI 48109

Persons with cerebrovascular disease are at risk from the marked shifts in blood flow evoked by the Valsalva maneuver (VM) or straining. We examined the influence of age, hypertension and position on carotid artery blood flow velocity (CABFV) during strain in the 70° upright and supine bed positions. Young healthy (n=180) and hypertensive (n=25) adults aged 30-55 years and older healthy subjects (n=66, >55 years) were studied. Subjects strained by blowing into a pressure gauge to 40 mmHg for 10 seconds. CABFV was measured by noninvasive Doppler technique. In the supine position, CABFV fell an average of 59% during strain for young hypertensives (p=.05). Following release of strain, young hypertensives had significantly greater overshoot above baseline than young healthy subjects (25% vs 17%, p=.01) and tended to have a greater overshoot than the older healthy group. During strain, supine and upright positions differentially altered CABFV in both young healthy subjects (-60% vs -46%, p<.05) and young hypertensives (-79% vs -56%, p=.001). Across the VM, total percent change in CABFV was less in the upright position vs supine for young hypertensives (699% vs 999%, p=.01) but not for controls. We conclude that CABFV changes during the VM are intensified in young hypertensives as compared to young and older healthy adults and that the intensity of these changes can be modified by body position.

COMPUTER-PROCESSED EEG FOR ANESTHETIC AND PSYCHIATRIC MANAGEMENT OF ELECTROCONVULSIVE SHOCK THERAPY (ECT). Michael R. Isley*, Paul G. Shinkman, Enid R. Kafer*, Dwight L. Evans, and Robert N. Golden*. Departments of Anesthesiology, Psychology, and Psychiatry, University of North Carolina, Chapel Hill, NC 27599.

Monitoring the brain during ECT has typically been restricted to the measurement of seizure duration, the most significant variable for therapeutic efficacy. With the introduction of "modified" ECT (i.e., the use of intravenous anesthetic drugs, neuromuscular blockade and controlled ventilation), this therapy now significantly involves anesthesiology. Thus, the purpose of the present study was to apply continuous monitoring of computer-processed EEG and EMG activity during ECT in order to tailor anesthetic and paralytic management to individual needs, and establish a reliable technique for on-line evaluation of seizure duration. All consenting patients met the DSM-III-R criteria for a major depressive episode (15 patients received 115 treatments). Nondominant unilateral or bilateral ECT was administered using brief bipolar pulses delivered by the Multiple-Monitor Electroconvulsive Therapy Apparatus (MECTA Corp., Portland, OR). Two channels of analog and computer-processed EEG were continuously monitored. The latter method involved power spectral analysis and display of the EEG as a dot-density modulated spectral array (DSA) with trended rms amplitude and spectral edge frequency (SEF 90%), using the 2-channel SRD Cerebro-Trac 2500+ (Misgav, Israel) and a standard ipsilateral, frontal-mastoid electrode configuration for the left and right hemispheres. The DSA profiles demonstrated that anesthetic induction, neuromuscular blockade, ECT seizure duration and recovery from each were more easily and consistently interpreted than using analog waveforms. We conclude that computer-assisted brain monitoring is superior to conventional techniques, and offers expanded capabilities for research on ECT and for its clinical management.

516.13

SCHIZOPHRENIA AND THE FRONTAL LOBES: COMPARISON OF MULTIPLE IMAGING TECHNIQUES AND NEUROPSYCHOLOGICAL TESTING. D.S. O'Leary, S.A. Kuperman*, G.A. Cohen*, and N.C. Andreasen NIMH-CRC, Psychiatry Department, University of Iowa, Iowa City, IA 52242.

Magnetic Resonance Imaging (MRI), Brain Electrical Activity Mapping (BEAM), and neuropsychological tests presumed to be mediated by the frontal lobes were administered to 41 patients with schizophrenia (n=35) or schizophrenia spectrum disorder (n=6), and to 23 normal controls. Regional Cerebral Blood Flow (RCBF) measures were also administered to 35 of the patients and 16 of the controls. BEAM and RCBF were conducted after a 21 day drug wash, or in 9 first episode patients, prior to neuroleptic treatment. MRI, BEAM, RCBF, and neuropsychological data were independently used to categorize patients into frontal lobe impaired and non-impaired groups. Two methods were used to dichotomize the group: a purely statistical method (i.e. upper quartile of each distribution is defined as impaired), and a more clinically-based technique (e.g. significant frontal slowing on BEAM, multiple perseverative errors on Wisconsin Card Sorting Test). Bayesian probabilities are used to compare the categorization produced by the two methods of dichotomizing the patients on each of the imaging and testing procedures. Results are complex and illustrate the difficulty of defining frontal lobe impairment in disorders such as schizophrenia in which there is no obvious lesion.

THE EFFECTS OF CONDITIONING MUSCULOCUTANEOUS STIMULATION ON THE SOLEUS H-REFLEX DURING WALKING IN SPASTIC PARETIC SUBJECTS. **J. Fung and H. Barbeau. School of Physical & Occupational Therapy, McGill University. Montreal, Quebec H3G 1Y5**

The soleus H-reflex amplitude in normal subjects is modulated throughout the gait cycle, which can further be inhibited by a conditioning musculocutaneous stimulation from the ipsilateral sole of the foot (Fung & Barbeau, Soc. Neurosci. Abstr. 15:1201, 1989). The present study was conducted to contrast the pattern of responses in 10 spastic spinal cord injured subjects during treadmill walking. The test soleus H-reflex was obtained by stimulating the tibial nerve in the popliteal fossa with a single 1 ms pulse, at an intensity that yielded a minimally detectable and constant M-response. The conditioning stimulus, consisting of an 11 ms train of three 1 ms pulses at 200 Hz, and preceding at 45 ms, was delivered to the ipsilateral medial plantar arch at a maximally tolerable intensity (up to 3X sensory threshold). The stimulation was delivered randomly in 8 different phases of the gait cycle.

Three different patterns of test responses could be identified. Two subjects showed a similar pattern to the normal, such that the H-reflex amplitude was reduced in early stance, progressively increased from midstance to push off, and was again decreased in swing. Four subjects showed generally elevated responses throughout stance, with a slight degree of depression present in swing. Four other severely spastic subjects showed a consistently elevated and similar H-reflex amplitude throughout the gait cycle with no phasic modulation. With musculocutaneous stimulation, the soleus H-reflex was significantly inhibited in the early stance and swing phases in 6 out of 8 subjects, but the trend was also present in the other 2 subjects. The effect was more pronounced in swing than in stance, relating functionally to an improved ability for the limb to swing through. The other two extreme cases included 1 mildly spastic subject who showed an almost complete inhibition of the H-reflex throughout stance as in the normal, and 1 severely spastic subject who showed an inhibition only in swing. The results support that Ia gating mechanisms are defective in spastic paretic gait, which can be modified by musculocutaneous stimulation. However, tonic gain mechanisms cannot be excluded. RELIEF OF SPASTICITY BY TENS IS ASSOCIATED WITH IMPROVEMENT IN REFLEX AND VOLUNTARY MOTOR FUNCTIONS. C.W.Y.Chan and M.F.Levin. School of Physical and Occupational Therapy, McGill University, Montreal, Canada. H3G 1Y5.

Our previous studies showed that single, 45 min applications of transcutaneous electrical nerve stimulation (TENS) prolonged H and stretch reflex latencies in hemiparetic subjects. In addition, nine, daily 30 min TENS applications enhanced vibratory inhibition of the H reflex and tended to decrease hyperactive stretch reflexes. These findings suggested that longer term TENS may be effective in the reduction of hemiparetic spasticity. Our present objectives were two-fold: to determine whether longer-term TENS stimulation would lead to a reduction in clinical spasticity and whether such a reduction could be associated with a decrease in stretch reflex excitability and an improvement in voluntary motor function.

Thirteen spastic hemiparetic subjects participated in the study. The effects of fifteen, daily 60 min TENS treatments over a three week period were contrasted with those of placebo stimulation applied to the common peroneal nerve of the affected leg. The test battery consisted of five measures of reflex and voluntary function in the calf. They were 1) clinical spasticity scores, 2) maximal H reflex to M response ratios, 3) vibratory inhibition of the H reflex, 4) stretch reflexes, and 5) maximal voluntary isometric plantarflexion and dorsiflexion in standing.

In contrast to placebo stimulation which produced no significant effects, repeated applications of TENS decreased clinical spasticity ($p<0.05$), increased vibratory inhibition of the H reflex ($p=0.02$), and decreased the magnitude of stretch reflexes ($p=0.05$) in the spastic ankle extensors. These changes occurred concomitantly with a substantial improvement in voluntary *dorsiflexion* force ($p<0.05$) and a decrease in agonist/antagonist EMG co-contraction ratios ($p<0.05$).

Our results thus demonstrated that repeated applications of TENS can reduce clinical spasticity and improve control of reflex and motor function in hemiparetic subjects. Furthermore, the mechanism of the improvement may be partly related to an enhancement in presynaptic inhibition, and a possible 'disinhibition' of descending voluntary commands to flexor motoneurons.

SPASTICITY IS INVERSELY CORRELATED WITH ANTAGONIST VOLUNTARY CONTRACTION IN SPASTIC HEMIPARETIC SUBJECTS. M.F.Levin and C.W.Y.Chan. School of Physical and Occupational Therapy, McGill University, Montreal, Canada. H3G 1Y5.

The correlation between the severity of spasticity and residual voluntary muscular activity is unclear, yet the latter is often used to investigate the effects of treatment in spastic movement disorders. The objectives of our study were to compare voluntary EMG and force generated by ankle plantar- and dorsi-flexors in normal and spastic hemiparetic subjects, and to investigate the reproducibility of these measures and their correlation with clinical spasticity.

Seven age-matched normal subjects were tested once, and thirteen spastic hemiparetic subjects at least twice with one week apart. Subjects generated maximal isometric ankle plantar- and dorsi-flexion in the standing position. Agonist and antagonist EMG areas, co-contraction ratios, maximal force and temporal characteristics of force production were compared between affected and non-affected legs of hemiparetic subjects, after the latter were found to behave similar to legs of normal subjects. Spasticity was evaluated by clinical scales.

During dorsiflexion, maximal agonist EMG area and force were significantly decreased to 39% and 33% respectively of the non-affected leg. During plantarflexion, agonist EMG and force was reduced to 63% and 59% resepectively of the non-affected leg. Measures of maximal and mean force, force onset and dorsiflexion co-contraction ratios were highly reproducible ($r=0.78$ to 0.99), while raw and normalized EMG area measures were less so. Most interestingly, the amount of dorsiflexing force produced by the paretic dorsiflexors was highly correlated with the amount of agonist/antagonist co-contraction ($r=0.91$), and inversely related to clinical measure of antagonist spasticity ($r=-0.65$).

The high reproducibility of the force measurements suggested that they could be used to evaluate the effects of therapeutic intervention over time. More importantly, our findings demonstrated that, in hemiparetic subjects, the motor deficit in the paretic dorsiflexors but not the spastic plantarflexors was a reliable and valid indicator of the *severity* of ankle spasticity.

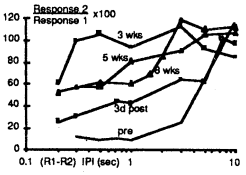
516.17

Long term recovery of sensory-motor function after spinal cord contusion in the rat. J.A. Gruner, N. Levine*. Dept. of Neurosurgery, NYU Medical Ctr., 550 First Ave., New York, NY 10016.

Following many types of CNS injuries, neurological function gradually recovers. Little is known, however, about the processes underlying this recovery. In spinal cord injury (SCI), the recovery time course is very consistent for physiological and behavioral measures; function is depressed for 1 wk, then gradually improves for another 2 to 3 weeks, and then plateaus.

To investigate the mechanisms of recovery after SCI, we developed a spinal cord contusion device capable of measuring the precise impact velocity and extent of cord contusion. Three neurophysiological tests were used to assess function after 12.5 or 25 mm x 10 gm weight drops: auditory startle responses (ASR), hindlimb myoelectric responses evoked by cerebellar stimulation (MEP), and somatosensory evoked potentials (SEP).

Rats were anesthetized and, using sterile surgical procedures, a T10 laminectomy performed to expose the spinal cord. The cord was contused and the wound closed. Evoked potentials were monitored before and after contusion. ASR, MEP, and SEP amplitudes showed a similar time course to that found previously. Of considerable interest, however, was the fact that MEP amplitudes, which typically begin to drop between 1 and 0.2 Hz, showed a substantial increase in ability to follow higher frequencies which was maintained as long as 8 weeks after injury (see figure).



ALZHEIMER'S DISEASE: NEUROPATHOLOGY III

517.1

REGIONAL DIFFERENCES IN CORTICOTROPIN-RELEASING FACTOR (CRF) AND SOMATOSTATIN (SRIF) IN ALZHEIMER'S DISEASE. W. H. Smith, G. Bissette, L. Cook, B. Crain, K. Dole and C.B. Nemeroff. Depts. of Psychiatry, Pharmacology and Pathology, Duke Univ. Med. Ctr., Durham, NC 27710.

Although several neuropeptides have been implicated in the pathology of Alzheimer's disease (AD), only corticotropin-releasing factor (CRF) and somatostatin (SRIF) have consistently been found to be reduced in post-mortem brain tissue in AD. The present study measured these two neuropeptides in 38 discrete brain regions. Tissue from 10 controls which consisted of both demented (non-AD) and non-demented patients, were compared to tissue from 15 patients with neuropathologically confirmed AD. CRF and SRIF concentrations were determined by sensitive and specific RIAs. CRF concentrations in AD patients were significantly lowered in 11 cortical regions (Brodmann's areas 4, 7, 10, 11, 12, 20, 21, 22, 39, 44 and middle frontal gyrus), the amygdala, insula, hypothalamus, and putamen. The concentration of SRIF was significantly decreased in 8 cortical regions (Brodmann's areas 6, 12, 17, 20, 21, 24, 39, 40), and the insula. These results differ somewhat from previous studies in the pattern of neuropeptide alterations. Such interstudy variations may reflect unique neuropathological changes manifested by individual disease course or etiology. Supported by NIMH MH-40524 and NIA AG-05128.

ALZ-50 IMMUNOREACTIVE PROFILES IN HIPPOCAMPAL COMPLEX OF AGED AND ALZHEIMER'S DISEASED (AD) BRAIN. D.R. Brady and E.J. Mufson. Inst. Biogeront. Res., Sun City, AZ 85351.

Alz-50 is a putative marker for cytoskeletal degeneration in AD. However, virtually no detailed studies exist that compare Alz-50 profiles in normal aged and AD brains. We used the Alz-50 antibody to ascertain the morphology and topography of Alz-50 immunoreactive (IR) profiles in postmortem paraformaldehyde fixed hippocampal formation (HF) and entorhinal cortex (EC) from "normal aged" ($\bar{X}$=73 yrs; n=10), "pre-senile" (clinically normal with moderate AD pathology; $\bar{X}$=85.5 yrs; n=4) and AD ($\bar{X}$=80 yrs; n=3) brains. Alz-50 staining in normal and pre-senile brains revealed Golgi-like neurons in CA2, CA1-Subiculum (Sub) and EC. In four normal and all pre-senile cases many dentate granule cells were also IR. Six normal and all pre-senile cases showed IR particulate in the neuropil of the dentate molecular layer, strata moleculare and oriens of CA1 and CA2, Sub and EC. In contrast, Alz-50 staining in AD showed numerous dystrophic neurons with marked neurofibrillary tangle (NFT)-like morphology throughout the HF and EC. In AD, dense Alz-50 IR neuropil staining differentiated each hippocampal subfield. Compared to HF and EC of normal brain, quantitation revealed 68% and 90% more IR neurons in pre-senile and AD, respectively. Sections stained with anti-ubiquitin (Ub) revealed a few IR NFTs in HF and EC of normals. In pre-senile cases, a small population of Ub IR NFTs were seen within CA1-Sub and layer 2 of EC, compared to numerous IR NFTs throughout HF and EC in AD cases. Thioflavin-S staining in normal aged HF and EC revealed a few random NFTs, whereas pre-senile cases contained many more NFTs with a preponderance in EC (68%). When present in normal and pre-senile cases, Alz-50/thioflavin-S double labeled profiles occupied CA1 and layer 2 of EC. In AD brains, thioflavin-S NFTs were 13 times more prevalent than in pre-senile brains, occupying CA1-4, Sub and EC. Many of these NFTs were also double labeled with Alz-50. Since a significant population of HF and EC neurons express Alz-50 in normal aged and pre-senile brains, it is possible that Alz-50 expression is a consequence of normal aging which is exacerbated in AD. Support: ADCRC 82-0686, YK-8365 and AHAF.

A LINE OF PLAQUES IN AREA 17 OF ALZHEIMER'S DISEASE: IMPLICATIONS FOR PATHOGENESIS. T.G. Beach and E.G. McGeer. Kinsmen Laboratory of Neurological Research, Univ. of British Columbia, Vancouver, B.C. Canada.

The laminar distribution of staining for senile plaques in area 17 was investigated in 16 patients with Alzheimer's disease (AD) and compared to the normal laminar distribution of afferent fibres, vascularity, acetylcholinesterase (AChE), and other chemoarchitectonic features. Senile plaques were aggregated at significantly higher density at the interface of laminae IVc and V. This did not correspond with any reported afferent, chemoarchitectonic, or vascular distribution. The line of plaques observed at the IVc/V interface is similar to that observed in the dentate gyrus (Crain, B.J., et al, Acta Neuropathol., 76:87, 1988). The line of plaques in the dentate gyrus also has no apparent correlate in normal anatomy, but, as in area 17, is located at an interface between laminae. At both sites, the line of plaques form where an Alz-50-immunoreactive neuritic field (Hyman, B.T., et al, Brain Res., 450:392, 1988; Beach, T.G., et al, Brain Res., 501:171, 1989) marking degenerating neurites meets a layer which has a high capillary density and a high cholinergic terminal density. The interaction between one or more of these elements may therefore be contributive to senile plaque formation.

517.4

STABILITY OF SYNAPSE NUMBERS IN THE ENTORHINAL CORTEX (AREA 28) IN PATIENTS WITH ALZHEIMER'S DISEASE. S.W. Scheff and D. A. Price*. Center on Aging, Dept. Anatomy & Neurobiology, Univ. Kentucky, Lexington, KY 40536-0230.

The parahippocampal gyrus, a portion of the temporal lobe and key component of the limbic system, lies adjacent to the hippocampus. Both structures are closely linked with human memory and known to be affected in Alzheimer's disease (AD). One part of this gyrus is the entorhinal cortex which receives information from other limbic structures and transmits it to the hippocampal formation. We have previously shown that several cortical regions (superior frontal, superior and middle temporal) demonstrate a highly significant reduction in synaptic density in AD. Because of the extensive connections of the entorhinal cortex with other limbic structures and its known involvement in AD, it is important to quantitatively assess its functional connectivity (synaptic density) and to determine the degree of neuropathological changes in AD.

Human brains were obtained at postmortem examination from 10 patients who met the NINCDS-NIA criteria for AD and from 10 age-matched controls. All tissues were obtained with 13 hours postmortem. Both lamina III and V were quantitatively assessed for synapse number and size. Unlike the widespread and significant loss of synapses in some association cortex, the entorhinal cortex shows ***no apparent synaptic decline***. This finding might be the result of a compensatory mechanism which overcomes the possible loss of connectivity as a result of cell loss in brain regions known to project to the entorhinal cortex. Supported by Alzheimer Association IIRG 87-042 and NIA AG05144.

517.5

AMYGDALAR DENDRITIC REGRESSION IN ALZHEIMER'S DISEASE: QUANTITATIVE GOLGI ANALYSIS. S.A. Scott, D.L. Sparks, S.T. DeKosky and S.W. Scheff. Sanders-Brown Center on Aging and Dept. Anatomy & Neurobiology, Univ. of Kentucky, Lexington, KY 40536-0230 and Depts. Psychiatry and Neurology, Univ. Pittsburgh Sch. of Med., Pittsburgh, PA 15261.

The amygdala undergoes severe degeneration in Alzheimer's disease (AD). To ascertain its available substrate for synaptic connectivity, we used a Golgi-Kopsch modification to study dendrites of the magnocellular basal amygdaloid nucleus (BNMC). The BNMC receives an especially dense projection from nucleus basalis of Meynert.

Five cognitively normal aged controls were compared to 4 AD cases (postmortem interval less than 5hr) meeting NINCDS-NIA criteria. Employing 15 neurons per case, the dendritic arbor was ordered somatofugally and each segment measured using an interactive, on-line computer tracing program (Kontron IPS). Mean total dendritic length per neuron was ***reduced*** in AD by 22%, due largely to changes among intermediate order segments. Significant alterations in total number of segments and average segment length, however, were not found. Despite the overall surface loss, ***increases*** in dendritic length and number with AD were noted amongst the ***most distal*** segments. These data suggest the presence of a subpopulation of excessively branched neurons in AD. However, since the majority have regressed dendritic trees, the net result is atrophy, suggesting a reduced amygdalopetal circuitry with key CNS regions.

UBIQUITIN IMMUNOREACTIVE DYSTROPHIC NEURITES IN SELECT AREAS OF THE NEOCORTEX IN DOWN'S SYNDROME. L.A. Mattiace, Y. Kress*, P. Davies*, S-H Yen and D.W. Dickson.
Dept of Pathology Albert Einstein College of Medicine, Bronx, NY, 10461.

Ubiquitin immunoreactive structures were studied in Down's syndrome brains ranging in age from 2 days to 60 years. Numerous randomly distributed ubiquitin immunoreactive dot-like structures in the white matter were shown to correspond to granular degeneration of myelin. These structures were first detected at age 21 and increased progressively thereafter with age. Other larger and more coarsely granular ubiquitin immunoreactive structures, most numerous in the middle and upper cortical layers, were consistent with dystrophic neurites. These ubiquitin immunoreactive structures were first detected at age six in the hippocampus and appeared to increase progressively with age. Immunoelectron microscopy demonstrated that these dystrophic neurites did not contain filamentous material. In the presence of amyloid in Down's syndrome adults, there was a substantial increase in the number of ubiquitin immunoreactive structures in the grey matter, beyond the increases seen with age. In the presence of diffuse amyloid plaques, these ubiquitin immunoreactive neurites were randomly distributed throughout the neuropil. However, in the presence of compact amyloid deposits, these ubiquitin immunoreactive dystrophic neurites formed plaque-like aggregations. This suggests that the disruption of the neuropil in areas of amyloid deposition may promote the formation of dystrophic neurites. In addition, since the presence of these dystrophic neurites appeared substantially earlier in the grey matter in Down's syndrome than in age-matched normals, this may be further evidence that selective aspects of aging may be accelerated in Down's syndrome individuals.

517.7

QUANTITATIVE NEUROPATHOLOGIC ANALYSIS OF ALS-PD CASES FROM GUAM. P.R. Hof, D.P. Perl, J.C. Steele[1]*, W. Janssen and J.H. Morrison. Fishberg Res Ctr and Dept of Geriatrics, Mt Sinai Sch Med, New York, NY 10029, and [1]Guam Memorial Hospital, Guam.

Guam, one of the Marianna islands in the Western Pacific, is characterized by a very high prevalence of ALS and Parkinson-Dementia (PD) in certain villages. We have undertaken a quantitative analysis of the laminar and regional distribution of neurofibrillary tangles (NFT) in the cerebral cortex of several cases presenting with different clinical symptomatology. Preliminary results revealed that areas within the temporal lobe are more heavily affected than frontal or parietal regions in PD cases. In particular, the hippocampal formation contained the highest NFT densities (up to 200 NFT/mm cortical traverse). ALS cases had very few cortical lesions. There were striking differences with Alzheimer's disease (AD) cases: NFT in neocortical association areas of Guam cases always predominated in superficial layers (up to 3-times more NFT in layer III than in layer V), whereas in AD, NFT are more frequently observed in layer V. The motor cortex was consistently involved in Guam cases, while it has very few NFT in AD. No amyloid was observed in any of these Guam cases. The differential NFT distribution in Guam cases still supports the hypothesis that a global corticocortical disconnection occurs in dementia, but suggests that in these cases a more circumscribed set of projections may be involved than in AD. These data are consistent with the notion that the disease may be caused by a pathogen retrogradely transported along specific corticocortical circuits that project heavily to mediotemporal areas. Supported by grants from NIH AG06647 and AG08802.

517.8

DOWN'S SYNDROME (DS), DEMENTIA PUGILISTICA (DP), AND ALZHEIMER'S DISEASE (AD): A QUANTITATIVE NEUROPATHOLOGIC COMPARISON. C. Bouras[1], P.R. Hof, R. Guntern[1]*, and J.H. Morrison. Fishberg Res Ctr and Dept of Geriatrics, Mt Sinai Sch Med, New York, NY 10029, and [1]Dept of Psychiatry, Univ of Geneva Sch Med, Geneva, Switzerland.

There is evidence that dementia in AD results from the global disconnection of specific corticocortical pathways. In order to further test this hypothesis we compared the laminar and regional distribution of neurofibrillary tangles (NFT) and neuritic plaques (NP) in 5 DS and 1 DP cases with brains from AD patients. The distribution of NFT and NP in DS was qualitatively and quantitatively comparable to that observed in AD, however lesions were found only in DS cases over 40 years. In association cortex NFT were predominant in layer V, whereas NP were more numerous in III. DS patients over 50-year old showed more lesions than cases below 50. The brains of two infants with DS had no lesions. In contrast, to the lesion distribution observed in AD and DS, the brain from a 58-year old retired boxer showed a massive involvement of the superficial layers: very high NFT densities were encountered in layer III throughout the cerebral cortex, while very few NFT were observed in V. No amyloid deposits or NP were present in the DP case. It is interesting to note that NFT predominate in layer III in both DP and Parkinson-Dementia of Guam, but are more equally distributed across III *and* V in DS and AD. This suggests that both DS and AD may involve a very global disruption of corticocortical circuits, whereas a subset, such as feedforward circuits may be more selectively involved in DP and Parkinson-Dementia of Guam. Supported by NIH grant AG06647 and ADRC AG05138.

517.9

NEUROPATHOLOGIC CHANGES IN THE HIPPOCAMPAL FORMATION OF ALZHEIMER'S DISEASE PATIENTS: A QUANTITATIVE MRI ANALYSIS. S.J. Kirsch, R.W. Jacobs, L.L. Butcher, & J. Beatty. Behavioral Neuroscience Program, Department of Psychology, UCLA, Los Angeles, CA 90024.

Traditionally, the monitoring and diagnosis of a neurologic disorder using magnetic resonance imaging (MRI) was based solely on the visual images obtained. New low field (LF) MRIs, however, greatly increase T1 and T2 tissue contrasts (which reflect the molecular environment of the tissue), allowing for easy and reliable quantification of different, or changing, tissues. Exploiting this advantage, T1 and T2 relaxation times of the hippocampal formation (HF) were measured in 21 normals (age 18-79 yrs) and 4 patients with suspected Alzheimer's disease (AD)(age 69-81yrs) using an Instrumentarium Magnaview 0.04T LF MRI (T1 = IR:1500 (50,375)/40; T2 = SE:1000/130 and 1000/200). A mid-thalamic, 10-mm coronal slice through the HF revealed T1 times of ADs to slightly, but consistently, exceed those of normals. T2 times of ADs, however, were substantially lengthened (by 15-65ms), and appear to be related to the degree of dementia. In addition, there were indications of differential pace of AD pathology in the two hemispheres. These results suggest that LF MRI may provide a means for diagnosing and quantifying the pathology of AD.

517.10

ENTORHINAL CORTEX IS AN EARLY SITE OF NEUROFIBRILLARY TANGLE PATHOLOGY IN NON-DEMENTED ELDERLY. P.V.Arriagada, B.T.Hyman. Dept. Neuropathology & Neurology, Massachusetts General Hosp, Harvard Medical School, Boston, MA 02114.

It is known that the occurrence of Senile Plaques(SP) and Neurofibrillary tangles (NFT) seems to increase with age in nondemented elderly. We have studied the question of whether certain cytoarchitectural areas are consistently vulnerable, and whether there is a relationship between the appearance of NFT and SP with one another and with age. We examined 15 cytoarchitectural areas including the hippocampal formation, entorhinal cortex (EC), amygdala, nucleus basalis, and neocortical areas 20 and 21 in 20 cases of presumed non-demented elderly, ages 58-85 years, using ThioflavinS (Thio S) and Alz-50 immunocytochemistry . Quantitation of NFT (Thio-S) showed that the greatest severity of involvement was in the EC . The severity of NFT pathology in the EC increased exponentially with age ($R=.600$, $p<.005$). The number of NFT in other areas (combined) was significantly correlated with the number of NFT present in the EC (Spearman correlation, $p<.004$). Although amyloid SP were present in nearly all cases, Alz-50 positive SP and immunoreactive dystrophic neurites were found only in cases with substantial NFT (more than 35 NFT/1.8 mm2 field) in EC. These results suggest that NFT and SP accumulate in a stereotyped, hierarchical fashion with age,and that the EC is an early site for NFT pathology . In addition, the presence of Alz-50 positive SP and dystrophic neurites is related to the severity of NFT. (Supported by the Brookdale Foundation, the Educational Commission for Foreign Medical Graduates and NIH AG08487). We thank P.Davies,New York, for the gift of Alz-50).

EPILEPSY: KINDLING II

518.1

TRANSFER KINDLING FROM THE AMYGDALA OR PIRIFORM CORTEX TO THE FRONTAL CORTEX IN FEMALE RATS WITH AND WITHOUT ESTRADIOL REPLACEMENT. G. G. Buterbaugh and G. M. Hudson*. Department of Pharmacology and Toxicology, University of Maryland School of Pharmacy, Baltimore, MD 21201.

In ovariectomized (OVX) female rats, estradiol (E) replacement facilitates kindling of the amygdala (Am) and frontal cortex (fCtx), but not the piriform cortex (pCtx). We therefore tested the influence of E on secondary fCtx kindling following antecedent kindling of E-sensitive (Am) and E-insensitive (pCtx) primary sites. Ten days after OVX, rats were kindled by daily Am or pCtx stimulation. At least two weeks later, daily fCtx kindling stimulations were initiated in these rats, with (E) and without (nE) estradiol replacement. Am-kindled nE rats completed secondary fCtx kindling after 13.6 $\pm$ 2.3 afterdischarges (AD) and 559 $\pm$ 132 AD sec, and pCtx-kindled nE rats completed fCtx kindling after 13.5 $\pm$ 2.4 ADs and 374 $\pm$ 51 AD sec, significant savings compared to fCtx primary site kindling of nE rats (38 $\pm$ 2.2 ADs and 840 $\pm$ 93 AD sec). In Am-kindled rats, E replacement did not significantly effect secondary fCtx kindling. In pCtx-kindled rats, E rats completed secondary fCtx kindling after significantly fewer ADs (32%) and AD sec (44%), compared to nE rats. These results suggest that E facilitates the kindling process by interacting with an anatomical/mechanistic substrate shared by E-sensitive kindling sites. (Supported by PHS NS20670)

518.2

PERFORANT PATH EVOKED SYNAPTIC CURRENTS IN THE DENTATE GYRUS STUDIED WITH CURRENT SOURCE DENSITY TECHNIQUES AFTER LTP AND KINDLING G. Golarai, T. Sutula. Neuroscience Training Program, Depts. of Neurology and Anatomy, University of Wisconsin, Madison, WI 53792.

The perforant path demonstrates physiological and morphological plasticity including reversible increases in synaptic efficacy (LTP) and kindling-induced synaptic reorganization. CSD analysis was used to investigate functional consequences of these phenomena in dentate gyrus (DG). CSD analysis in normal rats revealed the location of currents underlying PP evoked field potentials in the DG. LTP increased the magnitude but did not alter the spatial pattern of PP evoked currents in the DG. In contrast, PP activation in kindled rats evoked an altered pattern of current flow including a net inward current in the inner molecular layer at 5-7 msec after granule cell discharge. The spatial location of this current corresponds to the terminal zone of sprouted mossy fibers, suggesting that axonal sprouting and synaptic reorganization of the mossy fiber pathway may have functional consequences that could include increases in recurrent excitation mediated by the sprouted collaterals.

DEVELOPMENT OF POSTICTAL EEG DEPRESSION IN AMYGDALA-KINDLED RATS. B. M. Pedrosi* & R. F. Berman. Dept. Psychology, Wayne State University, Detroit, MI 48202.

Seizures produced by the kindling process are usually followed by a period of flattened electroencephalographic (EEG) activity called postictal EEG depression. The development of this phenomenon was observed in treatment-free subjects. Twelve, male, Long Evans rats were stereotaxically implanted with electrodes into the medial amygdala. Electrical brain stimulation thresholds that produce a brief epileptiform afterdischarge were then established for each rat. Animals were stimulated at threshold until five consecutive Stage 5 or 6 behavioral seizures were attained. Observations were made of the development of the afterdischarge and the duration of postictal EEG depression. The development of postictal spiking was also recorded. Postictal EEG depression appeared as early as Stage 0, and was represented in all subsequent stages. In addition, the duration of postictal EEG depression increased over the course of kindling, suggesting that inhibition also "kindled" over repeated stimulation trials. However,correlations between the durations of afterdischarge and postictal EEG depression were uniformly low and not statistically significant ($r^2=0.12$) indicating that the underlying mechanisms responsible for these two phenomena are different. Thus, kindling appears to be associated with long-lasting changes in both excitatory and inhibitory neural processes. (Supported by Grant No. RR-08167)

AMYGDALA KINDLING INFLUENCES THE EXCITABILITY OF BRAINSTEM SUBSTRATES. C.D. Applegate, G.M. Samoriski* and J.L. Burchfiel. Comprehensive Epilepsy Program, University of Rochester School of Medicine, Rochester, NY 14642.

Previous research has demonstrated a role for pontine reticular structures in the expression of tonic hindlimb extension (THE) following ECS stimulation (Browning, Fed. Proc., 44:2425, 1985). This study investigated the influence of amygdala kindling on ECS-induced THE. Male, Sprague-Dawley rats were implanted with bipolar electrodes into the left amygdala (N=14). Following recovery, the incidence of THE to a corneal ECS-stimulus was determined. Rats were then kindled to 5 consecutive stage 5 seizures, and the incidence of THE was again determined. In comparison with unkindled control animals (N=23), kindling significantly increased the incidence of THE from 23% to 79%. The incidence of THE in controls was 26% and 39% for test and retest, respectively. In a second experiment, amygdala-kindled rats (N=7) received mechanical lesions of the pontine reticular formation. While lesions blocked the expression of THE in these animals, no significant alteration in kindled seizure expression was observed. Results suggest that while kindling interacts with brainstem substrates necessary for aspects of tonic seizures, these same substrates are not necessary for kindled seizure expression.

c-fos Expression in the Magnocellular Neuroendocrine System During Amygdala Kindling

R.S. Greenwood, R.B. Meeker L. Rietz* and J.N. Hayward. Dept. of Neurology and Pediatrics and Neurobiology Curriculum, University of North Carolina, Chapel Hill, NC 27599.

In previous studies we have shown that resting plasma vasopressin (VP) is elevated and that vasopressin mRNA expression is chronically higher in the magnocellular neuroendocrine system after amygdala kindling. Since c-fos expression is elevated in other areas of the nervous system after seizures and may be involved in regulation of VP gene transcription we measured c-fos changes during the early phases of amygdala kindling. A 48 mer oligonucleotide specific for c-fos was 3'-end labeled with ^{125}I-dCTP and hybridized to 20 um sections from the brains of kindled or sham-stimulated rats. The hybridization of the antisense c-fos oligonucleotide probe was compared to hybridization of a sense oligonucleotide probe and to a specific probe for VP mRNA. Sections were analyzed with an image analysis system (Bioquant IV). A single train of the kindling stimulus (1 s, 60 cps, 1 ms, biphasic, 400 uA peak-to-peak trains) was administered to the kindled animals. A 50 % increase in c-fos mRNA without a corresponding change in VP mRNA expression was found. The c-fos mRNA in the cortex on the side of amygdala stimulation were also higher than in sham stimulated animals.

The results of this study suggests that proto-oncogenes could be involved in the regulation of vasopressin gene expression in kindled rats.

AMYGDALOID KINDLING INDUCES TRH mRNA IN SPECIFIC LIMBIC FOCI AS DETERMINED BY IN SITU HYBRIDIZATION HISTOCHEMISTRY (ISHH). M.J. Kubek, S.M. Knoblach, K.S. Fuson and M.R. Aydelotte*. Depts. of Anatomy, Psychiatry, & Program in Medical Neurobiology, Indiana University & VA Medical Centers, Indianapolis, IN 46202.

TRH levels are increased after either electrical or chemical kindling (Ann.N.Y.Acad.Sci.553:286,1989). ISHH was used to study the possibility that TRH mRNA might change in specific seizure foci as a consequence of this process. Rats were either electrically (5 stage 5 seizures) or sham kindled. After 2 weeks rats were killed 1,3,6,12,& 24hrs following one stage-5 seizure. Sections were hybridized with a 35S-CTP labeled 548b TRH riboprobe. Film and emulsion were evaluated via computer image analysis. Significant TRH mRNA increases (% of sham) were seen in dorsal & ventral dentate gyri at 3hrs (658 & 96) & 6hrs (2098 & 596), peaked at 12hrs (2692 & 955), and returned to 3hr levels at 24hrs (510 & 138). Significant TRH mRNA increases were also measured in CA3, CA1, & piriform ctx at 3hrs and remained elevated at 24hrs. No hybridization was seen in these same regions in sham or 1hr groups. This report is the first to quantitate temporal changes of TRH mRNA in seizure foci following kindling. Normally, TRH mRNA is not detectable in these same regions. ECS has similar effects on TRH mRNA (this meeting). We suggest that TRH increases following kindling and ECS are the result of de novo synthesis in specific loci. Supported by NS25661.

518.7

THE EFFECT OF A 12-WEEK INTERVAL ON PERMANENCE OF 'PARTIAL' (STAGE 1), 'FULL' (STAGE 5) AND LOW FREQUENCY (3 HZ) KINDLING IN THE RAT. Z. Dennison, T. Tandan*, G.C. Teskey and D.P. Cain. Dept. of Psychology, Univ. of Western Ontario, London, CANADA N6A 5C2.

We previously compared the effect of a 12-week interval on kindling to stage 3 or stage 5 and found that both groups demonstrated equal permanence and fallback (S.N. Abstr. 1989, 310.9). Here we examined the permanence of partial (stage 1) 60 HZ kindling and full (stage 5) low frequency kindling. Rats with amygdala electrodes were kindled using 1-sec trains of 60 Hz pulses to stage 1 (ST1, 4 afterdischarges [ADs]) or stage 5 (CONT), or to stage 5 using 3 Hz pulses (LF). A second control group had AD threshold only determined (ADT). Rekindling after 12 weeks was performed using 1-sec 60 Hz trains in all rats. Results showed that ST1 and CONT required the same total no. of ADs to kindle to stage 5; therefore ST1 demonstrated significant savings over the interval. LF and CONT required the same no. of ADs to rekindle to the second stage 5; therefore LF kindling demonstrated similar permanence to 60 Hz kindling. Supported by an NSERC grant to DPC.

LOCALIZED CHANGES IN CYTOCHROME OXIDASE STAINING IN HIPPOCAMPUS OF KINDLED RATS. J.N. Nobrega, J. Petrasek, L.M. Dixon, S.J. Kish and W.M. Burnham, Clarke Institute of Psychiatry and Pharmacology Dept., Univ. of Toronto, Toronto, Ont., M5T 1R8, Canada.

Kindling of limbic structures has been associated with a number of alterations in hippocampus, including abnormal neuronal excitability, changes in Ca++ concentrations, increases in paired-pulse inhibition, and increased GABA-BZP binding. In the present study cytochrome oxidase (CO) histochemistry was used to probe possible sustained alterations in metabolic activity in the hippocampus of kindled rats. Relative CO activity, the terminal complex of the mitochondrial respiratory chain, is thought to reflect local tissue metabolic capacity, which is coupled to neuronal activity (Wong-Riley, M.T.T. *TINS*, 1989, 12, 94-101). Rats were kindled via stimulation of the entorhinal cortex and sacrificed either 24 hr (n=7) or 28 days (n=7) after their sixth stage-5 seizure, together with equal numbers of non-stimulated controls. Brains were processed for CO histochemistry using a modification of the Wong-Riley (1979) method. Ten hippocampal areas were subjected to densitometric analyses, using callosum optical density (OD) as an internal densitometric standard for each section. OD values were further normalized by the overall mean. Results for the 24 hr groups revealed a small (-4.3%), but highly reliable decrease in CO staining in the superior blade of the dentate gyrus of kindled rats, as well as 2-3% increases in the oriens layer of CA1 and the hilar region (all $ps <$ 0.001). After 28 days, these differences were slightly reduced and were no longer statistically significant. The observed changes may relate to previously reported acute alterations in hippocampal function, although their significance for the permanent kindled state is unclear. These preliminary results suggest that CO histochemistry may provide a sensitive method for assessing localized changes in kindled brains.

ICTAL AND INTERICTAL BRAIN EEG MAPPING DURING AMYGDALOID KINDLING IN THE CAT: POWER SPECTRAL AND TIME DOMAIN STUDY. A.Fernández-Guardiola, A.Martínez*, R.Fernández-Mas*, R.Gutiérrez. Neurosci. Div. Instituto Mexicano de Psiquiatría. México, D.F., 14370.

The pattern of the cortical propagation of amygdaloid afterdischarges (AM/AD), was studied in daily kindled cats. By means of a computer program, 4-second samples of the recordings with an isometric 16-channel cortical matrix were acquired a minute before and 2, 14, 26 and 38 sec after the amygdaloid stimuli during the process. Behavioral video tape recordings were simultaneously carried out. Power spectra (4-16 Hz) and historical layout of isolated AM/AD ictal and interictal spikes were computed during each behavioral stage (I-VI). The cortical projection of the amygdaloid activation throughout the process is different when ictal or interictal spikes are considered. The analysis of the interictal activity showed less spectral density than that of the AM/AD and the projection corresponded to the prefrontal and frontal ipsilateral cortices, the anterior portion of the ipsilateral temporal lobe and a restricted area of the contralateral temporal lobe. The AM/AD projection was more evident in the insular and ectosylvian posterior cortices, bilaterally in the frontal regions and a strong activation of the contralateral temporal lobe appeared towards the end of the AM/AD. The electrical and the behavioral manifestations, e.g., the direction of circling, mioclonia, and the preictal rigidity, are asymmetrical, even during stage VI. The average of the interictal EEG maps were clearly different for each stage and showed a progressive activation beginning in the frontal cortex, and latter appearing in the temporal lobe, contralateral to the stimulated amygdala. Experiments on kindled seizures are commonly considered as a model of Grand mal epilepsy, from our results we conclude that kindling is rather a model of temporal lobe partial complex epilepsy.

FUNCTIONAL AND METABOLIC EVIDENCE FOR UNILATERAL MEDIATION OF INFERIOR COLLICULAR CORTICAL SEIZURES. T.J. McCown, G.E. Duncan and G.R. Breese. University of North Carolina, Chapel Hill, N.C. 27599-2750.

Unilateral electrical stimulation of a specific area in the inferior collicular cortex produces bilateral behavioral seizures, which progress from wild running seizures after acute stimulation to generalized seizure behaviors after repeated "kindling" stimulation (McCown et al., Exp. Neurol. 86:527,1984). Initially, we found that unilateral stimulation initiated non-synchronous, bilateral afterdischarge in the inferior collicular cortex that coincided with the behavioral seizure activity. However, unilateral kindling in the inferior collicular cortex did not influence the kindling rate from the contralateral inferior collicular cortex. Furthermore, contralateral collicular cortical lesions did not alter ipsilateral seizure parameters. Using ^{14}C-2-deoxyglucose autoradiography, the unilateral nature of seizure activity in the inferior collicular cortex was substantiated. Thus, unilateral activity in the inferior collicular cortex is sufficient to cause bilateral seizure behaviors. (Supported by HD-03110 and NS-26595).

OPPOSITE CHANGES OF DOPAMINE TURNOVER IN THE PREFRONTAL CORTEX AND NUCLEUS ACCUMBENS AFTER AMYGDALOID KINDLING. P. Rada*, E. Murzi* and L. Hernandez. Laboratorio de Fisiologia and Unidad de Neurologia, Facultad de Medicina, Universidad de Los Andes, Merida, 5101-A, Venezuela

An antagonistic relationship between psychosis and epilepsy called "forced normalization" has been described[1]. When anticonvulsant administration suppresses seizures, psychotic episodes appear, and vice versa, when neuroleptic administration ameliorates psychotic symptoms, seizures occur more often. It is believed that seizure and dopamine (DA) turnover are related. In fact, DA receptor blockers lower threshold seizures in rats[2]. However, in brain homogenates, DA turnover changes have not been observed after amygdaloid kindling[3]. Microdialysis was used to monitor extracellular DA and its metabolites in the nucleus accumbens (NAC) and the prefrontal cortex (PFC) in amygdaloid kindled rats. Under ketamine anesthesia, 10 male Wistar rats were chronically implanted with ipsilateral monopolar electrodes in the amygdala for electrical stimulation; guide shafts for microdialysis were aimed to the NAC in 5 rats and to the PFC in the other 5 rats. After a week of recovery, animals were stimulated daily in the amygdala until three consecutive stage 5 motor seizures were elicited (square-wave pulses of 300 μA, 0.4 msec and 60 Hz). DA and its metabolites were assessed by HPLC with electrochemical detection. DA turnover decreased in the NAC and increased in the PFC with kindling. These opposite variations in extracellular DA as a result of kindling suggest dopaminergic mesolimbic and mesocortical involvement in epilepsy and a mechanism for the "forced normalization" phenomenon.

ALZHEIMER'S DISEASE: MOLECULAR STUDIES

519.1

EXPRESSION OF SULFATED GLYCOPROTEIN-2, THE RODENT HOMOLOGUE OF pADHC-9, INCREASES IN RAT HIPPOCAMPUS AFTER EXCITOTOXIC LESIONING. P. C. May and M. Lampert-Etchells*#. Lilly Research Labs, Eli Lilly and Company, Indianapolis, IN 46285 and Andrus Gerontol Ctr.#, USC, Los Angeles, CA 90089.

pADHC-9 is a hippocampal cDNA clone which is overexpressed in Alzheimer's disease hippocampus (May et al., 1989, Can J Neurol Sci. 16:473). Sulfated glycoprotein-2 (SGP-2), the rodent homologue of pADHC-9, is a major secretory product of the rat Sertoli cell and presumably is involved in male reproductive function; its role in brain is unknown. To explore possible functions, young male F344 rats were subjected to bilateral intraventricular injections of kainic acid (0.5 ug/ul each) and sacrificed 14 d later. Total RNA or protein was extracted from the dorsal hippocampi and used in RNA or immunoblot analyses. SGP-2 RNA levels increased 2 fold in KA-lesioned hippocampi compared to saline-injected controls ($p< 0.05$; n=3-4). As expected, GFAP RNA prevalence in hippocampus also increased 4 fold following KA lesioning ($p<0.02$; n=3-4). Immunoblot analyses of hippocampal homogenates revealed comparable increases in SGP-2 and GFAP protein expression following the lesion. Immunocytochemical analyses detected little SGP-2 immunoreactivity in non-lesioned animals but marked accumulation of SGP-2 in atrophic CA3 and CA4 pyramidal cells present 14 d after the lesion. These data indicate that the increased expression of pADHC-9 in AD hippocampus can be duplicated in the kainate-lesioned rat and this model will be useful for identifying the function of pADHC-9/SGP-2 in the brain. BASAL AND WATER SOLUBLE FORSKOLIN STIMULATED SECOND MESSENGER FORMATION (cAMP) IN POST MORTEM OLFACTORY BULB, HIPPOCAMPUS AND CEREBELLUM OF CONTROLS AND ALZHEIMER-PATIENTS. T.G.Ohm, M.Schmitt*, J.Bohl* and B.Lemmer*. Centers of Morphology and Pharmacology, J.W.Goethe Universität, 6000 Frankfurt, FRG.

A water soluble forskolin analogue [F]; forskolin-7-deacetyl-7-butyryl, Calbiochem] was used to activate adenylate cyclase [AC] in post mortem olfactory bulb, hippocampus and cerebellum of 7 controls (C) and 7 Alzheimer patients (ALZ). Diagnose were done by clinical and histopathological examinations. Basal as well as stimulated AC activity cAMP/ mg protein/min] was measured by formation of cAMP from 0.5 mM ATP in the presence of an ATP-regenerating system, suspensions incubated for 6 min at 37°C without and with 100 uM F, formed cAMP determined by radioassay. Protein was determined after Lowry. Data are means ± SEM. For statistics the non-parametric Mann-Whitney U-test was used.

INTERLEUKIN-1 (IL-1), INTERLEUKIN-6 (IL-6) AND TUMOR NECROSIS FACTOR (TNF) IMMUNOREACTIVITIES ARE EXPRESSED IN MICROGLIA IN HUMAN BRAIN. D Dickson, L Mattiace, S-H Yen* and P Davies. Dept of Pathology (Neuropathology), Albert Einstein College of Medicine, Bronx, NY.

We have developed immunocytochemical methods for microglia in human brain to study the role of microglia in amyloidogenesis in aging and Alzheimer's disease. Microglia share a number of antigenic properties with macrophages, including presence of epitopes to class II major histocompatibility antigen (HLA-DR), Leu-M5 and leukocyte common antigen (LCA). Macrophages also produce a number of cytokines, including IL-1, IL-6 and TNF. In tissue fixed briefly in periodate-lysine-paraformaldehyde and sectioned with a Vibratome, microglia were immunoreactive with antibodies to IL-1, IL-6 and TNF. In Alzheimer's disease, the stained cells formed a reticular array in gray and white matter, and were clustered in areas of amyloid deposition. In control elderly brains, fewer microglia were immunostained. Double labeling studies showed that cytokine-reactive cells were microglia and not astrocytes, since they were co-labeled with antibodies to HLA-DR, Leu-M5 and LCA, but not antibodies to glial fibrillary acidic protein.

519.4

INTERLEUKIN-1ß mRNA LEVELS INCREASE IN ASSOCIATION CORTEX IN ALZHEIMER'S DISEASE. K. E. Rogers, A. B. Wadhams,* P. D. Coleman. Dept. of Neurobiology and Anatomy, University of Rochester, Rochester, N. Y. 14642 USA

Interleukin-1ß(IL-1ß) is a cytokine which has been shown to stimulate astrocyte proliferation. Additionally, it can induce expression of the ß-amyloid precursor gene. Thus, we have examined IL-1ß mRNA levels in superior frontal gyrus in normal aging and in Alzheimer's Disease(AD). Batch mRNA isolations were performed from 24 AD and nine age-matched control cases. Integrity of the mRNA was examined by Northern gel analysis and mRNA content was quantified by hybridization to an oligo dT probe. Serial dilutions of each sample were bound to a nylon membrane and probed with a cRNA transcript of human IL-1ß. Resulting autoradiograms were quantified by scanning densitometry. The total yield of mRNA per gram of tissue did not vary significantly between normal controls and AD cases. In control cases less than 80 years of age, Il-1ß transcripts were not detected. IL-1ß message was present in control cases 90 years and older, although at relatively low levels. In AD cases Il-1ß messages were present in all age groups. However, the IL-1ß message levels were higher in young AD cases than in AD cases 90 years and older. Thus, IL-1ß mRNA shows an age-related increase in normal aging and an age-related decrease in AD.(Supported by AG 09016, AG01121, AG 03644, AG 00107, PRG-89-120)

519.5

ANOMALOUS REACTION OF OLIGO PROBES FOR 3 HEAT SHOCK mRNAs IN ALZHEIMERS HIPPOCAMPUS. M. Morrison-Bogorad, S. Pardue*, K. Groshan*, C.L. White*, III, E.H. Bigio*, B. Border, E.K. Miller*, R. Gonzales* and J.D. Raese. Departments of Neurology, Biochemistry, Pathology and Psychiatry, University of Texas Southwestern Medical Center, Dallas, TX, 75235, and The Schizoprenia Research Center, Veterans Administration Medical Center, Dallas, TX, 75216.

The stress protein, ubiquitin, is expressed in some affected neurons in Alzheimers disease (AD). Little is known about the expression of other members of the heat shock family in AD. We hybridized oligo probes specific for human hsx70, hsp70 and hsc70 mRNAs to cerebellum and hippocampus from 3 control and 7 AD brains. Sections were counterstained with congo red to demonstrate AD pathology. All 3 probes showed a strong signal, highest for the hsc70 probe, in CA1-2, subiculum and entorhinal cortex of 6/7 AD hippocampi. These regions contained plaques and tangles. Grains were present in pyramidal neurons and were often associated with neurofibrillary tangles. No comparable reaction was present in either region of control brain or in AD cerebellum. Post-hybridization washing at high stringency (0.5 XSSC, 45°C) reduced but did not abolish signal. In 6/7 cases, signal intensity was markedly increased when sections were pretreated with ribonuclease. In contrast, a control 18S rRNA oligo showed normal cell-specific hybridization to each brain that was always completely eliminated by ribonuclease pretreatment. Further experiments will determine whether the anomalous reaction with the heat shock probes in affected regions of AD hippocampus is true hybridization and whether it has any mRNA-specificity. Supported by NIH grant AG08013 and by the Leland Fikes Foundation.

519.6

A DEVELOPMENTALLY EXPRESSED PROTEIN ISOLATED FROM NEONATAL RAT NEOCORTEX. M. Murtaugh, R. Maroko, J. Rabii, and M.W. Miller. Dept. of Anatomy, Univ. of Med. and Dent. N.J.-Sch. of Osteopathic Med. and R.W. Johnson Med. Sch., Piscataway NJ 08854, and Prog. in Physiol. and Neurobiol., Rutgers Univ., Piscataway NJ 08854.

Alz-50 is a monoclonal antibody which recognizes an antigen expressed in the cerebral cortices of patients with Alzheimer's Disease and Down's Syndrome and of normal human fetuses. An Alz-50-positive antigen is virtually absent from the cortices of normal human adults. A recent immunohistochemical study has shown that Alz-50 also identifies a population of cortical neurons in neonatal rats. We isolated the antigen recognized by Alz-50 in rat cortex using immunoaffinity column chromatography; the column was bound with Alz-50 and eluted with 3.0 M potassium isothio-cyanate. Unlike the Alzheimer's antigen (M.W. 68 kDa), the isolated rat protein had a molecular weight of about 50 kDa. This antigen was evident during the first postnatal week and its expression waned during the second postnatal week. Both the molecular weight of the neonatal antigen and the timing of its expression are reminiscent of rat juvenile tau. Funded by DE 07734 and AA 06916.

ANALYSIS OF GENE EXPRESSION IN ALZHEIMER'S DISEASE USING THE POLYMERASE CHAIN REACTION. T. Golde, M. Cohen* T. Cheung, S. Estus, C. Hopfer*, R. Kalaria, L. Younkin, and S. Younkin. Case Western Reserve University, Cleveland, OH 44106

To analyze the role of altered gene expression in the evolution of AD pathology, it is essential that methods be developed to analyze multiple mRNAs in the samples that can be obtained from discrete brain regions wherein pathology is well defined. In a previous study, we analyzed alternatively spliced ß amyloid protein precursor (ßAPP) mRNAS quantitatively by using the polymerase chain reaction to amplify ßAPP cDNAs produced by reverse transcription. Since this method appears to be well suited for the analysis of gene expression in AD, we have synthesized oligonucleotide primer pairs specific for ßAPP, ß-actin, cyclophillin, GFAP, alpha-1-antichymotrypsin, serum amyloid P, IL1-ß, MARCKS, and c-raf mRNAs. Using these primer pairs, we have amplified cDNAs specific for each mRNA from 1 µg or less of randomly primed reverse transcribed total RNA from AD or control brain, and we have confirmed by direct sequencing that these cDNAs do, in fact, correspond to the mRNAs targeted. Optimization of the amplification process has enabled us to simultaneously amplify up to 6 different cDNAs from 1 µg of RNA with minimal amplification of non-specific products. Moreover, by diluting randomly primed white matter cDNA, we find that the relative amounts of up to 5 different messages can be quantitated in a single PCR reaction as long as amplification is in the exponential phase and the messages are roughly equal in abundance. Furthermore, by comparing the relative amounts of 87 bp and 300 bp ß-actin cDNAs produced with appropriate primers, it is possible to evaluate the extent of degradation present in each postmortem RNA sample and to select, on the basis of the 87 bp / 300 bp ratio, samples in which degradation has minimal effect on the level of the mRNAs measured. We are currently using this method to analyze expression of many mRNAs in various regions of AD and control brains.

519.8

EPIDERMAL GROWTH FACTOR RECEPTOR EXPRESSION IN BRAIN, PITUITARY AND SKIN OF DEMENTED AND NONDEMENTED ELDERLY PATIENTS. S. D. Styren, E. J. Mufson, W. H. Civin and J. Rogers. L. J. Roberts Center, Institute for Biogerontology Research, Sun City AZ. 85351

Epidermal growth factor receptor (EGFR) is a 170KD integral membrane protein which contains a tyrosine kinase moiety capable of phosphorylating a variety of cellular proteins related to cellular proliferation. Stimulation of the tyrosine kinase can be accomplished by the binding of Vaccinia growth factor and transforming growth factor in addition to epidermal growth factor. We have previously reported the presence of EGFR on brain vascular endothelial cells in patients presenting with a variety of dementias, and the absence of EGFR immunoreactivity in neurologically normal or nondemented Parkinson's patients. In the present study we evaluated the distribution of pituitary (n=9), scalp (n=11), and abdominal skin (n=11) EGFR in nondemented (neurologically normal and Parkinson's disease) and demented patients (Alzheimer's, Parkinson's, multi-infarct, and Pick's dementias).

Vascular EGFR immunoreactivity in the pituitary is strongly correlated with dementia. Three of three demented patients exhibited strong pituitary vascular EGFR immunoreactivity, whereas 5 of 6 controls lacked EGFR expression. The one anomalous control patient had moderately high neuritic plaque and tangle pathology. EGFR immunoreactivity in scalp and abdominal skin is less consistently correlated with dementia than brain or pituitary EGFR. EGFR positive blood vessels were present in scalp in 8 of 12 demented patients, and in abdominal skin in 4 of 6 demented patients. Scalp (n=6) and abdominal skin (n=4) from nondemented controls lacked vascular EGFR immunoreactivity. These findings indicate that in demented patients the CNS may be a source of an EGFR inducing substance, or that vascular endothelial cells may have differential sensitivity to the inducing substance depending on their systemic location.

ISOFORMS OF RIBOSOMAL PROTEINS ASSOCIATED WITH ALZHEIMER'S DISEASE. J.Gotlib*, D.Vanderputten*, N.Khowong*, R. Poglod*, V. Haroutunian, L.Bierer, D.Perl, C.Merril, and W. Wallace Dept.Psychiatry and Center for Neurobiology, Mt. Sinai Med. School, New York and Lab. of Biochem. Genetics, NIMH, Washington, D.C.

We have shown previously that polysomes isolated from AD tissues exhibit reduced in vitro synthesis of proteins. Ribosomes were purified from control and AD polysomes and characterized to determine the mechanism responsible for this disruption. Control and AD ribosomes equally support translation of hemoglobin mRNA in the in vitro translation assay (69.2 ±17 vs. 76.4 ±44 X 10^6dpm 35S-met|A260 unit, n= 5). Likewise, the physical integrity of ribosomal RNA appeared similar by northern analysis of 18S rRNA. However, examination of ribosomal proteins by two dimension gels indicate three polypeptides that are consistently different in the AD ribosomes (50 kD,pI 7.8; 30 kD,pI 7.8; and 16 kD pI 8.2). These differences appear to be due to alterations in the predominance of isoforms of ribosomal proteins. Such alterations may represent differences in post-translational modifications of the proteins, such as protein phosphorylation. The altered proteins are currently being identified and their phosphate content, if any, measured.

NUCLEAR RUN-ON AS MEASURED IN NUCLEI FROM FROZEN BRAIN TISSUES: AN APPROACH TO MEASURING TRANSCRIPTION IN HUMAN BRAIN REGIONS. S.A. Johnson, S. Millar* and C.E. Finch. Andrus Gerontology Center and Dept. of Biol. Sci., Univ. So. Cal., Los Angeles, CA 90089.

Nuclear run-on analyses give in vitro measurements of relative transcription rates for individual genes. As shown in numerous other tissues, nuclear run-on can be used to monitor rapid transcriptional changes in response to various experimental stimuli. To study the effects of Alzheimer's disease on specific gene transcription, we have developed nuclear run-on transcription assays using nuclei isolated from**frozen** brain. Initial studies showed no difference in yield of nuclei per tissue mass, or amount of run-on transcript produced, between nuclei from fresh or frozen rat brain. Transcription was dependent upon added ribonucleotide triphosphates. Freezer storage time had no apparent effect upon the yield of nuclei or labeled run-on transcript produced. Nuclei isolated from frozen human post-mortem brain produced equivalent amounts of run-on transcript per isolated nucleus, as compared to fresh or frozen rat brain nuclei. Brain cell nuclei can be separated by sucrose gradient centrifugation into discrete fractions that containlarge vs small nuclei; large nuclei are thought to be of neuronal origin, while the fraction containing small nuclei represents glia and small neurons (Sarkander and Uthoff, FEBS Lett., 15, 53, 1976). Preliminary experiments show hybridization of run-on transcript to cDNAs for b-tubulin (neuronal and glia) and tyrosine hydroxylase (neuronal), but not for GFAP (astrocyte). The small nuclei transcript showed hybridization to GFAP cDNA. This now allows discrimination of neuronal and glial transcription rates in human brain. Supported by NIA AG07909 to C.E. Finch.

THE PROTEIN ENCODED BY pADHC9/SGP2 IS EXPRESSED IN ALZHEIMER'S DISEASE HIPPOCAMPUS AND IS ELEVATED IN THE RAT HIPPOCAMPUS FOLLOWING ENTORHINAL CORTEX LESION

M. Lampert-Etchells, P.C. May, N.J. Laping, S.K. Schrieber, C.E. Finch. Andrus Gerontology Center, University of Southern California, Los Angeles, CA 90089

Clone pADHC-9 encodes a 2 Kb RNA which is overexpressed in Alzheimer's disease (AD) hippocampus and is the human counterpart to rat testicular SGP2 (Jenne, D.E., Tschopp, J.,(1989) P.N.A.S. 86, 7123) Polyclonal antiserum was made to the human pADHC9/SGP2 protein to study the level of expression, the cellular distribution, and the function of this protein in Alzheimer and normal hippocampus. An XhoII fragment of pADHC9/SGP2 from nucleotide 921-1500 was inserted into the E. coli expression vector pATH-1. The fusion protein made from this vector was used to generate rabbit antibodies to pADHC9/SGP2 protein. Western blot analysis with the IgG fraction identified the expected 40kD reduced protein in human serum and identified a similar 40kD protein in human spinal fluid. In human Alzheimer and control hippocampus extracts this antiserum identified the 38kD reduced form of this protein along with its 55kD precursor. The pADHC9/SGP2 protein bands migrated as typical diffuse glycoprotein bands.

In the rat, entorhinal cortex lesion was used as a model for aspects of the hippocampal degeneration seen in AD. By northern blot analysis SGP2 mRNA was elevated in the hippocampus several fold by 2 days post lesion. It reached a peak at 6 days and decreased to normal levels by 14 days post lesion. The SGP2 protein at 4 days post lesion was also increased relative to the unlesioned contralateral hippocampus. We conclude that SGP2 mRNA and protein respond dynamically to brain lesions and give a new probe for molecular changes in AD. Supported by ADRDA IIRG-88-069 and NIH/NIA AG07909.

FRIDAY AM SYMPOSIA

521

SYMPOSIUM: GLIA: SYNTHESIS OF AND RESPONSES TO GROWTH FACTORS AND NEUROPEPTIDES. J.P.Schwartz, NINDS, NIH (Chairperson); D.E.Brenneman, NICHD, NIH; M.Dubois-Dalcq, NINDS, NIH; F.A.McMorris, Wistar Inst.; W.S.T.Griffin, Univ.Ark.Med.Sci.

Communication between neurons and glia can affect differentiation, mitosis and other processes: evidence will be presented that such communication can be mediated by both growth factors and neuropeptides. **D.E.Brenneman** will show that vasoactive intestinal peptide, a neuropeptide released from neurons, acts as a secretagogue for neurotrophic factors from glia. **J.P.Schwartz** will demonstrate developmental expression and regional specificity for neuropeptide synthesis by astrocytes. **M.Dubois-Dalcq** will compare effects of two growth factors, platelet-derived growth factor and basic fibroblast growth factor, on O-2A oligodendrocyte progenitor cells. **F.A.McMorris** will show that the insulin-like growth factors regulate three key steps in myelination by oligodendrocytes, with data from cell and organ cultures as well as transgenic mice. **W.S.T.Griffin** will show that the levels of interleukin-1, a microglia-derived astrocyte mitogen, and S100ß, an astrocyte-derived neurotrophic factor, are elevated in Alzheimer and Down syndrome brain.

522

SYMPOSIUM: PHYSIOLOGY OF PEPTIDERGIC NERVE TERMINALS IN THE VERTEBRATE NEUROHYPOPHYSIS.

C.W. Bourque *McGill University (chairperson)*, J.T. Russell *N.I.H.*, A.L. Obaid *U. Pennsylvania*, B.M. Salzberg *U. Pennsylvania*, M.C. Nowycky *Med. Col. of Pennsylvania*, J.R. Lemos *Worcester Fndn. Exptl. Biol.*

The hypothalamo-neurohypophysial system of vertebrates consists of the hypothalamic somata of magnocellular neurons synthesizing either oxytocin or vasopressin and their axonal projection to the posterior pituitary. Because of their relatively large size (several µm) and compartmentalization, neurohypophysial terminals have become a classic preparation to examine the physiology of peptide secreting terminals. This symposium will highlight a number of convergent advances in understanding the mechanisms that modulate the coupling between axonal firing, nerve terminal excitation and secretion from this neuroendocrine system. Russell will review the effects of activity patterns on neuropeptide secretion from the neurohypophysis, and describe the modulation of intraterminal [Ca^{2+}] signals in isolated terminals. Bourque will relate the activity-dependence of spike invasion and excitation of nerve terminals to the effects of firing patterns on peptide secretion. The mechanisms of Ca^{2+} influx in the intact terminals of the neurohypophysis as probed with potentiometric dyes will be described by Obaid. Salzberg will describe changes in light scattering consequent to nerve terminal excitation and detail their relation to excitation-secretion coupling. Nowycky will describe patch clamp studies of neurohypophysial Ca channels in isolated terminals and discuss their role in exocytosis as studied with capacitance measurement techniques. Finally, Lemos will characterize ion channels in isolated terminals and neurosecretory granules, and comment on their possible role in the control of peptide secretion.

SENSORY SYSTEMS—VISUAL CORTEX: INTRACORTICAL INTERACTIONS

523.1

INTER-AREAL AND INTER-HEMISPHERIC SYNCHRONIZATION OF OSCILLATORY RESPONSES IN CAT VISUAL CORTEX.

A.K. Engel*, P. König*, A.K. Kreiter* and W. Singer. Max-Planck-Institut für Hirnforschung, Deutschordenstr.46, 6000 Frankfurt 71, F.R.G.

We have previously demonstrated that oscillatory responses can synchronize across orientation columns in area 17 of cat visual cortex. We proposed that this synchronization may provide a temporal coding mechanism for scene segmentation. This hypothesis predicts that 1. similar oscillations should occur in other visual areas, 2. there should be evidence for inter-areal synchronization and 3. inter-hemispheric synchronization should be observed. To test these predictions, we made simultaneous recordings of multi-unit activity from area 17 and PMLS in 4 adult cats. In 3 additional cats, we recorded simultaneously from area 17 of either hemisphere. The oscillatory nature of the responses and the strength of synchronization were quantified by computation of auto- and cross-correlograms. We obtained the following results: 1. More than 70% of the PMLS recordings displayed an oscillatory modulation in the frequency range of 40-60Hz. 2. In more than half of the cases tested, we observed a response synchronization between area 17 and PMLS. 3. The inter-areal response synchronization depends on the overlap of the receptive fields, but not on differences in orientation preferences. 4. The 17-PMLS interaction is sensitive to global stimulus features, such as continuity of contours and coherence of motion. 5. In 70% of the cases where we recorded simultaneously from area 17 of both hemispheres, we observed a response synchronization. The interactions are in strength comparable to those within area 17. 6. We observed phase-locking also between cells with non-overlapping fields and dissimilar orientation preferences. Our results support the hypothesis that oscillations in the range of 40-60Hz may be a general phenomenon in cat visual cortex and that response synchronization can involve cells located in different hemispheres or visual areas. The inter-areal synchronization may serve for the binding of different feature maps. The inter-hemispheric interactions may provide a mechanism to link features of objects extending across the vertical meridian.

523.2

SQUINT AFFECTS OCCURRENCE AND SYNCHRONIZATION OF OSCILLATORY RESPONSES IN CAT VISUAL CORTEX.

Peter König*, Andreas K. Engel*, Siegrid Löwel* and Wolf Singer. Max-Plank-Institut für Hirnforschung, Deutschordenstr. 46, 6000 Frankfurt 71, F. R. G.

We could recently demonstrate that neurons in cat visual cortex display responses with an oscillatory temporal structure in the range of 40-60Hz which can synchronize over distances of 7mm in area 17. This synchronization may serve to establish relations between features in different parts of the visual field. We have now investigated occurence and synchronization of oscillatory responses in area 17 of strabismic cats. We wondered whether in these animals response synchronization primarily occurs between cells of similar ocular dominance (OD).

We recorded multi-unit activity (MUA) to appropriately oriented moving light bars simultaneously from 4-6 spatially separate sites in cortical area 17. We used 4 adult cats in which divergent strabismus had been surgically induced at the age of 3 weeks. To determine the temporal relationship of the firing patterns, we computed auto- and crosscorrelation functions of the spike trains.

Analysis of 112 recording sites gave the following results: 1) 87% of the responses were monocular or strongly dominated by one eye. 2) The occurrence of oscillatory responses was with 63% as frequent as in normal cats, but response rhythmicity was much weaker. 3) Only 30% of the 115 pairs of MUA recordings showed a response synchronization versus 59% for overlapping receptive fields in normal cats. 4) Response synchronization occurred primarily between cells with the same OD and less frequently between cells with different OD.

Our data support the hypothesis that the functional organization of area 17 is profoundly altered in strabismic cats. The weak oscillatory activity might reflect disturbed integrative capacities in the visual cortex of squinting animals. The preferential synchronization between neurons driven by the same eye suggests that cells with different OD become functionally independent, which implies not only changes in thalamo-cortical but also in cortico-cortical connectivity.

523.3

Temporal Dynamics of Oscillatory Neuronal Interactions in Cat Visual Cortex. Charles M. Gray, Andreas K. Engel*, Peter Koenig* and Wolf Singer, Max-Planck-Institute for Brain Research, 6000 Frankfurt/M 71, F.R.G.

Previously we have demonstrated that a subpopulation of visual cortical neurons exhibit oscillatory responses to their preferred stimuli at a frequency near 50 Hz (Gray and Singer,PNAS,1989). These responses can selectively synchronize over widespread areas of cortex in a stimulus-specific manner (Gray,et al.,Nature,1989). Here we report the results of a new analysis which reveals the fine temporal structure inherent in these interactions. We utilized pairs of recordings of the local field potential (LFP) activity from area 17 in the cat which met two criteria: The LFP was correlated with the underlying unit activity at each site and the recording sites were at least 5 mm apart in cortex. A moving window technique was applied to compute time-lagged cross-correlograms on 100 msec epochs of data repeated at intervals of 30 msec for a period of 3 sec during each direction of stimulus movement. And a statistical test was devised to determine the significance of detected correlations. In this way we were able to determine the magnitude, phase-lag, frequency and duration of correlation events as well as an estimate of the time needed to achieve phase-locking. The results demonstrate that 1) synchrony can be established within 1-2 cycles of oscillation, 2) the duration of synchrony is variable and lasts from 50-500 msec, 3) the phase and frequency of synchronized events is also variable within and between events and ranges from +- 3 msec and 40-60 Hz, respectively, 4) multiple correlation events can occur within a single stimulus period. These results demonstrate a high degree of dynamic variability among interacting populations of neurons which is consistent with the requirements of a mechanism for feature integration.

523.4

ORIGINS OF OSCILLATORY ACTIVITY IN THE CAT'S VISUAL CORTEX. G.M. Ghose*, R.D. Freeman. Biophysics and Neurobiology Groups, Univ. of Calif., Berkeley, CA 94720.

The activity of neurons in the visual cortex, generally studied by spike activity or gross potentials, has been reported to exhibit oscillatory firing patterns. We have analyzed spike trains of cortical neurons and lateral geniculate fibers in the visual cortex of the cat under different types of visual stimulation in order to ascertain the nature and origin of these oscillations.

Two types of visual stimuli were presented for extended periods of time to determine the stability and stimulus dependence of oscillatory firing. The first type consists of large drifting gratings of sinusoidal intensity at optimal orientations and spatial frequencies. The second type of stimuli consists of random sequences of small optimally oriented bright and dark bars flashed for 50 ms. at different locations within and around the receptive fields. For both stimuli power spectra of extracellularly recorded action potentials are computed to provide quantitative assessments of the degree of oscillatory firing.

Oscillatory firing, as exhibited by a peak above noise at around 50 Hz in the power spectrum, is observed in 35% of the cortical cells and LGN fibers studied by grating stimulation. The oscillations of several LGN fibers are among the strongest found. Oscillations are generally highly variable over a period of seconds in both frequency and magnitude. Moreover, the relative magnitude of this oscillatory firing is sometimes inversely related to firing rate. These findings suggest that such oscillations are at least in part due to intrinsic spontaneous firing properties. Oscillations do not depend on the presence of large coherent stimuli, since 30% of the cells studied with small bars also fire rhythmically at around 50 Hz. In conjunction with previous studies in the LGN and retina, these results support the notion of a subcortical, rather than intracortical, origin of oscillatory firing. (EY01175)

523.5

MODULATION OF CLASSICAL RECEPTIVE FIELD RESPONSES BY MOVING TEXTURE BACKGROUNDS IN MONKEY STRIATE CORTEX: SPATIAL AND TEMPORAL INTERACTIONS. J.M. Fox, T. Delbruck*, J.L. Gallant, C.H. Anderson*, and D.C. Van Essen. Div. of Biology 216-76, Caltech, Pasadena, CA 91125.

We have examined the effect of texture patterns moving outside the classical receptive field (CRF) on the spatial sensitivity profile of single units in striate cortex (V1) of anesthetized macaque monkeys. Our stimuli consisted of a target and a moving background. The target was an optimally oriented line segment flashed at different locations along an axis orthogonal to the preferred orientation within the CRF, and in different phases relative to the background motion. The background was a random dot pattern lying entirely outside the CRF and oscillating at a temporal frequency of 2Hz along this axis. Responses were compared for 3 to 5 positions of the flashed target, and across 4 phases of the background motion. We also examined responses to targets flashed in the absence of a background, and to moving backgrounds alone.

In the 35 cells subjected to detailed analysis thus far, we found that approximately half (17/35) showed a significant modulation of the responses to the target by the moving background. The background caused enhanced responses to the target in some instances and suppression in others; the magnitude of the effect was two-fold or more in some cells. In the majority of cells the background produced enhancement or suppression only within a subset of the spatial locations and phase conditions tested. In a minority of cells there was a differential effect, such that targets presented at a particular phase were enhanced at one target location and suppressed at another. These observations suggest that complex spatio-temporal interactions between target and background occur in V1.

523.6

SPATIAL ORGANIZATION OF SUPPRESSIVE SURROUND EFFECTS IN NEURONS OF AREA V1 IN ALERT MACAQUES. J. J. Knierim and D. C. Van Essen. Caltech, Division of Biology 216-76, Pasadena, CA 91125.

In a majority of neurons in V1, responses to a line segment within the classical receptive field (CRF) are suppressed by a texture pattern lying entirely outside the CRF. We studied the spatial organization of these surround effects by presenting texture surrounds to the quadrants along the flanks of the CRF and separately to the quadrants at the ends of the CRF. The orientation of the line segments in the surround was made either identical to that in the CRF (uniform orientation) or orthogonal to it (orientation contrast), since we have previously shown that orientation contrast reduces the suppressive effect in many cells (Knierim & Van Essen, *Soc. Neurosci. Abstr.*, 1989).

For the sample of 122 cells tested, both the flank quadrants and the end quadrants suppressed the response by an average of 25%, which was smaller than the 35% suppression induced by the full surround. Thus, the surround effects are spatially distributed and not exclusively attributable to end-stopping or to side-band suppression. In each case, the suppression induced by the uniform orientation surround was about 9% greater than that induced by the orientation contrast surround. However, we did encounter a spatial asymmetry for the subset of 39 cells that showed a significantly greater response to orientation contrast than to uniform orientation on the full-field tests. In these cells, for the end quadrants, the uniform orientation surround suppressed the response 17% more than the orientation contrast surround, whereas for the flank quadrants, the difference in suppression was 9%. Thus, the orientation contrast effect originates from both the end zones and the flanks, but more strongly from the former.

We also recorded responses to a full-field texture in which the surrounding line segments were randomly oriented. This stimulus is similar to the uniform orientation surround in that there is no orientation contrast between the line segment in the CRF and those outside. Of the 50 cells tested, 9 responded more strongly to the orientation contrast texture than to the random orientation texture, whereas only 3 responded in the opposite fashion. These differences were comparable to those for the uniform orientation comparison. Thus, the differential effects depend on the overall presence or lack of orientation contrast, rather than on the presence of a uniform orientation surround.

523.7

SINGLE UNIT AND 2-DEOXYGLUCOSE STUDIES OF MULTI-CYCLE INHIBITION IN MACAQUE STRIATE CORTEX. R.T. Born and R.B.H. Tootell, Dept. of Neurobiol., Harvard Medical School, Boston, MA.

In the course of single unit studies to map spatial frequency tuning in supragranular striate cortex of the macaque monkey, we discovered that a large population of neurons in the interblob regions responded poorly or not at all to extended gratings, but gave vigorous responses to single bars or edges. To characterize this property we have recorded from 93 single units in the interblobs of layers 2 and 3 in striate cortex of the anesthetized, paralyzed macaque.

In these cells, gratings became effective stimuli only when they were spatially delimited from the sides so that the grating had fewer cycles. This property, which we call multi-cycle inhibition, was present in 65 (70%) of the neurons we studied. It was independent of and more common than end-stopping (27%). Thirty-three cells studied quantitatively gave a maximal response to 1.3 +/- 0.6 (mean +/- sd) grating cycles and a half-maximal response to 3.5 +/- 1.7 grating cycles. In a few cells tested with separate center and surround grating patches, the inhibition occured only when the orientation of the surround grating was similar to that of the center.

In 2 animals, 2-deoxyglucose was used to compare brain activation produced by a sine-wave grating vs. a rectangular grating (same white bar width but 60% fewer bars), in retinotopically discrete regions. As one would expect from the single unit evidence, interblob cells in layers 2 and 3 of striate cortex had higher uptake when stimulated by the rectangular grating. In other layers, uptake produced by the two stimuli was equal (5 and 6) or greater for the sine-wave grating (4C). Subsequent single unit studies have shown that the 2-deoxyglucose result in not due to low-pass modulation transfer functions of the interblob cells.

Multi-cycle inhibition is a short-range spatial antagonism between contrasts of like orientation. We think of these cells as "contour-pass filters" that may help to discriminate highly redundant, texture-like regions of a visual scene from contours representing object boundaries. Supported by grants NIMH 14275 and EY 07980.

523.8

GABA-INDUCED LOCAL INACTIVATION AND CROSS-ORIENTATION INHIBITION IN AREA 18 OF THE FELINE VISUAL CORTEX.
J.M. Crook and U.T. Eysel. Department of Neurophysiology, Faculty of Medicine, Ruhr-Universität Bochum, D-4630 Bochum, F.R.G.

We investigated the influence of iontophoresis of GABA through four pipettes, each located at a horizontal distance of some 500–600μm from the recording site, on the orientation tuning of 74 cells in area 18 of cat visual cortex. Sixty-one percent showed significant broadening of orientation tuning during GABA iontophoresis, with a 79% increase in mean tuning width. The results were quantitatively similar to those from comparable experiments in area 17 (Crook et al., *Eur. J. Neurosci.* 2:259, 1989; Eysel et al., *Soc. Neurosci. Abstr.* 15:324, 1989). Since the tangential distance between recording and inactivation sites was approximately half that required for a complete sequence of preferred orientations, we interpret the results in terms of a loss of 'cross-orientation' inhibition during GABA iontophoresis.

To provide more direct evidence on this point, we have more recently determined the orientation and directional specificity, ocular dominance and receptive field limits of single and multi-unit activity at the inactivation sites, before applying GABA. Depending on the orientation preference at each inactivation site, GABA was applied either simultaneously through all four pipettes or selectively through one or a number of pipettes. The initial results from these experiments support our original conclusion that inhibition between cells with overlapping receptive fields and dissimilar preferred orientations enhances the orientation selectivity of cells in cat visual cortex.

523.9

RELATIONSHIP BETWEEN EXCITATORY AND INHIBITORY LONG RANGE CONNECTIONS IN THE CAT VISUAL CORTEX. Z.F. Kisvárday and U.T. Eysel. Dept. Neurophysiology, Ruhr-University Bochum, Pf. 102148, D-4630 Bochum 1, FRG.

To study long range intracortical connections the neuronal tracer biocytin was focally injected into areas 17 or 18 after recordings at several sites. The labelling was analyzed in horizontal sections. Labelled cells and axons with Golgi-like appearance were found in distinct patches 0.8-3.5mm from the injection site. Axons and dendrites of identified cells were reconstructed, and their distribution compared between labelled patches.

Most frequently, pyramidal and spiny stellate cells, but occasionally smooth dendritic cells of the large basket cell types were encountered in layers 2-5. Axons of long range pyramidal and spiny stellate cells terminated predominantly in 3-6 distinct patches providing similar feed-back connections to the same and other labelled patches. In contrast, basket cells with comparable axonal extent did not form patches, but instead arborized in large horizontal slabs terminating primarily outside the area covered by the axons of other labelled spiny cells.

We conclude that some of the long range reciprocal connections allow integration of information over a greater area of the visual field than that covered by their classical receptive field. GABAergic large basket cells could enhance the specificity of these interactions by inhibiting populations of cells outside these patches.

523.10

EXTRINSIC AND INTRINSIC INHIBITORY CONNECTIONS IN RAT VISUAL CORTEX. C.T.McDonald and A.Burkhalter. Dept. of Neurosurgery and McDonnell Center for Higher Brain Function, Washington Univ. Sch. of Med. St.Louis, MO 63110.

Intrinsic long-distance interactions and feedback inputs from higher cortical areas are two mechanisms proposed to account for some of the receptive field properties seen in primary visual cortex (area 17). We have examined whether inhibitory neurons participate in such circuits by combining retrograde labeling and immunocytochemistry with a monoclonal antibody to glutamic acid decarboxylase (Chang and Gottlieb, J.Neurosci. 8:2123, 1988).

Following injection of fluorescent latex microspheres into area 17, double labeled GABAergic neurons can be identified in flat mount sections several millimeters lateral to the injection site in the extrastriate visual area 18a. In parasagittal sections through area 17, local inhibitory neurons are seen in layers 1-6 within 0.3mm of the injection tract. However, a second population of double labeled cells with much more extensive collateral arbors are seen at the layer 5/6 border up to 1mm from the injection site. Occasionally, cells with a simlar distribution are also encountered in layer 2/3.

These results suggest that neurons in primary visual cortex are under direct inhibitory feedback control from specific higher visual areas. They also suggest that direct, inhibitory, long-range connections do exist in rat primary visual cortex and that they are mediated by neurons with a unique laminar distribution.

Supported by grant NIH EY05935.

523.11

ORGANIZATION OF EXCITATORY LOCAL AXON COLLATERALS WITHIN RAT VISUAL CORTEX. R.R.Johnson and A.Burkhalter. Dept. of Neurosurgery and McDonnell Center for Higher Brain Function, Washington Univ. Sch. of Med., St. Louis, MO 63110.

Amino acid mediated excitatory neurotransmission plays an important role in the plasticity of intracortical circuits in developing and adult animals. To identify the cells which participate in these processes and to study the organization of their axon collaterals we have used retrograde tracing with D-^{3}H-aspartate in rat primary visual cortex.

Injections into superficial and middle layers labeled cells in layers 2-6 in a stereotypical horizontal and sublaminar distribution pattern. The projections within layer 3 and from the top and the bottom of layer 5 were much wider (0.75-1.5mm) than those from layers 4 and 6 which were contained within a ~0.5mm wide column. Typically, labeling in layer 2 and the corticotectal output zone in the middle of layer 5 was sparse. Alternatively, injections into deep layers produced a different labeling pattern and revealed long-range connections (~1mm) within the bottom of layer 5 and the top of layer 6. The projections from layers 2-4 and the corticogeniculate output zone in the lower half of layer 6 were narrow (<0.5mm) and topographically precise. Interestingly, cells at the grey/white matter border in layer 6 which are known to project widely throughout all layers were always confined to a small region below the injection site. These results suggest that we have selectively labeled glutamatergic/aspartergic neurons and that they participate in specific circuits which mediate short and long-range interactions.

523.12

INTERACTIONS AND STIMULUS-DEPENDENT CHANGES OF SYNAPTIC POTENTIALS EVOKED BY ACTIVATING INTERLAMINAR AND HORIZONTAL PATHWAYS IN THE CAT'S STRIATE CORTEX.

J.A. Hirsch and C.D. Gilbert. Laboratory of Neurobiology, The Rockefeller University, New York, NY 10021.

Interlaminar and long-range horizontal pathways converge on single cells in the cat's primary visual cortex. To gauge the effects and interactions of these two sources of input on their target neurons, we made intracellular recordings from layer 2+3 in slices of area 17. Pyramidal cells, identified by injection of biocytin, responded to electrical shocks delivered both to layer 4, in vertical alignment with the recording electrode, and to those applied at a horizontal distance of $\geq$1 mm in layer 2+3. Responses from each site appeared to arise largely through separate circuits since fatigue of one by tetanization rarely influenced the other. Moreover, simultaneous activation of interlaminar and horizontal paths produced summation.

Long-lasting changes in synaptic responses could be produced by repetitively pairing EPSPs activated from one or the other site with the injection of suprathreshold pulses of depolarizing current. Following conditioning with 10 to 50 pairs presented at frequencies of 2-5 Hz, facilitation of the paired response was observed for up to 2.5 hours. For some cells, after facilitating one of the two paths, the second could be conditioned and strengthened as well. The enhancement was most pronounced in polysynaptic EPSPs and was greatly reduced by blocking NMDA receptors. We are currently exploring whether facilitation of one pathway can alter the efficacy of the other. (Supported by NIH grant NS22789 and NSF grant BNS8918951)

524.1

SPECIFICATION OF RETINAL CELL PHENOTYPES: EVIDENCE FOR A DEFAULT PATHWAY OF PHOTORECEPTOR DIFFERENTIATION. **A. Repka*, and R. Adler. Wilmer Institute, Johns Hopkins Univ. Sch. of Med., Baltimore, MD. 21205.**

Previous studies led us to hypothesize that retinal precursor cells remain plastic after terminal mitosis. Unless induced to develop as neurons by intraretinal signals, cells will follow a photoreceptor "default pathway" (*Science*, 243:391-393, 1989). This hypothesis predicts that precursor cells that undergo terminal mitosis *in vitro*, and therefore differentiate in the absence of intraretinal signals, should give rise predominantly to photoreceptors. We tested this prediction by *in vitro* labeling of dividing precursor cells dissociated from embryonic day (ED)5-8 chick retinas, using ^{3}H-thymidine or BUDR. Their fate was determined by phase contrast microscopy, opsin immunocytochemistry and sequential photography. Labeling indices were highest during the first day *in vitro*, with cells becoming postmitotic on *in vitro* days 2-3. In all cases, 80-95% of the differentiated cells "born" *in vitro* showed a photoreceptor phenotype, regardless of the phenotypes of neighboring cells that were already postmitotic at the time of their isolation for culture. These observations are consistent with and add support to the photoreceptor default pathway hypothesis.

524.2

A RETINAL ANTIGEN WITH ALTERED STAINING PATTERN DURING METAMORPHOSIS IS ALSO EXPRESSED BY NEURAL CREST. S. Hoskins and G. Kirchbaumer.* Department of Biology, City College of New York, NY, NY 10031.

Using immunosupression methods, we generated IPS6, an antibody whose expression appears to be developmentally modulated during both metamorphosis and embryogenesis in *X. laevis*. In premetamorphic retinas, IPS6 stains pigment epithelium, photoreceptor outer segments throughout the retina, and the peripheral germinal zone, which contains retinal stem cells. During metamorphosis, staining is lost from central retina, becoming restricted to the pigment epithelium and the peripheral stem cells. This change in staining pattern correlates temporally with metamorphosis, but appears to be independent of thyroid hormone. Blocking metamorphosis does not prevent the loss of immunoreactivity in central retina, nor does intraocular injection of thyroxine accelerate the change in staining pattern.

Although IPS6 was raised against retina from young postmetamorphic frogs, it also stains the eye rudiment, ectoderm overlying the eye, and neural crest of embryos. Both neural crest and the retinal germinal zone are stem cell populations, and in each, individual precursors may give rise to pigment cells as well as to neurons. Work in progress is aimed at determining why immunoreactivity is lost from central retina, and the significance of IPS6 co-expression by precursor cells of both the central and peripheral nervous system.

NEURONAL LINEAGE AND DETERMINATION IN THE CHICK RETINA USING RETROVIRUSES AND CELL TRANSPLANTS. D.M. Fekete, E.F. Ryder, A.W. Stoker*# and C.L. Cepko. Harvard Medical School, Boston, MA 02115 and #Lawrence Berkeley Lab., Berkeley, CA 94720.

Clonal analyses in the retinas of rodents and frogs have shown that different cell types can arise from a common progenitor. This has led to the suggestion that cell fates are determined by environmental cues rather than by lineage. In retinas with protracted development, these cues are presumed to change over time since clonal size and composition vary as the retina develops. To test this hypothesis we are studying cell fates after heterochronic transplantation of progenitors in the chick, where the eye is accessible to manipulation at all stages of development.

For transplantation, donor embryos are infected at embryonic day 2 (E2) with a replication-competent retrovirus which allows the virus to spread throughout the embryo. At E6, labelled retinal cells are dissociated and injected into an E3 host chick which is resistant to infection by the marker virus. Isochronic transplants (E6 to E6) are used as controls. Retinas are harvested at E14-16 and transplanted cells are detected in whole mounts using antibody to viral *gag* protein. Results show that clones generated after heterochronic transplants (E6 to E3) are considerably larger than those derived from isochronic transplants.

We are comparing these data with *in situ* lineage analysis of normal retinas. Progenitors are labelled by co-infection with two replication-incompetent retroviruses encoding distinguishable markers. Analysis at E14-16 shows that average clone size is much larger after infection at E3 versus E6.

In conclusion, we have developed a new transplantation protocol that does not suffer from limitations due to interspecies differences and should be of general use throughout the CNS. Using this method in the retina, we have generated data suggesting that the environment can influence the proliferation potential of progenitors.

STABLE CELL LINES SHOWING NEURONAL PHENOTYPES ESTABLISHED FROM THE MURINE TELENCEPHALON BY TARGETED RETROVIRAL TRANSFORMATION.

Jerold J.M. Chun and Rudolf Jaenisch* Whitehead Institute for Biomedical Research, Nine Cambridge Center, Cambridge, MA 02142

The mammalian CNS exhibits a formidable degree of complexity that makes many molecular biologic issues related to development (e.g. gene expression and function) difficult to approach. The multitude of different cell types at different stages of development is an example of this complexity. In particular, the vast assortment of different neurons - themselves intermixed with non-neuronal cells - makes the study of a homogeneous neuronal population in isolation difficult. Cell lines from different parts of the developing CNS and showing neuronal (rather than mixed non-neuronal) phenotypes could provide a useful reagent to studies of gene expression and function.

We have developed a strategy that appears to target mitotic neuroblasts in the CNS. Since retroviruses require a round of mitosis for proviral integration, and since the "birthdates" of neurons in the cerebral cortex are known, mitotic cells in the ventricular zone could be infected with oncogene-containing retroviruses (similar to lineage studies using LacZ). The results of this approach produced immortalized colonies of neuron-like cells that could not be passaged. Isolation of such colonies followed by reinfection with a different oncogene-containing retrovirus produced rapidly growing transformed cells. Over 30 lines were established by colony expansion (colony selection based on morphology). Four lines were examined in more detail and express all three neurofilaments (200kd, 150kd by Western blot; 68kd by Northern blot; GFAP absent by Northern). Transfection with the 68kd neurofilament promoter driving LacZ or CAT produces expression in the cell lines but not in 3T3 cells. Electron microscopy reveals axon-like processes that appear to contain neurofilaments. Molecular studies using these lines as a tool are in progress.

We thank Drs. S. Lewis and N. Cowan for the gift of promoter NF68. Supported by NIH (R.J.) and the Helen Hay Whitney Foundation (J.J.M.C.).

LAMINAR COMMITMENT OCCURS PRIOR TO MIGRATION IN THE DEVELOPING CEREBRAL CORTEX. S.K. McConnell and C.E. Kaznowski*, Dept. of Biological Sciences, Stanford University, Stanford, CA 94305.

The nervous system is populated by an astonishing variety of neurons, differing in their connections, morphologies, and locations. We are studying the generation of this phenotypic diversity in the mammalian cerebral cortex. Each cortical layer contains neurons with similar morphologies, axonal connections, and birthdays. The relationship between cell birthday and adult fate has suggested that newly postmitotic neurons may already be committed to sitting in a certain layer and forming specific axonal projections at the time of their final mitotic division. We are using heterochronic transplantation techniques in ferrets to determine the time at which embryonic neurons become committed to their normal deep-layer fates. Neurons normally destined for layers 5/6 are labeled with [^{3}H]thymidine during S-phase and removed at various times after the pulse. These cells are then transplanted into older host brains, in which upper-layer neurons are being generated; many transplanted neurons migrate into the foreign cortical plate. Our experiments show that young cortical neurons become committed to their normal laminar fates by the time of their terminal mitotic division. If cells are transplanted shortly after [^{3}H]thymidine labeling, when many cells are still in S-phase, transplanted neurons migrate to both the deep and upper layers; thus they represent a mixture of committed and multipotent cells. However, when cells are transplanted 24 hours after labeling, to allow all cells to go through their terminal division in the donor environment, transplanted neurons adopt positions exclusively in the deep layers of the host cortex. Thus, shortly after their final division, all the neurons that migrate display a commitment to their normal fate. We hope to pinpoint the time that commitment occurs by comparing transplant results at different intervals to the dynamics of the cell cycle in the embryonic cortex.

This evidence is consistent with the notion that neuronal progenitors are multipotent, and can be influenced by environmental cues at the time of mitosis to produce a variety of neuronal phenotypes. However, by the time of their final mitosis in the ventricular zone, their progeny become committed to adopting a particular laminar position within the cortex. Laminar commitment thus occurs prior to neuronal migration into the developing cortical layers. (Supported by grants from NIH, Pew Scholars, Searle Scholars, and Clare Boothe Luce Foundation.)

SEPARATE PROGENITOR CELLS GIVE RISE TO NEURONS, ASTROCYTES AND OLIGODENDROCYTES IN THE RAT CEREBRAL CORTEX J.A. Barfield*[1,2], J.G. Parnavelas[3] and M.B. Luskin[1,2]. Depts. of Anatomy & Cell Biology[1] and Pediatrics[2], Emory Univ. Sch. of Med., Atlanta, GA 30322 and Dept. of Anatomy & Developmental Biology[3], University College London, London WC1E 6BT, U.K.

We have undertaken a study to identify the ultrastructural phenotype of individual cells composing a clone in the rat cerebral cortex using a recombinant retrovirus containing the gene for E. coli ß-galactosidase (*LacZ*) as a lineage tracer. In order to introduce the retroviral marker into precursor cells of the telencephalic ventricular zone, from which all the neurons and macroglia of the cortex originate, recombinant retrovirus was injected into the lateral ventricles of rat embryos on the 15th and 16th days of gestation (corresponding to the onset of neurogenesis). Vibratome sections of adult cortex were incubated with X-Gal to reveal LacZ(+) cells histochemically and processed for electron microscopy. Camera lucida drawings were made to document the position and morphology of LacZ(+) cells and to reconstruct clones. However, we relied on well-established ultrastructural criteria for definitive cell-type determination of serially sectioned LacZ(+) cells; the blue reaction product observed in cells with light microscopy is electron dense under the electron microscope.

When we considered discrete groups of LacZ(+) cells to be clonally related, that is, derived from a single precursor, virtually all of the clones examined contained cells of a single phenotype; they were composed of all neurons, all astrocytes or all oligodendrocytes. Some clones of astrocytes we encountered occurred entirely in the gray matter or white matter, while others extended across both zones. In conclusion, our results provide evidence that the lineages for cortical neurons, astrocytes and oligodendrocytes have diverged by the onset of neurogenesis.

LINEAGE RELATIONSHIPS OF PYRAMIDAL AND NONPYRAMIDAL NEURONS IN THE RAT CEREBRAL CORTEX. J.G.Parnavelas[1], J.A.Barfield*[2] and M.B.Luskin[2]. [1]Dept.Anatomy, Univ. College London, U.K., & [2]Depts. of Anatomy & Cell Biol. and Pediatrics, Emory Univ., Sch. Med., Atlanta, GA.

In our previous abstract (Barfield et al., 1990) we provided ultrastructural evidence that neuronal and glial lineages in the rat cerebral cortex diverge by embryonic day 15(E15). Here we sought to investigate whether the two principal classes of cortical neurons, the pyramidal and nonpyramidal cells, originate from a common precursor cell. For this purpose, recombinant retrovirus containing the gene for E.coli β-galactosidase (*LacZ*) was injected into the telencephalic ventricles of rat embryos on E15 or E16. Vibratome sections of adult cortex were histochemically stained for LacZ and processed for electron microscopy. The positions of β-Gal(+) cells were mapped to determine in reconstructions which neurons constitute a clone. Clonally related β-Gal(+) neurons were serially sectioned and examined with the electron microscope to ascertain their morphological phenotype.

We used nuclear, cytoplasmic and synaptic features to classify cells; pyramidal neurons have exclusively symmetrical axosomatic synapses, while nonpyramidal cells have both symmetrical and asymmetrical synapses. The clones encountered contained 2-8 neurons and, with one exception, were composed of either all pyramidal or all nonpyramidal neurons. These observations suggest that pyramidal and nonpyramidal neurons are derived from different precursor cells in the ventricular zone.

ABSENCE OF PERINEURIAL SHEATH AND ASSOCIATED CELLS IN TWIST, A MESODERMLESS MUTANT OF Drosophila melanogaster. J.S. Edwards, L.S. Swales* and C.M. Bate*. Zoology Dept., Cambridge Univ., Cambridge, UK CB2 3EJ.

Both the extracellular neural lamella, which sheaths the CNS, and its underlying cell layer, the perineurium, fail to develop in Drosophila embryos which are homozygous for a mutation in the gene twist (twi^{1d96}/twi^{1d96}). In contrast, the perineurial bracelet cells which underlie the perineurium and which constitute the permeability barrier, appear normal at the ultrastructural level, as do neurons and neuropile glia.

Twist function is required for gastrulation. In loss of function mutants mesodermal cells fail to segregate and all structures of mesodermal origin are thus absent (Nüsslein-Volhard et al., 1984).

The apparent derivation of perineurial sheath cells (perineurium), from mesodermal precursors distinguishes them from neurons and other non-neuronal components of the CNS, all of which are ectodermal in origin. This finding supports the exclusion of the perineurium from the major categories of glia, as proposed by Strausfeld (1976) on anatomical grounds.

PROPERTIES OF THE SERUM GLYCOPROTEIN(S) THAT INDUCE RAT CEREBRAL TYPE 2 ASTROGLIA FROM BIPOTENTIAL GLIAL PROGENITORS. S.W. Levison and K.D. McCarthy. Curriculum in Neurobiology and Department of Pharmacology. The University of North Carolina at Chapel Hill, Chapel Hill, North Carolina 27599.

Bipotential glial precursors known as O-2A progenitors become type 2 astroglia rather than oligodendroglia when cultured in fetal bovine serum (FBS) supplemented medium. We have characterized and partially purified an astroglia inducing molecule (AIM) from FBS. An ELISA for glial fibrillary acidic protein (GFAP) and double label immunofluorescence for GFAP and the cell markers A2B5 and ganglioside GD_3 were used to assess AIM's effects on process-bearing cerebral glia. A 200 fold enriched AIM preparation was prepared by precipitating AIM from FBS with 45% ammonium sulfate followed by sequential chromatography on heparin agarose, lentil lectin, and a Superose 12 FPLC sizing column. AIM has a minimum molecular mass of 50 kDa based on gel filtration; however, we have also observed 100 kDa and 440 kDa forms. It is possible that these higher molecular mass AIMs are aggregates of the 50 kDa form since aggregation is observed after exposure to low pH. Alternatively, multiple AIMs may exist. AIM does not appear to be a heparin binding growth factor (HBGF) since it has a higher molecular mass and a lower affinity to heparin agarose than other HBGFs, and its activity is not potentiated by heparin. AIM appears to have an isoelectric point greater than pH 9; however, proteins with a PI near pH 4 also increase the percentage of astroglia in our cultures. To date GFAP inducing activity has not been observed using known serum glycoproteins suggesting that AIM is a novel differentiation factor. (Supported by MH 9828 and NS 20212).

ROLE OF BRAIN-DERIVED NEUROTROPHIC FACTOR (BDNF) AND NERVE GROWTH FACTOR (NGF) IN THE COMMITMENT OF PLURIPOTENT NEURAL CREST CELLS. M. Sieber-Blum. Dept. of Anatomy and Cellular Biology, Medical College of Wisconsin, Milwaukee, Wisconsin 53226.

The influence of BDNF and NGF on the expression of traits specific for sensory and autonomic neurons by cloned neural crest cells was examined. Pluripotent neural crest cells in clonal culture give rise to melanocytes, adrenergic cells, sensory neuroblasts and to as yet unidentified cells. The mechanisms that lead to these phenotypic restrictions are largely unknown. Neural crest cells at clonal density were grown in the presence or absence of BDNF (10 ng/ml) and/or NGF (25 ng/ml) on a collagen-laminin-fibronectin substratum. All cells within a colony were analyzed by triple labeling, using antibodies against the stage-specific embryonic antigen-1 (SSEA-1) to identify cells in the sensory neuron lineage and against dopamine-β-hydroxylase to visualize adrenergic (autonomic) cells, as well as Hoechst nuclear stain H33258 for total cell counts. In a typical experiment, addition of BDNF caused a 22-fold increase in the number of $DBH^-/SSEA\text{-}1^+$ (sensory) cells (p=0.0001), addition of NGF caused a 4.9-fold increase (p=0.10), whereas in the presence of both BDNF and NGF, a 28-fold increase was observed (p=0.03). The total number of cells per colony did not differ significantly under the various conditions (p=0.82 to 0.89). A newly observed, rare (0.06-0.29%) cell type, $DBH^+/SSEA\text{-}1^+$, expressed both autonomic and sensory traits. These cells developed only in the presence of NGF and/or BDNF and were most numerous when both factors were present. $DBH^+/SSEA\text{-}1^-$ (autonomic) cells developed exclusively in the presence of NGF. Preliminary data indicate that the embryo contains a laminin-dependent cell type, in the presence of which virtually all unpigmented crest cells in clonal culture express SSEA-1, even in the absence of added BDNF and NGF. The results suggest a) that BDNF directs pluripotent neural crest cells or their immediate progeny to differentiate along the sensory neuron lineage, b) that NGF has a similar but less pronounced effect, c) that the stimulatory effect of both factors most likely is additive, d) that NGF may be required for directing pluripotent crest cells to develop along the autonomic cell lineage, and e) that a neural tube- or neural crest-derived cell type produces a strong signal that supports the formation of cells developing along the sensory neuron lineage. Supported by USPHS grant HD21423 and a research grant from the Dysautonomia Foundation.

CATECHOLAMINERGIC (CA) DIFFERENTIATION IN EMBRYONIC RAT CRANIAL SENSORY GANGLIA: POSSIBLE ROLE OF NERVE GROWTH FACTOR (NGF). D. M. Katz and M. I. Erb*, Depts. of Medicine and Neuroscience, Case Western Reserve Univ. Sch. of Med., Cleveland, OH 44106.

Tyrosine hydroxylase (TH) is transiently expressed by a large subpopulation of nodose and petrosal ganglion (NPG) cells between embryonic days (E) 11.5 and 15.5 in vivo (Jonakait, et al., 1984; Katz and Erb, 1990). In contrast, TH cells are only rarely observed in other cranial sensory ganglia, such as the jugular-superior ganglion (JSG) of the glossopharyngeal and vagal nerves. Consequently, we asked whether or not this difference was due to the absence of cells with CA potential in the JSG. Although mechanisms regulating transient TH expression in embryonic sensory ganglia are unknown, we recently found that NGF treatment of embryonic day (E) 13.5-14.5 NPG neurons in culture increases the proportion of TH cells. In the present study, therefore, we examined whether exposure of JSG cells to NGF in culture would stimulate detectable expression of TH in ganglion cell bodies. Explant and dissociated cultures of E13.5-14.5 JSG were grown for 24 hours in the presence or absence of 25 ng/ml NGF and monitored for TH and neurofilament (NF) protein expression by immunocytochemical staining. In contrast to the JSG in vivo and in control cultures, at least 20% of NF+ ganglion cells in NGF-treated cultures were TH+, indicating the presence of NGF-responsive neurons or neuroblasts with CA potential. These findings raise the possibility, therefore, that the ganglion- specific pattern of transient TH expression observed in vivo may reflect regional differences in extrinsic regulatory influences, such as NGF. EFFECTS OF GROWTH FACTORS ON NEURONAL DIFFERENTIATION BY NEURAL CREST CELLS. M.J. HOWARD, K.A. HEIDENREICH, T.P. ROTHMAN AND M.D. GERSHON. DEPT. ANAT/CELL BIOL. COLUMBIA UNIV. NEW YORK, NY 10032 AND DEPT. OF MED. UCSD, LA JOLLA, CA 92092

Cells of the neural crest give rise to diverse derivatives. In tissue culture, the types of neurons that differentiate can be affected by components of the growth medium. Factors in 11 day chick embryo extract (CEE) will support adrenergic differentiation by some neural crest cells in-vitro. The present studies were undertaken to characterize further, responses to the CEE-derived factor and test the possibility that this factor might be insulin. For all studies in which the effect of putative growth factors was being tested, the growth medium was supplemented with 2% CEE, conditions that do not support adrenergic differentiation. When the medium was supplemented with 1-20ng/ml insulin no adrenergic differentiation was detected in trunk neural crest cells after 7 days in culture. Photoaffinity labelling using iodonated B2-2-nitro, 4-(azidophenyl acetyl)-des-PHE^{B1}-insulin, a photoreactive analogue of insulin, failed to detect insulin receptors in membranes prepared from trunk neural crest cells, however, a large number of receptors were labelled in membranes from primary neuronal cultures of E7 chick forebrain. In contrast to the absence of effects with insulin, TGF-β (0.5-5ng/ml) supported adrenergic expression; serotonergic differentiation was enhanced as well. Both arborization of neurites and expression of neurotransmitter related enzymes were enhanced. This is the first characterized growth factor that can substitute in tissue culture for CEE-derived signals that are required for adrenergic differentiation by neural crest cells. The ability of crest cells to respond to CEE-derived factors appears to be transient since cells maintained under restrictive growth conditions for at least 4 days do not show adrenergic differentiation when moved into permissive conditions. In contrast, some crest cells will develop along an adrenergic lineage if they are first exposed to 10% CEE-containing medium for 2-3 days and then transferred to medium containing 2% CEE. Some crest-derived cells will thus express an adrenergic phenotype in response to TGF-β but not to insulin. For CEE-derived factors there appears to be a critical time during which the adrenergic phenotype becomes specified.

AUTO INHIBITION OF NOREPINEPHRINE RELEASE IN SYMPATHETIC NEURONS IS DUE TO CALCIUM MODULATION AT THE NERVE TERMINAL NOT AT THE CELL BODY. D. Przywara, S. Bhave, A. Bhave*, T. Wakade* & Arun R. Wakade. Dept. of Pharmacology, Wayne State Univ. School of Medicine, Detroit, MI 48201.

We examined the mechanism of inhibition of ^{3}H-norepinephrine (^{3}H-NE) release in cultured neurons from the superior cervical ganglion (SCG) of newborn rats. Electrically evoked (2Hz for 60 sec) release of neuronal ^{3}H-NE was blocked (76±7% maximum decrease) by NE (5 to 50 μM). Similar results were obtained with epinephrine (EPI). The α-2 adrenergic agonist, clonidine (10 μM) had no effect on stimulation evoked ^{3}H-NE release. Whole cell voltage clamp was used to determine the effects of adrenergic agonists on Ca^{2+}-current (I_{Ca}). NE and EPI had no effect on I_{Ca} when ATP or ATP + GTP were included in the recording pipette solution. NE (and EPI) produced only 15% decrease in I_{Ca} when GTP alone was included. Intracellular free Ca concentration ($[Ca^{2+}]_i$) was measured in cell bodies and nerve terminals using Indo-1 fluorescense technique. NE and EPI had no effect on the stimulated (2Hz for 5 sec) rise of $[Ca^{2+}]_i$ in the cell bodies. However, NE and EPI significantly depressed the stimulated rise of $[Ca^{2+}]_i$ in several, but not all, of the nerve terminals. We conclude the effects of NE and EPI on are selectively mediated on the terminal regions of sympathetic neurons, but not on the cell bodies.

525.2

CALCIUM CURRENT OF SYNAPTIC TERMINALS OF GOLDFISH RETINAL BIPOLAR CELLS. Gary Matthews and Ruth Heidelberger, Dept. of Neurobiology, SUNY, Stony Brook, NY 11794-5230

Retinal bipolar cells are non-spiking interneurons that relay information from the photoreceptors to the amacrine and ganglion cells. In goldfish, one class of bipolar cell has a large, bulbous synaptic terminal (~8 μm in diameter) that is well-suited for physiological study. Previously (1990, *Invest. Ophth. Vis. Sci.*, 31, 389), we have used fura-2 to show that depolarization elicits Ca-influx in these cells via dihydropyridine-sensitive Ca-channels. Here, we present a patch-clamp characterization of the Ca-currents in single synaptic terminals. All experiments were done on bipolar cells acutely isolated from adult goldfish retina after papain treatment. Whole-cell Ca-currents were isolated using Cs/TEA pipette solution. From a holding potential of −60 mV, depolarization positive to about −30 mV elicited sustained inward currents that peaked at about 0 mV. There was no transient current component, even with hyperpolarizing prepulses. Removing [Ca]$_o$ abolished the inward current, while isotonic Ba greatly enhanced it. The current was blocked by nitrendipine (0.1 μM) and Cd (0.2 mM) and potentiated by Bay K 8644 (0.1 μM). Currents in somata and terminals were compared, either by severing the axon or by local superfusion of Cd on the terminal or soma. There was no qualitative difference between somatic and terminal Ca-currents, but the terminal accounted for 50–90% of the whole-cell current. Ca-current washed out during whole-cell recording, usually disappearing within a few hundred sec. Wash-out was prevented by leupeptin (Chad & Eckert, 1986, *J. Physiol.*, 378, 31). Indeed, with 0.2 mM leupeptin in the pipette, Ca-current *increased* progressively over the first 60–100 s following break-in, suggesting that Ca-channels in the terminal are subject to regulation. Supported by the National Eye Institute (EY03821).

525.3

THE CALCIUM CURRENT IN THE PRESYNAPTIC NERVE TERMINAL OF THE CHICK GIANT SYNAPSE IS INSENSITIVE TO THE DIHYDROPYRIDINE NIFEDIPINE E.F. Stanley and Aisar H. Atrakchi, LB NINCDS, Bld. 9 Rm 1E124, NIH, Bethesda MD 20892.

We have used the cholinergic chick ciliary ganglion calyx-synapse to test the effect of the DHP, nifedipine, on Ca current (I_{Ca}) recorded directly from a presynaptic nerve terminal (c.f. Brain Res. 505:341). We first used the whole-cell voltage clamp technique in a control neuron to define the holding potential (-50 mV) at which L-type calcium channels are blocked by 10 μM nifedipine. We then used the same conditions to test the effect of the DHP on I_{Ca} recorded from the presynaptic calyx terminal. Locally applied nifedipine did not reduce the calyx I_{Ca}, neither did it block chemical transmission through the ganglion. We conclude that the predominant calcium channel in this presynaptic nerve terminal is not DHP-block sensitive and, hence, can not be characterized as L-type.

525.4

DIFFERENTIAL BEHAVIOR OF SOMA AND GROWTH CONE OF SYMPATHETIC NEURON. Arun R. Wakade, S. Bhave, A. Bhave*, T. Wakade* & D. Przywara. Dept. of Pharmacology, Wayne State Univ. School of Medicine, Detroit, MI 48201.

Neuronal cell bodies have become popular structures to study Ca^{2+} homeostasis by applying the techniques of electrophysiology and fluorescence microscopy. Conclusions derived from these studies are used to explain the role of Ca^{2+} in transmitter release. We demonstrate that Ca^{2+} is handled differently in the cell body and the growth cone, and that changes in Ca^{2+} in the cell body are not reflected in release of ^{3}H-norepinephrine (^{3}H-NE) from cultured sympathetic neurons. Electrical stimulation (10 pulses at 2Hz) produced an almost equal rise in Ca^{2+} in the cell body and growth cone, but it's removal was much faster and complete in the growth cone. Substitution of Ca^{2+} by Ba^{2+} enhanced current in the cell body but not in the growth cone. Caffeine (10 mM) enhanced cell body Ca^{2+} but did not change growth cone Ca^{2+} levels and did not increase ^{3}H-NE release. Although cadmium and verapamil (50 μM) completely blocked Ca^{2+} transport in the cell body these agents produced only partial inhibition (60-73%) of ^{3}H-NE release even when used in high concentrations (200 μM). We conclude that examination of Ca^{2+} movements only in the cell body is insufficient to understand the role of Ca^{2+} in the release of transmitter and it's modulation by pharmacological agents.

525.5

DISTRIBUTION OF CALCIUM CHANNELS ALONG FROG MOTOR NERVE TERMINALS. M.W. Cohen, O.T. Jones* and K.J. Angelides. McGill Univ., Montreal, Que. and Baylor Col. of Med., Houston, TX.

Tetramethylrhodamine-conjugated ω-conotoxin (TRωCT; Science 244 1189, 1989) was used to examine the distribution of voltage-gated calcium channels on motor nerve terminals in the sartorius muscle of Xenopus laevis. In most experiments acetylcholine receptors were also stained with fluorescein-conjugated α-bungarotoxin. TRωCT blocked neuromuscular transmission and stained neuromuscular junctions faintly. In face views the fluorescence consisted of discrete transverse bands at intervals of about 1 μm along the length of the synapse. In side views it consisted of discrete dots, also at 1 μm intervals. This staining was not observed when muscles were pretreated with ωCT or when the motor nerve terminals were made to degenerate by nerve resection. Additional observations indicated that the TRωCT staining was restricted to the synaptic side of the nerve terminals and aligned with the junctional folds. It is concluded that voltage-gated calcium channels on frog motor nerve terminals are clustered at active zones. This distribution ensures that during the presynaptic action potential intraterminal Ca^{++} reaches its peak concentration at the same sites where synaptic vesicles are clustered. (Supported by MRC of Canada and by NIH).

525.6

MEASUREMENT OF INTRACELLULAR CALCIUM IN CULTURED PURKINJE CELLS UNDER VOLTAGE CLAMP. M.H. Dickinson and J.A. Connor. Dept. of Neurosciences, Roche Institute of Molecular Biology, 340 Kingsland St., Nutley, NJ 07110.

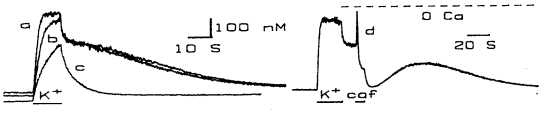
Traditional methods of whole cell patch recording which disrupt endogenous buffering systems have made it difficult to study calcium localization in voltage clamped neurons. By using the Nystatin perforated patch technique, we have been able to voltage clamp the somata of cultured Purkinje cells while simultaneously imaging intracellular calcium in both soma and dendrites with the indicator fura-2. Using this approach, we are examining the spatial and temporal changes in calcium concentration caused by alteration of membrane potential and iontophoretic application of excitatory amino acids.

Glutamate stimulation of Purkinje cells causes a transient calcium influx with components sensitive to both nifedipine and APV (Hockberger, et al., J. Neurosci. 9: 2272, 1989). Repetitive stimulation can result in maintained elevations of intracellular calcium that long outlast the glutamate pulses. Such elevations might be involved in tonic alterations of Purkinje cell membrane properties, such as those produced during Long Term Depression. We are using the simultaneous voltage clamp-imaging technique to determine the relative contributions of the voltage and ligand gated conductances in both the transient and maintained calcium responses.

525.7

TWO PHARMACOLOGICALLY DISTINCT Ca^{2+} STORES WHICH MODIFY $[Ca^{2+}]_i$ ELEVATIONS PRODUCED BY DEPOLARIZATION IN SYMPATHETIC NEURONS D.D. Friel and R.W. Tsien, Department of Molecular and Cellular Physiology, Stanford Univ. School of Medicine, Stanford, CA 94305.

We studied effects of intracellular compartments on $[Ca^{2+}]_i$ responses elicited by 50 mM K^+ in bullfrog sympathetic neurons, focusing on contributions from two stores, a ryanodine (ryan) and a caffeine (caf)-sensitive store (RSS) and a ryan and caf-insensitive store (RIS). Either store appears to act as a Ca source or sink depending on its Ca content and $[Ca^{2+}]_i$. Ryan was used to study the ability of the RSS to act as a Ca source. Responses elicited in the presence of 1 μM ryan (b), which inhibits caf responses, were slower in onset but otherwise similar to controls (a), suggesting that the K^+-induced $[Ca^{2+}]_i$ rise is normally speeded by Ca release from the RSS. Caf was used to transform the RSS into a Ca sink. When K^+ was applied (in the absence of caf) shortly after a caf-induced $[Ca^{2+}]_i$ transient, $[Ca^{2+}]_i$ rose slowly (c), in contrast to the rapid $[Ca^{2+}]_i$ rise elicited in the continued presence of caf. One explanation for the slow onset (and fast recovery) in (c) is that under these conditions the RSS behaves as a Ca sink. The other store (RIS) appears to prolong recovery by releasing Ca that it accumulates when $[Ca^{2+}]_i$ is elevated, producing a ryan-insensitive plateau (compare a,b). If caf is applied briefly during the plateau (d), $[Ca^{2+}]_i$ rises transiently; after caf is removed, $[Ca^{2+}]_i$ falls and then undergoes a second transient rise, even in the absence of external Ca, suggesting that the plateau arises from release of Ca from an internal source. In the presence of 1 μM FCCP, K^+ elicits larger $[Ca^{2+}]_i$ responses with no obvious plateaus, suggesting that Ca uptake and release by this store is sensitive to FCCP. Acting together, the RSS and the RIS may shape stimulus-evoked $[Ca^{2+}]_i$ transients in a way that reflect the cells' history of stimulation.



525.8

SINGLE CHANNEL BEHAVIOR OF L-TYPE CALCIUM CHANNELS DURING CALCIUM-DEPENDENT INACTIVATION. R.H. Kramer & E.S. Levitan HHMI and Columbia U., NY, NY 10032, and Dept. of Pharmacol., Yale U. Sch. of Med., New Haven, CT 06310.

The L-type Ca current in many cells is inactivated by intracellular Ca^{2+}, but the single-channel basis for this is not known. We are using the perforated patch technique to study Ca-dependent inactivation of single L channels in pituitary tumor cells (GH3). In all experiments BAY K 8644 was present to accentuate L channels. First, we recorded single outside-out L channels in a nystatin-perforated excised vesicle, replete with intact second messenger systems and organelles. Application of the neuropeptide TRH inactivates L channels in the vesicle (5 of 8 tries). TRH decreased opening, without affecting single channel conductance (γ). In two analysed cases, mean open time decreased by about 50%. Evidence strongly suggests that TRH generates IP3 which mobilizes internal Ca^{2+}, thereby inactivating L channels. The TRH-induced rise in Ca^{2+} is coincident with inactivation and is both necessary and sufficient; e.g. the TRH effect is blocked by EGTA, while activators, inhibitors, and down-regulation of protein kinase C have no effect, and many other agents that release internal Ca^{2+} also inactivate L channels.

Second, we used a double patch configuration: one pipette for whole-cell perforated voltage-clamping the cell, the second for cell-attached recording of Ba^{2+} current through single L channels. Depolarizing the cell reversibly decreases channel opening without affecting γ, and the inactivation is Ca-current dependent. These experiments provide a direct observation of Ca-dependent inactivation of Ca channels in intact cells.

525.9

PHYSIOLOGICAL MODULATION OF Ca2+ CHANNELS IN THE LIVING HUMAN BRAIN STUDIED WITH P.E.T.

P.E.Roland, G. Blomqvist, R.J. Seitz, S.Stone-Elander, E Schwenner#, H.Kraft#, C. Halldin, H. Böshagen#. PET section, Karolinska Institute and Hospital, S10401 Stockholm Sweden. # BAYER Wuppertal. FRG.

Ion channels in mammalian brains have so far only been studied in vitro. Under in vivo conditions we thought that the 1,4-dihydropyridine nimodipine would show use-dependent binding to the Ca^{2+} L-channel. (11)C-nimodipine was injected in normal volunteers performing a somatosensory discrimination task (Roland, *Arch. Neurol.* 44: 543, 1976) while the fate of the tracer in the brain was measured with a PET camera. In another group of volunteers the regional cerebral blood flow (rCBF) was measured during the same somatosensory discrimination task and during rest. The rCBF increases marked the cerebral structures participating in the task. The maximal binding capacity, Bmax, of (11)C-nimodipine was calculated from differential equations describing a three compartmental model (Blomqvist et al. 1990). Injections of cold nifedipine and nimodipine demonstrated that the specific binding originated from the brain cells and not the vasculature. Bmax was in the average 2.3 pM/cc in un-stimulated cortex, but 33- 68% higher in the anatomical structures participating in the task: contralateral ventral thalamus, sensory-motor cortex, putamen-pallidum (bilat.) and ipsilateral ant. lobe of cerebellum. The results demonstrate use dependent binding of nimodipine **in vivo** and that the L-channel activates during physiological brain work in the structures participating in the task.

STUDY OF CALCIUM CHANNELS IN ACUTELY ISOLATED CA3 HIPPOCAMPAL PYRAMIDAL NEURONS SUGGESTS FOUR DIFFERENT TYPES D.J. Mogul and A.P. Fox* Dept. of Pharmacology and Physiology, University of Chicago, Chicago, IL 60637

Pyramidal neurons from the CA3 region of young adult guinea pig hippocampus were enzymatically dissociated (Kay & Wong, 1987). Cells were voltage-clamped using both the whole-cell and single-channel configurations. Three of the channels resembled T-, N-, and L-type channels seen elsewhere. These channels had unitary conductances of 7 pS, 12 pS, and 23 pS, respectively. T channels activated at test potentials (TP) between -60 and -50 mV, showed rapid inactivation, were blocked by 100 μM Ni^{2+} and 500 μM amiloride, and showed resistance to 50 μM Cd^{2+} block. N channels required negative holding potentials (HP) to reprime, activated when TP > -30 mV, and were blocked by 1 μM w-CgTx. L channels showed sensitivity to dihydropyridine agonists (BayK 8644) and antagonists (nimodipine) and displayed negligible inactivation during a test pulse. However, certain differences were found in these channels compared to previous reports. T channels showed a slower inactivation rate and required a very negative holding potential to be reprimed ($V_{1/2}$~-110 mV). L-type Ca^{2+} channels were suppressed by 2 μM nimodipine (NIM), from HP = -50 mV. In contrast, from HP = -90 mV, NIM augmented the L-type currents elicited by TP between -50 and -20 mV and shifted the peak of the I-V in a manner similar to BayK 8644 (1 μM). In addition to these differences, a high-threshold whole-cell current component was present in these cells that was not blocked by NIM or w-CgTx at any concentration. No direct measurement of unitary current for this component has yet been recorded suggesting that its conductance is either very similar to one of the other three channels or it is situated outside the soma where the cell-attached patches were taken.

CALCIUM CHANNEL SUBTYPES IN ACUTELY ISOLATED ADULT RAT AND FROG SENSORY NEURON SOMATA. R.S. Scroggs and A.P. Fox. Department of Pharmacology and Physiology, University of Chicago, 60637

Dihydropyridines (DHP) and omega-conotoxin GVIA (ω-CgTx) were tested on Ca^{2+} currents recorded from acutely isolated rat and frog dorsal root ganglion cells. Bay K 8644 increased peak current in rat cells by 56% ± 16.2 SE (N=5). Sequential treatment with 2μM nimodipine and then 1μM ω-CgTx, blocked different portions of the total current in rat and frog cells. ω-CgTx was more effective, nimodipine less effective, and more current was left unblocked in cells held at -80mV versus -60mV (Table below).

Species	Holding Potential	% Decrease 2uM Nimod	% Decrease 1μM ω-CgTx	% Current Remaining	N
Frog	-60mV	50 ± 4.8 SE	47 ± 4.0 SE	2 ± 1.8 SE	7
Frog	-80mV	14 ± 3.4 SE	71 ± 3.7 SE	12 ± 2.0 SE	6
Rat	-60mV	64 ± 4.1 SE	20 ± 2.7 SE	8 ± 2.0 SE	5
Rat	-80mV	26 ± 4.0 SE	43 ± 3.6 SE	22 ± 2.6 SE	10

The increase in ω-CgTx induced block at negative holding potentials may reflect an increase in the number of primed N channels. Since changing the holding potential from -60mV to -80mV increased peak current by 80% (N=6), the proportion of current blocked by nimodipine at -80mV is less than the expected (36% decrease in rat, 28% decrease in frog) based on the effect of nimodipine observed at -60mV. Thus, the unblocked current may reflect a decrease in efficacy of DHP antagonists on L channels at negative holding potentials. More unblocked current was observed in rat than frog which may reflect the presence of DHP and ω-CgTx resistant channels in the rat cells.

INACTIVATION PROPERTIES AND PHARMACOLOGY DISTINGUISH TWO CALCIUM CURRENTS IN CULTURED MOUSE PANCREATIC ß-CELLS. W.F. Hopkins, L.S. Satin, and D.L. Cook*, Depts. of Physiology/Biophysics and Medicine, Univ. of Washington and VA Medical Center, Seattle, WA 98108.

We have shown that two types of insulin-secreting cells (neonatal rat ß-cells and HIT cells) each possess two calcium currents (Satin and Cook, *Pflügers Arch.* **411**: 401-409, 1988; *Pflügers Arch.* **414**: 1-10, 1989). In contrast, mouse ß-cells have been reported to possess only L-type calcium channels. To reexamine this question, we studied calcium currents in adult mouse ß-cells using the whole-cell voltage clamp technique. When calcium currents were elicited with 10 sec test pulses, the time course of inactivation was well fit by the sum of two exponentials. The fast component's time constant was 75 ± 5 msec (at 0 mV) and it displayed calcium- and voltage-dependent inactivation, while the slow component's time constant was 2750 ± 280 msec and it inactivated primarily via voltage. The fast component showed greater steady-state inactivation at holding potentials between -100 and -40 mV and had a lower voltage threshold than the slow component. Nimodipine (0.5 μM) blocked 43 ± 4% of the fast component (from -100 mV) but had no effect on the slow component. Higher doses of nimodipine (≥ 1 μM) decreased both components. The amplitude of the slow component was significantly increased by replacing calcium with barium, while the fast component was not changed. The slow component also displayed a ten-fold greater sensitivity to cadmium block than the low-threshold, fast component. The data suggest that mouse ß-cells, as with other insulin-secreting cells, possess at least two distinct calcium currents.

mRNA REGULATION: PEPTIDES AND C-FOS

526.1

ESTROGEN (E) INFLUENCES ON OXYTOCIN mRNA EXPRESSION IN PREOPTIC AND ANTERIOR HYPOTHALAMIC REGIONS STUDIED BY IN SITU HYBRIDIZATION. S.K. Chung and D.W. Pfaff, The Rockefeller University, New York, NY 10021.

In order to analyze possible influences of E on oxytocin mRNA expression at preoptic and anterior hypothalamic levels of the rat brain, in situ hybridization was used, supported by immunocytochemistry and compared to vasopressin mRNA in situ hybridization. A tritiated 25 base oligomer was used, previously confirmed as oxytocin-specific (Kawata et al., Brain Res. Bull., 1988). Ovariectomized female rats were treated for 2 days or 2 months with estradiol (10%, mixed in cholesterol) or cholesterol (control) in subcutaneous capsules (5mm length). Oxytocin mRNA in situ hybridization and immunocytochemistry both showed neurons expressing in MPOA, ACN, periventricular stratum, PVN, SON, perifornical nucleus, BNST, NC and intersupraoptico-paraventricular islands. While there was a trend for the number of oxytocin mRNA-containing neurons to increase (about 2X) after 2 days of E treatment, this was not significant. When the amount of oxytocin mRNA per labelled neuron was quantified, E treatment (either 2 days or 2 months) was shown to significantly increase oxytocin expression in SON and ACN, approximately doubling pixels per neuron. The E effect could depend on an ERE identified upstream of the oxytocin gene, but it could also be secondary to changes in release of the peptide.

526.2

TRANSCRIPTION FACTORS BINDING TO THE PREPROENKEPHALIN PROMOTER: EXPRESSION IN NEURONS OF NORMAL AND STIMULATED NUCLEUS CAUDALIS. G.R. Uhl, M.G. Buzzi, D. Appleby*, M.A. Moskowitz and T. Nishimori. Lab. of Mol. Neurobiol., NIDA/ARC and Depts. of Neurol. & Nsci., Johns Hopkins Sch. of Med., Bx 5180, Baltimore, MD 21224 and Dept. of Neurol & Nsurg, MGH and HMS, Boston, MA 02114

Neurons expressing preproenkephalin in lamina I and II of the nucleus caudalis display exquisite activity-related changes in preproenkephalin gene expression. A region of the proenkephalin promoter that may bind and be regulated by a specific set of transcription factors has been identified. To understand possible mechanisms of trans-synaptic preproenkephalin regulation in these neurons, mRNAs encoding these factors were studied in nucleus caudalis neurons from brains sacrificed after unilateral stimulation of the trigeminal nerve using in situ hybridization with matched oligonucleotide cDNA probes.

Levels of hybridization to Jun B mRNA are greater than those for cJun, with only scattered neurons hybridizing with Jun D probes. Expression of Jun B is also greater than that of cFos, AP2, NF1-X and NF1-red1. After primary afferent stimulation, expression of both Jun B and cfos mRNAs is noted in more neurons. These results are consistent with a role for AP-1 factors in the upregulation of proenkephalin noted after primary afferent stimulation.

526.3

SEX STEROIDS REGULATE THE DEVELOPMENT AND ADULT EXPRESSION OF PRO-OPIOID mRNA IN THE ANTEROVENTRAL PERIVENTRICULAR NUCLEUS (AVPv). R.B. Simerly. Oregon Regional Primate Research Center, Beaverton, OR 97006.

Opioid peptides are generally believed to exert important regulatory influences on gonadotropin secretion. Recently (Simerly et al., *J. Comp. Neurol.* **276**:442), a sexually dimorphic population of enkephalinergic cells was identified in the AVPv, a nucleus previously shown to play a critical role in the neural control of ovulation (Weigand & Terasawa, *Neuroenocrinol.*, **34**:395). Neither proopiomelanocortin- nor dynorphin-immunoreactive neurons were found in the AVPv, however, the nucleus appears to contain a discrete population of cells that contain prodynorphin (PDYN) mRNA suggesting that an opioid peptide other than authentic dynorphin may be the predominant peptide derived from PDYN in these neurons. In the present study we used *in situ* hybridization and asymmetric RNA probes synthesized from cDNAs, generously provided by Drs. S. Sabol and J. Douglass, to examine the distribution and hormonal regulation of mRNAs encoding proenkephalin (PENK) and PDYN in the AVPv. As suggested by our previous immunohistochemical results, the AVPv contains more cells that express PENK mRNA in male rats. In contrast to PENK, a greater number of PDYN mRNA-containing neurons are found in female rats, and both of these neurochemical sex differences are determined, at least in part, by perinatal exposure to androgens. In order to evaluate the possible regulation of PENK and PDYN expression within these sexually dimorphic populations of neurons, we measured PENK and PDYN mRNA hybridization in the AVPv of female and male rats that were either intact, or gonadectomized and implanted with pellets of 17β-estradiol (or testosterone) for 1, 3, or 7 days before sacrifice. Within 24 hrs. estradiol treatment increased PDYN mRNA levels by over 60% relative to either intact estrous females, or ovariectomized controls. In contrast, comparable differences in PDYN mRNA levels were not found in male rats, nor were changes in levels of PENK mRNA detected within the AVPv in hormone-treated animals of either sex. Taken together these results suggest that circulating sex steroids differentially influence the development of PENK- and PDYN-containing neurons in the AVPv during the perinatal period, and that estrogen upregulates PDYN gene expression in the adult female rat. Thus, the maintenance of PENK cells, and the loss of hormone-sensitive PDYN cells, in the AVPv may represent important developmental influences of perinatal androgens on the sexual differentiation of gonadotropin secretion. Supported by NIH grant NS2672.

IN SITU DETECTION OF POMC HETERONUCLEAR RNA IN INDIVIDUAL NUCLEI IN RAT BRAIN AND PITUITARY. M.K.-H. Schafer*, J.P. Herman, R.C. Thompson and S.J. Watson. Mental Health Research Institute, University of Michigan, Ann Arbor, MI 48109.

In- situ hybridization techniques (ISH) using exon coding probes to study the regulation of neuroendocrine peptide mRNA expression are well established. However, measurement of cytoplasmatic mRNA levels are less suitable to determine acute or small changes in biosynthetic activity. In contrast, transcription assays measuring the primary gene transcript in the nucleus appear to reflect the transcriptional rate of the gene much more precisely. Recently, Fremeau et al. (Science, 1986) have succeeded in studying the expression of the POMC gene in individual pituitary cells by ISH using riboprobes specific for intervening sequences (introns). Due to the low abundance of the primary transcript and the long exposure times these studies have been tedious.

In this study we localized POMC hnRNA both in individual cells of the rat arcuate nucleus and the pituitary gland by ISH. Riboprobes specific for Intron A of the POMC primary transcript were labeled either with high specificity ^{35}S or digoxigenin-UTP for non-radioactive detection. Radioactively labeled hybrids could be detected in pituitary nuclei after one week of exposure time and in the arcuate nucleus after one month. The enzymatic detection of the non-radioactive labeled hybrids yielded positively stained cells in the pituitary gland within 24 hours. However, in the arcuate nucleus the latter method failed to produce a detectable signal. While the quantifiablity of the non-radioactive approach needs to be determined, it shows a clear advantage of both excellent morphological resolution and rapid signal detection. At present we are investigating, whether the hnRNA detection by ISH using intron specific probes truelly reflect transcriptional activity.

526.5

LOCALIZATION AND REGULATION OF VASOPRESSIN HETERONUCLEAR RNA IN THE RAT HYPOTHALAMUS. J.P. Herman, T.G. Sherman, M.K.-H. Schäfer, and S.J. Watson. Mental Health Research Institute, University of Michigan, Ann Arbor, MI 48198-0720.

We have used a cRNA probe directed against a purely intronic sequence of the rat provasopressin (VP) gene to localize VP heteronuclear (hn) RNA within individual hypothalamic neurons via *in situ* hybridization histochemistry. The sequence used for probe construction was free from known repetitive sequences and yielded a single band upon Southern blot analysis of Sprague-Dawley genomic DNA, confirming its specificity for study of proVP hnRNA. Standard ISHH procedures using this probe yielded a positive signal in hypothalami of normal rats localized to nuclei in the supraoptic, paraventricular and suprachiasmatic nuclei. In contrast, ISHH using probes directed against exon C of proVP showed a primarily cytoplasmic localization of proVP mRNA in these nuclei. No signal was observed in tissue pre-digested with RNAse A or in tissue incubated with sense-strand intron probe. The signal intensity obtained with the intron probe was surprisingly robust, being visible within 24 hours of exposure to Kodak XAR X-ray film and acheiving optimal intensity at 41 hours. Preliminary regulation studies indicate a consistent up-regulation of VP hnRNA in the SON and PVN in response to 4 days of salt-loading (2% saline), suggesting that osmotic stimuli effectively increase hnRNA levels in a long-term manner.

It is generally believed that hnRNA is rapidly processed in the nucleus, with the spliced-out intervening sequences rapidly degraded. As such, levels of nuclear hnRNA may be taken to reflect recent gene transcription. These data suggest that detection of hnRNA by ISHH may represent a technique whereby gene transcription can be studied in anatomically-specified neurons.

EFFECT OF GONADAL STEROIDS ON PITUITARY PRODYNORPHIN mRNA LEVELS IN THE MALE RAT. R. Day, M. Hoversten* and H. Akil. Mental Health Research Institute, University of Michigan, Ann Arbor, MI, 48109-0720.

Prodynorphin (PDYN) is the precursor of a series of well characterized opioid peptides with leucine-enkephalin extended sequences which include dynorphin A 1-17, dynorphin B and α-neo-endorphin. In the rat pituitary, PDYN derived peptide-immunoreactivity (IR) has been detected in the anterior pituitary, co-localized with a subset of gonadotrophs, the cells known to produce LH and FSH. The influence of gonadal steroids on gonadotrophs is relatively well understood. In the male rat, testosterone has an inhibitory feedback on LH and FSH. Recent studies looking at the effect of gonadal steroids on the PDYN peptides, showed that short term castration (3-5 days) lowers PDYN peptide-IR, while long term castration (30 days) increases PDYN peptide-IR and that testosterone reverses this effect. In the present study, we examined the effects of short and long term castration on anterior lobe PDYN mRNA. Male rats (200-225 g) were castrated for periods of 5 days, 14 days or 30 days. In one experiment, testosterone (2x day, 100 µg/100 g body weight, sc) was given for 10 days, 7 days after the castration surgery. Anterior pituitaries were dissected and total RNA was extracted and submitted to Northern gel analysis. A significant increase in PDYN mRNA was observed in rats castrated for 5, 14 or 30 days. Testosterone reversed the effects of castration, returning PDYN mRNA to normal levels. Interestingly, sham-operated rats receiving tetosterone had significantly lower levels of PDYN mRNA than sham-operated rats. Our data indicate that anterior pituitary PDYN is under the inhibitory influence of gonadal steroids and that removal of this feedback mechanism activates its synthetic capacity. 526.7

DIFFERENTIAL EXPRESSION AND DEVELOPMENTAL REGULATION OF TACHYKININ RECEPTOR mRNAS IN THE RAT CENTRAL NERVOUS SYSTEM. J.E. Krause, A.D. Hershey, Y. Takeda, and S.P. Sivam. Department of Anatomy and Neurobiology, Washington University School of Medicine, St. Louis, MO 63110 and Department of Pharmacology and Toxicology, Indiana University School of Medicine, Gary, IN 46408.

We are interested in the functions and mechanisms of action of tachykinin peptides in the rat central nervous system (CNS). Toward this end, we have cloned cDNAs encoding a rat substance P receptor (SPR; NK-1 type) and a rat neurokinin A receptor (NKAR; NK-2 type). In the present studies, we have addressed some issues of expression of these mRNAs in discrete CNS regions and during CNS development. The mRNAs encoding these tachykinin receptors are low abundance species, consequently highly specific and sensitive nuclease protection assays were established for receptor mRNA detection and quantitation. SPR mRNA is widely expressed throughout the adult CNS, with highest level present in striatum, hippocampus and midbrain. SPR mRNA was detected in many other CNS regions, and overall the levels of abundance in CNS regions ranged from 0.001% (striatum) to 0.00008% (cerebellum) of total RNA. NKAR mRNA was detectable only in striatum and hippocampus, and these mRNA levels were at least 100-fold lower than that observed for SPR mRNA. The expression of SPR mRNA is developmentally regulated in whole brain and striatal RNA, with detectable levels present at E14 and levels greater than adult were present from embryonic day 18 to postnatal day 21. Similar studies are currently underway for NKAR mRNA. Overall, these studies demonstrate that 1) SPR and NKAR mRNAs are of extremely low abundance in the CNS, 2) the mRNAs show region specific patterns of expression and 3) they are developmentally regulated.

526.8

REGULATION OF c-FOS EXPRESSION BY VIP AND OTHER ACTIVATORS OF THE CYCLIC AMP SYSTEM IN PRIMARY CULTURES OF RAT CEREBRAL CORTEX. F.M. Vaccarino, M.D. Hayward*, J.F. Tallman, R.S. Duman, and E.J. Nestler. Lab. of Molecular Psychiatry, Depts. of Psychiatry and Pharmacology, Yale Univ. School of Med., New Haven, CT 06508.

The c-fos gene promoter is known to respond to calcium and cyclic AMP, but virtually all studies have focused on activators of the calcium system (e.g., seizures, excitatory amino acids) as inducers of c-fos expression in the nervous system. The present study demonstrates that activation of the cyclic AMP system also induces c-fos expression in brain.

We studied the regulation of c-fos mRNA levels by Northern blotting in primary cultures of rat cerebral cortical neurons. A number of neurotransmitter ligands, known to increase cyclic AMP levels, increased c-fos expression, including VIP, isoproterenol, dopamine, and serotonin. The VIP-induced increase in c-fos was similar in magnitude to that seen in response to glutamate, which was found to induce c-fos via actions at both NMDA and non-NMDA receptors, probably through activation of the calcium system. However, the effect of VIP was not modified by the glutamate receptor antagonists MK-801 and CNQX, indicating that VIP induction of c-fos is not secondary to the release of endogenous glutamate. Forskolin (which stimulates adenylate cyclase) or lipophilic derivatives of cyclic AMP also increased c-fos mRNA levels in these cultures.

Taken together, the data demonstrate that, in differentiated cerebral cortical neurons, diverse types of neurotransmitters, through multiple intracellular pathways, lead to regulation of c-fos expression which could then mediate some of the long-term effects of the neurotransmitters on gene expression.

526.9

WOUNDING OF THE CORNEA LEADS TO THE RAPID EXPRESSION OF C-FOS IN TRIGEMINAL NEURONS. H.W. Thompson 1, S. Griffin 1, R.W. Beuerman. Lions Eye Research Labs and Laboratory of the Molecular Biology of the Ocular Surface, L.S.U. Eye Center, New Orleans, LA 70122.

The cornea has the most densely innervated epithelial surface in the body. Previous studies from this laboratory have shown that removal of a 6mm, 150-200 um thick disc of tissue from the rabbit extirpates free nerve endings and the underlying subepithelial plexus while inducing the formation of a dense ring of collateral sprouts by 24 hrs(Roza, Guss, Beuerman, Invest Ophthalmol Vis Sci 24:1983,1033-1051). Sensory stimulation of free nerve endings in the epithelium around the wound shows a loss of modality specificity, spontaneous activity, and an increase in action potential output to a given stimulus. The present study has investigated gene expression in the soma after wounding by analysis of the mRNAs of the rabbit trigeminal ganglion at 0, 15, 30, 45 min, and 1 hr after wounding. Total cellular RNA was extracted denatured and dotted on nitrocellulose. The polymerase chain reaction (PCR) was use to detect c-fos mRNA and dot blots of RNA and PCR products were hybridized with 32P labelled c-fos plasmid (ATCC #41042). Compared with RNA extracted from cortex of the same animals, and trigeminal ganglia from unwounded animals the level of c-fos mRNA rose to a peak at 15 minutes following wounding, and was in decline by 1 hr. The change in electrical activity following corneal wounding may lead to the increased expression of c-fos message in this sensory ganglia. (EY04074, EY02311)

526.10

ELEVATION OF STRIATAL C-FOS mRNA AND AP1 COMPLEX FORMATION AFTER TREATMENT WITH COCAINE. M.J. Iadarola, C.L. Yeung*, Y. Hoo* and +J.P. Quinn*. Neurobiology and Anesthesiology Branch NIDR and +Laboratory of Pathology, NCI, NIH, Bethesda MD.

Levels of Fos protein and Fos-related antigens are elevated by indirect-acting dopaminergic agonists (e.g. cocaine) acting through D1 receptors. The present experiments address the relationship of protein elevations to c-fos mRNA and the ability of tissue extracts to reconstitute a fos/jun (AP1) complex. RNA blot analysis was performed to measure the levels of c-fos mRNA in caudate, frontal cortex, hippocampus and cerebellum. AP1 complex formation was assessed by gel mobility shift assays using extracts from these brain regions and an oligonucleotide from the gibbon ape leukemia virus enhancer (GALV) which contains the AP1 consensus sequence(TGAGTCA). Cocaine (5 to 40 mg/kg, ip) produced dose-related increases in c-fos mRNA of up to 8 fold within 30 min. The most marked increases were observed in straitum, consistent with its dense dopaminergic innervation. The cerebellum also consistently showed an increase in c-fos mRNA while little or no alteration occurred in frontal cortex or hippocampus. Gel shift analysis showed that all areas contained proteins capable of forming an AP1 complex with GALV. An additional mobility shift of the AP1 complex was consistently observed upon addition of an antibody to c-fos. While the intensity of the AP1 shifts was somewhat greater in striatal extracts from the cocaine treated rats in comparison to saline treated rats, it did not exceed two-fold. These data indicate that cocaine elevates c-fos gene expression in discrete brain regions and further suggest a role for specific Fos proteins in the regulation of neuronal genes containing AP1 sites.

AMPLIFICATION OF REGULATED mRNA FROM OPIATE-TREATED CELLS. SA Mackler & JH Eberwine. Dept of Pharmacology, Univ. of Pa. School of Medicine, Phila. PA 19104.

We are using amplification of mRNA (aRNA;PNAS 87:1663) to study the effects of opiate stimulation or withdrawal of opiate stimulation on neuronal gene expression. The goal of these studies is to define the molecules underlying opiate tolerance and physical dependence.

In efforts to clone and characterize opiate-regulated mRNAS from discrete brain regions we are using *in situ* transcription-aRNA based differential hybridization. This technique permits us to screen multiple candidate cDNA clones to determine whether they are opiate-regulated using radiolabeled probe made from individusal tissue sections. We have also used these probes in differential hybridization screening of a library.from delta opiate receptor-expressing NG108-15 cells to select several clones which are now being characterized.

We have studied G protein coupled receptors in NG108-15 cells. A degenerate 51mer oligonucleotide was synthesized based upon a conserved sequence of cloned G protein coupled receptors. This 51mer contained a T7 RNA polymerase promoter five prime to the sequence used to prime cDNA synthesis on total RNA isolated from three separate tissues: untreated NG108-15 cells, cells treated with 10nM DADLE for 24 hrs and cells treated with 10nM DADLE for 16 hrs followed by 10uM naloxone alone for 8 hrs. After second strand cDNA synthesis, aRNA was synthesized with 32-P CTP and used to screen rat genomic DNA. Reversal of opiate stimulation resulted in an increase in abundance of RNA hybridizing to a 2.2kB Eco R1 fragment. This aRNA is being used to screen NG108-15, PC12h, and rat striatum libraries.

It is hoped that a more complete understanding of the molecular changes from opiate use will illuminate the mechanisms of addiction.

526.12

REMOVAL OF CRANIAL BONES INCREASES GENE EXPRESSION OF RAT CORTICAL NEURONS D.K. Meyer *, C. Olenik * and J.J. Vanderhaeghen. Dept. Pharmacol., Freiburg University, D-7800 Freiburg, Fed. Rep. Germany and Neuropathol. Res. Lab., Free University, B-1070 Brussels, Belgium.

Removal of cranial bones is a prerequisite for stereotaxic operations. We have observed that this procedure transiently enhances the concentration of mRNAs coding for preprocholecystokinin (CCK-mRNA) and preprosomatostatin in rat cortex (Olenik and Meyer, Neuropeptides, 15: 115, 1990). Both neuropeptides are co-localized with GABA in a subpopulation of cortical interneurons (Jones and Hendry, TINS, 9: 71, 1986).

In the present study, we have investigated where the respective peptide neurons are located and whether the expression of other genes is also changed under these circumstances. In situ hybridization studies showed that the neurons containing CCK-mRNA are mainly located in layers II and III as well as V and VI of rat neocortex. Removal of the right parietal bone enhanced the labeling of these layers, but only of the ipsilateral side.The density of CCK-mRNA was not changed in subcortical areas. Thus, the phenomenon seemed to be restricted to the ipsilateral cortical areas. The activity of glutamate decarboxylase, the rate limiting enzyme of GABA synthesis, was not affected in rat cortex after parietal bone removal indicating that the operation did not activate all GABA-interneurons, but only the subpopulation which contains the peptides. Parietal bone removal strongly enhanced ipsilaterally the concentration of c-fos-mRNA in a time-dependent manner. Already after 60 min, mRNA levels of the proto-oncogene were elevated as compared to the control side. They declined thereafter to be enhanced again after 24 hours. The distribution of cells containing c-fos mRNA in rat cortex was similar to that of CCK-containing neurons.

These findings indicate that the proto-oncogene c-fos may play a mediator role in the changes in gene expression of cortical peptide-neurons.

ACUTE DEFICITS IN BRAIN-CSF MAGNESIUM RESULT IN CEREBROVASOSPASM AND RUPTURE OF CEREBRAL MICROVESSELS: POSSIBLE RELATION TO STROKE. B.M. Altura, A. Gebrewold*, Q.F. Huang* and B.T. Altura*. Dept. of Physiology, State University of New York, Science Health Center, Brooklyn, N.Y. 11203.

Recent in-vivo studies from our laboratory suggest that magnesium ions (Mg^{2+}) can alter arteriolar (AR) and venular(v) tone and vascular reactivity in the peripheral microcirculation. The present studies were undertaken to determine if $[Mg^{2+}]_o$ can influence AR and V tone and reactivity in the rat cortical (pial) microcirculation in-vivo. Quantitative, high-resolution television-image intensification was utilized to perform the microcirculatory studies. Perfusion of the cerebral microcirculation with CSF containing reduced $[Mg^{2+}]_o$ (i.e., 0.3, 0.6 or 0- mM) resulted in rapid and progressively pronounced spasm of AR (15-85 μm o.d.) and V (15-120 μm o.d.) followed by irreversible rupture of V and capillaries, leading to focal hemorrhages and brain edema. Perfusion of the cerebral microcirculation with $[Mg^{2+}]_o$ > 0.8 mM was found to induce dose-dependent vasodilation (VD) of cerebral AR and V, irrespective of the route of administration, i.e., topical, IV or IA. Mg^{2+}-induced increments in diameter and blood flow occurred rapidly and in physiological concentration (μmolar range) irrespective of the salt used (i.e., $MgCl_2$, $MgSO_4$, Mg acetate, Mg aspartate HCl). Constrictor responses to phenylephrine and $BaCl_2$ were attenuated in a dose-dependent manner by all 4 Mg salts. No known pharmacologic antagonist, cyclo-oxygenase or lipoxygenase inhibitor, or opiate antagonist could modify or inhibit: 1) the cerebral vascular damage induced by low-$[Mg^{2+}]_o$ or 2) the VD induced by Mg salts. The present findings suggest that CSF and brain levels of $[Mg^{2+}]_o$ play an important role in controlling the cerebral microcirculation. Lower than normal dietary intake of Mg may be an important risk factor for stroke. (Supported in part by Research Grants from the USPHS).

527.2

SURVIVABILITY OF TURTLE AND RAT CORTICAL NEURONS UNDER ANOXIA AND ISCHEMIA IN VITRO. C.J. Doll, P.W. Hochachka*, and P.B. Reiner. University of British Columbia, Depts of Psychiatry and Zoology, Vancouver, B.C. V6T 2A9.

Turtles are extremely anoxia tolerant being able to survive for over six months while overwintering in anoxic pond bottoms. This strategy has lead to the turtle brain being used as a model for anoxia studies. Intracellular recordings from slices of rat and turtle cortex were obtained during various treatments. Turtles survived both N_2 and pharmacological anoxia ($NaCN+N_2$) for 180 min. with no noticeable effect. Rat pyramidal neurons responded with a rapid loss in membrane resistance, followed by a transient hyperpolarization, and a subsiquent depolarization to a zero membrane potential (41.3±6.5 min, N_2; 25.8±12.6 min, CN). Pharmacological ischemia (cyanide+iodoacetic acid) also caused a rapid loss in membrane resistance, transient hyperpolarization, and a rapid depolarization (3.1±.5 min, rat; 4.6±1.1, turtle). Iodoacetic acid alone had similar effects on the rat (6.5±.8 min), but the turtle had a more prolonged response (53.5±4.6 min). Ouabain caused a depolarization (8.6±1.1 min), but no initial loss in membrane resistance or a hyperpolarization. These results suggest that the turtle, which survives anoxia, is no better at surviving pharmacological ischemia than the rat. In addition, anoxia takes 13 times longer to depolarize a cell than pharmacological ischemia, and neither of these treatments is mimicked by ouabain alone.

HISTOLOGIC ANALYSIS OF FOCAL ISCHEMIC CHANGES PRODUCED BY MIDDLE CEREBRAL ARTERY OCCLUSION (MCAO). R.K.Clark, C.Fish,* E.V.Lee,* W.J.Price,* R.F.White,* G.Z.Feuerstein and F.C.Barone. SmithKline Beecham Pharmaceuticals, King of Prussia, PA 19406

MCAO in the rat produces an initial hemispheric swelling and infarction followed by a substantial decrease in hemispheric volume. Histologic analysis was used to elucidate the mechanisms of these changes. Microsurgical techniques were used to produce MCAO in spontaneously hypertensive rats. Paraffin sections of forebrains were prepared at 1, 2, 3 and 15 days post- occlusion and stained with hematoxylin and eosin, or immunohistochemically stained for GFAP. Initially (days 1 and 2), a well demarcated infarct was observed in the cortex with necrosis extending from the meningeal surface to the radiation of the corpus callosum. A zone of glial activation (with increased GFAP positivity) was present at the medial boundary with surviving brain tissue. Polymorphonuclear cells (PMN) infiltrating from the cerebral and meningeal vasculature were present at the periphery of the infarct. By day 5, the infarct was beginning to cavitate along its medial aspect. Macrophages and PMNs were more abundant, especially in discrete foci just below the meninges. By day 15, the once necrotic tissue was replaced by a fluid filled cavity. The meninges over the lesion were thickened and attached to a layer of loose connective tissue containing fibroblasts and macrophages. The medial aspect of the cyst was walled off by GFAP positive gliosis. Ischemic changes were absent in contralateral hemispheres and in sham-operated control animals. These results indicate that the initial hemispheric edema and infarction produced by MCAO are associated with necrosis, PMN infiltration and diffuse gliosis. The later loss of hemispheric volume results from phagocytosis of the necrotic tissue, concomitant with the formation of the glial scar.

526.4

RELEASE OF PLATELET-ACTIVATING FACTOR IN THE PENUMBRAL AREA OF FOCAL BRAIN INJURY IN RATS. **K.U. Frerichs, J.M. Hallenbeck", G.Z. Feuerstein' and A.-L. Sirén. Dept. of Neurology, USUHS, Bethesda, MD 20814 and 'Dept. of Pharmacol., SmithKline Beecham, King of Prussia, PA 19406**

Membrane phospholipid degradation is a rapid consequence of ischemic as well as traumatic brain injury, which could provide opportunity for production of platelet-activating factor (PAF). PAF has been suggested to be a potent mediator of injury responses in various tissues.

In the current report, the PAF content in brain microdialysis samples was assessed acutely after focal brain injury (Nd:YAG laser; Frerichs,K.U. et al.,Stroke 21:180, 1990) by a specific PAF-radioimmunoassay (DuPont). Dialysis probes (Carnegie) were inserted into the penumbral area of progressive neuronal damage surrounding the lesion core as well as into a remote control area in the parietal cortex of anesthetized rats (n=7). No detectable PAF levels were found under baseline conditions prior to injury. Acutely after injury, PAF levels in the dialysate from the injury site were 0.63±0.34ng/ml ($p<0.05$) and remained elevated throughout the observation period of 60 min (0.32±0.09ng/ml,$p<0.05$), while no PAF activity could be detected in the remote sampling site.

These data support the hypothesis that PAF, produced by the penumbral tissue, may trigger early events in the sequela of progressive neuronal death following cerebral ischemia and neurotrauma.

CHARACTERIZATION OF PHOSPHOLIPASE A_2 (PLA_2) ACTIVITY IN GERBIL BRAIN AFTER ISCHEMIA AND REPERFUSION. G.A. Rordorf*, R. A. Nemenoff*,Y. Uemura* and J. V. Bonventre. Departments of Medicine and Neurosurgery,Massachusetts Genl. Hosp., Harvard Med. Sch., Boston, MA 02114.

PLA_2 activation has been proposed as an important mechanism of ischemic brain injury based upon studies in which PLA_2 activity has been measured indirectly from tissue arachidonic acid (AA) release. We characterized PLA_2 enzymatic activity in gerbil brain after 10 min. of common carotid artery occlusion, followed by 10 min of reperfusion. Cytosolic, mitochondrial and microsomal fractions were prepared by differential centrifugation of forebrain homogenates. PLA_2 activity was assayed by release of AA from exogenous [^{14}C]AA-phosphatidylcholine. Fractions from ischemic-reperfused brains had significantly higher specific PLA_2 activities (pmol/mg protein/min):

	Cytosol	Mitochondrial	Microsomal
Control	4.3±0.4	7.7±0.6	2.2±0.2
Ischemic	6.7±0.7($p<.02$)	13.9±0.1($p<.001$)	3.0±0.2($p<.05$)

PLA_2 activity was then fractionated by gel filtration chromatography. Two forms of this enzyme were identified: cytosolic and membrane (mitochondrial, microsomal)-associated forms, migrating at approximately 60kDa and 12-14 kDa, respectively. PLA_2 activities of both forms were Ca^{2+} dependent with optimal activities at pH 8.5.

In conclusion, ischemia results in a stable activation of two distinct forms of brain PLA_2, a soluble and membrane-associated form. This stable activation of PLA_2 may play a major role in cellular injury associated with ischemia and reperfusion.

527.6

BLOOD FLOW IN THE BORDERZONE OF FOCAL CEREBRAL INFARCTS IN RATS M. Jacewicz, J. Tanabe*, X-J Wang* and W. Pulsinelli Dept. of Neurology and Neuroscience, Cornell University Medical Center, New York, NY 10021

Spontaneously hypertensive (SHR) and Fisher 344 (F344) rats had their right middle cerebral and common carotid arteries occluded under halothane anesthesia to induce focal, graded cortical ischemia (Brint et al, 1988). The rats awoke, and 24 hr later, they underwent a quantitative CBF study (^{14}C-iodoantipyrine autoradiography) and a simultaneous histologic analysis (H&E staining). CBF at the infarct border measured just under 50 ml/100g/min:

CBF (mean±SD in ml/100g/min)	SHR (N=7)	F344 (N=8)
0.5 mm within the infarct	31 ± 12*	32 ± 13*
At the infarct border	48 ± 19	44 ± 15
0.5 mm outside the infarct	74 ± 25*	61 ± 25*
Left (nonischemic) cortex	128 ± 29	---

*$p<0.05$, 2 WAY-ANOVA (vs. CBF at the infarct border)

The results are consistent with observations that the volume of cortex with CBF <50 ml/100g/min at 15 min, 1, 2, 3 and 24 hr after ischemia onset approximates the 24 hr infarct volume (Jacewicz et al, 1989, in press). The CBF threshold for ischemic damage exceeds the 10 - 17 ml/100g/min reported for larger mammalian brains (Astrup et al, 1981) and may reflect the higher baseline cerebral metabolism and CBF found in rodents (Kennedy et al, 1978).

527.7

DEXTROMETHORPHAN ALTERS CEREBRAL BLOOD FLOW AND PROTECTS AGAINST CEREBRAL INJURY AFTER FOCAL CEREBRAL ISCHEMIA. G.K. Steinberg, E.H. Lo, D.M. Kunis, and G. Grant*. Dept. of Neurosurgery, Stanford Univ. Sch. of Med., Stanford, CA 94305

Previous studies have demonstrated that dextromethorphan (DM) is neuroprotective in animal models of cerebral ischemia and it has been suggested that this effect is related to noncompetitive antagonism of neuronal NMDA receptors. We studied the effect of DM on cerebral blood flow (CBF) and cerebral injury in a rabbit model of transient, focal ischemia. Rabbits underwent two hour occlusion of the left internal carotid, middle cerebral and anterior cerebral arteries, followed by four hours of reperfusion. Ten minutes after the onset of ischemia they were treated with either i.v. DM (n=6) 20 mg/kg followed by 10 mg/kg/hr, or normal saline (NS, n=5). Regional cerebral blood flow (rCBF) was measured continuously using a laser Doppler flow meter (TSI) and in some animals with radioactive microspheres. DM attenuated the sharp, post-ischemic rise in rCBF seen with reperfusion in the ischemic core of NS controls (DM 42% pre-ischemic values; NS 108%; $p<.05$). Preliminary data indicate that DM may also prevent the delayed, post-ischemic hypoperfusion in the ischemic penumbra. DM treated animals demonstrated recovery of the somatosensory evoked potential, compared with NS controls (DM 77% pre-ischemic values; NS 20%; $p<.05$). DM's effects on CBF may contribute to its neuroprotective action or alternatively, the CBF changes may be secondary to prevention of neuronal excitotoxicity.

527.8

QUANTITATIVE COMPARISON OF MAGNETIC RESONANCE IMAGING (MRI) AND HISTOLOGIC ANALYSES OF ISCHEMIC DAMAGE FOLLOWING OCCLUSION OF THE MIDDLE CEREBRAL ARTERY(MCA). F.C.Barone, R.K.Clark, G.Z.Feuerstein, R.E.Lenkinski* and S.K.Sarkar*. SmithKline Beecham Pharmaceuticals, King of Prussia, PA 10406.

Microsurgical techniques were used to occlude the MCA in spontaneously hypertensive rats. Decreased microvascular perfusion in the ischemic cortex was verified using Laser-Doppler Flowmetry. MRI experiments were performed 2 days later using a GE 1.5T whole body imaging unit. Images of 3mm coronal sections were collected with a spin-echo pulse sequence having a TR of 2.5s and a TE of 80ms. Forebrains then were sectioned coronally (2mm), stained with 1% triphenyltetrazolium (TTC), photographed, and fixed by infiltration in 10% buffered formalin. Sections were embedded, cut (6 μm) and stained with hematoxylin and eosin (H&E). MRI images and corresponding stained sections were analyzed for the quantification of ipsilateral hemispheric swelling and infarct size using image analysis (Amersham RAS 3000). Morphological changes quantified using MRI paralleled those observed in stained sections. Ipsilateral hemispheric swelling of matched sections for MRI , TTC and H&E (range 7.1±1.3% to 9.8±3.3%) were similar and significantly correlated ($r=0.67$ to 0.75; $p<0.005$). Hemispheric infarct size of matched sections for MRI, TTC and H&E (range 38.1±3.1% to 32.9±2.5%) were similar and highly correlated ($r=0.94$ to 0.98; $p<0.001$). The identification of infarction by MRI was obvious with the MRI signal intensity in the infarcted cortex being much greater than in the normal contralateral area (increased 54.4±3.1%; $p<0.001$). Forebrain changes were absent in sham operated animals. These data indicate that quantitative MRI can non-invasively detect ischemic tissue damage with results that are well correlated to those obtained by histologic methods.

527.9

TEMPORAL ASSESSMENT OF NMR T2 RELAXATION TIMES AND DIFFUSION COEFFICIENTS OF WATER IN ISCHEMIC RAT BRAIN. R.J. Ordidge*†+, R. Knight*†+, J.A. Helpern*†+, M. Chopp*†+, L.C. Rodolosi °, and K.M.A. Welch +. + Department of Neurology, Henry Ford Hospital, Detroit, MI 48202, † Department of Physics, Oakland University, Rochester, MI 48309 and ° Parke-Davis Pharmeceutical Research, Ann Arbor, MI 48105.

The objective of this study was to investigate the utility of NMR imaging for the study of the time course of ischemic damage in brain. Middle cerebral artery occlusion (MCAO) in rats was used as a model of permanent focal ischemia. Approximately 25 animals were studied progressively from 1.5 hours to 1 week following MCAO. T2-weighted images were acquired using variable echo time two-dimensional Fourier transform (2DFT) imaging. Intravoxel incoherent motion (IVIM) imaging was used to produce diffusion-weighted images (LeBihan, D., Breton, E., Lallemand, D., et al., *Radiology* **168**:497, 1988).

The data showed a gradual increase in T2 which maximized at 24 hours post MCAO at a level of 150% that of pre-ischemic values. This was followed by a gradual decline towards normal over the following week. T2 values, however, never completely returned to normal. The contralateral side showed no variation in T2.

The diffusion-weighted images demonstrated an immediate decrease in the diffusion constant ($D\text{-}H_2O$) to 50% of normal at the earliest time point studied (1.5 hours). This was followed by a gradual increase toward a normal value at 1 week. The contralateral side showed no variation in $D\text{-}H_2O$.

We conclude that changes in $D\text{-}H_2O$ provide a measure of the early evolution of ischemia. This change in water diffusion is presumably related to changes in the structural integrity of the tissue. In addition, the variation in T2 is similar in temporal evolution to reported increases in tissue water content. Histological studies are presently in progress to establish the origin of these changes in the NMR parameters.

UNBIASED ESTIMATION OF BRAIN DAMAGE IN A RAT MODEL OF MIDDLE CEREBRAL ARTERY OCCULSION. S.M. Evans & A. Møller. Stereological Research Laboratory, Aarhus University and Neurological Research Laboratory, Hvidovre University Hospital, Copenhagen, Denmark.

Rat animal models for studying brain damage in cerebral ischaemia have been used for a number of years. However, even though these methods have been highly successful models for showing brain damage due to cerebral ischaemia, the quantitative assessment of the results has been poor. Although many attempts have been made to quantify the infarct size the methodology employed has been biased and highly inefficient. Cavalieri's principle was used to estimate the infarct volume of six rat cerebral heimispheres whose middle cerebral artery had been occluded. The method used approximately ten sections from each hemisphere and an unbiased estimate of the infarct volume could be obtained in five minutes with a coefficient of error of less than five percent.

HELIX NEURONS UNDERGO REGULATORY VOLUME DECREASE IN THE PRESENCE OF OUABAIN. F.J. Alvarez-Leefmans, S.M. Gamiño* and L. Reuss*. Dept. Physiol. & Biophys., Univ. of Texas Med. Branch, Galveston TX, U.S.A. and Dept. of Neurobiol., Instituto Mexicano de Psiquiatría, México 14370 D.F.

It is accepted that living cells prevent colloidosmotic swelling by the operation of the Na pump. Hence inhibition of the latter should lead to cell swelling and eventual lysis. Testing this hypothesis is important for understanding the mechanisms underlying neuronal volume control and because Na pump inhibition secondary to ATP depletion has been proposed as one of the factors generating cytotoxic brain edema. We have used a potentiometric technique to simultaneously measure transmembrane potential and cell water volume changes using intracellular tetramethylammonium as a volume indicator (Cotton et al, J. Gen. Physiol. 93: 649, 1989). 11 snail (Helix aspersa) neurons were exposed to 1 mM ouabain, a dose expected to inhibit the Na pump. As expected for an electrogenic pump, all cells were depolarized. 5 neurons initially swelled and down-regulated their volume rapidly. The cells started to swell within 1 min of exposure to ouabain, swelling to a maximum of 10 to 35 % above their initial volume within less than 30 sec. Then, cell volume decreased (initial rate -10 to -60 %/min). Cells not only fully recovered their volume in the presence of ouabain but actually shrank to a maximum of about 10 %. 6 neurons showed no detectable cell volume changes in the presence of ouabain.

SOMATIC AND VISCERAL AFFERENTS IV

THE EFFECTS OF PHORBOLDIBUTYRATE ON SLOWLY CONDUCTING AFFERENTS OF THE CAT'S KNEE JOINT. R.F. Schmidt, K. Schepelmann* and K. Meßlinger*. Physiologisches Institut, D-8700 Würzburg, FRG.

Inflammatory mediators, such as bradykinin and prostaglandins, which excite and sensitize nociceptive primary afferents, are proposed to bind to cellular receptors and activate intracellular second messengers. We studied the effect of the protein kinase C activating Phorboldibutyrate (PDB) on slowly conducting afferents in adult cats anesthetized with α-chloralose. Extracellular single unit recordings were made from 35 slowly conducting units, 17 belonging to group III and 18 to group IV of the medial articular nerve. In regard to their sensitivity to passive movements in the knee joint the afferents were classified as low threshold- and high threshold-units. PDB in concentrations of 10^{-6} up to 10^{-4}M was applied by an arterial bolus injection close to the joint. In 49% of the fibers studied (53% of the group III and 44% of the group IV) the discharge behavior was altered by PDB. Three distinct effects could be observed. 1. An enhancement of spontaneous activity dependent on the applied dose of PDB (12 units), 2. an enhancement of responses to passive movements in the joint (6 units), and 3. a decrease of spontaneous activity (3 units). No correlation of the effects with the mechanical threshold could be observed. From these results we conclude that in a population of slowly conducting articular afferents, nociception as well as the peripheral component of hyperalgesia are mediated partly by intracellular mechanisms which involve protein kinase C.

528.2

MULTIPLE EFFECTS OF HISTAMINE ON ELECTRICAL MEMBRANE PROPERTIES OF TRIGEMINAL ROOT GANGLION NEURONS. **B. M. Hutcheon, E. Puil, and R. M. Miura. Dept. of Pharmacology and Therapeutics, Univ. of British Columbia, Vancouver, B.C., Canada, V6T 1W5.**

Histamine was applied to in vitro slices of trigeminal root ganglion (TRG) as part of an investigation on the ability of endogenous pain producing substances to modulate sensory transmission. Slices (500 μm) were prepared from ganglia of decerebrate guinea pigs. Bath applications of histamine (1-200 μM) during intrasomatic recording produced slow, transient depolarizations in 21 neurons (1-30 mV), hyperpolarizations in 6 neurons (1-7 mV), and multiphasic responses in 6 neurons. Eight neurons did not respond despite high doses (≤ 200 μM) of histamine. The responding cells (n = 33) varied widely in their sensitivities to histamine although they individually exhibited dose-dependent responses. Input resistance increased during depolarizations (mean = +28%), and decreased during hyperpolarizations (mean = -20%). In those neurons which exhibited afterhyperpolarizations (AHPs) in the spikes evoked by current pulse injections, histamine application reduced AHP amplitude and duration. We suggest that histamine produces the depolarizing response by blocking a resting K-conductance, and the hyperpolarizing response by increasing a K-conductance. The multiphasic responses may indicate the involvement of more than one type of K-channel. The possibility is therefore raised that histamine may modulate sensory signals travelling through the TRG.

528.3

ISCHEMIC BLOCK OF LARGE FIBER FUNCTION IN REFLEX SYMPATHETIC DYSTROPHY: A PARADOX. R.H. Gracely*, S. Lynch, and G.J. Bennett. Neurobiology and Anesthesiology Br., NIDR, NIH, Bethesda, MD 20892.

Mechanical-allodynia (pain evoked by light tactile stimuli) is often observed in Reflex Sympathetic Dystrophy (RSD). Sensory assessment of 8 patients with RSD showed that 1) Just detectable sensations evoked by constant current electrical stimuli (1 sec trains, 1 msec pulses, 100 hz) applied to the allodynic area are perceived as painful, but are innocuous on the unaffected side, 2) Reaction times to painful electrical stimuli are too fast to be due to C-fiber activity, and 3) Mechanical allodynia and light touch are both absent 19-27 min after initiation of ischemic block at a time when small fiber function (warmth and cold detection) is unaffected. These three lines of evidence indicate that allodynic pain sensations are mediated by Aß low threshold mechanoreceptive (AßLTM) afferents that usually only mediate innocuous tactile sensations.

However, we have noted a paradox: in several RSD patients mechanical-allodynia is relieved by ischemic block at 2-3 min duration, well before empirical detection of any impulse blockade. Contractures and other motor abnormalities may also accompany the perceptual dysfunction of RSD. In an RSD patient with severe, chronic (24 months) contractures of all 5 toes who received an ischemic block applied to the upper thigh, we observed (and videotaped) a complete release of the contractures within 6 min. At this time there was no indication of impaired afferent or efferent transmission - sensory testing failed to show any change in detection thresholds and the patient's toes moved normally.

These results suggest that the perceptual and motor effects of these short-duration ischemic blocks are due to factors other than direct blockade of nerve transmission (e.g., hypoxia, pH change, depletion of circulating catecholamines) that may drive or enable peripheral mechanisms necessary for the expression of sensory and motor abnormalities.

528.4

NOREPINEPHRINE INDUCED SENSITIZATION OF C-FIBER CUTANEOUS NOCICEPTORS IN THE RAT. A.A. Cameron*, D.M. White and J.D. Levine* Depts. of Anatomy and Medicine., Box 0724, U.C.S.F., CA. 94143.

Norepinephrine (NE) is thought to be a mediator of sympathetically maintained pain that may occur following nerve injury. In normal animals however, NE alone has no effect on nociceptive threshold. Recent behavioural studies have demonstrated that NE-induced hyperalgesia can be produced in normal animals if NE is injected in combination with the Ca^{++} ionophore, A23187. In this electrophysiological study we examined the effects of NE alone or in combination with A23187 on mechanical thresholds of C-fiber mechano- and mechano-heat nociceptors.

Action potentials of single C-fibers were recorded from the saphenous nerve of pentobarbital anaesthetised rats (50mg/kg, ip). Receptive fields were located on the hairy skin of the hindpaw and mechanical thresholds were determined using calibrated von Frey hairs.

Intradermal injections of saline, NE or A23187 alone did not produce sensitization in 12 neurons tested. However, NE+A23187 produced a significant decrease in mechanical threshold (baseline=3.5±0.1g; post NE+A23187=2.5±0.2g; n=12; $p<0.05$) with latency to onset of 5-10 min.

These data show that local changes in Ca^{++} can induce a state in which NE elicits sensitization of nociceptors. Studies are in progress to address the cell type affected by the increase in Ca^{++} to produce hyperalgesia.

528.5

ANTIDROMIC VASODILATATION OVERRIDDEN BY SOMATOSYMPATHETIC REFLEXES IN MAN. INTRANEURAL STIMULATION AND THERMOGRAPHY. J Ochoa, D Yarnitsky, P Marchettini, R Dotson, M Cline, Good Samaritan Hosp. & Med. Ctr. and Oregon Health Sciences Univ., Portland, OR, USA

Early diffuse cooling of skin in normal hand is consistently elicited by excitation of sensory fibers in peripheral nerve trunks. In turn, delayed regional warming is also consistently recorded, provided stimulation activated nociceptor afferent fibers. We have studied, thermographically, interactions between these two physiological responses, as elicited in healthy volunteers and patients by microstimulation of median and ulnar skin-nerve fascicles. Cooling response starts rapidly after onset of stimulation, affects the whole ipsilateral hand, and less so, the contralateral. The response disappears after ipsilateral sympathectomy: it is a somatosympathetic vasoconstrictor reflex. Warming response surfaces after stimulation is discontinued, once reflex vasoconstriction relaxes. It is regionally confined to the receptive field of the stimulated nerve, persists after sympathectomy and disappears with degeneration of small caliber fibers: it is due to antidromic vasodilatation.

Once regional antidromic vasodilatation is established it persists for many minutes, to fade spontaneously thereafter. However, re-stimulation of the nerve rapidly overrides regional vasodilatation through re-engaging reflex vasoconstriction. These findings demonstrate predominance of catecholamine-mediated vasoconstrictor response over substance P-mediated vasodilator response. It is thus possible that, in nerve disease, antidromic vasodilatation triggered by ectopic discharge in nociceptor fibers may become masked by superimposed reflex sympathetic vasoconstrictor activity as a response to orthodromic, afferent, ectopic nerve impulses.

528.6

SYMPATHETIC EFFECTS ON HUMAN LOW THRESHOLD MECHANORECEPTORS. R Dotson, J Ochoa, M Cline, W Roberts, D Yarnitsky, D Simone, P Marchettini, Good Samaritan Hospital & OHSU, Portland, OR 97210

A proposed role for the sympathetic nervous system in causalgia/reflex sympathetic dystrophy (RSD) is through activation of low threshold mechanoreceptors which would in turn excite sensitized pain-signalling neurons in the spinal cord. Animal studies have shown that low threshold mechanoreceptors can be activated by direct stimulation of sympathetic efferents (Roberts 1986). We investigated the effect of sympathetic activation upon response characteristics of low threshold mechanoreceptors in normal subjects and patients with causalgia/RSD. The microneurographic (MCNG) technique was used to record receptor responses of low threshold mechanoreceptors in peripheral nerves of 8 normal subjects and 7 patients with causalgia/RSD. All units studied in patients had receptive fields within the painful/hyperalgesic areas of skin. The receptive field, mechanical threshold, and presence of resting discharge were determined for the units prior to, during, and after sympathetic activation. Sympathetic reflexes were induced by: 2-5 minutes of contralateral limb ice water immersion; startle; mental calculations; and inspiratory gasp. Changes in sympathetic efferent neural activity and effector organ response were monitored (MCNG and laser doppler capillary flowmetry).

Ten units (**5** RA, 1 SAI, and 4 SAII) in 8 normal subjects and 23 units (7 RA, 5 PC, 10 SAI, and 1 SAII) in 7 patients were studied. All units had normal stimulus-response characteristics which did not change during increased sympathetic efferent output. Resting discharges in SAII units also remained unchanged with sympathetic activation. We conclude that reflexly induced increase in sympathetic efferent neural output does not cause activation of low threshold mechanoreceptors in distal limbs in normal human subjects or in painful areas in causalgia/RSD patients.

528.7

STIMULATION OF RENAL AFFERENT NERVES INHIBITS CARDIOPULMONARY REFLEX RESPONSES IN THE CONSCIOUS RAT. S.J. Lewis, C. Barres*, H.J. Jacob* and M.J. Brody. Dept. of Pharmacology & Cardiovascular Ctr., Univ. of Iowa, Iowa City, IA 52242.

Recent electrophysiological studies have demonstrated a functional interaction between renal baroreceptor and cardiopulmonary afferents within the nucleus tractus solitarius. The present study examined the effect of renal afferent nerve stimulation (RANS) on the cardiopulmonary reflex (CPR)-mediated cardiovascular (CV) responses, produced by i.v. 5-HT, in conscious sham-operated (n=12) Sprague-Dawley rats and rats with sino-aortic denervation (SAD, 14 days post-surgery, n=8). The rats were instrumented chronically with arterial and venous catheters and an electrode on the left renal nerve. The effects of concurrent RANS (0.1 mA, 2 msec, 2.5-25 Hz for 10 sec) on the CPR-mediated CV responses were determined before and again 48 h after contralateral vagotomy. In rats with vagi intact, the CPR-mediated reductions in heart rate and blood pressure were not modified by concurrent RANS. However, in SHAM and SAD rats with contralateral vagotomy, RANS virtually abolished the CPR hypotension and bradycardia. These results indicate that afferent renal nerve activity can profoundly inhibit CPR responses by mechanisms that are independent of the baroreflex.

528.8

FUNCTIONAL EVIDENCE THAT $5HT_2$-RECEPTORS EXIST ON RAT VAGAL AFFERENT PERIKARYA. P.J. Lacolley, S.J. Lewis and M.J. Brody. Dept. of Pharmacology & Cardiovascular Ctr., Univ. of Iowa, Iowa City, IA 52242

We have shown that administration of serotonin (5-HT) into the occipital artery (OA) blood supply to the nodose ganglia (NG) of urethane-anesthetized rats produces cardiovascular effects via interaction with vagal sensory perikarya (FASEB J. 4(3):A1107, 1990). The purpose of this study was to determine the 5HT-receptor subtypes involved in the actions of 5-HT on sensory perikarya (activated by the OA route) and those on sensory terminals (iv route). The initial reductions in heart rate and arterial pressure produced by 5-HT (10-60 µg/kg)-induced activation of either vagal afferent terminals or NG cell bodies were abolished by pretreatment with the $5HT_3$-receptor antagonist ICS-205930 (100 µg/kg, iv). In contrast, the reflex hypotension and bradycardia produced by OA but not iv injections of 5-HT were markedly attenuated by the specific $5HT_2$-receptor antagonists ketanserin and xylamidine (200 µg/kg, iv) and the mixed $5HT_1/5HT_2$-receptor antagonist methysergide (500 µg/kg, iv). These results suggest that $5HT_2$-receptors, present on vagal afferent perikarya within NG, appear to mediate the component of the 5HT-induced reflex evoked by direct activation of these sensory nerve cells.

528.9

TYROSINE HYDROXYLASE EXPRESSION AND REGULATION IN NEURONS OF RODENT DORSAL ROOT GANGLIA (DRG). K.B. Seroogy, B.W. Brighton*, N.K. Mohapatra*, P.K. Lund* and E.R. Perl. Department of Physiology, University of North Carolina, Chapel Hill, NC 27599.

In contrast to the rare presence of the catecholamine cellular phenotype in rat and hamster spinal ganglia, a substantial subpopulation of small-sized neurons, 10-20% of the DRG cell population in guinea pig and mouse, exhibit immunoreactivity (I) for the catecholamine-synthesizing enzyme tyrosine hydroxylase (TH), but not for dopamine β-hydroxylase. A similar proportion expresses TH mRNA as determined by in situ hybridization with ^{35}S-labeled synthetic oligonucleotide probes complementary to regions of rat TH mRNA. Northern blot analysis of poly $(A)^+$ RNA from guinea pig DRG revealed a single TH mRNA species of expected size (1.9 kb). TH-I coexists extensively with galanin-I but rarely with substance P-I or CGRP-I. By combining TH immunocytochemistry with retrograde tracing using Fluoro-Gold, some of the TH-I perikarya of guinea pig DRG were shown to be distributed to somatic targets via the sciatic and sural nerves. Transection of the sciatic nerve in guinea pig results in a dramatic reduction in the number of DRG cells exhibiting TH-I. These data suggest that significant subpopulations of guinea pig and mouse primary sensory neurons synthesize dopamine (or L-dopa) and that the catecholamine phenotype of DRG cells is modulated by integrity of the neurons. (Supported by grants NS 08525 and NS 10321 from NINCDS.)

LABELING OF FOS PROTEIN INCREASES IN AN EXPERIMENTAL MODEL OF PERIPHERAL NEUROPATHY IN THE RAT. K.C. Kajander, S. Wakisaka*, G. Driasci* and M.J. Iadarola. Department of Oral Science, University of Minnesota, Minneapolis, MN 55455, and Neurobiology and Anesthesiology Branch, NIDR, NIH, Bethesda, MD 20892

An experimental model of a painful peripheral neuropathy has been introduced by Bennett and Xie (Pain 33:87 -107, 1988). In this model, 4 chromic gut ligatures tied loosely around the common sciatic nerve in rat produce behavioral signs of neuropathic pain. In models of tissue injury, Fos protein, the product of the *c-fos* proto-oncogene, has been used as a marker of activity in spinal cord neurons. We used immunocytochemical techniques in this study to evaluate changes in Fos labeling in the spinal cord at times between 1 and 60 days after induction of the peripheral neuropathy.

The left common sciatic nerve in each of 8 rats was ligated and a sham surgical procedure was performed on the right side. Then at selected times, rats were deeply anesthetized and perfused transcardially with 4% paraformaldehyde. After post-fixing, sections from the L-4 and L-5 spinal segments were sectioned (25 µm thick) and stained using the peroxidase-antiperoxidase method. Locations of labeled cells were reconstructed using a drawing tube at 100X.

There was an increase in nuclear labeling for Fos in the spinal cord on the side of the nerve injury at 3 and 5 days after the injury ($p<0.05$, Student's t-test). The increase in labeling occurred in both the superficial (I-II) and deep laminae (V-VII). At 14 days, the increase was still apparent but was diminished. There was no side-to-side difference in labeling at 1 or 60 days.

These data suggest that Fos labeling increases and is at its greatest soon after induction of a painful peripheral neuropathy. The increase occurs in areas of the spinal cord thought to be important in nociceptive signaling.

SEVERAL CHANNELS COMBINE TO MEDIATE THE MECHANICAL ASPECTS OF TOUCH IN HAIRY SKIN. S.J. Bolanowski, G.A. Gescheider, R.T. Verrillo and T. A.Vaughn*. Inst. Sens. Res., Syracuse Univ., Syracuse, NY 13244 and Hamilton College, Clinton, NY 13323.

We have proposed a four channel model for taction based on psychophysical experiments performed on glabrous skin and have tentatively linked afferent types to the individual channels (Bolanowski, et al, JASA, 84, 1988). It is known that hairy skin is innervated by a different compliment of receptors than is glabrous skin suggesting that psychophysical experiments on this type of skin may show an organization of channels different than found for glabrous skin. We used bursts of sinusoidal displacements (duration, 700 ms; rise-fall time, 500 ms) in the 0.4 to 500 Hz frequency range. Thresholds of human observers (n=5) were obtained. Stimuli were applied to the volar forearm through either a 2.9 or 0.008 cm^2 contactor. Skin-surface temperature was controlled at 15°, 30° and 40°C. Three channels were identified by examining threshold changes that occurred under varying conditions: 1) a low-frequency channel (0.4-2 Hz) which is temperature insensitive and affected by stimulus size; 2) a mid-frequency channel (2-70 Hz) which is sensitive to temperature changes and insensitive to stimulus size and 3) a high-frequency channel (70-500 Hz) which is slightly temperature sensitive and substantially sensitive to changes in stimulus size. These three channels for hairy skin have characteristics different than those of the analogous low-, mid-, and high-frequency channels identified in galbrous skin as would be expected from the difference in physiology and antomy of the two skin types. Whether additional channels exist for hairy skin remains to be determined.

TEMPORAL SUMMATION, THE P CHANNEL, PACINIAN CORPUSCLES AND THE NEURAL CODE FOR THRESHOLD. C.M. Checkosky and S.J. Bolanowski. Institute for Sensory Research, Syracuse University, Syracuse, NY 13244

We have suggested that the neural code used by the psychophysically defined P channel may be 2-4 neural spikes occurring per stimulus. This suggestion was based on psychophysical and physiological data obtained for short-duration stimuli but did not take into account temporal summation, a centrally mediated phenomenon known to exist for the P channel. Temporal summation has been shown to produce a decrease in threshold at a rate of -3 dB/doubling of (sinusoidal) stimulus duration, the temporal integrator having a time constant (τ) of 200 ms. We have verified this effect on 5 human observers. Additionally, Pacinian corpuscles isolated from cat mesentery were stimulated with bursts of 300 Hz displacements having durations from 10 to 1000 ms and intensities producing numbers of spikes/stimulus from 1 to 10 (short durations) or 1 to 50 (long durations). The spike train responses so obtained were passed through an energy integrator (τ =200 ms) and various threshold output values were assumed. Values of stimulus intensities and durations were selected to produce a function which coincided with the psychophysically obtained curve and the average number of spikes per stimulus required at each datum noted. The shorter duration stimuli (10-100 ms) required roughly 3-5 spikes per stimulus. Longer durations required a greater number of impulses: 250 ms required 7-10 spikes; 600 ms required 19-23. Thus it is not the number of spikes per stimulus which produces a threshold response in the system: it is probably the number of spikes per time constants of the system. Based on the above values we tentatively conclude that for the P channel, the criterion is 4-8 spikes per one time constant. Supported by NS 23933.

REGENERATION: CHAMBERS AND GRAFTS

529.1

TIME-COURSE OF REGENERATION OF ADULT DORSAL ROOT AXONS INTO TRANSPLANTS OF FETAL SPINAL CORD (FSC). Y. Itoh, M. Kowada*and A. Tessler. Dept. of Neurosurg., Akita Univ. Sch. of Med., Akita 010, Japan, Philadelphia VA Med. Ctr., and Med. Coll. of Pennsylvania, Philadelphia, PA 19129.

We have shown that cut adult rat dorsal root ganglion (DRG) axons regenerate into transplants of FSC and form synapses there. The time course over which the innervation develops is unknown, and it is also unknown whether or not the regenerated DRG axons persist. Since calcitonin gene-related peptide (CGRP) is a marker for dorsal root axons, it is also a marker for regeneration. In this study we used CGRP immunocytochemistry to label regenerated axons in FSC transplants, and quantitative stereological methods to assess the time course and persistence of axon ingrowth.

Transplants of embryonic day (E)14 spinal cord were introduced into a cavity aspirated in the lumbar enlargement of adult Sprague-Dawley rats, and the L4 or L5 dorsal root was cut and juxtaposed to the graft. Sagittal cryostat sections were prepared for CGRP immunocytochemistry after survivals of 1day to >1year. Regenerated DRG axons are present within the transplants by 4 days po and begin to form dense bundles by 1 week. The area fraction of the transplant occupied by CGRP-labeled axons increases until 3 months, and then persists unchanged for >1year. DRG axons therefore may reach the FSC transplants before a glial barrier is established, grow for several months within the transplants, and establish an apparently permanent innervation. Transplants may provide a lasting restoration of damaged neural circuits. Supported by VA Medical Research Service, NIH grant NS24707, and USAMRDC grant 51930002.

529.2

ASTROCYTES MAY CONTRIBUTE TO REGENERATION OF DORSAL ROOT (DR) AXONS INTO FETAL CNS TRANSPLANTS. K. Kikuchi, P. Levitt and A. Tessler. Philadelphia VA Medical Center and Departments of Anatomy and Neurology, Medical College of Pennsylvania, Philadelphia, PA 19129.

Transplants of fetal spinal cord support or promote regeneration of severed adult DR axons and allow synapse formation. To analyze the components of the transplants that provide this favorable environment, we studied whether or not astrocytes could support dorsal root regeneration. We used calcitonin gene-related peptide (CGRP) immunocytochemistry to identify regenerated axons because in normal dorsal horn CGRP specifically labels a population of DR axons. Astrocytes were cultured from embryonic (E) day 14 or 18 spinal cord or E18 neocortex and labeled with rhodamine microspheres to distinguish them from host astrocytes. Harvested cells (1-6 x 10^5) were transplanted as part of a Matrigel mixture or plasma clot into a cavity aspirated in the L4 segment of adult female Sprague-Dawley rats. The L4 or L5 dorsal root was cut and juxtaposed to the transplant. One month later sagittal cryostat sections were processsed for Nissl-Myelin stain and CGRP immunocytochemistry. CGRP-labeled axons regenerated into all types of fetal astrocyte grafts, but were also identified in control transplants consisting of either Matrigel or plasma clot alone. These results indicate that dorsal roots regenerate in response to various environments and suggest that one common feature is the absence of inhibitory influences known to be present in the adult mammalian CNS. Supported by VA Medical Research Service, NIH-NS24707, and USAMRDC grant 51930002.

529.3

SMALL DIAMETER CARBON FILAMENTS IMPLANTED INTO THE TRANSECTED SPINAL CORD OF THE ADULT RAT SUPPORT AXONAL GROWTH AS DEMONSTRATED BY IMMUNOFLUORESCENT TECHNIQUES USING ANTI-NEUROFILAMENT ANTIBODY. M. Dauzvardis, T. Khan, S. Sayers*, R. Hauser*, G. Gaik, and K. Burket*. Neuro-Regeneration Lab., RR&D Center, VA Hospital, Hines, IL 60141.

Carbon filaments have been shown to support the growth of embryonic spinal cord in tissue culture (Khan, T. et al. Abstr. Soc. Neurosci. 11:586, 1985) and to function as a "scaffolding" for the growth of regenerating axons in spinalized rats (Dauzvardis, M. et al. Abstr. Soc. Neurosci. 15:876, 1989). The present study was undertaken to further characterize the cellular processes observed growing into carbon filament implants positioned into the transected spinal cord of the adult rat.

Fifteen 200g Wistar rats sustained total spinal cord transection at level T8-T9 with the use of a #11 scapel blade followed by withdrawal of fine wire hook through the transection site. In ten of these animals the resulting transection gap was then filled with a 5mm long bundle of approximately 10,000 carbon filaments of 4.0μ diameter. Five rats served as surgical controls.

After a six-week survival period cryostat cut sections from both groups of animals were examined for the presence of nerve fibers using an indirect immunofluorescence technique with anti-neurofilament as primary antibody and fluorescein-conjugated IgG as secondary antibody. In surgical control animals, sections taken through the transection site were virtually devoid of fluorescent label while sections taken thru carbon filament implants demonstrated the presence of many neurofilament-positive axons.

Although these findings do not address the origin or course of the neurofilament-positive axons, they do demonstrate that small diameter carbon filaments can support and direct the regrowth of damaged spinal pathways. Supported by funds from Veterans Affairs, Rehabilitation R&D Service, Rehab. R&D Grant B423R.

529.4

SOMATOSENSORY EVOKED POTENTIALS RECORDED ACROSS CARBON FILAMENTS IMPLANTED INTO THE SITE OF A COMPLETE SPINAL CORD TRANSECTION IN THE ADULT RAT. R Hauser*, T. Khan, S. Sayers*, M. Dauzvardis, and K. Burket*. Neuro-Regeneration Lab., RR&D Center, VA Hospital, Hines, IL 60141.

Carbon filaments have been shown to support the growth of embryonic spinal cord in tissue culture (Khan, T. et al. Abstr. Soc. Neurosci. 11:586, 1985) and to function as a "scaffolding" for the growth of regenerating axons in spinalized rats (Dauzvardis, M. et al. Abstr. Soc. Neurosci. 15:876, 1989). The present study was conducted to determine whether axons observed growing across a carbon fiber implant were capable of transmitting SSEP's across a transection site.

Fifteen 200g wistar rats sustained total spinal cord transection at level T8-T9 with the use of a #11 scapel blade. In six of these animals the resulting transection gap was then filled with a 5mm long bundle of approximately 10,000 carbon filaments of 4.0 diameter. Six rats served as surgical controls. Three rats, (in which the transection gap was filled with ordinary cotton) served as substrate controls.

Noninvasive SSEP's were elicited by applying a constant current anodal stimuli to the distal tail. SSEP's were recorded at the proximal tail, lumbar-sacral spine junction, thoracic spine (T9) and cervical spine (C6-7) at one week intervals. After a 6-week survival period, a final SSEP was recorded and the animals were studied histologically. No SSEP were recorded at any time across the transection site in the regular controls and the cotton controls. Three out of six animals with carbon filament implants were found to have SSEP's, at six weeks post surgery, across the transection site that were not present in earlier SSEP recordings.

Carbon filaments by providing a favorable adhesion surface and also a possible guilding function, may prove useful in the treatment of spinal cord injury. Funding: VA, Rehab. R&D Service, Rehab. R&D Grant #B423R.

IMMUNOCYTOCHEMICAL CHARACTERIZATION OF CNS AXONAL REGENERATION THROUGH TRANSPLANTS OF SCHWANN CELL/MATRIX CABLES. R.W. Cohen*, T. Goodglick* and L.F. Kromer, Dept. of Anatomy & Cell Biology, Georgetown University, Washington, DC 20007

Prior experiments demonstrated that forebrain cholinergic axons regenerate through transplants of selectively permeable polymer tubes (ARCs) containing dissociated Schwann cells in an extracellular matrix (ECM) cable. The present study further characterizes this regeneration by identifying specific axonal and glial proteins localized on cellular processes within the regeneration cables. For these experiments Schwann cells were dissociated from monolayer cultures obtained from neonatal rat sciatic nerve and then mixed with tumor-derived ECM. This material was allowed to form a cable within the ARC before transplantation to the lesioned septo-hippocampal pathway. After survival times of 4-28 days the following observations were made on immunocytochemically stained sections: Schwann cells consistently stained intensely for the low affinity receptor for nerve growth factor (NGFR) and usually stained for glial fibrillary acidic protein (GFAP), but rarely for S-100. Glial cells from the host CNS that migrated onto the ECM cables stained for GFAP and S-100 but not NGFR. Regenerating axons (stained for GAP-43 and L1) closely associated with the Schwann cells and appeared to fasciculate near them. Much less growth occurred on the ECM cables colonized by CNS glia which lacked NGFR or L1. These results are consistent with the hypothesis that growth factors and cell adhesion molecules help mediate CNS axonal growth *in vivo*. Supported by NIH grant NS23522 and the American Paralysis Assoc.

DO AXON-FREE NERVES LEAD TO THE FORMATION OF SCHWANN CELL-CABLES WITHIN SILICONE CHAMBERS ?. A. A. Zalewski, N. A. Azzam and L. R. Williams. Lab. of Neural Control, NINDS, NIH, Bethesda, MD 20892 and CNS Diseases Research (L.R.W.), The Upjohn Co., Kalamazoo, MI 49001

After suture of proximal and distal nerve stumps into the ends of a silicone tube, a tissue cable forms through which axons regenerate. Schwann cells are critical for this regenerative success. If the distal nerve stump is omitted or skin or tendon substituted, a fibrin matrix or granulation tissue develops in the tube but axons do not regenerate into it. In this study, we sought to determine whether axons were needed to induce the formation of a Schwann cell-containing cable. The transected stumps of rat sciatic nerves were sutured into silicone chambers prefilled with dialyzed plasma, leaving a 10-mm interstump gap. In order to eliminate axons from entering the chamber, the proximal nerve was further transected, ligated and reflected, leaving a 2-mm plug of nerve in the proximal chamber. After four weeks a cable was visible that extended the length of the silicone chamber. Light microscopy revealed the presence of blood vessels and cellular elements, but the absence of myelin. Electron microscopy demonstrated the presence of Schwann cells and fibroblasts. Surprisingly, some Schwann cells were seen surrounding unmyelinated axons. These axon-associated Schwann cells developed a basement membrane whereas those free of axons did not. The blood- and perineurial-nerve barriers did not form in these cables since the barrier-tracer HRP flooded them after an IV injection. In other animals bearing a four-week cable, the reflected nerve stump was re-attached to the nerve plug in the proximal end of the chamber. Three months later, the cable and the distal nerve were filled with myelinated axons, and the perineurial, but not the blood, barrier was restored. We uncovered a source of non-myelinated axons from the distal nerve stump that needs to be eliminated to determine if axon-free tissue can form a Schwann cell-cable. Nevertheless, a cable did form that was capable of attracting axons from a re-anastomosed proximal nerve stump. A cable formed by our surgical method has the potential to be used clinically for delayed nerve repair.

529.7

CHARACTERIZATION OF RAT SPINAL CORD CHANGES FOLLOWING PHOTOCHEMICALLY-INDUCED INJURY.
A.T. Salvatierra, V.R. Holets and M.B. Bunge The Miami Project and Departments of Neurological Surgery and Cell Biology and Anatomy, University of Miami School of Medicine, Miami, FL 33136.

A model of spinal cord injury in rats was developed using a dye laser in combination with injected Rose Bengal (Prado et al., J. Neurosurg. 67:745, '87). We are characterizing this lesion prefatory to transplantation studies. A central cyst develops with regions of the lateral and ventral white matter and ventral horns remaining intact. Light and electron microscopic evaluation of lesioned spinal cords was done at 2, 5, 14, 28 and 56 d, and 4 and 6 mo post-lesioning. At 14 d, demyelination and beginning remyelination were evident outside the border of the cyst. The cystic cavity contained macrophages that were less numerous by 28 d. Also at 28 d, numerous thin myelin sheaths of both oligodendrocyte and Schwann cell origin were visible; they occurred side by side. Nonmyelinated axons were still observed. Astrocytic processes formed an intermittent border around the perimeter of the cyst. At 56 d the edema and tissue debris inside the cyst had been largely resolved, resulting in a shrunken dorsal cord and an area of ventral white matter that appeared larger than would be expected. Some Schwann cells related to axons were positioned in perivascular spaces. A surprisingly large number of axons myelinated by Schwann cells were seen in more dorsal regions, suggesting the possibility of considerable axonal regrowth with increasing time post-lesion.

529.8

AXON GROWTH INTO IMPLANTS OF SCHWANN CELLS PLACED IN LESIONED SPINAL CORD **C.L. Paino and M.B. Bunge The Miami Project to Cure Paralysis and Depts. of Neurol. Surg. and Cell Biology & Anatomy, University of Miami School of Medicine, Miami, FL 33136.**

Richardson and coworkers (Nature 284, '80) found that CNS axons regrew into segments of peripheral nerve implanted into the spinal cord but Kuhlengel et al. (J. Comp Neurol. 293, '90) found no axonal ingrowth into implants containing sensory neurons as well as Schwann cells (SCs). Here we test whether orphaned SCs raised in culture elicit axon ingrowth from lesioned cord tissue. SCs were allowed to ensheathe and myelinate parallel arrays of axons from dorsal root ganglion neurons in culture. Bands of longitudinally oriented SCs within basal lamina tubes were created by severing the fascicles. After undergoing Wallerian degeneration for 4 d, the collagen substratum supporting these bands of Büngner was rolled to form an implant. Rolls of collagen seeded with dissociated SCs or with no cells were also tested. Adult female rats (170-200 g) were lesioned photochemically by irradiating the spinal cord through the T9 lamina with a laser beam of 562 nm after the i.v. application of Rose Bengal. This procedure reliably causes a cystic lesion affecting the dorsal 2/3 of the spinal cord at the epicenter, and extending 4-6 mm rostrocaudally. Five or 28 days after lesioning, implants were placed into cyst cavities where they remained for 14, 28 or 90 days. Light microscopy of the spinal cords revealed good graft-host integration with a highly vascularized interface, minimal astrocytic scarring, and numerous SCs. Electron microscopy confirmed the survival of SCs and the presence of both myelinated and unmyelinated axons within the implant after 14 days. We conclude that SC implants devoid of neurons provide a more effective bridge for axonal ingrowth. (Supported by The Miami Project and the Spanish Ministry of Education.)

529.9

A COMPARISON OF DORSAL AND VENTRAL SPINAL ROOT REGENERATION M.L. McCormack, M. Goddard*, V. Guénard, and P. Aebischer. Section of Artificial Organs, Biomaterials, and Cellular Technology, Brown University, Providence, RI 02912

Semipermeable guidance channels were used to compare dorsal and ventral root regeneration across 4 mm and 10 mm gaps. Acrylic copolymer hollow fibers with a molecular weight cutoff of 50 kDa were used in a transected rat spinal root model. The 4 mm gap group was examined at 4, 10, and 24 weeks post-implantation and the 10 mm gap group was analyzed at 4 weeks post-implantation. Regeneration was assessed by quantifying the number of myelinated axons, unmyelinated axons (24 weeks only), and the endoneurial and connective tissue components of the cable cross sectional area. Both the dorsal and ventral roots regenerated across the 4 mm gap at all time periods. However, at all times the regenerated dorsal roots contained fewer myelinated axons than found in the contralateral control roots and featured an abundance of connective tissue. In contrast, by 10 weeks the regenerated ventral root contained twice the number of myelinated axons observed in the contralateral root and was composed predominantly of large, myelinated axons. DRG neuronal cell loss due to the dorsal root lesion was examined at 4 weeks post-implantation and found to be consistent with the loss documented after peripheral axotomy. Only granulation tissue devoid of myelinated axons bridged the 10 mm gap in both the dorsal and ventral roots. This study reports a difference in the regenerative capacities of dorsal and ventral roots and suggests that the environment within the semipermeable guidance channels is not sufficient for the repair of large deficit spinal root injuries. Studies involving modifications of the regenerative environment using glial cells are underway in an attempt to elucidate the factors involved in spinal root regeneration.

529.10

PERIPHERAL NERVE SEGMENTS PROVIDE A MATRIX FOR AXONAL OUTGROWTH OF AXOTOMIZED BASAL FOREBRAIN CHOLINERGIC AND ANTERIOR THALAMIC NEURONS. R.E. Clatterbuck, V.E. Koliatsos and D.L. Price. Neuropathology Laboratory, The Johns Hopkins University School of Medicine, Baltimore, MD 21205.

Fimbria-fornix resection and cingulectomy were used to remove distal axons of basal forebrain cholinergic neurons projecting to hippocampus and anterior thalamic neurons projecting to cingulate and retrosplenial cortices. Immediately following the lesion, segments of tibial nerve were apposed to the proximal stump of the fornix or cingulate bundle. Subsequently, distal ends were either externalized and placed on the parietal bone of the opposite hemisphere or connected with hippocampus or cortex. After a three-month survival, retrograde tracing from distal ends of grafts and anterograde tracing from the septum or anterior thalamus were used to study axonal regeneration within grafts. Examination of sections through basal forebrain, hippocampus, cortex, and thalamus showed that axotomized medial septal cholinergic and anterior thalamic neurons extended new axons into grafts and that these responses were associated with extended survival of axotomized neurons. To date, in survival times examined, regeneration of axons of basal forebrain and thalamic neurons do not appear to result in effective reinnervation of natural targets.

TRANSPLANTATION: EXPRESSION OF SPECIFIC NEURONAL MARKERS

530.1

IMMUNOHISTOCHEMISTRY OF HUMAN EMBRYONIC RETINA TRANSPLANTED TO ADULT RAT RETINA. [1] M. Seiler, [1] R. Aramant, [2] B. Ehinger, [2] A. Bergström* and [1] A.R. Adolph. [1] Eye Research Inst., Boston, MA 02114; [2] Dept. of Ophthalmology, Univ. of Lund, Sweden.

Human embryonic retinas (postconceptional age 3-10 wks) were grafted to the retina of immunosuppressed adult rat hosts. The donor tissue became rearranged in folded sheets or rosettes. The development of the xenografts was followed from 19 to 37 wks of total age. Immunohistochemistry was performed on Bouin's fixed paraffin sections with monoclonal antibodies for Vimentin (clone V9), S-antigen (A9-C6; gift of L.A. Donoso, Philadelphia, PA) and α-transducin (TF15; gift of B.K.-K. Fung, Los Angeles, CA). **Vimentin** stained some glial cells in the inner plexiform layer and the vitreal surface of the grafts in the earliest stages studied (19 wks). Clear staining of radial fibers and endfeet of Müller cells inside the graft was first seen at 28 wks total age. An inner limiting membrane was present inside the graft but not on the vitreal surface. At 31 and 37 wks, some horizontal cell processes and phagocytotic cells inside rosettes were stained. Both rods and cones were immunoreactive for **S-antigen**. The first staining of photoreceptors, mostly cones and some rods, with inner and occasionally outer segments was observed at 20 wks total age. At 31 wks, rods were more differentiated, showing S-antigen-positive inner and outer segments. In some darkly stained rosettes, cones were not immunoreactive. Different staining intensities of graft rosettes indicated areas of different maturation in the grafts. Similar results were obtained with the antibody for **α-transducin**. In the grafts, the first faint α-transducin immunoreactivity of inner segments and of some cell bodies was seen at 20 weeks. At 31 weeks, photoreceptor inner and outer segments were more intensively stained; cone cell bodies appeared to be mostly unstained, whereas rod cell bodies were lightly stained. This study shows that human embryonic retina transplanted to adult rat retina develops different cell types, contains proteins necessary for processing light, and can reach a degree of maturity comparable to newborn retina.

530.2

TRANSPLANTED NEURAL RETINA EXPRESSES ANTIGEN SPECIFIC FOR NORMAL DORSAL RETINA K. T. Yee and R. D. Lund Department of Neurobiology, Anatomy and Cell Science, School of Medicine, University of Pittsburgh, Pittsburgh, PA 15261

We have previously shown that embryonic mouse retinae transplanted into brains of newborn rats project to appropriate visual target regions and make functional connections. To examine the development of connectivity in more detail, we have used a mouse monoclonal antibody specific for dorsal retina (Dolce) which recognizes a 68kd-laminin receptor during the latter part of embryonic development through early postnatal life (Dräger, et al., Neurosci. Abs. 15:456, 1989). Staining with this antibody is optimal between embryonic day 13-14 but can be seen at diminished levels up to postnatal day 13. In this current study, we have examined if mouse retinae transplanted into the brains of rat hosts express this antigen.

Donor embryonic CD-1 mouse retinae were transplanted into the brains of neonatal Sprague-Dawley rats. Following survival periods of at least 5 days, animals were perfused and fixed for light microscopsy. Brains were sectioned and incubated in Dolce with 0.3% Triton. Antibody binding was visualized with an HRP conjugated secondary antibody and a diaminobenzidine nickel intensification reaction.

Our data show staining of cells in a localized region of the transplanted retinas as well as axons emerging from the transplants. This ocurrs even when the transplants are highly folded. While there can be changes in the overall anatomical conformation of the retina, staining with Dolce is still seen. This data provides further evidence that transplanted retinae develop characteristics of normal retinae.

VARIATIONS IN PERIVASCULAR LAMININ IMMUNOREACTIVITY DURING BRAIN ANGIOGENESIS. J.M. Krum and J.M. Rosenstein. Dept. of Anatomy, George Washington University Medical Center, Washington, D.C. 20037.

Changes in the distribution and quantity of laminin within the basement membranes (BM) of rat CNS vasculature during vascularization of fetal neocortical grafts, wound healing and perinatal development were investigated using two immunocytochemical techniques. In paraffin sections, which were routinely enzyme pre-treated, all vessels reacted with antilaminin; those at graft or wound sites in adult brains were the most intensely stained. In immunoprocessed 40μ vibratome sections of normal adult brains, only the meninges and vasculature of circumventricular organs were stained; CNS parenchymal vessels reacted only if the sections were enzymatically pre-treated. In contrast, the nascent vasculature in developing brain and the regenerating vessels at transplant and wound sites were strongly immunoreactive without enzymatic pretreatment. Electron microscopic examination revealed that laminin immunoreactivity decreased after perivascular astroglial contact occurred. The existence of a variant form of laminin, differences in vascular BM structure or differences in neuropil density between developing or injured and intact adult brains might account for these observations. (NIH-NS-17468)

CALBINDIN D-28K IN EMBRYONIC BASAL FOREBRAIN GRAFTS TO ADULT RATS. S.Shoham and E.Wertman*, Dept. Neurogeriatric Research, Sara Herzog Hospital, Jerusalem 91001, Israel.

In Alzheimer's disease (AD) there is substantial reduction in the number and size of cells containing the calcium binding protein calbindin D-28K (CB) in cortex and in nucleus basalis of Meynert (nbM) (Ichimiya Y. et al., Brain Res., 475:156, 1988). To explore relation of CB cells to the cholinergic nbM-cortical system which also degenerates in AD, adult rats received ibotenate damage to nbM and then grafts of embryonic rat E16 basal forebrain (the primordial nbM), to cortex (methods of Fine et al., Neuroscience 16:769, 1985). After 3-8 months CB neurons were identified immunohistochemically and cholinergic regions by acetylcholinesterase (AChE) histochemistry (7 rats, 14 grafts) in 25um thick sections. There were 37±5 CB cells/mm^2 in graft AChE patches, significantly more (paired t-tests) compared to 17±4 CB cells/mm^2 in AChE-negative graft regions, and to 4±1 CB cells/mm^2 in the areas of the host deep cortex and corpus callosum where grafts were placed. Some CB-neurons in AChE patches extended axons into the host cortex. This is preliminary evidence that CB-neurons of nbM are part of the cholinergic nbM-cortical system and that CB is expressed in nbM neurons even without their normal afferent inputs from amygdala, striatum and other regions.

530.5

DEVELOPMENT OF SYNAPSIN I AND SYNAPSIN II IN INTRAOCULAR HIPPOCAMPAL TRANSPLANTS. A-Ch Granholm[1], E. M. Dudek[2], H. Bergman*[1], and M. Browning[2]. [1]Department of Cell Biology, Univ. of Linköping Fac. Health Sci, Linköping, Sweden, and [2]Department of Pharmacology, Univ. of Colorado Health Sci. Ctr., Denver, Colorado. Synapsin I and II are synaptic vesicle-associated neuronal phosphoproteins that are thought to play a role in the regulation of neurotransmitter release. The levels of these proteins are low in cortical regions of newborn rats but exhibit a dramatic increase postnatally, parallel to synaptogenesis. The aims of the present study were to evaluate whether hippocampal grafts would follow a normal time course of synapsin development. Hippocampal tissue was dissected from rat fetuses of embryonic day 18 and transplanted to the anterior chamber of the eye of adult hosts. Grafts and *in situ* tissue was homogenized in 1% SDS-solution or fixed and sectioned on a cryostat for immunohistochemistry. The levels of synapsin I and II were assayed by immuno-blot methods. The following time periods were used: fetal day 18, birth, 1, 2, 4 and 8 weeks postnatally. The transplants developed levels of synapsin close to the *in situ* levels, with no obvious delay due to transplantation. The ratio of synapsin I and II reflected a CNS rather than a PNS ratio. The histological analysis showed a similar development, with accumulations of synapsin-positive profiles adjacent to the pyramidal cell layer. Synapsin levels in aged transplants are under investigation. In conclusion, these studies demonstrate biochemical evidence of a close to normal development of isolated hippocampal formation transplants *in oculo*. TRANSPLANTS OF MIGRATORY GNRH CELLS INTO THE BRAIN ARE CAPABLE OF INDUCING GONADAL RECOVERY IN HYPOGONADAL (HPG) MICE. I. Livne, M. J. Gibson and A. J. Silverman. Dept. of Medicine, Mount Sinai Sch. of Med., New York, N. Y., 10029 & Dept. of Anat. Cell Biol., Columbia Univ., New York, N. Y. 10032.

GnRH neurons are derived from the olfactory placode and migrate into the CNS during embryogenesis. In this study we examined the capability of transplants containing this migratory population of GnRH cells to establish functional connections with the median eminence (ME), and hence to induce gonadal recovery in mutant hpg mice. Nasal area tissue from normal mouse embryos at E12 or E13 was grafted bilaterally into the anterior hypothalamus or preoptic area of adult hpg males (n=9). Following survival of 2 to 8 weeks the animals were perfused, their testes weight recorded, and the brains processed for GnRH immunocytochemistry. In 4 animals the grafts proliferated across the midline, with some tissue entering the third ventricle. Of these, L28 showed gonadal recovery (testes weight of 23.6 mg, mean weight of untreated hpg testes: 7.5 mg). This recovery corresponded to the presence of a small number of GnRH cells in the graft and a sparse innervation of the ME. L20 had a much more robust ME innervation but due to early sacrifice (20d) gonadal recovery was not yet evident. In those animals where the graft remained wholly within the parenchyma, testicular recovery did not occur. However interesting observations were made. In N31 GnRH cells appeared to migrate out of the graft into the host and these cells elaborated long bifurcating axons some of which coursed medially in the direction of the third ventricle. In L30 migration of cells into the host was less clear cut, but again GnRH axons grew toward midline and then headed ventrally to the ME. These observations suggest that migratory GnRH neurons when grafted into the brain of adult hpg mice retain some migratory potential and can elaborate extensive axonal projections, which upon innervation of the ME can induce gonadal recovery. PINEAL GLAND TRANSPLANTS INTO THE CEREBRAL HEMISPHERE OF NEWBORN RATS REVERSE THE EFFECTS OF PINEALECTOMY ON SERUM MELATONIN LEVELS. J.A. McNulty, R. Swenson, R.J. Handa, T. Hogan*, P.L. Shaw*, B.S. Klausen*, L.Kus, A.J. Castro. Department of Cell Biology, Neurobiology and Anatomy., Loyola University, Maywood, IL 60153

The functional activity of neonatal pineal glands grafted into the cerebral hemisphere of littermate rats (0-1 day old, Long Evans, black-hooded) was tested in 4 groups: unoperated controls (C; n=7); pinealectomized rats (PX; n=6); pineal transplants (PT; n=6); and pineal transplants that had been pinealectomized (PT+PX; n=7). Using hypothermic anesthesia, pineal glands were placed into small cortical lesion cavities made rostral to bregma immediately before grafting. At 4-5 months, rats were chronically cannulated and serum melatonin levels measured by RIA (CIDTech) during the light and dark period of the 24-h L:D cycle (10 h L: 14 h D). A significant nocturnal decline in melatonin was observed between C vs PX ($p<0.05$), but not between C vs PT and C vs PT+PX. These findings indicate that pineal transplants were functionally capable of restoring nocturnal levels of serum melatonin. Elevated daytime melatonin levels in the PT+PX group suggests that some transplants may have been free-running.

IMPLANTATION OF FETAL BASAL FOREBRAIN CELLS INTO CAUDATE OR NUCLEUS BASALIS AFTER LESION OF THE RAT NUCLEUS BASALIS: A NEUROANATOMICAL STUDY. L.Lescaudron, R.L.Sutton and D.G.Stein. Brain Research Lab.,Rutgers Univ.,Newark,NJ 07102.

The effects of delay (8-17 d) between lesion and transplant (TP) and delay (1-4.5 h) between harvest and TP of fetal (E15-E17) cholinergic cells into the lesion site or the caudate n. (CN) were examined in 16 rats with ibotenic acid lesion of the left n. basalis magnocellularis (NBM). Brains were processed for cresyl violet, ChAT- and GFAP-ICC, and for AChE and cytochrome oxidase (CO) 2 months after TP. Survival was always poor in the CN, with small, immature TP-cells, extensive gliosis, and low levels of CO activity. In the NBM, the best TP survival was observed for fetal cells implanted less than 2h after harvesting and 14-17d postlesion. In these cases large, healthy TP-neurons displayed robust CO activity. Also an intense cholinergic innervation was observed within these TPs, with TP-cholinergic neurons sending processes throughout the TP. A small astrocytic reaction was noticed within TPs and at the host-TP interface. In about 1/3 of the TPs, a Status Marmoratus-like profile was noted. The effects of TPs on the host tissue will also be presented.

GAP-43 IMMUNOREACTIVITY DURING THE DEVELOPMENT OF TRANSPLANTED FETAL MESENCEPHALIC NEURONS. G.H.Clayton, T.J.Mahalik, T.E.Finger. *Dept. Cell. & Struct. Biol.; UCHSC; Denver, CO 80262*

GAP-43 is a neuron-specific phosphoprotein which is differentially regulated during normal development. High levels of this protein are correlated with axonal elongation in-vitro, regeneration in-vivo, and highly plastic neural structures such as the hippocampus and olfactory bulb. Work in our laboratory shows that in the developing rat nigrostriatal pathway GAP-43 immunoreactivity is highest during the 6 day period E15 until birth at which time it declines rapidly to adult levels. This time course corresponds with the period of axonal extension for the majority of the substantia nigra dopaminergic neurons. In the present study we use an antibody against GAP-43 to characterize the time course of development of transplanted fetal mesencephalic neurons. For these experiments 6OHDA lesions of the nigrostriatal tract were made in Sprague Dawley rats. Adequacy of the lesion was determined by apomorphine-induced rotation prior to the transplantation of pieces of ventral mesencephalon (VM) obtained from E15 fetuses. Immunocytochemistry revealed high levels of GAP-43 at 5, 11 and 15 days post transplant but lower levels at 3 weeks. By 13 weeks the immunoreactivity present within the transplant tissue is equivalent to normal background levels within the host neuropil. Thus, the presence of high levels of GAP-43 immunoreactivity is prolonged compared to the developing VM in situ. This suggests that axon elongation occurs over a longer period in VM grafts than in situ. Such retarded graft development could be the result of a number of different phenomena such as: surviving cells whose processes were sheared off during surgery may reinitiate axonal elongation; the altered environment of the host may not contain trophic factors in sufficient quantities to support rapid growth; or a lack of normal targets for grafted neurons may extend their growth period in a search for alternatives.

NUCLEAR MAGNETIC RESONANCE (NMR) IMAGING OF FETAL BRAIN GRAFTS N. HAWRYLAK, P. GHOSH, J. BROADUS, W.T. GREENOUGH and P.C. LAUTERBUR Beckman Inst., Neurosci. Prog., Dept. Psych., & Biomed. Magnetic Resonance Lab., Coll.of Med., Univ. of Illinois, Urbana 61801

Progress in neural transplantation would be aided by improved monitoring of the fate of donor tissue. We are developing techniques for in vivo nuclear magnetic resonance (NMR) imaging of grafted neural tissue.

Fetal rat (E17-E18) posterior neocortex was employed in grafting studies by two methods: (a) **Neonatal** (P0-P1) host rats had fetal tissue fragments grafted into posterior cortex. (b) **Adult** (P150) host rats received grafts as dissociated cell suspensions, labeled with iron oxide particles using reconstituted Sendai viral envelopes. NMR imaging of the adult and neonatal hosts was performed on post-transplantation days 10 and 120 respectively. Histochemistry (Prussian blue test for ferric iron) and immunohistochemistry (GFAP) of host brains were performed on 30μ thick adjacent sections.

In the NMR images of intact perfusion-fixed neonatal host brains (excitation slice thickness=700μ; pixel= 60μ x 60μ; TE=55ms; TR=4s), the tissue fragment grafts appear equivalent to the surrounding cortical structures but bright with respect to the immediately adjacent white matter.

Images (excitation slice thickness=700μ; pixel=150μ x 150μ; TE=30ms; TR=4s) of the brain of adult hosts, both in vivo and after fixation, showed dark regions . Light microscropy of these regions demonstrated iron oxide positive cells of probable donor origin. The iron oxide appeared as a dark blue precipitate within soma and proximal processes, suggesting good short term survival of the donor cells. The exact location of the exogenous iron and the possible gliotic response within the host tissue are currently being investigated. Supported by ONR N00014-89-J-1556

TRANSMISSION ELECTRON MICROSCOPY OF WHOLE FETAL HIPPOCAMPAL TRANSPLANTS INTO LESION CAVITIES. R. H. Baisden and M. L. Woodruff. Dept. of Anatomy, East Tenn. St. Univ., J. H. Quillen Coll. of Med., Johnson City, TN 37614

Implants of fetal hippocampus were placed into aspiration cavities in adult rat brains. After 45 days the animals were killed and perfused with Karnovsky's fixative and processed for electron microscopy. Elements typical of the matured hippocampus were observed. These included small and large neurons, glial cells, and a typical neuropil including axon bundles, dendritic fields, and regions of high synaptic density. A group of small multipolar cells were found. These cells showed a very pale cytoplasm with prominent mitochondria, lysosomal bodies and bundles of filaments scattered throughout the cytoplasm. Many of these cells appeared multinucleated. Macrophages were also found within the transplants. The surfaces of the transplants were covered with ciliated and nonciliated ependyma or were bounded by an external membrane. In many areas bundles of processes exited the neuropil onto the surface of the transplant. Some of these processes contained vesicles typical of axons. Supraependymal cells could be found. Some of these had characteristics of neurons; some of glia; and some appeared to be macrophages. (Supported by a grant from the NIH (ES04070-04) to MLW.)

ULTRASTRUCTURAL CHARACTERISTICS OF FETAL SUPRACHIASMATIC NUCLEUS TRANSPLANTS IN LATERAL AND THIRD VENTRICLES AND IN CULTURE. U. Vaidya and R. Y. Moore. Dept. of Neurology , SUNY, Stony Brook N.Y. 11794

Fetal suprachiasmatic nucleus (SCN) transplants have been shown to restore circadian rhythmicity in SCN lesioned hosts if the transplants are located in the thrid, but not the lateral ventricle. In the present study, SCN transplants in each location and in culture were examined to detect any site specific differences in development. Female Sprague-Dawley host rats received 2 to 3-1 mm^3 pieces of SCN from E16 donor fetuses injected unilaterally into the lateral ventricle. Explants of 200 u slices of SCN from the same set of donors were placed in culture. Hosts with transplants were allowed to survive for 30 days, while cultrues were examined at 2 or 4 weeks after explanting. Sections of brains from host animals were processed for VIP immunocytochemistry and electron microscopy. Cultures were fixed *in situ* and processed similarly. In all host animals, transplants developed in the lateral ventricle and at least one piece of transplanted tissue developed in the third ventricle. Infrequent discontinuities in the ependymal lining allowed direct contact between the host and transplant and the passage of axons. The degree of appostion of the transplant to the host brain was greater in the third ventricle. Transplants in both locations and explants in culture had VIP positive neurons, and in the neuropil, myelinated and unmyelinated axons, and synapses. Blood vessels were also seen in transplants. The organization of neuropil in cultured explants was less complex than transplants in hosts. The results suggest that SCN transplants into the lateral and third ventrilcle have a similar organization and development. The greater degree of host-transplant apposition in the third ventricle was the only notable site-related difference.

LONG TERM IDENTIFICATION OF TRANSPLANTED RODS. P. Gouras, J. Du*, R. Kwun*, R. Lopez*, H. Kjeldbye*. Columbia University Department of Ophthalmology, 630 W. 168 St. New York 10032

Rat rods in mitosis (at least 50%) can be radiolabeled by administering ^{3}H-thymidine subcutaneously to newborn rats. At 1-2 months of age these rods are isolated enzymatically from the retina, mixed with dissociated retinal pigmented epithelial cells from non-labeled donors and transplanted to the subretinal space of 4-5 month old congenic albinotic dystrophic RCS rats. At this time the dystrophic rat has virtually no rods. The transplant site is identifiable by the speckling of pigmented epithelium in the albinotic retina observable both ophthalmoscopically and histologically. Examination of the host retinas after transplantation reveals the unequivocal nuclear stain of tritiated thymidine in these transplanted rods at three months (longest time) after transplantation. Electronmicroscopy reveals that these rods can have spherules and abortive outer segments, the former containing synaptic vesicles, ribbons and forming synaptic complexes. The postsynaptic cells are presumably host because they are neither rods nor pigmented epithelial cells.

531.5

ADRENAL MEDULLA SURVIVES FOR LONG TIME PERIODS AND PREVENTS DEGENERATION OF THE SUBSTANTIA NIGRA WHEN CO-GRAFTED IN THE PNS. L.C. Doering and M.A. Tokiwa*. Department of Biomedical Sciences (Anatomy), McMaster University, Hamilton, Ontario, CANADA L8N 3Z5.

Grafts of fetal substantia nigra (SN) undergo a series of degenerative changes when transplanted into the peripheral nervous system (PNS). This study was performed to determine if the adrenal medulla (AM) could prevent the death of SN neurons when combined in the PNS.

The sciatic nerves of Lewis rats (180-200g) received single embryonic day 15 SN grafts or co-grafts of SN plus young adult AM. Transplants were examined after one year by immunohistochemistry with antibodies against tyrosine hydroxylase (TH), the rat nerve growth factor receptor (192-IgG), phosphorylated (RT97) and non-phosphorylated (SMI-32) neurofilament proteins.

Single nigral grafts were shrunken, contained only a few TH positive cells and displayed abnormal patterns of RT97 and SMI-32 immunoreactivity. In contrast, when combined with the AM the loss of TH neurons was prevented and the SN did not show the aberrant cytoskeletal changes. Furthermore, all AM grafts were viable after one year in the peripheral nerves and consisted of hundreds of chromaffin cells identified by expression of the TH and 192-IgG epitopes.

These experiments illustrate that the PNS can support grafts of AM for up to one year and the AM can offset the degeneration of SN neurons when co-grafted under the present experimental conditions. (Supported by The Parkinson Foundation of Canada)

INFLUENCE OF AFFERENT INPUT ON SURVIVAL OF FETAL NEURAL TRANSPLANTS INTO A HOST TARGET. J.H. McLean and A.H. Darby*. Div. of Basic Medical Sciences, Memorial Univ. of Newfoundland, St. John's, Nfld., Canada, A1B 3V6.

In Alzheimer's disease, several regions of the brain degenerate, including cortical structures such as the olfactory bulb and several afferent inputs to cortices. One means of providing replenishment of depleted pathways in the brain is to provide the brain with trophic and/or neural transplants. In these experiments, we have transplanted fetal rat (E15-E17) cholinergic and serotonergic neurons from the diagonal band and raphe nuclei, respectively, into olfactory bulbs of adult rats that have been previously depleted of cholinergic (ibotenic acid into diagonal band) or serotonergic (5,7-dHT into anterior olfactory nucleus) afferent inputs. The contralateral olfactory bulb and non-depleted animals served as control for influence of afferent inputs/trophic substances on transplant survival. Following survival of 4 to 8 weeks, the animals were sacrificed by perfusion and the olfactory bulbs were cut frozen at 30 μm. The sections were analyzed by immunocytochemistry and AchE histochemistry to determine the location and degree of integration of transplanted cells into the host brain. Cholinergic and serotonergic neurons generally exhibited good survival and integration into the host olfactory bulb. Transplanted cholinergic neurons on the side ipsilateral to cholinergic depletion and serotonergic neurons on the side ipsilateral to serotonin depletion survived better than transplanted cells on the contralateral side. In addition, transplanted neurons appeared to survive less well in animals that had not previously been depleted of afferent input to the bulb. These results suggest that trophic substance released in the target as a result of afferent depletion increased the survival of transplanted cells and the trophic effect may not be limited to the side of the brain that was previously depleted of transmitter. This work was supported by the American Health Assistance Foundation and MRC of Canada.

AUTORADIOGRAPHIC STUDY OF FETAL STRIATAL GRAFTS PLACED IN HOST STRIATUM PULSE-LABELED WITH [^{3}H]-THYMIDINE. F.-C. Liu, A.M. Graybiel and S.B. Dunnett, Dept. Brain and Cognitive Sci., MIT, Cambridge, MA, USA, and Dept. Exp. Psychology, Univ. of Cambridge, Cambridge, UK.

A fundamental issue in assessing fetal striatal grafts is whether the resulting graft, which is usually surrounded by a ring of gliotic tissue and fibers, contains cells that migrated from the host striatum. In the present study, we pulse-labeled host striatal cells with [^{3}H]-thymidine to test for possible spatial interactions between host and donor cells in the zones of intrastriatal grafting. Three groups of host rats were pulse-labeled with [^{3}H]-thymidine at embryonic days E12-E15 or E12 and E15-E18 or E12 and E16-E19, and were allowed to reach maturity. One week prior to grafting, ibotenic acid-induced lesions were made unilaterally in the host striatum. At grafting, dissociated cells from E15 rat striatal primordia were injected bilaterally into the host caudoputamen. Tissue was processed for autoradiography 8-9 months postgrafting. Despite the presence of many intensely-labeled cells in the host striatum of rats in all three groups, very few intensely-labeled cells were found in the cores of grafts either in the ibotenate-treated or in the intact host striatum. A few weakly-labeled small cells appeared in the graft cores, and a few strongly- or weakly-labeled cells appeared at the margins of the graft zones. Some perivascular cells associated with blood vessels in the grafts were also weakly labeled, but the gliotic tissue surrounding the graft zones was not labeled. These results suggest that few striatal cells migrate into the cores of graft zones, or that, if they do, such cells do not survive. At most, a few surviving host striatal cells have limited spatial interactions with donor cells at the margins of the grafts, both in the damaged and intact host striatal environment. These observations, combined with our previous finding that [^{3}H]-thymidine-labeled cells derived from E15 striatal primordia do not appear in the host striatum, indicate that no extensive mutual migration between striatal donor neurons and host neurons occurs in the zones of grafting. Supported by NSF BNS 8720475 and NATO grant RG.85/0180.

A PARTIALLY PURIFIED MUSCLE FACTOR INDUCES CATECHOLAMINE DIFFERENTIATION IN THE LESIONED AND GRAFTED RODENT BRAIN L. Iacovitti and J. E. Springer, Institute for Neuroscience, Dept. of Neurology, Hahnemann University Philadelphia, Pa. 19102

Our previous studies have demonstrated that a partially purified muscle factor called MDF induces novel expression of the catecholamine (CA) enzyme tyrosine hydroxylase (TH) in cultures of embryonic caudate nucleus (CN) and greatly amplifies TH expression in the CA neurons of cultured substantia nigra. In the present study, we examined whether MDF retains biological activity in vivo by testing its ability to 1) induce TH expression in embryonic CN neurons transplanted into the lesioned adult brain and 2) affect TH expression in CA fibers originating from the host substantia nigra. The CN of adult Sprague-Dawley rats was partially denervated after unilateral injections of the 6-hydroxydopamine into the substantia nigra. Lesions were verified by monitoring rotational behavior after amphetamine challenge (5mg/kg). Ten-14 days after the lesion, a suspension of $3x10^5$ CN cells from embryonic rats (E15) was transplanted into the denervated adult CN. Rats were simultaneously implanted with an indwelling canula placed immmediately adjacent to the transplant and connected to a mini-osmotic pump containing either partially purified MDF or PBS (control). Test solutions were delivered at a rate of 1ul/hr for a total of 72-168 hrs. To examine the effects of MDF on local CA fibers in the CN, some rats were infused with MDF but did not receive CN transplants. Brains were then processed for the immunocytochemical localization of TH. In MDF-treated rats, those transplanted CN neurons that became well integrated into the brain parenchyma were TH immunoreactive, and extended long neuritic processes into the host CN. In MDF-treated rats which did not receive a CN transplant, an extensive network of host TH fibers with swollen endings was observed adjacent to the infusion site. These findings suggest that MDF retains its biological activity in the adult brain, capable of both inducing CA differentiation in transplanted embryonic CN neurons and increasing TH expression in local CA fibers from the host adult brain. Supported by NIH NS 24204-01A2.

FETAL LIVER AND MUSCLE GRAFTS DO NOT PROTECT AGAINST QUINOLINIC ACID STRIATAL LESIONS. M. Levivier[1], A.A. Hurrell*[1], S.H. Pearlman[2], D.M. Gash[2] and J. Brotchi*[1]. Dept. Neurosurgery, Erasme Hospital, Universite Libre de Bruxelles, Brussels, Belgium[1] and Dept. Neurobiology and Anatomy, University of Rochester, Rochester, NY 14642[2].

We have recently reported that fetal striatal grafts in the adult rat striatum protect the host against the damages produced by a subsequent local injection of quinolinic acid (QA) (Levivier, M. et. al., *Soc. Neurosci. Abstr.*, 15:1355, 1989). One of the mechanisms of this protective effect could be a specific trophic effect generated by the fetal striatum.

In order to confirm the tissue specificity of this phenomenon, our group has begun to study grafts of various types of tissue. In the present experiment, we tested the effect of transplants of embryonic non-neuronal tissues known to have trophic activity. Using the same experimental paradigm, i.e. two unilateral intrastriatal grafts, followed 10 days later by an ipsilateral QA injection, we compared transplants (n=10/group) of fetal striatum, fetal liver, fetal muscle, sham transplants and non-transplanted animals. The data show that transplants of fetal muscle and liver provide a variable but not statistically significant protection against QA. However, significant protection was again seen with fetal striatal grafts, indicating some specific effect of this tissue upon the host brain. Studies are continuing to elucidate the mechanisms underlying the fetal striatal graft-induced protective effect. Supported by NIH NS 15109.

CHOLINERGIC GRAFTS INNERVATE THE RETROSPLENIAL CORTEX IN A DIFFUSE PATTERN. S.R.Keim, S.L.Gage and W.C.Low.,Prog. in Med. Neurobiol. and Dept. of Physiol. and Biophys., Indiana Univ. Sch. of Med., Indpls., IN 46202.

Recent studies have shown that the retrosplenial cortex (RSC) plays a role in spatial memory function and habituation. In the hippocampus (HC) the cholinergic system has been shown to be closely associated with similar functions of learning and memory. It is therefore notable that like the HC the RSC receives its cholinergic input from the medial septal nucleus (MSN) and the diagonal band of Broca (DBB), unlike lateral cortex which receives cholinergic input from the nucleus basalis. With the present study we begin to assess the role of the cholinergic projection to the RSC by developing a model of cholinergic transplantation into the denervated RSC. The RSC of 8 animals was cholinergically denervated by performing combined cortical/fornix aspiration lesions (Gage, et al., Neurosci.Abs., 1990). Four animals then received bilateral 0.5 ul injections of a suspension of fetal MSN/DBB cells (16 days gestational age) in Hank's balanced salt solution (HBSS), using a 1 ul Hamilton syringe (-5.8 mm AP; 0.7 mm ML; -2.2 to - 1.0 mm DV). Two of the other lesioned animals received similar injections of HBSS alone, while the final 2 lesioned animals received no injections. Two additional animals served as non-lesioned controls. Survival time was 4 weeks, at which time all 10 animals were perfused and placed in 30% sucrose in 0.1 M phosphate buffer for 3-5 days prior to sectioning at 50 um with a freezing microtome. Alternate sections were processed for ACHE histochemistry or cresyl violet (CV) histology. The CV stain in non-lesioned controls displayed the normal cortical cell layers I-VI of the RSC. In addition, the normal controls showed the ACHE staining pattern typical to the RSC, including an increased density of staining in cell layers I and IV, with a more diffuse staining pattern in layers II, III, V and VI. Lesioned animals without transplant (both with and without injection) all displayed normal cellular histology per CV, but showed a complete and consistant lack of ACHE staining in all cell layers of the RSC. Lesioned animal with transplants displayed normal cellular histology per CV, with the addition of clusters of putativly transplanted cells near the injection site. These animals also displayed the presence of ACHE staining from 1.5 to 2.0 mm surrounding the injection site, in a predominantly non-laminar pattern. While transplant survival and diffuse ACHE staining of all cell layers was present in all 4 transplant animals, only one RSC transplant displayed an area of increased staining density in cell layers I and IV limited to approximately 600 um surrounding the injection site. This study indicates that while it is possible for cholinergic transplants into the denervated RSC to survive 4 weeks and extend fibers, the normal ACHE lamination was not regained.

531.11

AN ORGANOTYPIC ROLLER TUBE COCULTURE OF NEONATAL RAT STRIATUM AND ADRENAL MEDULLA. C.Spenger[1]*H.-R. Lüscher[2] and H.J. Reulen[1]* Dept. of Neurosurgery, Inselspital[1], CH-3010 Bern; Dept. of Physiology[2], University of Bern, CH-3012 Bern, Switzerland.

Some beneficial effects of autologous adrenal medulla implants in patients with Parkinson's disease have been reported. Adrenal medullary implants in unilaterally 6-OH-dopamine-lesioned rats have repeatedly been shown to reduce apomorphine-induced turning behavior of these animals. The physiological mechanisms underlying these behavioral changes are not understood. In order to study possible cellular interactions between chromaffin and striatal cells an *in vitro* model was developed.

The caudate-putamen (CP) and adrenal glands were dissected out of newborn rats. By means of a tissue chopper the CP was cut into 350 µm thick coronal slices. With a cut off and sharpened hypodermic needle pieces of 2.0 mm diameter were punched out of these slices. The adrenal gland was cut into 150 µm thick sections. Sections with a large portion of medulla were selected and cut in half. A piece of CP together with a piece of adrenal gland was mounted on a cover slip in a drop of chicken plasma, coagulated with thrombin. The cover slips were transferred to a tube and fed with 1.1 ml of medium containing 5 ng/ml NGF. The cultures were incubated in a roller drum. Details of the culture technique used are described by Braschler et al. (*J. Neurosci. Meth.* 29: 1989).

Within two weeks *in vitro* the explanted tissues flattened nearly into a monolayer. Numerous large multipolar, cholinergic neurons could be seen in the CP explant. A large number of neurons did not stain for AChE and probably represented the GABAergic neurons of the CP. On the surfaces of these cells, synapse-like cholinergic nerve terminals were seen. Neurites from the cholinergic neurons had grown into the adrenal coexplant where they formed a fine varicosity-rich plexus among the chromaffin cells, to which they formed close contacts. The adrenal medullary cells stained positive for AChE and their somata gave rise to several neurites. The large CP cells were easily accessible for microelectrode exploration, and action potentials could be evoked by injection of small depolarizing current pulses.

These preliminary results demonstrate that this *in vitro* model can be used for investigating cellular interactions between striatal and adrenal medullary cells.

VASCULARIZATION AND MICROVASCULAR PERMEABILITY IN SOLID VS. CELL SUSPENSION EMBRYONIC NEURAL GRAFTS. K. E. Leigh, K. Elisevich and K. A. Rogers*, Dept. of Anatomy, The University of Western Ontario, London, ON N6A 5C1

Postmortem study of transplanted adrenal medullary tissue in human striatum has shown poor survival raising questions regarding the adequacy of vascularization. With the advent of human fetal neural transplantation, similar concerns are raised. Vascularization (VAS) and microvascular permeability (MVP) of solid and cell suspension preparations of rat embryonic mesencephalic tissue (E 13-15) were studied after transplantation in adult rat striatum deafferented by injection of 6-hydroxydopamine into the median forebrain bundle. Both VAS and MVP were assessed following intravascular infusion of horseradish peroxidase (HRP; M.W. 40 000) after 7, 14 and 30 days survival. Vascularity and HRP leakage from grafts were studied using tetramethylbenzidine (TMB) as the chromogen. Tyrosine hydroxylase (TH) immunoreactive cells in the grafts were identified in each case and rotational behaviour assessed by injection of amphetamine (5mg/kg; i.p.) before grafting and in those animals surviving 30 days. Cell suspension grafts exhibited a VAS slightly in excess of that found in adjacent striatum and HRP leakage in most cases had resolved by day 14. TH positive cells with extensive fiber outgrowth were consistently present in all animals after 14-30 days. In contrast, solid grafts displayed poor VAS in most cases. This was confined to the borders of the graft. MVP was normal by 30 days postgrafting. At 30 days, TH positive cells were either absent or very low in number and situated in the periphery of the graft. The cell suspension technique of grafting offers a higher success rate for viability with a lesser duration of blood-brain barrier dysfunction than do solid grafts. (Supported by the Parkinson Foundation of Canada)

BLOOD-BORNE ACCESS TO CNS TRANSPLANTS BY ENDOGENOUS PROTEIN AND EXOGENOUS NEUROTRANSMITTER. R.J. Walsh and J.M. Rosenstein, Departments of Anatomy and Neurosurgery, The George Washington University Medical Center, Washington, D.C. 20037.

Previous studies have indicated that barrier properties within the neovasculature of CNS grafts may be altered such that exogenously administered protein such as HRP may infiltrate the neuropil. To further examine this system, non-injected rats bearing cortical or nigral transplants (10 days-1 year postoperative) were perfused with 4% paraformaldehyde and examined immunocytochemically for endogenous rat serum albumin (RSA). The distribution of anti-RSA with regard to the sources and extent of permeability mimicked that of injected proteins; permeation was consistent in ventricular grafts and considerably less and variable in intraparenchymal grafts. Where the allografts appeared to be immunologically rejected, anti-RSA was prominent for months. To examine access of a neurotransmitter, ^{3}HGABA (250 µCi) was systemically administered for 30 minutes. Portions of ventricular grafts were inundated and neurons avidly sequestered the blood-borne transmitter which normally never crosses the blood-brain barrier. The results confirm that barriers may be altered and CNS grafts can be exposed to endogenous protein and administered neurotransmitters such as GABA (NS-17468).

531.14

BLOOD-BRAIN BARRIER PERMEABILITY TO A PERIPHERAL ACETYLCHOLINESTERASE INHIBITOR FOLLOWING FETAL TISSUE TRANSPLANTS INTO ADULT RAT STRIATUM. K.J. Bertram*, S.Y. Lu, A.B. Norman, E.C. Somoza, M. Ennis, M.T. Shipley, and P.R. Sanberg. Division of Neuroscience, Depts. of Psychiatry, Physiology, and Anatomy, University of Cincinnati, College of Medicine, Cincinnati, OH 45267.

The post-transplantation status of the blood-brain barrier (BBB) remains a controversial issue. When treating neurodegenerative disorders, a compromised BBB following neural transplantation could disrupt the homeostatic environment of the CNS. To determine the integrity of the BBB following neural transplantation, unilateral 16-18 day fetal striatal transplants (1-1.3mm3) were placed stereotaxically into the striatum of adult male Sprague-Dawley rats (190-220g). Sham operated rats received equivalent amounts of vehicle. At one week post-transplantation BBB permeability to phospholine iodide (PI), an irreversible acetylcholinesterase inhibitor which normally does not cross the BBB, was examined. Half of the rats from each treatment group were injected with PI (65ug/kg i.m.) 30 minutes prior to cardiac perfusion with a paraformaldehyde/glutaraldehyde fixative. Brains were sectioned (40um) on a microtome and stained for cresyl violet and acetylcholinesterase. In a control experiment, PI (32.5ng) was injected unilaterally into the striatum of normal adult rats 30 minutes prior to perfusion. There was a marked inhibition of acetylcholinesterase in the injected striatum. In rats which received transplants or sham operations, no penetration of systemically administered PI into the transplant or the host striatum was detected. It was concluded that the BBB within the transplant and the host was intact because the BBB was not permeable to PI via the fetal striatal transplants.

CONCENTRATION DEPENDANCE OF PHOTORECEPTOR CELL RESCUE BY RPE TRANSPLANTS. L. Li and J. E. Turner Dept. of Neurobiology and Anatomy, Bowman Gray School of Medicine, Wake Forest University, Winston-Salem, NC 27103

We have reported previously that photoreceptor cells are rescued by retinal pigment epithelial (RPE) cell transplants in RCS dystrophic rats (Li and Turner, Exp. Eye Res., 1988). Further studies showed that healthy RPE cells were required for the long term rescue including outer segment integrity. However, vehicle injections initiated a transient, local beneficial effect which diminished with time. In this study, different concentrations of RPE cells were injected into the subretinal space of RCS rats. When analyzed at 1 and 2.5 months after transplantation photoreceptor cell rescue was seen in all groups. However, the results revealed a concentration dependence and saturation of this effect. Therefore, we conclude that healthy RPE cells are required for long term rescue of photoreceptor cells and this rescue is concentration dependent and saturable which is not the case with vehicle injections. This research was supported by grants from NIH (EY04377-08), the National Retinitis Pigmentosa Foundation and Retinitis Pigmentosa Intl.

DEVELOPMENT AND PLASTICITY—VISUAL SYSTEM: RETINOTECTAL CONNECTIONS

532.1

DEVELOPMENT OF THE RETINOTECTAL PROJECTION OF NASO-VENTRAL QUARTER EYES IN XENOPUS LAEVIS. N.Degen,L.Peter* and K.Brändle*.

Zool.Inst.,Univ.Frankfurt,Siesmayerstr.70,D-6000 Frankfurt 11,West Germany.

According to Sperry's chemoaffinity hypothesis (Sperry,R.W., Proc.Natl.Acad.Sci.USA 50:141,1963) the projection of a small eye fragment with a reduced amount of optic fibers should be restricted to that position in the tectum corresponding to its own specificity. In order to verify this assumption, we removed three quarters of the eye anlage in Xenopus embryos of tail bud stages. The remaining quadrant originated from the nasoventral (NV) retina. Beginning with stage 45 up to metamorphosis we examined histologically the retinal projection to the midbrain. Despite the developmental stage of the larvae the projection field of the NV-eyes was always confined to the rostro-lateral part of the tectum. Since quarter eyes seem to retain their original specificity (Degen,N. and Brändle,K. Acta Biol.Hung. 39:191,1988) it can be excluded by this results that fibers of a quarter eye initially occupied an area corresponding to their own specificity. Electrophysiological recordings in the tectum revealed that despite the abnormal location of the projection field, the optic fiber terminations of the NV-eyes are retinotopically organized. Our results indicate a selfassembling of ingrowing optic fibers rather than the preexistence of markers in a virgin tectum. This supports the initial establishment of the retinotectal map.

532.2

ACTIVITY DEPENDENT AND INDEPENDENT ASPECTS OF TOPOGRAPHIC MAP FORMATION IN MAMMALS D.K. Simon and D.D.M. O'Leary Departments of Neurosurgery and of Anatomy and Neurobiology, Washington University School of Medicine, St Louis MO 63110

Retinal axons form a highly ordered, topographic map in the superior colliculus (SC) of adult rats. However, developing retinal axons mistarget widely in the SC, resulting in an initially diffuse retinocollicular projection (O'Leary et al 1986 J Neurosci 6:3692; Simon & O'Leary 1990 Dev Biol 137:125). Normally, most mistargeted axons are eliminated by P12. Retrograde labeling suggests that major targeting errors are removed even when retinal activity is blocked (O'Leary et al 1986). Here we use DiI as an anterograde tracer to examine directly the remodeling of rat retinocollicular axons and the focusing of their arbors in the absence of activity. TTX was injected intraocularly daily from P0 - P12. Each injection was 1/3 of the lethal dose for a single injection. The 24 hr duration of the retinal activity block was confirmed by inactivation of the pupillary light reflex. At P10, in addition to the daily TTX injection, DiI was focally injected into peripheral temporal retina, which is retinotopically matched with rostral SC. We find that when retinal activity is blocked, more mistargeted axons remain at P12 than in age-matched controls. Many of these axons extend into the caudal half of the SC and have multiple branches along their length. Some axons arborize at topographically incorrect regions, but a few mistargeted axons extend a collateral branch into the appropriate terminal zone. It is very apparent, though, that a dense zone of overlapping terminal arborizations do form at the appropriate topographic position in rostral SC. This observation indicates that even in the absence of retinal activity many axons are able to arborize at the topographically appropriate region. Therefore, the formation of a topographically appropriate arbor can be governed by activity independent mechanisms. In contrast, the elimination of aberrantly positioned axons and branches is to some extent activity dependent since their removal is deterred (or delayed) by blocking retinal activity.

532.3

FUNCTIONAL DEVELOPMENT OF THE NEONATAL RAT RETINOTECTAL PATHWAY. S.K. Itaya and S. Molotchnikoff. Dept. Biomed. Sci., Univ. So. Alabama, Mobile, AL 36688, and Dept. Sci. Biol., Univ. Montreal, Montreal, Que.

During the first week after birth, the neonatal rat visual system undergoes several major developmental processes, e.g., synaptogenesis and cell death. We investigated whether action potentials or synaptic transmission could play a role in these processes by measuring spontaneous and evoked responses in the developing retinotectal pathway. In preliminary experiments, we studied 16 rat pups from postnatal day 6 (P6) to P14. Glass microelectrodes (NaCl, 1-2 Mohms) were lowered through the superficial superior colliculus while measuring for field potentials, multiunit, or single unit activity. On P6/7, spontaneous activity was rare (n=3 cases). Starting on P8, there was spontaneous activity in collicular neurons (n=12). Evoked action potentials were measured in response to electrical stimulation of the contralateral optic nerve. From P6-P9 (n=7), evoked responses were inconsistent, with latencies of about 35 msec. However, from P10-P14 (n=7), there were action potentials to optic nerve stimulation. The responses were spikes with a latency of about 15 msec and a stimulus threshold of 60 V. Both spontaneous and evoked responses were biphasic, indicating a somatic origin. In a previous abstract (Soc. Neurosci., 1988), we reported that flash evoked responses first appear around P12/13. Our results suggest that the rat retinotectal pathway becomes functionally capable in three stages: 1) spontaneous activity first appears on P8; 2) electrically evoked collicular responses develop on P10; and 3) flash-evoked responses appear on P12/13. This suggests that the retinotectal pathway becomes functional during the second week after birth.

EM ANALYSIS OF NMDA-TREATED TECTA IN THREE-EYED *RANA PIPIENS*. Lai-Hsing Yen and M. Constantine-Paton, Dept. of Biology, Yale University, New Haven, CT 06511

Previous work in this lab has shown that chronic NMDA application to the striped tecta of three-eyed frogs causes a dramatic decrease in branching within retinal ganglion cell (RGC) terminals (Cline & Constantine-Paton. 1990. J. Neurosci. Vol 10, April). We would like to know whether changes in the distribution, or the amount of synaptic contact supported by individual RGC terminals accompany the pronounced NMDA related changes in terminal morphology.

Elvax slices with 10^{-4} M NMDA were placed on the tecta of young three-eyed post-metamorphic frogs. The elvax causes release of approximately 0.3 % of the total drug amount per day. The animals survived for 4-5 weeks and a few RGCs were labeled with HRP before sacrifice. The tecta were cut into 40μm sections, reacted with DAB, and processed for EM. The morphology of isolated single RGC terminals was reconstructed at the light microscope level. Semi-thick and intervening ultra-thin sections through these terminals are being used to quantify HRP labeled synaptic profiles at the EM level.

We have previously found that the fine structure of tecta perfused acutely with normal saline is indistinguishable from that of tecta perfused acutely with saline containing 33 μM NMDA. Qualitative inspection of the chronically treated striped tecta in this study also showed no signs of neurotoxicity.

Ordering of branches of the reconstructed RGC terminals with the centripetal Strahler scheme showed that the chronically NMDA-treated terminals have a lower branch order consisting of order 1 to 5 as compared to order 1 to 6 of the same type terminals in control tecta. This decrease in branching with NMDA treatment is consistent with our previous finding. In addition we have found more synaptic convergence in NMDA-treated tecta: 3 to 5 pre-synaptic profiles on the same post-synaptic profile are often seen. Quantitation of this observation is now underway. (Supported by NIH grant EY06039)

532.5

PROTEIN COMPONENTS OF THE RETINOTECTAL MAPPING MECHANISM. P. Steen and M. Constantine-Paton. Biology Dept. Yale Univ., New Haven, CT 06511

The NMDA receptor is an integral component of the activity dependent retinotectal mapping mechanism in the frog, *Rana pipiens*. Chronic treatment with the receptor antagonist, APV, disrupts the precision of this map (Cline and Constantine-Paton, Neuron 3:413, 1989) and disrupts eye-specific segregation in three eyed frogs; whereas chronic agonist (NMDA) treatment sharpens this segregation (Cline et al., PNAS, 84:432, 1987). It is our objective to identify other molecular components of this mechanism. Since activation of the NMDA receptor appears to be the first step in a cascade of events, we have chronically treated animals with APV and NMDA (10^{-4}M in ELVAX implants for 4-6 weeks) and examined tectal proteins for response to these treatments. We have previously reported results of two-dimensional gel analysis after such treatments (Steen and Constantine-Paton, Soc. Neurosci. Abstr. 16:1211, 1990). However, since high molecular weight proteins do not focus well in these gels, they were omitted from these analyses. Therefore, we have utilized silver stained SDS-PAGE 7% gels, which were allowed to run until a 116kD prestained standard migrated to the end of the gel. This procedure allowed us to visualize proteins from 116 kD to well over 400 kD.

We have identified two proteins of approximately 240 and 175 kD which increase in abundance following chronic APV treatment, a 185 kD protein which decreases in abundance after APV treatment, and a 150 kD protein which decreases in abundance following chronic NMDA treatment. The 185 kD protein also appears to migrate slightly slower in the APV treated animals, with an increased apparant molecular weight of about 5 kD. We suggest that not only are these changes coincident with changes in the retinotectal map, but that they are a response of integral components of the mechanism which forms and maintains this map. *Supported by EY06039 NIH Grant.*

532.6

Localization of [^{3}H]Nicotine Binding Sites in the Goldfish Optic Tectum and Recovery During Optic Nerve Regeneration. G.T. Prusky. Yale University, Department of Biology, New Haven, CT 06511.

This study applied the techniques of [^{3}H]nicotine autoradiography to the retinotectal system of the goldfish in order (1), to obtain autoradiographic maps of [^{3}H]nicotine binding in the goldfish optic tectum to determine their relationship to previously published reports of [^{125}I]α-BTX binding, and (2), to determine whether [^{3}H]nicotine binding sites are associated with specific phases of retinal regeneration in the optic tectum. [^{3}H]Nicotine binding sites were located almost exclusively in the SO-SFGS region of the normal goldfish optic tectum. These binding sites were dramatically reduced in the tectum following enucleation of the innervating eye, indicating that they had a presynaptic loci on retinotectal fibers. The expression of [^{3}H]nicotine binding sites was also associated with the loss and subsequent regrowth of retinal terminals in the tectum. [^{3}H]Nicotine binding was reduced to enucleation levels within 1 week of the crush and only recovered to pre-crush levels between 12 and 26 weeks following optic nerve crush. These data suggest that the distribution of [^{3}H]nicotine binding sites in the goldfish optic tectum is different from that of [^{125}I]α-BTX labeling, but like [^{125}I]α-BTX binding, is associated with optic nerve terminals. Also, the recovery of [^{3}H]nicotine binding sites was not associated with primary regeneration of optic nerve terminals in the tectum, but rather with secondary or tertiary events after vision was reestablished. G.T.P. was supported by an N.S.E.R.C. of Canada Fellowship.

532.7

PATTERN OF CYTOCHROME OXIDASE ACTIVITY IN THE DEVELOPING CHICK OPTIC TECTUM. W.J. Crossland and J.D. Peduzzi. Dept. Anat. & Cell Biology, Sch. Med., Wayne State Univ., Detroit, MI 48201 and Dept. Physiol. Optics, Sch. Opt., Univ. AL at B'ham, Birmingham, AL 35294.

Cytochrome oxidase (CO) expression in some visual centers has been shown to be correlated with retinal activity levels (Wong-Riley, 1989). Furthermore, during development transient CO activity in some visual areas has been correlated with cell birthdate (Peduzzi, 1987). Is embryonic CO activity closely linked to the arrival of retinal axons or is it an independent cell property (Lachica et al., 1987) correlated with tectal neuronal birthdate? We have investigated this question in the optic tectum of the embryonic chick. The order of tectal laminar neurogenesis in the chick (LaVail and Cowan, 1971) is: First, the deep layers - stratum griseum centrale (SGC) and stratum periventricularis (SP), then the superficial layers - stratum griseum et fibrosum superficiale (SGFS) a-g, followed by the intermediate layers - SGFS h-j. Standard histochemical methods (Wong-Riley, 1979) were used on free-floating frozen sections of aldehyde-fixed brains from E9 to adult chickens. On E9, when the tectum is only 1/2 innervated by the retina, CO activity was heaviest in SP, SGC, and a band within the presumptive SGFS. Little difference was evident between innervated and noninnervated tectal regions even though CO reactive retinal ganglion cells were evident at this age. (The role of visual input in the pattern of CO activity is further explored in the companion study.) From E9-E14, the addition of new CO bands corresponded with further laminar differentiation in the SGFS a-g and, at E14, in the SGFS h-j. By E18, the mature pattern of neuropil and cellular CO reactivity was recognizable (greatest activity in SGC and SGFS a-c & f). Thus, CO activity appears in a complex pattern, resembling the neurogenetic sequence of the tectal laminae rather than initial retinal ingrowth. 532.8

CHANGES IN THE PATTERN OF CYTOCHROME OXIDASE ACTIVITY IN THE CHICK VISUAL SYSTEM FOLLOWING DEAFFERENTATION. J.D. Peduzzi and W.J. Crossland. Dept. Physiol. Optics, Sch. Opt., Univ. Alabama at Birmingham, Birmingham, AL 35294 and Dept. Anat. & Cell Biology, Sch. Med., Wayne State Univ., Detroit, MI 48201.

In the visual system of several species, intense cytochrome oxidase (CO) activity is found in particular laminae or structures that receive direct visual input. To determine the extent that CO activity in the chick visual system is dependent on visual input, newly hatched chicks were unilaterally enucleated under deep anesthesia and allowed to survive for a variable length of time. Sections from control and experimental animals were processed in the same solution for identical lengths of time using the CO protocol of Wong-Riley (1979). In normal chicks, strong CO activity was present in all retino-recipient and visuomotor centers. Tectal layers SP, SGC and SGFS (greatest activity in sublaminae a-c and f) were reactive, as noted in our companion study. Most nuclei that connect with the tectum were also heavily labeled. Ten days after enucleation, the intensity of CO activity appeared to be similar in most deafferented and control visual nuclei (including the ventral lateral geniculate and ectomamillary nuclei). The isthmo-optic nucleus (ION), which projected to the retina of the enucleated eye, underwent retrograde degeneration. However, CO activity in sublamina f (retino-recipient, cell-free sublamina) of the tectal SGFS was reduced compared to the control. Similar results were observed a month after enucleation. The lack of dramatic reduction in CO activity in most visual areas of the chick following eye removal suggests that CO activity is more a property of individual cells in a region than the result of afferent activity. However, with the exception of ION, the few changes that did occur were restricted to areas receiving direct visual input. Supported by EY01338, EY03039, RR05807 (J.D.P) and EYO4068, EY07093 (W.J.C.).

CELL SPECIFIC MONOCLONAL ANTIBODY IN THE GOLDFISH VISUAL SYSTEM. S. Braverman*, S. Sharief*, I. Rappaport* and S.C. Sharma. Depts. Immunol. Micro. and Ophthalmology, New York Medical College, Valhalla, NY.

Monoclonal antibodies made against goldfish tectal tissue labeled specific cell types in the brain. In the tectum, the pyramidal neurons (Type I) whose soma are located in the SFGS were intensely labeled with mAb 2F8. Purkinje neurons in the corpus cerebellum and valvula cerebelli and the oculomotor neurons were also labeled. In addition to the neurons, labeled glia types include: a) Muller cells in the retina, b) oligodendrocyte-like cells in the optic nerve and c) radial glia in the tectum. No labeled glia were observed in other regions of the brain. During development the antigen recognized by mAb 2F8 appeared first on the Muller cells of the retina before hatching and by 11-14 days post hatching within the cells of the tectum, cerebellum and oculomotor nuclei. At present, it is not clear whether the antigen recognized by mAb 2F8 is the same in the different cell types or a single epitope is shared by several antigens. This antibody will be useful for studying the response of tectal and Purkinje neurons to injury and will aid in the isolation of the different cell types in a tissue culture system. Supported by NEI01426.

532.10

LONG TERM SURVIVAL OF CONNECTIONS BETWEEN FETAL EYES SUTURED TO PERIPHERAL NERVES AND TECTUM B. H. Hallas, A. Feller, S. Fettahlioglu, C. Kaiser, L. Nguyen, M. Wells and M. Zanakis. Dept. of Neuroscience, New York College of Osteopathic Medicine, Old Westbury, NY 11568.

Eighteen day embryonic rat eyes (E18) were either sutured to a 3 cm segment of adult rat sciatic nerve or attached with purified gelled cyanoacrylate. In animals that provided the sciatic nerve segment, the left optic nerve was completed transected 2 mm distal to the orbit and the lens removed. The E18 eye/sciatic nerve bridge was then implanted into the host's eye, while the proximal end of the sciatic nerve bridge was inserted through a burr hole in the cranium into the contralateral superior colliculus.

One year post-implantation of the fetal eye/sciatic nerve bridge, a 20% solution of HRP was injected intraocularly. Twenty-four to forty-eight hours post injection, the animals were sacrificed and the fetal eye bridge and brain processed for HRP histochemistry or electron microscopy. At the light microscopic level, HRP was observed in the bridge and superior colliculus while at the EM level, labelled myelinated axons in the bridge and synapses in the superior colliculis were observed.

532.11

EARLY MONOCULAR ENUCLEATION AND GENICULO-CORTICAL TOPOGRAPHY IN THE GOLDEN HAMSTER. A.J.Trevelyan* and I.D.Thompson*. (SPON: Brain Research Association). University Laboratory of Physiology, Parks Road, Oxford OX1 3PT, United Kingdom.

We have used a double-label technique to study mapping precision in the geniculo-cortical projection of normal adult hamsters and those enucleated as neonates. Green and rhodamine fluorescent latex microspheres (Katz and Iarovici, 1990, Neurosci.,**34**, 511-520) were used as the retrograde tracers. Small, discrete injections (150nl) of each tracer were made (through glass micropipettes) into area 17 on both sides, contralateral and ipsilateral to the remaining eye. The labelling in the dorsal lateral geniculate nucleus (dLGN) was studied in serial brain sections under UV epifluorescence. The number of cells labelled from a single injection was very similar in both normal and deafferented nuclei. This suggests that the number of geniculate cells projecting to a unit area of cortex is not altered by enucleation. In the enucleated animal, the dLGN still receiving retinal input has an essentially normal pattern of projection. However, analysis of the distribution of double-labelled cells and of the overlap in the two populations of labelled cells in the deafferented dLGN shows that early removal of retinal input perturbs the development of precision in geniculo-cortical topography.

532.12

THE EARLY DEVELOPMENT OF VISUAL THALAMOCORTICAL PROJECTIONS IN THE GOLDEN HAMSTER. B. Miller, L. Chou,* and B. L. Finlay Department of Psychology, Cornell University, Ithaca, New York, 14853.

Little is known about the development of topographic organization between thalamic projections and their cortical target. In the hamster, the lateral geniculate nucleus is produced between E9.5 and E12.5 (birth is E16). Their axons do not invade their cortical target until around three days after birth. We examined the development of these projections and their interactions with developing cortex. DiI was placed in the dorsal thalamus of fixed brains of E14 and E16 hamster pups. After two months the brains were sectioned with a vibratome at 75-100um and examined with fluorescent microscopy.

The growing axons are fasciculated in part of the internal capsule but do not maintain nearest neighbor relations. Fascicles branch and cross, and fibers leave one fascicle to join another. In E14 animals thalamic fibers have grown through the internal capsule, but only a few extend beyond this to traverse for a short distance under the developing cortical plate. No retrogradely labeled cell bodies are seen in the region of the cortical plate in E14 animals. In E16 animals thalamic fibers have grown beyond the internal capsule and extend well into dorsal regions of the developing cortex. Retrogradely labelled cell bodies are seen scattered within the growing fibers and more superficially in the developing cortical plate. Thus, subplate projections do not reach the thalamus until approximately the same time that the thalamic projections reach the cortex. Supported by NIH R01 NS19245.

532.13

DISTRIBUTION OF FAL-EPITOPES IN DEVELOPING INTERLAMINAR AND LAMINAR REGIONS OF THE MONKEY AND HUMAN DORSAL LATERAL GENICULATE NUCLEUS. J.K. Mai* and Ch. Schönlau*. (SPON: European Neuroscience Association). Dept. of Neuroanatomy, Heinrich-Heine-University of Düsseldorf, D-4000 Düsseldorf, F.R.G.

Paraffin sections of ontogenetic series of 45 monkey brains (Cercopithecus aethiops aethiops L.) and of approximately 100 human brains were obtained from the C.& O. Vogt-collection. We investigated the expression of the carbohydrate epitope 3-fucosyl-N-acetyl-lactosamine (FAL) by means of immunohistochemistry, using the mouse monoclonal antibody anti-Leu-M1, one member of the CD 15 family. The FAL expression within the dorsal lateral geniculate nucleus (dLGN) followed a biphasic course. A first prominent peak was found before and around birth with intense neuropil and astroglial staining in the interlaminar space. This laminar pattern disappeared short after birth and by 10 weeks of age in the monkey and by 6 month in the human the dLGN appeared nearly unstained. Thereafter, increasing numbers of phenotypically different FAL-positive astrocytes became visible in the segregated layers of the dLGN, which resulted in a second pattern of lamination. The findings suggest, that the FAL expression coincides with neuropil development and related functional maturation of the visual system. Supported by grant from the DFG (SFB 200).

533.1

DONOR CLIMBING FIBERS SYNAPSE ON HOST PURKINJE SPINES
K. Kawamura, S. Murase, S.Yuasa and K. Yoshida
Dept. of Anatomy, Sch. of Med. Keio Univ., Tokyo 160, Japan.

In the host rat cerebellum, where the inferior olive and climbing fibers had been destroyed by intraperitoneal injection of 3-acetylpyridine (3-AP), the medullary primordial tissue (from E14-16) containing the inferior olive was grafted. After 3 weeks, climbing fiber type preterminals bearing closely-packed round vesicles were found that established synaptic contacts on dendritic spines of the host Purkinje cells. Quantitative analysis at the ultrastructural level has been carried out. The control was taken from 3-AP treated, non-grafted site. Main results are the followings. (1) The number of typical climbing fiber preterminals increased from 0.3% -0.9% to 5% after grafting, which was statistically significant (p=0.01). (2) The number of typical parallel fiber type preterminals that contained sporadically distributed round vesicles increased from 13% to 27% after grafting, which was also statistically significant (p=0.01). It is considered that competition of searching targets is likely to occur between the donor climbing and the host parallel fibers in the process of re-modelling of the brain.

533.2

A QUANTITATIVE ELECTRON MICROSCOPIC STUDY OF SYNAPSE FORMATION BETWEEN CULTURED CEREBRAL CORTICAL NEURONS.
Masumi Ichikawa, Kazuyo Muramoto*, Kazuo Kobayashi* and Yoichiro Kuroda. Dept., Anat., & Embryol., and Neurochem., Tokyo Metropolitan Inst. for Neurosciences, Fuchu, Tokyo 183, Japan.

Monitoring of the formation of functional synapses among dissociated cerebral cortical neurons in vitro using video-assisted multi-site Ca^{2+} fluorometry has shown that the presence of the ecto-protein kinase inhibitor (K-252b) inhibits synapse formation (Muramoto et al., 1988). We examined quantitatively the effect of K-252b on synapse formation using electron microscopy. Cerebral cortical cells of rat embryo (18 days) were cultured. After 7 days, the cultured cells were fixed and embedded. Ultrathin sections were cut and photographed randomly, and synaptic contacts were counted on the electron micrographs. The examined area covered more than 3800 μm^2 per culture. The density of synapses was 1.35 ± 0.23/190 μm^2 in control. In the presence of 0.8μM K-252b, the density of synapses was decreased to 0.58 ± 0.23. This result shows that synapse formation is inhibited by K-252b and confirms the result of the functional assay using fluorometry. These data support the idea that ATP released from nerve terminals phosphorylates surface proteins involved in synapse fomation.

533.3

ONTOGENY OF CHOLINE UPTAKE SITES AND M1 MUSCARINIC RECEPTORS IN THE BABOON HIPPOCAMPAL FORMATION
In-Hei Hahn, Harvey S. Singer, Larry Walker, Pedro Lowenstein, Paul Slesinger, Donald Price, Joseph Coyle. Johns Hopkins Univ Sch of Med, Baltimore, MD 21205.

The developmental maturation of the cholinergic septohippocampal system in baboon hippocampal (HF) was analyzed using quantitative receptor autoradiography. On frozen sections, from midgestation, newborn, juvenile, and young adult baboons, we used [^{3}H]-hemicholinium-3 ([^{3}H]-HC3) to label the choline uptake carrier site and [^{3}H]-pirenzepine ([^{3}H]-PIR) to label M1 muscarinic receptors. Both were present in CA1 - CA4, dentate gyrus (DG), and subiculum (SUB) at 100 days gestation, with highest densities in CA1 and CA2. Total [^{3}H]-PIR binding increased rapidly during gestation, peaked at birth in all regions except SUB, then declined by adolescence. Between ages 3 to 5 years, densities were stable in CA1, CA2, DG, and SUB. [^{3}H]-HC3 binding, after only modest increases from midgestational levels, tended to peak at birth with only slight alterations into adulthood. [^{3}H]-PIR was always greater than [^{3}H]-HC3 binding. Density in CA1 and CA2 was most intense over the pyramidal layer; in DG, the molecular layer exceeded the granular layer. In baboon HF, although cholinergic uptake carrier sites and postsynaptic receptors are present in an adult distribution by midgestation, binding densities have different developmental patterns.

AN ANALYSIS OF RECURRENT EPSPS RECORDED IN IMMATURE CA_3 HIPPOCAMPAL NEURONS.
J.W. Swann, and K.L. Smith, Wadsworth Center for Labs and Research, NY State Dept. of Health, Albany, NY

Excitatory synaptic interactions between pairs of CA_3 hippocampal neurons were studied in in vitro slices of hippocampus taken from rats 10-16 days of age. Experiments were performed in the presence of penicillin in order to suppress synaptic inhibition and permit the full expression of local circuit excitatory synaptic interactions. In 4 of 141 pairs of cells monosynaptic interactions were recorded. The unitary epsps were unusually large and prolonged. At membrane potentials between -60 and -70 the average amplitude was $2.78 \pm .46$ mV. Epsps were usually more than 200 msec in duration. The probability of occurrence was also high $0.94 \pm .04$. The decay of the epsps was much slower than that of responses to somatically injected current. Typically the recurrent epsps were not followed by an afterhyperpolarization or undershot as has been reported in CA_3 pyramidal cells from mature animals. This would suggest that the K+ conductance that has been reported to underlie such undershots has yet to appear at this stage in hippocampal development. Presynaptic burst firing results in dramatic facilitation of unitary epsps. Our results suggest that, while recurrent excitatory synapses are present early in postnatal life, the epsps they produce differ in many ways from their counterparts of adulthood. Support NS18309.

MORPHOLOGIC STUDIES OF CA3 HIPPOCAMPAL NEURONS IN THE DEVELOPING RAT.
C.M.Gómez[1], F.L.Rice[1], K.L.Smith*[2], J.W.Swann[2]. [1]Dept. of Anat, Cell Biol. & Neurobio., Albany Medical College, Albany, N.Y. 12208 and [2]WCLR, NYS Dept. of Health, Albany, N.Y. 12201.

We are studying the morphological substrates which may be related to an increased propensity the immature hippocampus for seizures. CA3 hippocampal neurons from animals of different ages were characterized physiologically in slice preparations and injected intracellularly with biocytin. Preliminary morphometric analysis of serially reconstructed filled pyramidal cells revealed that the most extensive axonal arborizations occur in the second postnatal week as compared to the first or to adulthood. In week two, we observed the most elaborate axonal networks with varicosities (likely sites of synaptic contact) in Stratum oriens (S. oriens). Several axons were also found in S. radiatum but few were seen in the cell body layer. Neurons from the first postnatal week had more restricted processes. Adult neurons had a dramatic reduction in the axonal networks of S. oriens. Some unique cells had pyramidal cell-like bursting characteristics but basket cell-like axonal plexi in the cell body layer and unusual fine axons in S. oriens and radiatum. We postulate that a developmental overproduction of synapses occurs which results in a surplus of excitatory contacts and enhanced seizure susceptibility in week two. Excess synapses regress with maturation imparting decreased propensity for seizure induction.

533.6

ONTOGENY OF DOPAMINERGIC AND GABAERGIC INNERVATION OF THE INTERMEDIATE LOBE OF THE RAT PITUITARY GLAND.
K.A. Gary and B.M. Chronwall. School of Basic Life Sciences, University of Missouri-Kansas City, Kansas City, MO 64108.

Dopamine and GABA are co-localized in axons innervating melanotropes of the intermediate lobe (IL) of adult rat pituitary. Transmitters co-localized in the adult may not appear at the same time during development. To determine the time sequence and spatial distribution of IL innervation, we stained Sprague-Dawley ILs at embryo days (E) 17-20 and post-natal days (PN) 2, 5, 10, and 28 immunohistochemically using dopamine, tyrosine hydroxylase (TH), GABA, and a glutamine decarboxylase (GAD) antisera. TH and GAD localization allows early identification of axonal populations prior to the presence of neurotransmitter in terminals. Demonstration of the synthesizing enzyme and the final neurotransmitter is important to show neuronal synthesis rather than axonal uptake of the neurotransmitter. No immunoreactivity was observed in E 17 through PN 2. At PN 5, TH, dopamine, and GABA immunoreactivities were all demonstrated. GABA distribution at PN 10 was very similar to the pattern of innervation in the adult. Conversely, TH and dopamine concentrations at PN 10 are highest in the caudal aspect of the IL, and gradually decrease as one moves rostrally. By PN 28, the spatial distribution of TH and dopamine is similar to that observed in the adult, but staining intensity is much less than seen in adult IL. These results indicate a possible difference in onset of dopaminergic and GABAergic innervation occurring in the IL during ontogeny.

POSTNATAL DEVELOPMENT OF MONOAMINERGIC RECEPTORS IN THE PRIMATE NEOCORTEX. M.S. Lidow, P.S. Goldman-Rakic, D.W. Gallager, and P. Rakic, *Section of Neuroanatomy, Yale University, School of Medicine, New Haven, CT 06510*

Quantitative *in vitro* autoradiography was used to determine the postnatal development of D_1 and D_2 dopaminergic, α_1, α_2 and β noradrenergic, and 5-HT_1 and 5-HT_2 serotonergic receptors in prefrontal, motor, somatosensory, parietal association and visual cortex of rhesus monkey. At least two animals have been examined at birth, 1, 2, 4, 8, 12, 36 and 60 months of age. We found that the densities of these monoaminergic receptors undergo remarkable similar course of postnatal changes which take place simultaneously throughout all cortical areas examined. The overall density of receptors (as indicated by B_{max} values of specific radioligands) increases within the first few months after birth, reaches levels approximately two times higher than in adults and then begins to decrease toward puberty. These changes in receptor density correlate well with previously reported developmental changes in the density of synapses on spines in the cerebral cortex of the same species (Rakic *et al. Science* 232:232 '86). In addition, we found that monoaminergic receptors undergo postnatal change in their laminar distribution. For example, the tendency of monoaminergic receptors to concentrate in the upper cortical layers, characteristic for adult primates, is not present during first four month when most of these receptor subtypes display the highest densities in the deep layers. After that, receptor density increases predominantly in supragranular layers, achieving an adult pattern in the majority of cases by the end of the first year. Our findings of virtually isochronic course of development of monoaminergic receptors in anatomically and functionally diverse cortical regions stands in contrast to the traditional view of hierarchical development of the cortical regions. This indicates that the entire cerebral cortex develops as a whole and that the establishment of interneuronal communication in this structure may be orchestrated by a single genetic or humoral signal.

533.8

INDUCTION OF SULFATED GLYCOPROTEIN (SGP-2) GENE EXPRESSION IN THE STRIATUM FOLLOWING CORTICAL DEAFFERENTATION. T. H. McNeill, H.-W. Cheng, M. Lampert-Etchells, C. E. Finch and G. Pasinetti. Andrus Gerontology Center, Univ. of Southern Calif., Los Angeles, CA 90089

The present study was undertaken to identify potential molecular markers that may characterize the cellular mechanisms that promote cell survival and induce synaptic remodelling following neuronal deafferentation. For this study, we used an established rat lesion model in which contralateral corticostriate fibers are induced to sprout and innervate deafferented striatal target neurons following a unilateral cortical lesion. In particular we examined mRNA prevalence and protein content for glial fibrillar acidic protein (GFAP), an established marker for reactive astroglia and sulfated glycoprotein-2 (SGP-2), a putative inhibitor of complement-dependent cytolysis.

We found that mRNA prevalence for both GFAP and SGP-2 in the ipsilateral ST was increased at 3 days postlesion and reached a maximum (5-10 fold) at 10 days postlesion. By 27 days postlesion GFAP and SGP-2 mRNA prevalence were reduced but still elevated over levels found in the intact ST. Changes in mRNA prevalence for GFAP and SGP-2 were correlated with an increase in the density of immunoreactive fibers for both markers in the ipsilateral ST and paralleled the time course required for the homotypic reinnervation of the lesioned ST by axonal fibers from the contralateral cortex. We hypothesize that both GFAP and SGP-2 play important roles in the cellular events associated the phenomenon of reactive synaptogenesis following neuronal deafferentation and that SGP-2 serves to protect striatal neurons from phagocytic attack while reactive astrocytes remove surrounding degenerative axon and dendritic profiles from the lesion site. This hypothesis is based in part on previous studies that have reported that SGP-2 has a 76% amino acid sequence homology with complement cytolysis inhibitor (CLI) and that CLI suppresses the formation of the terminal complement attack complex (C5b-9) on cell membranes.

ACTIVITY-DEPENDENT RELEASE OF ATP ACTIVATES ECTO-PROTEIN KINASE TO STIMULATE SYNAPSE FORMATION BETWEEN CULTURED CEREBRAL NEURONS. Yoichiro Kuroda, Kazuyo Muramoto*, Kazuo Kobayashi*, Masumi Ichikawa#. Depts. of Neurochem. and #of Anat. and Embryol., Tokyo Metropolitan Inst. for Neurosciences, Fuchu-shi, Tokyo 183, Japan.

Presynaptically released ATP and its break down products, adenosine derivatives inhibit *and* facilitate synaptic transmission in the CNS and have been proposed as the main mediators of activity-dependent synaptic competition in "tracing circuits" for human long-term memory (Y. Kuroda: *Neurochem. Intern.*, 14, 339, 1989). In a functional assay system to measure synapse formation between dissociated CNS neurons, the continuous presence of an ecto-protein kinase inhibitor (K-252b) inhibits the synapse formation *in vitro* (Muramoto et al: *Proc. Japan Acad. Ser.B*, 65, 319, 1988). Extracellular addition of ATP induced phosphorylation of several cell surface proteins in the culture. To demonstrate the role of released ATP in activity-dependent changes of synaptic contacts, we cultured dissociated cerebral cortical neurons with various concentration of ATP for 7 days. ATP significantly stimulated the synapse formation as observed quantitatively by electron microscopy. These data indicate that the activity-dependent release of ATP provides substrate for the ecto-protein kinase to phosphorylate functional proteins on the synaptic membrane, which stimulate sprouting and synapse formation. This could selectively stabilize the "tracing circuits" for human long-term memory.

GP39 - AN AVIAN HOMOLOGUE OF THE MAMMALIAN SYNAPTOPHYSIN MOLECULE. A.M. Cunningham* and P.L. Jeffrey, Children's Medical Research Foundation, Sydney, NSW, Australia, 2050.

Synaptophysin (p38) is the major integral membrane protein of small synaptic vesicles. We have characterized a glycoprotein with an apparent molecular weight of 39 kD, designated GP39, from chick brain using a monoclonal antibody. Purification of the protein from chick forebrain by immunoaffinity chromatography and N-terminal sequence analysis showed GP39 to be a homologue of mammalian synaptophysin.

Our immunohistochemical results indicate that similarly to synaptophysin, GP39 was present in virtually all nerve terminals studied in addition to adrenal medullary cells. The pattern of immunoreactivity in the brain, spinal cord, retina and neuromuscular junction was consistent with that reported for synaptophysin and supports the belief that this is an abundant component of small neurosecretory vesicles regardless of the neurotransmitter involved. Solubilization experiments confirmed GP39 was an integral membrane component without any tight cytoskeletal associations. It was N-glycosylated and was demonstrated to produce a 34 kD form with N-Glycanase treatment. The glycoprotein was highly susceptible to proteolysis with a tendency to form a 23-25 kD fragment.

The deduced amino acid sequences of mammalian synaptophysin indicate an evolutionarily highly conserved molecule with four transmembrane spanning regions and a novel cytoplasmic domain. Such a structure has been proposed to imply a possible function as an ion channel with the carboxyl cytoplasmic domain perhaps serving as an extravesicular binding site [Sudoff, T.C. et al., *Science* 238:1142-1144, 1987]. Alternatively, it has been suggested to function in calcium-mediated neurotransmitter release. Our studies of the avian molecule aim to define its role in the development and function of the synaptic terminal.

ONTOGENY OF NEUROENDOCRINE SYSTEMS

534.1

DEVELOPMENT OF GAP-43 EXPRESSION IN THE FOREBRAIN OF NORMAL MICE AND LITTER MATES WITH NEONATAL LESIONS OF THE BASAL FOREBRAIN. C. F. Hohmann, G. Capone, R. L. Neve, L. I. Bennowitz and J.T. Coyle, Depts. of: Psychiatry and Pediatrics, JHU School of Med., Baltimore, MD; Psychobiol., UC Irvine, Irvine CA; Psychiatry, Harvard Med. School, Boston MA.

GAP-43 is a neuronal phosphoprotein associated with axonal growth during development, plasticity and regeneration. Studies in various species have shown that both GAP-43 mRNA and protein are expressed at high levels early during postnatal development and decrease precipitously during the course of maturation. The aim of the present experiments was to closely compare mRNA expression (as visualized by *in situ* hybridization) and appearance of the GAP-43 protein (visualized by immunocytochemistry [IC]) in several forebrain regions during postnatal development of the BALB/CByJ mouse. In addition, we performed neonatal lesions among the cortically projecting, cholinergic basal forebrain neurons [nBM] to determine whether changes in the time course of cortical morphogenesis would alter GAP-43 expression. Such nBM lesions have previously been shown by us to result in a retardation of cortical neuronal differentiation.

Our results confirm that expression of both mRNA and IC for GAP-43 is highest during the first week postnatal, decreased by 2 weeks and is further reduced by one month. However, incongruencies between mRNA expression and IC localization became apparent, both with regard to the pattern of distribution and relative levels between different regions of the forebrain. For example, mRNA expression was higher in cortex and hippocampus than in the striatum at all ages while immunoreactivity appeared higher in the striatum, particularly in adulthood. On the other hand, the ventrobasal complex of the thalamus did not express high levels of either mRNA or IC at any time in postnatal development. Furthermore, we observed GAP-43 expression in cortical pyramidal neurons as late as 1 year postnatal. Finally, neonatal nBM lesions appear to subtlely affect the time course of GAP-43 IR in cell bodies of the ipsilateral cortex and hippocampus.

534.2

NPY Gene Expression in Developing Mouse Brain: An in situ Hybridization Study G. Capone, C. Hohmann, and J.T. Coyle, Johns Hopkins School of Medicine, Depts of Pediatrics, Psychiatry and Behavioral Sciences; The Johns Hopkins University School of Medicine, Baltimore, MD

Previous immunocytochemical studies have shown "NPY like" immunoreactivity throughout the rat brain during development and in adulthood.We have used *in situ* hybridization (ISH) to examine the regional distribution of NPY mRNA in the brains of Balb/CByJ mice at various postnatal ages (including adulthood). A specific, clearly discernable ISH signal was seen overlying discrete cell bodies within the cortex, hippocampus, caudate-putamen, claustrum, olfactory tubercle, endopiriform nucleus, accumbens nucleus, and several thalamic nuclei. On PND 7, signal intensity was highest in cells from the thalamus, caudate-putamen, and hippocampus, and low throughout most of the cerebral cortex. By PND 14, signal intensity increased in the cortex, remained about the same in hippocampus and caudate-putamen, and decreased slightly in thalamus. In the cerebral cortex and several other brain regions, there is an apparent increase in the number and intensity of NPY expressing cells during the first several weeks of postnatal life, relative to adults. The regional anatomic distribution of NPY gene expression is generally compatible with previous immunocytochemical studies performed on adult rat brain. Previously, we have demonstrated a transient increase in the number of somatostatin (Smst) expressing cells in the cerebral cortex following neonatal nbM lesions. Because NPY and Smst are co-localized in many of the same cortical neurons, we are examining NPY gene expression in the cerebral cortex following nbM lesions.

534.3

COMPARISON OF PERINATAL ANGIOTENSIN BINDING IN THE BRAINS OF SHR AND WKY RATS. V.I. Cook, K.L. Grove, J.W. Harding and R.C. Speth. Department of Veterinary and Comparative Anatomy, Pharmacology and Physiology, Washington State University, Pullman, WA 99164-6520.

Angiotensin is best known for its role in blood pressure and electrolyte balance; however, recent experiments have indicated that angiotensin may also have a role in growth and development. Angiotensin can stimulate cell growth, increase release of platelet-derived growth factor, and increase expression of growth-related proto-oncogenes. Therefore, the localization of angiotensin in the brain during early development would be a logical first step in the examination of a possible growth role in the CNS. Of additional interest would be any differential angiotensin growth-related patterns between the spontaneously hypertensive rat strain (SHR) and the normotensive rat Wistar-Kyoto (WKY) that could be indicative of a hypertensive pathogenesis. This study, therefore, utilizes receptor autoradiography to show the localization of ^{125}I-Sar^1,Ile^8-AII receptor binding in the brains of SHR and WKY rats during perinatal development. Specific receptor binding sites were localized and quantified in several angiotensin-related areas of both SHR and WKY rat brains.

THYROID HORMONE ALTERS THE POSTNATAL DEVELOPMENT OF CHOLINE ACETYLTRANSFERASE (CHAT) IMMUNOSTAINED CORTICAL FIBERS. J.D. Oh, N.J. Woolf and L.L. Butcher. Dept. of Psychology, UCLA, Los Angeles, CA 90024-1563, U.S.A.

The effects of thyroid hormone treatment on the development of ChAT immunoreactive fibers in the cerebral cortex were evaluated. Rat pups were made hyperthyroid by administering 1 mg/kg triiodothyronine (T3) i.p. daily, or hypothyroid by providing 0.3% propylthiouracil in the diet of the dams. Pups were sacrificed at 1, 2, 3, and 4 postnatal weeks. Brain sections were immunostained for ChAT and fiber densities within the frontal, parietal, piriform, cingulate, perirhinal, and retrosplenial cortices as well as the hippocampus, dentate gyrus, and basolateral amygdala were compared between the groups. In the 1 week postnatal brains, faint staining was observed for all groups. At 2 weeks postnatally, more ChAT fibers were present than at 1 week, however, fiber density analyses showed no differences between the hyperthyroid, control, and hypothyroid rat brains. Levels of ChAT fiber staining density increased in the 3-week animals but no further increases were detected in 4 week postnatal brains. At both 3 and 4 weeks, the optical density of ChAT fibers in cortical areas were greater in the T3 treated pups than both control ($p < 0.05$) and thyroid deficient rat pups ($p < 0.01$), and ChAT fibers of hypothyroid pups were were less dense than those in control pups ($p < 0.05$). VIP ANTAGONIST PRODUCES NEURONAL DAMAGE AND RETARDATION OF BEHAVIORAL DEVELOPMENT IN NEONATAL RATS. I. Gozes, J.M. Hill, R.F. Mervis, M. Fridkin and D.E. Brenneman. Lab. of Dev. Neurobiol., NICHD, Bethesda, Md. 20892, Peptide Design L.P., Germantown, Md. 20874, Div. Neuropath. Ohio State Univ., Columbus, Ohio 43210, Dept. Organic Chem., Weizmann Institute of Science, Rehovot, Israel.

An antagonist to the vasoactive intestinal peptide (VIP) receptor(s) was synthesized using a hybrid peptide strategy. Previous studies indicated that this antagonist potently inhibited VIP receptor binding, blocked VIP-stimulated cAMP formation in CNS cultures and produced neuronal cell death in spinal cord cultures. The purpose of the present study was to determine if this antagonist would influence neuronal integrity and the behavioral development of neonatal rats, based on the demonstrated neurotrophic action of VIP (PNAS 83:1159, 1986). Rats received daily injections subcutaneously from birth to day 14. Compared with saline-injected controls, cortical pyramidal neurons from the antagonist-injected animals showed widespread dystrophic changes including dendritic spine loss, and coarse, thickened dendrites with grossly abnormal spines. Dendritic branching in such neurons appeared reduced. Observations of developmental milestones/behaviors were made daily, 24 hours after the injection and without knowledge of treatment group. The following were significantly delayed by the antagonist: air righting, negative geotaxis, grasping and fore and hindlimb placing. VIP co-treatment attenuated or prevented the delays. The following were not influenced by the antagonist: surface righting, eye opening, corneal reflex, auditory startle, crossed extensor reflex and cliff aversion. These data suggest that VIP action is important in the development of cortical neurons and complex motor behaviors.

534.6

TRANSIENT INCREASE IN EXPRESSION OF A GAD mRNA DURING POST-NATAL DEVELOPMENT OF THE RAT STRIATUM. K.F. Greif, N.J.K.Tillakaratne, M. Erlander, and A.J. Tobin, Dept. of Biology, UCLA, Los Angeles, CA 90024

We have studied the development of GABA neurons in the rat striatum by measuring levels of GAD mRNA by in situ hybridization, Northern blot analysis, and enzymatic assays. Two genes encode two molecular forms of GAD, GAD_{65} and GAD_{67}, which differ in their dependence on pyridoxal phosphate (PLP), with GAD_{65} more dependent on exogenous PLP for activity. Between P4 and P7, GAD_{65} mRNA increases markedly in the striatum, but not in other regions of the brain. We observe no similar increases in GAD_{67} mRNA. Elevated levels of GAD_{65} mRNA persist for one week and then decline. In parallel with the increase in GAD_{65} mRNA is an increase in PLP-dependent enzyme activity in midbrain homogenates, which include the substantia nigra (SN), the primary projection of GABAergic striatal neurons. We suggest that the postnatal increase in GAD_{65} mRNA is associated with the innervation of the SN by GABAergic neurons of the striatal matrix, which innervate the SN from P3 to P7. The increased expression of GAD_{65} is responsible for the increase in PLP-dependent activity in midbrain homogenates. The selective increase in GAD_{65} may be responsible for increased susceptibility to PLP-antagonist induced seizures after P7. Supported by NS08713 (KFG) and NS22256 (AJT).

DEVELOPMENTAL REGULATION OF ENDOTHELIN GENE EXPRESSION IN THE HUMAN BRAIN. Alan K.Hall*[1], Michael R.Condon*[1], Stuart D. Cook[2], Lynne H, Parker-Botelho*[3], and Christina Cade*[3].
[1]Urology Research Laboratory,UMDNJ,Newark,NJ,07103
[2]Department of Neurosciences,UMDNJ,Newark,NJ,07103
[3]Department of Pharmacology,Berlex Laboratories Inc,Cedar Knolls, NJ 07927, U.S.A.

The endothelins comprise a family of small, (<2.5Kd), structurally related polypeptides,that exhibit potent vasoconstrictive activity. Other, non-vascular tissues, including the brain, also contain immunoreactive endothelin. We used radioimmunoassays for endothelin (ET)-1 and ET-3 to measure these two isoforms in human brain homogenates at various stages of normal neurogenesis. Low,but detectable (<200fmoles/mg protein) of both proteins were present in fetal brain as early as 47 days post-conception. Neural ET-1 and ET-3 levels increased during gestation and were maximally expressed in the neonatal/adult brain. These findings suggest that the endothelin gene(s) are regulated during human neuroembryogenesis.

METABOLIC-ENDOCRINE CORRELATES OF THE LATERAL HYPOTHALAMIC SYNDROME:THE FIRST 48 HOURS. L.Bernardis and L.Bellinger. VAMC Buffalo, Sch. of Med., SUNY/Buffalo, 14215 and Dept. Physiol., Baylor Coll. Dent., Dallas, TX, 75246

Mature male rats received bilateral electrolytic lesions (L) in the lateral hypothalamic area (LHA). One group of sham-operated controls was fed ad libitum (CON-ADLIB), a second CON group was pair-fed to the LHA rats (CON-PF). Two days later all rats were killed by decapitation. Body weight, food intake (FI), food efficiency, carcass fat, liver weight, epididymal fat pad (PAD) weight, incorporation of glucose-U-C14 carbon (GLUCINC) into liver total lipid and glycogen, plasma glucose and insulin were significantly (SIG) reduced in LHA vs. CON-ADLIB. Carcass protein, PAD protein and GLUCINC into PAD lipid and glycogen were normal and liver protein and plasma free fatty acids (FFA) were SIG higher in LHA vs. CON-ADLIB. Compared to CON-ADLIB, CON-PF showed the identical changes seen in LHA rats, except that PAD weight was comparable to CON-ADLIB and that CON-PF had SIG less GLUCINC into PAD glycogen than CON-ADLIB. Furthermore, CON-PF had SIG lower plasma glucose, GLUCINC into liver glycogen and PAD total lipid and lower carcass protein than LHA rats. Plasma FFA were SIG higher in CON-PF than in LHA rats. Some metabolic changes in LHA rats appear sooner after LHAL and appear to be food-related. Other changes appear to be independent of reduced FI. Supported by VA and Baylor Coll. Dent. Research funds.

535.1

PRODYNORPHIN mRNA REGULATION BY GABA-A RECEPTOR IN THE MOUSE STRIATUM. C.Jomary[1], J-C. Schwartz* and C. Llorens Cortes*. [1]Johns Hopkins University, Medical School, Molecular Neurobiology Unit, NIDA/ARC, P.O.Box 5180, Baltimore MD21224 USA; Unité de Neurobiologie et Pharmacologie (U109) de l'INSERM, Centre Paul Broca, 2 ter rue d'Alesia, 75014 Paris, FRANCE.

There is clear evidence that striatal GABA receptors control enkephalin levels, release in vitro and in vivo and biosynthesis. Early studies have shown that GABA-A receptor stimulation induced a decrease in striatal enkephalin release and an inhibition of enkephalin gene expression in mouse striatum. In order to know if GABA receptors also modulate dynorphin biosynthesis, we have investigated the effect of GABAergic agents on dynorphin gene expression in mouse striatum. An acute or chronic I.V. administration of muscimol (GABA-A receptor agonist) plus diazepam (benzodiazepine receptor agonist, which potentiates the effect of muscimol) has been tested. Northern blot analysis showed that while striatal prodynorphin mRNA content was not modified after chronic injection of muscimol and diazepam, an increase (1.6X) was observed after acute treatment. The *in situ* hybridization studies, done on half of the same animals treated, supported these observations. These results suggest that muscimol and diazepam have a early stimulation effect (acute treatment) on dynorphin neurons, which is followed by a compensation event (chronic treatment) reflecting an adaptative control of the precursor biosynthesis in dynorphin perikarya. It appears that in the mouse striatum, the GABA system may regulate the expression of preproenkephalin and preprodynorphin genes in a different manner.

535.2

REGULATION OF GLUTAMIC ACID DECARBOXYLASE (GAD) EXPRESSION IN DEVELOPING MOUSE BRAIN: EMBRYONIC TRANSCRIPT CODES FOR A TRUNCATED GAD PROTEIN. G. Szabo*, Z. Katarova*, Zs. Urban*, T.J. Gorcs† and R. Greenspan. *Dept. of Biochem., BRC, Szeged P.O. Box 521, H-6701, Hungary; †Neuromorphology Lab., Semmelweis Med. Univ., Budapest H-1094, Hungary; Dept. of Neurosciences, Roche Inst. of Molec. Biol., Roche Research Center, Nutley, NJ 07110

Two major GAD transcripts are present in developing mouse brain (3.7kb and 5.7kb) as early as embryonic day 13. The 5.7kb message is predominant in embryo and virtually undetectable after birth. The quantity of the 3.7kb transcript increases only by 50% and reaches its adult level by birth. On the other hand the adult forms of GAD protein (59 kDa and 62 kDa) are hardly detectable until the end of the first postnatal week. At the same time a 40 kDa protein can be detected by immunostaining of Western blots of brain extracts from ages E13 to P14. Recently we have identified 2 GAD genomic loci in the mouse Gad-1 and Gad-1ps on Chr 2 and 10 respectively. Gad-1ps by many criteria resembles a processed pseudogene which has a moderately and highly homologous region with mouse GAD cDNA separated by an inframe stop codon. This indicates that Gad-1ps might have arisen from a different transcript expressed very early in development. A MET following the stop codon could serve as a very strong potential initiation site for the translation of the rest of the ORF coding for a 45 kDa protein which is in good agreement with the size of the embryonic form of GAD. Based on our results we propose that a transcript different from the adult one codes for a truncated embryonic GAD protein.

535.3

HALOPERIDOL TREATMENT INCREASES D_2 DOPAMINE RECEPTOR PROTEIN INDEPENDENT OF RNA LEVELS IN MICE. J. R. Goss, A. B. Kelly, S. A. Johnson*, and D. G. Morgan. Andrus Gerontology Center, U.S.C., Los Angeles, CA 90089-0191.

Haloperidol and other antipsychotic drugs require 1-2 weeks before they ameliorate some of the symptoms of schizophrenia. Rats treated with these drugs develop increased numbers of D_2 dopamine receptors. The mechanism involved in this receptor up-regulation is unknown but may result from: a) an increased synthetic rate caused by elevated steady state RNA levels, or b) reduced internalization/degradation due to decreased agonist activation. We treated fifty C57Bl/6J male mice with 3mg/kg/day of haloperidol in their drinking water for 7 days, with no withdrawal period. Haloperidol treatment increased D_2 receptor density (B_{max}) measured with [^{3}H]spiperone by 20% with no change in the K_d (n=8). Northern blot analysis (n=6) failed to detect any difference in D_2 receptor RNA between treated and untreated mice, although differences were easily detected when 10% more RNA was intentionally added to the gels. Prepro-enkephalin RNA increased in the haloperidol treated mice, as described by others previously. These results indicate that increased steady-state RNA levels are not necessary for receptor up-regulation. ANTISENSE OLIGONUCLEOTIDE INHIBITS EXPRESSION OF ACETYLCHOLINE RECEPTORS. J.P.Alsobrook II. Child Study Center, Yale University School of Medicine, New Haven, CT 06510.

In a preliminary effort to understand the transcriptional regulation of nicotinic acetylcholine receptor (nAChR) expression, a non-ionic antisense oligonucleotide was used to inhibit transport and/or translation of the mRNA coding for the four nAChR subunits.

Expression of nAChRs in muscle cells is regulated at the level of transcription of its four subunits, and can be modeled in BC3H1 cells, a myogenic line which expresses nAChRs when incubated in low serum media. To inhibit this expression, a 12-mer antisense methylphosphonate oligonucleotide (Marcus-Sekura,C., *Anal.Biochem.* 172:289-295, 1988) was designed using a "universal" nAChR cDNA sequence as a guide (Buonanno et al., *J.Biol.Chem.* 261:16451-16458,1986) . Mitotic BC3H1 cultures were incubated in low serum in the presence of 0.4uM and 4.0uM oligonucleotide. Surface nAChRs were assayed at 2.5 days and 5 days using ^{125}I-labeled bungarotoxin. The lower oligo concentration had no effect compared to control, while the higher concentration reduced surface nAChRs by approximately 50%. Subunit-specific antisense oligonucleotides will provide a new tool for analysis of the regulation of nAChR transcripts.

535.5

RAPID QUANTITATION OF TYROSINE HYDROXYLASE (TH) mRNA BY SOLUTION HYBRIDIZATION (SH). Y.S. Zhu, S.B. Jones*, A.D. Branch*, H.D. Robertson*, S.O. Franklin* and C.E. Inturrisi. Cornell Univ. Med. Coll. and Rockefeller Univ., New York, N.Y. 10021.

To facilitate the study of the regulation of TH gene expression, a rapid, sensitive and quantitative method for measuring TH mRNA levels was developed. The assay is based on ribonuclease protection of a 32P-labeled riboprobe (from a 380 bp cDNA of the rat TH mRNA sequence). After hybridization for 16 hrs at 75°C, resistant riboprobe is precipitated with TCA and filtered using a cell harvester. Analysis was by scintillation counting and quantitation of mRNA was by use of a standard curve generated from a TH sense transcript. A novel feature of our approach is the concurrent use of an SH assay which uses a probe for 18S rRNA to calculate total cellular RNA present in each sample subjected to the TH mRNA assay. The hybridization conditions produced a linear curve from 2 to 125 pg of TH sense transcript (equivalent to 10 to 625 pg of TH mRNA). Reserpine treatment (4 mg/kg sc, once daily for two days), produced at 24 hours after the second dose a 4-fold increase in adrenal TH mRNA (4.8 to 21.3 pg/ug RNA) in Lewis rats, a 4-fold increase in SD rats (5.3 to 21 pg/ug RNA) and an 8-fold increase in Syrian hamsters (4.5 to 36.8 pg/ug RNA). These results demonstrate the sensitivity and utility of this method for quantitation of TH mRNA. (Supported in part by NIDA Grants DA-01457 and DA-05130.)

535.6

APPEARANCE OF TYROSINE HYDROXYLASE-LIKE IMMUNOREACTIVITY AND TYROSINE HYDROXYLASE mRNA IN CEREBELLAR PURKINJE CELLS OF THE MUTANT TOTTERING AND LEANER MOUSE. M.C. Austin, L. Abbott †, P. Montpied*, J. Evers*, S.M. Paul*, J.N. Crawley and M. Schultzberg, Clinical Neuroscience Branch, NIMH, Bethesda, MD, †Dept. Vet. Bioscience, University of Illinois, Urbana, IL.

Tottering (tg) and leaner (tg^{la}) are autosomal recessive murine mutations that are characterized by the development, at approximately 4 to 5 weeks of age, of spontaneous absence seizures, focal motor seizures, and ataxia, which continue throughout adulthood. The tg/tg^{la} mutants have considerably more severe focal motor seizures and ataxia compared to the tg/tg mutants. Noebels (1984) reported that the major neurochemical abnormality in the brain of these mice is a noradrenergic hyperinnervation in terminal regions of neurons located in the locus coeruleus (LC). Based upon this finding we examined tyrosine hydroxylase (TH) mRNA levels and TH-immunoreactivity in the brains of these mice. *In situ* hybridization results did not reveal a significant difference in concentration of TH mRNA in LC neurons in tg/tg or tg/tg^{la} mice. However, we now confirm and extend the previous finding by Hess and Wilson (Neurosci Abstr 393.12;1989) of high levels of TH mRNA and TH immunoreactivity (IR) in cerebellar Purkinje cells of these mice. We have found a significant increase in TH grain density and TH-IR in Purkinje cells of young (pre-seizure) and adult tg/tg and tg/tg^{la} mice. Also, Purkinje cells of young and adult tg/+ and +/+ wild type control mice expressed TH mRNA and TH-IR, but at a much lower level. Northern blot analysis confirmed the findings from the *in situ* and immunohistochemical studies. Purkinje cells containing TH mRNA and TH-IR were more numerous in the caudal portions of the vermis and central portions of the flocculus and paraflocculus. These findings indicate that the expression of TH in cerebellar Purkinje cells of tg and tg^{la} tottering mice is independent of seizure onset, and may be related to the genetic defect in this neurological syndrome.

MECHANISM OF INDUCTION OF mRNA FOR TYROSINE HYDROXYLASE BY MEMBRANE DEPOLARIZATION OF PC12 CELLS.
E.J. Kilbourne and E.L. Sabban. Dept. Biochem & Mol. Biol., N.Y. Med. Coll. Valhalla, NY 10595.

Membrane depolarization is a model of prolonged neuronal activity or stress. We studied the effect of 50 mM KCl, or 150 μM veratridine, on mRNA levels for tyrosine hydroxylase (TH) and dopamine β-hydroxylase (DBH). TH mRNA increased up to five fold after continuous treatment for 1 to 12 hrs with 50 mM KCl. Depolarization with 150 μM veratridine had a similar effect. In contrast, DBH mRNA levels were unchanged by either KCl or veratridine treatment.

The increase in TH mRNA was inhibited by the chelation of calcium with 3 mM EGTA. Although the calcium channel blockers nitrendipene and verapamil inhibited the secretion of norepinephrine from depolarized cells they had no effect on the increase in TH mRNA. Calmodulin antagonists trifluoperizine and W7, which inhibit the depolarization dependent phosphorylation of TH enzyme, had no effect on TH mRNA levels. Lithium (7 mM), an antagonist of the recycling of inositol, alone had no effect. However, when added together, lithium and verapramil prevented the rise in TH mRNA due to membrane depolarization.

We conclude that either extracellular, or IP3 sensitive intracellular, pools of calcium may be required for the induction of TH mRNA in depolarized PC12 cells.

535.8

REGULATION OF TYROSINE HYDROXYLASE GENE TRANSCRIPTION IN PC18 CELLS BY CELL DENSITY.
C. D. Carlson and A. W. Tank, Department of Pharmacology, University of Rochester, Rochester, NY 14642.

Increasing cell-cell contact in rat pheochromocytoma PC18 cells elevates the levels of tyrosine hydroxylase (TH) and TH-mRNA. In previous studies we have shown that these increases are due at least partially to an elevation in the transcription rate of the TH gene. In this report we further investigate the effect of cell density on TH gene transcription. When PC18 cells are cultured at high density (2×10^5 cells/cm^2), the transcription rate of the TH gene is identical to that observed in cells cultured at low density (1×10^4 cells/cm^2) for approximately 6-12 hours. After this prolonged lag period, the transcription rate of the TH gene in high density cells increases 2-3 fold over that observed in low density cells and remains elevated for at least 48 hours. This time course correlates well with that observed for the effect of high cell density on TH-mRNA levels in PC18 cells. In addition, we have examined the role of cAMP in the density mediated induction of TH. The effects of high cell density and the cAMP analog, 8-chloro-4-phenylthio cAMP, are additive on TH-mRNA levels and TH gene transcription rate. These results suggest that in PC18 cells the cell-cell contact mediated stimulation of the TH gene is not elicited by a cAMP-dependent pathway. Furthermore, the time course of this effect on TH gene transcription shows a delayed onset; hence, this effect may depend upon the initial synthesis of factors that regulate the transcription rate of the TH gene.

HYPOXIA STIMULATES TYROSINE HYDROXYLASE GENE EXPRESSION IN RAT CAROTID BODY.
M.F. Czyzyk-Krzeska, D.A. Bayliss and D.E. Millhorn, Department of Physiology, University of North Carolina, Chapel Hill, NC 27599.

Tyrosine hydroxylase (TH) is the rate limiting enzyme in the biosynthesis of dopamine, a transmitter in the body (CB). The present studies were undertaken to carotid determine if gene expression for TH is increased in CB during hypoxia, a natural stimulus of CB. Adult rats were exposed to either hypoxia (10% O_2) or air (control) for periods lasting from 2 to 48 hr. They were anesthetized and CB, superior cervical ganglion (SCG) and petrosal ganglion (PG) were removed and processed for *in situ* hybridization with [^{35}S]-labeled oligonucleotide probes. TH mRNA was increased at all time points in CB after hypoxia relative to control. In contrast, TH mRNA was not increased in SCG and PG by hypoxia. To determine if increased expression of TH in CB is unique for hypoxia, another group of rats was exposed to hypercapnia (10% CO_2), another natural stimulus of CB. In no case did hypercapnia cause increased expression of TH in CB. Importantly, the increased TH mRNA during hypoxia in CB was unaffected by complete denervation of CB. We conclude that hypoxia, but not hypercapnia, acts directly on CB (*i.e.* does not require neural input) to enhance TH gene expression. (NIH HL33831, HL34919, AHA 881108 and ALA)

RAT TRYPTOPHAN HYDROXYLASE GENE EXPRESSION IN BRAINSTEM AND PINEAL GLAND.
R.P. Hart, R. Yang* and L.A. Riley. Dept. of Biol. Sci., Rutgers University, Newark, NJ 07102.

We have cloned a segment of the rat tryptophan hydroxylase gene using synthetic oligonucleotides from the cDNA sequence (Darmon et al., J. Neurochem. 51: 312, 1988) as probes. The 15 kb region encodes five exons of the pineal cDNA sequence. Exon sequences are completely homologous to the published cDNA sequence, and the intron-exon junction positions match those predicted by homology with phenylalanine hydroxylase and tyrosine hydroxylase gene sequences.

Using oligonucleotides from the cDNA sequence, we detect two species of mRNA on Northern hybridization (1.8 and 4.5 kb) in both pineal and brainstem RNA. The brainstem TPH mRNA is present at exceedingly low levels--detection was only possible with poly(A)$^+$ RNA and long exposures. However, TPH mRNA was easily detected in pineal total cellular RNA.

In order to begin to determine why such a discrepancy in TPH mRNA levels exists between pineal and brainstem, we utilized our cloned TPH gene sequences in a nuclear run-on assay for transcription. Results indicate similar levels of transcription from the TPH gene in pineal gland, medullary raphe and midbrain raphe regions. This indicates that levels of TPH mRNA are controlled post-transcriptionally. (Supported by NSF BNS 890551.)

STIMULATION OF PNMT mRNA EXPRESSION BY Ca^{2+} ION INFLUX.
M.J. Evinger, T.H. Joh and D.J. Reis. Dept. Neurobiol. and Lab. Molec. Neurobiol., Cornell Univ. Med. Coll. NY, NY 10021 USA.

Previously we demonstrated that specific neurotransmitters can alter steady state levels of messenger RNA for the epinephrine-synthesizing enzyme phenylethanolamine N-methyltransferase (PNMT). In primary bovine adrenal chromaffin cell culture, PNMT mRNA increases upon treatment with cholinergic (nicotine and muscarine), histaminergic, and imidazole agonists, probably through activation of defined second messenger systems. Because certain neurotransmitter effects are mediated in part by increasing intracellular Ca^{2+} levels, we tested the hypothesis that elevated levels of calcium may independently stimulate production of PNMT mRNA. Accordingly, incubation of bovine chromaffin cells with the Ca^{2+} channel ionophore A23187 or the agonist BAY K 8644 (100 nM) elicited a 2-4-fold increase in PNMT mRNA detected by quantitative hybridization, increases consistent with and of greater magnitude than those produced by 20 mM Ca^{2+}. In chromaffin cells, nicotinic receptors are positively associated with the influx of extracellular calcium. Likewise, blocking Ca^{2+} entry diminishes nicotine-induced increases in PNMT mRNA levels: the Ca^{2+} channel antagonists nifedipine, verapamil and ω-conotoxin as well as EGTA attenuate to varying (40-85%) degrees the PNMT mRNA response to 50 μM nicotine. Considering that Ca^{2+} also stimulates other adrenal medullary genes, notably enkephalin, these results collectively establish a regulatory role for calcium ion influx as an independent and significant neuromodulator of PNMT gene transcription.

535.12

RAT PINEAL/RETINA HYDROXYINDOLE-O-METHYLTRANSFERASE (HIOMT): cDNA ISOLATION, PCR CHARACTERIZATION AND EXPRESSION.
V. Simonneaux and C.M. Craft. Lab. of Mol. Neurogenetics, Psychiatry, UT Southwestern & VA Med. Ctr., Dallas, TX 75235

Melatonin is a unique indoleamine synthesized in pineal and retina from serotonin. Circadian utilization of serotonin during darkness or adrenergic stimulation for melatonin synthesis are achieved through expression of the enzymes arylalkylamine N-acetyltransferase (NAT) and HIOMT. As a first step in the elucidation of the mechanism that regulates these enzymes and the genetic basis of circadian rhythms, we isolated cDNAs which encode these pineal/retinal specific enzymes.

A rat pineal (RP) LambdaZap^{TM} library (Craft et al., J. Neurochem., in press) was screened (1×10^5 plaques) with a cDNA probe for bovine pineal HIOMT (cBPH) (Ishida et al., 1987, JBC 262:2895). Plaque-purified recombinants (cRPH/1-6) were amplified by polymerase chain reaction (PCR) with +SK/-KS cloning site primers. Products were electrophoresed on a 2% agarose gel. Insert sizes were 0.4 to 2.1 kb. Sequence verification of cRPH/1-6 are being analyzed. PCR of the 2.1 kb cRPH paired with +/-BPH primers revealed bands of similar size as cBPH control. PCR of cDNAs synthesized from total rat pineal/retinal mRNA with +/-BPH primers revealed fragments of the predicted size in both tissues with lower levels in retina.

Hybridization of an RNA transfer blot of total RNA electrophoresed on 1.2% denaturing agarose gel with cBPH probe revealed a 2.1 kilobase (kb) mRNA in BP and RP but no detectable signal in retina. RNA blot analysis of mRNAs isolated from RPs throughout the 24 hr cycle with cBPH suggests higher expression of the HIOMT mRNA during darkness. Although HIOMT enzyme activity remains nearly constant thoughout the 24 hr, the mRNA appears to fluctuate. (Support NINCDS/NIH 1R29/NS28126-01, Veterans Admin.)

Six novel behavioral mutations identified by transpositional mutagenesis in *Drosophila*. L.C. Timpe, T.E. Crowley*, S. Barbel*, Y.-N. Jan and L.Y. Jan. Howard Hughes Med. Inst. and Depts. of Physiology and Biochemistry, UCSF, S.F. Calif. 94143.

In a search for new mutations which affect proteins important for electrical excitability, we screened 3800 mutant lines created by insertion of a P element-derived transposon. The transposon contained the *white* gene and the *E. coli lacZ* gene under the control of a weak promotor. The tissue specificity of *lacZ* expression in these mutants is controlled by the genomic sequences flanking the insertion site (Bier et al., Genes and Development 3:1273, 1989). Screening for embryonic X-gal staining yielded over 1000 lines with CNS patterns; 500 of these were screened for leg shaking under ether. Six autosomal shakers were found, and the transposons were mapped by *in situ* hybridization to larval polytene chromosomes. One mutation is male sterile in addition to being an ether shaker. The sperm from this mutant are immotile when released from the testis into saline culture.

Are the shaking phenotypes due to insertion of the mutagenic transposon? The transposons were excised by a second mobilization, and the revertants scored for shaking. Shaker$^+$ revertants were found for 5 of 6 mutants.

Genomic DNA flanking the sites of the insertion has been obtained by plasmid rescue and by screening a genomic library. This DNA is being used to identify messages on Northerns, for whole mount *in situs* of embryos, and to screen cDNA libraries.

536.2

THE DEVELOPMENT OF ACTIVE MEMBRANE ELECTRICAL RESPONSES AND GLUTAMATE RECEPTORS IN CULTURED RAT CEREBELLAR PURKINJE CELLS. J.R.Brorson[1], J.A. Holzwarth[2], and R.J. Miller[2]. Depts. of [1]Neurology and [2]Pharm. and Phys. Sci., University of Chicago, 947 E. 58th St., Chicago IL 60637.

We have studied the development of active membrane properties of a relatively pure population of cultured Purkinje cells, using whole cell patch clamp and fura-2 based [Ca^{2+}]i microfluorimetry techniques, with a view to elucidate the role of Ca^{2+} in intracellular regulation in these neurons. Cerebella from day 16 embryonic rats were dissociated and cultured in defined serum-free medium over a feeding layer of astrocytes. By immunocytochemical staining for calbindin, which is specific for Purkinje cells within the cerebellum, approximately 90% of cells stained positively. Within the first several days in culture, these cells exhibited voltage activated Na^+ and Ca^{2+} conductances and fired single action potentials. By the end of the first week in culture the conductances were larger and the cells began to fire bursts of Na^+ action potentials during current stimuli. During the second week in culture, trains of spontaneous action potentials became common, similar to the repetitive action potentials reported in Purkinje cells in slices (Kapoor, R. et. al., Neurosci. 26:493-507, 1988). Sensitivity to glutamate, as indicated by a rise in [Ca^{2+}]i, was observed from the earliest times in culture and increased as the cells matured; these responses were greater in Mg^{2+}-free solutions. Thus, these cultured Purkinje neurons show an early progression towards mature cell characteristics.

536.3

DEVELOPMENT OF EXCITABLE MEMBRANE PROPERTIES IN EARLY POSTNATAL RAT SEPTAL NEURONS. J.B. Suszkiw+•, A.E. Schaffner• and J.L. Barker•. •Laboratory of Neurophysiology, NINDS, NIH, Bethesda, MD and +Department of Physiol. & Biophysics, Univ. of Cincinnati Med Sch., Cincinnati, OH.

Septal neurons dissociated from PN1-2 and PN6-7 rats were studied between 24-120 hrs in culture using whole cell patch recording. The neurons had RMPs in the range -40 to -80 mV, resistances 0.5 to 1 Gohms, and 50-90 mV APs. Depolarization from HP -80 mV elicited fast, TTX-sensitive inward (2-3 nA) I_{Na}'s and transient and sustained outward K^+ currents. Pharmacological dissection of the outward currents indicated that by PN6-7 several types of K^+ currents (I_A, I_C, TEA-sensitive and -insensitive I_K) are expressed in various proportions in the septal neurons. Sustained inward Ca^{2+} currents (50-150 pA) were recorded in all PN6-7 neurons tested, but were not routinely detectable in the PN1-2 neurons. All PN1-2 and PN6-7 neurons tested were sensitive to glutamate and GABA but did not respond to ACh or NE. Application of glutamate usually elicited multiple AP's. Preliminary experiments with cell-attached patch recording indicated that like glutamate, GABA also produces depolarizing, functionally excitatory responses. These results suggest that PN1-PN7 septal neurons are still in the process of differentiation of their membrane electrical and chemosensitive properties.

CALCIUM SPIKES AND CALCIUM PLATEAUX EVOKED FROM DISTAL DENDRITES OF TURTLE SPINAL MOTONEURONES BY APPLIED ELECTRIC FIELDS. J. Hounsgaard* and O. Kiehn*, Inst. of Neurophysiology, Univ. of Copenhagen, Blegdamsvej 3C, DK-2200 Copenhagen N., Denmark.

In motoneurones in transverse slices of the turtle spinal cord nefidipine insensitive Ca spikes are promoted by TEA while nefidipine sensitive Ca plateaux are promoted by 5-HT and apamin (Hounsgaard et al. J. Physiol. 398: 575-589, 398: 591-603, 414: 265-282). We have used differential polarization by applied electric fields (Chan et al., J. Physiol. 402: 751-771 and 409: 145-156) to determine the compartmental origin of the two Ca mediated regenerative responses. During experiments the transmembrane potential was measured at the motoneuronal soma while electric fields were established by passing current between plate electrodes on either side of the preparation. Synaptic responses were minimized by the presence of TTX, 2APV, CNQX bicuculline, strychnine and picrotoxin.

In the presence of TEA electric fields in the ventrodorsal or the mediolateral direction could evoke Ca spikes independent of the polarity of the field and of the membrane polarization at the soma. In the presence of apamin Ca plateaux were generated by the same regime of differential polarization that was used to generate Ca spikes.

The results show that distal dendritesin motoneurones can support Ca spikes and Ca plateaux. This suggests that voltage dependent current generators are involved in local processing of synaptic responses in the dendrites of motoneurones.

DIRECT DETECTION OF VASOPRESSIN FROM INDIVIDUAL NERVE TERMINALS OF THE RAT NEUROHYPOPHYSIS AFTER WHOLE-CELL PATCH-CLAMP RECORDING. X. Wang*, S.N. Treistman and J.R. Lemos. Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545.

We have developed an immunoblotting technique to detect arginine vasopressin (AVP) in individual isolated nerve terminals from the neurohypophysis. After standard whole-cell patch-clamp recording, the contents of terminals were sucked up into the recording electrode and stored at -20°C. The immunoblot control assays were prepared by blotting known amounts of three antigens (AVP, oxytocin and met-enkephalin) on the nitrocellulose membrane and then exposing to AVP-antibody. AVP showed positive reactions in concentrations ranging from 50 pg - 10 ng, while oxytocin and met-enkephalin showed no reactions. A total of 59 terminals were assayed, 44 of which showed positive reactions and 15 of which showed no reactions. We were also able to characterize the Ca-currents of these individual isolated neurohypophysial terminals. This technique is uniquely designed to assist in direct identification of a variety of antigens and other markers from individual cells (or sub-cellular compartments such as terminals) after whole-cell patch-clamp studies characterizing voltage-gated currents and drug effects, and should allow direct correlation between physiology and cell type. This research supported by PHS grant AA08003.

ATP RECEPTOR-OPERATED CA INFLUX AND ^{3}H-NOREPINEPHRINE RELEASE IN PC12 CELLS. K. Inoue*, K. Nakazawa, K. Fujimori ,and A. Takanaka, Div. Pharmacology, NIHS, 1-18-1 Kamiyoga, Setagaya, Tokyo 158, Japan

We have previously reported that ATP stimulates ^{3}H-norepinephrine (NE) secretion by a mechanism not coupled with voltage-gated Ca channels (Neurosci.Let.,106,294, 1989). We report here more details of this mechanism as determined using the batch method previously reported (J.Biol. Chem., 263, 8157, 1988), and the whole cell voltage-clamp technique. ATP stimulated intracellular Ca increase and NE secretion from PC12 cells in a dose-dependent manner which paralleled that of the ATP-activated current in the concentration range from 15 μM to 1 mM. The secretion and increase of intracellular Ca were dependent upon extracellular Ca, but were not inhibited by the Ca-channel blockers nicardipine (up to 10μM) or cadmium (up to 300μM). ATP-stimulated NE secretion was not influenced by an increase of extracellular Ca up to 18 mM, but was inhibited by higher concentrations in accord with our report on the ATP-activated Ca current (J.Physiol. (Lond.), in press, 1990). Secretion was inhibited by the P2-purinoceptor blocker suramine (30-300 μM). The rank order of potency of agonists in evoking the secretion was ATP > ATP-γ-S » ADP. β,γ-Methylene ATP, AMP or adenosine had no effect. These findings suggest that extracellular ATP activates P2 receptor-operated Ca channels in PC12 cells and that the resultant Ca influx evokes NE secretion.

4-AMINOPYRIDINE ALTERS CYCLE FREQUENCY AND PHASE RELATIONSHIPS AMONG PYLORIC NEURONS IN THE LOBSTER STOMATOGASTRIC GANGLION. A.J. Tierney and R.M. Harris-Warrick. Section of Neurobiology and Behavior, Cornell University, Ithaca, N.Y. 14853.

The presence of I_A in certain pyloric neurons (PD,AB,PY) suggests that this conductance could influence cycle frequency and burst phasing of PY cells (Hartline, 1979; Hartline and Graubard, 1984). We used 4-aminopyridine (4-AP; 1 mM) to reduce I_A in cells within the intact circuit and in individual cells isolated from other pyloric neurons. In the intact circuit, 4-AP always increased cycle frequency (X = 27%; n = 8). 4-AP also altered the phase relationships of all cells relative to the PD burst onset. LP, PYs and IC were phase advanced (Xs = 12%, 10%, 6%, respectively, of the total cycle period). The VD was greatly phase delayed (X = 37%), possibly due to enhanced LP inhibition. In all cells, spikes/burst and spike frequency within bursts were significantly increased by 4-AP. Changes in oscillation amplitude were inconsistent, except in the AB neuron where oscillation amplitude always increased during 4-AP application (4-5 mV; n = 4). When cells were isolated from other pyloric neurons (using photoinactivation and PTX; no sucrose block) 4-AP enhanced tonic or bursting activity in all cells. These data are consistent with the hypothesis that cells thought to lack significant I_A (LP, VD, IC) may possess this conductance in nonsomatic cell regions. Supported by NRSA #NS08337-01 (AJT) and NIH #NS17323 (RMH-W).

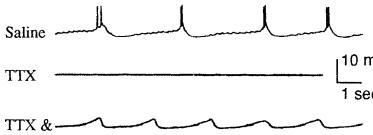
EFFECTS OF NICKEL ON STOMATOGASTRIC NEURONS. *L. Zirpel, D. Baldwin* and K. Graubard*, Depts. of Physiology & Biophysics and Zoology, Univ. of Washington, Seattle, WA 98195

The divalent cation Ni^{2+} has been shown to specifically block T-type calcium channels in mammalian neurons. However, the effects of this ion on invertebrate neurons are relatively uncharacterized. The objective of this study was to determine the effects of Ni^{2+} on pyloric neurons of the spiny lobster, *Panulirus interruptus*.

The stomatogastric ganglion was maintained *in vitro* at 14°C and perfused with chloride saline. Data were obtained from pre- and postsynaptic somata using 2 two-electrode current clamps. TTX was added to the saline to eliminate spikes and rhythmic activity.

Concentrations of 50-100μM Ni^{2+} induced voltage oscillations of similar amplitude and frequency as the endogenous rhythmic activity. Lower concentrations of Ni^{2+}, 25-50μM, increased the input resistance of the neurons, enhanced both synaptic and electrical transmission and altered the voltage waveforms. These effects are qualitatively different from the simple blocking action of 1mM Cd^{2+}.



These results indicate that Ni^{2+} exerts qualitatively different effects on crustacean and mammalian neurons.

CALCIUM DEPENDENCE OF SPIKE REPOLARIZATION IN RAT MAGNOCELLULAR NEUROSECRETORY CELLS (MNCs). **K. Kirkpatrick and C.W. Bourque** ***Centre for Research in Neuroscience, Montreal General Hospital and McGill University, Montreal, Canada H3G 1A4.***

Activity dependent changes in spike duration in MNCs result from the variable expression of a Ca^{++}-component (Bourque and Renaud, 1985, J. Physiol. 363). This study reveals an additional role for Ca^{++} in controlling spike duration. Intracellular recordings were made from 37 supraoptic nucleus MNCs in hypothalamic explants superfused with artificial CSF (32°C). Single spikes were elicited at 0.5 Hz from a fixed subthreshold membrane potential by applying 8 ms depolarizing pulses. Addition of Ni^{++} or Cd^{++} (100-400 μM, n=17) or removal of extracellular Ca^{++} (n=8) consistently and reversibly decreased spike duration. In contrast, raising $[Ca^{++}]_o$ from 2 to 4 mM had either no effect or decreased spike duration (n=4), but increased the rate of spike repolarization. This apparent paradox suggests that Ca^{++} influx may contribute to the activation of repolarizing currents. In agreement, intracellular injection of BAPTA, a Ca^{++} chelator, progressively increased spike duration (n=8) in concert with the disappearance of the AHP. These results suggest that a rapid Ca^{++}-dependent K^+ current may contribute to spike repolarization in MNCs. ***Supported by FRSQ and MRC.***

MODULATION OF MOTONEURON REPETITIVE FIRING BY MULTIPLE OUTWARD CURRENTS. F. Viana and A.J. Berger. Dept. of Physiology & Biophysics, Univ. of Washington School of Medicine, Seattle, WA 98195.

We examined the firing properties of hypoglossal motoneurons in transverse brainstem slices (500 μm) from mature guinea pigs. Depolarizing constant current pulses from rest (-60 to -70 mV) evoked repetitive firing that showed a decrementing pattern (adaptation). Hyperpolarizing voltage-clamp pre-pulses (1 sec) caused an early decrease in firing rate, which then reversed to an accelerating type of discharge pattern. At slow firing frequencies (<25 Hz) the hyperpolarizing pre-pulse caused a significant delay to the first spike (delayed excitation). Solutions with nominally zero Ca^{2+} and 0.5 mM EGTA (or addition of 300 μM Cd^{2+}) caused an approximate two-fold increase in the slope of the steady-state frequency-current relationship but did not prevent the early decrease in firing and the delayed excitation caused by the hyperpolarizing pre-pulse. The spike duration, including the fast repolarization, was virtually unaffected by removal of Ca^{2+}, but the medium duration afterhyperpolarization was abolished.

In voltage-clamp, after TTX, removal of Ca^{2+} caused a strong reduction of the steady-state outward current evoked by depolarizing voltage steps. Hyperpolarizing pre-pulses resulted in removal of inactivation of a slow transient outward current not blocked in Ca^{2+}-free solution. Both outward currents decreased in amplitude with high extracellular K^+. In some cells, 4-AP (500 μM) caused only modest reduction of the transient current. We conclude that the pattern of discharge of hypoglossal motoneurons is modulated by voltage- and Ca^{2+}-activated potassium currents. These results may prove relevant for aspects of synaptic integration and recruitment timing. (Supported by NS 14857)

I_H AND RHYTHMIC FIRING IN IDENTIFIED VISUAL CORTICAL NEURONS. J.S. Solomon and J.M. Nerbonne. Dept. of Pharmacology, Washington University Medical School, St. Louis, MO 63110.

We have previously demonstrated that β-adrenergic agonists attenuate a hyperpolarization-activated inward current, I_H, in layer V superior colliculus-projecting (SCP) neurons of rat primary visual cortex. Because norepinephrine disrupts rhythmic firing of lower layer cortical neurons in vivo, we are investigating the role of I_H in patterning the response of SCP cells to inhibitory inputs.

Dissociated SCP neurons from postnatal day 7-13 Long-Evans rats were identified in vitro following in vivo retrograde labeling with rhodamine beads. Whole-cell recordings were obtained within 48 hrs after isolation. In all SCP cells, hyperpolarizations from a holding potential of -40 mV evoke an instantaneous, noninactivating inward current; steps negative to ≈-70 mV also reveal the slowly activating I_H. The current-voltage relation for I_H is linear at potentials more negative than -90 mV (n=5), and I_H is selectively and reversibly blocked by 3 mM extracellular Cs^+ (n=7). The rates of rise of I_H are best fit by single exponentials with mean (±SD) activation time constants of 1.88±0.74 and 0.45±0.22 sec at -80 mV (n=7) and -110 mV (n=11), respectively. Under current clamp, the activation of I_H attenuates the response to hyperpolarizing current pulses. Moreover, deactivation of I_H on removal of the hyperpolarizing current augments the firing of action potentials. I_H, therefore, appears to be important in modulating the efficacy of sustained inhibitory inputs to SCP neurons and patterning cell firing following release from inhibition. DIFFERENT ELECTROPHYSIOLOGICAL CELL TYPES IN ENTORHINAL CORTEX LAYER II IN RAT BRAIN SLICES. A. Alonso and R. Llinás. Dept. of Neurology & Neurosurgery, McGill University, Montreal, Canada, H3A 2B4 and Dept of Physiology & Biophysics, NYU School of Medicine, New York, N.Y, 10016.

Intracellular recordings were obtained from medial entorhinal cortex (MEC) neurons. Two distinct cell types were identified on electrophysiological and morphological basis. The most abundant (65%) cell type (type 1) corresponded to the "large stellete cells" characteristic of MEC layer II (Alonso & Llinas, Nature, 342: 175-177, 1989). These neurons displayed a pronounced time-dependant anomalous rectification (due to a Q-like current) and rhythmic subthreshold Na-dependent membrane potential (Vm) oscillations (7-12 Hz) which persisted the blockage of Ca-conductances. The second cell type (type 2) also had a stellete-like morphology but with one primary dendrite being thicker and longer than the others. Type 2 differed from type 1 cells by their slower action potentials, larger after-hyperpolarizations, weaker IQ "sag" and delayed firing upon depolarization. They also displayed subthreshold Vm oscillations that were less stable and of lower frequency than those in type 1 cells and which demonstrated a dual ionic mechanism being both Na- and Ca-dependent. Type 1 and type 2 neurons could also be distinguished by their sensitivity to cholinergic agonists which induced drastic changes only on type 2 cells membrane properties. In these neurons, in the presence of carbachol (40uM), post-train after-hyperpolarizations were substituted by long-lasting plateau depolarizations that sustained repetitive firing. Moreover, weak constant current injection induced slow rhythmic (< 1Hz) bursting activity. Because of the key anatomical position of EC layer II, these two cellular types will significantly contribute to the network behavior of the hippocampal system and may underlie the generation of the two known distinct types of limbic theta rhythm.

EFFECTS OF NEOMYCIN AND PHENCYCLIDINE ON TWITCH TENSION AND NERVE TERMINAL CURRENT AFTER POST-TETANIC POTENTIATION. M.C.Tsai and M.L.Chen*. Pharmacological Institute, College of Medicine, National Taiwan University, Taipei, Taiwan, R.O.C.

Post-tetanic potentiation (PTP) is a transiently increased responsiveness of the motor nerve and the increase in amount of transmitter release is responsible for the PTP. In the present study, the effects of neomycin and phencyclidine on the twitch tension and nerve terminal current after tetanic stimulation were studied on the isolated phrenic nerve diaphragm and m. triangularis sterni of mice. Neomycin and phencyclidine were associated with less post-tetanic potentiation of twitch tension if the duration of tetanic stimulation were 10 or 20 sec. Both compounds affected neither the compound action potential of phrenic nerve nor the sodium and potassium currents of the nerve terminal after repetitive stimulation. However, neomycin decreased while phencyclidine does not decrease the calcium current in the nerve terminal after repetitive stimulation. The results suggested that neomycin affected the PTP of twitch tension by pre-synaptic mechanism while phencyclidine affected the PTP by post-synaptic mechanism. ION CHANNELS IN PARANODAL SCHWANN CELL MEMBRANES OF ADULT MAMMALIAN MYELINATED FIBERS G.F.Wilson*, W. I. Welker and S.Y.Chiu.Neuroscience Training Program & Dept. of Neurophysiology, University of Wisconsin, Madison, WI 53706.

The intimate association between Schwann cell and axon in the nodal region suggests that this is a likely site for functional specialization. We examine whether there is a localized expression of channels in the Schwann cell paranodal regions using freshly isolated adult rat sciatic nerve fibers. Cell-attached and outside-out patch clamp recordings were made from paranodes where the myelin had been retracted by enzymatic treatment. Although no myelin was visible on the surface of retracted paranodes, significant portions of this surface stained with a marker (anti-galactocerebroside) for Schwann cell membrane suggesting that part of the axon still was covered by glial membrane. Indeed, Lucifer Yellow in recording pipettes diffused either into axons or Schwann cells when the membrane under the pipette tip was ruptured. Using this method to identify the origin of paranodal membranes we found delayed and inwardly rectifying potassium channels on both axon and Schwann patches. Sodium channels, however, were detected only in axon patches. This is the first report that voltage-gated glial channels are present in immediate vicinity to PNS axons. Coupled with earlier reports demonstrating that functional channels are absent in soma of adult myelinating Schwann cells, these results suggest that glial ion channels are regionally specialized for functional interactions with axons.

WHOLE-CELL PATCH CLAMP ANALYSIS OF THE PASSIVE MEMBRANE PROPERTIES OF HIPPOCAMPAL NEURONS

N. Spruston & D. Johnston, Division of Neuroscience, Baylor College of Medicine, Houston, TX 77030.

Passive membrane properties are important determinants of electrical responses in neurons with extensive dendritic arborizations. Intracellular microelectrode recordings have revealed that the specific membrane resistivity (R_m) of hippocampal neurons is relatively high. However, it is well known that microelectrode impalement introduces a leak conductance that may affect the passive membrane properties of the cell. We have used patch clamp recording of hippocampal neurons to test the hypothesis that this somatic leak conductance results in an underestimate of R_m.

Hippocampal neurons were acutely-exposed as described by Gray & Johnston (*Nature* 327:620, 1987). Whole-cell patch clamp recordings from dentate granule neurons revealed a rapid decrease of input resistance (R_N) and membrane time constant (τ_m) during the course of the experiment. Since the measured values of R_N and τ_m are directly dependent on R_m, it is likely that the observed rundown is mediated by a decrease in R_m. This rundown could be prevented by including an ATP regenerating system in the pipette or by using perforated-patch recording, suggesting that a conductance mediated by ATP-dependent K^+ channels may develop during cytoplasmic dialysis.

Under conditions where stable recordings of passive responses were obtained, we measured a τ_m of 49±7 ms (mean±SEM; $n = 6$) for dentate granule neurons and 35±6 ms (mean±SEM; $n = 6$) for CA1 pyramidal neurons. These findings suggest that R_m may in fact be higher than previously determined using microelectrodes. Such high values for R_m may serve to enhance the passive propagation of distal synaptic signals to the soma.

MATHEMATICAL MODELING OF THE SEROTONERGIC MODULATION OF ELECTROPHYSIOLOGICAL PROPERTIES OF SENSORY NEURONS IN APLYSIA. D.A. Baxter and J.H. Byrne, Department of Neurobiology and Anatomy, Univ. of Texas Medical School, Houston, TX 77225.

Serotonin (5-HT) enhances excitability and broadens the spike in the somata of pleural sensory neurons. In order to assess the relative contributions that the serotonergic modulation of three K^+ currents make to the overall effects of 5-HT, we have constructed a Hodgkin-Huxley type membrane model. The model consists of a membrane capacitance, a leakage conductance, differential equations that describe eight membrane currents, and a description of intracellular Ca^{2+}. The parameters were adjusted to simulate the characteristics of the membrane currents, spike, and excitability that are observed normally. The cAMP-dependent actions of 5-HT were simulated by reducing the maximum conductance of the 'S' K^+ current ($I_{K,S}$) and a slow component of the Ca^{2+}-activated K^+ current ($I_{K,Ca}$), whereas the cAMP-independent action of 5-HT was simulated by slowing the kinetics of the delayed or voltage-dependent K^+ current ($I_{K,V}$) (Baxter & Byrne 1989). The simulated effects of cAMP more than doubled excitability but produced only modest spike broadening. The subsequent modulation of $I_{K,V}$ doubled the duration of the simulated spike, without further increasing excitability beyond that produced by the cAMP-dependent modulation of K^+ currents. These results are remarkably similar to the physiological actions of cAMP and 5-HT, and support the hypothesis that the cAMP-dependent actions of 5-HT play a key role in regulating excitability, whereas the cAMP-independent effect of 5-HT has an important role in regulating the duration of the spike. Supported by Grant AFOSR 87-0274.

A MODEL OF THE CA3 HIPPOCAMPAL PYRAMIDAL CELL BASED ON VOLTAGE-CLAMP DATA. R.D. Traub, R.K.S. Wong and R. Miles. IBM TJ Watson Res. Ctr., Yorktown Heights, NY 10598, Dept. of Neurology, Columbia University CPS, NY, NY 10032, and Institut Pasteur, Paris, France.

It is desirable to have accurate models of CNS cells to understand the role of active membrane currents in synaptic integration and plasticity, and in determining different firing patterns, and to use as building blocks for network models. We have constructed a model of the CA3 cell as a non-uniform cable, with 6 spatially distributed active conductances: g_{Na} (4), $g_{K,delrect}$ (5), $g_{K(A)}$ (3), g_{Ca} (2), $g_{K(C)}$ (1), and $g_{K(AHP)}$ (3). The last 2 currents are Ca dependent; C-current is also voltage-dependent. Kinetics were derived from isolated pyramidal cells; C-current kinetics were derived from frog sympathetic ganglion cells. $[Ca^{2+}]_i$ had 1st order kinetics with removal τ 15 ms. Since the spatial distribution of ionic conductances is unknown, we found a consistent distribution by fitting simulated potentials to current clamp data from isolated cells, whole cells, and dendrites (7). The model then agrees with 2 critical experiments: generation of a depolarizing afterpotential after a stimulus subthreshold for bursting; and a transition from low-frequency bursting to high frequency repetitive firing as somatic membrane potential is raised (6). The model predicts the occurrence of repetitive Na-Ca spikes during steady stimulation of distal dendrites. When model cells are synaptically connected in an excitatory network, afterdischarges occur similar to those recorded in picrotoxin. REDUCTION OF DIMENSION IN DYNAMICAL SYSTEMS THAT DESCRIBE COMPLEX NEURONS. T.B.Kepler, L.F.Abbott and E.Marder, Departments of Biology and Physics and the Center for Complex Systems, Brandeis University, Waltham, MA 02155.

We develop a formal and systematic scheme of coordinate transformations and perturbation expansions for a class of dynamical systems which includes the Hodgkin-Huxley equations and many models of bursting neurons. To zeroth order, one subset of variables effectively decouples from the rest, leaving a system of fewer degrees of freedom, while preserving to the largest extent possible the time-dependent behavior of the membrane potential and conserving stability at the singular points.

When applied to models of neurons containing many conductances, this method provides direct understanding of the mechanisms underlying burst generation and provides computational efficiency when such models are used to construct networks.

Large-Scale Compartment Model of a Cerebellar Purkinje Cell. P.C. Bush and T.J. Sejnowski Salk Institute, La Jolla, CA 92037.

Cerebellar Purkinje cells have a variety of active conductances on both the soma and dendrites. These conductances produce a characteristic firing pattern in response to a depolarizing current pulse injected by a microelectrode at the soma. A computer model of a Purkinje cell has been constructed consisting of over 1000 compartments (Shelton 1986) and seven different conductance types. Instead of using Hodgkin-Huxley kinetics, a multivariable system difficult to apply in the absence of exact voltage-ciamp data, we used a channel model based on Markov chain kinetics, a system with fewer variable parameters that is easy to understand and manipulate.

The model reproduced the firing pattern of real cells in response to current input as reported by Llinas *et al* (1980); A slow depolarization due to sodium and calcium plateau currents causes an accelerating train of sodium-dependent action potentials at the soma. A high-threshold calcium-dependent spike is triggered in the dendrites just at the point of inactivation of the sodium spike train. Voltage- and calcium-dependent potassium currents then produce a large hyperpolarization which reactivates the sodium spikes, allowing the cycle to begin again. This cyclical firing pattern has a period on the order of hundreds of milliseconds, whereas single synaptic potentials last only for tens of milliseconds. Trains of EPSP's are being modelled to establish roles for these conductances under physiological conditions.

$5HT_3$ RECEPTORS

537.1

[3H]QUIPAZINE BINDING SITES IN HUMAN LIMBIC SYSTEM. A. Abi-Dargham*, M. Laruelle, M.F. Casanova*,D.R. Weinberger and J.E. Kleinman, CBDB, NIMH Neuroscience Center, Washington, D.C. 20032

Serotonergic $5HT_3$ receptor blockade antagonizes the secretion of dopamine in rat brain suggesting a potential antipsychotic property of $5HT_3$ antagonists. [3H]quipazine labels $5HT_3$ receptors in rat cortex (Milburn C.M. et al., J. Neurochem., 52:1787, 1989). Displacement of [3H]quipazine binding by the selective $5HT_3$ antagonist ICS 205-930 in human amygdala showed a high affinity site of 0.25±0.03 nM and a low affinity site of 660±130nM. We performed saturation studies with [3H]quipazine (0.25 to 20 nM), using ICS 205-930 (100nM) to define the non specific binding. In the frontal cortex and caudate, no specific binding was detectable. In amygdala, the Ligand analysis of the Scatchard plot was compatible with a one site model (n=3) : Kd= 5.8±0.5nM, Bmax=42.6±5.8 fmol/mg of Protein. Similar results were obtained in human hippocampus. The labelled site in human amygdala and hippocampus is comparable to [3H]quipazine binding site to 5HT3 receptor in rat brain. This confirms the selective limbic localization of these sites in human brain as previously described with [3H]zacopride (Barnes, J.M., J. Neurochem., 53:1787, 1989) and suggests a rationale for the investigation of the antipsychotic properties of $5HT_3$ antagonists.

537.2

IN VITRO INHIBITION OF K^+-EVOKED NOREPINEPHRINE RELEASE BY 5-HT3 RECEPTOR ACTIVATION. P. Blandina, J. Goldfarb, J. Walcott* and J. P. Green. Department of Pharmacology, Mount Sinai School of Medicine, City University of New York, New York, NY 10029 , U.S.A.

There is much evidence for 5-HT /NE (norepinephrine) interactions in the C.N.S. We show here that 5-HT modulates the release of endogenous NE. Hypothalamic slices (400µ) from adult, male Sprague- Dawley rats were superfused with a medium containing, in addition to the usual salts and glucose, nomifensine (10µM), l-tyrosine (50µM) and pargyline (10µM). NE in the effluent was extracted with alumina and measured by HPLC with electrochemical detection. Spontaneous release averaged 0.25 ± 0.03 pmol/mg protein/3 min (n=48).Two identical 20 mM K^+stimulations, given at a 54 min interval,each almost doubled NE release in a Ca^{2+} -dependent manner. 5-HT (1-10µM) and 2-CH3-5-HT (3-10µM) inhibited K^+-evoked release up to about 50%, the first only in the presence of 5-HT1-like/5-HT2 antagonists (ritanserin, methysergide, 1µM). Nanomolar cocentrations of the 5-HT3 antagonists ICS 205-930 and (-)zacopride (zac) reduced the effect of both agonists. (-)Zac was 10 times more potent than its (+)isomer. (-)Zac has a 10-25 times greater affinity for 5-HT3 receptors than (+)zac (Pinkus, L.P., Gordon, J., Sarbin, N. and Barefoot, D. (1989). Int. Symp. on Serotonin from Cell Biology to Pharmacology and Therapeutics,Florence,3/29-4/1,p.71.). Supported by a grant (DA 01875) from N.I.D.A.

537.3

BLOCK OF CISPLATIN-INDUCED EMESIS BY SEROTONERGIC ($5HT_3$) ANTAGONISTS IN SUNCUS MURINUS. N.Matsuki*, Y.Torii, M.Muto and H.Saito. Dept. of Chem. Pharmacol., Fac. of Pharm. Sci., Univ. of Tokyo, Tokyo 113, Japan.

We have shown previously that the Suncus murinus (house musk shrew), a species of insectivora, vomits in response to various emetic stimuli including cancer chemotherapeutic agents. In the present study emetic responses induced by cisplatin were characterized and effects of anti-serotonergic drugs were studied. Intravenous or intraperitoneal injection of cisplatin elicited vomiting responses dose-dependently. The ED_{50} values for intravenous and intraperitoneal administration of cisplatin were 8.4 and 10.0 mg/kg, respectively. Vagotomy completely abolished cisplatin-induced emesis. Di-aqo complex (DAC), which is considered as active form of cisplatin, similarly induced emesis with significantly shorter latency.

Selective serotonergic $5HT_3$ antagonists (ICS205-930, zacopride, BRL43694, GR38032F) strongly prevented cisplatin-induced emesis whereas the drugs were ineffective against veratrine, copper sulfate and motion stimulus. Intravenous or intraperitoneal injection of serotonin caused vomiting which was prevented by ICS205-930 and vagotomy. These results suggest that cisplatin is converted to DAC and releases peripheral serotonin which subsequently induces emesis through peripheral $5HT_3$-receptors.

537.4

2-METHYL-BUFOTENIN AS A SELECTIVE SEROTONIN (5-HT_3) RECEPTOR LIGAND. S.K.Long*, W.C.M.Cramer*, M.Th.M.Tulp* and B. Olivier. DUPHAR B.V., P.O.Box 900, 1380 DA Weesp, The Netherlands.

We have previously described the action of bufotenin, at the 5-HT_3 subclass of serotonin receptors. In functional assay systems bufotenin acts as a partial agonist (Cramer et al. IUPHAR, 1990). In this study we have pharmacologically profiled 2-methyl-bufotenin (2-Me-BUFO).

2-Me-BUFO showed marginal selectivity for 5-HT_3 receptors, over 5-HT_{1A}, 5-HT_{1B}; 5-HT_{1C}, 5-HT_{1D} and 5-HT_2 receptors in conventional ligand binding assays. K_i values were, respectively : 470, 1500, 3630, 535, 625, 4360 nM. 5-HT has previously been shown to depolarize vagal nerve fibres in vitro at an action at 5-HT_3 receptors (Ireland,S.J. and Tyers,M.B., Brit.J.Pharmacol., 90:229, 1987). However when assayed as a depolarizing agent, 2-Me-BUFO was only a weak partial agonist in comparison to 5-HT. The depolarizing effect of 2-Me-BUFO was sensitive to antagonism by ondansteron (GR 38032F); log K_b = 8.92 ± 0.07 (4). Further 2-Me-BUFO (1 µM) was capable of antagonizing the depolarizing response to 5-HT; log K_b 6.10 ± 0.06 (4).

In conclusion although 2-Me-BUFO shows some specificity for 5-HT_3 receptors, it is unlikely to be a useful 5-HT_3 receptor specific agonist.

^{3}H-GR 65630, ^{3}H-BRL 43694, AND ^{3}H-QUIPAZINE BINDING TO BOVINE AREA POSTREMA 5HT$_3$ RECEPTORS: AN IMPROVED RADIOLIGAND BINDING ASSAY. M. Teitler and S. Le Page*. Dept. of Pharmacology and Toxicology, Albany Medical College, Albany, N.Y. 12208

Brain 5HT$_3$ receptors have been detected using radioligand binding methodology (see ref.1). However the specific signal produced has either a) not been of sufficient reliability to allow routine screening of drugs or detailed examination of the molecular characteristics of 5HT$_3$ receptor/drug interactions, b) requires a radioligand not commercially available, or c) requires excessive amounts of brain tissue to be practicable. A recent autoradiographical study revealed a high density of 5HT$_3$ receptors in human area postrema (1). Therefore we decided to investigate the possibility of developing a reliable 5HT$_3$ receptor radioligand binding assay in bovine area postrema homogenates.

Radioligand (1nM)	Bound (pmol/g)	%Specific
^{3}H-GR 65630	3.0	82
^{3}H-BRL 43694	2.1	77
^{3}H-Quipazine	0.5	36

The preliminary data presented in the table were derived using 3 mg wet weight bovine area postrema homogenates and 10^{-5}M ICS 205930 as the non-specific determinant. The high levels of binding and the high % specific binding obtained using ^{3}H-GR and ^{3}H-BRL indicate that the assay using these radioligands should be highly reliable; the use of bovine tissue and commercially available radioligands (New England Nuclear) greatly increase the convenience of assaying the 5HT$_3$ receptor on a routine basis. A detailed characterization of the bovine 5HT$_3$ receptor will be presented.

ML-1035, A SPECIFIC 5HT3 ANTAGONIST, FACILITATES GASTRIC EMPTYING BY ACTIVATING MYENTERIC CHOLINERGIC NEURONS. MD Linnik, BT Butler*, RR Gaddis*, NK Ahmed* Dept of Pharmacology, Marion Merrell Dow Inc, Kansas City, MO.

Certain benzamides facilitate gastric emptying by modifing neurogenic activity in myenteric plexus. This report describes the pharmacology of ML-1035, a highly site-specific benzamide, in studies designed elucidate the neurogenic mechanisms underlying benzamide-induced prokinesis. The following evidence indicates that the activity of ML-1035 is specific for 5-HT3 receptors. In radioligand binding assays, ML-1035 readily displaced a 5-HT3 specific ligand, 3H-GR 65630, from rat entorhinal cortex membranes (Ki = 0.131 uM). In contrast, ML-1035 had a Ki > 10 uM at 9 other receptor sites, including 5-HT1, 5-HT2 and DA2 receptors. ML-1035 also dose-dependently inhibited the bradycardia induced by IV bolus injections of 5-HT to anesthetized rats (IC50 = 17 ug/kg/ IV). *In vivo*, ML-1035 enhances gastric emptying of a semisolid, caloric meal in the rat (EC50 = 3.1 mg/kg, ip). *In vitro*, ML-1035 elicited a dose dependent contraction in guinea pig ileum (EC50 = 15.5 uM). This contraction could be blocked by tetrodotoxin (1 uM) and by atropine (1-3 uM), suggesting that the contraction is the result of indirect activation of cholinergic fibers. Therefore, these data demonstrate that ML-1035 is a highly specific 5-HT3 ligand which enhances gastric emptying by facilitating cholinergic transmission in myenteric neurons.

537.7

5-HT$_4$-LIKE RECEPTORS MEDIATE SLOW EXCITATORY RESPONSES TO SEROTONIN IN THE CA1 REGION OF THE HIPPOCAMPUS. Y. Chaput and R. Andrade. Dept. of Pharmacol, St. Louis Univ. School of Medicine, St. Louis, MO 63104.

We have previously shown that 5-HT, acting on receptors that do not belong to either the 5-HT$_1$, 5-HT$_2$ or 5-HT$_3$ subtypes, elicits a a marked reduction of calcium-activated afterhyperpolarization (AHP) present in CA1 hippocampal neurons. We have now used intracellular recording techniques in *in vitro* brain slices to further characterize the pharmacology of this response.

Bath administered 5-HT dose-dependently reduced the AHP in the range of 1-100μM with an EC50 of 3-10μM while 5-methoxytryptamine and 5-carboxyamidotryptamine were less potent than 5-HT. In contrast, the 5-HT$_3$ receptor agonists 2-methyl 5-HT (30μM) and phenylbiguanide (30μM) were without activity at this receptor. Administration of the gastrokinetic benzamides BRL 24924 (1-30μM), cisapride (1-30μM) and zacopride (30μM) blocked the effect of 5-HT on the AHP without altering the AHP themselves, while the neuroleptic benzamide sulpiride was without effect.

These results support previous studies suggesting that the receptor mediating the decrease in the AHP in the hippocampus does not belong to he 5-HT$_1$, 5-HT$_2$, or 5-HT$_3$ subtypes and demonstrates the existence of 5-HT$_4$-like receptors in the adult rat CNS capable of mediating slow excitatory responses to 5-HT. Supported by Grant MH43985, an MRC postdoctoral Fellowship to Y.C and the Sloan Foundation.

SEROTONIN 5-HT3 ANTAGONISTS FAIL TO INFLUENCE THE INTRAVENOUS SELF-ADMINISTRATION OF COCAINE OR AMPHETAMINE BY LABORATORY RATS R. Peltier and S. Schenk, Texas A&M Univ., Dept. Psychol., College Station, TX, 77843.

It has been suggested that 5-HT3 receptor antagonists may be useful in the treatment of drug abuse. To assess this possibility, we compared the effects of two antagonists, ICS 205-930 (0.01, 0.1 or 1.0, mg/kg, IP) and GR38032F (0.01, 0.1 or 1.0 mg/kg, IP), with the specific D2 dopamine receptor blocker, haloperidol (0.125 mg/kg, IP), on the intravenous self-administration of cocaine (0.5 mg/kg/infusion) or amphetamine (0.05 mg/kg/infusion). Neither of the serotonin antagonists altered self-administration. In contrast, haloperidol increased reinforced responding, suggesting a shift to the right in the dose/response curve. These data fail to support a role for the serotonin 5-HT3 receptor system in the reinforcing properties of psychostimulants.

537.9

2-ME-5HT-INDUCED DA RELEASE IN THE NUCLEUS ACCUMBENS MEDIATED BY THE 5-HT$_3$ RECEPTORS. L.H. JIANG, L. FISHKIN, S.X. TIAN AND R.Y. WANG. Department of Psychiatry and Behavioral Sciences, SUNY at Stony Brook, Stony Brook, NY 11794-8790.

Using the technique of chronocoulometric recording, we have previous shown that the intraventricular (icv) administration of the 5-HT$_3$ receptor agonist 2-methyl-5HT (2-Me-5HT) dose-dependently increases the DA release in the nucleus accumbens (NAc). The present study was to characterize further the effect produced by 2-Me-5HT. Sprague-Dawley rats were anesthetized with chloral hydrate. A Nafion coated carbon-fiber electrode was calibrated in vitro and then was implanted in the NAc. The ratio for DA/AA and DA/DOPAC obtained from Nafion-coated carbon fiber electrodes was 6015 ± 597 (mean ± SE) and 574 ± 51, respectively, indicating the electrodes were highly selective for detecting DA. Moreover, addition of 5-HT or 2-Me-5HT into the buffer solution did not produce the signal, indicating the DA but not 5-HT is being detected. A computer-aided in vivo electrochemical system (Cypress system) was used to monitor the release of DA. As reported previously, icv injection of 2-Me-5HT dose dependently increased DA release in the NAc. In contrast, icv administration of either saline (n=4), 5-HT$_1$ agonist 5-CT (n=4) or 5-HT$_2$ agonist DOI (n=3) was without effect. 2-Me-5HT-induced increase of DA release could be prevented by icv injection of 5-HT$_3$ receptor antagonist BRL (n=9) and ICS (n=4). However, icv administration of 5-HT$_1$/5-HT$_2$ antagonist metergoline failed to significantly block the electrochemical signal elicited by 2-Me-5HT. These results strongly suggest that the 2-Me-5HT-induced DA release in the NAc is mediated by 5-HT$_3$ receptors in the rat brain. (Supported by USPHS Grants MH-41440 and MH-00378).

537.10

EFFECTS OF THE 5-HT$_3$ RECEPTOR AGONIST 2-METHYL-5HT ON THE NEURONAL ACTIVITY OF A10 DA CELLS. R. Y. WANG AND L.H. JIANG, Department of Psychiatry and Behavioral Sciences, SUNY at Stony Brook, Stony Brook, NY 11794-8790.

We have previously reported that the intraventricular administration of the selective 5-HT$_3$ agonist 2-methyl-5HT (2-Me-5HT) dose dependently increased the DA release in the nucleus accumbens (NAc). Moreover, 2-Me-5HT-induced effect dependent upon the impulse flow of DA neurons. The aim of present study was to determine whether the effects of 2-Me-5HT on the DA release can be explained by its action on the firing rate of A10 DA cells. The techniques of single cell recording and microiontophoresis were used to record A10 DA cells in chloral hydrate anesthetized Sprague-Dawley rats. The concentration of the drugs in the multibarrel electrodes was 10 mM. Of the 88 unidentified A10 DA cells tested with 2-Me-5HT, 33 (37.5%) were excited, 52 (59%) were not affected and 3 were inhibited. Of 12 antidromically-activated A10-NAc DA cells tested, 7 (58%) were activated by 2-Me-5HT. The rest were not affected. Iontophoresis of 2-Me-5HT onto non-DA cells (n=10) in the ventral tegmentum area was without effect. Both 5-HT$_3$ receptor antagonists BRL (n = 10) and ICS (n = 3) but not 5-HT$_1$/5HT$_2$ antagonists ritanserim or metergoline blocked the 2-Me-5HT's excitatory action ($p < 0.01$, t test). In addition, prolonged iontophoresis of high concentration of magnesium, which presumably blocked the neurotransmitter release did not alter the excitatory action of 2-Me-5HT (n = 8), suggesting the effect is a direct one. Our results indicate that 2-Me-5HT induced increase of DA release in the NAc could be accounted for, at least partially, by its excitatory action on the A10-NAc DA neurons. (Supported by USPHS Grants MH-41440, MH-00378).

537.11

CHARACTERIZATION OF 5-HT$_3$ RECEPTORS IN THE RAT MEDIAL PREFRONTAL CORTEX: A MICROIONTOPHORETIC STUDY. C.R. Ashby, Jr., E. Edwards and R.Y. Wang, Dept. of Psychiat. and Behav. Sci., SUNY at Stony Brook, Stony Brook, NY 11794-8790.

We have reported that the iontophoretic application of the 5-HT$_3$ agonist 2-methylserotonin (2-Me-5HT) suppresses the firing of medial prefrontal cortical (mPFc) cells and this effect is blocked by the selective 5-HT$_3$ antagonists granisetron and ICS 205930 (Ashby et al., Eur. J. Pharmacol., 173, 196, 1989). We here report the further characterization of mPFc 5-HT$_3$ receptors in anesthetized male Sprague-Dawley rats, using the techniques of single unit recording and microiontophoresis. The microiontophoresis of 2-Me-5HT and phenylbiguanide (PBG) produced a current-dependent (10-80 nA) suppression of spontaneously active mPFc cells' firing, with the effect of 2-Me-5HT being greater than that of PBG. The iontophoresis of 2-Me-5HT (0.5 - 20 nA) also produced a current dependent suppression of l-glutamate-activated mPFc cells. The microiontophoresis of 1M $MgCl_2$ for 15-20 mins. did not alter 2-Me-5HT's suppressant effect, suggesting that its action is direct. The suppressant action of 2-Me-5HT was blocked by the selective 5-HT$_3$ antagonists granisetron, ICS 205930, LY 278584, MDL 72222, ondansetron and (±)-zacopride at currents of 5-10 nA but not by the antagonists l-sulpiride (D_2), (±)-pindolol (5-HT$_{1A, 1B,}$ ß), mianserin (5-HT$_{1C, 2,}$ H_1), metergoline (5-HT$_{1A, 1B, 1C, 2}$), SCH 23390 (D_1, 5HT$_{1C, 2}$) and SR 95103 ($GABA_A$) The rank order of effectiveness for the 5-HT$_3$ antagonists to block 2-Me-5HT's action is: ICS 205930 = zacopride > granisetron = LY 278584 = ondansetron > MDL 72222. Overall, our results indicate that 2-Me-5HT's suppressant action is directly mediated by 5-HT$_3$ receptors. (Supported by USPHS grants MH-41440, MH-00378 to R.Y.W. and MH-09791 to C.R.A.)

EFFECTS OF ANTIPSYCHOTIC DRUGS ON THE SUPPRESSANT ACTION OF 2-METHYLSEROTONIN ON MEDIAL PREFRONTAL CORTICAL CELLS: A MICROIONTOPHORETIC STUDY. Y. Minabe, C.R. Ashby, Jr., E. Edwards and R.Y. Wang, Dept. of Psychiat. and Behav. Sci., SUNY at Stony Brook, Stony Brook, NY 11794-8790.

Previously, we have demonstrated that microiontophoresis of the 5-HT$_3$ antagonist 2-methylserotonin (2-Me-5HT) suppresses the firing rate of medial prefrontal cortical (mPFc) cells and this action is blocked by 5-HT$_3$, but not by various 5-HT$_1$/5-HT$_2$ antagonists (Ashby et al., Eur. J. Pharmacol., 173, 196, 1989). Furthermore, we have shown that 2-Me-5HT's action is blocked by the iontophoresis of the atypical antipsychotic drug (APD) clozapine (CLOZ) but not by the typical APDs haloperidol or chlorpromazine (Ashby et al., Eur. J. Pharmacol., 166, 583, 1989). We here report the effects of various putative atypical APDs on the suppressant action of 2-Me-5HT on mPFc cells in anesthetized, male Sprague-Dawley rats. The techniques of single unit recording and microiontophoresis were used. The microiontophoresis of 2-Me-5HT (10-80 nA) produced a current-dependent suppression of mPFc cells firing and this effect was blocked by the atypical APDs CLOZ and RMI 81,852. In contrast, the microiontophoresis (10-20 nA) of the putative atypical APDs CGS 10746B, CL 77328, risperidone, setoperone, sulpiride, SCH 23390 and thioridazine fail to block 2-Me-5HT's action. The intravenous administration of CLOZ, but not CGS 10746B or haloperidol, antagonized the suppressant action of 2-Me-5HT. Our results indicate that among all APDs tested, only CLOZ and RMI 81,852 interact with central 5-HT$_3$ binding sites. Whether the 5-HT$_3$ antagonistic action of these compounds contributes to their therapeutic action or lower potential for inducing neurological side effects remain to be determined. (Supported by USPHS grants MH-41440, MH-00378 to R.Y.W. and MH-09791 to C.R.A.)

AUTORADIOGRAPHIC LOCALIZATION OF 5HT-3 RECEPTORS IN THE RAT BRAIN USING [^{3}H]-LY278584. D.R. Gehlert, S.L. Gackenheimer*, D.T. Wong and D.W. Robertson. CNS Pharmacology, Lilly Research Labs.,Eli Lilly and Co., Lilly Corporate Center, Indianapolis, IN 46285.

The 5HT-3 receptor appears to mediate the excitatory actions of serotonin in the peripheral nervous system. Initially, it was believed that 5HT-3 receptors were present only in the periphery, but an increasing body of evidence indicates their presence in the brain. In order to localize 5HT-3 receptors in the rat brain, we have utilized the recently introduced high affinity antagonist ligand, [^{3}H]-LY278584.

Twelve micron frozen cryostat sections of rat brain were utilized for a variety of biochemical studies to determine the appropriate conditions for labelling to slide mounted tissue section. Nonspecific binding was determined by the addition of 10 uM 5HT in the incubation buffer. Following these experiments, labeled sections were exposed to tritium sensitive sheet film for 2-6 months.

[^{3}H]-LY278584 bound to tissue sections with a K_d of 0.69 nM and a B_{max} of 79 fmoles/mg tissue and was displaced by 5HT and 5HT-3 specific antagonists. The autoradiographic detection of [^{3}H]-LY278584 binding indicated a widespread distribution of the 5HT-3 receptor in the brain. The highest receptor densities were detected in the area postrema and nucleus of the solitary tract followed by high levels in the substantia gelatinosa of the trigeminal nucleus and spinal cord. Moderate levels of binding were found in the dorsal motor nucleus of the vagus, piriform cortex, olfactory bulb, superficial laminae of the cerebral cortex and the caudal hippocampus. These results indicate that [^{3}H]-LY278584 is a useful tool to study 5HT-3 receptors in the brain by autoradiography.

EFFECT OF 5HT$_3$ AGONISTS ON *in vitro* ^{3}H-5HT EFFLUX. G. M. Williams, D. L. Smith*, and D. J. Smith. Depts. of Pcol. & Toxicol. and Anes., WVU-HSN, Morgantown, WV 26506.

5HT$_3$ receptors appear to be present on rat spinal synaptosomes (EJP 156:287, 1988), and presynaptic 5HT$_3$ receptors have been shown to modulate neurotransmitter release (TINS 9:424,1986). The current study asks if release-modulating 5HT$_3$ receptors are present on spinal 5HT nerve terminals.

A synaptosomal fraction was isolated from rat spinal cord, incubated with 100nM ^{3}H-5HT, and aliquots superfused at 37°C with TRIS-buffered Krebs solution. A pre-drug fraction and a during-drug fraction were collected from each superfusion chamber.

2CH$_3$5HT and phenylbiguanide (PBG) did not alter basal efflux at concentrations < 1 uM. At concentrations ≥ 100 nM bufotenine increased basal efflux of both ^{3}H-5HT and ^{3}H-5HIAA. This pattern suggests that the agent may disrupt ^{3}H-5HT storage rather than promote release via receptors on the terminal surface. 5HT, PBG and 2CH$_3$5HT were also tested for effects on evoked release. At concentrations ≤ 1uM, only 5HT altered 15mM K^+-induced ^{3}H release, and 1 uM ICS 205-930 did not block this effect.

It would appear that 5HT$_3$ receptors are not involved in the regulation of synaptosomal ^{3}H-5HT efflux in the rat spinal cord tissue.

INDEPENDENT EFFECTS OF pH_i, Ca^{2+} AND PHOSPHODIESTERASE ON THE cAMP-GATED Na^+ CURRENT IN NEURONS OF THE MOLLUSK *Pleurobranchaea*. V. Mazzarella and R. Gillette, Neuroscience Program and Dept. of Physiol. & Biophys., University of Illinois, Urbana, IL 61801. Na^+ current gated by cAMP ($I_{Na,cAMP}$) in the ventral white cell buccal neurons of *Pleurobranchaea* is sensitive to small changes in intracellular pH (pHi), intracellular Ca^{2+}, and phosphodiesterase activity (PDE). We examined interactions of pH_i, Ca^{2+}, and PDE in voltage clamp experiments measuring the $I_{Na,cAMP}$ response to injected cAMP. Inhibition of PDE by IBMX causes increased current amplitude and slowed decay of the current. Intracellular acidification or alkalinization by addition of $NaHCO_3$ or $(NH_4)_2SO_4$ to the bath increases the amplitude but not the decay rate of the current. The constant decay rate in these experiments suggests that a mechanism other than a pH effect on PDE causes the increase in current amplitude. $I_{Na,cAMP}$ is suppressed by intracellular Ca^{2+} (J. Neurophys. 59:248). In the VWC, Ca^{2+} chelation by pressure injection of BAPTA into the cell did not alter the decay of $I_{Na,cAMP}$, suggesting that the inhibitory effect of calcium is not mediated via the PDE. Furthermore, the chelation of calcium did not diminish the increase in amplitude caused by intracellular acidification or alkalinization. Removal of extracellular calcium increased $I_{Na,cAMP}$ amplitude but not decay rate. When pH_i was decreased under these conditions, a further increase in amplitude is observed, indicating different modulation mechanisms for calcium and pH.

ALTERATIONS OF Na^+ DIFFERENTIALLY AFFECT AGONIST-INDUCED PHOSPHOINOSITIDE HYDROLYSIS IN RAT BRAIN SLICES. G.C. Ormandy, X. Li, L. Song*, M.B. Williams and R.S. Jope. Dept. of Psychiatry, University of Alabama at Birmingham, Birmingham, AL 35294.

The hydrolysis of inositol-containing phospholipids is an important signal transduction mechanism in the brain. Phosphoinositide hydrolysis in vitro is known to be influenced by the concentration of both K^+ and Ca^{2+} ions. In this study using rat brain slices we measured the effect of altered Na^+ concentrations on phosphoinositide hydrolysis induced in response to a number of agonists. Reductions of the Na^+ concentrations below 120 mM resulted in incremental increases in basal and norepinephrine stimulated accumulation of ^{3}H-inositol monophosphate in cortical slices that had been prelabelled with ^{3}H-inositol, and maximal responses were obtained with 0 and 5 mM Na^+. Similar effects of Na^+ were also observed in hippocampal and striatal slices. In contrast the responses to carbachol and ibotenate were similar in medium containing 120 or 5 mM Na^+. These results demonstrate that alterations of Na^+ concentration may differentially influence the effect of agonists on phosphoinositide hydrolysis.

538.3

SODIUM MODULATES CYCLIC AMP PRODUCTION IN RAT BRAIN SLICES. X. Li, L. Song* and R.S. Jope, Departments of Psychiatry and Pharmacology, University of Alabama at Birmingham, Birmingham, AL 35294.

Reduction of the sodium concentration from 120 mM to 5 mM in the incubation media dramatically increased the basal cyclic AMP concentration in rat brain slices, with or without rolipram to inhibit phosphodiesterase. This effect of low sodium was not changed by altering the calcium concentration or adding EGTA in the incubation media. Isoproteronal and norepinephrine (NE) significantly stimulated cyclic AMP production in slices from rat brain cortex, hippocampus and striatum. Reduction of sodium did not change isoproterenol-stimulated cyclic AMP, but significantly enhanced NE-stimulated cyclic AMP production. Ibotenate, an excitatory amino acid agonist, stimulated cyclic AMP production to twice the basal concentration, and this effect was not altered by lowering the sodium concentration in the media. In normal sodium, low concentrations (1 μM to 100 μM) of quisqualate slightly increased cyclic AMP, but 1 mM quisqualate significantly inhibited basal and Isoproteronal - or NE-stimulated cyclic AMP. However, in low sodium, the stimulatory effect of quisqualate was significantly increased at 1 μM to 100 μM, and the inhibitory effect was reduced by 50% or more.

These results suggest that sodium modulates cyclic AMP production, possibly by more than one mechanism. Phosphodiesterase inhibition is not likely to be involved and the effect is calcium-independent. Potentiation of NE-stimulated cyclic AMP by low sodium may be indirectly mediated by activating PI hydrolysis. The stimulatory effect of excitatory amino acids is independent of sodium concentration, whereas blockade of quisqualate-inhibited cyclic AMP production indicates a regulatory effect of sodium in neuronal activity.

538.4

MAITOTOXIN CAUSES INCREASED cAMP LEVELS IN SK-N-SH NEUROBLASTOMA CELLS. Jesse Baumgold and Robert Paek*, Dept. of Radiology, George Washington Univ. School Med., Washington, DC 20037.

We have previously reported that stimulation of muscarinic receptors in SK-N-SH cells causes increased intracellular cAMP via a pathway that is independent of protein kinase C (BBRC 154 1137, 1988) and that may involve stimulation of a calcium-calmodulin dependent adenylate cyclase (Soc. Neurosc. Abstract, 1988). The goal of the current work was to induce a similar increase in cAMP by stimulating other PI turnover-coupled receptors. Although SK-N-SH cells express bradykinin and histamine receptors, stimulation of these receptors produced only a fraction of the PI response obtained by carbachol (17% and 21%, respectively). Neither response was sufficient to increase cAMP levels. Maitotoxin has been shown to stimulate PI turnover directly and to increase intracellular calcium in a variety of neuronal cells (Mol.Pharm. 36 44, 1989). In SK-N-SH cells, 0.5 ng/ml of maitotoxin caused increasd PI turnover and an increase in cAMP levels. These results demonstrate that direct stimulation of PI turnover by maitotoxin also increases cAMP formation and further substantiates the hypothesis that stimulation of PI turnover can increase cAMP levels by stimulating a calcium/calmodulin dependent adenylate cyclase.

538.5

ATTENUATION OF cAMP EFFLUX BY COPPER: A MECHANISM FOR AMPLIFICATION OF PGE_2 ACTION IN THE BRAIN. P.Magni*, M.Sanghera and A.Barnea. Depts. Obstet. Gynecol., Physiol. & Psych., Univ. Texas Southwest.Med.Ctr., Dallas, Tx 75235

It is known that PGE_2 stimulation of peptide release (LHRH) from the median eminence (ME) is mediated by the cAMP pathway, and a short pre-treatment with copper (Cu) markedly amplifies this release process. Since in many tissues stimulation of cAMP accumulation is accompanied by cAMP efflux, we considered the possibility that Cu-amplified PGE_2 action is a result of attenuation of cAMP efflux. When rat ME were incubated in vitro, PGE_2 induced a rapid (<2.5 min) and sustained (15 min) cAMP efflux, the degree of which was a function of [PGE_2]: by 5 min exposure to 10 μM PGE_2, efflux was 584% of basal (100%) and it accounted for 12% of the total (tissue + medium) cAMP. A 5 min pre-treatment with Cu inhibited (49-66%) PGE_2-induced efflux regardless of the length of PGE_2-exposure and [PGE_2]; this reduced level of cAMP was not due to phosphodiesterase activity in the incubation medium. Unlike the dramatic increase in cAMP efflux, PGE_2 induced a moderate 37% increase in content which was not altered by Cu. Thus, the size of the functional pool of cAMP is very small relative to the total cellular cAMP and hence, changes in stimulated cAMP-efflux are not reflected in the tissue content. Since Cu amplifies PGE_2 stimulation of LHRH release, these results are consistent with Cu attenuation of cAMP efflux as a mechanism for amplification of PGE_2 action mediated by the intracellular cAMP pathway.

538.6

EFFECTS OF FORKOLIN ON DOPAMINE AND ACETYLCHOLINE RELEASE IN RAT NEOSTRIATAL SLICES. H. Lee*, V. Reid*, and M.H. Weiler. Univ. of Wisconsin, School of Pharmacy, Madison, WI 53706.

The involvement of the cyclic AMP (cAMP) effector system in the release of dopamine (DA) and acetylcholine (ACh) from rat neostriatal slices was assessed. Forskolin, an activator of adenylate cyclase, was used to enhance cAMP levels, and the consequence of this enhancement on potassium-stimulated release of DA and ACh from the same slice preparation was evaluated. Forskolin increased K^+-stimulated DA release in a dose-dependent manner. In the presence of 1, 10 and 50 μM forskolin, DA release increased 2- (p=0.15), 3- (p=0.0013) and 4.5-fold (p=0.000), respectively. ACh release from the same slices from which DA release was monitored was not altered in the presence of forskolin. This increase in DA release but no change in ACh release by forskolin occurred when acetylcholinesterase activity was either inhibited or intact (choline release was monitored). It was also confirmed that forskolin induced a dose-dependent increase in cAMP in the slices under similar experimental conditions. That forskolin increases neostriatal cAMP levels and enhances DA release but has negligible effects on ACh release suggests that the cAMP effector system is involved in mechanisms that increase DA release but not in mechanisms that enhance ACh release. Supported by grants from NIH (AG05953) and the American Parkinson's Disease Association.

A COMPARISON OF THE REGULATORY PROPERTIES OF STRIATAL AND CORTICAL FORMS OF ADENYLATE CYCLASE. L.A. DOKAS AND S.M. TING*. Departments of Neurology and Biochemistry, Medical College of Ohio, Toledo, OH 43699.

This study was undertaken to compare the properties of rat striatal and cortical forms of adenylate cyclase. Enzyme activity was measured in the lysed mitochondrial fraction with a radioisotope assay as described by Gil and Wolfe (JPET 232: 608, 1985). Although basal enzyme activity (approx. 400 pmol cyclic AMP/min/mg protein) is the same in both preparations, the striatal form is more responsive to forskolin (8-fold stimulation at 10^{-5} M) than is the cortical form (4-fold stimulation). Conversely, cortical adenylate cyclase activity is stimulated more by GTP. In both cases, 10^{-4} M GTP limits maximal forskolin stimulation to 60% of that seen with forskolin alone. Cholinergic agonists inhibit adenylate cyclase activity in both brain regions in the order oxotremorine > acetylcholine ≥ carbachol. More inhibition is seen in response to acetylcholine in the cortex. Although acetylcholine inhibits the striatal enzyme equally ± forskolin, less inhibition is seen with the cortical form in the presence of forskolin. The general muscarinic antagonist atropine blocks the effect of 10^{-3} M acetylcholine in both striatum and cortex, while the more selective antagonist pirenzepine has little effect at concentrations up to 10^{-5} M, suggesting a high-affinity, pirenzepine-insensitive receptor (m2 or m4) is involved. [D-Trp^8]-somatostatin inhibits both forms equally. These results indicate significant differences in interactions among subcomponents of the adenylate cyclase complex in striatal and cortical membranes. Supported by grants from NIH (NS 23598) and the Ohio Department of Aging.

538.8

DIHYDREXIDINE IS A POTENT AND FULLY EFFICACIOUS D_1 DOPAMINE RECEPTOR AGONIST IN VIVO AND IN VITRO. **L.L. Cook, D.M. Mottola, W.K. Brewster, D.E. Nichols, M.H. Lewis, R.B. Mailman. Brain and Development Research Center, Univ. of North Carolina, Chapel Hill, NC 27599 and Purdue Univ., West Lafayette IN 47907.**

Dihydrexidine (DHBP) is a new D_1 dopamine receptor agonist which has been shown, using in vitro studies, to be potent and fully efficacious relative to dopamine. This work characterizes the effects of DHBP on stimulation of D_1 receptors in vivo (i.e., using microdialysis to sample cellular cAMP efflux) and in vitro (i.e., using superfused striatal slices). For microdialysis studies, 4 mm unilateral probes were inserted in the striatum of conscious adult male rats via guide cannulae stereotaxically implanted 3–5 days previously. The probes were perfused overnight with Krebs Ringer buffer (2 μL/min). Samples were collected every 30 min, and cAMP quantified by RIA. Phosphodiesterase inhibitors like IBMX or rolipram were included to permit measurement of both basal and stimulated levels of cAMP efflux. Perfusion with 1 mM rolipram resulted in basal cAMP efflux of 0.48 ± 0.15 fmole/μL (n=5). DHBP at concentrations from 30–1000 μM produced a dose–dependent increase in cAMP, to a maximal increase of 300% of basal levels.

Similarly, superfused striatal slices were used to study DHBP–stimulated cAMP efflux. Slices were prepared with a McIlwain tissue chopper, and perfused (0.1 mL/min and 37°C) with oxygenated buffer containing 1 mM IBMX with or without test drugs. Fifteen min samples were collected for measurement of cAMP by RIA. DHBP was at least ten–fold more potent than DA and was fully efficacious in stimulating cAMP efflux from superfused striatal slices. The possible inhibitory effects of DHBP on uptake of DA and 5–HT were assessed to determine if these effects might be attributable to endogenous dopamine. Uptake of ^{3}H–DA and ^{3}H–5–HT was measured in striatal and cortical synaptosomes, respectively. Relative to its receptor potency (Lovenberg et al. Eur. J. Pharmacol. 166:111, 1989), DHBP was essentially 10^3 less active at either DA (EC50 = 50.7 μM) or 5–HT (EC50 = 23.3 μM) uptake sites. Together, these data demonstrate that dihydrexidine is a potent and fully efficacious D_1 agonist in two functionally intact preparations, and that these neurochemical effects are consistent with direct (rather than indirect) D_1 receptor action. CANNABINOIDS AND AMINOALKYLINDOLES BIND TO COMMON RECEPTORS TO INHIBIT ADENYLYL CYCLASE IN BRAIN. S. R. Childers, M.A. Pacheco, and S.J. Ward, Dept. Physiol. and Pharmacol., Bowman Gray Sch. Med., Winston-Salem, NC 27103, and Sterling Research Group, Sterling Drug Inc., Rensselaer, NY 12144.

Both cannabinoids (Cn) and aminoalkylindoles (AAI) bind to specific G-protein-coupled membrane receptors as demonstrated by radioreceptor binding, inhibition of isolated smooth muscle contractions and GTP-dependent inhibition of adenylyl cyclase in rat cerebellar membranes. Receptor binding assays have demonstrated that Cn and AAI bind to common receptors. The current experiments support this conclusion by examining effects of both Cn and AAI on adenylyl cyclase (AC) in brain. In rat cerebellar membranes, both AAI agonists and the potent Cn levonantradol inhibited AC with the same efficacy. The IC_{50} values for levonantradol and the most potent AAI agonists in inhibiting AC were 0.1-0.3 μM. The dose response curves of both Cn- and AAI-inhibited AC were shifted to the right by an AAI antagonist. The regional distributions of Cn- and AAI-inhibited AC in rat brain were identical, with maximal inhibition occurring in striatum and cerebellum. In cerebellum, no additivity in inhibition occurred when maximally inhibitory concentrations of both Cn and AAI agonists were added in the same assay tubes. Both AAI agonists and Cn inhibited cyclic AMP levels in intact cultured rat cerebellar granule cells to the same extent, and these inhibitory actions were blocked by the AAI antagonists. Also, AAI-inhibited cyclic AMP levels were blocked by treatment of cells with pertussis toxin. These data suggest that Cn and AAI bind to common G-protein-linked receptors which inhibit AC in rat brain membranes and in cerebellar granule cells.

538.10

S-ADENOSYL-L-METHIONINE MODULATES RECEPTOR-MEDIATED cAMP PRODUCTION IN RAT BRAIN. P. Zhong, J. McWilliam* and K.J. Kellar. Dept. of Pharmacology, Georgetown Univ. Med. Center, Wash., DC 20007.

S-adenosyl-l-methionine (SAM) can increase receptor-mediated cAMP production in several tissues in vitro. The mechanism for this effect is not known, but both phospholipid methylation (Hirata and Axelrod, Science **209**:1082, 1980) and protein carboxyl methylation (Backlund and Aksamit, J. Biol. Chem., **263**:15864, 1988) by SAM have been proposed as important steps in signal transduction. We investigated the effects of SAM on receptor-mediated stimulation and inhibition of cAMP production in brain slices from male, Sprague-Dawley rats (450 g). Slices were washed and preincubated with SAM and 50 μM IBMX before stimulation of cAMP production under the same incubation conditions. SAM potentiated cAMP production by norepinephrine (NE), 6F-NE and isoproterenol with an EC_{50} of = 60 μM. SAM also attenuated the inhibitory effect of the 5-HT-1A agonist DPAT on forskolin stimulated cAMP production. Neither the basal levels nor forskolin stimulated cAMP was affected by SAM. A single i.p. injection of SAM (20 mg/kg) 30 min before sacrifice potentiated cAMP production by NE in vitro. Treatment of rats for 2 weeks (10 mg/kg, bid) did not affect NE-stimulated cAMP production nor did it affect α-1 or ß-adrenoceptor nor 5-HT-2 receptor binding. However after the chronic treatment, SAM in vitro no longer potentiated NE-stimulated cAMP production. In addition, the chronic treatment with SAM appeared to blunt the inhibition of forskolin stimulated cAMP by DPAT. These data suggest that SAM can have potentially important modulatory effects on signal transduction mechanisms. (Supported by grant #MH 41819)

MELATONIN ACTS VIA TWO G-PROTEINS TO INHIBIT ADENYLATE CYCLASE. PJ Morgan and P Barrett*. Rowett Research Institute, Aberdeen, Scotland, UK, AB2 9SB

Melatonin receptors have been localized on the cells of the mammalian pars tuberalis (PT), and have been shown to be coupled through inhibitory G-proteins to adenylate cyclase (Morgan *et al.*, J. Mol. Endocrinol. 3:R5, 1989). The inhibitory effect of melatonin on intracellular levels of cyclic AMP could only be seen after stimulation with forskolin. *Bordetella pertussis* toxin (IAP) has been used to investigate the nature of the G-protein coupling between the melatonin receptor and adenylate cyclase.

Primary cultures of ovine PT cells were exposed to different doses of IAP (0.5-500 ng/ml) for 16 h, and the effect on the inhibition of forskolin-stimulated cyclic AMP formation by melatonin measured, as described previously (Morgan *et al.*, 1989). IAP attenuated melatonin's inhibitory effect at 10 ng/ml reaching a maximal effect by 100 ng/ml, yet even at this concentration and higher the melatonin response was not completely abolished, with significant ($p<0.001$) inhibition (>50%) still attainable. This result indicates that both an IAP-sensitive and IAP-insensitive G-protein are linked to the melatonin receptor.

Using ^{32}P-NAD, IAP (20 μg/ml) was shown to catalyze the ADP-ribosylation of a 41 kd protein in membranes, separated by 12.5% SDS-PAGE, confirming the presence of IAP-sensitive G-protein (G_i) in the PT. Furthermore in membranes prepared from PT cells pre-treated with IAP (0.5 ng/ml), the subsequent radiolabelling with ^{32}P-NAD was reduced.

The binding of 2-^{125}I-iodomelatonin (I-MEL) to PT membranes is regulated through G-proteins. IAP (0.1-20 μg/ml) attenuates I-MEL binding to PT membranes in a dose-dependent manner, reaching a maximum effect of 20% inhibition. GTP (1 mM) also attenuates binding by 40%, and in combination with IAP this effect is additive. Both of these changes occur through G-protein regulated alteration in melatonin receptor affinity, but IAP alters this affinity through covalent modification of a G-protein, whereas GTP acts via a reversible binding reaction. As IAP only inhibits 20% of I-MEL binding, this indicates that not all G-proteins linked to the melatonin receptor are IAP-sensitive G_i. This is emphasized by the fact that GTP can still inhibit I-MEL binding further after IAP treatment. These results confirm that both an IAP-sensitive and an IAP-insensitive G-protein must link the melatonin receptor to adenylate cyclase.

538.12

LOCALIZATION OF ADENYLATE CYCLASE AND GLUCOSE TRANSPORTER IN RAT BRAIN USING [^{125}I]-LABELED DERIVATIVES OF FORSKOLIN. N.M. Appel, K.B. Seamon* A. Laurenza*, I.A. Simpson* and E.B. De Souza. NIDA/ARC, Baltimore, MD 21224; FDA and NIDDK, Bethesda, MD 20892.

Two iodinated derivatives of forskolin have been synthesized that show differential specificity for adenylate cyclase (6-[^{125}I]Fsk, 2200 Ci/mmol) and for the glucose transporter (7-[^{125}I]Fsk, 2200 Ci/mmol). These iodinated compounds have been used to localize forskolin binding sites in rat brain sections using autoradiography. The distribution of both 6-[^{125}I]Fsk and 7-[^{125}I]Fsk binding sites was similar to that previously reported for [^{3}H]forskolin. Highest densities were noted in caudate putamen, nucleus accumbens, olfactory tubercle, substantia nigra (reticularis), superior colliculus (superficial grey) and cerebellar cortex (molecular layer). Binding in cerebral cortex and hippocampus was less intense, but while binding in cerebral cortex was uniform, binding in hippocampus was enriched in the molecular layer of dentate gyrus and pyramidal cell layer of regions CA2 and CA3. The binding of 6-[^{125}I]Fsk was inhibited by forskolin but not by 1,9-dideoxyforskolin, consistent with these sites being associated with adenylate cyclase. Agents that inhibit forskolin binding to the glucose transporter, such as cytochalasin-B and D-glucose, decreased 7-[^{125}I]Fsk binding but did not decrease 6-[^{125}I]Fsk labeling. Thus it appears that 6-[^{125}I]Fsk binds exclusively to adenylate cyclase and can be used as a specific ligand to measure adenylate cyclase binding sites. In contrast, 7-[^{125}I]Fsk binds to sites that are associated with the glucose transporter binding sites in brain. These novel derivatives can be used to study the differential localization of enzymes involved in signal transduction and proteins involved in glucose utilization.

538.13

CHARACTERIZATION OF D_1-STIMULATION AND D_2-INHIBITION OF ADENYLATE CYCLASE ACTIVITY IN RAT REGIONAL BRAIN AREAS. E.B.Hollingsworth and B.G.Huff*, Div. of Pharma., Burroughs Wellcome Co., Res. Tri. Pk., NC 27709.

Forskolin-induced, activation of adenylate cylase was used to explore dopamine$_1$ (D_1) stimulation and dopamine$_2$ (D_2) inhibition of adenylate cyclase accumulation in rat brain slices from striatal and limbic regions. Stimulation of cyclic AMP production was measured by quantitating the conversion of [3H]-adenine to [3H]-cyclic AMP. In striatal and limbic regions, the EC_{50} value for SKF38393-induced D_1-stimulation of adenylate cyclase, 3 x 10^{-9}M, was comparable to published values from other methodologies. The selective D_1 antagonist SCH23390 inhibited this stimulation. The D_2 agonist, PPHT, at 1 x 10^{-9}M, inhibited the D_1-stimulated increase in cyclic AMP accumulation in the striatal region by 50%. The D_2 antagonist, eticlopride, inhibited this accumulation, which indicates that the inhibition of adenylate cyclase by PPHT is a D_2 receptor-specific event. The D_1-mediated increase in cyclic AMP accumulation was detected in the brain areas that have the highest density of D_1 receptors. The D_2-mediated inhibition of cyclic AMP accumulation was seen in the striatal but not in the limbic region. The assay system characterized here enables efficient study of D_1-and D_2-receptor interaction and modulation.

COUPLING OF AMYGDALOID NEUROPEPTIDE RECEPTORS WITH THE ADENYLATE CYCLASE SECOND MESSENGER SYSTEM. S. Eldon,* R. Scibilia, C. Kilts. Duke Univ. Med. Ctr., Durham, N.C. 27710.

The amygdaloid complex is remarkable in the density and diversity of neuropeptides and neuropeptide receptors. We examined the effect of selected neuropeptides on the efflux of cyclic AMP from parallelepiped slices of the rat amygdaloid complex as an estimate of receptor effector coupling. Vasoactive intestinal peptide (VIP) produced a concentration-dependent increase in cyclic AMP efflux which did not vary between amygdaloid nuclei differing in VIP binding site density. Neither corticotropin releasing factor (CRF) nor neurotensin (0.1-30 uM) affected cyclic AMP efflux. However, neurotensin inhibited forskolin (10 uM)-stimulated cyclic AMP efflux. The delta opioid receptor agonist [D-Pen-D-Pen] enkephalin produced a significant inhibition of forskolin-stimulated cyclic AMP efflux. The inhibitory effect of the mu opioid receptor agonist (DAGO) was of lesser magnitude and similar to that of somatostatin. These results indicate that some amygdaloid neuropeptide receptors are positively and negatively coupled to adenylate cyclase and that receptor-effector coupling does not covary with receptor density. (MH-39967)

HORNET VENOM SAC EXTRACT ELEVATES INTRACELLULAR CYCLIC AMP IN HUMAN CILIARY EPITHELIAL CELLS A.R. Heath, J.S.Ishay*[1] and D.E.Potter*. Baylor College of Medicine, Center for Biotechnology, The Woodlands, TX 77381, USA and [1]Sackler Faculty of Medicine, Tel-Aviv University, Israel.

The neuroepithelial cells of the human ciliary body play a major role in the control of intraocular pressure (IOP) through their involvement in ion flux and aqueous humor formation. They possess several G protein-mediated and adenylate cyclase-linked receptors that have also been implicated in IOP regulation. Complete extracts of venom sacs (VSE) from the Oriental Hornet, Vespa orientalis, which contain several biogenic amines and peptides, have been shown to lower IOP radically (Kam, J et. al., *Comp. Biochem. Physiol.*, 92C:329, 1989). To determine the site and mechanism of action of VSE, we examined its effect on intracellular cyclic AMP (cAMP) production by human, transformed, non-pigmented ciliary epithelial cells (NPCEC) in culture (ODM Cl-2 line, Martin-Vasallo, P et. al., *J. Cell. Physiol.*, 141:243, 1989). VSE (a homogenate of one venom sac/0.4 ml Earle's BSS) induced a dose-related increase in intracellular cAMP as measured by RIA. Cultured NPCEC retain the native responsiveness of ciliary epithelial cells to beta-adrenergic agonists. Isoproterenol increased cAMP in a dose-related fashion (10^{-9} M to 10^{-4} M) with an average increase over basal levels of 66 ±12-fold at 10^{-5} M (n=8). Propranolol blocked this response but did not suppress the response to VSE. Thus, elevated cAMP levels in NPCEC following VSE challenge do not result from activation of the beta-adrenoceptor but may be due to other amines or peptides. Work is in progress to address this question. (Supported by EY06338).

ROLE OF TUBULIN IN THE REGULATION OF ADENYLYL CYCLASE IN C6 CELLS K. Yan, N. Wang, A. Ringer and M. M. Rasenick, Physiology &Biophysics, and Committee on Neuroscience, University Illinois College of Medicine, Chicago, IL 60680

Tubulin polymerized with GTP or hydrolysis resistant GTP analogs stimulates adenylyl cyclase activity in C6 membranes, probably via direct guanine nucleotide transfer from tubulin to Gsα. The modulation of adenylyl cyclase activity by tubulin appears to be agonist independent in the tightly coupled permeable C6 cell and membranes. Tubulin is able to stimulate the adenylyl cyclase even in the presence of l-propanolol, and in isoproterenol-desensitized C6 cells, where free GppNHp is without effect. We have also showed that there is a direct interaction between tubulin and G-proteins by using hybridization techniques. A high selectivity of tubulin binding to αs and αi1 has been found. It is known that there is a significant amount of tubulin in the plasma membranes (about 6% of the total membrane proteins), however, the role of this protein in the membrane remains largely unknown. In gel overlay experiments, [^{32}P]-AAGTP-transducin binds to both microtubule tubulin and membrane tubulin. Two classes of membrane tubulin can be distinguished on the basis of the hydrophobicity; αs associates with the more hydrophobic class whereas αi binds better to the less hydrophobic class. Proteolysis experiments indicate that the "binding site" on tubulin for G-proteins is near the carboxyterminal. Efforts are underway to determine the interaction between the membrane and these domains of tubulin as they relate to modulation of the signal transduction process.

538.17

TUBULIN-G PROTEIN INTERACTION: THE DYNAMIC ROLE OF THE CYTOSKELETON IN REGULATION OF THE NEURONAL SIGNAL TRANSDUCTION. N. Wang, K. Yan and M.M. Rasenick. Dept. of Physiology and Committee on Neuroscience, Univ. of Illinois at Chicago, Chicago, IL. 60680.

Tubulin, a GTP-binding protein with structural similarities to signal-transducing G proteins, has been implicated as a modulator of the neuronal adenylyl cyclase. This laboratory has previously shown that tubulin with GTP or hydrolysis-resistant GTP analogs bound is capable of inhibiting adenylyl cyclase. Photoaffinity labeling studies suggest a direct transfer of nucleotide from tubulin to the inhibitory GTP-binding protein, Gi. Hybridization as well as immunoprecipitation studies show a direct interaction between tubulin and α subunits of G proteins. This interaction is specific and distinct for different subtypes of Gα (J. Biol. Chem. 265:1239, 1990). Further studies designed to determine the Gα-binding domains of tubulin reveal that despite of the effectiveness of tubulin dimers, tubulin polymers (microtubules or rings) are inefficient in inhibiting adenylyl cyclase and binding to Gα. Furthermore, the polymerization of tubulin was inhibited by G proteins, implying that the tubulin-Gα interaction may involve tubulin domains which are located in or close to the tubulin domains involved in tubulin polymerization. These data suggest that tubulin, usually considered to function as a structural component in fully-differentiated neuronal cells may play a dynamic role in regulation of neurotransmitter response or responsiveness.

538.18

EFFECTS OF TUBULIN ON AGONIST BINDING AFFINITY IN C6 GLIOMA CELLS. M. Watanabe and M. M Rasenick, Dept. of Physiology and Biophysics and Committee on Neuroscience, University of Illinois at Chicago, Chicago, IL 60608

Guanine nucleotides have been known to modulate agonist binding affinity for G protein linked receptors. Our laboratory demonstrated that tubulin, which is an element of the cytoskelton, alters the coupling between receptors and G proteins involved in the stimulation or inhibition of adenylate cyclase via direct transfer of GTP from tubulin to Gsα and Gi1α. However, since results from many laboratories suggest that G protein modulation of receptor affinity is a process quite different from G protein modulation of adenylate cyclase, it was not clear that added tubulin would result in change in receptor affinity.

In this study, the effects of tubulin-GppNHp have been compared to those of GppNHp in changing β-adrenergic agonist affinity in both permeable C6 cells (by a newly devised method) and C6 membranes. Competitive binding studies were performed with isoproterenol and the β-adrenergic antagonist, iodopindolol. Tubulin-GppNHp was more effective than GppNHp in decreasing receptor affinity in both cells and membranes. These results suggest that tubulin might modulate neuronal signal transduction at multiple loci.

538.19

MODULATION OF ADENYLYL CYCLASE ACTIVITY BY G PROTEIN SPECIFIC SYNTHETIC PEPTIDES IN C6 GLIOMA CELLS. M.B.Lazarevic, M.M.Rasenick & H.Hamm. Department of Physiology & Biophysics and the Committee on Neuroscience, University of Illinois College of Medicine, Chicago, IL 60680.

Coupling of a neurotransmitter to a G protein and the subsequent activation of an intracellular effector (e.g. adenylyl cyclase, ion channels) by that G protein are processes which have been the subject of considerable experimentation over the past two decades. Despite this, little is known about the molecular details of receptor- G protein interaction in situ, especially as it relates to the G protein. We chose to explore β adrenoceptor-effector coupling in C6 glioma cells by introducing peptides which correspond to various domains of the G proteins, αs and αi2. These peptides were introduced into saponin-permeable C6 cells (which show a "tight coupling" between β adrenoceptor and Gs) as well as C6 membrane (in which this coupling is much lower) and effects upon adenylyl cyclase activity were measured. Peptides corresponding to the C terminal part of αs decreased isoproterenol stimulation of adenylyl cyclase in a dose dependent fashion. Curiously, in C6 membranes, adenylyl cyclase activation by GppNHp (receptor-independent) was blocked by these peptides as well. Furthermore, peptides corresponding to a similar region on αi2 increased adenylyl cyclase activity in either system. It is possible that this supports the idea of some interaction between the αi and αs subunits. These results demonstrate that synthetic peptides are a useful tool for the exploration of receptor-G protein coupling.

CHANGES IN DOPAMINE (DA) MEDIATED BEHAVIORS AND IN STRIATAL D2 DOPAMINE RECEPTOR (DAr) BINDING FOLLOWING NEUROTOXIC DOSES OF AMPHETAMINE. JZ Fields, LJ Wichlinski, K Engh, J Cronborg & JH Gordon. Res Svce 151, VA Hosp, Hines, IL 60141 and Dept of Pharmacology, Loyola Univ Med Sch, Maywood, IL 60153.

Acute injection of a single dose of amphetamine (A) (9.2 mg/kg, IP) in combination with iprindole (I) (10.0 mg/kg, IP) is known to produce, similar to repeated high doses of A or meth-A, a long-lasting depletion of DA in certain brain areas, particularly, striatum. Last year (SN Abst. #519.7, 1989, L. Wichlinski et al) we reported increases in apomorphine (APO) induced behaviors in male rats (locomotion, stereotypy) 3 & 10 weeks following A/I. We now report [1] replication of these behavioral data; [2] confirmation of DA depletion (at 4 weeks) in striatum (-49%) but not n. accumbens(-6%); [3] increases (+53%, 12 weeks post-A/I) in Bmax (but not Kd) for sulpiride sensitive [3H]spiroperidol binding to striatal D2 DAr ($p < .05$). Furthermore, the peptide cyclo(leu-gly)(CLG), a neuromodulator which we showed down-regulates DA receptors in many different paradigms, significantly reduced APO-induced behaviors in A/I rats and reversed the increases in D2 DAr binding (fmol/mg prot: con=17.4; A/I=26.6; A/I + CLG=21.6, $p < .05$). A/I may represent a useful model of long-term D2 DAr up-regulation. (Supported by grants from the VA, Scottish Rite Schizophrenia Res Pgm-NMJ, & NIH [NS26449]).

539.2

INCREASED SENSITIVITY TO GTP OF STRIATAL ADENYLATE CYCLASE ACTIVITY INDUCED BY PROLONGED ADMINISTRATION OF D1 AND D2 RECEPTOR ANTAGONISTS. C. Ventra, T. Florio, M. Grimaldi*, E. Landolfi*, and G. Schettini. Dept. of Pharmacology, II School of Medicine, Univ. of Naples, via S. Pansini 5, 80131 Naples, Italy.

Long term administration of neuroleptics is frequently associated with the development of receptor supersensitivity. We studied the response to GTP of striatal adenylate cyclase activity in membranes from D1, D2 and D1 + D2 supersensitive rats to evaluate the role of G-proteins in the coupling of rat striatal dopamine receptors to adenylate cyclase activity of up-regulated receptors. SCH-23390, Haloperidol, SCH-23390 + Haloperidol and saline was administered to male Wistar rats over a 21 days period. Our results show that, besides the expected variation of dopamine and D1 agonist (SKF-38393) stimulated adenylate cyclase activity induced by up-regulated receptors, also the response of the enzyme activity to GTP alone is modified. These results suggest that the increased sensitivity of G-proteins to GTP may participate in the mechanisms of induction of receptor up-regulation and be involved in their enhanced functional response.

539.3

EFFECTS OF CHRONIC TREATMENT WITH LOW DOSES OF 1-SULPIRIDE ON DOPAMINE RECEPTOR AND B-ADRENOCEPTOR FUNCTION IN RAT STRIATUM AND FRONTAL CORTEX. C. Missale, S. Sigala*, P. Rizzonelli*, A. Forgione* and P.F. Spano. Inst of Pharmacol Exp Ther, Sch of Med, Univ of Brescia, Italy.

There is now increasing evidence that 1-sulpiride has antidepressant activities when administered at low doses. Down regulation of ß-adrenoceptor function in the frontal cortex is a well documented adaptive response to chronic administration of antidepressants. On these basis we studied the responses of striatal and cortical DA receptors and ß-adrenoceptors to chronic administration of low doses of 1-sulpiride. Male Sprague-Dawley rats were treated with 2 mg/kg (i. p.) 1-sulpiride twice a day for 21 days and killed by decapitation 8 days after the last injection. The results showed that the function of striatal D-1 and D-2 receptors is decreased by 1-sulpiride administration, suggesting that at low doses 1-sulpiride preferentially blocks DA autoreceptors controlling DA release. 1-Sulpiride also induced a selective desensitization of cortical ß-receptors; this effect was not detectable in the striatum which contains a high density of ß receptors, but lacks norepinephrine (NE) innervation. Cortical NE terminals may be endowed with D-2 receptors controlling NE release and blockade of this endogenous DA inhibitory modulation may be involved in the antidepressant effects of 1-sulpiride.

539.4

NEUROLEPTIC COTREATMENTS WHICH ATTENUATE THE DEVELOPMENT OF BEHAVIORAL HYPERSENSITIVITY. L.C. Kao, R. Singh, H.L. Klawans*, P.M. Carvey. Rush Medical College, Chicago, IL 60612.

Rats, chronically treated with neuroleptic agents, develop an increased stereotypical behavioral response to a subsequent challenge with the dopamine (DA) agonist apomorphine (APO). DA receptor proliferation is widely believed to be responsible for this behavioral hypersensitivity (BH). We have studied a variety of cotreatment paradigms to examine the relationship between BH and DA receptor proliferation. Rats were treated for two months with haloperidol (HAL, 0.75 mg/kg) and a variety of cotreatments which included amantadine (AMAN), lithium (Li), scopolamine (SCOP), thioridazine (THIO), or clozapine (CLZ). Four days following the last treatment the animals were challenged with APO and 2 days later they were sacrificed. The striata were examined for alterations in D-2 receptor number using quantitative autoradiography. AMAN, Li, SCOP, and THIO cotreatments significantly attenuated the development of BH to HAL. SCOP cotreatment also attenuated the development of BH induced by fluphenazine. CLZ, however, failed to attenuate HAL-induced BH. AMAN and Li cotreatment prevented the D-2 receptor proliferation normally induced by HAL while SCOP, THIO and CLZ cotreatments did not. Therefore, D-2 receptor proliferation can exist in an animal that does not exhibit BH suggesting that factors in addition to D-2 receptor proliferation participate in the expression of BH. D-2 receptor proliferation is therefore permissive for the expression of BH.

Modulation of Striatal Dopamine (D2) Binding by Oral Etonitazene and its Antagonism by Chronic Naltrexone. J.B. Fishman* and K.R. Carlson. Dept. of Pharmacology, U. Mass. Med. Ctr., Worcester, MA 01655

Male Sprague-Dawley rats were implanted s.c. with Alzet osmotic minipumps containing either naltrexone (NTX; 70 mg/ml) or saline (SAL). Half of each group was then given free access to the potent opiate etonitazene (ET; 2 ug/ml) or water for 12 days. ET consumption of the SAL-implant rats gradually rose from 30 to 60 ml/day, but this effect was blocked by NTX. Striatal synaptosomes showed increased high affinity binding of [^{3}H]-raclopride to D2 receptors from SAL animals who ingested ET, with no significant change in B_{max}. These changes were abolished by NTX. D1 receptor binding was unchanged. Computer modeling was consistent with the high affinity D2 binding following chronic ET ingestion representing 10-20% of the D2 receptors having a 50- to 100-fold higher affinity. Since antagonists were used for binding and competition, it is unlikely that the modulation of binding is due to changes in receptor/G-protein interaction. (Supported by USPHS DK 39328, DA 06539 and ONR)

539.6

CHANGES IN BASAL GANGLIA DOPAMINE (DA) SYSTEMS AFTER NEONATAL INTRASTRIATAL 6-HYDROXYDOPAMINE (6-OHDA) INJECTIONS. B.S. Neal and J.N. Joyce. Departments of Psychiatry and Pharmacology, University of Pennsylvania School of Medicine, Philadelphia, PA 19104.

It is known that early lesions of DA systems result in different behavioral effects compared to adult lesions. Nonselective damage to DA systems in the early postnatal period results in enhanced responses to D1 agonists, but not to D2 agonists. Thus, there may be differences in DA receptor regulation depending upon the maturity of the system when lesioned. To selectively destroy the DA input to the patch (striosome) compartment, while leaving that to the matrix relatively intact, we administered 6-OHDA bilaterally into the striatum (4 µg per striatum) on day of birth (P0) or postnatal day 1 (P1). The rats were supersensitive to the behavioral effects of D1 agonists and subsensitive to the effects of D1 antagonists as adults. Our aim was to determine if DA receptor changes within the striatum could account for these effects. Quantitative autoradiography on coronal sections of brain tissue from rats given bilateral 6-OHDA lesions revealed a significant and patchy loss (30-50%) of presynaptic DA uptake sites (^{3}H-mazindol), with greater losses in the dorsomedial and dorsolateral striatum. Unlike adult lesions, there were no changes in the density of D2 sites (^{3}H-spiroperidol); however, there was a significant and heterogeneous loss (10-20%) of D1 sites (^{3}H-SCH23390). Decreases (40-50%) in the number of µ-opioid receptor (^{3}H-naloxone) patches were also apparent. A second set of neonatally-lesioned rats was killed on P7 (before the patch/matrix organization is obscured) in order to determine if there was a selective loss of D1 receptors in the patch compartment. Preliminary results suggest that this is the case. Tyrosine hydroxylase immunocytochemistry is also being used to examine the integrity of the patch and matrix-directed DA inputs in these animals. (Supported in part by USPHS Grant MH43852.)

539.7

UP-REGULATION OF DOPAMINE D-1 RECEPTORS IN RHESUS MONKEYS AND RATS FOLLOWING CHRONIC ADMINISTRATION OF SCH 39166, A D-1 SELECTIVE ANTAGONIST. R.A. Duffy*, G. Kaminska*, R.E. Chipkin and R.D. McQuade, Schering-Plough Research, Bloomfield, New Jersey, 07003.

It has been demonstrated that chronic administration of selective neurotransmitter antagonists produces an increase, or up-regulation, in the density of the specific receptor (Bmax). A novel D-1 antagonist, SCH 39166 ((-)-trans-6,7,7a,8,9,13b-hexahydro-3-chloro-2-hydroxy-N-methyl-5-H-benzo-[d]-naphtho{2,1b}azepine) was examined for its ability to produce such a change in Bmax when administered chronically. Adult rhesus monkeys received daily oral injections of either vehicle or SCH 39166 (3, 12 or 48 mg/kg) for three months. The caudate nucleus and putamen were dissected and the D-1 and D-2 receptors were analyzed for changes in their affinities (Kd) and densities. In the putamen, a significant increase in Bmax was seen for all three doses of SCH 39166 (58, 92 and 100% above control, respectively, $p < 0.05$, Duncan's multiple range test), while in the caudate nucleus only the 12 and 48 mg/kg doses produced a significant up-regulation when compared to vehicle controls (50 and 80%, respectively). No significant increase in the density of D-2 receptors was observed in either region.

Similar studies were performed in male rats that had received 50 mg/kg SCH 39166 orally for 7 consecutive days. Analysis of striatal membranes from these groups indicated that SCH 39166 produced a significant increase in the density of D-1 receptors (33% over control animals), without affecting the density of D-2 receptors.

These data demonstrate that in vivo, SCH 39166 is capable of crossing the blood-brain barrier and binding to D-1 receptors in rodents and primates. Further, the selective up-regulation of these receptors suggests that, in vivo, SCH 39166 binds to D-1 receptors without significant interaction at D-2 sites.

539.8

BRAIN *SIGMA* AND DOPAMINE RECEPTORS ARE NOT MODULATED BY CHRONIC D-PENTAZOCINE ADMINISTRATION IN RATS. A.D. Weissman and E.B. De Souza. Neurobiology Laboratory, NIDA Addiction Research Center, Baltimore, MD 21224.

Schizophrenia has been associated with alterations in the regional brain densities of σ and D_2 dopamine receptors. Recent studies have suggested that drugs with high affinities for the σ receptor may produce psychotomimetic effects by modulation of dopamine release. Long-term treatment of animals with σ drugs can regulate the number of σ binding sites. We hypothesized that chronic administration of a drug such as d-pentazocine, with high affinity and specificity for σ receptors, could alter the number of σ binding sites and indirectly affect basal dopamine release. This, in turn, should modulate the number of D_2 receptors. Rats (n = 6/group) were implanted s.c. with mini osmotic pumps to deliver either d-pentazocine (10 mg/kg/day) or saline for 4 weeks. Saturation studies using [^{3}H]YM-09151-2 or [^{3}H]haloperidol in the presence of 50 nM spiperone to label D_2 and σ sites, respectively, revealed no significant changes in the K_D or B_{max} of either site in nine brain regions of drug treated animals. The inability of the specific σ compound d-pentazocine to alter σ receptors differentiates this drug from compounds such as d-3-PPP and DTG that up-regulate σ binding, and from haloperidol, which down-regulates σ sites. Unlike d-pentazocine, the compounds that are able to regulate σ receptors bind to multiple sites. This suggests that chronic interaction with the haloperidol-sensitive site alone may not be sufficient to modulate σ or dopamine binding.

539.9

OPPOSING EFFECT OF CHOLECYSTOKININ OCTAPEPTIDE ON SPECIFIC DOPAMINE D1/D2 TYPE BINDING SITES IN RAT BRAIN. A.M. Kask*, C. Marin, L. Steardo, T.N. Chase, ETB, NINDS, Bethesda, MD 20892.

Blockade of either dopamine (DA) D1 and/or D2 receptors induces catalepsy in rats. Cholecystokinin-octapeptide (CCK8) affects central dopaminergic function, possibly by modulating DA interactions at both D-1 and D-2 receptor sites. The present study was designed to explore the effects of acute intrastriatal injection of CCK8 on D-1 and D-2 receptor mediated catalepsy and the binding capacities of DA receptors at the time of maximal behavioral response. Over a period of 2 minutes, CCK8 (50-800 ng) was injected into each striatum through surgically implanted cannulae. For catalepsy induction, rats received either the D-1 antagonist SCH 23390 (0.5 mg/kg sc), the D-2 antagonist raclopride (RAC, 2.5 mg/kg ip), or saline. Catalepsy was scored for the next two hours. Other rats were sacrificed 20 min after antagonist injection, when catalepsy peaked. Brains were removed and P2 membrane fractions prepared for ex vivo receptor assay. CCK8 significantly diminished SCH induced catalepsy but enhanced RAC induced catalepsy. Given alone, CCK8 did not affect motor behavior, but did increase the number of available receptors of both sub-types . The presence of SCH or RAC alone, reduced the number of respective binding sites available; intrastriatal CCK8 increased the number of available D-1 and decreased the number of available D-2 binding sites. The opposing effect of CCK8 on D1/D2 receptor binding and catalepsy may provide a mechanism for the modulation of the functional interaction of the dopaminergic system by CCK8 either directly or via one of its metabolites.

539.10

EFFECT OF AVP ADMINISTRATION AND AVP DEFICIENCY UPON ^{3}H-AVP BINDING SITES IN CNS AND PERIPHERY. P. Szot and D.M. Dorsa. GRECC, Seattle VAMC, WA 98108.

AVP (40 ug/100gbw, sc) was administered to Long-Evans (LE) pups from day 1-7 of life and sacrificed on day 8 or day 60. No significant changes were observed in ^{3}H-arginine^8-vasopressin (^{3}H-AVP) binding in the kidney, septum or cingulate gyrus of day 8 pups from control. No significant changes were observed in kidney or septum of day 60 animals. However, the chronic AVP treatment did result in a significant increase in the density of ^{3}H-AVP binding sites in the liver when compared to control in day 8 pups (control 44 ± 2; AVP 56 ± 3 fmol/mg protein) and day 60 rats (control 186 ± 9; AVP 239 ± 14 fmol/mg protein). The affinity in liver ^{3}H-AVP binding site remained unchanged for day 8 and 60 animals. This demonstrates a permanent alteration in the density of ^{3}H-AVP binding sites in the liver due to an early postnatal AVP treatment. A comparison of ^{3}H-AVP binding sites in 8 day old LE, heterozygous Brattleboro rat (BB-HET) and homozygous Brattleboro rat (BB-HOM) was performed to assess the effect of complete (BB-HOM) and partial (BB-HET) AVP deficiency on AVP binding sites in the CNS and periphery. The liver again was the only tissue that showed a change in ^{3}H-AVP binding characteristics. The BB-HOM rat (B_{max}=144 ± 6 fmol/mg protein) displayed a significant increase in AVP binding sites from the LE rat (B_{max}=100 ± 7 fmol/mg protein), while the ^{3}H-AVP binding sites in the BB-HET (B_{max}=69.8 ± 9 fmol/mg protein) liver were significantly lower than the LE rat. Thus, hepatic AVP receptors appear most sensitive to the presence or absence of AVP during the early postnatal period.

539.11

KINETICS OF NICOTINE BINDING TO BRAIN TISSUE AFTER CHRONIC NICOTINE INFUSION. R.V. Bhat, S.L. Turner*, M.J. Marks and A.C. Collins. Sch. of Pharmacy, Inst. for Behav. Genetics, Psychology Dept., Univ. of Colorado, Boulder, CO 80302.

The basic model for desensitization of the nicotinic receptors from *Torpedo californica* can be viewed as two conformational states of the receptor having differential affinities for the agonist. Although less studied, it has been suggested that a similar situation occurs with the nicotine binding sites in the brain since receptors in fast (Bf) and slow (Bs) phases of association binding can be detected. Chronic nicotine treatment increases the number of [^{3}H]nicotine binding sites in rodent brain and in decreased sensitivity to nicotine. A conformational shift from a low affinity ground to a higher affinity desensitized form may be responsible for this adaptive effect. Thus, chronic nicotine treatment should cause a shift in the ratio of Bs to Bf binding. C57BL/6 mice were continuously infused with saline or 0.5, 1, 3, 6 mg/kg/hr nicotine for 7 days. The kinetics of [^{3}H]nicotine binding to brain membranes obtained from these mice revealed biphasic association and a monophasic dissociation kinetics. Chronic nicotine treatment did not alter the Bs:Bf ratio. Since the rate of resensitization of the receptors is not known, additional data are necessary to test whether the Bs:Bf ratio is altered *in vivo*. Supported by DA-03194 and DA-00116.

540.1

IN VIVO RELEASE OF ACETYLCHOLINE IN THE BASAL NUCLEAR COMPLEX FROM NEURONS OF THE PONTOMESENCEPHALIC TEGMENTUM (PMT) S. Consolo, R. Bertorelli*, G.L. Forloni and L.L. Butcher+. Istituto "Mario Negri", 20157 Milan, Italy and +University of California, Los Angeles, CA 90024-1563, USA.

In an attempt to determine possible interactions between the basal forebrain (NB) cholinergic complex and the PMT cholinergic neurons, we measured the acetylcholine (ACh) release in vivo from the NB, both alone and in combination with lesion and pharmacologic manipulations. The ACh release was calcium dependent and it was increased by scopolamine (SCOP) (0.5 mg/kg s.c.). The rise in ACh release induced by SCOP (a) persisted in the presence of quisqualate lesions of the NB complex (b) was blocked by tetrodotoxin infusion, and (c) was abolished by ablation of PMT cell bodies. Thus, the calcium dependent ACh release in the NB complex (a) is largely axonal in nature, (b) derives substantially from cholinergic PMT axons, and (c) appears to be controlled by presynaptic muscarinic receptors on PMT axon terminals. Thus, the PMT cholinergic complex might influence cortical ACh release, in part at least, by means of serial-order cholinergic-cholinergic interactions in the basal nuclear complex.

540.2

Effects of an M_1 receptor agonist (AF102B) on the central cholinergic system, evaluated by brain microdialysis. N. Ogane, Y. Takada*, Y. Iga*, G. Kawanishi*, and F. Mizobe. Res. Inst. of Life Sci. Snow Brand Milk Products Co. Ltd., Tochigi 329-05, Japan.

The effects of a novel M_1-receptor agonist, AF102B (FKS-508; cis-2-methylspiro (1,3 - oxathiolane - 5,3') quinuclidine, on the central cholinergic system *in vivo* were evaluated by determination of acetylcholine (ACh) content in the rat brain after microwave irradiation and by measurement of ACh release with microdialysis perfusion in freely moving rats. Intraperitoneal administration of AF102B resulted in a significant decrease of ACh content in the brain, while AF102B produced an increase of *in vivo* ACh release. The present results suggest that ACh content in the brain after treatment with muscarinic agents may be related to the changes of ACh release, in which both M_1 and M_2 muscarinic receptors may be involved.

540.3

MODULATION OF HIPPOCAMPAL ACETYLCHOLINE RELEASE BY NMDA RECEPTORS M.G. Giovannini* and G. Pepeu, Department of Pharmacology, University of Florence, Florence, Italy.

Evidence has been accumulating that the cholinergic and glutamatergic systems of the hippocampus are involved in cognitive processes. While the neuroanatomical organization of the cholinergic and glutamatergic systems in the hippocampus is well known, little is known of the possible interactions between the two neurotransmitter systems. The aim of the present study was to investigate the effect of the modulation of hippocampal NMDA receptors on the release of ACh in freely moving Wistar male rats by means of a transversal microdialysis probe implanted in the proximity of the CA1 region in the dorsal hippocampi. Perfusion of the microdialysis probe with 500 uM NMDA dissolved in Ringer solution brought about a decrease of ACh release compared to the mean of three basal control values (-48 %, $P < 0.05$, Duncan test). A decrease (- 45 %, $P < 0.05$) was also observed following perfusion with the NMDA antagonist 2-amino-7-phosphonoheptanoate (AP7). On the contrary, i.c.v. injection of AP7 (10 ug/rat) was followed by an increase in ACh release (+79 %, $P < 0.05$). These findings indicate a complex modulation of the cholinergic system by NMDA receptors. Supported by C.N.R. grants.

ACETYLCHOLINE RELEASE IN THE HIPPOCAMPUS, CORTEX AND STRIATUM OF RATS CORRELATES WITH LOCOMOTOR ACTIVITY: AN IN VIVO MICRODIALYSIS STUDY. J. DAY, G. DAMSMA, H.C. FIBIGER. Div. of Neurological Sciences, Dept. of Psychiatry, Univ. of British Columbia, Vancouver, B.C. V6T 1W5

Simultaneous measurements of locomotor activity and dialysate concentrations of acetylcholine (ACh) and choline (Ch) in the dorsal hippocampus, frontal cortex, and dorsal striatum of rats were made under three conditions: 1) drug-free, after the administration of vehicle (H_2O); 2) after administration of the muscarinic receptor antagonist, scopolamine (0.4 mg/kg); and 3) during the change from light to dark in the rats' daily cycle. Vehicle injections increased ACh concentrations in the cortex and hippocampus, but not in the striatum. Scopolamine stimulated locomotion and increased extracellular concentrations of ACh to 404% (striatum), 1241% (hippocampus) and 1435% (cortex) of basal values. Ch concentrations in the hippocampus and cortex were lowered slightly by scopolamine; Ch in the striatum was transiently increased by this drug. Within 20 minutes after dark, ACh increases of 58%, 77% and 169% were measured in the striatum, cortex and hippocampus, respectively. Locomotor activity also increased during this time. Dark exposure did not change Ch in any area. Significant positive correlations between ACh release and locomotor activity were found for each brain region under all three conditions. These results indicate that cholinergic transmission can undergo regionally selective changes in response to environmental and pharmacological stimuli.

AMPHETAMINE-INDUCED INCREASES IN STRIATAL ACETYLCHOLINE RELEASE AS MEASURED BY MICRODIALYSIS ARE NOT DEPENDENT ON NIGROSTRIATAL DOPAMINE. R.J. MANDEL, O.G. NILSSON*, E. ROSENGREN*, and A. BJÖRKLUND. University of Lund, Dept. of Medical Cell Research, Biskopsgatan 5, S-223 62 Lund, Sweden.

One of the most consistent findings in the study of striatal dopamine (DA) receptor pharmacology is the inhibitory control by D-2 receptor stimulation of striatal acetylcholine (ACh) release *in vitro*. The present study was undertaken to characterize the *in vivo* dopaminergic control of ACh release in the rat striatum. In preliminary experiments, we observed a consistent 100-200% increase in striatal ACh release in response to 5 mg/kg systemic amphetamine (AMPH, ip) but no effect when AMPH was administered locally in the probe (10 µM AMPH, with 5 µM neostigmine, 15 min samples). Since the systemic data are in direct contrast to many reports using the *in vitro* slice technique, an experiment was undertaken to determine whether the effect was dependent on striatal DA. Eleven rats were administered unilateral 6-hydroxydopamine lesions with 5 receiving desmethylimipramine to protect noradrenergic striatal projections. All rats were implanted with bilateral loop-type microdialysis probes in the striatum (AP +0.7 mm, LAT ±2.6, DV -6.0, from bregma and dura). There was no effect of lesion on either baseline or AMPH-induced striatal ACh release with systemic AMPH causing a 100-200% increase compared to baseline levels. A preliminary experiment (n = 3) utilizing an extremely ventrolateral striatal placement of the dialysis probe in intact rats also indicates a large increase in striatal ACh release in response to systemic AMPH. These data suggest that local striatal release of DA is not responsible for the observed effect of AMPH on ACh release and there is no differential dopaminergic control of striatal ACh in these striatal subregions. Thus, some multisynaptic pathway, perhaps that can be influenced by the opposite nigrostriatal DA projection, must be responsible for the effects reported here.

540.6

NEUROTENSIN REGULATES ACETYLCHOLINE RELEASE FROM STRIATAL INTERNEURONS: EFFECT OF 6-OHDA LESIONS OF THE SUBSTANTIA NIGRA. R. Quirion, A. Beaudet, D.M. Araujo and P.A. Lapchak. Douglas Hosp. Res. Ctr. and Neuroanat. Lab., Mtl. Neurol. Inst., McGill Univ., Montreal, Canada.

Neurotensin (NT) immunoreactivity and receptors are present in the striatum, a region enriched with dopaminergic and cholinergic innervation. The present study determined whether NT alters the activity of striatal cholinergic interneurons and if nigral DA neurons modulate this effect. NT (10 µM) increased K^+-evoked (50%), but not basal, ACh release from striatal slices. The effect was concentration-dependent and tetrodotoxin-insensitive. In the presence of the dopamine antagonist sulpiride (50 µM), the effect of NT (10 µM) was further enhanced by an additional 40%. In slices from 6-OHDA lesioned rats, in which striatal ChAT activity was not changed, but basal and evoked ACh release were increased (33% and 40%, respectively), the effect of NT on evoked ACh release was similar to control (48% increase). In addition, in lesioned animals, sulpiride (50 µM) did not alter evoked ACh release, nor did it augment the effect of NT (10 µM) alone. These results suggest that in the striatum, NT regulates ACh release by a direct action on cholinergic elements. (Supported by MRC, Canada and FRSQ, Quebec).

PHARMACOLOGICAL STUDIES OF ACETYLCHOLINE RELEASE BY MICRODIALYSIS IN THE FREELY MOVING RAT. L.K. Gorman, D.S. Olton, S. Plano* and G.L. Wenk. Neuromnemonics Lab., Dept. of Psychology, The Johns Hopkins Univ., Baltimore, MD 21218.

Sodium dependent high affinity choline uptake levels are increased following i.p. injections of scopolamine or pentylenetetrazol, and decreased by pentobarbital. This study examined the effects of these pharmacologic manipulations on two other measures of cholinergic activity, ACH release and the number of high affinity choline uptake (HACU) sites. Changes in release of ACH were determined by in vivo microdialysis. Six 5-minute microdialysate samples, from the hippocampus and overlying cortex, were collected to obtain baseline levels prior to drug injection and an additional twelve successive dialysate samples were collected after drug injection. Levels of choline and ACH were assayed using HPLC with electrochemical detection. One hour prior to the determination of HACU binding by hemicholinium-3, each rat was given an injection of one of the three drugs. A correlation between the kinetics of ACH release and HACU binding following drug injections that alter the activity of the cholinergic system can be determined using this technique. Supported by NSF BNS 88-07010 and NIH NS 20471.

540.8

EFFECT OF THE PHYSOSTIGMINE DERIVATIVE HEPTASTIGMINE ON ACETYLCHOLINE RELEASE ASSESSED BY MICRODIALYSIS IN RAT BRAIN. E. Messamore, N. Ogane, E. Giacobini and E. Williams*. Dept. of Pharmacology, Southern Illinois Univ. Sch. Med. Springfield, IL 62974, USA

Heptastigmine [heptyl-physostigmine(MF-201), Mediolanum Farm., Milan, Italy] is a new derivative of the carbamate acetylcholinesterase (AChE) inhibitor physostigmine (Phy) with lower toxicity and longer inhibitory action on brain AChE than the parent compound. Following single dose administration of 5 mg/kg i.m. an 80% inhibition of brain AChE is reached at 60 min; at 360 min inhibition is still 67%. Increases in acetylcholine (ACh) levels measured in brain homogenates are seen in all brain regions with a maximum increase of 60% occurring in striatum 2h after injection. Local AChE inhibition by Phy as well as MF-201 administered via microdialysis probe elevates ACh recovered from striatum in a dose-dependent manner. In contrast to the ACh elevating effect of AChE inhibition observed in the aforementioned studies, systemic administration of MF-201 (5 mg/kg) decreases ACh recovered by microdialysis from the striatum of freely moving rats; ACh falls to 84% of its baseline value 2 hours after i.p. injection. Microdialysis permits recovery of ACh from the extracellular space, while assay of brain homogenate reflects extracellular as well as intracellular compartments. MF-201 decreases ACh measured by microdialysis yet increases ACh measured in brain homogenate. Therefore ACh elevation in brain homogenate following a high level of AChE inhibition reflects a predominantly intracellular drug effect.

EFFECT OF TRH AND A TRH ANALOGUE YM-14673 ON EXTRACELLULAR ACH LEVELS OF RAT IN FREELY MOVING CONDITIONS

M.Okada* and T.Yamaguchi Central Res. Labs., Yamanouchi Pharmacetical Co. LTD., 21 Miyuki-gaoka, Tukuba, Ibaraki, 305, Japan.

TRH and YM14673 has been reported to possess analeptic actions such as shortening effects on pentobarbitone-induced sleeping time in rodents. These effects were inhibited by anti-muscarinic agents, suggesting the involvement of stimulation of cholinergic system. Therefore, using in vivo brain dialysis combined with HPLC-ECD system, we have measured flux of ACh induced by TRH and YM-14673 in the frontal cortex(FC) and the caudate nucleus(CN) of freely moving rat.

In the FC, TRH(10 mg/kg i.p.) increased the extracellular ACh by 250% reaching a peak at 40 min post drug. YM-14673 produced a dose-dependent increase in ACh levels. YM-14673 at 0.1 mg/kg i.p. enhanced ACh release by 220% reaching a maximum at 60 min and lasting for 40 min. While, in the CN, a higher dose of YM-14673(3 mg/kg i.p.) increased the extracellular ACh levels by only 25%. These results suggested that a part of the CNS-stimulating action of TRH and YM-14673 might be ascribed to the increase of ACh release in the cortex.

540.10

DIISOPROPYLFLUOROPHOSPHATE IS NOT A RELIABLE AGENT FOR THE STUDY OF CHOLINERGIC FUNCTION. A.W. Kirby & A.T. Townsend*. U.S. Army Aeromedical Research Laboratory, Ft. Rucker, AL 36362.

Diisopropylfluorophosphate (DFP) is an irreversible inhibitor of cholinesterase (ChE), and is used widely to investigate cholinergic function. Recent results have suggested that DFP might have significant actions totally independent of cholinergic circuitry.

All experiments were done on fully anesthetized adult cats. Release of labeled DA, GABA, and glycine from isolated retina was increased by DFP exposure, but not by physostigmine or excess ACh as would be expected if DFP were acting solely on cholinergic mechanisms. The increase persisted with exposure to atropine or mecamylamine, and without synaptic transmission, suggesting a direct effect of DFP on retinal neurons. Direct application of DFP to the cortical surface caused changes in the visual evoked response and cortical neurochemistry, similar, but of less magnitude than those resulting from i.v. DFP. A direct effect of DFP on cortical neurons, independent of or in addition to cholinergic effects, could explain these changes. Because of apparent noncholinergic actions of DFP, other anticholinesterase agents should be used to validate DFP results.

540.11

EFFECTS OF TRIHEXYPHENIDYL (TH) AND BIPERIDEN (BP) ON BRAIN NEUROTRANSMITTER LEVELS OF RAT INTOXICATED WITH SOMAN.

T.-M. Shih, B. Capacio* L. Cook*, T. Koviak*, T. Sewell* and N. Adams*. U.S. Army Med. Res. Inst. Chem. Defense, Aberdeen Proving Ground, MD 21010-5425.

It has been reported that antimuscarinics possessing antiparkinson activity are effective in preventing convulsions induced by the cholinesterase (ChE) inhibitor soman. The purpose of this study was to see if the drugs, given to rats at an anticonvulsant dose of 0.125 mg/kg, im, would cause changes in cholinergic or catecholaminergic parameters in the striatum of rats poisoned with soman (100 ug/kg, sc). The time courses (up to 2 hr) for ChE activity and levels of acetylcholine (ACh) and catecholamine were measured after soman, TH, BP, soman + TH, or soman + BP treatment. Soman inhibited ChE activity (60%; 15 min) and increased ACh levels (35%; 15 min). It did not affect norepinephrine or dopamine (DA), but elevated levels of the DA metabolites 3,4-dihydroxyphenylacetic acid (DOPAC) and homovanillic acid (HVA), thus indicating increased DA turnover. BP and TH alone did not affect any of the neurochemical parameters studied. TH and BP each significantly reversed the effects of soman on DOPAC and HVA levels, but neither affected cholinergic parameters. Our data suggest that, in addition to actions on muscarinic receptors, the anticonvulsant effects of TH and BP in soman poisoning may be partially related to their actions on the striatal dopaminergic system.

540.12

EFFECT OF THE CHOLINESTERASE INHIBITOR HUPERZINE-A ON ETHYLCHOLINE AZIRIDINIUM (AF64A) CHOLINOTOXICITY IN THE RAT.

S. Laganiere, J.C. Corey*, X.C. Tang*, E. Wulfert* and I. Hanin. Dept. Pharmacology, Loyola University Chicago Stritch School of Medicine, Maywood, Il 60153; and UCB s.a.*, Pharmaceutical Sector, Brussels, Belgium.

Huperzine-A (Hup-A) is a natural and long lasting acetylcholinesterase (AChE) inhibitor isolated from a *Lycopodium* found in China. Hup-A was reported to elevate levels of acetylcholine in rat brain by up to 40% for several hours and has been proposed as a palliative treatment in Alzheimer's disease (Tang et al., J. Neurosci. Res. 24:276, 1989). Previous studies on chronic treatment with Hup-A (0.5 mg/kg, twice daily for 4.5 days) showed a 19 to 30% reduction of AChE in various areas of the brain. We also observed a 25% transient inhibition of high affinity choline transport (HAChT) in hippocampal synaptosomes 45 min. after injection. However, the inhibition was completely recovered at 90 min. This effect was secondary to (AChE) inhibition, since Hup-A had no effect on HAChT in hippocampal synaptosomes *in vitro*.

Hemicholinium-3, a potent inhibitor of HAChT, has been shown to protect efficiently against AF64A hippocampal cholinotoxicity *in vivo*. We thus explored whether the reduction of HAChT in the Hup-A-treated rat would also protect against AF64A cholinotoxicity. Male Sprague-Dawley rats were pre-treated for 4.5 days with Hup-A (i.p., 0.1 or 0.5 mg/kg, twice daily). Bilateral administration of AF64A (2 nmol/ventricle icv; 3 ul/3 min) was performed within 45 min after the 9th pre-injection. Hup-A was continued (C) or withheld (W) in groups of AF64A-treated rats, for 6 days, until sacrifice. In Hup-A treated rats, results clearly indicated that hippocampal HAChT activity was 30% ($p<0.03$) lower than in AF64A-injected controls. AChE activity was also significantly lowered by 22%, but only in the W groups. Levels of choline acetyltransferase were not further decreased by Hup-A. The usual absence of striatal cholinotoxicity following AF64A was not modified. In conclusion, Hup-A-induced reduction in hippocampal HAChT was not sufficient to protect against AF64A cholinotoxicity *in vivo*. Supported by NIA Grant #AG07591 and by UCB s.a., Brussels.

DOSE-TIME EFFECT OF ETHYLCHOLINE AZIRIDINIUM (AF64A) ON CYCLIC AMP (cAMP) LEVELS IN RAT BRAIN: CORRELATION WITH THE REVERSIBILITY OF CHOLINERGIC DISRUPTION AT LOW DOSES OF AF64A. A. El-Tamer*[•§], E. Wulfert*[§], and I. Hanin[•]. Loyola University Chicago Stritch School of Medicine, Maywood, Illinois 60153[•], and UCB s.a., Pharmaceutical R&D, Brussels, Belgium[§].

AF64A-induced reduction in cholinergic function may, through a possible feedback loop, involve noradrenergic mechanisms (Hortnagl et al., J. Neurosci. Methods 27: 103, 1989). We wondered whether the second messenger cAMP might reflect these AF64A-induced catecholaminergic changes. Animals were treated with various doses of AF64A (0.25, 0.5, 1.0 and 2.0 nmol) icv, bilaterally, and killed by decapitation at 2, 4, 7, 14, 28 and 42 days after such treatment. Hippocampus, striatum and frontal cortex were rapidly dissected out and tissues were subsequently extracted in 6% TCA. cAMP was measured by radioimmunoassay. Choline acetyltransferase (ChAT) and acetylcholinesterase (AChE) activities were also measured in a portion of the same tissues, employing conventional radioenzymatic techniques. Changes in cAMP, ChAT and AChE were observed only in the hippocampus, thus indicating region-specific effects of AF64A. By 2 days following AF64A treatment, at all doses tested, there was a dose dependent (23% -36%) decrease in hippocampal cAMP levels, respectively. By 7 days, all values returned to normal. Hippocampal ChAT and AChE reductions following doses of 0.25 and 0.5 nmol/ventricle reached a nadir (25% - 60%) by 4 and 7 days, respectively, but returned completely to normal values within 14 days following AF64A treatment. ChAT and AChE levels following treatment with 1.0 and 2.0 nmol AF64A/ventricle were reduced significantly by 4 days, and did not recover even 42 days post AF64A. These combined data imply a modulatory role for cAMP dependent mechanisms in the disruption of central cholinergic function induced by AF64A treatment.

540.14

AF64A DOSE-DEPENDENTLY BUT NON-UNIFORMLY DECREASES THE NUMBER OF CHOLINE ACETYLTRANSFERASE (ChAT) IMMUNOREACTIVE (IR) CELL BODIES IN THE SEPTAL COMPLEX. S.A. Lorens, G. Kindel*, X.W. Dong*, J.M. Lee and I. Hanin. Dept. Pharmacology, Loyola University Chicago Medical Center, 2160 S. First Ave., Maywood, IL 60153.

The cholinotoxin, AF64A (0.5,1.0 or 1.5 nmole/ventricle), or vehicle (3.0 ul) was injected bilaterally into male F344 rats (n=23). ChAT-IR perikarya in the four subgroups of the septal complex (Amaral, D.G. & Kurz, J., J. Comp. Neur., 240:37-59, 1986) were visualized (40 um sections at 0.2 mm intervals; PAP technique) 28 days post-injection and counted using a microprojector (x25). The 0.5 nmole dose of AF64A significantly reduced (31%) the number of ChAT-IR cell bodies in the intermediate subgroup (rostral extension of nucleus basalis). Higher doses did not produce additional reductions. The largest AF64A dose resulted in significant reductions in ChAT-IR cell bodies in the dorsal (51%) and midline (35%) subgroups (medial septum), but did not affect the number of ventral subgroup (horizontal limb of the diagonal band) ChAT-IR neurons. Electrolytic lesions were placed in 6 rats in order to produce non-selective damage to the corpus callosum, cingulum and overlying cingulate gyrus, similar to that seen following higher doses of AF64A. These lesions failed to significantly affect the number of ChAT-IR cell bodies in any of the septal subdivisions. These results suggest that the distinct subgroups of septal ChAT-IR neurons are differentially sensitive to the toxic effects of i.c.v. administered AF64A: intermediate >> dorsal > midline >> ventral subgroup. AF64A may diffuse into the cingulate gyrus and hippocampal formation where it is taken up by cholinergic terminals and produces retrograde degeneration of septal cell bodies. Alternatively, AF64A may spread directly to the septal complex where it is transported into cholinergic cell bodies and induces cytotoxicity, the cholinergic perikarya in the intermediate cell group being the most sensitive. Supported by Grant #MH42572.

540.15

DECREASED CHOLINE ACETYLTRANSFERASE ACTIVITY AND ^{3}H-ACETYLCHOLINE RELEASE IN THE RAT MEDIAL SEPTAL/ DIAGONAL BAND COMPLEX AFTER FIMBRIA-FORNIX TRANSECTION. R.H. METCALF and R.J. BOEGMAN. Department of Pharmacology and Toxicology, Queen's University, Kingston, Ontario, Canada K7L 3N6.

We have previously shown that ACh release in the medial septal/diagonal band complex (MSDB) may be stimulated by 35 mM potassium (K^+). However, the origin of this release is unknown. Electrophysiological and morphological data suggest that the release may be from local collaterals originating from cholinergic neurons projecting to the hippocampus. Transection of the fimbria-fornix pathway produces retrograde losses of MSDB cholinergic markers. Studies were undertaken to determine if FF transection would alter ChAT activity and/or ^{3}H-Ach release as well as AchE histochemistry in the MSDB. Rats received complete FF transections and then were allowed to recover for 1, 3, and 5 weeks. AchE histochemistry 1 week following transection revealed an abundance of swollen AchE-positive fibers in the MSDB which by 3 weeks had disappeared, along with a large majority of AChE-positive cell bodies. This loss was still evident at 5 weeks. ChAT activity measured in the hippocampi and MSDB of non-operated controls was 65.4 ± 7.3 and 137 ± 10.7 nmoles/mg protein/hr respectively. When compared to normal animals, ChAT activity in the hippocampus decreased by 80% 1 week following transection. In the MSDB, ChAT activity decreased by 20% 1 week following transection and was decreased by 32% at 3 weeks. This decrease was still present at 5 weeks. In normal animals, 35 mM K^+ produced an 11.2 ± 1.9 fold increase in MSDB ^{3}H-ACh release. One week following transection, ^{3}H-ACh release was the same as that observed in control experiments. At 3 weeks, a 50% decrease in release was observed in the MSDB. ^{3}H-ACh release was still decreased at 5 weeks. These results suggest that a portion of cholinergic activity seen in the MSDB may be due to local collaterals of cholinergic neurons projecting to the hippocampus. Supported by the MRCC & OMHF.

540.16

RECOVERY OF ACH RELEASE AND ACH CONTENT FROM AH5183 INHIBITION IN HIPPOCAMPAL SLICES. R. Cabeza and B. Collier. Department of Pharmacology, McGill University, Montreal, Quebec, Canada, H3G 1Y6.

2-(4-phenylpiperidino)cyclohexanol (AH5183) inhibits vesicular ACh uptake and ACh release. Though all cholinergic vesicles are sensitive to AH5183, their sensitivities differ. We investigated the recovery of the subcellular ACh contents following treatment with AH5183 to see if different fractions recover at different rates. Hippocampal slices were exposed to the drug, stimulated, and allowed to recover for 10 to 50 min by removing AH5183 and exposing the slices to ^{3}H-Ch. At each time point slices were processed for the determination of subcellular ACh and ^{3}H-ACh contents. Cytoplasmic ACh (S_3 fraction) declined after 40 min while that of the occluded pools (P_3 fraction) peaked at 30 min. By 50 min both fractions were not different from controls. The specific activity (S.A.) of the S_3 fraction increased with time where as that of the P_3 plateaued at 30 min. Since the P_3 fraction is an amalgamation of several fractions it was further separated to see if differences in the recovery of the occluded pools existed. Though the D fraction is most sensitive to the drug's inhibition, the ACh of all fractions increased at the same rate and peaked at 30 min. Interestingly, the D fraction's increase in ACh content did not include ^{3}H-ACh for its ACh S.A. remained at or near 0 for all the time points. (supported by M.R.C. and TS-MH-18882-01).

EFFECTS OF CHOLINE AND FETAL SEPTAL GRAFTS ON SOME CHOLINERGIC PARAMETERS IN FIMBRIA-FORNIX LESIONED RATS. İ. H. Ulus, E. Korfalı,* S. Uysal,* V. Savcı*, N. Demiröz* and B. K. Kıran*. Departments of Pharmacology and Neurosergury, Uludağ Univ. Med. Sch., Bursa, Turkey.

A 2x3 mm cavity was made by suction unilaterally on the surface of right hippocampus, and fimbria-fornix was lesioned in 31 rats under thiopental (45 mg/kg) anesthesia. Two weeks later, the cavity was re-opened and fetal septal grafts were inserted in 15 rats ("septal-grafted"). The remaining 16 rats served as the "sham-grafted" group. Six rats in each group were given choline in their drinking water (15 mg/ml) for period of 8 weeks by starting 5th week of the grafting. 11th week of grafting motor activities of rats were measured, and 12th week of the grafting rats were killed and their brains removed. Choline acetyltransferase (CAT) activity and ^{3}H-QNB binding were assayed in the right hippocampus.

CAT activity, B_{max} for ^{3}H-QNB binding and motor activity were 36%, 71% and 20%, or 74%, 98% and 113% of control in sham- or septal-grafted rats, respectively. Supplementation of choline altered none of these parameters in septal-grafted rats, but restored, greatly, toward normal decreased motor activity in sham-grafted rats.

These results show that long term choline supplementation has no harmfull effect on the repairing action of cholinergic fetal septal grafts, and restores some of behavioural consequence of cholinergic neurones lost.

540.18

IMMUNOHISTOCHEMICAL EVIDENCE THAT A VESAMICOL ANALOGUE REDUCES THE EXPRESSION OF CHOLINE ACETYLTRANSFERASE (ChAT) IN THE RAT BRAIN WITHOUT AFFECTING OTHER NEUROTRANSMITTER-SPECIFIC MARKERS. L. L. Butcher, S. M. Parsons# and P. L. Di Patre. Dept. of Psychology, UCLA, Los Angeles, CA 90024-1563; #Dept. of Chemistry, UC Santa Barbara, CA 93106.

The compound *trans*-2-(4-Phenylpiperidino)cyclohexanol (now called Vesamicol) is known to inhibit the storage of acetylcholine in nerve terminal synaptic vesicles. A number of analogues have been synthesized recently and their potencies evaluated on purified synaptic vesicles from *Torpedo* electric organ (Rogers et al., *J. Med. Chem.*, **32**: 1217, 1989). We tested the effects of intracerebroventricular (i.c.v.) administration of one of these drugs, here called OD72. Adult Sprague-Dawley rats were treated i.c.v. with OD72, 10 nmol or vehicle, and transcardially perfused 7 days after surgery. In OD72-treated rats we found a disappearance of neurons expressing ChAT in the cholinergic nuclei of the basal forebrain on the injected side, while ChAT-positive neurons in the brainstem were not affected. Other cholinergic markers (nerve growth factor receptor, acetylcholinesterase) were not changed. In addition, the number of neurons expressing GABA-like immunoreactivity in medial septum, as well as cells in the *locus coeruleus* immunoreactive for dopamine-*B*-hydroxylase (DBH) was unaltered as a consequence of OD72-administration. No alterations of Nissl stained cells were observed. These data suggest that OD72 might be a drug capable of reducing ChAT expression selectively in the basal forebrain, without affecting noncholinergic markers like DBH or GABA. [Support: NS 10928]

541.1

COLOCALIZATION OF 11β-HYDROXYSTEROID DEHYDROGENASE AND MINERALOCORTICOID RECEPTOR IN RAT BRAIN. R.R. Sakai, V. Lakshmi*, C. Monder*, J.W. Funder*, Z. Krozowski* and B.S. McEwen
The Rockefeller Univ., Lab. of Neuroendocrinology and The Population Council, New York, NY, 10021; and Medical Research Centre, Prince Henry's Hospital, Melbourne 3004, Australia.

The activity of 11β-hydroxysteroid dehydrogenase (11-DH), which converts corticosterone and cortisol to receptor inactive 11-dehydro metabolites, may provide a mechanism which enables aldosterone to gain access to Type I (mineralocorticoid) receptors, despite the concurrent availability of 100-1000 fold higher competitive concentrations of corticosterone. To further test this possibility, we examined the immunocytochemical localization of Typed I receptors and 11-DH in rat brain, with antibodies directed against renal mineralocorticoid receptors and purified hepatic 11-DH. Type I positive cells were localized throughout the brain, complementing their known distribution by receptor binding assay. The hippocampus was the area of highest Type I receptor density, followed by the cortex, paraventricular nucleus of the hypothalamus and amygdala. 11-DH colocalized with Type I immunoreactivity in all brain areas listed above, and was best demonstrated in the hippocampus. These data support the idea that 11-DH is important in mediating the expression of aldosterone specific effects at the Type 1 receptor and further suggest that the action of 11-DH in relation to the mineralocorticoid in the brain may be via an autocrine rather than a paracrine mechanism as is believed to occur in the kidney. Supported by NS 08537(RRS), MH 43787 (BSM), DK 37094(CM) and the NHMRC of Australia (ZK, JWF).

541.2

NEUROPEPTIDE Y AND DYNORPHIN IN THE BRAIN AND PITUITARY GLAND OF A TELEOST FISH. L. M. Cepriano*, M. P. Schreibman and S. Holtzman*. Department of Biology, Brooklyn College, CUNY, New York 11210.

The distribution of neuropeptide Y (NPY) and dynorphin (DYN) in the brain of immature and mature male platyfish (Xiphophorus maculatus), a freshwater teleost, was studied using immunocytochemistry on Bouin's-fixed, paraffin-embedded material. Immunoreactive (ir)-NPY was found in perikarya and nerve tracts of the nucleus olfactoretinalis, telencephalon, ventral tegmentum and in the neurohypophysis and specific cells of the adenohypophysis. Ir-DYN was found in nerve tracts in the olfactory bulb and in association with cells of the pars intermedia and caudal pars distalis of the pituitary gland. The association of NPY and DYN with brain structures and pituitary gland regions previously found to be involved with sexual maturation, growth and differentiation, suggests that these neuropeptides play a role in these events. THE ROLE OF ESTROGEN IN THE SEXUALLY DIMORPHIC DISTRIBUTION OF CHOLECYSTOKININ (CCK) RECEPTORS IN THE RAT BRAIN: A QUANTITATIVE IN VITRO AUTORADIOGRAPHY STUDY. K.D. Richardson Morton, J.S. Ackman* and N.J. MacLusky. Dept. of Reproductive Science, University of Toronto, Toronto, Ontario M5G 1L7.

Quantitative in vitro autoradiography studies have shown sex differences in CCK receptor levels in rat brain. Male and female rats were gonadectomized and implanted (s.c.) after 1 week with either vehicle or 10% estradiol Silastic capsules 3 days prior to sacrifice. Tissue sections (10 um) were preincubated at 25°C for 15 min. with 50 mM Tris-$MgCl_2$ buffer with 0.2% bovine serum albumin, 1mM dithiothreitol,and 0.2% bacitracin (pH 7.7) followed by a 1 hr incubation with 0.1 nmol ^{125}I-CCK-8 in the preincubation buffer. Females showed increased levels of CCK receptors in the hypothalamic ventromedial nucleus (VMN) and the cingulate cortex compared to the males. Estrogen treatment produced significant decreases in CCK receptors in both the VMN and cingulate cortex of female rats, but had no effect in the male rats. These findings are in agreement with Akesson et al. (Neuroendo. 45: 257-262, 1987) who reported that a bolus injection of estradiol 24 hrs prior to sacrifice significantly reduced CCK binding in the VMN in ovariectomized rats. These results suggest a sexually dimorphic distribution of CCK receptors in the rat brain, and a role for estrogen in modulating these receptors in the female rat. Supported by MRC Canada.

IMMUNOHISTOCHEMICAL LOCALIZATION OF CALRETININ IN RAT FOREBRAIN. L. Winsky and D.M. Jacobowitz, Lab. of Clinical Sciences, NIMH, Bethesda, MD 20892

A specific and sensitive calretinin antibody (Winsky et al., 1989, PNAS 86: 10139) was used to reveal cell bodies, fibers and pathways within rat forebrain. Sections were incubated in calretinin antibody followed by preparation for fluorescence or peroxidase staining. Results revealed calretinin-specific stain of neurons and fibers in several regions including: olfactory bulb (granule cells, periglomerular cells), hypothalamus, amygdala, cerebral cortex and hippocampus (non-principal cells). Several neuronal circuits were also revealed. Fibers of intensely fluorescent lateral mamillary nucleus cells could be traced along the mamillothalamic tract to terminal areas in the anterior medial nucleus of the thalamus. Labeled cells and fibers of the medial habenula projected to the interpeduncular nucleus via the fasciculus retroflexus. The nigrostriatal and mesolimbic systems were also revealed by calretinin antisera. Other regions with particularly dense calretinin stain included the septofimbrial n., medial amygdaloid n. and periventricular, reticular, anterior dorsal and reunions nuclei of the thalamus. These results extend previous findings indicating a high density of calretinin in brainstem sensory regions and reveal a unique localization of this calcium binding protein in forebrain regions of clinical significance.

541.5

THE ONTOGENY OF TRANSFERRIN RECEPTORS IN THE DEVELOPING CHICK RETINA, Arnold G. Hyndman and Sa Sun Cho. Department of Biological Sciences, Rutgers University, Piscataway, NJ 08855.

Transferrin is a growth factor likely to play a significant role in CNS development. In this study, the appearance of the transferrin receptor (TfR) in the developing chick retina is examined immunohistochemically. TfR immunoreactivity is first detectable in the ganglion cells of E (embryonic day) 4 retina. At E10, TfR immunoreactivity appears in the inner nuclear layer and in photoreceptor cells. In contrast to transferrin, which is characteristically located in the plexiform and nerve fiber regions, and in the outer segments of the photoreceptors, TfR is located primarily on soma. TfR immunoreactivity in ganglion cells and the inner nuclear layer decreases during the later stages of embryonic development (E15 to hatching), but remains strong in the photoreceptors. In addition to neurons, Müller cells and glia of the optic nerve fiber layer are TfR positive. The TfR positive glia of the optic nerve fiber layer are distinctive in their morphology, location and developmental pattern. At E6, they appear along the central portion of the optic streak. They have an ovoid soma and either unipolar or bipolar processes. From E6 to E15, these cells increase rapidly in number and can be gradually found in the peripheral regions of the retina. At E15, star shaped TfR positive glia can be observed. These glial cells, in time, become the predominate population of TfR positive glia.

THE DISTRIBUTION OF TAURINE-LIKE IMMUNOREACTIVITY IN THE AVIAN CENTRAL NERVOUS SYSTEM. D.S. Henshel and J.D. Steeves. Department of Zoology, University of British Columbia, Vancouver, B.C. Canada V6T 3A4.

Taurine, or a taurine-containing dipeptide (γ-glutamyl- or glycyl-taurine) has been implicated as a neuromodulator or inhibitory neurotransmitter in the CNS. We have used a monclonal taurine antibody ("Tau2", kindly donated by K. Magnusson, J. Madl and A. Beitz) to examine the distribution of taurine-like immunoreactivity (TLI) in the brains and spinal cord of paraformaldehyde-perfused chicken (Gallus gallus) and heron (Ardea herodias) hatchlings. Many small and medium sized cells exhibit TLI throughout the brain. In the forebrain, especially in the striatum, hippocampus and parahippocampus, most of the immunoreactive cells appear to be neuronal. In the midbrain, brainstem and spinal cord the most intense TLI is seen in glial cells. In the cerebellum, a variety of cell types are immunoreactive, including glia, basket cells, and some purkinje cells. In general, the few very large neurons which are immunoreactive (i.e. cerebellar purkinje cells and neurons in a few cranial nuclei) have only light positive staining. Moderate to intense TLI is also seen in the pineal. Throughout the brain (white and grey matter) many fibers exhibit light, medium or dark TLI. In the white matter (brain and spinal cord) many small intensely immunoreactive glial cell bodies are seen. At least some of these immunoreactive glia appear to be oligodendroglia. Thus, TLI is found in both neurons and glia and is widely distributed throughout the avian brain.

Rapid feasability studies of new PET ligands: High resolution PET in small animals. M. Ingvar, L. Eriksson*, S. Stone-Elander*, G. Rogers*, L. Widén*, PET-Section, Karolinska Institute and Hospital, S-104 01 Stockholm, Sweden and Department of Chemistry, University of California Santa Barbara, CA.

The development of sufficient amounts of a radiotracer for use in PET is often a time-consuming process of optimizing radiolabelling yields and handling procedures. Sometimes the radiotracer is not the original drug, but rather a derivative with unknown in vivo biopharmacological properties. We have therefore developed a fast and relatively inexpensive method of testing new ligands in vivo. Small animal studies require relatively low amounts of radioactivity, can be performed without sterility and toxicology tests and may also serve as a preliminary basis for radiation safety calculations since whole body scans can be performed.

We have tested the procedure with an 18-F analog of Vesamicol, a drug that specifically binds in vitro to synaptic vesicles of cholinergic neurons. For the procedure the rats were anesthetised, ventilated and provided with arterial and venous catheters. The animals were placed in the PET scanner during the whole procedure and sequential scans were performed. After a bolus i.v. injection of 50-100 µCi of the ligand repeated arterial samples were taken. The plasma radioactivty was determined to obtain the brain input function. Following image reconstruction of the scans standard time/radioactivity plots were constructed. The camera (Scanditronix PC2048-15B) has a resolution of 4.5 mm FWHM and a rat brain is approximately 16-25 pixels in the 128*128 image. The major advantage of this procedure is that very few experiments are necessary to reliably determine the kinetic properties of the blood brain barrier transport and the magnitude of whole brain binding to a receptor system. In vivo displacement of a ligand from a receptor can be made with potentially toxic amounts of the drug. This is especially important since many receptors are characterized by a state-dependent binding that impairs a direct comparison of in vitro experiments with the in vivo situation.

PRESENCE OF IMIDAZOLEACETIC ACID RIBOSIDE, A METABOLITE OF IMIDAZOLEACETIC ACID, IN HUMAN CEREBROSPINAL FLUID. G.D. Prell, A.M.Morrishow*, E.Douyon* and S. Jotkowitz*. Department of Pharmacology, Mount Sinai School of Medicine, CUNY, New York, NY 10029 and Department of Neurology, Hackensack Medical Center, Hackensack, NJ 07601.

Imidazoleacetic acid (IAA), which we demonstrated in rat brain and in human CSF [J. Neurochem. 52: 1107, 1989], stimulates GABA-A receptors, produces analgesia, hypnosis, hypotension and other central effects. We found [Soc. Neurosci. Abstr. 15: 998, 1989] high concentrations of an acid-hydrolyzable conjugate(s) of IAA in brain (> 20 nmol/g) and CSF, whose levels exceeded those of free IAA by up to 100-fold. We postulated that the conjugate(s) may have been IAA-ribotide (IAA-Rt) and/or IAA-riboside (IAA-Rs).

IAA-Rs HCl, prepared for us by synthesis, was derivatized with trimethylchlorosilane (TMCS) and analyzed by gas chromatography (GC)-mass spectrometry (MS). IAA-Rs-TMS_4 was identified by chemical ionization [MH^+ 548] and electron impact ionization MS. We have extracted IAA-Rs from urine collected (>48 h) from rats multiply treated with IAA-HCl (i.p.) and D-glucose (p.o.). The TMS derivative(s) of IAA-Rs HCl prepared from urine and by synthesis showed identical GC and MS properties. Patients undergoing diagnostic or therapeutic procedures gave informed consent for collection of additional lumbar cerebrospinal fluid (CSF) for research purposes. In some patients, more than 30 ml of CSF was collected sequentially in 1-2 milliliter units. CSF aliquots of ml 4-5, 16-17 and 29-30, derivatized with TMCS, showed the presence of IAA-Rs. Derivatives of the latter showed GC-MS characteristics identical to those of IAA-Rs prepared from urine. This supports our previous postulate that IAA in brain may be ribosylated and suggests that IAA in CNS of humans may be metabolized by the only route of IAA metabolism known to occur in rodents, i.e. formation of IAA-Rt then dephosphorylation to IAA-Rs. [Research supported by grant NS28012 from NINDS.]

IMMUNOCYTOCHEMICAL DEMONSTRATION OF SYNAPTIC TRANSMITTERS IN THE LATERAL MEDIAL-SUPRAGENICULATE COMPLEX OF THE CAT. S. Onodera*, M. Norita, K. Takeda* R. Eason and T.P. Hicks Dept. of Psychology, UNC-Greensboro, Greensboro, NC 27412-5001

Immunocytochemical studies with several antibodies raised against various suspected synaptic transmitters have been performed at the light microscope level to identify and characterize the distributions of the neurons and axon terminals containing choline acetyltransferase (ChAT), Substance P, GABA, glutamate and aspartate in the lateral medial-suprageniculate nuclear complex (LM-SG) of the cat. Determination of the boundaries of LM-SG was aided by cytoarchitectonic criteria and by superimposition of adjacent sections treated for acetylcholinesterase (AChE).

The pattern of staining of varicosity-containing, ChAT-positive fibers corresponded well with the pattern of AChE staining seen throughout nearly all areas of LM-SG. Small neurons were heavily immunopositive for GABA. Aspartate and glutamate appeared to be present in moderate to low levels, and were found principally in larger neurons. Substance P staining was very weak and appeared to be located within a few small-diameter fibers that also possessed varicosities. These studies are continuing at the E.M. level to assess the likely nature of the transmitters of LM-SG afferents, particularly those from tectal and cortical sources.

THE MEDIAL AMYGDALOID NUCLEUS OF THE SYRIAN HAMSTER CONTAINS TWO DISTINCT POPULATIONS OF TYROSINE HYDROXYLASE-IMMUNOREACTIVE NEURONS. S.E. Asmus, C.R. Neal, Jr. and S.W. Newman, Department of Anatomy and Cell Biology, University of Michigan, Ann Arbor, MI 48109.

The medial nucleus of the amygdala (Me) integrates chemosensory and hormonal signals influencing sexual behavior in male Syrian hamsters (*Mesocricetus auratus*). Only in this species, to date, have dopamine (DA) neurons been described in Me (Vincent, *J. Comp. Neurol.*, '88), although DA is considered to be important in regulating sexual behavior in male rats. To extend Vincent's observations, we used colchicine to enhance tyrosine hydroxylase (TH)-immunostaining in Me. Nine adult males received intraventricular injections of 200 ug of colchicine and were perfused after 48 hours. Forty-um coronal brain sections were processed for peroxidase-antiperoxidase immunocytochemistry using 3 different TH-antibodies: one monoclonal (Incstar) or one of two different polyclonal antisera (Eugene Tech or East-Acres Biol.). Polyclonal antisera generated against DBH or PNMT (Eugene Tech) were also used to test for the presence of these other catecholamine synthetic enzymes. Unlike Vincent's observations, we found more than 100 TH-immunoreactive neurons within two distinct populations, one in the anterior, and the second in the posterodorsal region of Me. Similar staining patterns were obtained with all TH-antisera. Animals not given colchicine (n=2) had only a few TH-immunoreactive cells in Me. Absence of DBH and PNMT-immunolabeling of Me suggested that these TH neurons are dopaminergic. Whether these DA neurons are involved in regulating sexual behavior will be examined in future studies. (Supported by NIH, NS #20629 to SWN).

A MICRODIALYSIS STUDY OF BRAIN SEROTONIN FOLLOWING FENFLURAMINE AND QUIPAZINE ADMINISTRATION IN THE PIGEON. C. HARROD*, R.D. JOHNSON* AND J.E. BARRETT. Dept. of Psychiatry, Uniformed Services University of the Health Sciences, 4301 Jones Bridge Rd., Bethesda, MD 20814-4799.

Brain microdialysis techniques were used to examine effects of fenfluramine (10 mg/kg) and quipazine (3.0 mg/kg), both administered i.m., on serotonin (5-HT) release in the raphe and hippocampal areas of the pigeon brain. Dialysates were collected from the awake pigeon following earlier stereotaxic implantations of a guide cannula targeted at the respective sites. Both fenfluramine and quipazine increased 5-HT concentrations in both brain regions, with peak effects occurring approximately 60 minutes following drug injection; effects of both drugs lasted for about two hours before returning to near control levels. These studies demonstrated that the microdialysis procedure can be used to study 5-HT neurochemical systems in the awake, behaving pigeon. Supported by DA 02873.

MONOAMINES IN THE CHICK BRAIN: REGIONAL DISTRIBUTION AND PRESYNAPTIC MODULATION OF RELEASE. M.L. Dubocovich J.A. Siuciak, and S. Iacob*. Dept. Pharmacology. Northwestern Univ. Medical School, Chicago, Il. 60611.

The levels of monoamines (DA, NE, and 5HT) and their metabolites (DOPAC, MHPG, and 5HIAA) were measured in the brains of one week old chicks which were dissected into the following areas: hypothalmus (HYPO), thalamus (THAL), neo-striatum/ectostriatum (NEO/ECTO); hyperstriatum (HS), paraolfactory lobe/nucleus basalis area (LPO/NB), optic tectum (OT), cerebellum (CER), spinal cord (SC), and pineal (PIN) and assayed using the Coulochem Electrode Array System of ESA Inc. (Bedford, MA.). In the NEO/ECTO, LPO/NB, THAL and HYPO the levels of DA and DOPAC (pg/mg tissue) were: 2 and 16, 92 and 227, 5 and 34, 108 and 99; NE & MHPG were: 26 and 81; 80 and 32, 58 and 489, 526 and 41; and 5HT and 5HIAA were: 13 and 165, 75 and 304, 19 and 352, 206 and 306, respectively. The calcium-dependent release of ^{3}H-5HT from NEO/ECTO slices is inhibited by 5-OCH_3-tryptophan (1-1000 nM) and 8-OHDPAT (1-1000 nM) and is increased by methiothepin (1-1000 nM), suggesting modulation of release by 5HT autoreceptors. In addition the release of ^{3}H-DA is modulated through D_2 autoreceptors. The complete regional distribution of monoamine levels and release modulating presynaptic receptors will be presented. We conclude that in the chicken brain, as in mammals, presynaptic receptors modulate the release of monoamines. Supported by MH42922 to MLD and NS07140 to JAS.

QUANTATITIVE PHARMACOLOGICAL ANALYSIS OF MELATONIN BINDING SITES IN DISCRETE AREAS OF THE CHICKEN BRAIN. J. A. Siuciak[1], D. Krause[2], M. L. Dubocovich[1], Dept. Pharmacol., Northwestern Univ. Medical School, Chicago, Il. 60611 and [2]Univ. Calif., Medical College, Irvine, CA. 92717.

Melatonin binding sites are widely distributed throughout the chicken brain, predominantly in visual areas. The density and pharmacological characteristics of 2-[^{125}]-iodomelatonin binding sites were determined using quantitative autoradiography. Scatchard analysis of saturation data in representative areas of the chicken brain revealed saturable high affinity binding sites [K_d (pM); B_{max}, (fmol/mg protein)] in the optic tectum (35; 11.4), neostriatum (20; 10), suprachiasmatic nucleus (10; 6.9), and N. rotundus (22; 11.2). *Melatonin and 6-Cl-melatonin* were potent competitors of 2-[^{125}I]-iodomelatonin binding [K_i (pM)], (OT: 62 and 117; NEO: 8 and 63; vSCN: 19 and 47; and ROT: 57 and 68, respectively), while N-acetylserotonin and luzindole show lower affinity [K^i (nM)] (OT: 95 and 633; NEO: 307 and 188; vSCN: 292 and 491; and ROT: 56 and 149, respectively). A complete regional distribution of density and binding affinities for 2-[^{125}I]-iodomelatonin binding sites will be presented. We conclude that high affinity 2-[^{125}I]-iodomelatonin binding sites, with characteristics of ML-1 sites, are heterogeneously distributed through the chicken brain. Supported by MH42922 (MLD) and NS07140 (JAS).

NEUROENDOCRINE REGULATION: OTHER III

542.1

ESTROGEN RECEPTOR GENE EXPRESSION IN THE RAT HIPPOCAMPUS. A. Maggi and E. Bettini*. Milano Molecular Pharmacology Lab, Inst. Pharmacol. Sci., Univ. Milano, Italy.

Recent studies performed in rat hippocampus indicate the presence of relatively high amounts of a protein which is indistinguishable from estrogen receptor (ER) on the bases of electrophoretic, immunological and pharmacological criteria.

In order to fully prove the existence of estrogen receptor synthesis in this important limbic area, the presence of ER mRNA was tested by means of the polymerase chain reaction (PCR) technique. A sscDNA was therefore prepared by oligo dT priming of mRNA extracted from the hippocampus of ovariectomized rats and a series of oligonucleotides were utilized in order to amplify selected portions of the coding sequence. This analysis proved the presence of ER mRNA in rat hippocampus. Sequencing of the amplified section of ER cDNA permitted to determine that the mRNA present in the hippocampus is identical to that one synthesized in uterus.

Further studies are presently being carried on in order to obtain a correct extimate of the concentration of ER in the rat hippocampus.

542.2

SHORT-TERM ELEVATION IN GLUCOCORTICOID LEVELS IS SUFFICIENT TO ELEVATE ADRENAL MEDULLARY PNMT LEVELS P. Boksa, K. Betito, and J. Diorio*. Douglas Hospital Research Ctr., Depts. of Psychiatry & Pharmacology, McGill University, Montreal, Quebec, H4H 1R3

A well known effect of glucocorticoids in the adrenal medulla is the regulation of phenylethanolamine-N-methyl transferase (PNMT) activity. PNMT catalyzes the conversion of noradrenaline to adrenaline in chromaffin cells of the adrenal medulla. Two days of glucocorticoid (GC) treatment has previously been shown to be required for a significant elevation of PNMT levels in cultured bovine adrenal chromaffin cells. Since a short (1-2 hour) pulse of GCs is released in response to a single episode of acute stress, these studies examine the effects of treating cultured bovine adrenal medullary cells for a short time with high dose GCs, mimicking the physiological phenomenon, on PNMT activity 2 days later. Doses of 10 and 100 uM hydrocortisone (HC) were used in the treatments, and in all studies no differences were found between the two doses. Similar to previous results by others, continuous 2 day HC treatment increased PNMT levels to 247% of control. Acute HC treatments of 30 minutes or 2 hours elevated PNMT levels assayed 48 hours later to 174% & 190% of control, respectively. The increase in PNMT levels that resulted from a 2 hr pulse of HC persisted for 72 hrs following treatment. Preliminary data suggest that a 2 hr pulse of HC (100 uM) begins to elevate PNMT levels within 12 hours. These results suggest that short-term elevation in GC levels, as seen physiologically after an acute stressor, is sufficient to elevate adrenal PNMT levels. Supported by MRC of Canada and FRSQ.

542.3

ESTROGEN RECEPTOR BINDING IN REGIONS OF THE RAT HYPOTHALAMUS AND PREOPTIC AREA AFTER INHIBITION OF DOPAMINE-ß-HYDROXYLASE. T.J. Brown, J.D. Blaustein, R.B. Hochberg*, and N.J. MacLusky. Div. of Reprod. Sci., Toronto General Hospital, Toronto, ON M5G 1L7, Neurosci. and Behav. Prog., Univ. of Mass., Amherst, MA 01003, and Dept. of OB/GYN, Yale Univ. Sch. of Med., New Haven, CT 06510.

Previous studies have shown that administration of diethyldithiocarbamate (DDC), a dopamine-ß-hydroxylase inhibitor, results in decreased estrogen receptor concentrations in the rodent hypothalamus. To determine if this modulation of receptor content is region-specific, *in vitro* estrogen binding assays were performed on cytosol and cell nuclear extracts of microdissected brain regions from female rats treated with DDC. For cytosol binding comparisons, ovariectomized (OVX) rats were treated with 550 mg DDC/kg b. wt. or the saline vehicle 12 h before sacrifice. For cell nuclear binding comparisons, OVX rats received a maximal dose of estradiol 12 h after DDC and 1 h before sacrifice. No region-specific decreases in estrogen binding were observed in either cytosol or nuclear extracts. To further examine possible region specificity, quantitative autoradiographic analysis of the *in vivo* hypothalamic uptake of an iodinated analog of estradiol, 11ß-methoxy-16α-[125I]iodoestradiol, after DDC treatment was conducted. DDC treatment resulted in higher levels of radioactivity in serum and neural tissues of [125I]MIE2-injected rats, suggesting that DDC slows the clearance of MIE2. These results suggest that modulation of estrogen receptors in the rodent brain by inhibition of catecholamine synthesis is not manifest with any clear regional specificity, and underscore the need to consider possible multifocal sites of action of pharmacological agents used in studying neurotransmitter regulation of steroid hormone receptors.

542.4

INTENSITY OF NEURONAL ESTROGEN RECEPTOR-IMMUNOSTAINING CORRELATES WITH NORADRENERGIC INPUT IN THE ROSTRAL VENTROLATERAL HYPOTHALAMUS OF GUINEA PIGS. M.J. Tetel and J.D. Blaustein. Neuroscience and Behavior Program and the Psychology Department, University of Massachusetts, Amherst, MA 01003.

The noradrenergic (NA) system plays an important role in the regulation of female sexual behavior and gonadotropin release. We have previously reported dopamine-ß-hydroxylase-immunoreactive (DBH-IR) punctate structures in close association with estrogen receptor-immunoreactive (ER-IR) cell bodies and processes throughout the guinea pig hypothalamus. To determine if intensity of ER-immunostaining is influenced by the presence of NA input, the optical densities (OD) of these ER-IR cells were quantified using an imaging system. The rostral ventrolateral hypothalamus, an area containing many ER-IR cells, is sufficient for estradiol priming of progesterone-facilitated lordosis. In this area ER-IR neurons, with DBH-IR punctate structures closely associated with both the soma and processes, stained more darkly (OD=3.3) than neurons lacking this association (OD=2.6). However, in this experiment the α-NA antagonist, prazosin, did not result in a detectable decrease in the intensity of ER-immunostaining. Nevertheless, the initial finding suggests indirectly that the NA system may maintain the concentration of ERs transneuronally, and it supports the results of previous experiments showing modulation of ERs by the NA system.

542.5

EVENING MELATONIN INJECTIONS INHIBIT TUBEROINFUNDIBULAR DOPAMINE SYNTHESIS IN OVARIECTOMIZED HAMSTERS. N. A. Alexiuk and J. Vriend., Dept. of Anatomy, Univ. of Manitoba, MB, Canada R3E 0W3.

In the present study the effects of melatonin administration on the accumulation of serotonin (5HT) and dopamine (DA) after pargyline administration was studied in tissue punches of median eminence and of caudate n. of intact and ovariectomized Syrian hamsters. Concentrations of monoamines and metabolites were determined by HPLC with electrochemical detection. In median eminence, but not in striatum, the accumulaton of DA was reduced to 22% of controls in intact hamsters ($p < .05$) and to 9% of controls in ovariectomized hamsters ($p < .01$) by melatonin injections. Ovariectomy resulted in a significant increase in DA accumulation after pargyline in saline-injected, but not in melatonin -injected hamsters. No significant effects on the accumulation of 5HT in median eminence or in striatum could be detected. Increased levels of 5HIAA in hamsters not receving pargyline were observed both in median eminence and in caudate n. as a result of melatonin injections. These data show that evening melatonin injections inhibit daytime DA synthesis. The results suggest that melatonin may influence the activity of tyrosine hyroxylase in median eminence directly, or indirectly via serotonergic neurons which synapse on tyrosine hydroxylase containing neurons in the median eminence. (Supported by MRC).

542.6

AUTORADIOGRAPHIC LABELING OF NEURONS IN THE BRAINS OF SHORT AND LONG-TERM CASTRATED ADULT MALE RHESUS MONKEYS AFTER ADMINISTERING [^{3}H]TESTOSTERONE. A.N. Clancy, R.W. Bonsall and R.P. Michael, Department of Psychiatry, Emory University School of Medicine, Atlanta, Georgia 30322 and the Georgia Mental Health Institute, Atlanta, Georgia 30306.

In long-, but not short-term, castrated male macaques, testosterone administration does not suppress plasma gonadotropin levels or always fully reinstate copulatory behavior. To examine the proposition that long-term castration alters the uptake of androgens by the brain, 4 adult males castrated 3 days previously (BW 8.8-10.7 kg) and four adult males castrated more than 3 years previously (BW 7.2-10.9 kg) were administered 5 mCi [^{3}H]testosterone i.v. After 60 min, brains were rapidly removed and frozen for autoradiography. Sections were cut in a cryostat at 4 μm, thaw-mounted on emulsion-coated slides and exposed for 20-40 weeks. A total of 8,800 neurons in 11 brain regions were examined using a computerized grain-counting system (Bioquant Meg IV, RM Biometrics), and labeled neurons were identified using a rigorous criterion based on the Poisson distribution. In both short- and long-term castrates, there were significant regional differences in the percentages of labeled neurons ($P<0.001$). Highest percentages (50%-80%) occurred in the ventromedial and anterior hypothalamic nuclei, cortical and basal accessory amygdaloid nuclei, intercalated mammillary and premammillary nuclei, bed nucleus of the stria terminalis (BST), and medial preoptic area. Lower percentages (20-50%) occurred in the lateral septum, arcuate nucleus, and medial amygdala. However, there were no differences in the percentages of labeled neurons between short- and long-term castrates with the sole exception of the BST. Data derived from computerized grain-counting correlated highly ($r=0.8$, $P<0.0001$) with those derived from manual counting methods (USPHS grant MH 19506).

542.7

EFFECTS OF TESTOSTERONE PROPIONATE ON THE DENSITIES OF 5-HT1A AND 5-HT1B RECEPTORS IN THE BRAINS OF CASTRATED MALE RATS. S.D. Mendelson and B.S. McEwen. Laboratory of Neuroendocrinology, Rockefeller Univ. New York, NY 10021

Gonadal hormones modulate the density of 5-HT1 receptors in the male rat brain. However, it has not been known what effects the hormones might have on the subtypes of 5-HT1 receptors in male rats. Effects of activation of 5-HT1A and 5-HT1B receptors on testosterone-dependent sexual behavior have suggested that these receptors may be under gonadal hormone control. Accordingly, adult male rats were castrated under anesthesia and administered either testosterone propionate (TP, 0.2 mg) or the oil vehicle in 14 daily injections (n=7). Labellings of 5-HT1A and 5-HT1B receptors for autoradiographic analyses were accomplished by incubation of brain sections in tris-buffered solutions of 1.5 nM [3H]8-hydroxy-(di-n-propylamino)tetralin or 50 pM [125I]cyanopindolol plus isoproteronol, respectively. In each case, unlabelled serotonin was used to determine non-specific binding. TP produced significant increases in the density of 5-HT1A receptors in the medial preoptic nucleus (MPN), but had no effects on these receptors in areas that included the ventromedial hypothalamus, septum and cortex. TP had no effects on 5-HT1B receptors in any area measured, indicating that testosterone can have differential effects on the subtypes of 5-HT1 receptors. The present data suggest that 5-HT1A receptors in the MPN may mediate facilitation of male sexual behavior in the rat.

542.8

VAGINAL ORIFICE REFLEX DILATION IN INTACT AND OVARIECTOMIZED RATS IS MODULATED BY ESTROGEN AND PROGESTERONE. M. Martínez-Gómez, R. Chirino*, P. Carrillo*, C. Beyer* and P. Pacheco. CIRA-Univ. Aut. Tlaxcala-CINVESTAV, Tlaxcala, México; IIB-UNAM, México, DF; CIB-Univ. Veracruzana, Xalapa,Méx.

Lordosis in estrous rats is often associated with vaginal orifice dilation (VOD). This response is under control of pudendal nerve since electrical stimulation of this nerve induces ipsilateral displacement of the VO in anesthetized rats. Under unstimulated condition the VO is normally closed. Perineal tapping elicits a reflex dilation of the VO (VORD) which is facilitated by ovarian secretion since it is maximal (75%) during estrous and minimal during diestrous (7%). The effect of sex steroids treatment on VORD was studied in ovariectomized rats. Perineal tapping induced VORD only in 21% of ovariectomized nontreated subjects (SS). Treatment with 10ug of EB sc significantly increased the proportion of SS responding to perineal tapping (46%). On the other hand, maximal facilitation of the response occurs in those SS receiving estrogen 10ug plus progesterone 1mg, since 75% of these SS presented VORD by perineal tapping. The present results indicate that VOD is a reflex response that can be induced by perineal tapping in intact proestrous and estrous rats. This response is maximally stimulated in ovariectomized rats by the sequential administration of estrogen and progesterone which normally facilitate lordosis behavior in the rat. The results suggest that under normal conditions fluctuations in sex steroids modulate the responsiveness of pudendal motoneurons to sensory stimulation of the perineal area normally occurring during copulation.

GONADECTOMY INCREASES GLUCOCORTICOID CYTOSOLIC RECEPTOR (GCCR) NUMBER IN THYMUS BUT NOT SPLEEN OF ADULT RATS. **R.E. Landsman, A.N. Taylor, R.A. Gorski, B.J. Branch*, J.E. Shyrne*, L.A. Nguyen* and F. Chiappelli. Lab. of Neuroendocrinol., Brain Res. Inst., & Psychoneuroimmunol. Prog., UCLA, & West L.A. VAMC, Brentwood Div., Los Angeles, CA 90024.**

Gonadal hormone-dependent and -independent sex differences exist in GCCR binding sites in rat brain (Turner & Weaver, 1985). Because neuronal and lymphoid GCCRs exhibit some similarities (Lowy, 1989), we examined sex differences and hormone sensitivity in thymus and spleen weight and thymocyte and splenocyte GCCR sites/cell in 80-100 day old intact and gonadectomized (GNX) Sprague Dawley rats. There were no sex differences in spleen or thymus weight for either intact or GNX rats. GNX increased thymus weight 1.6-fold in males ($p<0.004$) and females ($p<0.01$), but had no effect on spleen weight. No sex differences occurred in GCCR sites/cell (using 64 nM [^{3}H]triamcinolone) in either organ for intact or GNX rats. GNX increased GCCR number in male thymus (2.4-fold, $p<0.01$), but not in females. Splenocyte GCCR number was not affected by GNX. Our data indicate that thymic, but not splenic, weight and glucocorticoid receptor number are depressed by gonadal hormones in the rat, suggesting that GCCR may provide a possible mechanism for gonadal hormone modulation of the effects of stress on immune function. **(NIH HD07228 & HD01182, Bettingen Fdn. & VA Medical Res.)**

EFFECTS OF ESTROGEN ON EXCITABILITY AND DYE COUPLING INCIDENCE AMONG RAT SUPAROPTIC NUCLEUS (SON) NEURONS. Q.Z. Yang and G.I. Hatton. Neuroscience Program, Michigan State University, East Lansing, MI 48824.

Castration in males results in decreased incidence of dye coupling among magnocellular lateral paraventricular neurons, an effect that is reversed by testosterone. In intact males there is more coupling than in intact females among SON neurons, suggesting a possible steroid-dependent sex difference. Effects of estrogen (E_2) removal via ovariectomy (Ovex) were studied in horizontally cut slices from 11 ovex and 11 sham ovex rats. Lucifer Yellow-filled electrodes were used to impale and inject SON neurons. 11 injections in sham ovex slices resulted in 10 single and 2 coupled, dye-filled neurons, whereas 11 injections in ovex slices yielded 6 single and 11 coupled, dye-filled neurons, $\chi^2=4.76$, $p<0.03$. An attempt to reverse the effects of ovex by addition of E_2 (10^{-12}M) to the medium yielded an intermediate amount of coupling, not significantly different from either of the other groups. E_2 added to the medium did augment excitatory responses to micropressure applications of glutamate in some neurons; in others E_2 appeared to interfere with glutamate excitation. We conclude that removal of E_2 has an enhancing effect on interneuronal coupling, opposite in direction to the effects of testosterone removal. Also, E_2 may modulate the effects of glutamate via a direct action on neuronal membranes.

KYNURENIC ACID BLOCKS EXCITATORY SYNAPTIC RESPONSES OF RAT SUPRAOPTIC NUCLEUS (SON) NEURONS TO LATERAL OLFACTORY TRACT (LOT) STIMULATION. K. G. Smithson & G. I. Hatton Neuroscience Program & Physiology Dept., College of Osteopathic Medicine, Michigan State University, East Lansing, MI 48824

The main (Smithson, K. G. et al. *Neuroscience* 31:277, 1989) and accessory (Smithson, K. G. et al. *Anat. Rec.* 220:91A, 1988) olfactory bulbs project to the SON. Intracellular electrophysiological analysis of this connection in brain slices revealed predominantly short-latency excitatory responses to electrical stimulation of the LOT (Hatton, G. I. & Yang, Q. Z. *Neuroscience* 31:289,1989). Since much evidence suggests that mitral cells of the olfactory bulbs employ excitatory amino acids (EAA) as neurotransmitters, we investigated the possibility that these short-latency responses observed in SON neurons were mediated through an EAA receptor. Using an explant preparation that contained virtually the complete olfactory projection from the rostral end of the LOT to the SON, we examined the effects of bath application of 1 mM kynurenic acid (KYN) on the evoked responses in SON neurons from LOT stimulation. Intracellular recordings were obtained from 66 SON neurons, of these, 50 neurons responded to electrical stimulation of the LOT. The responses observed were all excitatory and had variable latencies. In 15 neurons in which long-term stable impalements were maintained, KYN blocked LOT-evoked responses. In all cases, action potentials could be evoked during the KYN-blockade by intracellular current injection , or when previously possible, antidromically by neural stalk stimulation. These results confirm previous reports of the excitatory nature of this connection. An additional finding in the present study is that these excitatory responses are blocked by KYN a specific antagonist of EAA receptors, a result supporting the notion that mitral cell neurotransmission is mediated, at least in part, via EAA's. FURTHER CHARACTERIZATION OF HYPOTHALAMIC β-ENDORPHIN NEURONS AND MODULATION OF OPIOID RESPONSES BY ESTROGEN. M.J. Kelly, M.D. Loose and O.K. Ronnekleiv. Dept. Physiology, Oregon Hlth Sci Univ., Portland, OR 97201.

Intracellular recordings were made from arcuate (ARC) neurons with biocytin-filled electrodes in slices prepared from ovariectomized guinea pigs treated with estradiol or oil. Fifty-seven neurons were identified and immunoreacted for β-endorphin (βEND). Fourteen of these cells were immunopositive for βEND. βEND neurons had membrane characteristics (i.e. RMP: -56 ± 1 mV; R_{in}: 380 ± 67 MΩ; τ: 16.5 ± 4.2 ms) similar to immunonegative neurons and often fired spontaneously (6.1 ± 2.0 Hz). βEND neurons exhibited an instantaneous as well as time-dependent rectification. A subpopulation of βEND neurons (N = 4) exhibited an I_A. The μ-opioid agonist Tyr-D-Ala-Gly-MePhe-Gly-ol (DAGO) induced membrane hyperpolarization (12 ± 2 mV) and decreased the R_{in} (38 ± 4%) of the β-endorphin neurons. This response was similar in non-βEND neurons. In preliminary experiments, the EC_{50} for the effects of DAGO (~0.15 μM) was similar in cells recorded from oil- and estradiol-treated animals. The pA_2 values for naloxone antagonism of the effects of DAGO in both groups were in the range reported for other tissues. Experiments are in progress to determine if estrogen causes any shift in the pA_2 value. Thus, μ-receptors may be autoreceptors on ARC βEND neurons, and this "ultra-short loop" feedback mechanism may be modulated by estrogens. (PHS DA 05158, HD 00718).

IMMUNOCYTOCHEMICAL LOCALIZATION OF AROMATASE AND ESTROGEN RECEPTORS IN THE BRAIN J. Balthazart, A. Foidart, C. Surlemont*, N. Harada*, C. Leranth, and F. Naftolin, Lab. Biochem, Univ.Liège, B-4020 Liège, Belgium, Mol. Genetics, Fujita-Gakuen Health Univ., Toyoake, Japan and Dept. Obstetrics and Gynecology, Yale Univ., New Haven, CT 06510.

The distributions of aromatase (ARO) and estrogen receptors (ER) were studied in the brain of intact male Japanese quail (*Coturnix c. japonica*) by double label immunocytochemistry using a polyclonal antiserum against human placental ARO (J. Biochem.103: 106,1988) and Abbott's monoclonal antibody H222SPγ against human ER. Abundant aromatase-immunoreactive cells (ARO-ir) were found in the medial preoptic nucleus (POM), in the septal region and in a large cell cluster extending from the dorso-lateral aspect of the ventromedial nucleus to the tuberal region of the hypothalamus. Estrogen receptor-immunoreactive cells (ER-ir) were also found in each of these brain areas but their distribution was much broader and included larger parts of the preoptic, septal and tuberal regions. Only a limited proportion of cells were double-labeled (5-30% in POM, <5% in the septum but more than 50% in the tuber). At the EM level, ARO-ir was limited to certain neurons and filled the entire perikaryon, including presynaptic boutons. There were ARO-ir positive boutons forming synapses with ARO-ir neurons (Abst.669, The Endocrine Society, 1990). CONCLUSIONS: The present study shows that ER-ir is more broadly distributed and only present in some of the ARO-ir cells. These findings indicate that in addition to the usual ER-mediated actions, locally formed brain estrogen may have non-ER-mediated actions including the synaptic level and elsewhere in brain neurons. SENSORY SYSTEMS—SUBCORTICAL VISUAL PATHWAYS: MIDBRAIN, ETC.

543.1

THE LAMINAR DISTRIBUTION AND MORPHOLOGY OF CENTRIFUGAL AXONAL TERMINATIONS IN THE PIGEON RETINA (*Columba livia*). W. Woodson, T. Shimizu and H. J. Karten. Dept. of Neurosciences, U.C.S.D., La Jolla, CA 92093.

Following injections of phaseolus vulgaris leucoagglutinin, PHA-L, and rhodamine isothiocyanate into the isthmo-optic nucleus (ION), the laminar distribution and morphology of ION afferent fibers to the retina (centrifugals) were studied in transverse and horizontal sections.

In transverse sections through the retina, while both markers revealed a heavy band of terminals confined to lamina 1b of the inner plexiform layer(IPL), and fibers penetrating into the inner nuclear layer, PHA-L also showed sparse labelling in lamina 5b. Immunocytochemical studies have indicated that 5-HT is also located in laminae 1b and 5b of the IPL.

Horizontal sections through the retina showed that fibers entering the optic nerve head, some of which bifurcated, ranged in diameter from 0.1 to 1 μm. Three types of centrifugal arborizations were observed: Type 1: thin fibers expanding over a large area of the retina, having as many as 70 terminal arborizations, Type 2: thin axons, terminating over a confined surface area, possessing up to 80 terminal endings, and Type 3: thick fibers, having a restricted terminal field with as many as 60 terminal boutons. While there was little variation in the number of terminations for the three categories of fibers, the terminal surface area occupied by type 1 axons was approximately 7 times greater than the other types of axonal terminal endings.

In summary, a large number of amacrine and displaced ganglion cells are influenced by single centrifugal fibers, either over a widely spaced or confined surface area of the retina. Moreover, centrifugals could modulate 5-HT positive amacrine cells, suggesting that the ION modulates various subpopulations of morphologically and biochemically distinct amacrine cells in the retina.

POTENTIAL PATHWAYS FOR VISUAL AND ELECTRO-SENSORY INFORMATION TO REACH THE TELENCEPHALON. **E. Sas and L. Maler, Dept. Anatomy, Univ. of Ottawa, 451 Smyth Rd., Ottawa K1H 8M5 Canada.**

This is the first attempt in Apteronotus leptorhynchus, to investigate possible routes for visually related and electrosensory information to reach the pallium. To this end electrophoretic injections of WGA-HRP were placed in the dorsal subdivision of the dorsolateral telencephalon (DLd) which resulted in labeling of the following nuclei: telencephalic areas dorsalis pars magnocellularis, dorsolateralis pars posterior, dorsalis centralis (DC), and the large cells of rostral nucleus entopeduncularis (Er); the diencephalic preglomerular complex pars lateralis (PGl), the mesencephalic nucleus raphe centralis, and in the rhombencephalon, the locus coeruleus and the paramedian medullary reticular formation. Although DLd appears as a homogenous cellular mass in cresyl violet sections, superficial and deep injections into DLd indicated a stratified arrangement of some of its afferents and also some differences in input to rostral versus caudal DLd. An interesting observation was that the region of PGl that receives tectal input, projects to DLd, whereas cells dorsal to these PGl cells, are the target of toral input; these latter cells project to the dorsal telencephalon, therefore providing a route for these two types of sensory information to reach the dorsal pallium via separate populations of the preglomerular complex. Injections into more medial telencephalic regions resulted in labeling dorsal and medial aspects of the preglomerular complex. The densest projection from DLd is to that region of DC which projects to the tectum; therefore visually related information reaching DLd via PGl may be fed back into the tectum.

543.3

THE MEDIAL BASAL OPTIC ROOT IS COMPRISED OF AXONS ORIGINATING FROM GANGLION CELLS IN THE CENTRAL RETINA OF FROGS. Z. Li* and K. V. Fite, Neuroscience and Behavior Program, University of Massachusetts, Amherst, MA 01003.

The nucleus of the basal optic root (nBOR) of anuran amphibians is innervated by the basal optic root (BOR) which includes both medial (BORm) and lateral (BORl) fascicles. BORm innervates the mediodorsal portion of nBOR and 98.5% of its axons are unmyelinated (mean = .27 μm diameter). In contrast, BORl innervates the ventrolateral and central portions of nBOR and contains many more myelinated axons. Unmyelinated axons are of larger caliber (mean = .42 μm) than in BORm (Fite, et al, 1988).

Large, efferent ganglionic neurons occur in the mediodorsal portion of nBOR and project exclusively to the dense-core region of the pretectal nucleus lentiformis mesencephali (nLM). The dense core of nLM receives optic afferents from the central portion of the contralateral retina and contains large neurons which project to the optic tectum (Montgomery, et al, 1985).

Localized HRP injections of mediodorsal nBOR retrogradely labelled axons only in BORm and small ganglion cells in the central one-third of the contralateral retina. Thus, the projection from nBOR to nLM may also convey information from the central retina, with specific effects upon the dense core and large neurons of nLM and its function in oculomotor reflexes and optokinetic nystagmus (Supported by NSF grant: BNS 8819870).

543.4

GAD-LIKE IMMUNOREACTIVITY IN CENTRAL VISUAL AREAS OF RANA PIPIENS. C. J. Tyler, K. V. Fite, and G. J. DeVries, Neuroscience and Behavior Program, University of Massachusetts, Amherst, MA 01003

Immunocytochemistry was used to characterize the presence of glutamic acid decarboxylase (GAD), the synthesizing enzyme for gamma-aminobutyric acid (GABA), in primary retinal terminal fields and thalamic nuclear groups postsynaptic to primary retinal terminal zones.

Preliminary observations revealed GAD-like immunoreactivity in all primary visual nuclei. Dense GAD-like immunoreactive (GAD-LIR) puncta were observed in the posterior thalamic nucleus, uncinate nucleus, and nucleus lentiformis mesencephali (nLM). In addition, GAD-LIR perikarya were observed positioned along the lateral and ventral margins of nLM. Present evidence suggests the presence of GAD-LIR terminals in all lamina of the optic tectum, with GAD-LIR perikarya appearing most noticeably in the 6th and 8th lamina. The lateral margins of the basal optic root nucleus contained scarce populations of GAD-LIR perikarya which surrounded the GAD-LIR puncta within the nucleus itself. Both the corpus geniculatum and nucleus Bellonci contained GAD-LIR fibers and puncta. Magnocellular neurons in the nucleus profundus also showed dense GAD-LIR perikarya and dendritic morphology.

In the thalamus, the ventrolateral area, posterocentral nucleus, and posterolateral nucleus (cell groups in contact with retinal afferents) contained both GAD-LIR perikarya and puncta.

Comparisons between GAD- and GABA-like immunoreactivities in these areas will also be presented. (Supported by NSF Grant BNS 5-25576 to K.V.F.)

EVIDENCE FOR DIRECTION-SENSITIVE (DS) RETINAL INPUT TO THE TURTLE'S BASAL OPTIC NUCLEUS (BON). A.F. Rosenberg and M. Ariel, *Dept. of Behavioral Neuroscience, University of Pittsburgh, Pgh., PA 15217.*

Turtle BON cells respond best to global image motion in a preferred direction (Rosenberg & Ariel 1990), consistent with their purported role in encoding retinal slip. The DS character of BON cells is thought to be signalled by DS retinal ganglion cells (RGC) via the direct contralateral retinal input, based on evidence that BON cells are (1) DS in the absence of the telencephalon, but (2) not DS during retinal bicuculline application (Schuerger et al. 1990).

To test whether DS RGCs project directly to the BON, RGCs were characterized during single unit recordings and then were tested for antidromic activation by electrically stimulating the BON. The preparation was an *in vitro* whole turtle brain, with the eyes attached and telencephalon removed. RGCs were characterized based on their response to steps of diffuse illumination and moving whole-field checkerboard patterns. Current passed through a bipolar electrode was used to stimulate the BON.

Of 34 RGCs recorded, 5 could be activated antidromically using current < 200 μA. Four of these were DS. Antidromic spikes had latencies ranging from 1.6 to 3.8 ms, and could follow stimulation trains exceeding 100 Hz. These latencies were shorter and less variable than those of orthodromic spikes (2.5 - 7 ms, n = 15) recorded from BON cells, elicited by contralateral optic nerve stimulation. Orthodromic spikes recorded in the BON failed to be evoked by consecutive current pulses delivered to the optic nerve at stimulation rates > 30 Hz. Based on these measurements, the direct retinal input to the BON is moderate to rapidly conducting, as suggested by Woodbury and Ulinski (1986). This antidromic activation of DS RGCs is direct evidence for retinal processing providing direction-sensitivity to BON neurons. (Supported by EY05978)

FUNCTIONAL ORGANIZATIONS IN THE NUCLEUS ROTUNDUS OF PIGEON. Y-C. Wang and B.J. Frost, Departments of Physiology and Psychology, Queen's University, Kingston, Ontario, Canada, K7L 3N6.

Anatomical studies have shown that different rotundal zones receive input from different tectal laminae and in turn project to different areas of ectostriatum. Our previous results indicated that there were at least 6 different types of stimulus specific cells in the nucleus rotundus (Rt), and in this study on Ketamine/Rompun anestheized pigeons, we report correlations between these functional classes and their location within Rt. We have found that most luminance units were located in ventral zones of the nucleus. These units had very large receptive fields (100-140 degrees on average) and either systematically increased or decreased their responses to increases in luminance of the whole visual field. In contrast, most loom units were found in the dorsal-medial part of the Rt. These units respond to Z-axis movement, that is expanding or contracting stimulus patterns, and exhibited neither X-Y directional selectivity nor "on-off" responses. Occlusion sensitive units, of both the excitatory and inhibitory type, were mostly located in posterior Rt zones which receive input from deep tectum. We have also found that although some loom and occlusion units decrease their response to changing wavelengths, most of them still give reliable responses to equiluminous chromatic stimulus movement. Supported by NSERC grant A0353 to BJF.

543.7

DISTINGUISHING ROTATION FROM TRANSLATION: NEURONS IN PIGEON VESTIBULOCEREBELLUM SPECIFY DIFFERENT PATTERNS OF WHOLEFIELD MOTION: D.R. Wylie and B.J. Frost. Dept. of Psychology, Queen's University, Kingston, Ontario, Canada, K7L 3N6.

Several studies demonstrate that the Accessory Optic System (AOS) is involved in the analysis of wholefield visual motion which results from self-motion of an animal. Electrophysiological studies have found that neurons in the pigeon AOS respond best to wholefield visual stimuli moving in a particular direction in the contralateral visual field, however, few cells are binocular. By combining information from both eyes, translation can be distinguished from rotation. Neurons preferring the same or opposite directions in the two eyes would encode translation and rotation respectively. The pigeon vestibulocerebellum (VbC) receives bilateral input from primary AOS structures directly and via the inferior olive, thus there is the potential for binocular interactions. It was the purpose of this study to investigate the responses of neurons in the pigeon VbC to wholefield visual motion. Pigeons were anaesthetized with urethane and extracellular recordings were made with glass covered tungsten microelectrodes. Complex spike activity of Purkinje cells and presumed climbing fibre potentials isolated outside the Purkinje layer responded to wholefield motion. Three functional types were found: neurons preferring upward motion in both eyes, which would result from downward translation; neurons preferring downward motion in both eyes, which would result from upward translation; and neurons preferring backward and forward motion in the contralateral eye and ipsilateral eyes respectively, which would result from a horizontal head or body rotation. Binocular wholefield motion of the preferred direction in both eyes always resulted in a facilitation of the response relative to the dominant eye. A few presumed granule cells responded to monocular wholefield motion. We conclude that neurons in the VbC integrate wholefield information from the two eyes so that self-produced translation can be distinguished from rotation.

543.8

IMMUNOHISTOCHEMICAL PARCELLATION OF THE VENTRAL LATERAL GENICULATE NUCLEUS & INTERGENICULATE LEAFLET IN THE GROUND SQUIRREL (Citellus tridecemlineatus).
S. AGARWALA*, M.A. BASSO*, J.G. MAY , J.K. MOORE, & H.M. PETRY. Depts. of Psychology and Anatomical Sciences, SUNY at Stony Brook, NY 11794.

The ventral lateral geniculate nucleus (vLGN) is well developed in the ground squirrel and may be differentiated into four divisions (the inter-geniculate leaflet (IGL), dorsal cap (DC), external magnocellular (vLGNe), and internal parvocellular divisions) based on it's connectional anatomy and cytoarchitecture (Agarwala et al., 1989). The immunohistochemical signature of these subdivisions and that of the subgeniculate nucleus (SGN) was evaluated with Neuropeptide Y (NPY), Leu-Enkephalin (L-Enk), Cytochrome Oxidase (CO) and Acetylcholinesterase (ACHE). NPY+ cells were found in the external portion of the vLGNe, the IGL, and along the ventral and lateral margin of the DC. These cells formed a shell around the DC which was itself free of NPY+ cells. In contrast to the IGL, the DC and vLGNe were highly reactive for CO and ACHE. Preliminary results from L-Enk correspond to the NPY pattern, (i.e, heavy staining in IGL, faint staining in DC and vLGNe). The SGN was highly reactive for NPY, L-Enk, CO, and ACHE. These immuno- and histochemical results suggest that a functional differentiation may coincide with the anatomical divisions of the vLGN and SGN. Interestingly, this pattern differs from that of the rat and hamster.

ULTRASTRUCTURAL CHARACTERISTICS OF THE MEDIAL PRETECTAL NUCLEUS IN THE CAT. R.Pisana*, A.D.Pearsall, and B. Hutchins. Baylor College of Dentistry, Dallas,Tx. 75246

The present study was undertaken to analyze the ultrastructural characteristics of the medial pretectal nucleus, located at the meso-diencephalic junction. According to the basic terminology of Guillery, ('69), the following terminals were identified within the nucleus, RLD, RSD, RLP, PD1,and PD2. All terminals were found to be extraglomerular. The predominant terminal was of the presumptive dendritic type, the PD2, which were primarily found to contact medium sized dendrites. RLD terminals, which have been identified as afferent terminals to the pretectal complex [eg, visual cortex, Hutchins and Weber, Anat. Rec. 205 ('83); Neurosci. Abst. 19 ('89); superior colliculus, Lieberman, et al., Neurosci. Lett. 56 ('85)], were observed to contact small to medium size profiles. Fewer profiles were of the presumptive retinal terminal type, the RLP, which were primarily found contacting medium sized dendrites. In order to identify retinal terminals, HRP was injected in one eye, the tissue was reacted with TMB, and then replaced with DAB for electron microscopy. In this tissue, a few small terminals were labelled with HRP. Thus, this study provides preliminary data demonstrating direct retinal input to the medial pretectal nucleus in the cat.

Supported by NIH grant EY06977.

543.10

THE VISUAL ORGANIZATION OF THE POSTERIOR PRETECTAL NUCLEUS IN THE CAT. B.Hutchins and R.Pisana*. Baylor College of Dentistry, Dallas, Tx. 75246.

The pretectal complex is located at the meso-diencephalic junction and is composed of five separate nuclei. After tissue is processed for either an HRP or a ^{3}H-proline injection into one eye of an adult cat, the direct retinal projections to the pretectal complex were identified. One little studied pretectal nucleus, the NPP receives a patchy, bilateral input. These patches appear to follow the dorsal posterior border and extend the entire medial to lateral extent of the nucleus. This leaves the majority of NPP without identifiable retinal projections. To test whether the remaining portions of NPP are visually related, the nucleus was sampled electrophysiologically in paralyzed chloralose anesthetized cats. Data collected thus far, indicated the full extent of NPP is visually responsive. Representations of the periphery were identified along the NPP/superior colliculus border, while representations of the vertical meridian were identified more anterior and the lower visual field was located lateral. In addition, approximately one half of the extracellular tissue sampled responded to auditory stimuli..Thus, these preliminary data indicate a more complex role for NPP in integrating multisensory information.

Supported by NIH grant EY06977.

CONTROL OF POSTURE AND MOVEMENT: CLINICAL STUDIES

544.1

ARE THE ABNORMAL MOVEMENTS OF TARDIVE DYSKINESIA COMPLETELY RANDOM? JB Lohr, L Ing*, and MP Caligiuri. Motor Function Laboratory, VA Medical Center, V-116A, San Diego CA 92161.

One of the clinical hallmarks of choreoathetoid disorders is their spatial irregularity. In the case of tardive dyskinesia, however, questions have been raised as to how truly random the movements are. In an effort to address this question, we attached a biaxial accelerometer to the tip of the thumb of the more dyskinetic hand in patients with TD of varying degrees of severity as determined by the AIMS upper extremity score. Data were analyzed by plotting the acceleration values associated with the abnormal movements in cartesian coordinates. We then quantified the proportion of activity associated with a particular acceleration vector, yielding an r value, which is a measure of the spatial irregularity. Results showed that greater r values were associated with more severe TD, indicating that with increasing severity of the dyskinesia, the movements were more irregular. Therefore, the movements of patients with milder TD are not completely random, but do show spatial regularity. These results will be contrasted with similar measurements made in patients with Huntington's disease, the prototypic choreoathetoid disorder.

544.2

DIMENSIONALITY OF POSTURAL STEADINESS. JB Myklebust, TE Prieto*, BM Myklebust, DG Lange. Marquette University, College of Engineering, Laboratory of Sensory-Motor Performance,VA Medical Center, Medical College of Wisconsin, Milwaukee, WI 53295 and Sec Computers & Insts NIH-NINDS, Bethesda, MD.

Deviations of the center of pressure (CP) during quiet standing have been characterized for healthy adults. These measurements have been used to assess neurological disorders of vestibular and cerebellar systems, and lesions of pyramidal and extrapyramidal tracts. In previous studies[1] the fractal dimension of the planar curve was used to analyze balance data. The algorithm was developed for segmental curves and may be a simple, practical method to assess standing balance and characterize pathology. In the present study, the fractal dimension, computed using the "coastline method", and a box counting method were compared to the previous algorithm. The slope of the frequency spectrum was a power law function. For comparison, the time series was embedded in higher dimensions and the correlation dimension computed[2].

Data was used from 5 normal young adults (age<40), 5 healthy aging subjects (age 55-65), and 5 elderly patients with Alzheimer's disease with clinical impairments of gait and balance. Standing balance trials were sampled at 100Hz for 1 minute with eyes open and 1 minute with eyes closed. The CP was analyzed for each trial. The fractal dimension obtained by the coastline and box counting methods did not differ significantly from the value computed using the previous algorithm. The mean value tested with eyes open was 1.97 (sd=0.22) for young subjects, 1.73 (sd=0.06) for healthy aging subjects and 1.58 (sd=0.09) for Alzheimer's patients. With eyes closed, the normal subjects did not change; the Alzheimer's group improved to 1.79 (sd=0.05). The slope of the power spectrum was -2.5 for young adults, -3.0 for healthy aging subjects and -3.2 for Alzheimer's patients. The correlation dimension calculated from the embedded time series was lower than the fractal dimension.

544.3

Evidence for Separable Effects of Alzheimer's and Parkinson's Diseases on Movement Preparation and Execution Processes. PC Amrhein, Dept. of Psychology, Univ. of New Mexico, Albuquerque, NM 87131, and JC Morris, Dept. of Neurology, Washington Univ. Sch. of Med., St. Louis, MO 63110.

A study was conducted to determine the effects of Alzheimer's Disease (AD) and Parkinson's Disease (PD) on cognitive/motor processes underlying motor plan preparation and execution. Using a 2 [AD: Absent or Present] X 2 [PD: Absent or Present (unmedicated)] design, four subject groups: 10 control subjects; mean age = 71.1 yrs), 6 AD subjects; (mean age = 73.1 yrs, very mild dementia), 11 PD subjects (mean age = 70.6 yrs, no dementia), and 5 AD/PD subjects (mean age = 69 yrs, very mild dementia) were assessed with respect to upper extremity movement for reaction time (RT) and movement time (MT). A paradigm was used in which 75% of the trials had valid precue stimuli (i.e., identical to the target stimuli) but the remaining 25% had invalid precue stimuli (i.e., different from the target stimuli), thus necessitating restructuring of the prepared response. Subjects responded to one of four target stimuli by pressing a corresponding button. Group differences concern overall RT and MT: AD, but not PD, increased RT [$F(1,28) = 4.11, p = .05$ and $F < 1$, respectively]. However, AD and PD exhibited additive effects in increasing MT [$F(1,28) = 6.08, p < .025$ and $F(1,28) = 13.7, p < .001$, respectively]. Results indicate that AD (at a very mild level of dementia) and PD independently influence cognitive/motor task performance: AD, but not PD, slows motor plan preparation (RT); however, AD and PD each slow motor plan execution (MT).

MOTOR LEARNING IN PARKINSON'S DISEASE: SCHEMA FORMATION, ADAPTATION TO ALTERED GAIN, AND LIMB KINEMATICS. C.J. Worringham, C.L. Cross* and A.L. Smiley-Oyen.* Department of Kinesiology, The University of Michigan, Ann Arbor, MI 48109.

Motor learning in Parkinson's disease (PD) subjects was studied in a task requiring the learning of an arbitrary relationship between the length of visually-presented horizontal bars and the amplitude of linear, horizontal arm movements. Four targets were initially learned with error feedback. Learning and extrapolation were assessed using no-feedback trials to, respectively, the original targets and targets beyond the range of those previously practiced. A final phase required adaptation to an altered gain. PDs were capable of learning the initial task, and, along with controls, exhibited a range effect (short and long targets over- and undershot, respectively). On extrapolation, the slope of the function relating actual to required movement amplitude fell sharply for PDs, with larger undershoots of longer targets. PDs showed substantial adaptation to a new gain within 144 trials. These results and kinematic data show that the formation and use of higher-level "schema" representations of motor tasks is not lost in PD but in some subjects is degraded.

SENSORIMOTOR DISINHIBITION IN PARKINSONISM MP Caligiuri, WC Heindel and JB Lohr. Motor Function Lab. VA Medical Center, San Diego, CA 92161

The inability to execute simultaneous movements is well recognized in Parkinson's disease (PD). Investigators have proposed a number of hypotheses to explain this inability, including deficits of attention, motor programming, or both. In the present study we investigated the role of sensorimotor disinhibition as a mechanism underlying the inability of PD patients to execute simultaneous motor acts. The patients were examined after a 10h drug-free interval. The motor examination required that the subject exert low levels of isometric finger flexion force for 20 seconds under two conditions: (a) with the non-test hand at rest and (b) with the non-test hand engaged in a reaction time (RT) test in which ballistic force pulses served as the response to auditory stimuli. Analyses were made of the degree and pattern of force instability. Results indicated that the PD patients exhibited significantly greater isometric instability than controls. Force instability increased in both control and PD groups during the RT task; however, this increase was significantly greater for the PD than the NC groups. Further analyses revealed that the isometric force waveforms for the PD patients, but not the controls, varied systematically with the RT pulses of the contralateral hand. This pattern of coherence for the two hands may be explained by sensorimotor disinhibition. In PD, the motor commands for executing ballistic muscle force (RT) may be uninhibited and pass through the system programmed for isometric control.

ABNORMALITIES IN GAIT INITIATION IN PATIENTS WITH PARKINSON'S DISEASE. K. Tako*, R.G.Lee, and W.J. Becker. Dept. of Clinical Neurosciences, University of Calgary, Calgary, Alberta, Canada T2N 4N1.

Patients with Parkinson's disease (PD) often show difficulty in gait initiation. To investigate this further, we studied the timing of movement onset of the trunk and legs during the initiation of walking from the standing position.

Shoulder, hip, knee and foot movements were recorded with a Watsmart position analysis system and EMG was recorded with surface electrodes from the lower leg muscles during the 1st step while patients and controls began to walk in response to an auditory tone.

Preceding toe off of the swing leg, prominent EMG activity occurred in the pretibial muscles bilaterally, the knee of the stance leg began to move forward and then forward movement of the shoulder and hip occurred in both patients and controls. Forward movement of the shoulder and hip followed the initial forward displacement of the stance knee with a shorter time interval in patients than controls. Patients with PD showed a greater delay in gait initiation in response to the auditory tone and a longer time interval between pretibial muscle EMG onset and toe off of the swing leg than controls.

In gait initiation, patients with PD show not only delayed initiation of movement, but also a disordered pattern of leg and trunk movements.

DURATION OF POSTURAL RESPONSES IN CLUMSY CHILDREN: ANOTHER LOOK AT TIMING CONTROL. H. Williams, S. Jay*, M. Woollacott. Motor Control Laboratory, U of Oregon, Eugene, Oregon 97403.

Skilled movement requires appropriate timing of muscle activity. Children with developmental apraxia are known clinically to have difficulty performing a wide variety of motor tasks & have been shown to have disturbances in both sequencing of postural responses & in timing of rhythmic, repetitive movements of distal extremities.

The purpose of the study was to further examine timing control in clumsy children by studying duration of muscle responses to perturbations of balance. 14 clumsy and 14 normal children stood on a moveable platform; balance was perturbed in randomly ordered trials in forward/backward directions, with/without vision, with modified & normal vestibular input. 3-way repeated measures MANOVAs were used to analyze mean & variability of duration of EMG activity in 8 muscle groups. Duration of muscle activity was longer in clumsy children & was significantly longer with vision than without. With modified vestibular input, both clumsy and normal children showed increased duration & variability of postural responses. These data suggest that clumsy children may have widespread problems with timing of muscle responses integral to movement control.

EMG CHANGES IN GAIT FOLLOWING TENDO-ACHILLES LENGTHENING IN CEREBRAL PALSY CHILDREN, B. R. Einyre[1], C. S. Chambers[2] and N. H. Scarborough[2]. [1]Human Performance and Health Sciences Dept., Rice University, Houston, TX 77251, [2]Gait Analysis Laboratory, Shriners' Hospitals for Crippled Children, Houston Unit, Houston, TX 77030

Due to spasticity, children with cerebral palsy typically demonstrate an equinus gait from overactivity of the triceps surae muscles. Surgical correction for the equinus gait pattern is done either by lengthening the Achilles tendon or recession of the gastrocnemius aponeurosis. The purpose of this study was to determine if surgery reduced muscle activity and if one surgical method could be considered more effective for reducing muscle overactivity during gait. Twenty-three hemiplegic or diplegic children participated both pre- and post-operatively in a gait analysis laboratory. EMG was collected using surface electrodes applied over the triceps surae muscle of the involved limb or limbs. Percent time of muscle activity during each step cycle was calculated for each subject. Analysis of variance revealed significant reductions of muscle activity during the gait cycle between pre-operative (64.0%) and post-operative (50.4%) measures, $F(1,21) = 47.5$, $p < .001$. No significant difference in EMG for percent of gait cycle between the two surgical methods was observed. It was concluded that either surgical method of Achilles lengthening was effective in reducing the spastic activity in triceps surae muscles of cerebral palsy children. These structural changes were apparently effective in changing either the level of spastic response or the motor program for walking which resulted in a more normal pattern of EMG activity during each gait cycle.

THE PHYSIOLOGY OF GAIT INITIATION. R.J. Elble, C. Moody* and C. Higgins*. Southern Illinois University School of Medicine, Springfield, IL 62794-9230.

Patients with neurological disturbances of gait frequently have particular difficulty initiating a first step. We therefore undertook a study of gait initiation in eight neurologically normal adults, ages 18 to 87. A quick step forward was taken in response to a green light. The center of pressure of each foot was recorded with floor-mounted force plates, and surface electromyograms were recorded from the tibialis anterior, quadriceps femoris, hamstrings, and gastrocnemius. Motion of the upper and lower extremities and torso was recorded with computerized infrared stroboscopic photography. With a simple reaction time of 0.16 to 0.31 seconds, a forward step was initiated by synchronous contraction of the tibialis anterior and quadriceps femoris. Approximately 0.4 seconds later, synchronous contraction occurred in the gastrocnemius and hamstrings. This stereotypic pattern of muscular activity caused the resultant center of pressure of both feet to move posteriorly toward the swing foot and then ultimately toward the stance foot. These foot-floor reaction forces and muscular activities created forward moments of force about the ankles and hips that propelled the body into forward motion. A COMPARISON IN NEUROLOGICALLY INTACT AND SPINAL CORD INJURED OF ANKLE JOINT COMPLIANCE AND REFLEX ACTIVITY TO ANGULAR PERTURBATIONS USING VOLITIONAL AND ELECTRICALLY STIMULATED BIASES. B. Flaherty,*[1,2] C.J. Robinson,[1,4] G.C. Agarwal[3] & G.L. Gottlieb.[5] Hines VA Rehabilitation R&D Center,[1] Hines, IL 60141; Bioengr.[2] & EECS[3] Depts., Univ. of Illinois @ Chicago; Neurology Dept,[4] Loyola Univ., Maywood, IL; Physiology Dept.,[5] Rush Medical College, Chicago, IL

Ankle compliance characteristics were investigated for complete (n=3) and incomplete (n=1) paraplegics and in 4 intact subjects using a 10° perturbation about neutral ankle angle at various constant velocities (13.3 to 100 °/sec) against a plantarflexed torque bias that was achieved via soleus stimulation. Responses were compared with those obtained via volitional plantarflexed bias in the neurologically intact. Soleus and tibialis anterior surface EMG activity was recorded using an artifact-suppression stimulator/preamplifier. Torque, angular displacement and acceleration were measured and used to calculate stiffness, damping and inertial factors.

During the first 100 msec of a perturbation (any speed), the compliance of the joint was the same under stimulated and volitional biases, indicating that the passive properties of the joint were the predominant influence since no reflex EMG activity was seen until at least 80 msec. After 100 msec, torque continued to be proportional to displacement for the volitional torque bias experiments, while in the stimulated case torque was not linearly related to angle. This was particularly apparent at the end of the perturbation where torque exponentially decayed to a steady state value that was significantly less than the post-perturbation torque under volitional bias. The ankle was also stiffer with voluntary plantarflexion than with soleus stimulation, and the compliance model was more complicated with soleus stimulation.

KINETIC ANALYSIS OF INTERLIMB COORDINATION DURING DYNAMIC TRANSITIONS IN STANCE SUPPORT IN ADULT HEMIPARESIS. M.W. Rogers, L.D. Hedman*, and Y.C. Pai*. Physical Therapy, Northwestern Univ. Med. Sch., Chicago, IL 60611.

Dynamic transitions in stance support accompanying intentional leg flexion movements are due in part to the coordinative interaction of the ground reaction forces (GRFs) beneath the upcoming flexing (fl) and single stance (st) limbs prior to and during unloading (UNL) of the fl leg.

The extent to which the spatial and temporal features of the lateral horizontal (Fy) GRF components prior to UNL may be altered by right hemiparesis due to stroke, was investigated in 8 adult subjects who stood on 2 separate force platforms and performed single rapid leg flexion movements with the paretic (PL) and the uninvolved (UL) limbs. The results indicated that the resultant Fy onset always preceded UNL onset (-270 ± 93ms), and was responsible for the linear displacement of the body mass laterally. For UL flexion movements, however, Fyfl contributed a greater ($p<.05$) proportion (89 ± 15%) to Fy than Fyst (11 ± 15%), while PL flexion movements showed a reverse trend ($p<.05$) whereby Fyfl and Fyst became 30 ± 13% and 70 ± 13% of Fy. Strikingly, while Fyfl and Fyst onsets are normally coincident, 4 subjects showed a delay (140 ± 21ms) in PL Fy vs. UL Fy onset times. Moreover, in 2 cases of UL flexion movements Fyst of the PL was exerted in the opposite direction to that of Fyfl of the UL so as to brake rather than assist in the weight transfer to the PL. Overall, such changes in both the timing and scaling of interlimb GRFs may contribute to deficits in lateral weight transfer regardless of the direction of the postural transition.

PRESENCE OF RESIDUAL MOTOR UNIT ACTIVITY UNDER VOLITIONAL CONTROL IN THE PARALYZED MUSCLES OF SPINAL CORD INJURY SUBJECTS. W.B. McKay, M.R. Dimitrijevic, M.A. Lissens*, W.A. Nix*. Division of Restorative Neurology and Human Neurobiology, Baylor College of Medicine, Houston, Texas 77030.

We have carried out neurophysiological studies in 297 clinically complete spinal cord injury subjects; in 6 of them we were able to demonstrate the subclinical presence of volitionally controlled single motor units (SMU). Three of these 6 subjects showed the activation of SMU only during particular single-joint motor tasks repetitively and consistently. Therefore, it is possible to demonstrate the preservation of a specific motor command even in subjects who have a limited number of conducting axons reaching their target.

We shall discuss how these reported results are pertinent for the understanding of neurocontrol of an isolated single-joint movement motor task as compared to the patterned, multi-joint motor task.

544.13

FEATURES OF NEUROCONTROL DURING GAIT WITH REDUCED BRAIN INFLUENCE IN HUMANS WITH TRAUMATIC SPINAL CORD INJURY. J.H. Schild*, M.M. Dimitrijevic*, I. Petronic*, A.M. Sherwood. Division of Restorative Neurology and Human Neurobiology, Baylor College of Medicine, Houston, Texas 77030.

We have studied neurocontrol in 13 ambulatory spinal cord injury subjects while they walked on a 10 meter path. We recorded bilaterally and simultaneously during gait with surface electrodes the polyelectromyographic activity of the paraspinal, quadriceps, hamstring, tibialis anterior and triceps surae muscles. In addition, we also recorded gait with foot switches and anterior, posterior and lateral videocameras.

The analysis of data during gait revealed 3 different neurocontrol features: the 1st resembled the neurocontrol in a subject with intact nervous system; the 2nd the patterned organized neurocontrol of flexor extensor movement; the 3rd had no organized neurocontrol.

We shall discuss how these neurocontrol patterns are generated and describe the effectiveness of different features of neurocontrol for gait.

MECHANISM OF RECOVERY FROM CEREBELLAR INCOORDINATION. H.P. Goodkin and W.T. Thach. IWJ Rehab. Institute and Depts. of Anatomy and Neurology, Washington Univ. Sch. Med., St. Louis, MO 63110.

A 61 year old man was studied during the performance of single and multijoint movements 6 weeks after right cerebellar infarct.

Wrist, instrumented single-joint: 45° ballistic flexor movements were normal except for an end point oscillation on the affected side. No statistical difference in reaction time, peak velocity, movement time or terminal position were found between performance on the two sides.

Shoulder and elbow, multi- (reach) and single-joint: the patient sat in a chair with forearms on the armrests and was instructed to reach out for a target held in front at head level. On the affected side, frame-by-frame video analysis demonstrated that reaches were performed by first elevating the arm at the shoulder and then by extending the elbow (decomposition of movement). There was no difference between single joint elbow and shoulder movements on the two sides.

Thumb and forefinger, multi- (pinch) and individuated: the patient was then asked to remove a quarter that slightly protruded from a well too narrow to admit the digits. On the normal side, the patient retrieved the coin with a precision pinch. On the affected side, the patient instead picked at the rim with the index finger in a single-digit strategy, and did not hold the other digits still.

It is commonly held that in cerebellar injury single joint angle error is the same in single and in multijoint movements (Holmes, 1939). However, we have shown in monkeys (Kane, et al. Soc Neurosci Abst. 15:52) that dentate inactivation impairs multijoint movements and spares single joint movements. Similarly, our patient used a strategy of substituting spared single joint movements for impaired multijoint movements. Thus, cerebellar damage in humans also may impair multijoint more than single joint movements. (NIH grants NS12777 and NS15070; the McDonnell Center).

STATIC ELBOW TORQUE-ANGLE RELATIONS IN HEMIPARETIC STROKE. J.P.A. Dewald, M. Munson*, T.S. Buchanan, and W.Z. Rymer. Sensory Motor Performance Program, Rehabilitation Institute of Chicago, Chicago, IL 60611.

In previous studies of muscle activation patterns in hemiparetic stroke, we observed limited changes in elbow muscle EMG activities during force exertions in three dimensions (flexion/extension, varus/valgus, and supination/pronation). In an effort to better qualitatively characterize length-tension relations in the impaired versus the unimpaired upper extremity, we evaluated torque productions for different angles of shoulder flexion/extension abduction.

Maximal forces and EMG activities were recorded at 5 angles of flexion/extension shoulder abduction ranging from -20 to 30 degrees (0 degrees = humerus was aligned with the coronal plane). The angle changes only altered the length of the biceps since no other agonists cross the shoulder joint. The elbow angle was constant at 90 degrees. The vertical shoulder abduction angle was constant at 65 degrees. The forearm was maintained in the neutral supination/pronation position. These EMG values were then used to set constant submaximal activation levels by having the subject match a given fraction of the maximal EMG at each angle. Desired levels of EMG activity along with the subject's RMS EMG were displayed on an oscilloscope. The subject was asked to maintain the RMS EMG at the desired level for 1.5 seconds.

On the unimpaired side, as angle changed from -20 to +30 degrees and the biceps shortened, elbow torque decreased 20 to 30%. There were no systematic differences in this percent reduction as a function of activation level. Similar results were obtained on the impaired side. However, torque-angle relations tended to have steeper slopes in the unimpaired versus the impaired upper extremity. The degree of this difference was variable across subjects. Less steep slopes for the impaired side would be consistent with an increased in-series compliance.

FINE MOTOR PERFORMANCE IN CLOSED HEAD INJURY AND DEPRESSION. Hanneke van Mier (1,4), Wouter Hulstijn (1), Everdien Tromp (2), Jac van Hoof (3) & Marion Pagen (1). 1. Nijmegen Inst. for Cogn. Res. and Info. Tech. (NICI), Univ. of Nijmegen, 2. Dept. of Rehab. Res., St. Maartenskliniek, Nijmegen, 3. Dept. of Psychiatry, Univ. of Nijmegen, The Netherlands. 4. Dept. of Neurol., Wash. Univ., Sch. of Med., St. Louis, MO 63110.

One of the characteristics shared by patients with depression (DEP) and closed head injury (CHI) is retardation of psychomotor performance. A central question is to what extent cognitive and motor factors contribute to the observed motor slowing.

An experimental method is presented that attempts to differentiate between cognitive and motor components underlying psychomotor retardation. Two figure-copying tasks, both differing in motor and cognitive complexity, were run. Task A consisted of simple line figures and task B of more complex figures. Recording of the pen movements by means of an XY-tablet (digitizer) provided objective measurements of a number of movement parameters, and made it possible to divide Movement Time (MT, time between the start and end of the drawing) in the time that the pen was on the paper (MT-down) and the time that the pen was off the paper (MT-up). MT-down was supposed to reflect motor execution and MT-up cognitive processing.

Subjects, 10 CHI patients (mean 24 yr) and 9 DEP patients (mean 50 yr), each with a matched control group, were tested on the two tasks. Both patient groups had significantly longer MT's than their controls in task B, but this was not found for the simple line drawings in task A. However, no significant difference was found between patients and controls on MT-down in task B, so the difference in MT was due to longer MT-up times for the patients. Furthermore, no interactions were found between patients and controls for motor complexity. These findings suggest that cognitive processes, rather than motor processes, are delayed. Differences in RT, errors and figure inspection are in line with these results.

545.1

FOCAL MOVEMENT VELOCITY AND PREMOVEMENT POSTURE EFFECTS ON THE ANTICIPATORY POSTURAL RESPONSE. D.L. Weeks* and S.A. Wallace. Motor Behavior Lab., Ball State Univ., Muncie, IN 47306, and Dept. of Kinesiology, Univ. of Colorado, Boulder, CO 80309.

It is unclear how the motor system self-organizes anticipatory postural muscles accompanying goal-directed upper-limb movement(focal movement) during: a)changes in focal movement velocity, or b)variations in premovement postural condition, such as locus of center of pressure, prior to focal movement initiation. The present study investigated coordination of intentional upper-limb movement concurrent with supporting postural activity in adult males during variations in arm velocity while premovement postural condition was monitored. Seven subjects performed a rapid 60 deg elbow flexion (focal movement) to a target in movement times of 170, 195, or 220 ms while standing on a force platform. Each subject adopted individual premovement postural preferences such that locus of center of pressure resided in one predominant quadrant of the foot prior to movement. Each premovement locus of center of pressure preference was accompanied by one most common postural muscle onset sequence as indicated by EMG analysis of rectus femoris and biceps femoris. In addition, onset times for postural muscles occurred earlier relative to biceps brachii onset as focal movement velocity increased. The finding that each premovement postural condition was accompanied by a particular postural muscle onset sequence was interpreted as an attempt by the motor system to constrain the degrees of freedom present in a multi-joint task by forming postural synergies. The emergent coordination may be dependent on principles of self-organization based on the concept of pattern stability.

545.2

ANTICIPATORY POSTURAL ADJUSTMENTS IN SEATED SUBJECTS. S.Moore and D.Brunt*. School of Physical Therapy, Texas Woman's University, Houston,Tx 77030.

Effects of reach velocity and postural support on anticipatory postural adjustments (APA) were analyzed in the interest of determining spatial and temporal characteristics of APA in seated persons. Increased durations of APA (EMG, kinetic and kinematic evidence) in standing subjects have been associated with fast, unsupported, loaded and unilateral arm movements. Postural muscle activity in slow and supported reaches has been reported as minimal.

15 healthy subjects (aged 24-43 years; right-hand dominant) made seated right upper extremity reaches to a target placed just within arm's length in the parasaggital plane with the right shoulder. Evidence for APA (surface EMG, kinematics, kinetics) was evaluated for two series of reaches in which maximum velocity (range 0.84-3.38 meters/sec) and 4 conditions of postural support (supported-chest belt and chair back; supported- chair back only; unsupported-erect trunk; unsupported-slumped trunk) were manipulated.

Anticipatory contralateral thoracic paraspinal (TPS) activity was present in greater than 90% of trials regardless of reach velocity or postural support. TPS preceded prime mover activity(deltoid) in 50% of all trials and preceded or occurred simultaneously with deltoid in 90% of trials. TPS onset was correlated with onsets of anticipatory vertical and A-P forces ($r=.77$, $r=.80$) exerted through the subject's chair to a force platform. Kinematic analysis revealed occasional (30%) head, trunk or leg movement prior to onset of hand movement for the fastest reaches only. These findings suggest that APA for seated subjects provide a stable upper trunk to offset the torque to be created by the mass and movement of the upper extremity. This study has implications for evaluation of postural and voluntary systems' coupling in persons unable to stand for testing.

545.3

THE RELATIONSHIP BETWEEN AGONIST AND POSTURAL ACTIVITY IN A MICROGRAVITY ENVIRONMENT. C.S. Layne, Dept. of Kinesiology, B.S. Spooner*, Bioserve Space Technologies, Kansas State University, Manhattan, Kansas 66506.

Rapid, unilateral arm raising movements are preceded by anticipatory "postural" neuromuscular activity in the back and lower limbs. Whether anticipatory postural activity is an integral component of one motor command controlling agonist activity or if agonist and anticipatory activity are independently controlled is presently not clear. A microgravity environment would presumably eliminate the functional utility of the anticipatory postural activity, thereby providing a unique environment to investigate the relationship between agonist and anticipatory activity. We used microgravity episodes during KC-135 (NASA 930) parabolic flights to collect surface EMG data from the deltoid, paraspinals and biceps femoris, during right shoulder flexions. Microgravity data was compared with baseline data collected in unit gravity. Results indicate an absence of anticipatory biceps femoris activity with anticipatory paraspinal activity remaining intact, thus suggesting biceps femoris and paraspinal activity may be components of unique postural synergies.

545.4

KINEMATIC BEHAVIOR OF HUMANS IN RESPONSE TO BASE OF SUPPORT PERTURBATIONS P.D. Hansen and M.H. Woollacott. Motor Control Lab., Uni. of Oregon, Eugene, OR 97403.

The purpose of this study was to describe the behavior of humans to postural perturbations. To do this the kinematics of 30 subjects were examined to horizontal backward perturbations (3.7 cm at 15 cm/s). Major joint movements and surface EMG from bilateral, major agonist / antagonist muscles of the leg, thigh and trunk were analyzed. Pre-perturbation subject position was controlled. Kinematic data were also collected from a model constructed of plywood and steel proportioned to a 172 cm, 73 kg male. Ankle, hip and neck joints were modeled with hinges and fixed springs.

The following conclusions were drawn from the data: 1, The initial ankle angle reversal occurred prior to EMG activity onset and was related to the termination of the perturbation; 2, There was a progressively increasing delay before the onset of joint movement in a caudal to rostral direction; 3, Two kinematic phases were discernable, a consistent phase (0 to 150-250 ms), and a subsequent variable phase; 4, The amount of movement decreased over successive trials. The mechanical model validated these findings by showing: 1, The joint movement reversed when the perturbation was terminated; 2, Increasing delays in joint movement onset in a caudal to rostral order; 3, The early phase's mechanical nature and the latter variable phase's CNS dependency.

CORRECTIVE REACTIONS TO NOVEL PERTURBATIONS OF THE HUMAN LOWER LIMB. W.E.McIlroy, J.D.Brooke and D.F.Collins, Neurophysiology Lab, University of Guelph, Guelph, Ontario, CANADA. N1G 2W1.

It is rare to find studies which report corrective reactions to completely unanticipated perturbations. The present study uses such an approach to identify contributions, to the corrective motor responses, which are strongly determined by prior planning. Subjects (n=10) were seated in a customized, leg extension apparatus. They held control loads (200 N) with instructions to keep the slide at the starting position. Control samples, taken during the static hold, acted as decoys to help ensure the first perturbation trial was completely unanticipated. A further 15 perturbation trials were later sampled at random time intervals. In all perturbation trials an external load (220 N) was added rapidly to cause whole limb flexion. EMG activity, in vastus medialis (VM) and tibialis anterior (TA), varied over the 16 perturbation trials. In contrast, activity remained constant in soleus, gastrocnemius and semitendinosus. The specificity of the influence of prior anticipation, seen in TA and VM, was observed as a significant difference in response characteristics between trials 1 and 2. Changes observed at early (<70 ms) and late latencies revealed changes in both tuning and triggered reactions. Systematic attenuation in TA and VM response magnitudes, from trials 2 to 16, revealed refinement of the prior plan (NSERC #A0025).

545.6

STEADY STATE GAINS OF POSTURAL REACTIONS TO SUPPORT SURFACE TRANSLATIONS OF STANDING HUMANS. W.A. Lee, H. Sveistrup,* M.H.Woollacott, Physical Therapy, Northwestern University, Chicago IL 60611 and Physical Education, University of Oregon, Eugene OR 97403

Postural reactions in leg and trunk muscles follow perturbations of standing humans that are induced by translations of the support surface. Postural reactions are thought to restore the person's center of mass (CM) to its initial location relative to the ankle, but the gain of this proposed feedback process has not been measured. This study will describe the steady state gains of postural reactions that follow support surface translations of different amplitudes and velocities.

Healthy young adults were perturbed by 12 sets of support surface translations (5 trials/set) that were blocked by displacement and velocity. Six anterior (A) and posterior (P) displacements were used (-6A, -4A, -2A, +2P, +4P, +6P cm) with a velocity = 4 cm/sec. Translations of +6 and -6 cm with velocities of 10, 22, and 30/sec also were applied. Set order was counterbalanced. Initial center of pressure location was controlled by feedback about AP ankle torque. A SELSPOT system recorded vertical and horizontal displacements of the ankle, knee, hip, shoulder, elbow, wrist and head, which allowed estimation of the CM. We also recorded EMG activity in the left soleus (SOL), medial gastrocnemius (GS), tibialis anterior (TA), biceps femoris (BF) and rectus femoris (RF) muscles, and AP torque. We measured the mean horizontal displacement of the CM, mean rectified EMG amplitudes, and mean AP torque for 300 ms before the translation (baseline), and for three sequential 300-ms periods after the end of the translation.

Preliminary analyses suggest that postural reactions often did not completely restore the CM to its initial location, suggesting that steady state gains were less than one, and that a new equilibrium point could be adopted after a perturbation. Steady state gains appeared to vary with the amplitude and velocity of the translation. Steady-state changes in EMG amplitudes of the SOL, GS and TA but not the BF or QD muscles were linearly related to platform amplitude or velocity ($R^2 > .94$). Further analyses and experiments will be performed to quantify CM gains and assess the reliability of the preliminary findings.

THE FREQUENCY CONTENT OF HUMAN GAIT: KINEMATIC SAGITTAL PLANE MEASUREMENTS. B. Myklebust, J. Myklebust, T. Prieto*, D. Kreis*, S. Balisreri*. Laboratory of Sensory-Motor Performance, Zablocki VA Medical Center, Medical College of Wisconsin, and Department of Biomedical Engineering, Marquette University, Milwaukee, WI 53295.

Sagittal plane (flexion-extension) movements of the hip, knee, and ankle of healthy adult subjects during level walking have been measured using a variety of data collection methods with a range of sampling rates. Knowledge of the frequency content of movements during the entire gait cycle[1] impacts on the selection of equipment for data collection, appropriate choice of sampling rates, and filtering methods to smooth individual data records.

We evaluated the frequency content of sagittal plane movements in level self-paced walking at 3 mi/hr. Data were collected simultaneously using 2 data acquisition systems: voltages from potentiometers of an electrogoniometer (Lamoreux / Orthopedic Systems, Inc.)[2] were sampled at 1000 Hz, and digitized video data (Motion Analysis Corp.) were sampled at 60 Hz. Standard observational analysis and digitized video analysis were completed simultaneously with data acquisition from the electrogoniometer in 5 gait trials of right-side limb movements. Five trials of video analysis of gait without the electrogoniometer were monitored to compare the effect of the device on gait.

While joint angle profiles for electrogoniometry and digitized video analysis are similar, differences occur in regions where movements in the transverse and frontal planes cannot be corrected in the sagittal plane. Despite significant differences in sampling rates from the video analysis and the electrogoniometer, spectral analysis of both methods demonstrate that the frequency content of gait is below 5 Hz for sagittal plane movements of the hip, knee, and ankle. Because sagittal plane movements in gait are represented by signals under 5 Hz, video sampling rates at 60 Hz are adequate. However, filtering methods for smoothing raw data must be used with care.

STIMULUS PARAMETERS AND PHASE DEPENDENT RESPONSES IN LOCOMOTION IN MAN. A.H. Seif-Naraghi*, J.J. Fuller*, R.M. Herman, R.A. Yapp*, S.C. D'Luzansky*, Samaritan Rehabilitation Institute, 1111 E. McDowell, Phoenix, AZ 85006; M.J. Perlow, Arizona Heart Institute, 2632 N. 20th Street, Phoenix, AZ 85006.

Phase dependent motor responses to electrocutaneous stimulation have been observed during locomotion in intact and spinal animals, and to a lesser extent in normal man (J. Yang & R. Stein, Neurosci. Abs., 14:522.3, 1988); however, human studies have not stressed the potential influence of stimulation parameters nor the reaction of the contralateral limb. This investigation was conducted to observe EMG and kinematic patterns of ipsilateral (i-) and contralateral (co-) limbs to transcutaneous posterior tibial nerve stimulation during the mid-swing and mid-stance phases of the locomotor cycle under varying stimulus conditions (pulse number, frequency, duration, intensity). M-wave of the abductor hallucis muscle was monitored to adjudge stimulus intensity. Agonist/antagonist pairs of proximal and distal muscles were evaluated. Prominent observations were (1) enhanced i-tibialis anterior (TA) and co-soleus (SOL), unchanged i-SOL and co-TA, and increased i-swing duration when stimulation was delivered during the swing phase, and (2) unchanged i-TA and i-stance duration during the stance phase. Such phase dependency was most pronounced when the stimulation conditions were 3-5 pulses, 200-300 Hz, 0.5-2.0 ms duration, and 70% of maximum M.

THE EFFECTS OF DYNAMIC VISUAL ROLL STIMULATION ON SELF-MOTION PERCEPTION AND POSTURAL CONTROL. Fred H. Previc and Thomas J. Mullen*. USAF School of Aerospace Medicine, Brooks AFB TX 78235-5301.

A widely studied visual orientation phenomenon is illusory self-motion (vection), although it may not be a good model for other visual orientation effects because it occurs at a very long latency, depends on higher-order perceptual inferences, and is cortically mediated. In this study, the latencies and magnitudes of vection and visually induced postural changes were compared using a visual roll image consisting of ~100 small white collimated squares on a wide field-of-view screen. After an initial 10-sec baseline, the image was rotated at 25 deg/sec. Subjects viewed each scene while standing on a force platform, which measured the continuous change in center-of-pressure. The latency of postural change was defined as the moment at which lateral sway first exceeded a 3-SD criterion above baseline, and was compared to vection latency. It was shown that the onset of postural change occurs within 2 sec, whereas vection commences on average around 7 sec. The two latency measures correlated significantly with each other, but not with the amplitude (magnitude) measures. These and previous findings imply that the experience of vection probably arises from both visual motion and a discounting of vestibular inputs after several seconds have elapsed. STABILITY OF MULTI-LOOP NEURAL CONTROL SYSTEMS. H.B. Nudelman and D.B. Rosenfield*. Stuttering Center Laboratory for Speech Motor Control, Department of Neurology, Baylor College of Medicine, Houston, Tx 77030.

A control system can become unstable i.e. "not work" even though all its components are functioning. The instability is an emergent property of the system and occurs only when the components are connected. As Norbert Wiener observed instabilities can occur in neural control systems. This means it is possible to have a neural disorder without a lesion in the classical sense.

Complex nervous systems have many interactive neural loops. Following Grimm and Nashner it is useful to distinguish between anatomic, functional, and performance loops. Functional loops perform functions that we propose must be accomplished to produce the observed behavior and performance loops are ones that are "closed" by behavior, i.e. a muscle spindle measures the length of a muscle and feedsback to the motoneuron pool of that muscle. One measures the behavior of a "performance loop" that is driven by a group of proposed "functional loops" that are composed of a subset of the possible anatomic loops. To consider instability we lump the system into a functional loop that is driving a performance loop.

The dynamics of the performance loop can be measured. We assume they can be approximated by a linear term and a nonlinear term and that the phase margin of the linear term is specified. Neurophysiology tells us there will be time delays in the outer loop. These time delays effect a phase lag into the total systems transfer function. This phase lag is equal to the time delay divided by the period of the sinusoidal component under consideration.

The system will become unstable whenever this phase lag equals the phase margin on the performance loop. Biological examples will be given.

HFOS IN BILATERAL AND IPSILATERAL SYNERGIST MUSCLE PAIRS IN HUMAN MASTICATION. M. Denny* and A. Smith. Audiology & Speech Sciences Dept., Purdue University, West Lafayette, IN 47907.

Correlated high frequency oscillations (HFOs) observed in respiratory-related neural and EMG activity are thought to represent a widely distributed output of the respiratory CPG (e.g., Bruce & Ackerson, 1986). We have proposed that bilaterally correlated HFOs observed in human masseter muscles during mastication may represent a similar phenomenon resulting from the action of a masticatory CPG (Smith & Denny, J. Neurophysiol, 1990). If HFOs observed during chewing represent a distributed output of a CPG, they should appear in ipsilateral as well as bilateral synergist muscle pairs. If correlation of HFOs increases with neural drive, ipsilateral correlations may be higher on the working side. Activity was recorded from jaw-closing muscles during natural chewing and chewing controlled for working side. Power and coherence spectra were calculated to estimate the strength of correlation between bilateral and ipsilateral pairs. Preliminary analyses indicate that ipsilateral pairs of jaw-closing muscles show significantly correlated activity during mastication.

CONTROL OF HUMAN JAW MOVEMENT IN MASTICATION AND SPEECH. D.J. Ostry, K.G. Munhall*, J.R. Flanagan and A.G. Feldman. McGill University, Montreal, Canada and Institute for Information Transmission Problems, Moscow, USSR.

The X-ray microbeam was used to record jaw movement kinematics in the mid-saggital plane. The jaw movements were examined in terms of the rotation of the condyle and the translation of its axis of rotation along the articular eminence. Mastication trials employed rubber tubing in which compliance and diameter was systematically varied. In speech trials, consonant-vowel combinations were produced at different rates and loudnesses. It was found that when movements of the jaw in mastication were plotted in joint coordinates, the relationship between jaw rotation and jaw translation was essentially fixed. However, when jaw movements in speech were examined, the relationship between rotation and translation was not constant but varied in a systematic way with the composition of the utterance. The evidence from speech suggests that the nervous system is capable of altering the relationship between jaw rotation and jaw translation. Microbeam recordings were also used to recover bite force during the cycle by relating the recorded separation of the teeth at the point of contact with the bolus to separately measured tension-compression functions for each of the tubes. Simulations of human jaw movement based on the equilibrium point hypothesis were found to adequately capture both free and compliant motion phases of orofacial movements. The model allows for changes in coordination between translation and rotation as well as the control of stiffness.

HUMAN MOTOR UNIT FIRING DURING QUASI-SINUSOIDAL ISOMETRIC MUSCLE CONTRACTIONS. M.B. Iyer, C.N. Christakos and C. Ghez. Center for Neurobiology and Behavior, Columbia University and New York State Psychiatric Institute, NY 10032.

This study was designed to investigate the role of motor units (MUs) in the generation of time-varying isometric muscle forces in humans. Subjects produced nearly sinusoidal contractions of the first dorsal interosseus muscle of the hand about fixed force levels (range 15% to 55% of maximal voluntary contraction - MVC), with frequencies in the range 0.25 Hz to 5 Hz and amplitudes in the range 6% to 30% MVC. Single-MU discharges and multi-unit EMG were recorded from the muscle and subjected, together with the force signal, to spectral analysis. The auto-spectra of single-MU activities, as well as of multi-unit EMG, showed a modulation of the discharge rates of the units, with the carrier rates (MU mean discharge rates) remaining more or less constant for a given level of contraction. This rate modulation of MU firing was at the frequency of the sinusoidal variation of the muscle force and showed a phase advance over it. The modulating component in a unit's auto-spectrum increased in size as the depth of the modulation of the force increased. Further, such modulating components were much stronger for multi-unit EMG than for single-MU discharges, which implies correlations between the modulations of different MUs. This was verified by computing coherences between the various signals, which showed large values at the common modulation frequency. Indeed, high coherences between single units, subsets of units, and the entire population signify correlations between unitary activities. These observations therefore strongly suggest that a time-varying isometric muscle force is produced by correlated variations of MU discharge rates, caused by a common, time-varying drive to the alpha-motoneuron pool. ESTIMATING THE STRENGTH OF COMMON INPUTS TO MOTOR NEURONS FROM THE CROSS-CORRELOGRAM. M.A. Nordstrom[1], A.J. Fuglevand[2], R.M. Enoka[1,2] and K.S.Türker*[3]. Dept. Physiology[1] and Dept. Exercise & Sport Sciences[2], Univ. of Arizona, Tucson AZ 85724 and Dept. Physiology[3], Univ. of Adelaide, Adelaide 5001, Australia.

Common synaptic input to motor neurons produces a degree of synchronization of discharge times which is related to the strength of the common input. A method for deriving the strength of common synaptic input (CIS) to pairs of human motor neurons (in terms of average amplitude and input frequency of common EPSPs) has been developed from measures of synchrony in the cross-correlogram using a model of the membrane trajectory between spikes (Miles, T.S. et.al., *Exp. Brain Res.* 77:628,1989). The model can also explain the dependence of the size of the synchronization peak in the cross-correlogram on the motor neuron discharge rates. In the present study, the predictions of the model were compared to empirical relationships obtained from cross-correlation of pairs of human first dorsal interosseous motor units that were voluntarily activated at different mean rates (range 7.5 - 18 Hz). Unlike other measures of correlation derived from the cross-correlogram, the CIS is not directly influenced by the respective motor neuron firing rates, and also describes the correlated activity in terms of the underlying physiological processes (i.e. frequency and amplitude of common EPSPs). Due to this independence, the CIS is the preferred descriptor of correlated activity of motor neurons under conditions in which the relative discharge rates of the motor neurons change with time, such as with a fatiguing voluntary contraction. THE FATIGABILITY OF SINGLE MOTOR UNITS IS DEPENDENT IN PART ON THE PATTERN OF ACTIVATION. Y. Laouris, L. Bevan, R.M. Reinking and D.G. Stuart. Department of Physiology, College of Medicine, University of Arizona, Tucson, AZ, 85724.

To assess motor unit (MU) fatigue, trains of constant-frequency stimuli have conventionally been delivered to motoneurons or their axons, either repetitively or continuously (e.g.: J. Physiol. (Lond). 234:723, 1973; Brain Res. 327:203, 1985). However, observations of MU behavior in conscious humans suggest that their frequency of activation is not constant, even when muscle force is constant (J. Physiol. (Lond). 340:335, 1983; J. Exp. Biol. 115: 125, 1985). Recently, we reported that MU force can be augmented during fatigue by subtle changes in the activation pattern and that the efficacy of such changes increases as fatigue ensues (Soc. Neurosci. Abstr. 15:396, 1989). We now report an extension of this finding by assessing four indices of fatigue for the two activation patterns. The patterns were 500 ms in duration and delivered in random alternation at 1/s to the ventral-root axons of 22 fast-fatigable (FF) MUs of the tibialis posterior muscle from 6 cats during a 4-min fatigue test. One pattern (*regular*) was comprised of a constant-frequency train (interstimulus intervals set at 1.8 x contraction time of the unit; usually 15-30 Hz). The other (*optimized*) pattern, contained the same number of stimuli. However, the initial part of this train contained a triplet (three stimuli separated by 10 ms intervals). The overall force records were decomposed to extract the force profiles attributable to each pattern (Soc. Neurosci. Abstr. 15:396, 1989). The indices of fatigue used to quantify fatigability were: 1) a progressive fatigue index; 2) a cumulative force index; 3) the time to 50% of the initial force; and 4) the time to 50% of the total cumulative force-time integral. The results indicate that MUs are relatively less fatigable when stimulated with an optimized pattern rather than a regular pattern, irrespective of the way in which fatigability is quantified. USE OF FLUTTER FREQUENCY PERIODIC TORQUE MODULATION AS A MONITOR OF Ia REFLEX GAIN DURING MOVEMENT J.S. Thomas, Department of Physiology, Meharry Medical College, Nashville, TN 37208

Flutter frequency (10-50 Hz) periodic torque modulation can be used as a "sounding signal" to monitor Ia reflex gain during ongoing movement. Averaging of averaged sets of EMG and movement parameter records, obtained with torque modulations of opposite phase relative to the TASK imperative signal (target jump and/or discrete torque change), allows unambiguous recovery of the EMG activity and movement parameters associated with the TASK movement. Comparison of these "demodulated" EMG envelopes with those from the same TASK, but without periodic torque modulation, indicates that superimposed flutter frequency perturbation had NO EFFECT on TASK related performance. Subtraction of "phase180" from "phase0" data sets removes TASK specific responses and allows cycle by cycle assessment of the amplitude of EMG and movement parameter response to periodic perturbation during the TASK movement. Typically the "volitional" phases of TASK movement show a profound inhibition of periodic EMG modulation (assumed to reflect Ia reflex gain), sometimes followed by an enhancement of periodic reflex gain as the new posture is stabilized.

545.17

MOTOR UNIT ACTIVATION IS NOT TOPOGRAPHICALLY LOCALIZED IN HUMAN MUSCLE. G. Kamen, Y. Masakado*, C. J. De Luca. NeuroMuscular Research Center, Boston University, Boston, MA 01701.

In an effort to investigate the notion that muscles may be organized into functionally distinct neuromuscular compartments, the independence of motor unit action was assessed in different regions of the human tibialis anterior (TA) muscle. Motor unit recordings were obtained from the TA of five subjects using two quadrifilar needle electrodes inserted 5-6 cm apart. During isometric contractions at 30% MVC, signals obtained from each needle were decomposed to obtain individual motor unit action potential firing trains. Motor unit firing histories from within each needle site and between the two sites were studied to determine the frequency of simultaneous (synchronous) discharges, and to determine the level of common fluctuation of firing rates. These analyses indicated a high degree of synchronization at zero or near-zero latency from units recorded in both distal and proximal needle sites and a similar level of synchronous firing among units measured between the two sites. Also, the fluctuation of firing rates was similar among distal, proximal and between-needle motor units, with cross-correlations of firing rate trains of about 0.6 obtained in each case. These data suggest the existence of a strong central command to all motor units within a given muscle, without regard to motor unit topographical organization.

546.1

Sexually Dimorphic Spatial Abilities in the Morris Water Task. S.G. Warren , L.A. Wilson and L. Nadel. Dept. of Psychology, Univ. of Arizona, Tucson, AZ 85721.

One consistently observed difference between the sexes concerns spatial ability. Males have generally been observed to outperform females on tasks that require them to acquire and retain spatial information. Several possible explanations for these differences have been suggested. First, males might make more efficient use of the euclidian geometric properties of the environment while females rely more heavily on information provided by single landmarks or cues. Second, males could prefentially use distal landmarks or cues while females' spatial behavior is controlled primarily by proximal landmarks or cues. This notion is consistent with the ecological view that the ability of male rats to utilize distal cues more efficiently reflects the larger territory through which they roam, whereas females spend their reproductive life in a more restricted environment. The present study hypothesized that males would perform better than females on a spatial task requiring the use of distal cues whereas females would perform at least as well as males when only proximal cues were available. Forty-nine male and female Long-Evans hooded rats were tested on two versions of a water-maze task. In the proximal condition a curtain was hung just outside the perimeter of the tank. The curtain was marked with eight cues. The curtain was removed for the second condition, thus forcing subjects to rely on distal information within the larger environment. This information included cues placed around the room. There were no differences between males and females when the curtain was in place, and only proximal cues available. Males performed significantly better when the curtain was removed, and distal cues available. This advantage was not evident for the females. These results suggest that males have an advantage when the situation permits the use of distal cues; however when only proximal information is available males and females do not differ in their performance on a spatial task.

546.2

A NEURAL NETWORK APPROACH TO HIPPOCAMPAL FUNCTION IN CLASSICAL CONDITIONING. Nestor A. Schmajuk and James J. DiCarlo*. Department of Psychology, Northwestern University, Evanston, IL 60208.

We describe hippocampal participation in classical conditioning in terms of Grossberg's (1975) attentional theory. According to this theory, pairing of a conditioned stimulus (CS) with an unconditioned stimulus (US) causes both an association of the sensory representation of the CS with the US (conditioned reinforcement learning) and an association of the sensory representation of CS with the drive representation of the US (incentive motivation learning). Sensory representations compete among themselves for a limited-capacity short-term memory (STM) that is reflected in a long-term memory (LTM) storage.

We introduce the "STM regulation" hypothesis which proposes that the hippocampus controls incentive motivation, self-excitation, and competition among sensory representations thereby regulating the contents of a limited capacity STM. Under the "STM regulation" hypothesis, we map nodes and connections in Grossberg's neural network onto a three-dimensional hippocampal circuitry. The resulting neural model provides (a) a framework for understanding the dynamics of information processing and storage in the hippocampus and cerebellum during classical conditioning of the rabbit's nictitating membrane, (b) principles for understanding the effect of different hippocampal manipulations on classical conditioning, and (c) numerous novel and testable predictions.

546.3

IMPROVED PERFORMANCE ON DRL TASKS IN RATS WITH HIPPOCAMPAL LESIONS TREATED WITH THE CALCIUM ENTRY BLOCKER, NIMODIPINE. S. Finger, L. Green*, M. Tarnoff*, K. Mortman* and A. Anderson*. Department. of Psychology, Washington University, St. Louis, MO 63130.

Rats were trained to lever press and then were given either bilateral electrolytic lesions of the hippocampus or control operations. Half of the rats in each group received oral nimodipine, while the remaining animals received vehicle, for the 14 days following surgery. The rats were then tested on a DRL-20 sec schedule of reinforcement that required them to withhold a lever press for 20 sec in order to earn a liquid reward. Rats with lesions not given nimodipine performed very poorly while those treated with the drug performed well within the control group range. Similar trends were obtained when the rats were advanced to a DRL-40 sec schedule one month later. These findings show that nimodipine can attenuate the behavioral effects of large hippocampal lesions on even difficult memory tasks.

546.4

DIFFERENTIATION OF PASSIVE AVOIDANCE DEFICITS PRODUCED BY LESIONS OF THE CENTRAL AMYGDALOID NUCLEUS OF THE RAT. G.D. Coover and B.W. Santi*. Department of Psychology, Northern Illinois University, DeKalb, IL 60115.

Electrolytic but not ibotenate lesions placed rostrally in the central amygdaloid nucleus (rostral ACE) produce a very marked deficit in passive avoidance (PA) of drinking (Coover et al., Soc. Neurosci. Abstr., 15:1251, 1989). The present study with electrolytic lesions addresses the possible contribution of more central neurons of the ACE nucleus, and uses an additional PA task.

Rats with rostral ACE lesions required 33.1 ± 2.9 (Mean ± SEM) footshocks of an ascending series of intensities to passively avoid drinking for 5 min. In contrast, control rats required only 18.7 ± 1.4 footshocks ($p < .001$). Rats with lesions aimed at the middle of the ACE nucleus (middle ACE), just 1.0 mm caudo-ventral to rostral ACE coordinates, required only 22.7 ± 1.9 footshocks, fewer than rostral ACE ($p < .05$) but not more than controls.

In contrast, both lesion groups exhibited deficits in a one-trial step-through PA task. Of the controls, 10 of 11 remained in the brightly lit chamber for the maximum of 10 min on the test trial one day after receiving a footshock for stepping into the dark chamber, while 0 of 8 rostral ACE and 1 of 6 middle ACE rats did so ($p's < .02$).

The amygdala plays some role in PA behavior, but electrolytic lesions of some portions may cause a more profound deficit for which ACE neurons aren't responsible.

546.5

SELECTIVE AND TRANSIENT BEHAVIORAL BENEFITS ARE PRODUCED BY NEURAL GRAFTS THAT PROMPTLY FOLLOW RADIATION-INDUCED HYPOPLASIA OF FASCIA DENTATA GRANULE CELLS. G.A. Mickley[1,2], J.L. Ferguson[1], T.J. Nemeth*[1,2] and B.A. Barrett[1]* BHS, AFRRI, Bethesda, MD 20814 USA[1] and USAFSAM, Brooks AFB TX 78235[2].

X-irradiation of the neonatal rat hippocampus produces a selective hypoplasia of fascia dentata granule cells, locomotor hyperactivity, perseverative movements and deficits in passive avoidance. Transplantation of fetal hippocampal neurons into the adult (age=182±4 days) brain produced a partial behavioral recovery. (Mickley et al., Brain Res., 509:280, 1990).

Since graft/host interconnections are more prominent when transplants are conducted soon after brain damage, we transplanted hippocampal or cerebral cortex neurons when host rats were 33±5 days of age (i.e., only 16 days after radiogenic brain damage). Behavioral evaluations were conducted 80 and 182 days after grafting or surgical control procedures.

Hippocampal transplants failed to reduce deficits in passive avoidance. However, in the first test series only, selective components of locomotion (e.g., stereotypy) and perseverative turning (e.g., mean bout length and rapid turning) were improved by the grafts. These data suggest that the timing of neural graft placement may influence the pattern and duration of behavioral recovery.

547.1

ICI D7569: A CINNOLINE CARBOXAMIDE ANXIOLYTIC WITH PARTIAL AGONIST ACTIVITY AT THE BENZODIAZEPINE RECEPTOR. J.B. Patel, A.I. Salama, J.B. Malick, J.F. Resch*, D.C. U'Prichard, R.E. Giles, B. Hesp*, B.M. Meiners, and M.E. Goldberg. ICI Americas Inc., Wilmington, DE 19897.

ICI D7569 (ID) exhibited potent anticonflict activity in the rat (MED = 0.8 mg/kg) as well as in monkeys (MED = 6.25 mg/kg) procedures predictive of anxiolytic activity in man. The compound showed no effects on rotorod performance in rat up to 200.0 mg/kg, p.o. indicating non-sedative profile. It is less likely to potentiate the sedative actions of ethanol than benzodiazepines (BZ). In addition, ID demonstrated potent oral activity (MED = 1.0 mg/kg) against metrazole-induced convulsions in rats. Of particular interest, and unlike diazepam, chronic ID treatment did not cause an antagonist (RO 15-1788) precipitated withdrawal syndrome (seizures) in mice, suggesting lack of physical dependence liability. Furthermore, ID (12.5 mg/kg, p.o.) antagonized diazepam-induced sedation suggesting partial agonist activity.

Neurochemically, ID is potent (IC_{50} = 0.31 nM) and selective for Type 1 (cerebellar) BZ receptor. Since, GABA increases the affinity of ID at the BZ binding site and its potency is reduced by photoaffinity labeling, this suggests that it has agonist properties at the BZ receptor. Thus, ID should be a potent non-sedative partial agonist anxiolytic in man with considerably reduced physical dependence liability compared to BZ.

547.2

U-78875, A BENZODIAZEPINE ANTAGONIST WITH ANXIOLYTIC PROPERTIES IN RATS AND MICE. P.J.K.D.Schreur, N.F.Nichols, J.F.Pregenzer*, and J.A.Oostveen*. CNS Research, The Upjohn Company, Kalamazoo, MI 49001.

U-78875 {3-(5-cyclopropyl-1,2,4-oxadiazol-3-yl)-5-(1-methyl-ethyl)-imidazo-(1,5-a)quinoxalin-4(5H)-one} is a non-benzodiazepine which binds with the benzodiazepine (BZ) receptor and has some antagonist and agonist properties. We compared U-78875, Ro 15-1788, diazepam, and alprazolam in 5 anxiolytic tests.

In Upjohn-reared Sprague-Dawley rats, U-78875 is active in the center test (increases time away from the walls of a cage) and hole-board (HB) test (increases number of holepokes) and causes locomotor disinhibition (LD) (increases exploratory locomotor activity) at doses of 1-10 mg/kg s.c. In CF-1 mice, U-78875 increases the amount of social interaction in the face to face test (10 mg/kg orally) and suppresses isolation-induced aggression (10 mg/kg i.p.). However, in C57BL/6 mice, it does not impair rotarod performance even at 100 mg/kg i.p. Flumazenil (Ro 15-1788), the classic BZ antagonist, is inactive as an anxiolytic in the center, HB, LD, and face tests (it was not tested against aggression). Diazepam (Valium) was active in all 5 anxiolytic tests (1-10 mg/kg in 4 tests, 0.1 mg/kg or more against aggression). Alprazolam (Xanax) was 3-30 times more potent than diazepam in 4 anxiolytic tests (not tested against aggression). Diazepam and alprazolam impaired rotarod performance.

In conclusion, U-78875 is anxiolytic in a variety of rodent models, but does not have the sedative activity of classical BZ agonists.

547.3

EFFECTS OF DIAZEPAM ON THE STRESS-INDUCED INCREASE IN EXTRACELLULAR DOPAMINE AND NOREPINEPHRINE IN MEDIAL PREFRONTAL CORTEX. Janet M. Finlay, Michael J. Zigmond and Elizabeth D. Abercrombie. *Dept. of Behavioral Neuroscience, University of Pittsburgh, Pittsburgh, PA, 15260.*

A variety of stressors increase extracellular dopamine (DA) and norepinephrine (NE) in medial prefrontal cortex (mPFC) and these neurochemical responses may play a role in the etiology of clinical anxiety. We therefore assessed the effects of the anxiolytic benzodiazepine diazepam on the stress-induced release of catecholamines in mPFC. Simultaneous determination of extracellular DA and NE concentrations was performed using *in vivo* microdialysis in freely moving rats. Rats were given an injection of either diazepam (2.5 mg/kg, IP) or its vehicle and 1 h later subjected to 30 min of tail-pressure stress. Diazepam alone elicited a 60-70% decrease in basal extracellular DA and NE concentrations. When this diazepam-induced shift in basal DA and NE concentrations was accounted for, tail-pressure stress elicited an 80-90% increase in DA and NE levels in both the vehicle and diazepam pre-treated rats. Thus, whereas diazepam does not eliminate the response to stress, it may exert its anxiolytic effects by decreasing the absolute magnitude of DA and/or NE release in mPFC during stress. Additional experiments will examine the effects of diazepam on the stress-induced increase in NE and/or DA in the hippocampus and amygdala, sites which also have been implicated in anxiety and in the mechanism of action of anxiolytics. *(Supported by an MRC of Canada Postdoctoral Fellowship to JMF, USPHS Grant MH45156 and MH43947, and a gift of diazepam from Hoffman-La Roche.)*

547.4

THE EFFECTS OF ORAL IDAZOXAN VS YOHIMBINE IN HEALTHY SUBJECTS. C.J. McDougle, M.D., J.H. Krystal, M.D., S.W. Woods, M.D., L.H. Price, M.D., D.A. Herbst, B.S., G.R. Heninger, M.D., D.S. Charney, M.D., Yale Univ. Dept. of Psychiatry, 34 Park St., New Haven, CT 06519.

The primary purpose of this study was to investigate the effects of oral Idazoxan, an alpha-2 adrenoceptor antagonist, on behavior and norepinephrine (NE) turnover in healthy subjects. In addition, the study sought to determine if the biochemical and behavioral effects of Idazoxan are similar to those of the alpha-2 adrenoceptor antagonist yohimbine. Methods: Ten healthy male subjects received randomized, double-blind oral administration of placebo, 20 mg, 40 mg, and 80 mg of Idazoxan as well as yohimbine 20 mg, on five separate test days. Blood samples for plasma 3-methoxy-4-hydroxyphenylglycol (MHPG) (ng/mL) and cortisol (ug/dL), vital signs, and behavioral ratings were obtained at baseline and at intervals for up to 4 hrs following the oral study dose. Results: The 20 mg (1.31±0.84, p<.001), 40 mg (1.21±0.95, p<.003), and 80 mg (2.04±1.34, p<.002) doses of Idazoxan resulted in consistent, significant increases in plasma free MHPG. The 20 mg dose of yohimbine also resulted in a significant increase in plasma free MHPG (1.76±1.12, p<.002). Plasma cortisol levels were significantly increased following the 80 mg dose of Idazoxan (5.34±7.35, p<.05) and following the 20 mg dose of yohimbine (4.61±6.54, p<.05). Systolic and diastolic blood pressure (sitting and standing) increased significantly following all three idazoxan doses and following yohimbine. Conclusion: The robust increase in plasma MHPG following all three doses of oral Idazoxan demonstrates that Idazoxan increases NE turnover in human subjects. Although Idazoxan and yohimbine may differ in their selectivity for alpha-2 receptor subtypes, this study suggests that neuroendocrine and behavioral responses to these drugs are similar in human subjects. The measurement of the effect of Idazoxan on NE turnover and behavior may provide a means of assessing alpha-2 adrenoceptor function in human subjects.

547.5

BEHAVIORAL EFFECTS OF TANDOSPIRONE IN MALE BABOONS. C.A. Sannerud[1], N.A. Ator[1], C.T. Fischette[2] & R.R. Griffiths[1]. Johns Hopkins Univ. Med. Sch.[1] & Pfizer Pharmaceuticals[2].

Tandospirone [T (SM3997) Pfizer Pharmaceutics Inc.] is a pyrimidinylpiperazine compound with activity at 5-HT_{1A} binding site which is under development as an anxiolytic/antidepressant. Four baboons were maintained on 50 mg/kg/day T via continuous i.g. infusion for 7 consecutive weeks. Chronic T produced few behavioral signs of sedation; lip droop was seen in only 2 baboons. There was equivocal evidence that chronic T changed the sensitivity to flumazenil. Flumazenil (5 mg/kg, i.m.) given on day 8 of chronic T increased limb tremor in 2 baboons and body tremor in 1 baboon, but did not produce other signs typical of benzodiazepine (BZ) precipitated withdrawal (WD). Vehicle substitution after week 7 produced transitory increases in signs of limb tremor and abnormal postures, and decreases in food intake. No signs of vomit or myoclonic jerks/seizures were observed in any baboon. These patterns of behavioral change indicated a very mild BZ-like WD syndrome that was less severe than from lorazepam (LOR) or diazepam. The discriminative stimulus effects of T were assessed in baboons trained to discriminate 1.8 mg/kg LOR, (n=3) or 10 mg/kg pentobarbital (PB, n=3) from no drug. BZ compounds generally show dose-related increases in drug-lever responding in LOR or PB trained baboons. T (0.1-32 mg/kg), however, did not occasion drug-lever responding in either training group after i.m. or p.o. administration. T was more potent at decreasing response rates when given i.m. than p.o. Taken together, T appears to have behavioral effects in baboons different from BZ agonists.

547.6

AUTORADIOGRAPHIC DISTRIBUTION OF 5-HT1A RECEPTOR BINDING SITES FOLLOWING SUBCHRONIC TREATMENT WITH IPSAPIRONE. K. McMonagle-Strucko* and R.J. Fanelli. Institute for Preclinical Pharmacology, Miles Inc., West Haven, CT 06516.

Ipsapirone has been shown to have potent anxiolytic and antidepressant properties in a variety of animal models. Ipsapirone, a high affinity ligand for the 5-HT1A receptor subtype, is a full agonist at presynaptic serotonergic sites and a partial agonist at postsynaptic sites. Experiments were done to determine whether treatment with ipsapirone would differentially affect binding to 5-HT1A receptors at these different sites. Rats were treated twice daily with ipsapirone (10 mg/kg ip) for 14 days. Quantitative analyses were done of autoradiograms of in vitro [3H]8-OH-DPAT binding (1 nM, with or without 10 μM 5-HT, apposed to [3H]-sensitive film for 5 weeks) to selected brain regions. Binding in untreated rats was highest in the hippocampus, septum, entorhinal cortex and raphe nuclei. Subchronic ipsapirone treatment resulted in a large decline ($\cong$ 50%) in binding in raphe nuclei and to a lesser extent in the entorhinal cortex, without altering other regions analyzed. These data support the hypothesis that region specific effects of ipsapirone contribute to its behavioral profile.

THE 5-HT1A AGONIST, 8-OH-DPAT, STIMULATES FOOD INTAKE OF RHESUS MONKEYS. S.M. Pomerantz, Dept. of Physiology, Univ. of Pittsburgh School of Medicine, Pittsburgh, PA 15261.

There is a great deal of interest in evaluating pharmacological agents which may be clinically applied in the treatment of eating disorders. In the present study, we developed a simple feeding paradigm to be used in primate species to examine the effects of pharmacological manipulations on food intake. Adult male rhesus monkeys were placed on a feeding schedule in which a main meal of Purina monkey chow was provided at 1000 hr and a supplemental meal of monkey chow was provided another time during the day. Monkeys generally ate most of their food during the first two hours following their main meal, but also "snacked" following supplemental food presentation. This supplemental feeding period was used to evaluate the effects of the 5-HT1a agonist, 8-OH-DPAT (DPAT). DPAT (10 μg/kg) increased food intake when administered at either 2 hr or 6 hr after the main meal, but not when administered immediately prior to the main meal. Facilitation of supplemental food intake by DPAT was most prominent during the first hour after its administration, but by 4 hours after its administration, food intake returned to control levels. Dose-response analysis revealed that DPAT exhibited a potent biphasic effect during the first hour after its administration (n=7), with low doses (5, 10, and 25 μg/kg) reliably stimulating food intake 186, 208, and 212%, respectively over control vehicle levels, and a high dose of DPAT (200 μg/kg) inhibiting food intake to 51% of control levels. These results indicate that pharmacological agents that interact with 5-HT1a receptors influence food intake in a primate species and that such agents may be clinically efficacious in humans in controlling food intake.

DOWN REGULATION OF BRAIN 5-HT_2 RECEPTORS UNDERLIES ANXIOLYTIC EFFECT PRODUCED BY SUSTAINED TREATMENT WITH GEPIRONE. D. Benjamin[1,3], E.I. Saiff[3], H. Lal[1], and J. Coupet[2]. [1]Texas Coll. of Osteopathic Med., Ft. Worth, TX and [2]Am. Cyanamid Med. Res. Div., [3]Ramapo Coll. of New Jersey, Mahwah, NJ.

Acute administration of gepirone, a 5-HT_{1A} agonist, produces anxiolytic-like effects in mice and rats. Gepirone also produces a treatment duration-dependent anxiolytic-like effect that persists for up to four days following its elimination. Our study was designed to characterize the alterations in serotonergic receptors which are produced by sustained treatment with gepirone, and which are related to the onset and continuation of the anxiolytic-like effect. Mice were injected chronically with gepirone, 15 mg/kg, bid, and after discontinuation of the treatment, performance on behavioral tests, and *in situ* receptor binding were assessed. In the gepirone-treated mice, a significant anxiolytic-like effect as revealed by specific performance in the elevated plus-maze was observed at 24-96 h following 7, 14 or 21, but not 1 d of treatment. There was a significant decrease (up to 50%) in the density of cortical 5-HT_2 receptors. No change was detected in 5-HT_{1B} receptors or in amine release sites; 5-HT_{1A} binding increased, but this effect was preceeded by the behavioral changes. Head-shakes induced in mice by 1-(2,5-dimethoxy-4-iodophenyl)-2-aminopropane (DOI; 1mg/kg), thought to reflect 5-HT_2 receptor function, were virtually abolished following 7, 14 and 21 d of gepirone treatment, but not after 1 d of treatment. 5-HT_2 receptor down regulation and decrements in the head-shake response to DOI were correlated with the anxiolytic-like effect, thus suggesting that decrements in the density and function of 5-HT_2 receptors underlie the anxiolytic-like effects of gepirone. Supported partially by NIAAA grant RO1 3521.

547.9

INTERACTION OF ADRENOCEPTOR ANTAGONISTS WITH 5-HT_{1A} AGONISTS IN DRUG DISCRIMINATION. L. Zhang and J. E. Barrett. Dept. of Psychiatry, Uniformed Services Univ. of the Health Science Bethesda, Maryland 20814

In order to investigate the mechanism of action of novel anxiolytic drugs such as buspirone, the beta- and alpha-adrenoceptor blocking drugs, pindolol and prazosin were studied in a drug discrimination procedure. Pigeons were trained to discriminate 8-OH-DPAT (0.3 mg/kg) from saline. Dose-response curves were tested with the drugs before and after chronic administration of 8-OH-DPAT (3.0 mg/kg/day for 4 to 6 weeks). Dose-response curves for 8-OH-DPAT and buspirone were shifted to the left after chronic administration. Prazosin did not generalize before or after chronic injection. Pindolol did not produce drug key responding before but it did so after chronic administration of 8-OH-DPAT. Although some report that pindolol has 5-HT receptor antagonist effects, it may have partial 5-HT_{1A} receptor agonist-like properties. After 8-OH-DPAT chronic administration, the 5-HT_{1A} receptor may be more sensitive to pindolol. The results indicate that alpha-1 antagonist properties are not directly involved in mediating discriminative stimulus effects of 8-OH-DPAT. 8-OH-DPAT and the beta-adrenoceptor blocking agent pindolol can share discriminative properties under certain conditions. Our approach may provide a useful behavioral model to investigate the mechanism of anxiolytic effects of 5-HT_{1A} agonist. (Supported by DA-02873).

REGION-SPECIFIC TOLERANCE TO THE 5-HT_{1A} AGONIST IPSAPIRONE. M.F.Piercey, Y.Tian*, J.T.Lum, W.E.Hoffmann, R.J.Collins*, M.M.Cooper*, K.Lookingland, and K.E.Moore. The Upjohn Company, Kalamazoo, MI USA and Michigan State University, E. Lansing, MI USA.

In order to better understand delayed therapeutic onsets of 5-HT_{1A} anxiolytics, we evaluated acute ipsapirone (IPS) in animals treated with chronic IPS (15 mg/kg/day i.v. infusion, 7 days). In chronic saline animals, IPS depressed 5-HT neuron firing (dorsal raphe, ED_{50} = 12 μg/kg i.v.), 5-HIAA/5-HT ratios, body temperature and regional brain energy metabolism (2-DG autoradiography), especially in hippocampus, cortex, basal forebrain and raphe areas. In chronic IPS animals, acute drug was less potent in depressing 5-HT neuron firing (ED_{50} = 53 μg/kg) and slightly less effective in producing hypothermia. Tolerance was observed to IPS's depression of 5-HIAA/5-HT ratios in spinal cord, but results were inconclusive elsewhere. In 2-DG autoradiography, acute effects were depressed by chronic treatment in some regions (e.g. prefrontal cortex, m. hypothalamus, basal forebrain, etc.) without being significantly affected in others, including the hippocampus. It is concluded that tolerance differentially develops among brain regions and this could be relevant to the delays observed in anxiolytic activities of the drug.

547.11

EFFECTS OF β-ADRENOCEPTOR ANTAGONISTS ON SEROTONIN METABOLISM AND AGGRESSION IN ISOLATED MICE. J.K. Chamberlain and J.P. DaVanzo. Department of Pharmacology, School of Medicine, East Carolina University, Greenville, NC 27858

β-adrenoceptor antagonists are known to inhibit isolation-induced fighting behavior in mice. Recent work correlated this effect with affinity for serotonin (5-HT)1a receptors and not β-receptors. Activation of 5-HT_{1a} receptors is known to decrease serotonergic impulse flow and the β-adrenoceptor antagonist propranolol is known to antagonize this effect. The effect of acute and chronic β-antagonist administration on 5-HT metabolism was examined in isolated fighting mice. Acutely, d,l-penbutolol significantly increased 5-HT levels in olfactory bulbs and hippocampus. Administration for ten days had no effect on 5-HT levels, but 5-hydroxy indole acetic acid (5-HIAA) was increased in septum and hippocampus of mice treated with d,l-penbutolol. Propranolol, l-penbutolol, and d-penbutolol at behaviorally effective doses had no effect on 5-HT or 5-HIAA levels in any group tested. Since decreased serotonergic activity is associated with decreased aggression, increased serotonin metabolism as indicated by increased 5-HIAA levels is probably not the mechanism by which β-antagonists inhibit fighting behavior. (Supported by Hoechst-Roussel Pharmaceuticals Inc.)

SIGNIFICANT SEDATIVE EFFECTS REPORTED WITH TWO PUTATIVE NONSEDATIVE ANXIOLYTIC DRUGS USING THE ACCELERATING ROTO-ROD. R. C. Meyer, C. E. Lints and W. J. Kasprow*. Department of Psychology, Northern Illinois University, DeKalb, IL 60115.

Previous research with the drugs buspirone and premazepam has demonstrated a lack of sedative properties with these agents (as measured by inclined screen test, wire-grasping test, and constant rotation rotorod), and hence they have been referred to as putative nonsedative anxiolytics (PNAs). This is in contrast to benzodiazepines such as diazepam which, although anxiolytic, possesses sedative side effects.

The present study investigated the sedative properties of buspirone, premazepam, and diazepam compared to vehicle controls in female Swiss-Albino mice (N=10/drug group) using the accelerating rotorod. Mice injected with a drug were placed on the rotorod, which slowly accelerated from 4-rpm to 40-rpm over a 5-min session. The latency (sec) to fall off the rotorod was recorded. Buspirone (1.25, 2.5 and 5 mg/kg), premazepam (10 and 20 mg/kg), and diazepam (1.25, 2.5 and 5 mg/kg) all produced significantly shorter fall-off latencies than controls in a dose-dependent manner. The results suggest that the accelerating rotorod may provide a more sensitive test for measuring the sedative properties of drugs than most experimental techniques currently in use, and also question the validity of classifying buspirone and premazepam as PNAs.

547.13

EFFECTS OF MUSCARINIC COMPOUNDS ON THE FIRING RATE OF CA1 PYRAMIDAL CELLS *IN VIVO* AND ON PHOSPHOINOSITIDE TURNOVER IN HIPPOCAMPAL SLICES *IN VITRO*. R.L. Arias*, J. Cutrera*, S. Amburn*, S.M. Leventer and J.T. Haskins. Wyeth-Ayerst Research, CN 8000, Princeton, NJ 08543-8000.

Loss of cholinergic innervation to the hippocampus may contribute to the etiology of Alzheimer's disease. M1-selective agonists may therefore be of therapeutic value.

In chloral hydrate anesthetized Sprague-Dawley rats, iontophoresis of dilute solutions of acetylcholine, arecoline, carbachol and oxa-22 (5-50 nA) caused a reliable, rapid, dose-dependent increase in cell firing rate. In all cases, this effect was completely and reversibly blocked by concurrent iontophoresis of pirenzepine (5 nA). Low doses of L-glutamate also increased firing, which was only attenuated, not blocked, by pirenzepine, possibly due to blockade of septohippocampal input. Effective doses of pirenzepine alone caused a slight decrease in baseline. Interestingly, while oxa-22 and carbachol induced large increases in phosphoinositide (PI) turnover in rat hippocampal slices *in vitro*, arecoline did not. Iontophoresis of the putative M1 agonists, McN-A-343, AF102B and SR-95639A, had variable effects. At times they caused an increase in firing rate, at times a decrease in baseline or antagonism of muscarinic agonists, and at times caused no noticeable effect at all. In PI turnover, these compounds exhibited profiles consistent with partial agonism and/or antagonism.

These data indicate that (1) pyramidal cell firing rate and PI turnover are useful for assessing M1 agonism, and (2) a simple correlation between these two tests is not readily apparent.

BOTH THE α_2 ADRENERGIC AND DOPAMINE SYSTEMS CONTRIBUTE TO THE PHARMACOLOGICAL EFFECTS OF B-HT 920 IN MICE. R.L. Lloyd and M.K. Menon. Psychopharmacol. Res. Lab., V.A. Med. Ctr., Sepulveda, CA 91343 and Dept. Psychiat. UCLA Sch. Med. Los Angeles, CA 90024.

Contributions of the α_2 adrenergic and DA systems to certain pharmacological effects of B-HT 920 were investigated. Male C57 Bl/6 mice (Simonsen) were used and all injections were made i.p. The profound hypothermic response to B-HT 920 (0.1-0.5 mg/kg) was reduced by haloperiodol (0.5 mg/kg), but not by idazoxan (1.0-3.0 mg/kg). B-HT 920 (0.1-1.0 mg/kg) prolonged the duration of the ethanol (3.9 g/kg) - induced loss of righting reflex in mice. Pretreatment with idazoxan (1.0-3.0 mg/kg) fully prevented this effect of B-HT 920. B-HT 920 (0.3-1.0 mg/kg) reduced the locomotor stimulant effect of d-amphetamine in mice. Even though idazoxan (1.0-3.0 mg/kg) by itself reduced the d-amphetamine-induced hyperactivity, pretreatment with this α_2 antagonist prevented the B-HT 920-induced blockade of the amphetamine effect. It was concluded that while the hypothermic effect of B-HT 920 resulted from postsynaptic DA receptor stimulation, the other two pharmacological effects are related to its α_2-adrenergic agonistic effects (Supported by the U.S. Veterans Administration).

EXOGENOUS TYROSINE POTENTIATES THE METHYLPHENIDATE-INDUCED RELEASE OF DOPAMINE IN THE NUCLEUS ACCUMBENS AS MEASURED BY IN VIVO MICRODIALYSIS. S.K. Woods and J.S. Meyer, Dept. of Psychology, University of Mass., Amherst, MA 01003.

The synthesis and release of dopamine (DA) may, under certain conditions, be altered by increased availability of its amino acid precursor, tyrosine (TYR). To examine whether exogenously supplied TYR could potentiate the release of DA induced by methylphenidate (MPD), 7 Sprague-Dawley rats were implanted with microdialysis probes aimed at the n. accumbens. Samples were collected from awake, freely moving animals beginning 20-24 hr after surgery. Twenty-min samples were continuously collected for a 4-hr period, once a day for 3 consecutive days in a repeated measures design. On a given day, the animal was infused with 30 uM MPD, 100 uM TYR, or 30 uM MPD plus 100uM TYR in artificial CSF. Periods of infusion with the active compound(s) were preceded and followed by baseline conditions and treatments were counterbalanced to control for possible order effects. MPD plus TYR significantly increased extracellular levels of DA compared to drug alone. This effect was long-lasting, persisting into the post-treatment period and peaking 40 min after the peak induced by MPD alone. TYR alone induced a small but steady rise in extracellular DA that did not reach significance until the time of the first post-treatment sample. These results have implications for the use of TYR along with MPD in the treatment of attention deficit disorder.

547.16

ANTICONVULSANT AND PROCONVULSANT EFFECTS OF BMY 14802: RELATIONSHIP TO THE DM/SIGMA BINDING SITE. E. Echevarria, L. Robles and F. C. Tortella, Neuropharmacology Br., Div. of Neuropsychiatry, Walter Reed Army Institute of Research, Washington, DC 20307-5100.

Using two rodent models of convulsive activity we have recently shown that ligands possessing different relative affinities for PCP/sigma/dextromethorphan (DM) binding sites also profile differently in vivo (Echevarria et al., FASEB J. 4: 1990). Namely, the group I "anticonvulsant" profile includes selective high affinity PCP ligands; the group II "proconvulsant" profile includes selective high affinity sigma ligands; while the group III "anticonvulsant/proconvulsant" profile is represented by high affinity DM/sigma ligands. The purpose of this study was to investigate the effects of the putative sigma antagonist antipsychotic BMY14802 in our models: the rat supramaximal electroshock (MES; spreading convulsion) and flurothyl (seizure threshold) tests. Against MES, pretreatment with BMY14802 (25-100 mg/kg, s.c.) blocked tonic hindlimb extention (anticonvulsant ED_{50} = 50 mg/kg). In contrast, in the flurothyl test pretreatment with BMY14802 (6.25-50 mg/kg, s.c.) caused a significant lowering of the convulsive threshold. At the highest dose, this proconvulsant effect of BMY14802 approached 68% of control seizure threshold (371 vs 255 sec). Based upon these results BMY14802 appears to exhibit an in vivo profile similar to other putative DM/sigma ligands, i.e. group III as defined by our model. However, clarification of whether this drug is a functional sigma antagonist awaits additional in vivo studies.

547.17

PRETREATMENT WITH DEXTROMETHORPHAN ANTAGONIZES THE ANTICONVULSANT/PROCONVULSANT ACTIONS OF PCP/SIGMA/DM SITE LIGANDS. F. C. Tortella, E. Echevarria and L. Robles, Neuropharmacology Br., Div. of Neuropsychiatry, Walter Reed Army Institue of Research, Washington, DC 20307.

The non-opioid antitussive dextromethorphan (DM) and PCP/sigma ligands such as (+)-SKF10047 and (+)-3-PPP appear to share a common binding site but display different pharmacological profiles in vivo. We suggested that DM may be a functional antagonist at these sites. Accordingly, using an in vivo EEG and behavioral rat model, we previously demonstrated that pretreatment with DM antagonized the dual peak EEG spectral profile of (+)-SKF10047 (Tortella and Robles, Neurosci Abst. 15: 1989). In the present study, we assessed the ability of DM to alter the anticonvulsant effect of the PCP/sigma ligand (+)-SKF10047, and the proconvulsant effect of the selective sigma ligand (+)-3-PPP, in the rat flurothyl test. In this seizure threshold (ST) test, doses of DM alone up to 25 mg/kg (s.c.) were ineffective. However, pretreatment with 25 mg/kg DM significantly attenuated the (+)-SKF10047-induced increase in ST and the (+)-3-PPP-induced lowering in ST. The maximal anticonvulsant and proconvulsant effects of (+)-SKF10047 (0.125-12.5 mg/kg, s.c.) and (+)-3-PPP (12.5-50 mg/kg, s.c) were antagonized by 88% and 79%, respectively. Importantly, increasing the "agonist" dose of both (+)-SKF10047 and (+)-3-PPP two-fold to 25 mg/kg and 100 mg/kg, respectively, was sufficient to overcome the "antagonist" effects of DM, suggesting that the interaction between these ligands is competitive and reversible.

547.18

EFFECTS OF CENTRALLY-ACTING MUSCLE RELAXANTS ON ACOUSTIC STARTLE REFLEX AND MORPHINE-INDUCED RIGIDITY IN RATS. G.C. Rigdon and R.D. Harper*. Pharmacology Div., Wellcome Research Labs., Research Triangle Park, NC 27709.

This study assessed acoustic startle reflex (ASR) as a screening test for centrally-acting muscle relaxants (CMRs). ED50s were calculated for inhibition of ASR (25-msec, 120-dB white noise stimulus) and antagonism of morphine-induced rigidity (30 mg/kg morphine sulfate SC) in male, Wistar rats. Ratios of ASR ED50 to rigidity ED50 were calculated for 8 CMRs. Cinflumide, chlorzoxazone, methocarbamol, and cyclobenzaprine antagonized rigidity and inhibited ASR with roughly equivilent ED50s (ratios = 0.9 - 1.1). Diazepam and carisprodol antagonized rigidity more potently than they inhibited ASR; ratios were 1.7 and 1.9, respectively. The CMRs with ratios of 0.9 or higher are effective for the treatment of muscle spasm associated with exertion or strain. Baclofen and tizanidine (ratios 0.4 and 0.02 respectively) inhibited ASR more potently than they antagonized rigidity. These two drugs are used to treat spasticity associated with spinal cord lesion or cerebral palsy. Therefore, ASR may be helpful in determining the clinical indication for which potential CMRs are best suited.

547.19

THE DISCRIMINATIVE STIMULUS PROPERTIES OF (+)-OPIATES DO NOT GENERALIZE TO THOSE OF MORPHINE AND HAVE ANTITUSSIVE EFFECTS. P. M. Beardsley and E. W. Anthony. Dept. of CNS Diseases Research, G.D. Searle & Co., Skokie, IL 60077.

Several (+)- opiates, which do not naturally occur in nature, in addition to their naturally-occurring (-)-isomer counterparts, were evaluated in rats trained to discriminate (-)-morphine to determine if they possessed morphine's discriminative stimulus properties. Male Long-Evans hooded rats were trained to discriminate 3.0 mg/kg s.c. (-)-morphine from water, vehicle, while lever pressing under fixed ratio 10 reinforcement schedules for food pellet delivery. Following discrimination training, dose-response functions for (-)-morphine were characterized. Subsequently, generalization tests with (+)-morphine, (+)- and (-)-heroin, (+)- and (-)-etorphine, (+)- and (-)-nordihydrothebainone, and (+)- and (-)-dihydrothebainone were conducted. The (-)- isomers of morphine, heroin, etorphine, and dihydrothebainone all generalized to the morphine discriminative stimulus in a dose-dependent fashion and induced greater that 90% morphine-lever responding at least at one dose tested. The order of potency for generalizing to the morphine stimulus was: (-)-etorphine>>(-)-heroin>(-)-dihydrothebainone=(-)-morphine. The (-)- isomer of nordihydrothebainone did not generate more than 25% morphine-lever responding up to 30 mg/kg, the highest dose tested. At doses of the (-)-opiates that did generalize to the morphine stimulus response rates were often reduced relative to vehicle-control levels. None of the (+)-isomers generalized to the morphine stimulus and only (+)-nordihydrothebainone had marked effects on response rates. In other studies it was found that the (+)-isomers of morphine, etorphine, heroin, codeine, dihydrocodeine, and dihydromorphine possessed antitussive activity when evaluated in the citric acid-induced coughing reflex test in the guinea pig. These results suggest that some of the (+)-isomers of the opioid alkaloids could be free of morphine's subjective effects, and thus possibly its abuse liability, while having therapeutic utility as antitussives.

NEUROETHOLOGY: FISH

548.1

SENSORY GUIDANCE OF PASSIVE ELECTROLOCATION: A STATIC AND A DYNAMIC ANALYSIS. C.D. Hopkins, D. McBride*, K-T. Shieh* and G.H. Harned*, Section of Neurobiology and Behavior, Cornell University, Ithaca, NY 14853.

South American electric fish (Gymnotiformes) make well directed approaches toward conspecifics or toward electrodes playing conspecific signals. We explored how electrosensory cues guide this "passive electrolocation" by observing, under infrared light, the approach responses to electric fields from dipoles. Behavioral trials were recorded on a video recorder, and analyzed frame-by-frame. *Gymnotus carapo* orients its body axis parallel to the local electric field while swimming toward the source, either forward or backward. We compared both the paths and the postures of the fish to the direction of the local electric field, and we computed an "error" angle between the fish's direction and the electric field. The direction of the electric field was determined by computation using the method of images to account for the effects of the tank boundary.

The error angle was consistently 0° or 180° for three electrode geometries. All parts of the body were similarly aligned, but the head showed the greatest variance around 0°. Even when the electrodes rotate at speeds up to 50 rpm, the fish continues to align to the electric field.

These fish frequently "err" to the left or the right of the electric field direction, but correct their error with a 0.2 to 0.5 s lag time, by bending the body in the appropriate direction. Fish that experience a rapidly-changing error angle may stop and reverse their direction in a V-turn. From these behavioral observations we conclude that the fish has an accurate sense of the direction of the local electric field through its body, and that this directional sense guides subsequent turning behavior with a short delay. Supported by NIMH grant # R01 MH 37972 and NSF grant # BNS 8810080.

548.2

DIRECTIONAL CHARACTERISTICS OF TUBEROUS ELECTRORECEPTORS IN THE WEAKLY ELECTRIC FISH, *HYPOPOMUS* SP. D.D. Yager and C.D. Hopkins, Section of Neurobiology and Behavior, Cornell University, Ithaca, NY 14853

Pulse type electric fish are able to localize the source of an electric field, such as that produced by a conspecific, by aligning their long body axis parallel to the local electric field and following the current lines until they reach the source. We are interested in the sensory cues that the fish could use to determine its alignment error. We recorded from > 150 afferents from tuberous electroreceptors in the ganglion of the anterior lateral line nerve in fish suspended at the center of a large circular tank. Stimuli mimicking the electric organ discharge (EOD) were presented through pairs of electrodes spaced at 15° intervals around the tank perimeter. We precisely located each receptor on the body surface using a monopolar probe.

Variations in stimulus angle cause systematic variations in the responses of both burst duration coder and pulse marker afferents. Polar plots of spike number, latency, and threshold all have two elliptical lobes oriented 180° apart. The lobes are often markedly asymmetrical with the major lobe pointed into the fish. The "best" angle varies systematically over the body surface with pulse markers and burst duration coders in the same area showing similar preferences. Units on the snout, tail, and dorsal midline prefer fields parallel to the body axis, while units located on the flank, especially over the thickest part of the body, respond best to transverse fields. The greatest overall sensitivity to any stimulus angle is found on the head; the lowest is found on the tail.

Our data establishes that information is available to the CNS to permit left versus right and head versus tail comparisons as a possible basis for correcting orientation errors. Supported by NIMH grant # R01 MH 37972 and NSF grant # BNS 8810080.

BEHAVIORAL TEST OF LATENCY SHIFT DETECTION IN MORMYRID ELECTRIC FISH. R. Zelick and C.C. Bell, Portland State Univ., Portland, OR 97207 and R.S. Dow Neurol. Sci. Inst., Portland, OR 97209.

African weakly electric fish (Mormyridae) possess three separate electrosensory systems. One of these, the mormyromast system, is adapted for detection of modulations in the fish's electric field caused by objects in the environment. Over a behaviorally relevant range of electric field intensities, primary mormyromast afferents produce only one to several spikes, but vary smoothly and monotonically in latency relative to the fish's electric organ discharge (EOD) or to the motor command signal that drives the EOD (Bell, C.C., *J. Neurophysiol.*, 63:319, 1990). This suggests that spike latency, rather than spike rate, may code for intensity modulations of the electric field. Therefore, a series of behavioral experiments was undertaken to test the sensitivity of the fish to shifts in electric field latency relative to the EOD command signal.

Latency sensitivity measurements were made on three species of mormyrids (*Brienomyrus niger, Gnathonemus petersii, Mormyrus rume*). Individuals were curarized and presented with computer generated and timed mimics of the fish's natural EOD. Latency timing was randomized between presentations. The novelty response, a transient acceleration of command signal rate, was the behavioral response measured.

Latency shifts of -2 ms were detected by the fish only over a range of latencies from 2 to12 ms following the command signal, with the greatest response at 4 ms latency. At a fixed latency of 2 ms, shifts greater than ± 0.5 ms were easily detected. This range of behavioral sensitivities correlates favorably with the responses of primary mormyromast afferents and supports the notion of a latency code for stimulus intensity. SUPPORTED BY BNS 8810571.

548.4

CELLS SENSITIVE TO TIME-DOMAIN INFORMATION IN THE MIDBRAIN OF MORMYRID ELECTRIC FISH. S.Amagai and C.D.Hopkins. Neurobiology & Behavior, Cornell University, Ithaca, NY 14853

Mormyrid electric fish are capable of recognizing brief externally generated pulsatile electrical stimuli by reference to the temporal, not spectral characteristics of the electrical waveform, with an acuity in submillisecond range (Hopkins & Bass *Science* 212: 85-87 1981). The Knollenorgan electroreceptor system is thought to mediate this behavior; it sends timing information from peripheral receptors to the toral nucleus exterolateralis pars anterior (ELa) via a rapidly conducting pathway. From there it projects to the adjacent nucleus exterolateralis pars posterior (ELp). A precise phase-locking is maintained up to ELa but disappears in ELp. Here we report findings on the properties of ELp using field and single-unit recordings.

Field potentials recorded from ELp revealed that a single outside positive voltage step is sufficient to elicit a large slow field potential with a latency of 6-8ms. Square waves of varying duration were used to simulate different waveforms having distinct temporal characteristics, but we could find no detectable differences in field potentials that is not predicted from the simple convergence of peripheral inputs at ELp.

Most single units recorded in ELp showed little or no spontaneous activity but units fire spikes in response to external square waves and steps. There is little evidence of the precise phase-locking evident in ELa, but rather, ELp cells seem to respond sporadically with a variable number of spikes ranging from one to about 10. Our preliminary findings suggest that there are at least two types of cells in ELp. First, there are cells which respond to unilateral stimulation of a specific body surface area with a latency of 8ms. They show no appreciable change in response when the stimulus duration or polarity is changed. Second, there are cells which are tuned to a specific duration of square wave stimuli. These temporally tuned cells are also polarity sensitive, have a longer latency (12ms) and often fire more spikes per burst compared to the other cell-type. Such sensitivity to temporal disparity of activation in different areas of the body can be used for recognition of the stimulus waveform. Supported by NIMH grant MH37972 to CDH.

CELL TYPES AND MODIFIABLE COROLLARY DISCHARGE SIGNALS IN THE MORMYROMAST REGION OF THE ELECTROSENSORY LOBE OF MORMYRID ELECTRIC FISH. C.C. Bell and K. Grant, R.S. Dow Neurol. Sci. Inst., Portland, OR 97209 and Lab. de Physiol. Nerv., C.N.R.S., Gif sur Yvette, 91190, France.

Mormyromast electroreceptors are the most numerous type of electroreceptor in mormyrid fish and are responsible for active electrolocation. Little is known, however, about the central processing of information from these electroreceptors. Single cells were therefore recorded in the mormyromast region of the electrosensory lobe, the first central relay of the system. The effects of local electrosensory stimuli to the skin and of the electric organ discharge (EOD) motor command were examined with extracellular recording.

Three major categories of cells were found: 1) cells excited by the EOD command and inhibited by electrosensory stimuli; 2) cells in which the EOD command had only moderate effects in isolation but strongly facilitated an excitatory response to a stimulus; 3) cells inhibited by the EOD command and excited by electrosensory stimuli. Distinct subtypes were present within the first two categories.

The effects of the EOD motor command were modifiable and depended on previous pairing of the command with a sensory stimulus. The direction of modification was to oppose the effect of the paired stimulus. Two types of modification in command effect were evident; a large modification occurring over several minutes, and a small modification occurring over a few seconds. The slow modification is similar to that described previously in the ampullary region of the electrosensory lobe and could serve in adjusting the system to slow environmental changes. The fast modification was not observed previously and could serve in the active electrolocation of rapidly changing events.

ELECTROSENSORY MODULATION OF ESCAPE. J. G. Canfield and G. J. Rose, Dept. of Biology, Univ. of Utah, Salt Lake City, Utah 84112.

Using a sudden-onset pressure stimulus, we show that the weakly electric fish Eigenmannia maintains a low threshold to startle, demonstrates a diverse array of escape responses, and easily avoids obstacles regardless of ambient light levels. These fish also suppress escape maneuvers through an electric field mimicking the presence of a conspecific.

In contrast, the highly visual goldfish, Carassius auratus, easily avoid obstacles and have a diverse range of maneuvers only when pressure-startled in a well lighted aquarium, and usually when the animal is actively swimming about the tank. Escape rarely occurs when goldfish are in a "freezing" position. In dim light, escape responses are rare, but obstacles are again avoided, though the magnitude and trajectory of the responses are highly restricted. (See also Emberly & Eaton, *Soc. Neurosci. Abstr.*, 1990) "Freezing" behavior is an ethologically important strategy to visually-oriented prey for maintaining concealment and optimal detection of predators.

Physiological evidence obtained from Eigenmannia support the above behavioral data. While the Mauthner cell does not appear to receive electrosensory inputs directly, such inputs have been recorded in other reticular formation cells. The spike activity of these cells is influenced by a mimic of the fish's own electric organ discharge. These putative "non-Mauthner" escape-modulating brainstem neurons (Eaton et al., *Brain, Behav. &Evol.*, in press) may be specific to weakly electric fish. The ability of Eigenmannia to maintain robust escape responses and avoid obstacles in a nocturnal environment appears to be related to its electrosensory abilities. Supported by NSF and the Sloan Foundation.

DISCRIMINATION OF THE SIGN OF FREQUENCY DIFFERENCES BY THE WEAKLY ELECTRIC FISH, STERNOPYGUS. G.J. Rose and J.G. Canfield. Dept. of Biology, Univ. of Utah, Salt Lake City, UT 84112.

In its 'Jamming Avoidance Response', the gymnotiform electric fish, Eigenmannia, shifts the frequency of its electric organ discharges (EODs) away from that of a 'jamming' signal. The fish is able to correctly determine the 'sign' of the frequency difference (Df) between its EODs and those of the other fish. Behavioral and neurophysiological studies indicate that Eigenmannia determines the sign of Df by a complex analysis of the temporal relationship between modulations of the amplitude and phase of signals received by different areas of the body surface.

To gain insight into the evolution of this behavior, studies were conducted on fish of the related genus, Sternopygus. An associative conditioning paradigm was developed to determine if Sternopygus, despite lacking a JAR, is able to discriminate the sign of Df. Movement of a 'shuttle' in one direction was preceded by presentation of a signal slightly higher in frequency than that of the fish's EOD, while a signal slightly lower in frequency was paired with the opposite direction of movement. Both species of Sternopygus were able to learn this discrimination within 1000 trials. Evidence will be presented supporting the notion that these fish achieve this discrimination by the same mechanism as does Eigenmannia and that they possess modulation filters. Supported by grants from NSF and Sloan Foundation.

NEURONAL CODING AND PROCESSING OF COMMUNICATORY SIGNALS IN THE ELECTRIC FISH, EIGENMANNIA. W. Metzner * and W. Heiligenberg. SIO, UCSD, La Jolla, CA 92093

Eigenmannia produces continual, nearly sinusoidal electric organ discharges (EODs) and has two classes of electroreceptors, ampullary units which code low-frequency signals (0 - 40Hz), and tuberous units which are tuned to the fish's fundamental EOD frequency (200 - 500Hz). Separate structures process the inputs from these two receptor classes in the electrosensory lateral line lobe (ELL) of the hindbrain and project to overlapping targets in the torus semicircularis of the midbrain, which in turn projects to the nucleus electrosensorius (nE) of the diencephalon. A regular courtship and aggressive signal are brief interruptions of the EOD, or 'chirps'. The low spectral frequencies of chirps stimulate the ampullary system, whereas fast transients excite the tuberous system. Another social signal are 'beats', phase and amplitude modulations of the electric signal which result from the interference of different EODs of similar frequencies. Beats, which lack low spectral frequencies, are coded by tuberous receptors only and control the fish's jamming avoidance response (JAR). Up to the level of the nE, responses to chirps become more distinct, and neurons are excited more selectively by either chirps or beats. A pathway of chirp-sensitive neurons leads from the nE to the inferior lobe and may affect the pituitary.

DIFFERENT CLASSES OF GLUTAMATE RECEPTORS MEDIATE DISTINCT MODULATIONS OF THE MEDULLARY PACEMAKER OF A GYMNOTIFORM ELECTRIC FISH. Masashi Kawasaki AND Walter Heiligenberg. UCSD, La Jolla, CA 92093

Gymnotiform electric fish generate distinct communicatory signals by modulating the rate of their electric organ discharges (EODs). Each EOD is triggered by a command pulse from the medullary pacemaker nucleus which contains pacemaker cells and relay cells. The firing rate of this nucleus is modulated by inputs from the diencephalic prepacemaker nucleus. The pharmacological separation of behaviors previously found in the 'wave' genus Eigenmannia has been confirmed in the 'pulse' genus Hypopomus. The NMDA receptor blocker APV and the kainate/quisqualate receptor blocker CNQX, administered to the pacemaker nucleus, suppress the frequency rises and 'chirps', respectively, indicating that different classes of glutamate receptors mediate the generation of different modulations. In Hypopomus, a form of sustained modulations, the 'sudden interruption', appears to be mediated by NMDA receptors as well. Despite the rather different frequencies of electric organ discharges observed in these genera, it appears to be a common feature that NMDA receptors are used for sustained modulations, whereas kainate/quisqualate receptors mediate rapid modulations.

CONDUCTANCES CONTRIBUTING TO THE ACTION POTENTIAL WAVEFORM OF ELECTROCYTES IN *STERNOPYGUS*. M.B. Ferrari and H.H. Zakon. Dept. of Zoology, Univ. of Texas, Austin, Texas, 78712.

Electrocyte spike duration (ESD) in this species varies with the electric organ discharge frequency. The ESD is longer in males than in females and can be modulated by steroid hormones. A current clamp study was used to investigate membrane properties using blockers and ion substitutions to determine some of the conductances (g's) which contribute to the shaping of the spike waveform (SPWF). The average resting potential was -84.9 +/- 9.8mV in cells with ESDs ranging from 3.45 to 11.6ms (n=62). The average overshoot amp. was 18.75 +/- 16.59mV (n=41). A complete but reversible block of the spike occured in 1.25uM TTX. In addition, AS-II, which blocks sodium inactivation, resulted in a dramatic increase in both ESD and amp. (5.05 to 14.35ms and +17mV amp in one case). Ca++ g's, however, do not appear to contribute significantly to SPWF as both 0 Ca++ and 500uM - 2mM Co++ do not alter SPWF or IV curves. These results also suggest that Ca++-activated K+ g's are not involved in shaping SPWF (this is further supported as 1uM apamin had no effect). Both the rising and falling phases of the spike appear to be shaped by K+ g's. Application of 20 - 40mM TEA prolonged the falling phase and resulted in a slightly faster rise time and increase in amp. The TEA effects were also reversible. The application of 1-5mM 4-AP, however, caused a more dramatic increase in spike amp. and resulted in an even faster rise time than that observed with TEA. The effect of 4-AP on the falling phase also appeared qualitatively different than that of TEA. These results suggest the presence of at least two separate K+ g's. An increase in g during hyperpol. was also blocked by 4-AP. In twin-pulse expts., a hyperpol. pre-pulse results in a spike onset delay during the depol. pulse, implicating an A-type cond. and/or an inward rectifier in shaping the rising phase of the spike. The results to date are consistent with a Na+ spike which is shaped by the interplay of at least 3 K+ g's: an inward rectifier, an A-type g, and a delayed rectifier. Supported by NIH.

BROMODEOXYURIDINE LABELLING OF REGENERATING ELECTRIC ORGAN REVEALS A CLASS OF SATELLITE-LIKE CELLS. J.M. Patterson, and H.H.Zakon. Dept. of Zoology, University of Texas at Austin, Austin Tx., 78712.

Weakly electric fish of South America, the gymnotiforms, are a highly regenerative vertebrate species. Many species regenerate their posterior body parts, including muscle, nerve, and electrocyte cells (EC) of the electric organ (EO). In *Sternopygus*, the EO is made up of long (1000 µm), cylindrical cells which have been reported as having a myogenic origin. EM micrographs of EO reveal small satellite-like cells around the periphery of the EC embedded in the extracellular matrix. We have studied these cells using the bromodeoxyuridine (BRDU) labelling technique and found that they divide and proliferate after EO amputation.

Nine *Sternopygus marcrurus* had a 10-20 mm segment of the tail posterior to the anal fin removed, and were injected with either 50 mg/kg BRDU or saline after 2, 4, and 6 days. After a 3 hr. labelling period, the proximal stump was fixed, frozen sections were cut, incubated with anti-BRDU Ab, and visualized with fluorescein or HRP-conjugated mouse secondary Ab.

Two days post-amputation (n=3), satellite-like cells close to the cut were labelled, as well as epidermal cells. At day 4 (n=3) there is extensive labelling of satellite-like cells near the wound margin, and at sites several hundred microns proximal to the cut. We observe an aggregation of rapidly dividing cells near the stump, indicative of a regeneration blastema. After 6 days of regeneration (n=3), labelled satellite-like cells occur throughout the stump, and a large blastema containing many labelled cells is present. No labelling was seen in any saline-treated control animals. These results suggest there may be a previously unreported pool of satellite cells within the electric organ, and that division of these cells may contribute to the formation of the regeneration blastema. Supported by NIH.

ELECTROSENSORY LATERAL LINE LOBE EFFERENTS: A MORPHOLOGICALLY DISTINCT CELL TYPE PROJECTS TO THE CAUDAL N. PRAEEMINENTIALIS OF WEAKLY ELECTRIC FISH. J. Bastian and J. Courtright*. Dept. of Zoology, Univ. of Oklahoma, Norman, OK 73019.

The electrosensory lateral line lobe (ELL) is the initial CNS processing area for the electric sense and previously two categories of electric organ discharge (EOD) amplitude encoding neurons have been described. The basilar and non-basilar pyramidal cells of the ELL respond to increases in EOD amplitude with predominantly phasic increases and decreases in activity respectively. These cells project to the torus semicircularis and the n. praeeminentialis (NP). Recent studies of the NP identified neurons which encode EOD amplitude tonically. Afferent terminals were also identified within the NP having tonic response properties. These results suggest that another category of ELL output neurons exists. Extracellular injections of HRP into the caudal NP retrogradely label a morphologically distinct ELL neuron type. These fusiform cells are found in the ELL granule cell layer, have somas that are smaller than those of the basilar and nonbasilar cells, and these ELL neurons project bilaterally to both the ipsi- and contralateral NPs. All of the retrogradely labelled deep cells had a basilar dendrite extending into the electroreceptor afferent fiber layer, and the apical dendrites of these neurons differed markedly from those of the previously described ELL output cells. Their apical dendrites are short, extending dorsally through about 50% of the ELL molecular layers and they are sparsely branched, whereas the apical dendrites of the basilar and nonbasilar cells branch extensively and extend through the entire dorsoventral extent of the ELL molecular layers. Physiological experiments are underway to determine if these deep ELL neurons provide the tonic measures of EOD amplitude seen within the n. praeeminentialis. Supported by NIH grant NS12337 and OCAST contract # 1669.

PHASE AND AMPLITUDE MEASUREMENTS OF THE ELECTRIC ORGAN DISCHARGE OF *APTERONOTUS LEPTORHYNCHUS*. C. Assad, B. Rasnow, J.M. Bower. Depts. of Elect. Eng., Physics, and Biology, Caltech, Pasadena, CA 91125.

A. leptorhynchus is a weakly electric gymnotiform fish with a high frequency (600 to 1000 Hz) wave-type electric organ discharge (EOD). Previous measurements of the EOD in the midplane distant from the fish have shown an approximate dipole field with poles centered in the trunk and tail. In the current experiments, we have mapped the electric potential and electric field components of the EOD adjacent to the skin at numerous horizontal and vertical positions over one side of the fish. Recordings from different positions were synchronized by an EOD phase reference measured at a stationary electrode, which allowed the precise temporal structure of the EOD to be determined. Electric field components normal to the fish's skin were calculated. Results reveal a more complex EOD portrait than that seen with far field measurements, especially in the tail region where complex phase relationships were found.

These results provide important constraints for our efforts to model both the generation of the EOD and the central analysis of electrosensory data. With respect to the electric organ, our data suggests the electrocytes do not fire synchronously. But the stability of the EOD waveform over multiple periods suggests that the relative phase of firing of these electrocytes is tightly controlled. With respect to the processing of electrosensory information, our results indicate that the tuberous electroreceptors found in the tail region experience a considerably different electrical environment than those in the trunk and head. In addition to complex phase relationships, field amplitudes near the tail are an order of magnitude larger than over the trunk. Since the sensory field is highly sensitive to tail position, the fish must either *control* this parameter precisely, and/or *compute* its effects. These results suggest that information from the caudal electroreceptors may be used differently in central processing.

THE DORSAL FILAMENT OF THE WEAKLY ELECTRIC APTERONOTIDS IS SPECIALIZED FOR ELECTRORECEPTION. C. Franchina*, C.D. Hopkins, and A. Schneiderman, Section of Neurobiology and Behavior, Cornell University, Ithaca, New York 14853.

Among the Gymnotiforms, weakly electric South American fish, only members of the Apteronotid family possess a dorsal filament (or thong). The filament is a long semicylindrical structure which lies in a shallow groove on the back and whose function is unknown. We investigated the gross anatomy of the filament in eight genera (fourteen species) of Apteronotids, and the cellular anatomy of the filament in one species of *Adontosternarchus*. We conclude that the dorsal filament functions primarily in electroreception.

We examined preserved specimens of Apteronotids collected in Venezuela and fresh tissue samples from euthanized animals which were fixed, embedded in paraplast, and sectioned at 6-20 µm. Sections were stained for general features (Mallory's trichrome), PAS+ elements (Schiff reaction), or neurofilaments (Bodian's silver stain).

The anterior origin of the filament varied in position from 0.64 body lengths behind the head (in *Sternarchorhynchus*) to 0.49 body lengths behind the head (in *Sternarchogiton*). The filament is a long thin structure, wedge-shaped in cross-section, and continuous with the body of the fish only at the anterior end. The filament and the groove in which it lies are covered by separate sheets of pigmented, unscaled epidermis, but are sealed together by a mucosal layer in living animals. The exposed dorsal surface of the filament is covered with tuberous electroreceptors whose heavily myelinated afferents join two nerves on the ventral margin. Blood vessels are also located ventrally. The bulk of the filament is a mucopolysaccharide matrix.

We speculate that the dorsal filament of the Apteronotidae may be homologous to the adipose fin of the Siluriformes and Characodei. The filament is ideally situated to detect the animal's own electric organ discharge without contamination from other signals. (Supported by A.D. White Fellowship to C.F. and NIMH Grant MH 37972 to C.D.H.)

AUDITORY NEUROPHYSIOLOGY OF THE MESENCEPHALON IN MORMYRID FISH. J.D. Crawford & R.R. Fay*. Parmly Hearing Institute, Loyola U., 6525 N. Sheridan Rd, Chicago, IL 60626.

We are interested in temporal processing and the neural representation of complex sounds, and are studying mormyrids because they use temporally-patterned sounds in communication (Crawford et al. 1986), they have peripheral gas bladders for sound pressure transduction at the sacculi, and their auditory pathways are known anatomically. Here we summarize responses of single neurons, in nucleus Medialis Dorsalis (nMD), stimulated with tones and clicks presented underwater.

We encountered neurons that gave either phasic responses or tonic responses to tones. Most had low spontaneous activity ($\leq$ 1.0 spikes/s) and responded with short latencies (5 ms). Typical thresholds were -30 to -15 dB r.e. 1.0 dyne/cm^2 (communication signals are +30 dB at 10 cm). Characteristic frequencies (CFs) of tonic neurons were at about 235 Hz and this is very close to the 220 Hz fundamental of a nearly tonal signal produced during courtship. Some of these tonic neurons exhibited sharp frequency selectivity ($Q_{10dB} \geq 5$). The CFs of phasic neurons have also been primarily in the 235 Hz range but some had higher CFs between 400 & 500 Hz and all were broadly tuned ($Q_{10dB} \leq 1.0$).

All phasic neurons showed tight synchronization to clicks during trains with intervals from 10-60 ms, a range that included intervals characteristic of two pulsatile sounds also used in communication. Many nMD neurons had non-monotonic rate-intensity functions with a peak at about +5 dB. We have also observed phasic units that gave both onset responses and *off-responses* 40 ms after tone bursts, but only at relatively high levels (e.g. 20 dB). We are currently investigating the possible role of inhibition in bringing about these nMD features.

These response properties are consistent with the idea that nMD functions in processing the tonal and click type sounds used in mormyrid communication (NIH NRSA DC00020-02 & CDR P50 DC00293-06).

LHRH-POSITIVE PREOPTIC CELLS IN A SEX REVERSING FISH: SEXUAL POLYMORPHISM AND MODULATION BY GONADAL STEROID HORMONES. M.S. Grober and A. Bass . Section of Neurobiology and Behavior, Cornell University, Ithaca, N.Y. 14853.

The sex-reversing fish, *Thalassoma bifasciatum*, exhibits two color morphs (primary phase, PP, and terminal phase, TP). PP fish are born either male or female, while TP males result from the transformation of PP males or females. Previously, we identified LHRH-like immunoreactive cells in the preoptic area (POA) of this species. This analysis provides a quantitative comparison of LHRH POA cells amongst the different sexual phases and addresses the role of gonadal steroid hormones in regulating cell size and number.

Total LHRH POA cell number was 2-3 times higher in TP males versus PP males or females, which were similar to each other. There was no significant difference in the size of LHRH POA cells between any of the sexual phases. For both PP males and females, intraperitoneal implants of 11 Ketotestosterone, a naturally occurring gonadal androgen, induced significant increases in the number of LHRH POA cells to levels observed in untreated TP males. There was, however, no significant effect of androgen implants on either cell number in TP males, or cell size in any of the sexual phases. Finally, all steroid treated PP fish assumed TP coloration. These results demonstrate a naturally occurring sexual polymorphism in LHRH POA cell number whose expression is influenced by gonadal steroid hormones. Given the known role of the POA in the control of reproductive function, LHRH POA cell number may in fact determine the differences in reproductive behavior that are characteristic of the different sexual phases in sex reversing fishes. Supported by a NIH Postdoctoral Training Grant (MSG) and NIH / NSF Grants (AB).

EFFECT OF SIZE AND SEX ON GRUNT PRODUCTION IN THE OYSTER TOADFISH. T.D. Waybright*, U. Kollenkirchen* and M.L. Fine. Dept. Biology, Va. Commonwealth Univ., Richmond, VA. 23284-2012.

Male and female toadfish (Opsanus tau) produce an agonistic grunt call by contracting a pair of sonic muscles intrinsic to the swim bladder. The swim bladder and sonic muscles increase in size for life and are both larger in males than in females. In this study we investigated the effect of fish size and sex on spontaneous grunts recorded in air. Fundamental frequency ranged between 120 and 160 Hz and did not vary with fish size or sex, confirming that the frequency spectrum is determined by muscle contraction rate and not swim bladder size. Individual grunt trains varied from 3 to more than 30 grunts, and grunt durations varied from 13 to over 200 ms. In a long series, durations tended to decrease and intergrunt intervals to increase with time. Although all fish were recorded under identical conditions, SPLs within a train ranged between 3-13 dB and were similar in males and females. Although the toadfish sonic system is thought of as all-or-none, this variation suggests that the fish can recruit different numbers of motor units. Maximum SPLs were approximately 70 dB re. 20uPa at 20 cm in males and females and tended to increase with fish size.

EMG AND KINEMATIC ANALYSIS OF THE STAGES OF THE MAUTHNER-INITIATED ESCAPE RESPONSE. M. B. Foreman and R. C. Eaton. Center for Neuroscience, University of Colorado, Boulder, CO 80309-0334.

We are using simultaneous electromyographic (EMG) recording and high speed image acquisition and analysis to understand the neural basis of the Mauthner initiated C-start escape of the goldfish. The initial biomechanical component, stage 1, is a sudden bending of the body whereas stage 2 is a forward acceleration that can also include a turn. Previously we reported results in which some of the kinematic parameters of the C-start were related to the underlying muscular activity based on EMG records. Here, we extend this analysis based on refinements in image and EMG processing. We report our findings based on seven strictly quantified kinematic descriptors that characterize the progression of the behavior.

Of the many correlations between the EMG and kinematic characters, of special interest is the fact that the rectified integral (volume) and duration of the stage 1 EMG burst are correlated with linear velocity and distance covered by the fish in stage 2. This suggests variable motoneuron recruitment during stage 1. Moreover, the duration of stage 1 movement is proportional to the stage 2 EMG burst latency. From this we postulate that the command underlying the stage 2 contraction serves to terminate stage 1. If this is the case, then neurons triggering stage 2 are coded by the angle of the impinging stimulus. [Supported by NIH grant NS22621].

548.19

SENSORIMOTOR COORDINATION BETWEEN ATTACK ANGLE AND THE STAGES OF THE MAUTHNER-INITIATED ESCAPE RESPONSE. D. S. Emberley* and R. C. Eaton. Center for Neuroscience, University of Colorado, Boulder, CO 80309-0334.

We are studying the Mauthner initiated C-start escape of the goldfish as a neuroethological model for sensorimotor coordination. This escape behavior has two biomechanical stages. Stage 1 is an initial bending of the body whereas stage 2 is a forward acceleration caused by a stroke of the tail. Stage 2 can also include a turn. To emulate predatory attacks, we dropped a ball into the water above the fish and we measured the relationship between the angle of attack and the stage 1 and 2 turns. We found that the attack angle reliably predicts these turns. For stimuli behind the fish, stages 1 and 2 are small such that the animal accelerates forward in the direction of its initial orientation. To avoid stimuli in front, stages 1 and 2 are large so that the animal reverses its initial orientation. Thus, the direction of the stimulus can code the neural commands controlling stage 1 and 2 muscle contractions. In addition, nearby obstacles can modulate the command and alter the escape route. In cases when the fish made an error and turned toward the stimulus, there was no trajectory correction. Thus, once generated, the neural commands are resistant to subsequent sensory modulation even though such errors might increase the probability of capture. [Supported by NIH grant NS22621].

QUANTITATIVE AUTORADIOGRAPHIC STUDIES OF T_3 AND IGF RECEPTOR BINDING AND PROTEIN SYNTHESIS IN THE BRAINS AND PINEAL OF COHO SALMON DURING SMOLT TRANSFORMATION

Sven O.E. Ebbesson[1], Thomas Östholm[1]*, Dennis Baskin[2], Lars O.E. Ebbesson[1]*, and Lawrence Duffy[1].

[1]Institutes of Marine Science and Arctic Biology, University of Alaska Fairbanks Fairbanks, AK 99775 and [2]Department of Medicine and Biological Structure, University of Washington, Seattle, WA 98108

Smolt transformation (ST) occurs midlife in coho salmon. During this brief period coho salmon imprint on olfactory cues of their natal stream and change behavior. ST is associated with a plasma thyroxine surge and our recent studies on the brains have revealed sequential surges in brain content of some monoamine and amino acid neurotransmitters, changes in immunoreactivity of substance P and FMRF amide in addition to extensive expansion of some axonal systems. In the search for factors controlling or affecting the neural events associated with ST we have employed standard methods for quantitative autoradiography of T_3 (*in vivo*) and IGF (*in vitro*) receptor binding and methionine (^{35}S) incorporation in salmon before, during and after ST. All three studies revealed significantly higher levels of radioactivity in the pineal than in any part of the brain. IGF receptor binding in the pineal and habenula was high in the three salmon populations while the olfactory bulb in the smolt exhibited greater binding than in presmolts and postsmolts. The telencephalon in the smolt also showed greater binding than in pre- or post smolts. Protein synthesis in the pineal, as measured by ^{35}S labeled methionine incorporation, was exceptionally high in the three populations and in the olfactory bulb and telencephalon synthesis decreased in smolts and post smolts. These results indicate that the pineal may play a significant role in ST and that the neural plasticity associated with it involves complex interactions of several hormonal and neurotransmitter systems.

LATERALIZED ESCAPE BEHAVIOR IN HEMISPHERICALLY ASYMMETRIC SALMONIDS. P. Ahluwahlia and G.L. Chew*. Psychology Dept., University of Lethbridge, Lethbridge, AB, Canada, T1K 3M4.

The escape behavior of rainbow trout (Oncorhynchus mykiss) and coho salmon (O. kisutch) (age approx 6 months) was found to be lateralized. That is, individual fish showed consistent preferences in the direction in which they swam to shelter upon release from entrapment. Moreover, different populations of trout and salmon were found to be differentially lateralized: some populations showed sinistral preferences whereas others showed dextral preferences.

As a first step in understanding the neural bases of these behavioral asymmetries we characterized the gross anatomical and volumetric properties of various discrete brain structures of left- and right-escaping fish. We found structural asymmetries, particularly in telencephalic regions, which paralleled the observed lateralization in escape behavior.

MIF-1 IMPROVES RETENTION PERFORMANCE OF AGED RATS IN AN ACTIVE AVOIDANCE PARADIGM. G. A. Olson, A. S. Wensel*, A. J. Kastin, M. C. Brown*, and R. D. Olson. Department of Psychology, University of New Orleans, New Orleans, LA 70148

As part of our program evaluating the Tyr-MIF-1 family of endogenous opiate antagonists, 24-month old male albino rats were injected IP with either morphine (1.0 mg/kg), MIF-1 (Pro-Leu-Gly-NH_2, 0.1 mg/Kg), or the diluent vehicle. Animals were injected immediately after Day I training and 11 days later 10 min before Day II retention testing. In both sessions, the animal was placed in an automated shuttle-box where the CS was a tone-light combination, the US was 0.5 mA of shock, and the CS-US interval was 10 sec. Trials were initiated on a VI-60" schedule. Testing continued on each day until the animal reached the criterion of 8 avoidances over the last 10 trials.

Results indicated that post-training injections did not yield any significant retention differences. The pre-retention injections with MIF-1, however, significantly reduced the number of avoidance responses required to reach criterion and decreased the response latenices from trial 1 to trial 2.

The results suggest that MIF-1 may play a role in facilitating performance of a previously learned active avoidance response in aged rats.

EFFECTS OF CORTICOSTEROIDS ON MEMORY IN HUMAN AMNESIA: A NEUROPSYCHOLOGIC CASE STUDY R.J. Caselli, M.R. Trenerry*. Departments of Neurology and Psychiatry, Mayo Clinic, Rochester, MN 55905.

A 41 year old amnesic man with bilateral hippocampal infarctions (larger on the right) underwent serial neuropsychological testing before, during, and following corticosteroid administration (prednisone 30 mg/day) to explore the hypothesis that steroids potentiate hippocampal contributions to memory. Effects were modest, but short term retrieval of noncontextual verbal material and delayed retrieval of contextual verbal material were improved on steroids. Visual memory showed no appreciable improvement. Test-retest effects were mild, except for marked improvement on the Wisconsin Card Sorting Test. No improvements were noted on tests of a variety of non-memory functions, including attention and psychomotor speed. We conclude that corticosteroids may have a modest, specific beneficial effect on certain aspects of declarative memory, independent of any effects on attention and psychomotor speed.

549.3

GALANIN PREVENTS RETENTION OF ONE-TRIAL REWARD LEARNING. D.H. MALIN, J.F. NOCK*, B.J. NOVY*, J.R. LAKE, R.E. PLOTNER*, A. LETT BROWN*, L.M. ARNDT* AND L.D. OSGOOD*. Univ. of Houston-Clear Lake, Houston, TX 77058.

Galanin is a neuropeptide that coexists with acetylcholine in the septohippocampal pathway. It appears to have a negative modulating influence on cholinergic transmission, suggesting that it might interfere with memory formation.

The apparatus was a starburst maze consisting of a start box, and 5 radiating alleys: 4 level alleys and 1 baited ascending alley with a grid floor. THe subjects were 20 Sprague-Dawley rats, handled for 10 days, cannulated in the body of the lateral ventricles and deprived to 80% of initial weight. Each rat was infused i.c.v. over 6 mins. with 8µg galanin in 24µl saline or with saline alone. Twenty mins. after completion of infusion, each rat was placed in the maze and observed under "blind" conditions for number of errors (blind alleys entered) and latency to reach reward. Each rat's speed score was 100 sec./latency. One day later, each rat was retested in the maze. Each rat's retention scores were its decrease in errors and increase in speed between the single training trial and the retention trial. Galanin-infused rats showed significantly less retention by both measures. (* p<.05, ** p<.01 vs. saline).

M ± SEM	SALINE I.C.V.	GALANIN 8µg I.C.V.
ERROR DECREASE	3.1 ± 0.9	-1.1 ± 0.9 **
SPEED INCREASE	4.1 ± 1.3	0.7 ± 1.1 *

"Reproductive Memory" - A New Model for the Study of Recognition Processes in the Male Rat: Effect of Vasopressin Antagonist Administration. T. Mencio-Wszalek and V.D. Ramirez. Program in Neuroscience, University of Illinois, Urbana, Illinois, 61801.

Studies have shown that arginine vasopressin, AVP, modulates memory processing in the rat (De Wied, 1983, Prog. Brain Res., 60:155). Current work in our laboratory, using a novel model of recognition in the rat, has sought to assess the role of AVP in the rat's ability to recognize a familiar female conspecific. Sexually naive adult male rats injected intraperitoneally with either 0.5 ml of saline or 0.5 ml of the V1 antagonist, ([β-mercapto-β, β-cyclopentamethylene-proprionyl^1, O-Met-Tyr^2-Arg^8]-VP) at a concentration of 10ug/100ul, ten minutes before the trial had no effect on the animal's ability to recognize a familiar female conspecific, i.e., males rapidly mounted and directed significantly less olfactory investigation toward a familiar female conspecific (latency to mount during second interaction period = 74±11 seconds as compared with latency = 300 seconds in first interaction period). In contrast, adult male rats which received intraperitoneal injections of the V2 antagonist, ([d(CH_2)5 D-Ile^2, Ile^4]-VP), failed to recognize sexually receptive female rats with which they had interacted thirty minutes before (latency to mount = 300 seconds). Furthermore, characterization of our model has shown that recognition within reproductive interactions persists for 120 minutes and is dependent upon the consecutive introduction of the same female rat to the male. These data indicate that vasopressin may be involved in this new reproductive recognition paradigm.

CENTRAL ADMINISTRATION OF A SPECIFIC V2 VASOPRESSIN ANTAGONIST BLOCKS THE MALE RAT'S ABILITY TO RECOGNIZE A FAMILIAR CONSPECIFIC FEMALE. S.M. Sigler, T. Mencio-Wszalek, and V.D. Ramirez. Dept. of Physiology and Biophysics, Univ. of Illinois, Urbana, IL 61801.

Studies in our laboratory have demonstrated the role of arginine-vasopressin in recognition and memory processing in the rat with regard to reproductive behavior . Male Sprague-Dawley rats given an intraperitoneal injection of the V2 antagonist [d(CH_2)$_5$ D-Ile$_2$, Ile$_4$]-AVP did not show the rapid latency to mount a familiar sexually receptive female conspecific characteristic of the saline injected controls. (Mencio-Wszalek, *Abstracts, Society for Neuroscience,* 1990) Since the drug was administered systemically, possible peripheral actions responsible for this phenomenon could not be ruled out. Therefore, in order to discriminate between peripheral actions and recognition and memory processing, the drug was administered centrally via push-pull perfusion. Because the septum has been shown to be important in learning and memory, is rich in AVP receptors, and exhibits a positive feedback effect for AVP which is sensitive to V2, but not V1, antagonists (Ramirez, et al., *Journal of Neuroendocrinology,* 1990), the septum was chosen as our site of implantation and perfusion. Male rats were implanted with cannulae 7-10 days prior to perfusion. One hour prior to the first five minute interaction period between the male and female, the stylet was removed and perfusion with CSF was begun. Twenty minutes prior to the first interaction period, the V2 antagonist was administered through the push side of the push-pull cannula for 10 minutes, resulting in an infused concentration of 10ng/100µL. No change in general activity level or other behaviors was observed during any portion of the perfusion period. During the second five minute interaction period, the experimental males (n=7) showed a mean latency to mount of 260±23 sec, which was not significantly different from the 243±35 sec latency to mount exhibited 30 minutes earlier in the initial 5 minute interaction period. In contrast, the control males (n=7) showed a mean latency to mount of 35±10 sec, significantly different from the 223±24 sec exhibited in the initial interaction period. The V2 antagonist proved to be a potent inhibitor of the male's ability to recognize a familiar sexually receptive female conspecific introduced into its home cage 30 minutes after the initial 5 minute interaction period.

The actions of the V1 antagonist in the septum, as well as the V1 and V2 antagonists in other brain areas are currently under investigation.

KAPPA OPIOID AGONISTS CAN CAUSE AMNESIA FOR ONE-TRIAL PASSIVE-AVOIDANCE TRAINING IN THE TWO-DAY-OLD CHICK. P.J. Colombo, H.A. Everill*, J.L. Martinez Jr., E.L. Bennett, and M.R. Rosenzweig. Dept. of Psychology, Univ. of California, Berkeley, CA 94720

Bilateral injection of either dynorphin 1-13 amide or the kappa selective agonist U50-488 into the region of the medial hyperstriatum ventrale causes amnesia for peck-aversion training, but injection of dynorphin 1-8 does not. Chicks injected with DYN 1-13 5 min pre-training and tested either 5, 15, 30, 45, 60, 90 min, or 24 hr after training show impaired memory performance compared to saline-injected controls at 15 min, and remain impaired at all subsequent test intervals. The time-course of appearance of amnesia is consistent with impaired formation of intermediate-term memory. DYN 1-13 is most selective for kappa receptors, but also has selectivity for mu receptors. The fact that the highly kappa selective agonist U50-488 as well as dynorphin 1-13 cause amnesia in chicks, suggests that memory performance can be disrupted through kappa receptor activation.

VASOACTIVE INTESTINAL PEPTIDE (VIP): AN AMNESTIC NEUROPEPTDE IN MICE.

J.E. Morley, J.S. Garland* and J.F. Flood. Geriatric Research, Educational and Clinical Center VA Medical Center, and Division of Geriatric Medicine, St. Louis University, St. Louis MO 63104

VIP is a neuropeptide present in high concentrations in the hippocampus. Mice were prepared for intracerebroventricular (i.c.v.) or the hippocampal injections of **VIP** or saline 24 to 48 hours prior to training on a T-maze left-right footshock avoidance task. Immediately ***after*** training saline or **VIP** was administered i.c.v. (0 to 5.0 ug) or bilaterally into the rostral portion of the hippocampus (0 to 1.0 ug total dose). When footshock avoidance training was continued one week later, **VIP** treatment resulted in dose-dependent increases in the number of trials to make 5 avoidance responses in 6 consecutive trails by either route of administration. When a **VIP** receptor antagonist ([4-Cl-D-Phe^6, Leu^{17}]-VIP) was administered into the hippocampus (0 - 2 ug), it yielded a dose-dependent improvement of retention, suggesting that **VIP** plays a physiological role in memory modulation.. The amnestic effect of **VIP** given i.c.v. was blocked by peripheral administration of memory enhancing compounds arecoline, a muscarinic agonist, and ST 587, a alpha noradrenergic agonist, but not by the gastrointestinal peptide, cholecystokinin octapeptide. Central administration of arecoline, but not NPY, blocked the amnestic effect **VIP**. The failure of NPY to block the amnestic effect of VIP was not due to using the same route of administration for both neuropeptides as centrally administered arecoline block **VIP**-induced amnesia. It is concluded that **VIP** is a potent endogenous amnestic peptide.

GP120 AND A VIP RECEPTOR ANTAGONIST IMPAIR MORRIS WATER MAZE PERFORMANCE IN RATS.

L.V. Panlilio[1], J.M. Hill[2], D.E. Brenneman[3], M. Fridkin*[4], I. Gozes[4] and J.R. Glowa[5] [1]Psychology Dept.,The American Univ., Washington,DC, 21209; [2]Peptide Design, Germantown, MD, 20874; [3]LDN, NICHD, Bethesda, MD 20892; [4] Weizmann Inst. Sci., Rehovot, Israel; [5]CNE, NIMH, Bethesda, MD 20892.

Gp120, the protein coat of HIV, has been shown to be neurotoxic to hippocampal cells in culture. These neurons support LTP, which is considered a physiological model of learning. These findings may explain, in part, the impairments in cognitive function seen in HIV positive patients. Gp120 mediated neurotoxicity in culture can be prevented by co-treatment with VIP, suggesting a basis for therapeutic intervention. In order to develop a model in which to assess this possibility, we attempted to create a comparable functional deficit in rats. We compared the effects of gp120 and a novel VIP receptor antagonist on the acquisition of Morris water maze performance. Male Sprague-Dawley rats were implanted with i.c.v. cannuli and dosed (once daily) with different agents for 7 days before exposure to the maze, and (1 hr before testing) for the entire training period. In control (saline and unoperated) rats, performance progressively improved over 15 days of training. Gp120 and the VIP antagonist impaired the acquisition of this performance. These results strongly suggest that experimental blockade of VIP receptors, or treatment with gp120, can impair performance in a learning- and memory-related task.

EFFECT OF IMMUNOACTIVE DRUGS ON MEMORY IN MICE

R.F.Ritzmann, A.Kling, A.Glasky, K.Lee*, & J.Gevorkyan*
Advanced Immunotherapeutics, VAMC/UCLA Sepulveda CA 91343

An animal model has been proposed for human memory loss which occurs during aging. This model is based on the observation that in a T-maze once a rat enters a goal box and consumes all the food, on the next trial it will enter the other goal box. By increasing the time between trial it can be determined if the rat can remember which side of the maze it entered on the previous trial. While this model has been well documented in rat it has not been tested in mouse. In the present study male Swiss Webster mice, food deprived to 80% of their free feeding weight, were tested in this model. At delays of 30 or 60 seconds a correct response occurred 75% of the time. When the delay was increased to 90 seconds the correct response rate fell to chance (46%). Since there is a considerable amount of interest in comparing immune and brain function we tested two compounds with immunomodulatory activity, AIT0082 and AIT0083, in this model. At low doses (0.5 mg/kg) both compounds improved performance at the 90 second delay to 60-65% correct. At high doses (30 mg/kg) AIT0082 improved performance to 80% correct, but AIT0083 treated mice preformed at chance level. Further studies indicated that AIT0083 at the high dose reduced performance at both the 30 and 60 second delays to chance while saline injected mice were correct 75% of the time.

AMYGDALA INJECTIONS OF DIAZEPAM FACILITATE LONG-TERM DECREMENTS OF THE ACOUSTIC STARTLE RESPONSE IN RATS BY REDUCING FEAR/SENSITIZATION.

B.J. Young, S.A.Rabchenuk, and R.N.Leaton. Dept. of Psychology, Dartmouth College, Hanover, NH 03755.

Borszcz, Cranney, and Leaton (1989) showed that fear conditioning in an acoustic startle habituation paradigm may mask long-term habituation through a long-term sensitization process. Physiological and behavioral manipulations that reduced fear, as indexed by freezing behavior, increased the rate of response decrements. Systemic injections of the anxiolytic drug, diazepam (Young, Helmstetter, and Leaton, 1988), facilitated long-term decrements of the acoustic startle response. The amygdala may mediate the anxiolytic effects of diazepam (Nagy, Zambo, and Decsi, 1979), and lesions of the amygdala, like systemic diazepam, facilitated long-term acoustic response decrements (Leaton and Supple, 1987). Therefore, injections of diazepam directly into the amygdala should facilitate long-term response decrements. Eight rats received bilateral intra-amygdala injections of diazepam (35 ug in 1 ul) prior to habituation training in the acoustic startle chamber, and 8 rats served as vehicle-injected controls. Ten stimuli were presented on a 60-sec interstimulus interval every other day for a total of three sessions. As predicted, diazepam injections (1) significantly enhanced, long-term decrements of the acoustic startle response, (2) did not alter initial response levels, and (3) reduced freezing in the startle chamber during the early stages of training. We conclude that the facilitatory effect of diazepam on long-term decrements of the acoustic startle response is related to its fear/sensitization reducing effects, and these effects may be mediated through the amygdala.

549.11

ANXIOLYTIC AND ANXIOGENIC DRUGS ON THE EARLY ACQUISITION OF TWO-WAY SHUTTLE AVOIDANCE IN RATS.

A. Fernández Teruel, R.M. Escorihuela*, A. Zapata*, J.F. Núñez*, F. Boix*, W. Salazar* and A. Tobeña*. Medical Psychology Unit, Dept. of Pharmacology & Psychiatry, School of Medicine. Autonomous University of Barcelona. 08193-Bellaterra, Barcelona-SPAIN

Genetic evidence (the performance of selectively bred Maudsley and Roman strains); the corticosterone response; defecation scores, as well as the results obtained with procedures reducing emotivity like postnatal or adult habituation to handling, had shown that the early acquisition of the two-way shuttle avoidance is an anxiety-mediated behavior. The purpose of the present study was to add pharmacological evidence to this view by systematically testing the action of anxiolytic and anxiogenic drugs on that task. Single forty-trials sessions with mild shocks (0.4 mA-0.6 mA) were used. In the first experiments the action of sodium pentobarbital (1.25, 2.5 and 5 mg/Kg), and three benzodiazepines (diazepam 2 and 4 mg/Kg; alprazolam 1, 1.25 and 1.5 mg/Kg and adinazolam 1, 2, 4 and 6 mg/Kg) were tested. The last two experiments were carried out to test a possible pro-anxiety action of Ro 15-4513 (2, 5 and 10 mg/Kg) and FG 7142 (5, 10 and 15 mg/Kg), two partial inverse agonists of benzodiazepine receptors, wich previus data had suggested to be anxiogenic in other animal models and in men. The results showed that the measure of early acquisition of two-way active avoidance is sensitive to detect either anxiolytic or anxiogenic effects of drugs.

549.12

DIAZEPAM IMPAIRS ACQUISITION BUT NOT RECALL OF SPATIAL INFORMATION IN THE MORRIS WATER MAZE.

R.K. McNamara & R.W. Skelton. Dept. Psychology, Univ. Victoria, P.O. BOX 1700, Victoria, British Columbia, Canada, V8W 2Y2.

Diazepam (Valium®), a frequently prescribed benzodiazepine, impairs acquisition, but not retention or recall, in humans (Lister, Neurosci. Biobehav. Rev., 9:87, 1985). Diazepam also impairs place learning in the Morris Water Maze (McNamara & Whishaw, Pyschopharmacology in press). This study sought to better define the nature of this impairment.

Three groups of rats were trained (14 days, 4 trials/day) to locate a hidden platform maintained in a constant position in a pool of cool (22±1 °C) opaque water. All groups were injected IP 20 min before training with either saline or diazepam (3 mg/kg). The diazepam and saline groups received those injections throughout training but the third group (saline-diazepam) was switched from saline to diazepam after reaching criterian performance on the seventh day of testing. Relative to the saline group, the diazepam group had longer swim paths, greater heading errors, and slower swim speeds. The saline-diazepam switched group swam slower under diazepam but showed no other deficit in maze performance. When the platform was removed from the pool, the saline and saline-diazepam groups, but not the diazepam group, showed a preference for the quadrant that previously contained the platform. None of the groups were impaired when required to swim to a black, visible platform. When the hidden platform was moved to the opposite quadrant, the diazepam and saline-diazepam group both exhibited an acquisition deficit relative to the saline group. When the platform was again removed from the pool, only the saline group preferred the new quadrant. These results demonstrate that diazepam impairs the formation of new spatial memories but not the utilization of previously stored spatial information.

CHRONIC FLUMAZENIL ENHANCES LEARNING OF A SWIM-ESCAPE TASK IN RATS. M. Urbancic and T.J. Marczynski. Dept. of Pharmacology, Univ. of Illinois, College of Med., Chicago, IL. 60612.

Chronic administration of the benzodiazepine receptor antagonist, flumazenil, was previously shown to have an anxiolytic effect in the elevated plus-maze test and the punished-drinking test (Urbancic, M. et al. Pharmacol. Biochem. & Behav., 35:503-509, 1990). Since the memory-enhancing effect of flumazenil was proposed (Lal, H. et al. FASEB J., 2:2707-2711, 1988) we investigated the mnemonic effects of this drug during chronic administration. Rats pretreated with flumazenil (4 mg/kg/day in the drinking water for 2 or 3 weeks) were tested for acquisition and retention of a swim-escape response in the round water tank and in the water T-maze. Flumazenil-treated group required fewer trials to reach the acquisition criterion than controls. When the rats were tested for retention 3 days after the last trial (without further drug treatment) there was no difference between the groups, but when retested on day 5 after drug withdrawal, the control group had greater difficulty reversing the maze habit than the flumazenil-exposed rats. These findings indicate that chronic flumazenil seems to combine anxiolytic action with enhancement of learning, in contrast to benzodiazepine agonists whose anxiolytic action is accompanied with impairment of learning and memory. Supported by USAF grant 87-0364.

ANXIOGENIC CENTRAL AND PERIPHERAL BENZODIAZEPINE RECEPTOR LIGANDS EXERT DIFFERENT EFFECTS IN LEARNING AND MEMORY TESTS IN RATS. P.V. Holmes & R.C. Drugan. Schrier Research Lab., Dept. of Psychology, Brown University, Providence, RI 02912.

Previous research has demonstrated that low doses of anxiogenic central benzodiazepine receptor (CBR) ligands, the beta-carbolines, improve performance in various learning and memory tests in animals if administered prior to training. The present experiments compared the effect of a beta-carboline (FG 7142) with that of a pharmacologically distinct anxiogenic compound, a peripheral benzodiazepine receptor (PBR) ligand (RO5-4864), in two tests of learning and memory in rats. As expected, FG 7142 significantly improved performance in a passive avoidance test. RO5-4864 was without effect. In a shuttlebox escape test, RO5-4864 significantly impaired performance while FG 7142 had no effect. The effect of RO5-4864 was antagonized by the specific peripheral benzodiazepine receptor antagonist, PK-11195. These results indicate that the differential impact of CBR and PBR anxiogenic ligands on performance in aversively-motivated learning tests may be a reflection of their distinct pharmacologies. Furthermore, the anxiogenic potential of a drug does not appear to be a sufficient requirement for enhancing acquisition in aversively-motivated learning. REVERSAL OF DIAZEPAM-INDUCED IMPAIRMENT IN DISCRIMINATION PERFORMANCE BY RO 15-1788. S.O. COLE, Department of Psychology, Rutgers University, Camden, NJ 08102

The effects of diazepam (DZ) alone and in combination with Ro 15-1788 on the performance of a previously-learned go-no go successive discrimination were studied in male, Sprague-Dawley rats. DZ 4 mg/kg impaired discrimination performance in five successive sessions, although animals showed some tolerance to the drug's action. The impairment in discrimination performance was due to an increase in responding during no go periods of the task (errors of commission). The benzodiazepine (BDZ) receptor antagonist Ro 15-1788 (5 and 10 mg/kg) reversed the impairment in discrimination performance and reduced the number of incorrect responses in a generally dose-dependent manner when co-administered with DZ. These findings suggest that the impairment in discrimination performance by DZ is mediated by central BDZ receptor sites. When administered alone, Ro 15-1788 10 mg/kg (but not 5 mg/kg) produced a mild impairment in discrimination performance. However, in contrast to the effects of DZ, this impairment was due to both small increases in no go period responses (errors of commission) and small decreases in go period responses (errors of omission). These findings suggest that Ro 15-1788 is not a neutral antagonist but has some intrinsic action of its own.

AN ELECTROPHYSIOLOGICAL COMPARISON OF MDL 26,479, A NOVEL TRIAZOLE, AND BETA CARBOLINES IN THE HIPPOCAMPAL SLICE: EVIDENCE FOR COGNITION ENHANCING POTENTIAL. **S.M. Sorensen, J.M. Zwolshen* and T.M. Humphreys*, Merrell Dow Research Institute, Cincinnati, OH 45215.**

Compounds which enhance memory in behavioral models have been shown to augment long term potentiation (LTP) in the hippocampus. Many of these compounds also have effects on the basal population spike amplitude. The beta-carbolines with benzodiazepine inverse agonist activity have been shown to enhance learning in animals. In these experiments we compared the effects of two beta-carbolines, DMCM and beta-CCM, with those of MDL 26,479, a novel triazole which may have cognition enhancing potential, in the hippocampus.

DMCM (5 μM) and beta-CCM (10 μM), increased the basal population spike amplitude of CA1 pyramidal neurons and the magnitude of the LTP produced by a tetanizing stimulus. At higher concentrations however, these compounds produced epileptiform activity in the hippocampal slice, consistent with their high dose convulsant properties.

MDL 26,479 (20 μM) produced similar effects on the basal population spike amplitude and on LTP suggesting that this compound will also have memory enhancing potential. Unlike the beta-carbolines however, high dose MDL 26,479 did not produce epileptiform activity, consistent with behavioral evidence that this compound does not have the high dose convulsant liability seen with many beta-carbolines.

COGNITIVE DEFICITS IN 16MO F-344 RATS AND IMPROVED PERFORMANCE WITH BMY 21502. M.D. Lindner, S.L. Moon, and V.K. Gribkoff. Bristol-Myers Squibb, CNS Biology, P.O. Box 5100, Wallingford, CT 06492-7660.

Morris Water Maze testing with a 60 minute inter-trial interval and 2 trials per day for 5 days revealed that 16mo F-344 male rats were dramatically impaired relative to 2.5 mo rats in acquiring this spatial-mapping task as measured by the swim distance to locate a submerged stationary platform. Impaired visual acuity was noted in 16mo rats by longer swim distances to a platform marked with a small visible cue than 2.5mo rats. 16mo rats were also vulnerable to hypothermia. Surprisingly, 16mo rats were already 0.5°C cooler than 2.5mo rats at baseline and their rectal temperatures dropped 0.5°C from baseline after a 60sec swim while 2.5mo rats maintained their temperatures. The possibility that these non-cognitive factors, poor visual acuity and hypothermia, might completely account for the deficits in spatial mapping performance was not supported by analysis of covariance or stepwise multiple regression. Age alone was the best predictor of spatial mapping ability which suggests that the deficit in 16mo rats may be partially due to some higher cognitive deficit. In part, the older rats' spatial mapping deficit was manifest as a delay in the appearance of a trials effect (improvement from trial one to trial two). BMY 21502, which has been shown to prolong LTP (Gribkoff, Neuropharmacology, 1990, in press) accelerated the appearance and magnitude of the trials effect in 16 mo rats.

549.18

PIRACETAM AND BMY 21502 FACILITATE PERFORMANCE OF TWO-CHOICE WIN-STAY WATER-ESCAPE IN NORMAL RATS. L.W.Means, T.R.Comer* and R.Moore*. Department of Psychology, East Carolina University, Greenville, NC 27858.

Sprague-Dawley rats given either 5 or 10 mg/Kg BMY 21502, 150 mg/Kg piracetam or methylcellulose vehicle (p.o.) daily for 38 days beginning two days before training were compared on performance of a win-stay water-escape task that required the use of trial-dependent working memory. Testing was conducted in a circular water maze that was divided into a start section and two choice sections by a T-shaped metal barrier. The task involved giving the rats pairs of trials in which the location of a submerged escape platform remained in the same choice section within a pair of trials but changed semi-randomly across pairs. Rats receiving either 5 mg/Kg BMY 21502 or piracetam made more correct choices than did rats receiving only the vehicle ($p<.05$ in each case). The facilitated performance was associated with making fewer perseverative responses that resulted in errors.

550.1

CIRCADIAN FACETS OF SENSITIVITY, RHODOPSIN & RHABDOMERE IN *DROSOPHILA*. D.-M. Chen, J. S. Christianson*, R. J. Sapp* and W. S. Stark. Div. Biol. Sci., Univ. of Missouri, Columbia, MO 65211.

Microspectrophotometry (MSP) had shown that R1-6 receptors in white-eyed *Drosophila*'s compound eye have a daily visual pigment rhythm (decreasing to 60% 4 hr after light onset, then recovering, Stark *et al., J. Neurocytol.* **17**, 499-509, 1988); the rhythm persists for 2 days in constant darkness (Stark *et al., Invest. Ophthalmol. Vis. Sci. Suppl.* **30** 291, 1989); the affect of *period* mutants was equivocal. In attempting to relate visual pigment turnover, membrane cycling and sensitivity, we followed our MSP with electron microscopy (EM), morphometry and electrophysiology (the electroretinogram, ERG). EM revealed that the cytoarchitecture of membrane cycling (autophagy and renewal) in white-eyed per^+ controls remanied constant throughout a 12 : 12 :: L : D cycle. Morphometry showed that there were no significant changes in rhabdomere cross sectional area in this diel photoperiod. However, the ERG corroborated the L:D and D:D cycles of visual pigment, with these details: (1) sensitivity varied about twice as much as visual pigment; (2) sensitivity decreases preceded visual pigment decreases by several hours; (3) UV and blue sensitivities varied in parallel in L:D but UV sensitivity decreased preferentially in D:D; (4) *per* mutants (*L* = long and *s* = short) had little influence on the timing of the ERG cycle in D:D; (5) per^s had less visual pigment and lower sensitivity. Supported by NSF grant BNS 88 11062 and NIH grant RO1 EY 07192 to WSS.

CIRCADIAN PACEMAKER CONTROL OF LOCOMOTOR ACTIVITY PHASE IN BULLA GOULDIANA. M.H. Roberts and X. Xie.* Department of Biology, Clarkson University, Potsdam NY., 13699-5805.

In order to determine whether the ocular circadian pacemakers of the marine snail Bulla gouldiana, exert phase control over the circadian rhythm in locomotor activity, we measured the phase angles for entrainment of the ocular pacemakers and the activity rhythm on four different photoperiods: L:D 15:9, 12:12, 9:15, and 4:20. We found that the phase angle for ocular entrainment was progressively advanced relative to dawn as photoperiod decreased (0.31±0.94 [29], 1.85±1.36 [10], 3.00±0.74 [22], 4.92±2.30 [17]; hrs±S.D. [n]), although the phase was fixed relative to the middle of the day. This entrained phase matches predictions based upon the two-pulse non-parametric entrainment model of Pittendrigh. In contrast, activity began near dusk on all photoperiods. On subsequent release into constant conditions, the free-running locomotor activity rhythm commenced near the time of previous activity onset. Thus, activity phase on light cycles represents the entrainment of a light sensitive pacemaker. The resulting lability in phase between ocular and behavioral rhythms in Bulla exposed to light cycles suggests that the ocular pacemakers are not the only determinants of locomotor activity phase in Bulla. We conclude that the circadian system of Bulla gouldiana consists of several pacemakers, some outside the eyes, whose internal phase relationship can be modified by altering photoperiod. 550.3

THE ROLE OF CHLORIDE CONDUCTANCE IN THE PERIOD SHORTENING OF THE CIRCADIAN PACEMAKER IN *BULLA*
S. Michel, S.B.S. Khalsa & G.D. Block Department of Biology, Gilmer Hall, University of Virginia, Charlottesville, VA 22901

The eyes of the marine snail *Bulla* express a circadian rhythm of compound action potentials (CAPs) *in vitro*. Although hyperpolarizing and depolarizing chronic treatments both lengthen the period of the pacemaker, inhibition of Cl^- conductance has recently been found to shorten the period by up to 2.5 hr. In order to address the possible mechanism underlying this period shortening, we have examined the phase at which Cl^- conductance is important for the circadian pacemaker. Detailed analysis of the CAP rhythms in Cl^- free artificial seawater (ASW, Cl^- substituted with SO_4^-) showed a significant decrease in the length of the non-spiking part of the cycle during the late subjective night, suggesting the involvement of Cl^- conductance during this phase of the cycle. The phase response curve for 6 hour pulses of Cl^- free ASW shows small phase advances during the subjective day (CT 5-11: 38 min ±16, CT 8-14: 35 min ±15) and larger advances during the subjective night (CT 14-20: +47 min ±9, CT 17-23: 93 min ±14). The observed phase advances during the late subjective night (CT 17-23) are comparable to those previously obtained with depolarization, whereas those during the late subjective day (CT 8-14) are comparable to phase shifts to hyperpolarization. Thus the all-advance phase response curve could be a result of an alteration of the circadian rhythm in membrane potential in response to a Cl^- conductance inhibition. Cl^- current could act as a passive leak damping the circadian membrane oscillations, or, alternately, be actively driven by the pacemaker. Intracellulary recordings currently underway should help identif y the role of Cl^- conductance in setting the circadian period. *Support by DFG Mi 328/1-1 to SM, NRSA NS09621 to SBSK and NS15264 to GDB.*

THE SPIKING PHOTORECEPTORS OF THE BULLA RETINA. M.E. Geusz and G.D. Block. Dept. of Biology, University of Virginia, Charlottesville, VA 22901.

When the eye of the mollusk Bulla gouldiana is maintained in constant darkness at 15°C, two circadian rhythms occur in the frequency of impulses in the optic nerve. One rhythm, in compound action potential frequency, is believed to be generated by neurons of the basal retina (Block et al., 1984). The second, a rhythm in small impulse frequency (Geusz and Page, 1990), could be generated by spiking photoreceptors of the distal retina. Impulses recorded intracellularly from the spiking photoreceptors occur in synchrony with small spikes in the optic nerve, whether they are generated spontaneously, through current injection, or by light. Impulses from the spiking photoreceptors cease briefly following a light onset, and then resume firing at an increased rate. The spiking photoreceptors display characteristics of the previously described H-type cells of Bulla, and may account for the firing pattern of small impulses in the optic nerve in darkness. Supported by NS08806 to MEG and NS15264 to GDB.

CHARACTERIZATION OF A PUTATIVE CIRCADIAN OSCILLATOR PROTEIN IN THE EYE OF *Aplysia*. U. Raju, M. Nunez-Regueiro*, R. Cook*#, and A. Eskin. Dept. of Biochem. and Biophys. Sci., Univ. of Houston, #Baylor College of Medicine, Houston, TX. 77204.

Elucidation of the circadian oscillating mechanism entails identifying its components, determining how the components interact with one another and testing whether these interactions account for properties of the circadian rhythm. A reasonable hypothesis is that proteins are components of entrainment pathways and they also are components of the oscillator. Light and serotonin (5-HT) both regulate the circadian rhythm in the eye of *Aplysia*. Therefore, we have looked for proteins whose synthesis is modified by light or 5-HT. Using 2-D gel electrophoresis to separate proteins, we found that exposure of eyes to light or 5-HT altered the incorporation of amino acids into a number of proteins. A particularly interesting finding was that a few proteins were modified by both light and 5-HT. As a result of their responses to light and 5-HT, a number of proteins may be considered putative components of the oscillator.

As a first step towards determining the role of these proteins in the circadian mechanism, we are obtaining amino acid sequences of the proteins. Protein spots were cut from 2-D gels, digested with V8 protease, and then separated on a 1-D gel. Peptides were electroblotted from the gel to Immobilon-P membrane and then placed into a gas-phase sequencer. A 38 amino acid sequence of a peptide was obtained from a protein (≈40k, pI 5.6) that was affected in opposite ways by light and 5-HT. Most exciting and important was the discovery of a significant homology (>60%) between our sequence and published sequences of a family of proteins called lipocortins. This family of calcium and phospholipid binding proteins is believed to play important roles in cellular regulation. The tentative identification of the 40k as a lipocortin has given us new ideas about where to look for the circadian oscillating mechanism. More specific hypotheses can now be tested based on the possible cellular functions of this protein.

MONOCHROMATIC LIGHT MODIFIES PERIOD LENGTH IN CRAYFISH ELECTRORETINOGRAPHIC CIRCADIAN RHYTHM. V. Inclán-Rubio and J.L. Herrera-León*. Departamento de Fisiología, Facultad de Medicina, U.N.A.M., Apdo. Postal 70-250, C.P. 04510, México, D.F.

One widespread effect of constant white light applied on electroretinographic (ERG) circadian rhythm in crayfish is changing in the period (Δt) of the freerunning rhythm. In previous works, we showed that it is possible to evoke a phase shift on this rhythm when it is exposed to a 50 min. and 400 lux light pulse with a different wavelength (λ). This work was designed in order to analyse a possible change on angular velocity ERG when monochromatic light is applied in continuous way. Adult and intact crayfish Procambarus bouvieri were monochromatic and white light adapted (λ: 465, 565 and 630 nm) with a 100 lux intensity during six days. The ERG was recorded by means of a metal electrode into the cornea to lead the photoreceptor's electrical response. The change in period (τ) length depends on the λ employed, thus, the lag between the ERG acrophase obtained with white light and with blue light was 210°, with green light (565 nm) was 20°, and with red light (630 nm) was 180°. These results indicated that the net change in angular velocity causes the observed change which depends on one photoreceptor's group altered by the λ used.

EFFECT OF TEMPERATURE UPON ULTRADIAN AND CIRCADIAN ERG RHYTHMS IN THE CRAYFISH. M.L. Fanjul-Moles, J.A. Prieto-Sagredo* and B. Fuentes-Pardo. Depto. de Fisiología, Fac. de Medicina y Depto. de Biología, Fac. de Ciencias, U.N.A.M. Apdo. Pos. 70-371, México D.F. México.

The Electroretinogram (ERG) in the crayfish shows during the earlier stages of ontogeny a clear ultradian rhythm (UR) ($\tau \simeq 4$ hs) which anteceds the circadian rhythm (CR). On the other hand, a persistent ERG amplitude CR with superimposed ultradian oscillation has been established in the isolated eyestalk of the adult crayfish. These findings suggest that the UR represent the output of a multioscillator system which, when in phase, gives rise to the overt CR. The aim of this work was to analize the mechanism of temperature compensation in both the juvenil stages and the excised eyestalk of the adult in order to prove that the UR and CR share this property. ERG recordings were performed individually in both preparations under darkness for at least six days at high and low temperatures; the oscillation period was measured and Q10 calculated. In the juvenil animal Q10 was 1.01 for the UR and 1.05 for the CR. For the eyestalk the Q10 values was 1.19 and 1.52 for UR and CR respectively. These results show that: a) UR shares with the CR the ability to compensate temperature; b) This mechanism is present since very early stages of development and persists in the adult animal. c) The isolated eyestalk maintains the temperature compensation mechanism but to a minor degree.

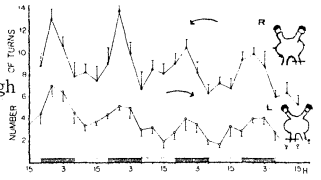
IS LEFT DOMINANCE INVOLVED IN THE COMMAND OF CIRCADIAN LOCOMOTION IN CRAYFISH? Elvira Barrera-Calva* and B. Barrera-Mera. Depto. de Fisiología, Facultad de Medicina, UNAM Apdo. Postal No. 70-250, 04510 México, D.F. México.

The protocerebrum of crayfish contains a pair of bilaterally located circadian pacemakers driving retinal sensitivity (B. Barrera-Mera, et. al., Soc. Neurosci. Abstr. 5, 1979) and glucose concentration in hemolymph (B. Barrera-Mera and S. March-Mifsut, Soc. Neurosci. Abstr. 11, 1985). In order to learn if hierarchical control exists between such cephalic pacemaking structures, we measured crayfish locomotion before and after unilateral (Left or Right) transection of either circummesophageal commisure. Both kinds of preparations resulted in a different amount and sense of movement throughout the day (Fig. 1), even though the recorded number of turns were obtained in constant conditions of light and darkness. We propose that the driving role for locomotion is continually exerted in a preferential manner from the left protocerebral circadian pacemakers.



Circadian variations in the amount of circling behavior of crayfish with surgical transection of either circumesophageal commisure (R L). Measurements were obtained each four hours

[14C] LEUCINE UPTAKE IN BRAIN DURING THE HIBERNATION CYCLE. T. S. Kilduff and H. C. Heller*. Depts. of Psychiatry and Biol. Sci., Stanford Univ., Stanford, CA.

Changes in arousal state such as sleep and hibernation are accompanied by changes in synthesis of neurotransmitters and neuropeptides. As an index of protein synthesis, 1-[^{14}C]-leucine uptake was measured autoradiographically in 50 brain regions of the squirrel Citellus lateralis during various stages of hibernation. Squirrels were injected with 50uCi of 1-[^{14}C]-leucine through chronic jugular catheters during euthermia (T_b=37^{o}C), entrance to hibernation, deep hibernation and arousal. The label was allowed to incubate for 2hr in euthermia and up to 2d in hibernation. Incubations were terminated by pentobarbital overdose, the brain removed, sectioned in a cryostat and exposed to X-ray film. The greatest levels of 1-[^{14}C]-leucine uptake are observed during euthermia in the hippocampal pyramidal cell layer, pontine nuclei, and habenula and the lowest levels observed in white matter. The pontine nuclei and the substantia nigra pars compacta show much greater levels of 1-[^{14}C]-leucine uptake in the euthermic squirrel than reported previously for regional protein synthesis in the rat brain. During hibernation, the fasciculus retroflexus is heavily labelled whereas very little labelling is evident in this region during euthermia. Tissues have now been formalin-fixed to determine actual 1-[^{14}C]-leucine incorporation into protein in different nuclei (Supported in part by the Upjohn Co.).

WARMING UP TO SLEEP?: HIBERNATING GROUND SQUIRRELS SPEND EUTHERMIC SPONTANEOUS AROUSALS IN REM AND NONREM SLEEP. B.M. Barnes, A. Strijkstra* and S. Daan*, Institute of Arctic Biology, University of Alaska, Fairbanks, AK 99775 and Zoological Laboratory, University of Groningen, PO Box 14, 9750 AA Haren, The Netherlands.

Hibernation in mammals consists of long intervals of deep hypothermia or torpor (1-3 weeks at body temperatures circa 0^{o}C) that are interspersed by short arousals to euthermy (8-20 hrs at 37^{o}C). These spontaneous arousals are very energetically expensive compared to torpor, and their functional significance remains unknown. This study sought to test the hypothesis that hibernators enter these arousals in order to sleep. Sleep may be a temperature dependent process that cannot occur during hypothermia; however, the need for sleep may continue to accumulate during torpor, albeit at a reduced rate. Spontaneous arousals to high body temperatures may be permissive of the required sleep. Arctic and golden-mantled ground squirrels (*Spermophilus parryii and S. lateralis*) were implanted with cranial and subcutaneous electrodes for measurements of EEG and EMG and kept from Dec-Apr in continuous darkness and 2^{o}C. Torpor patterns were followed by recording skin temperatures. Paper traces of EEG and EMG and EEG signal-power density in frequency bands from 0.5-13.5 Hz were recorded for spontaneous and induced arousals following different intervals of torpor. Traces were scored for wakefulness, nonREM (slow-wave) and REM sleep; power density is a measure of sleep intensity (Daan et al. Am J Physiol 246:R161). Ground squirrels spent >90% of their 14-20 hr arousal periods in sleep, directly entering sleep upon rewarming and then alternating between nonREM and REM sleep. Power density decreased during arousal sleep, and, in most animals, total power was less after short vs. long torpor bouts. A functional relationship between sleep and periodic rewarming from hibernation counters ideas of torpor as an extension of sleep and of sleep having evolved as a energy saving adaptation.

THE PERIOD OF THE CIRCADIAN OSCILLATOR PERSISTS IN SPACE WITH A DECREASED FREQUENCY. J.S. Ferraro, F.M. Sulzman*, D.J. Happe-Shelton*, M.L. Pence*, S.R. Golay*, K.H. Ekborg* and J.A. Dorsett*. Physiology Dept, Southern IL Univ, Sch of Medicine, Carbondale, IL 62901.

An experiment, designed to examine the endogenous nature and physiology of the circadian oscillator under microgravity conditions, was conducted aboard shuttle flight STS-32 in January of 1990. The circadian rhythm of conidiation (asexual spore formation) in *Neurospora crassa* was monitored in "race" tubes containing an acetate medium with agar, Vogel salts, casamino acids and 3% Brij (50% inoculated with BND and 50% with BND/CSP strains). The tubes, inoculated at one end, were grown in constant light for two days. Growth fronts were marked and the tubes were then place into constant dark. They were integrated into one of three sections of the light-tight mid-deck locker, which was delivered to the orbiter and fixed to the mid-deck wall. Nine hours after launch, mission specialists marked the growth fronts of tubes in the "Blue" and "Red" sections. "Red" contained 15 race tubes covered by a red filter 99.9% dense for wavelengths >610nm. "Blue" contained 25 unfiltered race tubes. The growth-front marking also occurred to all sections, including "White" (10 unfiltered tubes), at approximately launch plus 5 days and 22 hours (L+5D/22h), L+8D/22h and L+10D/3h. The conidiation rhythm persisted with a robust amplitude in-flight. In fact, the amplitude was more robust than that seen on a preliminary experiment flown in 1983 on STS-9. The average period of the oscillation was increased by as much as four hours, over the eleven day flight. These results suggest that circadian oscillations are endogenously generated by an internal clock; however, gravity and/or the absence of gravity, like light and/or the absence of light, can affect the period of the rhythm. Supported by NASA grants NAG 2-361 and NAG 2-452 (JSF).

CIRCADIAN CLOCK REGULATES ROD-CONE SHIFT IN THE RETINA OF THE JAPANESE QUAIL. H. Uchiyama, N.F. Buelow and R.B. Barlow,Jr. Inst. Sensory Res., Syracuse Univ., NY 13244-5290

Animals with duplex retinae can shift from rod- to cone-mediated vision. Associated with this shift is a change in maximum spectral sensitivity known as the Purkinje shift. We studied the Purkinje shift in the Japanese quail, a galliform bird with duplex retina, and found both ambient illumination and a circadian clock control the Purkinje shift in this bird.

Electroretinograms (ERG) were recorded intraviterally from immobilized, urethane-anesthetized animals in response to flashes of monochromatic light. Spectral sensitivities were measured (b-wave, constant response criterion) under different lighting conditions from birds previously maintained on a 12:12 LD cycle. Dark-adapted animals exhibited an endogenous rhythmic Purkinje shift. Their maximum spectral sensitivity was about 500 nm during subjective night and 600-625 nm during subjective day. Light-adapted animals had maximum spectral sensitivity of about 600 nm regardless of time of day. For animals maintained in constant darkness up to 35 hrs, the rhythmic changes in sensitivity had a period of about 24 hrs and were greatest for blue light stimuli (425-475 nm).

We conclude that a circadian clock modulates the functional organization of the Japanese quail retina. It shifts the retina from rod dominated to cone dominated with time of day. Others have reported that intraocular oscillators modulate retinal levels of melatonin, dopamine and related substances in galliform birds. The same oscillators may have a role in the circadian rod-cone shift in birds.

CIRCADIAN CONTROL OF *MANDUCA SEXTA* FLIGHT. H.K. Lehman. ARL-Division of Neurobiology, University of Arizona, Tucson, AZ 85721.

Circadian clocks have been described in a wide variety of organisms and are known to control several physiological processes, yet the neurotransmitters that mediate these processes are less well known. I have focused on the circadian flight of an insect, *Manduca sexta*, to study the transmitters and pathways in which a circadian clock controls behavior.

Flight activity was recorded from dorsal longitudinal flight muscles of individually restrained moths. Flight activity persisted in constant darkness, had a period length slightly less than 24 hours, and could be phase shifted. Circadian flight activity was abolished by severing the connectives between the suboesophageal and thoracic ganglia or removal of the brain, suggesting that the brain is the site of the circadian clock. Octopamine titers were then measured in the brain and hemolymph over a 24 hour period. Concentrations in the brain ranged from 2.5 to 8.6 to pmoles/brain and in the hemolymph from < .10 to .85 pmoles/50 µl. The greatest concentrations in each tissue were detected between 10 PM and 4 AM, coincident with peak levels of flight activity. In addition, injections of the octopamine agonist, chlordimeform, produced long lasting flight activity. Recently, immunocytochemical techniques have been used to visualize octopaminergic neurons in the brain, and studies are underway to characterize these neurons in order to determine which may participate in the circadian control of flight.

POSTNATAL HANDLING REDUCES THE AMPLITUDE OF THE DAILY TEMPERATURE RHYTHM IN THE RAT. S. Amir and A. Schiavetto*. Center for Studies in Behavioral Neurobiology, Concordia Univ., Montreal, Que., Canada.

Adult male Sprague-Dawley rats (90 days old) subjected to brief daily periods (60 min) of handling and separation from the mother during the first three weeks of life (H) exhibited significant reductions in the amplitude of the circadian temperature rhythm compared to non-handled controls (NH). The changes in rhythm amplitude persisted across different environmental lighting conditions or ambient temperatures. The amplitude of the daily temperature rhythm (mean±s.e.m., in °C) in H rats (n=5) tested for 10 days under 12h:12h light-dark cycle and ambient temperature of 24°C was 0.32 ± 0.01 compared to 0.46±0.01 in NH (n=5; $p<0.01$). When tested under similar lighting conditions but at ambient temperature of 4°C the amplitude values were 0.38±0.03 and 0.58±0.02 for H and NH rats, respectively ($p<0.01$). When tested for 10 days under constant light and normal ambient temperature the amplitude of the temperature rhythm was 0.38±0.03 and 0.52±0.03 for H and NH rats ($p<0.01$). Under constant light and ambient temperature of 4°C the amplitude values were 0.36±0.02 and 0.56±0.03 for H and NH rats ($p<0.01$). Previous studies have shown that brief periods of daily handling and separation of newborn rats from the mother result in changes in neuroendocrine and behavioral responses to stress which persist into adulthood. The present results show that such treatment also has a long-lasting effect on the amplitude of the circadian temperature rhythm.

550.15

STRAIN-DEPENDENT EFFECTS OF INCREASING LIGHT INTENSITY ON THE CIRCADIAN RHYTHMS OF LOCOMOTOR ACTIVITY IN MICE. A.R.Mayeda*, J.R.Hofstetter*, and J.I.Nurnberger,Jr. Institute of Psychiatric Res., Indiana Univ.Med.Sch., Indianapolis, IN 46223.

To investigate the genetic determinants of the effects of light on the circadian rhythms in mammals, male mice of several inbred strains were monitored under constant light of successively increasing intensity. They were housed individually, and their locomotor activity was monitored over the course of several months using photoelectric beams. The C57BL/6J mice seemed to have an all-or-nothing response to light. Their period ( ) increased with a change from constant dark to 8 lux constant light but did not increase further when the light intensity was increased to 93 lux. Furthermore, the daily bimodal pattern of locomotor activity of the C57 mice was lost when going from light:dark or dark:dark conditions to constant light. In contrast the period of activity for the DBA/2J mice increased as the light intensity increased from 0 to 8 lux and increased again as the light intensity went to 93 lux.

CIRCADIAN RHYTHMICITY IN SHR AND WKY RATS: EFFECTS OF LIGHT INTENSITY. A.M. Rosenwasser, Dept. of Psychol., Univ. of Maine, Orono, ME 04469.

Recent studies from this laboratory suggest that a noradrenergic mechanism may interact with light intensity to alter free-running circadian period. In the course of these studies, it was noted that the spontaneously hypertensive (SHR) and Wistar-Kyoto (WKY) rat strains, known to display characteristic behavioral and neurochemical differences, also differed in free-running period under constant light. In the present study, circadian drinking rhythms of SHR and WKY rats were monitored under a series of increasing light intensities, beginning with constant darkness. Least-squares spectral analysis was used to quantify parameters of free-running rhythms. As expected, periods lengthened, amplitudes decreased, and spectral profiles became more complex, with increasing light intensity. Strain differences in period, characterized by longer periods in the WKY strain, were seen only under the highest intensities, while strain differences in amplitude, characterized by greater amplitudes in the WKY strain, were seen only under the lowest intensities. In contrast, the two strains showed similar spectral profiles, and appeared equally likely to show disrupted rhythmicity under bright light. The strain by light intensity interactions seen in this study may be due to strain differences in noradrenergic systems.

RESPONSES OF MONTANE VOLES TO INCREMENTAL PHOTOPERIODS. C.N.Rowsemitt and P.J.Berger*. Dept. of Biology, Univ. of Utah, Salt Lake City, UT 84112.

Previous work suggests that montane voles may respond to small changes in day length at the winter solstice (WS) to schedule changes in body weight (Petterborg, L.J. Can.J. Zool. 56:431, 1978). We housed adult male voles (raised under LD 16:8) under decreasing photoperiod in the laboratory (-2 min/day) from Oct. 18 until WS at which time animals were divided into 3 groups: A-natural mimic (+2 min/day), B-slope hold (-2 min/day), and C-solstice hold (LD 9:54:14:06). Controls were housed under LD 12:12 (group D) or LD 16:8 (group E) after Oct. 18. Group F was housed in an unheated shed with natural lighting. Animals were sacrificed on Feb. 21. Groups A, C,D, and F lost weight between mid-Nov. and WS and maintained stable weights for the following month. Group B lost weight between mid-Nov. and WS but gained weight in the following month. Group E gained weight in both of these intervals. Analysis of covariance of log testes weight with log body weight as covariate demonstrates a significant effect of treatment. Group A has higher reproductive function than group B, with a trend existing when groups A and C are compared. Thus, post-solstice changes in growth rates appear to be spontaneous. However, gonadal function may respond to incremental changes in photoperiod.

550.18

THE PERIOD OF THE HAMSTER CIRCADIAN PACEMAKER SHORTENS IN CONSTANT LIGHT OF INTERMEDIATE LEVELS. Dwight E. Nelson and Joseph S. Takahashi Department of Neurobiology and Physiology, Northwestern University, Evanston, Illinois 60208.

The visual sensitivity of the hamster circadian pacemaker to brief stimuli has been studied extensively. Using the phase-shifting response to brief light pulses as an assay we have shown that this pacemaker can integrate the total photons in a single stimulus for 300 s and does not light-adapt to ambient illumination. We have measured the photic sensitivity of the freerunning period of the circadian activity rhythm to *continuous* irradiance levels that span 6 log units. Golden hamsters were maintained in constant light (530nm; HW=45nm) of 10^8 to 10^{14} photons cm^{-2} s^{-1} and the freerunning period of activity was measured after 1, 6 and 9 weeks. One group remained in darkness as a control. During week 1 of constant conditions the period of the activity rhythm shortened monotonically with increasing irradiance. At light levels less than 10^{12} photons cm^{-2} s^{-1} the freerunning period was not different from the period measured in darkness (23.99 ±0.01 h; mean ± SEM). At higher irradiance levels the period was shorter (23.70 ±0.03 h at 6 x 10^{12} photons cm^{-2} s^{-1}). After 6 weeks in constant conditions a biphasic relationship had developed between the constant irradiance and the freerunning period. The freerunning periods of hamsters in low and high levels of illumination were similar (approximately 24 h) yet the periods of animals kept in intermediate levels of illumination (approximately 10^{11} photons cm^{-2} s^{-1}) were significantly shorter (23.80 ± 0.06 h). After 9 weeks in constant conditions the period of the rhythm for hamsters in intermediate levels of constant light remained significantly shorter (23.80 ±0.02 h) than the periods for both animals in darkness (24.04 ±0.02 h) and the highest levels of illumination (24.20 ±0.11 h). The *shortening* of the freerunning period in hamsters maintained in intermediate levels (≈ 10^{11} photons cm^{-2} s^{-1}) of constant light has never been quantified however it has been predicted by Daan and Pittendrigh (*J.Comp.Physiol.* 106:267,1976) based upon the phase-shift responses of the hamster to brief light pulses. Our results suggest that changes in the freerunning period of the hamster circadian pacemaker to light can be predicted by the sensitivity of the pacemaker to brief light pulses.

EFFECT OF NOVELTY ON OVERT AND CENTRAL COMPONENTS OF ORIENTING AND ALERTING. L.D.Sanford*, W.A. Ball*, R.J.Ross, P.J.Gresch* and A.R.Morrison. Depts. Anim. Biol. and Psychiatry, Univ. of Penn. and VAMC., Phila, PA 19104.

Spontaneous ponto-geniculo-occipital (PGO) waves in REM, elicited PGO waves (PGO_E), acoustic startle (ASR) and orienting responses (OR) may reflect the operation of related components of alerting. To determine if mechanisms underlying PGO_E are central correlates of OR or ASR, we presented novel stimuli (NS) in waking and measured behavioral responses and PGO_E. Four cats received 140 consecutive stimuli (90 ms, 100 dB, 2 s ISI): 80 pure tones (T; 1 kHz), 20 white noise bursts (WN; 20 Hz - 50 kHz) plus 40 T. A week later the order of T and WN was reversed. The repeated initial presentation of T or WN alone resulted in a linear decrease in OR with no significant change in PGO_E magnitude (MAG). ASR was inconsistent yet did occur on the first T or WN trial in 3 cats. WN presented after T resulted in increased OR with responses qualitatively similar to those observed initially. PGO_E showed a significant interaction across days with the change from T to WN resulting in increased PGO_E MAG and the change from WN to T producing no increase. Novelty did not affect ASR. Thus, OR showed rapid habituation that was reversed by NS; PGO_E MAG did not readily habituate yet did increase in response to NS. This suggests that experience may dissociate overt and central mechanisms of orienting and alerting, but exposure to NS may quickly reintegrate OR and PGO_E without enhancing ASR. HIGHLY SELECTIVE REM-SLEEP DEPRIVATION IN RATS SUPPRESSES NON-REM-SLEEP DELTA POWER. J. H. Benington and H. C. Heller*, Dept. of Biological Sciences, Stanford University, Stanford, CA 94305.

Traditional approaches to REM-sleep deprivation (RD) in animals produce non-specific stress and early loss of non-REM sleep (NREMS) time. We have developed a highly selective method of RD, using mild electrical stimulation (4-6Hz, 15-30uA) of the dorsal raphe nucleus. RD by this method produces no loss of NREMS time, even in the first hour. Stimulated arousals are indistinguishable from normal arousals from REMS and usually last just 10-20 seconds.

EEG power spectra for 1-2 hour RD during the rest period were compared to time-matched baseline recordings and to control recordings in which NREMS was fragmented at circa 100 second intervals without disrupting REMS. RD produced a 35.8% suppression of EEG delta (0.5-4.0Hz) power in NREMS, as compared to 15.7% for NREMS fragmentation ($p<0.01$, two-tailed t-test).

The suppression of NREMS delta power by RD represents a deprivation of deep NREMS (slow-wave sleep) in spite of no loss of NREMS time, suggesting that cognitive and behavioral deficits following RD may be partly attributable to diminished NREMS quality.

Supported by a grant from the Upjohn Company.

FOOD DEPRIVATION AND RESTORATION AT DAWN DISTURBS THE CIRCADIAN FEEDING RHYTHM IN RATS. J.S. Kruse, K. Krauchi* and A. Wirz-Justice*.
Psychiatric University Clinic, Basel, Switzerland CH-4025.

In analogy to Borbely and Daan's two-process model of sleep, we studied feeding regulation in rats. We measured food intake after deprivation at different circadian phases and under different lighting conditions, to separate circadian from homeostatic effects.

Circadian rhythms of food intake were continuously registered with a computerised food hopper system in 10 male Wistar/Fullinsdorf rats (400-500 g) before and after 1-3 days of food deprivation that began either at the onset or offset of subjective day. In order to reduce masking effects of light, experiments were performed under skeleton 12:12 photoperiods with 1 hour light pulses, as well as under constant DD or RR conditions.

Two days of food deprivation followed by restoration at dawn increased the daily mean meal duration and meal size, without changing circadian amplitude. Meal number and intermeal interval were reduced in circadian amplitude without changes in daily mean values. In contrast, no marked rebound of any variable was found after food restoration at dusk. Thus, food restoration at the circadian antiphase induced a rhythm disturbance of increased feeding in the subjective day. This was seen under all lighting conditions, lasted about 3 days, and disappeared gradually. Additionally, under a skeleton photoperiod, food restoration at dawn, but not dusk, induced an advance (1 hour) in the time of cessation of eating, reducing the duration of the activity phase of feeding.

EFFECTS OF RESTRICTED FEEDING SCHEDULES USING A PALATABLE DIET ON CIRCADIAN ACTIVITY RHYTHMS IN HAMSTERS. H. Abe and B. Rusak. Dept. of Psychology, Dalhousie Univ., Halifax, Nova Scotia, Canada B3H 4J1.

The effects of daily feeding schedules have not often been studied in golden hamsters because they do not readily adapt to temporally restricted food access. We used a modified restricted feeding schedule with a highly prefered palatable diet and moderate food deprivation to examine whether feeding schedules influence the hamster circadian system. Hamsters were kept in constant dim red lighting and given sufficient food (an applesauce/chow combination) at a fixed time of day to maintain 80-90% of free-feeding weights. When body weights were reduced, many hamsters showed clear anticipatory increases in activity before the daily feeding times. Some hamsters also showed entrainment of their freerunning circadian rhythms to these schedules. When the feeding time was advanced by 4.5 hrs, the rhythms shifted toward the new feeding time and entrainment was re-established in some animals. No entrainment and no anticipatory activity were observed in control animals given excess palatable diet at a fixed time. These results suggest that in an appropriate motivational state, hamsters can be entrained by non-photic cues acting directly or indirectly on the circadian pacemaker. We are now examining the effects of suprachiasmatic nucleus (SCN) lesions on anticipatory activity and food-entrained rhythms to see whether hamsters have a food-entrainable system outside the SCN.

EPILEPSY: ANIMAL MODELS

551.1

MAPPING WHOLE BRAIN ACTIVITY DURING DRUG INDUCED SEIZURES WITH VOLTAGE SENSITIVE DYE. D.S. SACKS and R.M. DASHEIFF. Dept. of Veteran Affairs, VAMC, University Dr., Pgh, Pa, 15240 and Univ. of Pittsburgh Epilepsy Center.

The functional interrelationship between electrical activity and brain function is a central concern in the study of epilepsy. In vivo mapping of neural pathways during seizures can uncover new structure-function relationships. This study used the voltage sensitive dye diO-C(2)-5 as a fluorescent marker of electrical activity in neural structures during drug induced seizures in awake animals. The technique allows a complete histological survey of the brain using computerized image analysis (Exp. Neurol 105:189-196, 1989). The rats (yoked from surgery to image analysis) received one of four treatments prior to dye injection: 1) intrajugular injection of 0.25 mg/kg of bicuculline (BIC) + DMSO vehicle, 2) intrajugular injection of DMSO alone, 3) i.p. injection of 12 mg/kg Kainic Acid (KA) + saline vehicle, or 4) i.p. injection of saline alone. EEG activity was recorded via hippocampal electrodes and the dye injection timed to coincide with seizure activity. The neural activity of the septum, amygdala, anterior thalamus, hippocampus, mammilary bodies, substantia nigra, and entorhinal, frontal and posterior cortices was mapped.

Past work had shown that different patterns of hippocampal hyperpolarization and depolarization occurred during seizures induced by KA and BIC. We hypothesized that both a spatial and temporal pattern of polarization throughout the brain would be characteristic of different seizure inducing agents. These patterns should provide insight into both mechanisms of seizure propagation and strategies for medical interventions.

ALPHA-2 ADRENERGIC CONTROL OF THALAMIC OSCILLATION. G. Buzsáki, C. Slamka*, A. Salami*, F. H. Gage, Z. Horváth* and M. Hsu. Dept. of Neurosciences, UCSD, La Jolla, CA 92093

The effects of alpha-adrenergic drugs on neocortical high voltage spindles (HVS), reflecting thalamic oscillation, was investigated in freely moving rats. Bilateral microinjections of the alpha-2 agonists, xylazine and clonidine into the n. ventralis lateralis area of the thalamus, but not into the hippocampus or corpus callosum, as powerfully increased the incidence and duration of HVS as when these drugs were given peripherally. The HVS-promoting effect of clonidine was antagonized by prior intrathalamic injection of the alpha-2 antagonist, yohimbine. The amplitude of the HVS was increased by picomole amounts of unilaterally-injected clonidine. Neurotoxic destruction of the thalamopetal noradrenergic afferents by intracisternal or intrathalamic injection of 6-OHDA increased the incidence of HVS. Importantly, intrathalamic administration of xylazine continued to induce HVS after destroying the thalamic noradrenergic terminals. Downregulation of alpha-2 receptors by amitryptilene reduced the effectiveness of xylazine. We suggest that a major action of alpha-2 adrenergic drugs on thalamic oscillation is mediated by postsynaptic alpha-2 adrenoceptors located on the thalamocortical neurons and that the final physiological action of norepinephrine on thalamic oscillation is a function of the relative density and affinity of alpha-1 and alpha-2 adrenoceptor subtypes.

CHRONIC AND ACUTE EFFECTS OF TETANUS TOXIN IN RAT NEOCORTEX. Y. Chagnac-Amitai, K. Brenner* and M.J. Gutnick, Dept. of Physiology, Ben-Gurion University of the Negev, Beersheva, Israel.

We previously showed that injection of 50 MLDS of tetanus toxin (TT) into rat neocortex produces a potent chronic epileptic focus (J. Physiol. 413:34P, 1989). We now describe the neuronal activities in neocortical slices prepared from both hemispheres of rats that had been unilaterally injected with a minute quantity of TT (2-10 MLD in 0.5 μl) 16 hours to 35 weeks earlier. All slices showed hypersynchronous activity; spontaneous discharges were observed in 50% of the experiments. These took the form of prolonged, negative field potentials which coincided with intracellular DSs. In most slices, there was evidence of residual postsynaptic inhibition despite the profound epileptogenesis. However, IPSPs were only recorded in restricted regions of a given slice. APV (20 μM) abolished most of the DS, often unmasking a late, prolonged hyperpolarization. This is in contrast with the moderate effect of NMDA blockers on focal epileptogenesis induced by acute convulsants.

Hypersynchrony also followed exposure of normal slices to TT. This effect was dose and time dependent. Although fast IPSPs were selectively reduced at first, prolonged incubation led to eventual blockade of all synaptic transmission.

Supported by the DFG (SFB 200).

THE ROLE OF THE SPINAL CORD IN EXPERIMENTAL EPILEPSY. K.S. Blisard, K. Fagin*, O.U. Scremin. Univ. of Cincinnati Med. Ctr., Cincinnati, OH; Univ. of New Mexico Med. Ctr., Albuquerque,NM; Veterans' Admin. Med. Ctr., Albuquerque, NM

Although most seizures are thought to be mediated by higher structures, under certain circumstances the spinal cord can play an important role. We used frogs with thoracic spinal cord transections to investigate this question for several chemical epileptogens. Strychnine induced status epilepticus with tonic-clonic convulsions; these seizures were identical in the intact or cord-transected animal. This is consistent with the seizures originating in the spinal cord. Cis-platin (cis-diamminedichloro-platinum II) caused tonic-clonic seizures in intact frogs; after cord transection, seizure activity occurred in the upper extremity only while the lower extremity remained flaccid. These observations suggest that the seizures originated in structures above the level of the cord. Kainic acid and pentylene tetrazole gave intermediate results. With these agents, cord transected frogs showed some activity of the lower extremities (but decreased from that seen in the upper extremities), suggesting that spinal cord activity may contribute to seizures.

ROLE OF MK-801 IN THE γ-HYDROXYBUTYRIC ACID (GHB) MODEL OF GENERALIZED ABSENCE SEIZURES IN RATS. P.K. Banerjee and O. Carter Snead III Div. of Neurology, Childrens Hospital Los Angeles, Dept Neurology, Univ. South. Calif. Sch. Med., Los Angeles, Ca 90027

γ-Hydroxybutyric acid (GHB), a naturally occurring metabolite of GABA, induces bilaterally synchronous spike wave discharges (SWD) associated with behavioral changes reminiscent of petit mal seizures when given to animals. The GHB-treated animal thus represents a useful experimental model of generalized absence seizures. Although there is a wealth of data concerning excitatory amino acid (EAA) mechanisms in experimental generalized convulsive seizures, there is little information concerning EAA in animal models of absence seizures. In the present study, the effect of the noncompetitive antagonist of the NMDA receptor, MK-801, on GHB-induced SWD was ascertained using dose response and time course studies in rats chronically implanted with cortical electrodes which allowed continuous EEG recording in the freely moving state during all experiments. The GHB model of experimental absence seizures was standardized and quantitated as previously described (Snead, Epilepsia 29:361, 1988). The dose range of MK-801 used in these studies was 0.1-1 mg/kg.

MK-801 had a complex biphasic effect on the GHB-induced seizure in that it produced significant prolongation of the SWD in the early stages of seizure (25% increase), but attenuated later stages of the absence-like episodes. Lower doses (0.1 mg/kg) of MK-801 resulted in a 35% delay in latency to onset of SWD while doses of MK-801 in excess of 1 mg/kg resulted in trains of spike activity when given alone.

These data raise the possibility that EAA-mediated mechanisms may be involved in the genesis of GHB-induced SWD in this experimental model of generalized absence seizures.

GABAERGIC MECHANISMS IN THE γ-HYDROXYBUTYRATE (GHB) MODEL OF GENERALIZED ABSENCE SEIZURES. O.C.Snead , Div Neurol, Childrens Hosp Los Angeles, Dept Neurol. Univ South.Calif, Los Angeles 90027

γ-Hydroxybutyric acid is a naturally occurrring compound which has the ability to produce spike wave discharges (SWD) associated with behavioral arrest. The GHB-treated animal thus represents a useful experimental model of absence seizures. Both clinical and experimental absence seizures, including the GHB model, are exacerbated by GABAergic agonists. The purpose of this work was to explore possible GABAergic mechanisms in GHB-induced SWD.

The status of the GABA/BDZ/picrotoxin ionophore was determined during GHB-induced SWD and also in the presence of GHB in varying concentrations in in vitro experiments. GHB had no effect on ^{3}H-muscimol binding , its allostearic modulation by GABA, or ^{35}S-TBPS binding, but did result in a 10-15% decrease in ^{3}H-flunitrazepam binding with no effect on the allostearic modulation of this site by GABA.

At the onset of the SWD induced by GHB there was a significant decrease of ^{3}H-flunitrazepam binding in brain which continued for the duration of the SWD. There was no change of ^{3}H-muscimol binding at the onset of SWD, but one min after SWD onset, the was a significant, albeit transient, increase of ^{3}H-muscimol binding. Allostearic modulation of ^{3}H-muscimol and ^{3}H-flunitrazepam binding by GABA was unchanged throughout the GHB-induced SWD. Scatchard analysis revealed that all significant changes in both the $GABA_A$ and BDZ sites during GHB-induced SWD were due to changes in B_{max}.

These data do not support the hypothesis that the $GABA_A$ site is primarily involved in the genesis of SWD but raise the possibility that the BDZ site might be.

BIOLOGICAL CONSEQUENCES OF TRANSCRANIAL MAGNETIC STIMULATION IN THE MOUSE. SM Hersch, RC Green, JD Weissman*, HD Rees, KR Davey, CM Epstein* and RAE Bakay, Departments of Neurology and Neurosurgery, Emory Univ. School of Medicine, and Department of Electrical Engineering, Georgia Institute of Technology, Atlanta, Georgia.

Transcranial magnetic stimulation (TCMS) is a recently developed technique for non-invasive stimulation of cerebral cortex which has broad clinical and research applications in humans. However, there is little experimental data on physiologic or pathological effects in animal models. Circular coils are usually used in human TCMS and produce a diffuse field that is not useful for small animal studies. Our high-speed magnetic stimulator utilizes a specially designed U-shaped alloy core electromagnet with a gap of 6 cm and pole faces measuring 2.5 cm2. The induced field reliably stimulates human motor and sensory cortex and is painless as long as the poles do not directly contact the scalp. Male inbred C57BL/6 mice, aged 2-4 months were individually placed into an acrylic restrainer so that the head was within the gap of the U-shaped electromagnet, with the rostral/caudal axis perpendicular to the plane of the electromagnet. Peak electric field at the head position was 2.6 V/cm. Each mouse in the experimental group received a daily total of approximately 1000 stimulations, in three 23-second trains of 15 Hz. Stimulation trains were delivered 1-2 minutes apart over 10-15 minutes. Animals were stimulated daily, 5 days/week for 8 weeks and a total of approximately 40,000 stimulations per animal. Sham-stimulated control mice were placed in an adjacent restrainer outside the curve of the electromagnet exposing them to equivalent noise, but to an electric field less than .01 of that found within the gap of the electromagnet. Behavioral responses were the same in both groups of animals and consisted of a brief startle response and urination. No induced motor activity, weakness, or seizures were identified. Immediately following the final stimulation sequence, experimental and control mice were sacrificed, perfused and processed for histology. Blinded evaluations of Nissl and Fink-Heimer stains did not reveal any differences between experimental and control mice. Further comparisons utilizing electron microscopy and post-stimulation kindling rates are underway.

SEIZURE REGULATION BY CHOLINERGIC NUCLEI OF THE PONTOMESENCEPHALIC TEGMENTUM. J.W. Miller, M.E. Bardgett and B.C. Gray*. Dept. of Neurology and Neurological Surgery (Neurology), Washington Univ. Sch. of Med., St. Louis, MO 63110

We have previously shown that the central medial intralaminar nucleus of the thalamus (CeM) regulates both arousal and the threshold of seizures induced by chemical convulsants. This nucleus receives direct projections from cholinergic neurons of the pontomesencephalic tegmentum. The present study investigates the effects of injections of GABA agonists into this tegmental region on seizures induced by timed continuous intravenous pentylenetetrazol infusion.

Injections of the direct $GABA_A$ agonist piperidine-4-sulfonic acid (PSA; 5 to 50 nmoles in 50 nl) in the laterodorsal tegmental nucleus (LDTg, cell group Ch 6) depressed arousal and caused a significant ($p<.01$, Student-Newman-Keuls test) reduction in myoclonic seizure threshold (-47%) and clonic seizure threshold (-44%) relative to controls but had no effect on tonic seizures. The $GABA_B$ agonist (-)baclofen (5 to 30 nmoles in 50 nl) had similar effects on arousal and myoclonic (-35%) and clonic (-30%) seizure threshold ($p<.01$), as well as a trend (-16%, NS) towards lowering of tonic seizure threshold. In contrast, injections of PSA (15 nmoles in 50 nl) in pontomesencephalic cholinergic neurons outside the central gray in the vicinity of the pedunculopontine tegmental nucleus (cell group Ch 5) had no effects on spontaneous behavior or seizure threshold.

This study demonstrates that GABAergic mechanisms in the LDTg control seizure threshold and arousal in a fashion nearly identical to the CeM. We hypothesize that the observed effects of LDTg injections are mediated by its ascending cholinergic connections to the CeM.

EFFECT OF HYPOXIA ON SEIZURE THRESHOLD AND GROWTH ON NEONATAL RATS. W.H. Hoffman*, M.G. Hoffman*, G.F. Carl, B.B. Gallagher, P.K. Morse* and F. Yaghmi*. Depts. of Pediatr., Neurol. and Pathol., Med.Coll. of Ga. and Medical Research V.A. Med. Center Augusta,GA 30912

We evaluated the effect of hypoxia within the first 24 hrs on seizure threshold and growth in male Sprague Dawley pups. Pups were removed from their mothers and randomly assigned to control (air, 7 hrs, 30°C) and experimental (5% O_2, 95% N_2, 7 hrs, 30°C) groups. Body weight was significantly lower ($p<0.001$, t-test) in the experimental group at 10-150 days. Electroshock seizure threshold difference approached significance ($\bar{x}$ control=26.0 mA, $\bar{x}$ experimental= 20.3 mA, $p=0.08$). Discriminant analysis correctly classified 17 of the 18 rats at day 150, using day 150 weight and seizure threshold as predictors of group. No difference in seizure susceptibility was present for auditory or Indoklon stimuli for the two groups. Liver weight, heart weight, and tail length were significantly lower in the experimental group ($p<0.005$) but brain and testicle weights were not. We conclude that neonatal hypoxia permanently impairs growth and may predispose rats to a greater susceptibility to seizures.

PERINATAL HYPOXIA HAS LONGTERM EFFECTS ON EEG ACTIVITY AND SEIZURE SUSCEPTIBILITY IN RATS. F.E.Jensen[1], C.D. Applegate[2], AND M. Chansky[1], [1]Children's Hospital Medical and Harvard Medical School, Boston, MA, 02115, and [2]Univ. of Rochester, Rochester, N.Y.

We have shown that hypoxia acutely induces seizures in immature animals but not in adults (F.Jensen, Soc. for Nsci. Abs., 1989). In order to determine whether perinatal hypoxia induces more longterm changes, we exposed 10 day old Long Evans rat pups to hypoxia ($3\%O_2$) ($n=21$) or anoxia ($0\%O_2$) ($n=13$) and then in adulthood (55-65 days old) analyzed baseline EEG spectra and measured the seizure responsiveness to pentylenetetrazol (45mg/kg i.p.). Animals were compared to nonhypoxic littermate controls. During acute oxygen deprivation, the hypoxic group had more epileptiform EEG changes than the anoxic group.

In adulthood, baseline EEG spectra revealed increased slow activity (0-8Hz) in animals that had been hypoxic or anoxic perinatally compared to the controls. Significantly more animals that had perinatal hypoxia had PTZ induced generalized convulsions ($p<0.05$; $X^2=4.22$, $df=1$) than did controls. However, no difference was found between animals that had undergone perinatal anoxia and controls. No significant differences in latency to seizure onset or in seizure duration were found between the hypoxic or anoxic groups and controls.

These results suggest that perinatal hypoxia can have longterm effects on brain activity and seizure susceptibility in adulthood. Perinatal anoxia also appears to cause longterm changes in brain activity, but no effect on seizure susceptibility could be found. We are currently investigating whether blocking acute seizure activity during hypoxia will reduce these longterm effects. (Supported by NIH-NICHD #HD00807 and the Kaplan Foundation).

MAXIMAL ELECTROSHOCK SEIZURES (MES) IN RATS: ELECTRICAL RECORDINGS FROM CORTEX, FLEXOR AND EXTENSOR MUSCLES AND HEART. J. W. Woodbury and D. M. Woodbury, Dept. Physiol., Univ. Utah Sch. Med., Salt Lake City, UT 84108.

The results are control data for testing the effects of vagal stimulation on MESs. Electrocorticogram (ECoG), electromyograms (EMG) of hindlimb (HL) and forelimb (FL) flexors (Flx) and extensors (Ext), and a chest electrocardiogram (ECG) were recorded on an 8 channnel EEG recorder in awake rats. MESs were initiated by electroshock (150 ma, 60 Hz, 0.2 s). RESULTS. ECoG: Convulsion, 700 µv, 7 Hz spikes lasting 15-20 s, slow fall in size and frequency. Recovery, flat for 20 s; PEDs (paroxysmal epileptic discharges) waxing to 500 µv and waning to zero in 30 s; ECoG normal 90 s later. HL EMG: Flx activity present from onset, lasts 10 s; Ext starts at 2 s, ends at 10-12 s, 5 s before end of seizure in ECoG. FL EMG: Flx appears immediately; Ext starts 1 s sooner and lasts 2 s longer than in HL. ECG: Convulsion: QRS complexes, 2-3 times normal size (bundle branch block?), occur in pairs 0.13 s apart, repeated every 0.8 s. Heart rate (HR) falls from 400 to 150. Recovery. HR rises to 450 at 40 s and falls slowly to normal. ECoG and HR reflect the extreme asphyxia induced by the convulsion.

551.12

IS THE ANTICONVULSANT EFFECT OF NIGRAL INFUSION OF GAMMA-VINYL-GABA (GVG) MODIFIED BY THE GABA A RECEPTOR IN RAT PUPS? S.G.Xu, E.F.Sperber, S.L.Moshé. Depts of Neurology & Neuroscience, Albert Einstein College of Medicine, Bronx, N.Y. 10461

Nigral infusions of GABAergic compounds have provided pharmacological evidence indicating a crucial role for the GABAergic system within the substantia nigra in the control of seizures. Our previous studies showed that nigral infusions of GVG supressed flurothyl-induced seizures in rat pups, while nigrally administratered muscimol (GABA A receptor agonist) or bicuculline (GABA A receptor antagonist) facilitated seizures. In this report, we generated a dose-response curve of the GVG effects and investigated the possible role of nigral GABA A receptors in the mediation of the anticonvulsant effect of GVG in rat pups. Nigral infusions of GVG at a dose ≥ 5 µg significantly delayed the latency of flurothyl seizures compared to controls while doses >10 µg induced sedation. Bilateral nigral infusions of muscimol (100 ng) or bicuculline (100ng) reduced the anticonvulsant effect of GVG.

These findings suggest in rat pups, the optimal dose of intranigrally infused GVG against flurothyl seizures is between 5 and 10 µg/.25µl. There are at least two explanations for the results obtained by the coadministration of the drugs. Since both a GABA A agonist (muscimol) and a GABA A antagonist (bicuculline) had the same effect, one explanation is that the reversal of the GVG effect is due to the algebraic sum of concurrent anticonvulsant and proconvulsant effects. Alternatively, if the muscimol effect is not specific and thus not mediated by the GABA system, our results may suggest that the anticonvulsant effect of GVG may, in part, involve the nigral GABA A receptors.

IN VIVO ON-LINE ANALYSIS OF CYTOCHROME A,A_3 REDOX STATE WITH EEG AND MICRODIALYSIS IN AN UNANESTHETIZED CAT CORTICAL FOCAL EPILEPSY MODEL. D. Garant*, B. Leheta*, B. Vern*, and T. Bleck. Dept. Neurosci., Rush Med Ctr, Chicago, IL, 60612.

Nine cats received bilateral chronic implants onto the pial surface of the suprasylvian gyrus of an 8mm diam. lens for reflectance spectrophotometry of cytochrome a,a_3. Around each lens were ECoG electrodes and a port for CSF collection; a flow-through dialysis fiber traversed the field. Removable lenses allowed intracortical injections without surgical anesthesia, and easy removal of tissue upon termination.

Unilateral tetanus toxin injection (2.5mm subpial) induced focal epileptiform discharges in all cats by 2-7d postinjection, persisting up to 30d; 5 cats had secondary generalized tonic-clonic convulsions.

Tonic-clonic seizures were associated with profound oxidations of cytochrome ≈15% total reflectance (TR), 3-5x max. oxidation after exposure to 95% O_2/5% CO_2; non-generalizing EEG discharges <3s duration were associated with 2-8%TR oxidations, indicating that even focal epileptiform activity places nontrivial metabolic demands on involved cortex.

Results of biochemical and histopathological analyses pending.

Supported by the Epilepsy Foundation of America.

AN ELECTRODE TO RECORD SLOW POTENTIAL CHANGES IN DIFFERENT STRUCTURES OF THE BRAIN IN AWAKE ANIMALS DURING CONVULSION AND SPREADING DEPRESSION. F.A.M.de-Azeredo,C.H.Bonfim*,C. Heringer* & J.Fuzimoto*. Laboratorio de Biociências,Universidade Federal Fluminense, CP 100229,Niteroi,RJ,Brazil.

Cortical slow potential(SPC) usually occur during convulsions and spreading depression(SD) but we do not have any information about the occurrence of SPC in subcortical regions.We know that SPC of SD occur in subcortical areas and can remotely influence cell activity at other regions of the brain.We then decided to develop an electrode to record SPC at different brain structures in freely moving animals. The electrode consists of a 1 cm long isolated silver wire with 0.2 mm dia. 1 mm of the tip is peeled off and immersed in 6% NaClO . The Ag/AgCl tip is then coated with a silicone elastomer (elongation rate of 600%).Convulsions were induced in gerbils by ip picrotoxin (PTX) and SD in rats by KCl microinjection.We recorded SPC at cortex,thalamus,striatum and hippocampus and observed SPC in all these regions after PTX and KCl microinjection. The SPC, which is sometimes accompanied by a decrease in EEG activity, reflects a percentage of cells which became refractory to stimulation and will possibly interfere in the firing activity of other cells.Considering the complex cell network we have in the brain we expect that motor and sensory functions will be influenced by the occurrence of SPC in different regions of the brain.

SUPPRESSIVE EFFECT OF INTERICTAL SPIKES ON EXPERIMENTAL SEIZURES. Z. Elazar, M. SCHWARTZ* and G.P. Friedmann*. Department of Physiology and Pharmacology, Tel-Aviv University, Tel-Aviv, 69978, Israel

An inverse correlation between the frequency of occurance of the interictal spikes (IS) and of seizures was indicated by previous studies. Other studies did not find any relation between the two epileptic phenomena. We studied this problem in experiments on rats anesthetized with urethane. Penicillin epileptic foci were produced on the cortical somatosensory area. Electrical stimuli (100-500 uA, 1 msec) were delivered to the VPl nucleus. The stimuli strength was adjusted until triggering of the IS was effective. Driving of IS was displayed as a graph in which the Trigger Index (TI = rate of stimulation/frequency of IS) was plotted as a function of the rate of stimulation. The rate of stimulation was increased until TI=1, where no spontaneous IS were recorded and all stimuli were effective. A Suppression Rate (SR) above which seizures were suppressed for the period of stimulation was established for each experiment. The SR was close or above the TI=1. The difference between the SR and the stimulation rate which gave a TI=1 varied with the excitability of
the cortex (depth of anesthesia) and the strength of the thalamic stimuli.

These results suggest that in certain conditions the interictal spike has an inhibitory effect on the mechanism generating the seizure. This inhibitory effect accumulates during trains of IS.

EFFECTS OF PHYSIOLOGICAL PARAMETERS ON MOTOR AND SENSORY EVOKED POTENTIALS. J.L.Browning, M.L.Heizer*, and D.S.Baskin Dept. Neurosurgery, Baylor College of Medicine, Houston, TX 77030

Motor evoked potentials(MEP) and sensory evoked potentials(SEP) are useful measures for evaluating and monitoring spinal cord and brain function. We therefore studied the effects of temperature, anesthesia, and pCO2 on SEP and MEP.

Cats were anesthetized with halothane(hal) and SEP and MEP recorded and assessed as described by Simpson and Baskin '87. Temp was varied from 42^{0}C to 28^{0}C. Halothane was varied from 0.5 to 2.2%. The CO2 level was adjusted by ventilation rate to paCO2 of 28 to 120.

MEP amplitude(amp) and latency(lat) increases as temp decreases to 28^{0}C. Likewise, decreasing temp causes an increase in SEP lat. SEP amp reveal a parabolic pattern reaching a maximum at 34^{0}C. The level of hal anesthesia had little or no effect on MEP amp or lat. However, SEP amp diminishes and lat increases with increasing hal anesthesia. The effect of paCO2 is to decrease amp and increase lat for both MEP and SEP.

These results suggest that physiological parameters should be closely monitored when making assessments based on MEP and SEP measurements. Additionally, these parameters have different effects on the MEP than the SEP.

DOSE RESPONSE STUDY OF NIMODIPINE IN ACUTE EXPERIMENTAL SPINAL CORD INJURY. I.B. Ross, C.H. Tator, E. Theriault. Playfair Neuroscience Unit, University of Toronto, 399 Bathurst St., Toronto, CANADA M5T 2S8.

Recent studies of nimodipine treatment in acute experimental spinal cord injury (SCI) in the rat have demonstrated its effectiveness for partially reversing post-traumatic ischemia up to 3 hours after injury. There is also evidence that it improves spinal cord function, as measured by motor and somatosensory evoked potentials. These effects have only been seen when nimodipine is combined with either a vasopressor or a volume expander.

A study being completed in our laboratory at the present time is designed to determine if nimodipine alone, without vasopressor or volume expander, is of any benefit in the treatment of acute experimental SCI in the rat. Thirty minute infusions of .05, .025, .01, .005 or 0 mg/kg of nimodipine after injury are being assessed. Spinal cord blood flow (H2 clearance) and motor and somatosensory evoked potentials are recorded before and after injury and after drug infusion. Preliminary analysis indicates that nimodipine alone is not able to reverse post-traumatic ischemia or improve function as measured electrophysiologically. Supported by Miles Inc. and Rick Hansen Man in Motion Legacy Fund.

RAPID CLEARANCE OF $[K^+]_o$ FOLLOWING SPINAL CORD CONTUSION IN RAT. M. Chesler, K. Sakatani, Z. Hassan* & W. Young, Dept. of Neurosurgery, NYU Med. Ctr., 550 1st Ave. N.Y. N.Y. 10016.

In cat spinal cord, contusion causes a large increase in extracellular potassium ($[K^+]_o$)(Young, W. et al., Brain Res. 253: 115, 1982). After rising rapidly to a mean of 54 mM, $[K^+]_o$ cleared slowly ($t^{1/2}$ = 45 min.). While rats rather than cats are increasingly used to study spinal injury, comparable data on $[K^+]_o$ are not available. We have therefore studied $[K^+]_o$ following contusion of the rat cord.

Adult Long-Evans rats were anesthetized with pentobarbital, paralyzed and artificially ventilated. Arterial pressure was recorded and sciatic-evoked cortical SEP's monitored. After a T9-11 laminectomy, a 10 gm piston was dropped 5 cm onto the dorsal surface of the cord, with the verterbral column clamped and dura intact. Within 5 min., the dura-arachnoid and pial membranes were incised allowing insertion of a double-barreled K^+-selective microelectrode (valinomycin).

Within 9 minutes of injury, the peak $[K^+]_o$ was 63 ± 9 mM (mean ± SEM, n = 7 rats). In several instances, a gradient of $[K^+]_o$ was noted, the peak value occuring below 500 µm. Compared with previous studies on cats, $[K^+]_o$ cleared rapidly, with a mean $t^{1/2}$ of 12 ± 3 min. The cortical SEP did not recover, despite the return of $[K^+]_o$ to physiologic levels within one hour.

These data demonstrate that after severe spinal contusion, the dynamics of $[K^+]_o$ differ markedly in cat and rat. The rapid clearance in rat may be due to a smaller absolute volume of injured tissue, as well as differences in post-traumatic blood flow. In evaluating mechanisms of secondary injury in the rat cord, our results indicate that $[K^+]_o$ elevation must be considered a relatively transient phenomenon.

552.4

SIGNIFICANT SECONDARY PATHOLOGY IN SPINAL CORD TRAUMA DELAYED BY MORE THAN 24 HOURS. Andrew R. Blight. Ctr. for Paralysis Res., Purdue Univ., W. Lafayette, IN 47907.

Most concepts of secondary pathology in central nervous system trauma have concerned rapid processes of membrane biochemistry, toxin release, edema or ischemia. Evidence of a more delayed damage to axons was described previously from a model of spinal cord contusion in cats (Blight, A.R., *Cent. Nerv. Syst. Trauma* 2: 299, 1985). A functional measurement of such delayed pathology has been possible in a new model of spinal cord injury in guinea pigs. Following lateral compression of the cord at T13 with a specially designed pair of forceps, under ketamine / xylazine / acepromazine anesthesia, animals awoke within a few hours with little or no neurological deficit . From 24-48 hours after injury there was a rapid loss of sensory and motor function below the level of the lesion. Normal hindlimb posture, locomotion and placing responses were lost, together with pain appreciation. The cutaneus trunci muscle reflex of the skin and the free-fall toe-spreading response of the hindlimbs were used to quantify these behavioral deficits over time. Some of the animals recovered most or all of the secondarily lost function within 2-3 weeks after injury. Others remained paralyzed for the 2-3 month duration of the study. The most significant secondary pathology in the guinea pig model appears to be delayed to times well beyond the expected window for numerous proposed mechanisms: lipid peroxidation, lysosomal enzyme or excitatory amino acid release, hemorrhage, edema, ischemia, calcium influx etc. It fits more closely with the time-course of inflammatory responses occurring in the tissue. Similar delays in other injury models may be hidden by some form of "spinal shock". (Supported by grant NS 21122 from NIH/NINDS).

CHANGES IN BONE FORMATION IN NEONATALLY SPINAL CORD TRANSECTED RATS. V.R. Holets, E. Gunther*, E.L. Hill, C. Cone* and E. Morey-Holton*. The Miami Project, University of Miami, Miami, FL 33136 and NASA-Ames Research Center, Moffett Field, CA 94035.

The mechanism of bone loss following spinal cord trauma is not understood. The purpose of this study was to investigate the rate of bone formation following transection of the spinal cord in neonatal rats that recover some function of their hindlimbs post-lesion. A complete spinal cord transection was done at the T8 spinal cord level in 5 day old rats. Sham lesioned animals served as controls. The rats received alternate (fluorescent) calcein and declomycin injections (s.c.) at 30, 37, 72 and 89 days post-lesion (DPL) to label bone formed during different periods and were sacrificed 90DPL.

Transverse sections (50 um) of tibial diaphyses at the level of the tibiofibular junction were used for bone histomorphometry. Tibial length, medullary area, and cortical area (30DPL and 90DPL) were significantly smaller in lesioned animals as compared to controls. Other bones, above and below the lesion, were evaluated for mechanical properties and trabecular bone histomorphometry. During the period 30-37DPL periosteal bone formation rates were the same in lesioned and control animals (.051 mm2/day), but by 72-89DPL the formation rate in lesioned animals (.013 mm^2/day) was less than that of control animals (.019 mm2/day, $p \leq .01$). This indicates that 1 month after lesion, bone is formed at a normal rate in the tibia. The difference in length and areas of lesioned and control bones 2 months later may be due to an initial lag in growth immediately after lesion that is never compensated for although formation rates return to normal; a decrease in bone formation in older animals, possibly due to secondary changes (neuropathy); or a combination of these. Differences in the cross-sectional shape of the tibiae in lesioned animals indicate that they may use their hindlimbs differently than normal.

A SENSITIVE FLUOROMETRIC METHOD FOR MEASUREMENT OF VASCULAR PERMEABILITY IN SPINAL CORD INJURY. Z.X. Qu*, J. Xu*, P.L. Perot, Jr.*, N.L. Banik and E.L. Hogan. Depts. of Neurology and Neurosurgery, Med. Univ. of S. Carolina, Charleston, SC 29425-2232

A sensitive fluorometric method was modified for the evaluation of drug action upon rat spinal cord injury. Fluorescein isothiocyanate-labeled dextran (FITC-D, MW 71,200) used as a tracer, was injected IV 2 hr before sacrifice. pH 8.2 was optimal for fluorescence with FITC-D. The recovery in spinal cord was 100.1 ± 4.0% (X ± SD). The extent of FITC-D extravasation was expressed as the vascular injury index (VII).

$$VII = \frac{\text{ng of FITC/mg tissue protein}}{\text{ng of FITC/10 ul of plasma}}$$

and increased in proportion to the trauma force. The VII were 0.16 ± 0.04 (20 g-cm), 0.31 ± 0.03 (40 g-cm), 0.42 ± 0.10 (100 g-cm) and 0.03 ± 0.01 (sham). The peak VII after trauma was at 2 hr. U-50488H (a K opiate agonist) decreased the VII in traumatic cord (0.11 ± 0.03) compared to control (0.16 ± 0.06) at 20 g-cm trauma (X ± SD, n = 6 in each group). This fluorometric method is sensitive, simple and reliable for evaluation of drug effects upon vascular permeability in CNS trauma. Supported by grant NS-11066 from NINDS.

REGENERATION OF PERIPHERAL NERVES IN PRIMATES THROUGH SEMI-PERMEABLE SYNTHETIC GUIDANCE CHANNELS. M. Goddard*, R. Valentini, J. Cohen and P. Aebischer. Section of Artificial Organs, Biomaterials, and Cellular Technology., Brown University, Providence, RI, 02912.

As part of an effort to develop devices that may improve functional recovery following surgical repair of peripheral nerve injuries, semi-permeable nerve guidance channels (AC) made of the copolymer, poly (acrylonitrile vinyl chloride) were used to repair transections of the recurrent branch of the median nerve in a group of 5 cynomologous monkeys. Nerve transections in one hand were repaired with AC channels and the recovery compared to that of identical lesions on the contralateral side which were repaired with impermeable control channels made of silicone elastomer (SE). Functional recovery was evaluated daily using a timed behavioral paradigm and at the conclusion of the 1 year implantation interval using open electrophysiology. Morphologic evaluation of the regenerated nerve cables was based on myelinated axon counts. Results of the behavioral testing indicated that excellent functional recovery was achieved in this model with both guidance channel designs, however, return to pre-lesion performance levels was faster with the AC devices. The electrophysiology studies demonstrated a mean combined muscle action potential and stimulus threshold of 2.9±2.3 V and 208±53.6 μA respectively for the AC channels versus 2.1± 1.1 V and 252±173.6 μA respectively for the SE channels. Mean regenerated myelinated axon counts were 2476±516 for the AC devices and 1885±727 for the SE devices. The results of this study confirm previous rodent studies which indicated that semi-permeable AC nerve guidance channels show improved regeneration relative to impermeable channels and may hold promise for clinical repair of nerve injuries.

GLUTAMATE NEUROTOXICITY IN SPINAL CORD CELL CULTURE. R.F. Regan and D.W. Choi. Dept. of Neurology, Stanford Univ. Med. Sch., Stanford, CA 94305.

The neurotoxicity of glutamate was investigated quantitatively in mixed neuronal and glial spinal cord cell cultures from E12 - 13 fetal mice. Five minute exposure to 10 - 1000 μM glutamate produced widespread acute neuronal swelling, followed by neuronal degeneration over the next 24 hr (EC_{50} for death about 100-200 μM); glia were not injured. Glutamate was neurotoxic in cultures as young as DIV 4, although greater death was produced in older cultures. By DIV 14 - 20 approximately 90% of neurons were destroyed by a 5 min exposure to 500 μM glutamate.

Acute neuronal swelling following glutamate exposure was prevented by replacement of extracellular sodium with equimolar choline, with minimal reduction in late cell death. Removal of extracellular calcium enhanced acute neuronal swelling but attenuated late neuronal death. Both acute neuronal swelling and late degeneration were effectively blocked by the noncompetitive NMDA receptor antagonist dextrorphan and by the novel competitive antagonist CGP 37849. In contrast, 100 μM 6-cyano-7-nitroquinoxaline-2,3-dione (CNQX) in the presence of 1 mM glycine produced only weak neuroprotection. 7-chloro-kynurenate also inhibited glutamate neurotoxicity, with near complete protection noted at 10 μM; protection was completely reversed by the addition of 1 mM glycine to the bathing medium.

These observations suggest that glutamate is a potent and rapidly acting neurotoxin on cultured spinal cord neurons, and support involvement of excitotoxicity in acute spinal cord injury. Similar to telencephalic neurons, degeneration of spinal neurons induced by brief glutamate exposure is dependent on extracellular Ca^{2+} and the activation of NMDA receptors.

552.9

COMBINED N-METHYL-D-ASPARTATE (NMDA) BLOCKADE AND HYPOTHERMIA (HT) AS A TREATMENT FOR NEURITE TRANSECTION INJURY. G. Wang, J. H. Lucas and G.W. Gross. Center for Network Neurosci., Dept. of Biol. Sci., Univ. of North Texas, Denton, TX 76203.

We have previously reported that temperature reduction to 17°C for 2 h significantly increased the percentage of neurons which survived amputation of a primary dendrite. (Br. Res. 517: 354). Below 17°C, however, both lesioned and uninjured neurons showed dendrosomatic swelling, and, upon rewarming to 37°C, most swollen neurons died (ibid.). We conducted studies to determine: 1) whether swelling during HT involves the NMDA complex, and 2) whether NMDA blockade + HT increases lesioned neuron survival more than HT alone.

Mouse spinal cord (SC) neurons were grown in monolayer cultures. In Study I, 10-15 neurons in each culture were selected for observation. In 3 groups (3-9 cultures/group) the maximum nontoxic concentration of ketamine (100 μM), MK801 (10 μM) or D-APV (30 μM) was added to the medium. No antagonist was added to control cultures. Cultures were kept 2 h at 10°C and 22 h at 37°C. NMDA antagonists minimized swelling during HT. At 24 h only 10% of the selected neurons in each experimental group had died compared to 74% of the controls.

In Study II, a laser microbeam was used to amputate a primary dendrite from each of 10 neurons in each culture (distance from soma = 100 μm). After cell surgery the culture medium was replaced with medium at 10°C, 17°C, or 37°C. D-APV (30 μM) was added to 5 of the 10 cultures at each temperature. Each culture was kept 2 h at its initial temperature, and then 22 h at 37°C. In the groups with initial temperatures of 10°C, 17°C, and 37°C, 24 h survival in the presence or absence of D-APV was 58% ± 10 (SD) vs. 25% ± 13, 66% ± 9 vs. 60% ± 7, and 46% ± 7 vs. 43%± 9 respectively. We conclude that NMDA blockade: 1) protects SC neurons from HT injury, but, 2) compared to HT (17°C) alone, does not significantly increase neuron survival after a transection-type mechanical injury.

NEUROTRANSMITTER RELEASE FOLLOWING IMPACT INJURY AND GLUTAMATE NEUROTOXICITY IN THE RAT SPINAL CORD. Danxia Liu and David J. McAdoo. Marine Biomedical Institute, University of Texas Medical Branch, Galveston, TX 77550

Worsening of damage to the spinal cord following initial injury has been attributed to release of damaging substances including neurotransmitters. To investigate this, we sampled released neurotransmitters following impact injury with a dialysis fiber inserted transversely through the rat spinal cord. Glutamate, aspartate, and serotonin, but not norepinephrine, increased substantially following injury. Much of the serotonin detected may come from bleeding. For two hours after impact glutamate and aspartate were estimated to be in a range that can kill neurons. $MgCl_2$ administered through the dialysis fiber reduced the release of the excitatory amino acids, suggesting that part of the ameliorating effect of Mg^{2+} on experimental CNS injury could result from reduced release of excitatory amino acids. NMDA and kainate were administered through the dialysis fiber while stimulating the sciatic nerve and recording field potentials from the dorsal surface of the cord. Responses clearly decreased over 4 h of administration, and histology demonstrated damaged cells.

PRETREATMENT WITH NMDA ANTAGONISTS LIMITS RELEASE OF EXCITATORY AMINO ACIDS FOLLOWING TRAUMATIC BRAIN INJURY. S. S. Panter and A. I. Faden. Department of Neurolgy, V.A.M.C., San Francisco, CA 94121.

After central nervous system trauma, there are marked elevations in the extracellular levels of excitatory amino acids, which are believed to contribute to delayed tissue damage. Administration of NMDA antagonists reduces injury severity after brain or spinal cord trauma, presumably by blocking the postsynaptic NMDA receptor. In the present studies, levels of extracellular excitatory amino acids were monitored by microdialysis during, and after, a moderately severe (2.8 atmosphere) lateral fluid percussion brain injury to rats, as previously described (Science, 244:798-800, 1989). At the end of the first sampling interval, 10 minutes following injury (n = 6), extracellular glutamate and aspartate increased 20- and 15-fold, respectively, over controls (n = 8). Pretreatment (15 min. prior to injury) with the non-competitive NMDA antagonist dextrorphan (10 mg/kg i.v., n = 4) or the competitive NMDA antagonist CGS 19755 (30 mg/kg i.v., n = 5) significantly attenuated the posttraumatic increase in extracellular glutamate (from 110.9 ± 26.6 (SEM) μM in dialysate from untreated animals to 51.5 ± 7.6 and 64.5 ± 11.2 μM, respectively; $p < .05$ for both groups). Pretreatment with dextrorphan attenuated the posttraumatic increase in extracellular levels of aspartate (15.7 ± 4.3 μM in untreated animals to 10.6 ± 2.1 μM in dextrorphan treated animals); although these differences did not reach significance when examined as absolute values, they were sign when analyzed as percent increase over pre-trauma baseline levels. These results are consistent with recent in vitro experiments and suggest that dextrorphan and CGS 19755 may limit the release of glutamate and aspartate after trauma through mechanisms involving presynaptic modulation.

552.12

THE EXPRESSION OF HEAT SHOCK PROTEIN AFTER BRAIN INJURY IN THE RAT: COMBINED EFFECT OF NMDA ANTAGONIST, VOLTAGE-DEPENDENT CALCIUM BLOCKER, AND A FREE RADICAL SCAVENGER. T. Sanada, L.H. Pitts*, and M.C. Nishimura*. Dept of Neurosurgery, San Francisco Gen'l Hosp and Univ. of Calif., San Francisco CA, 94110.

The pathobiology of head injury has been attributed to a variety of physiological and biochemical events. Given the variety of derangements, we hypothesize that a combination of therapeutic agents may be more efficacious than any single therapy. We examined the effects of combined therapies after brain injury, using the expression of heat shock protein (HSP) as a marker for stressed neurons. Rats were subjected to a temporal fluid percussive brain injury followed by 45 min of hypoxia. Animals were divided into 5 groups: I. saline , II. U74006F (a free radical scavenger) + nimodipine (Ca++ channel blocker), III. U74006F + CGS19755 (an excitatory amino acid antagonist), IV. nimodipine + CGS19755 and V. U74006F + nimodipine+ CGS19755. U74006F (10 mg/kg), CGS (10 mg/kg) or saline were given 10 min (i.v.), and 12 and 24 h (i.p.) after impact. Nimodipine pellets (20 mg) were implanted (s.c.) 10 min after injury. At 72 h post injury sections were prepared for HSP immunocytochemistry , using a monoclonal antibody directed against HSP 72.

The percentage of rats demonstrating HSP 72 immunoreactivity (IRR) in the temporal cortex, parasaggital cortex, caudate-putamen, and hippocampus was calculated for Groups I-V as follows: I- 29, 43, 14, 43, II- 0, 18, 9, 18; III.- 0, 13, 0, 0; IV.- 0, 0, 0, 20; V. 8, 8, 8, 8. Groups III and V showed significantly less IRR in the hippocampus. This preliminary data suggest that combined therapy may ameliorate the expression of heat shock proteins in neurons.

552.13

Intravenous Administration of Heat Shock Protein-70 (HSP-70) Stevens FA*,Gower DJ Section on Neurosurgery and Anatomy, Univ. Of Oklahoma, OKC

Endogenous HSP's are protective for cellular stress. Berbarian et. al 1989 found that exogenous HSP-70 protected cultured cells. We have examined the fate of HSP-70 following intravenous administration in a mammal.

HSP-70 was purified from bovine brain (Schmidt and Rothman 1985). The purified protein was labeled with I-125 and the purity demonstrated by SDS-PAGE. Anesthetized adult rats were administered 25 ug of labeled HSP-70 combined with 10 uCi of TC-99M labeled albumin. Blood and tissue samples were harvested and examined. Initial counts were done in the energy range for the TC-99M. The tissue was allowed to decay for at least 12 half-lives and recounted for I-125.

The albumin space for each organ was determined and the amount of HSP-70 above the amount accounted for by vascular space was calculated. Liver 171.04ng/g,spleen 183 ng/g, kidney 63.33ng/g, and lung26.72ng/g were the only organs to uptake HSP-70. The brain and spinal cord had no selective uptake above vascular space. These data suggest that HSP-70 may be administered intravenously but the usefulness in CNS disease will be limited by an intact blood brain barrier.

MEASUREMENT OF RHEOLOGICAL PROPERTIES OF INDIVIDUAL NEURONAL CELLS IN RESPONSE TO TRAUMA. T.C Hung*, R.M. Lewis and T.K. Hung. University of Pittsburgh, Pittsburgh, PA 15261.

We are developing a technique for measuring rheological properties of individual neuronal cells. We plan to use this technique to determine how neurons might be affected by mechanical forces, such as those experienced in physical trauma. The technique also will be used to quantify the adhesive properties of neuronal cell adhesion molecules. Dissociated neuronal cells are grown on substrates of varying adhesive properties, or on monolayers of glial cells. The cells are transferred to, or grown in, a chamber which is attached to a pump capable of delivering a controlled flow of solutions of chosen viscous properties. This chamber is placed on a microscope set up for videotape recordings. The shear stress necessary to deform, detach or disrupt individual cells is determined. Cells are seeded onto patches of purified neuronal cell adhesion molecules. The relative adhesiveness of the molecule is determined by the fluid shear force required to dislodge the cell. This technique can be utilized to quantify the adhesive regions of proteolytic fragments or deletion and point mutation products of cell adhesion molecules.

DEGENERATIVE DISEASE—PARKINSON'S: MPTP MONKEYS AND RODENTS

553.1

EARLY BEHAVIORAL AND NEUROCHEMICAL CHANGES CAUSED BY MPTP IN MONKEYS. I. Irwin*, L.E. DeLanney, L.S. Forno, K.T. Finnegan, D.A. Di Monte, and J.W. Langston. California Parkinson's Foundation and California Institute for Medical Research, San Jose, CA 95128.

In this study, the acute evolution of the neurotoxic effects of MPTP were evaluated in the monkey model. Squirrel monkeys (n=17) were given a single subcutaneous injection of MPTP (2.5 mg/kg). The behavioral changes were monitored and the concentrations of dopamine (DA), dihydroxyphenylacetic acid and homovanillic acid were measured in the striatum and substantia nigra 1, 3, 5 and 10 days after drug administration. Neuropathological examination of two animals 8 and 9 days after MPTP revealed severe nerve cell destruction in the substantia nigra. MPTP produced severe parkinsonian behavior changes in all animals after 1 day. Interestingly, although 50-75% reductions were observed in the substantia nigra 1 and 3 days after MPTP, DA was not reduced in the caudate and, actually, was increased in the putamen at these time points. Five and 10 days after MPTP, nigral DA depletion remained greater than 60% of control and striatal DA was reduced 50-85%. At these time points, the putamen was always more affected than the caudate. DA metabolites were decreased in both the substantia nigra and striatum at all time points. These results indicate that: (a) nigral cell bodies may represent an important initial site of MPTP-induced damage; and (b) the interregional pattern of striatal DA deficits caused by MPTP is similar to that seen in idiopathic Parkinson's disease.

553.2

QUANTIFICATION AND TOPOGRAPHY OF MIDBRAIN DOPAMINERGIC NEURONS IN NORMAL AND MPTP-TREATED RHESUS MONKEYS. A.C.Cummins*, K.Bankiewicz, R.Plunkett*. Surg. Neurol. Branch, NINDS, NIH

This study quantifies the tyrosine hyrdoxylase - immunoreactive (TH-IR) cells in the A8-A13 areas of normal and MPTP treated monkeys. Monkeys (n=7) were individually caged and given free access to food and water. Procedures were approved by NINDS Animal Care and Use committee.

Four monkeys received MPTP (0.4 mg/kg by intracarotid infusion) and developed hemiparkinsonism. Four to six months after treatment these and three normal monkeys were euthanized. Brains were cut serially at 25 um and every 15th section stained for TH-IR. Adjacent sections were stained with thionin and for dopamine beta hydroxylase-IR.

TH-IR cells were decreased in MPTP-treated monkeys by 88-96% in A9 and 60-72% in A10. The medial portion of A10 was relatively spared. These cells are likely to represent the population from which sprouting dopaminergic fibers; seen in the caudate of transplanted monkeys, arise. Preliminary data from areas A8 & A11-A13 show no significant depletion after MPTP treatment.

553.3

QUANTITATIVE EFFECTS OF ACUTE MPTP-TREATMENT ON BEHAVIORAL AND BIOCHEMICAL INDICES OF DOPAMINE FUNCTION IN MONKEYS. J.R. Taylor, J.D. Elsworth, R.H. Roth, J.R. Sladek, Jr.†, and D.E. Redmond, Jr. Depts. of Psychiat. & Pharm., Yale Univ. Sch. of Med., New Haven, CT 06510, and † Dept. of Neurobiol. & Anat., Univ. of Rochester, School of Med. & Dent., Rochester, NY 14642

The neurotoxin MPTP produces effects in primates which appear similar to Parkinson's disease. The development of a useful animal model of this disorder requires accurate assessment of the quality, severity, duration of the effects, and complications of this treatment.

Sixty *Cercopithecus aethiops sabaeus* were treated with MPTP (0.3-0.4 mg/kg, 4-5 times, cum. dose 1.2 - 2.4). Trained observers 'scored' and 'rated' behavior twice daily (5 min, 5 x week) for varying periods after MPTP. Scored behavior was one-zero scored (e.g. freeze, immobility, chew, yawn) or scored per 5 sec duration (e.g. eating, drinking). Behaviors were also quantitated on a rating scale of 0-5 (e.g. poverty of movement, limb and head tremor) and after 'challenges' (e.g threat). Individual behaviors were analyzed, as well as summary scores for parkinsonian-, healthy-, anxiety-, and arousal-related behavior. Levels of CSF HVA were determined. In some subjects, performance was also examined on 'executive' or cognitive tasks.

MPTP resulted in behavior not observed in control subjects (i.e., tremor, freezing, immobility, eating problems, delayed and poverty of movement) and reduced signs of healthy, arousal, and anxiety associated behavior. The parkinsonian summary score was used to categorize the severity of MPTP deficits. Identical doses and treatment schedules led to behavioral deficits ranging from extremely mild to severe. All MPTP subjects had reduced levels of HVA in CSF at sacrifice. Medical and physiologic complications analogous to those observed in parkinsonian patients were also observed.

BEHAVIORAL EVALUATIONS OF MPTP-INDUCED HEMIPARKINSONISM IN RHESUS MONKEYS. R.D. Smith*, R.M. Kurlan*, M.H. Kim*, Z. Zhang*, L.A. Cunningham and D.M. Gash.

Department of Neurobiology and Anatomy, University of Rochester, Med. Ctr., Rochester, NY 14642

When induced in monkeys, hemiparkinsonism has been associated with contralateral motor dysfunctions, including bradykinesia and spontaneous rotation. We have developed a diagnostic system to assess the efficacy of hemiparkinsonism as a model for Parkinson's disease (PD). Multiple clinical evaluations were done over 4-5 months before and after MPTP was administered unilaterally to 4 adult female rhesus monkeys. Completeness of MPTP lesions was indicated by apomorphine-induced rotations and behavioral impairment. Monkeys were observed continuously using computer-assisted, infrared activity monitors. For the course of the experiment, the amount of activity changed in only one animal (up 40% due to spontaneous rotation after lesion). A 24-item rating scale developed to assess parkinsonian features (eg., tremor) and general behavioral responses (eg., grooming) was used to monitor the course of impairment. Ratings indicated that the maximal effect of the lesion occurred at 10-15 days. Not all monkeys demonstrated the full range of symptoms characteristic of hemiparkinsonism. Impairment was variable (range=52-91%) and the severity of parkinsonism diminished by 27+/-17%. This partial recovery occurred within 20 days and had stabilized at 8 weeks. The use of an afflicted limb often varied with the type of challenge. Thus, symptoms routinely associated with hemiparkinsonism in non-human primates reflect only some of those symptoms normally associated with PD.

Supported by NIH grant NS 25778 and the PEW Foundation.

553.5

EFFECTS OF LOCUS COERULEUS LESIONS ON MPTP-INDUCED PARKINSONISM IN SQUIRREL MONKEYS. Mihalis Mavridis*, A.J. Lategan*, A.-D. Degryse*, M.R. Marien and F.C. Colpaert, FONDAX-Groupe de Recherche SERVIER, 92800 Puteaux, France.

Female squirrel monkeys (7 pairs, 550-750 g) received daily i.p. injections of n-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP; 0.63-1.25 mg/kg) for 9-14 days, beginning on the day of either a bilateral 6-hydroxydopamine lesion of the locus coeruleus (LC) or a sham operation. Seven to nine weeks after the start of MPTP treatment, and in marked contrast to the sham-operated animals, the LC-lesioned monkeys showed a profound decrease in striatal dopamine levels (>84% depletion), extensive cell loss in the substantia nigra, and little or no recovery from the parkinsonian motor symptoms (tremor, bradykinesia, hypokinesia and reduced blink rate) induced by MPTP.

These neurological, biochemical and histological assessments indicate that lesioning of the LC impairs the recovery which typically occurs from the parkinsonian manifestations induced by MPTP in squirrel monkeys. Results of this study support the hypothesis (F.C. Colpaert, Neuropharmacol. 26: 1431, 1987) that deficient LC-noradrenergic mechanisms might play an underlying role in the progression of Parkinson's disease.

553.6

EFFECTS OF D1 AND D2 AGONISTS AND ANTAGONISTS ON DYSKINESIA PRODUCED BY L-DOPA IN MPTP-TREATED MONKEYS. B.G. Mancilla, R. Boucher, and P.J. Bédard. Lab. of Neurobiology, Univ. Laval and Hosp. Enfant-Jésus, Québec, CAN. G1J 1Z4.

In order to study pharmacologically the action of D_1 and/or D_2 receptor agonist on dyskinesia produced by L-DOPA, we performed the following experiment. A group of 5 female cynomolgus monkeys (±3kg) was rendered parkinsonian by one or repeated doses of MPTP (0.3-10 mg/kg). At least two months after the last injection, a daily oral treatment with L-DOPA/carbidopa 150/37.5 mg was begun and continued for two months. All animals showed evident dyskinesia mainly in the lower limbs starting at 6 weeks of treatment. After two months, several days a week the daily dose of L-DOPA was replaced by an experimental agent and the animal monitored for dyskinesias and other effects. All D_2 agonists (dose in brackets in mg/kg) reproduced the same dyskinesia as L-DOPA, Quinpirole (0.01, 0.1), PHNO (4μg), Bromocriptine (5).

The partial D_2 agonists terguride (5) and -3-PPP (5) also reproduced the same dyskinesia. The D_1 agonist SKF (5) was without effect and so was the D_1 agonist CY208243 at dose of 0.1. However a dose of 0.5 mg/kg of CY208243 induced some dyskinesia.

The D_1 antagonist SCH23390 (0.05) as well as th D_2 antagonist Sulpiride (30) were without effect by themselves. However, dyskinesia induced by Quinpirole could be antagonized by SCH23390 as well as by Sulpiride and prevented by previous treatment by alpha-methyl-paratyrosine. Our results show that although dyskinesia are mediated mainly by D_2 receptors, D_1 receptor activation appears necessary for their manifestation. Supported by MRC of Canada and Parkinson Foundation of Canada.

PHARMACOLOGICAL MANIPULATION OF COGNITIVE PERFORMANCE AND IMPERSISTENCE IN MOTOR ASYMPTOMATIC MONKEYS CHRONICALLY EXPOSED TO MPTP. C.J. Kovelowski, II and J.S. Schneider. Dept. of Neurology, Hahnemann University School of Medicine, Philadelphia, PA. 19102.

Monkeys exposed to low doses of MPTP over several months have been shown previously to develop specific cognitive deficits in the absence of overt motor disturbances. In the present study, three M. nemistrina monkeys were trained to perform delayed response (DR), delayed match-to-sample (DMS), visual discrimination (VD), object discrimination reversal (ODR), and object retrieval (OR) tasks. Thus far, monkeys have received up to 4 months of MPTP treatment (0.05-0.15mg/kg, i.v.) given 2-3 times/wk. In all animals, DMS was the task most sensitive to disruption. In time, performance of ODR, OR, and DR was also disrupted. In contrast, VD performance has remained intact. In addition to performing the previously learned tasks incorrectly, animals demonstrated striking impersistence during attempted task performance with many incomplete trials recorded. On the object retrieval task, after numerous MPTP injections, animals consistently failed to retrieve food that was not readily accessible via direct line of sight. These animals continue to do poorly and fail to make appropriate detour movements even when shown how by the experimenter. Preliminary pharmacological studies have shown that the dopamine D2 agonist LY-171555 and to a lesser extent, the nonspecific agonist apomorphine reduce the impersistence in these animals. While monkeys can complete the trials more consistently under these drugs, their cognitive performance is not improved. The partial D1 agonist SKF-38393 caused a slight but insignificant improvement in the impersistence and also did not help cognitve performance. Clonidine, an alpha 2 adrenergic agonist significantly improved DR performance. The effects of other drugs will also be discussed. The results thus far suggest that the mechanisms responsible for impersistence and the correct performance of the cognitive tasks may be different. 6-[^{18}F]FLUORO-L-DOPA METABOLISM PARALLELS DOPAMINERGIC SYSTEM CHANGES IN MPTP-TREATED MONKEYS. W.P. Melega, J.S. Schneider, M.E. Phelps, and J.R. Barrio*. UCLA School of Medicine, Los Angeles, CA 90024

6-[^{18}F]Fluoro-L-DOPA (FDOPA), an L-DOPA analog, is used with positron emission tomography (PET) for the in-vivo assessment of the functional integrity of presynaptic dopaminergic mechanisms in humans. The significance of these studies is, however, dependent upon the demonstration that the biochemistry of FDOPA can be correlated with that of the endogenous dopamine system. In the present work, two unilateral MPTP-treated monkeys and three controls, pretreated with carbidopa (5 mg/kg, i.v.) were administered FDOPA (5-8 mCi, i.v.) and sacrificed 60 min later. Putamen, caudate, frontal cortex , and cerebellum were dissected and analyzed by HPLC for endogenous catecholamine and FDOPA metabolite levels. For both MPTP treated monkeys, lesioned side dopamine (DA) and 6-[^{18}F]fluorodopamine (FDA) levels were reduced by at least 98% when compared with controls; DA and FDA metabolites were also significantly reduced. The homovanillic acid (HVA):DA ratio, an index of dopamine turnover, increased to 7:1 from control values of 1.9:1. Similarly, the 6-[^{18}F]fluorohomovanillic acid (FHVA): FDA ratio increased to 6.4:1 from 0.34:1 (controls). In one MPTP-treated monkey that also sustained a partial contralateral lesion, DA and FDA levels were reduced 84 and 81% respectively; metabolite levels and turnover ratios were intermediate between those of controls and total lesions (HVA:DA 4.3:1; FHVA:FDA 1.4:1). These results indicate that analysis of human PET studies with kinetic models to distinguish FDA storage from clearance can provide evidence of DA turnover changes in vivo.

EFFECTS OF MPTP ON ENKEPHALIN-, SOMATOSTATIN- AND SUBSTANCE P-CONTAINING NEURONS IN MOUSE BRAIN. K.Mitsuo*, J.D.Harvey-White* and J.P. Schwartz. Clinical Neuroscience Br., NINDS, NIH, Bethesda, MD 20892

We have examined the effects of MPTP on three neuropeptides, met-enkephalin (ME), somatostatin (SS) and substance P (SP), which have been observed to change in Parkinsonian brains. MPTP (4 x 24 mg/kg i.p., MPTP-HCl) was given to young adult C57Bl mice. Mice were sacrificed 1 day to 6 wks later and dopamine(DA) and its metabolites (DOPAC, HVA), as well as the peptides and their precursor mRNA levels were measured in striatum (ST), olfactory tubercle (OT) and prefrontal cortex (PF) of the same animal. DA content was depleted 70% in ST and 40% in OT with no change in PF except for a decrease of HVA. ME increased in all three regions. Proenkephalin mRNA increased in OT, decreased in PF,and decreased at 1 day but increased at 3 days in ST. Both SS and SS mRNA increased in PF. SP mRNA decreased in ST. These data suggest that MPTP can differentially affect these neuropeptides. The discrepancy between the expected effects due to DA loss and the actual changes observed suggest that MPTP can affect these neurons not only through DA loss but also by some direct action.

CHANGES IN DOPAMINE (DA) RELEASE IN VITRO FROM THE CORPUS STRIATUM (CS) OF YOUNG AND AGED RATS AS A FUNCTION OF INFUSION MODE OF L-DOPA, K^+ AND AMPHETAMINE (AMPH). J. McDermott, D. Dluzen, and V. Ramirez. Departments of Medicine-Carle Hospital and Physiology and Biophysics, University of Illinois, Urbana, IL 61801.

We have reported differences in DA release in vitro from the CS of young versus aged rats in response to a pulse infusion of L-DOPA (Dluzen, et al. Exp. Neurol., 106:259, 1989). In the present experiment, CS tissue fragments from young (Y:2-4 months) and aged (A:18-24 months) male rats were superfused in vitro and received either two 10 min pulses (80 min inter-pulse interval) or continuous (120 min) infusions of L-DOPA (5μM), K^+ (30 mM) or AMPH (10μM). For both young and aged rats the peak response ratios of the second/first response for the two infusions were virtually identical for K^+ (Y=0.3±.07, N=4 vs A=0.42±.05, N=7) and AMPH (Y=0.46±0.8, N=4 vs A=0.46±.03, N=6). However, there was a significant difference ($p<.005$) in response to L-DOPA pulse infusions (Y=2.48±0.33, N=7 vs A=1.24±0.17, N=7). Overall DA release to continuous infusions ($\bar{x}$±SEM-pg/120 min) were greater in young vs aged CS for K^+ (Y=84.6 ±18.7, N=4 vs A=21.2±3.5, N=6) and AMPH (Y=97.3±13.2, N=4 vs A=52.5±8.5, N=6). In contrast, a continuous infusion of L-DOPA resulted in a greater release of DA from aged CS (Y= 258.2±46.3, N=7 vs A=410±45.4, N=6). These results demonstrate infusion mode dependent differences in DA release from the CS of young versus aged rats in response to these secretagogues.

VITAMIN E DEFICIENCY IN 6-OHDA SUBSTANTIA NIGRA LESIONED RATS. B.I. DIAMOND, E.A. O'NEAL*, S.D. SMITH*, J. WANG*, and J.L. THOMPSON. Psychiatry Dept., Med. Coll. of Georgia, Augusta, GA 30912.

The role of vitamin E (VIT E) deficiency on striatal dopamine (DA) system function was studied in rats. 6-OHDA unilateral lesions of the substantia nigra (SN) were induced in 20 male Sprague-Dawley rats (250-300 g) which were then tested 14 days later for turning behavior in response to i.p. injections of the DA agonist, apomorphine (APO), 1mg/kg, and the indirect agonist, d-amphetamine (AMP), 3.5 mg/kg. Rats were assigned to either a normal or a VIT E deficient diet. They were challenged weekly for 9 weeks with APO, followed in 48 h by AMP. Completed turns were counted. We hypothesized that since neurons in the SN undergo loss with aging, VIT E deficiency would result in an even more rapid loss due to oxidative damage and that this would result in a more rapid decrease in turning rate. However, there were no group differences in the turning rates, although VIT E deficient rats exhibited a trend towards increased turning in response to AMP ($p=0.12$). This result is consistent with our other findings of significantly increased striatal DA levels in rats on a VIT E deficient diet.

INHIBITION OF MITOCHONDRIAL RESPIRATION BY N-METHYLATED BETA-CARBOLINE ANALOGS OF MPP+. M.A. Collins, E.J. Neafsey, R. Albores*, G. Drucker, and J.Z. Fields. Depts. of Biochem., Anatomy, and Pharm., Loyola Univ. of Chicago Stritch Sch. of Med. Maywood, IL 60153.

Since the 2[N]-methyl-beta-carboline (2Me-BC), 2Me-harmine, approaches MPP+ in potency of inhibition of mitochondrial respiration in vitro (Hoppel et al., 1987), we have examined a number of physiologically possible 2Me-BCs and dihydro-BCs (2Me-DHBCs) for their effects on O_2 utilization by rat liver mitochondria. Following 6 min pre-incubations, 2Me-harmine, 2Me-harmol, and 2Me-harmaline had IC50's comparable to MPP+, whereas 2Me-norharman and 2Me-harman were only weak inhibitors. Like MPP+, inhibition by 2Me-DHBC/BCs was augmented by tetraphenylboron and reversed by DNP, consistent with the involvement of cationic 2Me-DHBC/BC forms. However, the inhibitory time courses and DNP uncoupling patterns were dissimilar from MPP+, indicating a role for uncharged 2Me-DHBC/BC forms as well. The neutral 2Me-BC tautomers may arise from deprotonation of the indole N, since 2,9-dimethyl-norharman, a cationic BC that cannot deprotonate, had an inhibitory time course and response to DNP that resembled MPP+ rather than other BCs. Also unlike MPP+, the 2Me-DHBC/BCs blocked succinate-supported respiration almost as effectively as NAD+-linked respiration. The findings are consistent with the hypothesized role of endogenous 2Me-DHBC/BCs in the etiology of Parkinson's disease. (Support: NIH NS23891)

INDOLE METHYLATION OF 2-METHYL BETA-CARBOLINES DRAMATICALLY INCREASES THEIR TOXIC EFFECTS IN PC12 CELLS. R.J. Cobuzzi, Jr., E.J. Neafsey and M.A. Collins, Depts. of Biochem. and Cell Biology, Neurobiology and Anatomy, Loyola Univ. Stritch Sch. of Med., Maywood, IL 60153

In ongoing studies of the neurotoxic capabilities of MPP+-related beta-carbolines (BCs), we have found that the PC12 cell cytotoxicity exerted by cationic 2[N]-methyl BCs is significantly enhanced by further methylation of the indole-9 nitrogen. This was suggested by initial results with isolated mitochondria in which 2Me-norharman, a very weak inhibitor of respiration, became more effective than MPP+ when the 9-N proton was replaced by methyl. Previously in PC12 cells, we observed that 2Me-norharman produced negligible release of LDH or decrements in cell protein and dopamine uptake (indicators of cell toxicity) in 4 day incubations. In contrast, 2,9-diMe-norharman was equipotent with MPP+ in all three measurements after 2 days. Similarly, 2,9-diMe-harmine was identical with MPP+ and 2,9-diMe-norharman, whereas 2Me-harmine showed minimal toxicity at 2 days. A 3rd compound, 2,9-diMe-harman, achieved toxicity equal to MPP+ at 4 rather than 2 days, while the monomethylated 2Me-harman was without effect throughout. If metabolically feasible, replacement of the indole proton with a methyl or other group may be an effective means of enhancing the neurotoxicity of endogenously-derived 2Me-BCs. (Support: NIH NS23891).

EXTRACELLULAR VOLUME FRACTION AND DIFFUSION CHARACTERISTICS OF THE RAT STRIATAL SLICE DURING NORMOXIA AND HYPOXIA. M.E. Rice & C. Nicholson. Dept. Physiology & Biophysics, New York University Medical Center, New York, NY 10016.

Replacement therapies for Parkinson's disease often rely on the diffusion of dopamine (DA) or related compounds into the striatum. Surprisingly little is known about the diffusion characteristics of this region, however. As a prelude to further studies of DA diffusion in the striatum (Rice et al. *Neuroscience* 15: 891, 1985), we evaluated the extracellular volume fraction (α) and tortuosity (λ) of the striatal slice using ion selective microelectrodes (ISMs) and iontophoresis of tetramethylammonium (TMA^+) (Nicholson & Phillips, *J. Physiol.* 321: 225, 1981; diffusion curves illustrated in Figure). Extracellular field potentials (fp), evoked by stimulation of afferent fibers from the cerebral cortex, were monitored to assess slice viability.

Under normoxic conditions (superfusion with saline equilibrated with 95% O_2 / 5% CO_2), α was 0.21 ± 0.04 and λ was 1.57 ± 0.13 (mean ± SD; n = 170). Under hypoxia (saline with 95% N_2 / 5% CO_2 for 10-20 min), evoked field potentials were reversibly eliminated, while α decreased by 30% to 0.14 ± 0.04 and λ rose slightly to 1.61 ± 0.23 (n = 23). In normal media, α and the quality of evoked fields were correlated; α was 0.10-0.18 in slices with small post-synaptic fields. These results demonstrate the sensitivity of brain extracellular volume to tissue condition.

NEUROTENSIN RECEPTORS ON DOPAMINERGIC NEURONS:EVIDENCE ON CELL CULTURES AND APPLICATION FOR FETAL TISSUE TRANSPLANT VISUALIZATION

W.Rostene,Y.Masuo*,D.Scherman*,JP.Herman* and D.Pelaprat*.INSERM U.55 Hop. St Antoine 75012 Paris;CNRS Institut Curie Paris; INSERM U.259 Bordeaux, France.

We previously demonstrated on tissue sections Neurotensin (NT) binding sites located on dopaminergic (DA) cell bodies and dendrites in the rat mesencephalon. We show here the presence of NT receptors on rat mesencephalic DA neurons in culture, by a double labeling procedure based on 125I-NT receptor binding autoradiography coupled with tyrosine hydroxylase (TH) immunocytochemistry. NT binding was first followed by a glutaraldehyde fixation, secondly by an immunohistochemical procedure and finally by an emulsion step. Light microscopic observation demonstrated that 80% of the TH-positive cells were endowed with NT receptors, the latter being distributed on both cell bodies and processes. We thus used 125I-NT as a marker of fetal mesencephalic cell suspension grafted into the striatum of previously 6OHDA-lesioned rats. Three months after graft, rats which recovered normal behavior showed 125I-NT binding located at the periphery of the graft where TH cells are found. Moreover, on adjacent sections, 3H-dihydrotetrabenazine binding, a marker of DA nerve terminals integrity (Masuo et al, Neurosc. Lett, in press), allowed us to follow the reinnervation of the host striatum by the graft processes. These two ligands can thus be used to label DA pathways and follow nerve degeneration or reinnervation in various experimental and pathological diseases such as Parkinsonism. EXCESSIVE METHYLATION AND PARKINSON'S DISEASE: MODULATION OF DOPAMINE. B.Crowell,Jr. and C.Charlton. Dept. of Physiology, Meharry Medical College, Nashville, TN 37208

Catecholamine neurotransmitters, eg. dopamine (DA) are metabolized by the enzyme catechol-O-methyltransferase (COMT) which uses S-adenosyl-methionine (SAM). When SAM is injected into the lateral ventricle of rats tremors, hypokinesia and abnormal posture are observed. These impairments are also observed in Parkinson's disease (PD), along with a decrease in DA. Therefore, SAM may play a role in PD. We tested this hypothesis by manipulating the levels of SAM in the brain of rats and observed changes in motor performance and levels of DA in the caudate nucleus (CN).

Rats (150-200gm) were cannulated and 1.88 and 0.65 umol of SAM in 5 ul of phosphate buffered saline (PBS) administered intraventricularly. Controls recieved 5 ul of PBS. The rats were briefly observed and sacrificed 15 min after injection. DA was determined using radioenzymatic assay and HPLC.

SAM produces tremors, abnormal, hypokinesia, etc. The onset was 1-2 min. SAM decreased DA levels in the CN by 34.1 and 31.5% in animals receiving 1.88 and 0.65 umol of SAM respectively. In comparing the ipsilateral with the contralateral CN the 1.88 umol dose reduced DA by 45.9 and 25.4%, the 0.65 umol dose by 49.1 and 9.5%. These results complement our previous finding of SAM-induced depletion of tyrosine hydroxylase in the CN.

Motor disorders caused by SAM are typically those that also occur in PD. DA is also decreased in the brain of PD patients. Since SAM is involved in the metabolization of DA it is possible that SAM may play a role in PD.

EXCESSIVE METHYLATION AND PARKINSON'S DISEASE: L-DOPA EFFECTS. R. Benson, J. Clark, C. Charlton. Dept. of Physiology, Meharry Medical College, Nashville, TN 37208.

When injected into the brain of rats and mice, S-adenosyl methionine (SAM) causes Parkinson's disease (PD)-like symptoms, such as tremors, dyskinesia, and abnormal movements. The major treatment for PD is l-dopa. L-dopa is metabolized to dopamine (DA) and reacts with SAM. Therefore, the increase in DA as well as the depletion of SAM may elicit the positive benefits of l-dopa therapy. It follows that the lack of efficacy from prolonged l-dopa therapy may be due to a rebound increase in SAM via activation of methionine adenosyl transferase (MAT), the enzyme that synthesizes SAM from methionine and ATP. We tested this hypothesis by administering (i.p.) saline, or l-dopa to rats and mice and assaying for MAT activity.

About 73% and 53% of the activity of MAT was observed in the insoluble fraction of the brain and liver, respectively. L-dopa increased the activity of MAT in the brain by 32% and 37% in the 100 and 500 mg/kg, as compared to saline, treated rats. L-dopa, 50 mg/kg, increased the MAT activity by 37% in mouse brain. No significant changes occurred in the liver of rats or mice. Since l-dopa increases MAT, the decreased efficacy of chronic l-dopa in PD therapy may be explained partly by an increased MAT activity, which will increase SAM and create a vicious cycle. SAM will react with both l-dopa and DA to produce methylated products. It has been shown that high plasma levels of methyldopa were observed in patients exhibiting l-dopa induced dyskinesia; also, in animals, methyl-DA and SAM caused motor deficits antagonistic to l-dopa.

A MONOCLONAL ANTIBODY (MAb) TO DARP (DOPAMINE RELEASING PROTEIN) SELECTIVELY KILLS NEURONS IN CULTURE FROM THE MESENCEPHALON AND REDUCES DOPAMINE (DA) LEVELS IN THE STRIATUM (CS) AND HYPOTHALAMUS OF IMMATURE RATS. V.D. Ramirez, D.E. Dluzen, S. Kuhananthan, S. Miklasz* and F. Marcus*, Department of Physiology, U of IL and Chiron Corp.

Cell cultures from mesencephalon (M) and diencephalon (D) of 17-18 day-old rat embryos were prepared. On day 9, substances dissolved in minimal essential medium were added. On day 16, cells were counted. A dramatic arrest of growth and neural differentiation of M cultures that received the MAb (14 μg/well) was observed. The numbers of neurons/1.7mm^2 were: 14.6±1.4, n=27 controls vs 2.0±0.5, n=24 MAb-treated. In the D cultures were: 8.1±1.7 n=9 control vs 6.8±1.3, n=12 MAb-treated. Recent born pups were injected subcutaneously daily for 10d with MAb-E$_2$ 20 or 5 μg/rat or with 20 μg γ-globulin. On day 11 or 25 DA levels were measured in the CS or hypothalamus. The MAb decreased DA concentrations in the CS on day 11 (3.9±0.26, 3.7±0.19 and 2.6±0.16 ng/mg, n=5-6 for controls, 5 μg and 20 μg groups, respectively) and in the hypothalamus on day 25 (840±70 controls vs 482±61 pg/mg 20 μg/MAb-treated, n=5). These data suggest that an endogenous neurotrophic factor is released from cells of M cultures that is essential for their growth and neuronal differentiation. The anti-DARP MAb blocks this action and is also capable of reducing DA levels from the CS and the hypothalamus.

COGNITIVE-MNESTIC INFORMATION PROCESSING IN MULTIPLE SCLEROSIS PATIENTS. H.J. Markowitsch+, P. Calabrese+, M. Haupts+ and W. Gehlen+ (SPON: ENA), Lab. of Biopsychology and Knappschafts-Hospital, Ruhr-University, D-4630 Bochum, Federal Republic of Germany.

Hospitalized patients with multiple sclerosis were given a variety of psychometric tests with emphasis on cognition and memory. Prior to neuropsychological testing, all patients had been intensely scrutinized neurologically and neuroradiologically, including MR-imaging for some of them. Aside from an intelligence test we used a modified form of the Rivermead Behavioural Memory Test, and further tests on nonverbal memory span and problem solving abilities. In general, we found - compared to non-brain damaged subjects - a deterioration on most of the intellectual abilities tested. The poor performance was, however, less obvious for verbal memory as opposed to conceptual-intuitive and visuo-spatial abilities. Performance on the Corsi-cube test, for instance, was not only worse than in Korsakoff subjects, but also worse than in amnesics with profound damage of limbic-system related structures. We conclude from our results that multiple sclerosis patients even at an early stage of the disease process need intensive neuropsychological testing and might profit from continuous cognitive rehabilitation training and/or guidance.

HIGH EXTRACELLULAR CALCIUM INCREASES CONDUCTION IN EXPERIMENTALLY DEMYELINATED FIBERS OF RAT FIMBRIA. K. H. Reid and J. Newmark*. Depts. of Anatomical Sciences and Neurobiology and of Neurology, Univ. of Louisville and Louisville VA Medical Center, Louisville KY.

Using a previously developed in vitro model of acute CNS demyelination (stereotaxic injection of 0.3 ul of lysophosphatidyl choline 7 days pre-test), we exposed partially demyelinated rat fimbrias to artificial cerebrospinal fluid containing [Ca^{++}] of 2.5 mM (physiologic), followed by alternations between 4.4 mM (high) and 0.25 mM (low). We recorded population spike amplitudes both of the normal peak, which we associate with undamaged fibers, and of the delayed peak, which we associate with partially demyelinated fibers. In high [Ca^{++}] both peaks increased in amplitude, while in low [Ca^{++}] both decreased in amplitude. The effect was reversible and was not seen in control (undamaged) fimbrias. This effect is consistent with a model of membrane stabilization by calcium ions which has been proposed as a basis for dietary prevention of colon cancer. Our findings suggest that increased extracellular [Ca^{++}] may be protective in acute exacerbations of multiple sclerosis. IMMUNOLOGICAL REACTIONS IN AMYOTROPHIC LATERAL SCLEROSIS BRAIN AND SPINAL CORD TISSUE. T. Kawamata*, H. Akiyama, T. Yamada, P. L. McGeer, E. G. McGeer. Kinsmen Laboratory of Neurological Research, University of British Columbia, Vancouver, B.C. Canada, V6T 1W5.

Expression of proteins associated with immune function was investigated immunocytochemically in postmortem brain and spinal cord tissue from patients with amyotrophic lateral sclerosis (ALS). These included the leukocyte surface glycoproteins LCA, CD4, CD8, FcγRI, FcγRII; complement receptors CR3 and CR4; complement proteins C3d and C4d; LFA-1 and its ligand ICAM-1; and HLA-DR. Reactive microglia expressed high levels of LCA, FcγRI, FcγRII, CR3, CR4, LFA-1 and HLA-DR. They were found in abundance in the primary motor cortex, motor nuclei of the brain stem and the anterior horn of the spinal cord. Throughout the corticospinal tract from subcortical white matter of the motor cortex to the anterior and the lateral funiculi of the spinal cord, the cells were lipid filled having the morphology of classical fat granule cells. A significant number of lymphocytes positive for LCA, CD4 and CD8 were observed marginating along the walls of blood vessels and invading the parenchyma of inflamed areas. Clusters of C3d and C4d coated fibres were frequently associated with oligodendroglia. We describe these as complement-activated oligodendroglia. Labelling of the central nervous system components with complement proteins might be evidence of opsonization, which could stimulate phagocytosis by reactive microglia/macrophages bearing complement receptors. Expression of HLA-DR by these phagocytes indicates their capability of antigen presentation to T-lymphocytes, possibly followed by the production of specific antibodies.

554.4

ISOLATION OF MOTONEURONS AND CHARACTERIZATION OF RNA AND NEURONAL INTERMEDIATE FILAMENT PROTEINS FROM AUTOPSY VENTRAL SPINAL CORDS OF PATIENTS WITH AMYOTROPHIC LATERAL SCLEROSIS. B.A. Brody, D.C. Kelley-Geraghty* and B. Jubelt*. Northwestern Univ. Sch. of Med., Chicago, IL 60611.

A variety of methods have been utilized to isolate large numbers of neurons from the brains of adult animals or from human autopsy material. A quantitative analysis of motor neuron RNA has been reported for bovine spinal cord (Capps-Covey, P. and McIlwain, D.L., J. Neurochem., 25:517, 1975). The resulting membrane defects caused by mechanical dissociation of neurons as well as postmortem autolysis make obtaining intact neurons from human autopsy tissue particularly difficult. We are able to obtain highly enriched fractions of neurons from the ventral horns of frozen spinal cords from both patients with amyotrophic lateral sclerosis (ALS) and control patients with nonneurological disease. The neuronal yield from ALS patients is approximately 1/10 that of the controls. We have been successful with autopsy material with as much as an 18 hour postmortem interval or frozen for as long as 4 years. We describe immunoperoxidase and immunofluorescence studies on these neuronal fractions utilizing antibodies to high molecular weight and to 57kDa neurofilament proteins. We have also quantitatively isolated nondegraded RNA from frozen ventral spinal cord tissue of both ALS and neurologically normal patients. These studies will provide a basis for biochemical, immunological, and biological characterization of ALS versus normal tissue.

554.5

CELLULAR CHANGES IN THE MOTOR CORTEX OF PATIENTS WITH AMYOTROPHIC LATERAL SCLEROSIS. E. J. Kasarskis, H. Liu*, H. Wang*, and S. Khare*. Dept Neurol, VA and Univ of Kentucky Med Ctrs, Lexington KY 40536-0084.

Amyotrophic lateral sclerosis (ALS) is characterized by selective death of motor neurons in the spinal cord. Pyramidal tract involvement and pathological changes in the motor cortex are also recognized. However the extent of neuronal loss in precentral cortex has not been quantitated.

Four patients dying with ALS and 4 age-matched controls were studied. A series of images, comprising a "core" of cortex taken from the leg region of Broadmann's area 4 and measuring 270 x 3400 sq microns, were analyzed by a computerized image analysis system. A total of 4 cores were examined from each subject. The apparent area and position of each cell relative to the pial surface was determined.

The total number of cells increased by 19% in ALS cortex, reflecting primarily a 30% increase in the number of glial cells. However neurons measuring >100 sq microns, were reduced by 50% in lamina V of ALS cortex.

These data indicate that significant neuronal loss occurs in lamina V of Broadmann's area 4 in ALS. Changes of similar magnitude, if present in other cortical regions which contribute to the pyramidal tract, may explain the cortical hypometabolism seen in PET scanning of ALS patients. (Supported by NS 25165).

Tubulin Distribution is Altered in Spinal Cord Perikarya of the Motor neuron degeneration (Mnd) mouse.

L. Callahan and J.E. Mazurkiewicz, Anatomy, Cell Biology, Neurobiology, Albany Med. Col., Albany, NY 12208

We previously reported that neurofilaments were abnormally distributed in spinal cord perikarya of the Motor neuron degeneration (Mnd) mouse, an animal model for human motoneuron disease. The study reported here investigated the distribution of tubulin, another major cytoskeletal element in neurons. An immunoperoxidase technique using antibodies to polymeric or dimeric tubulin was employed to analyze lumbar spinal cord perikarya in transverse and horizontal 30um vibratome sections. One severe and two moderate stage Mnd and two age-matched controls were examined.

In control perikarya, immunoreaction product for tubulin was distributed throughout the cytoplasm. Immunoreactivity of the peripheral cytoplasm was increased relative to the inner cytoplasm. In contrast, perikarya of Mnd contained prominent cytoplasmic regions devoid of tubulin immunoreactivity. This distribution was similar to that found for neurofilaments in affected cells in Mnd. The affected neurons were found predominantly in one lamina, suggesting a selection of neurons may be occurring in this disease. The lamina containing most of the affected neurons was lamina IX; the region containing alpha motoneurons. The alteration in the distribution of tubulin and neurofilament proteins suggests that changes in cytoskeletal function, including axonal transport, may play a role in the pathogenesis of the disease.

BRAIN UPTAKE AND DISTRIBUTION KINETICS OF BETA-N-METHYL AMINO-L-ALANINE IN THE RAT. Q.R. Smith, P. Pearson*1, N. Villacreses*, L. Wyatt*1, S. Markey2, I. Kopinl, and M. Duncanl. Lab. of Neurosciences, NIA; 1Intramural Res. Program, NINDS; and 2SAB, NIMH, NIH, Bethesda, MD 20892.

Beta-N-methylamino-L-alanine (BMAA) is a neurotoxic nonprotein amino acid present in cycads that has been implicated in the pathogenesis of the amyotrophic lateral sclerosis-parkinsonism dementia complex of the western Pacific. To evaluate its kinetics and brain uptake, BMAA (25-400 mg/kg) was administered to rats either acutely or chronically, and then plasma and brain concentrations were determined at various times thereafter by GC-MS. Following single dose i.v. injection, BMAA was cleared from plasma in a rapid distribution phase (Vd = 21.5 L/kg) followed by a slower elimination phase (t1/2 = 1 day). Brain uptake proceeded at a low rate (PA = 2.5 $\pm$ 0.2 x 10^{-3} ml/s/g) mediated in part by the large neutral amino acid carrier of the blood-brain barrier. Brain levels peaked within 8 hr after injection and then declined with a t1/2 similar to that of plasma. After two weeks of continuous infusion (100 mg/kg/day), steady-state brain concentrations equalled 10-30 ug/g and only moderately exceeded those in plasma. The results suggest that BMAA may reach potentially toxic levels in brain (>250 uM) following large doses (100-400 mg/kg). However, such doses are orders of magnitude greater than those available from diet or medical use of cycads.

IMMUNOHISTOCHEMICAL AND BIOCHEMICAL STUDIES ON WORSTER-DROUGHT DISEASE. D. Walker, H. Akiyama, T. Kawamata*, T. Pearson* and P.L. McGeer. Kinsmen Lab of Neurological Research, Univ. of British Columbia, Vancouver, B.C., Canada V6T 1W5

Worster-Drought and colleagues (J. Neurol Psychopath 14:27, 1933) described an autosomal dominant dementia with amyloid angiopathy and cerebral amyloid plaques. The index family has been followed through six generations (Plant et al. Brain:113, 1990). We have confirmed the original pathological findings in a 64-year old 5th generation decendent. There was extensive vascular amyloidosis and plaque formation particlarly in the inferior olive, hippocampus and amygdaloid nucleus, ischemic damage to selected areas, and patchy accumulations of neurofibrillary tangles. The amyloid deposits stained positively for amyloid P, but negatively for b-amyloid protein (antibodies courtesy D. Selkoe and T. Ishii). They also stained negatively for the prion protein (antibodies courtesy H. Wisniewski). These results ruled out Alzheimer and Gerstmann-Straussler as the cause of this disorder. The neurofibrillary tangles stained positvely for ubiquitin (antibody courtesy R. Kascsak), Alz-50 (antibody courtesy P Davies) and Tau-2. Partial sequence analyses of the transthyretin gene, using PCR amplified DNA extracted from the patient's brain, as well as gas-sequence analysis of transthyretin protein purified from the serum of an apparently affected daughter, showed no abnormality. The disease is unlikely to be a form of familial amyloidotic polyneuropathy. It appears to be a unique form of amyloidosis exclusively affecting brain tissue.

LOCALIZATION OF IL-1α AND IL-1β IN DISEASES WITH GLIOSIS, DEMENTIA, AND IMMUNE SUPPRESSION. L.C.Stanley and W.S.T.Griffin, Departments of Anatomy and Pediatrics, UAMS, Little Rock, AR 72205

Temporal lobe gliosis and immune suppression are present in several diseases having the clinical presentation of dementia. One manifestation of the immune suppression is a decrease in macrophage-derived IL-1 peripherally. In contrast, we have shown that IL-1 is elevated in reactive microglia and astrocytes in postmortem brain from individuals with Alzheimer disease (AD), Down syndrome (DS), and AIDS. Two forms of IL-1 have been described: IL-1α and IL-1β. We examined formalin-fixed, paraffin-embedded temporal lobe sections from AD, DS, AIDS, and controls, using specific antibodies to IL-1α and IL-1β. Cells containing IL-1α immunoreactive product were identified as either reactive microglia (process-bearing), brain macrophages (round), or endothelial cells. Microglia-like cells were found throughout grey and white matter; whereas, brain macrophages were located near blood vessels or within the choroid plexus. IL-1β immunoreactive product was found in endothelial cells and reactive astrocytes located near blood vessels. IL-1 within the lumen of blood vessels was predominantly labeled with the specific antibody for IL-1β. We conclude that excessive expression of IL-1α, by microglia and brain macrophages, and IL-1β, either produced or taken-up from the blood by astrocytes, accounts for the elevation of brain IL-1 in the diseases studied.

PROTEIN KINASE C ACTIVITY IN CEREBRAL CORTEX OF CATS WITH GM_1 GANGLIOSIDOSIS. G. Shanker, H. J. Baker* and A. L. Perrow* Department of Comparative Medicine, Bowman Gray School of Medicine, Winston-Salem, NC 27103.

GM_1 gangliosidosis is a lysosomal disease due to reduced activity of β-galactosidase with resulting decreased hydrolysis and lysosomal accumulation of glycolipids, glycoproteins, and other metabolites in brain, liver and other tissues. Pathogenesis of neuronal dysfunction in this and other lysosomal diseases is not understood. Our previous studies using feline models of the gangliosidoses indicate defective transmembrane signal transduction, including calcium dyshomeostasis. In vitro studies suggest that protein kinase C (PKC) inhibition by sphingolipids may play a role in these diseases. We measured calcium dependent PKC activity in cerebral cortex of cats with GM_1 gangliosidosis, age matched normal siblings, and unrelated normal controls using the Amersham assay procedure. Tissue preparations included: whole brain homogenate, P_2 fraction, synaptosomes and cytosol. PKC activity in unrelated normal cat brain was: homogenate 808 ± 55 pmoles/min/mg protein ($\bar{x}$ ± 1sd); cytosol 731 ± 63; P_2 284 ± 30; and synaptosomes 81 ± 6.4. Enzyme activity in all fractions was stable at - 70° for at least 10 days of storage. PKC activity in whole brain homogenate of 4 feline GM_1 gangliosidosis mutant cats was 1437 ± 90 pmoles/min/mg protein ($\bar{x}$ ± 1 sd), which was not statistically different from normal cat brain activity of 1166 ± 135. Further studies in progress will compare PKC activity in subcellular fractions of mutant and control cats. Supported by NINCDS grant NS10967.

^{3}H-PRAZOSIN BINDING IS REDUCED IN BRAIN OF PATIENTS WITH NARCOLEPSY. L.M. Dixon, M. Mamelak*, O. Hornykiewicz and S.J. Kish. Clarke Institute of Psychiatry, and Sunnybrook Hospital, Toronto, Canada.

Narcolepsy is a sleep disorder characterized by sleep attacks, cataplexy, sleep paralysis and hypnagogic hallucinations. Studies in human narcolepsy and its animal (canine) model have demonstrated that treatment with prazosin, an alpha-1-adrenergic receptor antagonist increases cataplexy and sleep time. We measured ^{3}H-prazosin binding (0.2nM) as well as levels of noradrenaline and its metabolite MHPG in four brain areas in autopsied brain of three narcoleptic patients and five age-matched controls. Binding was significantly decreased in the frontal cortex (-53%, $p<0.02$) and amygdala (-46%, $p<0.05$) but was normal in caudate and putamen. Although noradrenaline levels were normal in all brain areas studied, in frontal cortex MHPG levels (+131%, $p<0.01$) and turnover ratio MHPG/noradrenaline (+79%, $p<0.05$) were elevated, suggesting increased activity of locus caeruleus noradrenergic neurones and consequent down regulation of the post synaptic alpha-1-receptor. We suggest that altered brain noradrenergic mechanisms may be involved in the pathophysiology of human narcolepsy. (Supported by the American Narcolepsy Association).

IN SITU HYBRIDISATION STUDIES OF SYMPATHETIC GANGLIA IN MULTIPLE SYSTEM ATROPHY AND PURE AUTONOMIC FAILURE

OJF Foster and SL Lightman. Medical Unit, Westminster Hospital, 17 Page St, London SW1P 2AP U.K.

Although sympathetic ganglion cell numbers are reduced in Pure Autonomic Failure (PAF) but seem to be maintained in Multiple System Atrophy (MSA) (Matthews 1988), we know little about the behaviour of the residual ganglion cells in either disorder. Messenger RNA (mRNA) is relatively stable post-mortem and we have been able to apply in situ hybridisation histochemistry to the study of cell function in human sympathetic ganglia in PAF and MSA.

Eight micron frozen sections of sympathetic ganglia from MSA, PAF and control subjects were studied using probes directed against mRNA encoding tyrosine hydroxylase (TH), neuropeptide Y (NPY), the structural protein beta-tubulin (BT). Preliminary studies show reduced TH probe binding in the remaining ganglion cells in the PAF tissue studied, but well maintained levels in cells from MSA ganglia, with similar changes in NPY and BT probe binding.

Our initial studies suggest that ganglion cell biosynthesis of neurotransmitter and microtubular proteins is maintained in MSA but may be greatly reduced in the residual ganglion cells in PAF. Further work is underway to quantify these changes.

THE G-PROTEIN SYSTEM IS ALTERED IN DIABETIC ENCEPHALOPATHY. A.M.Di Giulio, M.L.Malosio*, B.Tenconi*, M.L.Donadoni*, M.P.Abbracchio, F.Cattabeni and A.Gorio.Dept. of Med.Pharmacol.; Inst. of Pharmacol. Sci.; Univ. of Milano, Italy.

We have recently reported that the G-protein system is functionally altered in some CNS areas of diabetic rats. Two different stages of alloxan-induced diabetes were considered. In the early stage (5 weeks after alloxan injection) the G-protein mediated transductional signal was apparently unaffected troughout the CNS except for the retina, where a functional reduction of the Gi/Go system was observed. At later stages (14-16 weeks after alloxan injection) an involvment of the Gs retinal system as well as a reduced functional capacity of the striatal Gi/Go system were observed. The mRNA Northern Blot analysis revealed that at the earlier stage of diabetes the synthesis of Gi and Gs proteins is unaffected troughout the CNS except for the lumbar spinal cord. However, at a later stage of the disease the Gi mRNA is increased in retina and reduced in caudate. These data indicate that the various CNS areas are subjected to differential insults , thus suggesting a foundamental difference between the diabetic encephalopathy and the degenerative nature of the peripheral diabetic neuropathy.

GAP-43 mRNA LEVELS IN ASSOCIATION CORTEX DURING NORMAL AGING AND ALZHEIMER'S DISEASE. P. D. Coleman, A. B. Wadhams*, K. E. Rogers. Dept. of Neurobiology and Anatomy, University of Rochester, Rochester, N. Y. 14642

GAP-43 is a protein which has been found to be abundant in developing neurons as well as regenerating neurons. We have suggested that GAP-43 may be used as a marker of neuronal plasticity in aging brain, and conversely, Alzheimer's Disease(AD) could represent a loss of neuronal plasticity. Thus, mRNA levels of GAP-43 may reflect the degree of neuronal plasticity. RNA from frontal association cortex of AD patients and age-matched controls was isolated and checked for integrity by Northern blot analysis. Four serial dilutions of each sample were bound to a nylon membrane and hybridized under saturating conditions to a probe representing the entire coding region of rat GAP-43. Results showed no difference between AD and control samples in total yield of mRNA per gram of tissue obtained from each case. In normal aging, GAP-43 message levels decreased by approximately 47% between 50 and 70 years of age and did not significantly decline thereafter. GAP-43 message levels in AD samples were not significantly different from the levels found in normal age-matched controls. (Supported by AG 09016, AG 01121, AG 03644, AG 00107, PRG-89-120)

INCREASED SPECTRIN BREAKDOWN IN FIBROBLASTS FROM AGED AND ALZHEIMER DONORS. C. Peterson[1], P. Vanderklish[2*], P. Seubert[2], C. Cotman[1] and G Lynch[1,2]. [1]Dept. Psychobiology & [2]Bonney Center of Learning and Memory, University of California, Irvine, CA 92717, USA.

Several lines of evidence suggest that calcium homeostasis is altered by aging and Alzheimer's disease. For example it has been previously shown that there are deficits in calcium uptake and cytosolic free calcium but increases in bound calcium in fibroblasts from aged and Alzheimer donors (Ann. N.Y. Acad. Sci. 568: 262). Activation of a calcium sensitive protease, as evidenced by increased spectrin breakdown, occurs early in the course of neuropathology in several animal models. Since changes in calcium homeostasis may lead to abnormal regulation of calcium dependent proteases (e.g., calpain), the present study describes spectrin proteolysis in cultured skin fibroblasts from young, aged and Alzheimer donors. Cultured skin fibroblasts from young (21±1.2 yrs), aged (61±1.3 yrs) and Alzheimer (62.3±1.2 yrs) donors were obtained from the NIA Aging Cell Repository. Cells that had been deprived of serum for twenty-four hours were reexposed to 1% serum for 10 min. Electrophoretically separated proteins were transferred to nitrocellulose paper and spectrin breakdown products were immunodetected. The concentration of the 150 and 155 kD spectrin breakdown products was greatest in fibroblasts from Alzheimer donors (231.7±17.4%) and less in aged controls (183.9±15.6%) as compared to young donors (100±8.3%). Changes in calpastatin activities could not account for these alterations. Thus, abnormal calcium mediated proteolysis may contribute to the altered cytoskeleton dynamics that occur during aging and Alzheimer's disease. Supported in part by AG07855.

555.3

DISTRIBUTION OF PROTEASE NEXIN-1 (PN-1) mRNA IN RAT BRAIN AND ITS RESPONSE TO LESION . AN IN SITU HYBRIDIZATION STUDY. F. Gómez-Pinilla, S. Wagner, D. Cunningham and C. W. Cotman. Depts of Psychobiology and Genetics, University of California, Irvine CA 92717.

Protease nexin-1 is a serine protease inhibitor which shows neurite outgrowth activity *in vitro*. Recent evidence suggest that PN-1 may be involved in the etiology of Alzheimer's disease (AD) since PN-1 protein is reduced in AD brains. Thus, AD appears to be associated with an imbalance of proteases and protease inhibitors, possibly in part due to a break down of the blood brain barrier. In this study we have studied the cellular origin of PN-1 and the effect of injury on the expression of PN-1 mRNA in the hippocampus and cortical areas severely impacted by AD. We used a ^{35}S-labeled 603-base anti-sense RNA probe for *in situ* hybridization. The hippocampus was deafferented either by transecting the fimbria-fornix or by electrolitically lesioning the entorhinal cortex; rats were sacrificed at 1, 2, 3, 4, 5, 10, 14 or 30 days after lesion. Experimental and normal brains were processed for *in situ* hybridization. PN-1 mRNA hybridization was observed to be enriched in the hippocampus (dentate and pyramidal cell layer), cerebral cortex layer III, olfactory bulb periglomerular area. After either lesion, there was a transient increase (days 1 through 5) in PN-1 mRNA labelling density in the hippocampus ipsilateral to the lesion. There was not an exact topographical correlation between deafferented areas and lesion effect. This suggests that PN-1 can be induced as a general response to trauma as a possible mechanism to protect the brain and mobilize growth related events.

QUANTITATIVE IMMUNOREACTIVITY OF ALZHEIMER-LIKE ANTIGENS INCREASED BY ELDERLY HUMAN SERUM TREATMENT OF CULTURED NEURONS, G.J. Brewer, B.K. Miksanek* and J.W. Ashford, Southern Illinois Univ. Sch. Med. Springfield, IL 62794.

The mechanism for promoting the development of distinct types of lesions in the Alzheimer disease (AD) brain and other changes outside the brain is unknown. We examined unprotected neurons in culture to determine if exposure to serum would affect markers for Alzheimer brain lesions. Rat hippocampal neurons were first grown in a new serum-free culture medium, then exposed for 24 hr. to sera. Sera from AD patients and their spouses, but not young adult human or fetal bovine, each increased three molecular markers characteristic of Alzheimer senile plaques and neurofibrillary tangles: Alz-50, β-amyloid and MAP2. By quantitative immunofluorescence, neuronal exposure to the elderly human sera produced 2.5 to 3.8 fold increases in fluorescent area/cell and 17 to 37% increases in brightness of these three markers relative to no serum exposure. Anti-β-amyloid immunogold labeling and whole-mount electron microscopy revealed immunoreactivity associated with extracellular fibrillar deposits, adjacent to neurons in samples treated with elderly human serum which was reduced and restricted to apical dendrites in samples treated with young serum. These studies direct attention toward a common mechanism of induction of both plaques and tangles in AD. Supported by the Pearson Family Foundation and SIUSM.

INTRADENTATE COLCHICINE LESIONS: A PROPOSED ANIMAL MODEL OF WANDERING BEHAVIOR IN ALZHEIMER'S DISEASE. J.P. Ryan, M. Saxby*, T. McBain*, B. Kunkel*, D. Hoffman*, T. Brown*, and P. Stewart*. Dept. of Psychology, State University of New York at Plattsburgh, Plattsburgh, New York 12901.

Wandering behavior in Alzheimer's Disease is one of the most problematic characteristics of the disease. The human literature suggests that there may be two subtypes of wandering, goal-directed and non-goal-directed. The present study attempted to dissociate the two subtypes in an animal model using the Morris Water Maze. Twenty-nine Long-Evans hooded rats were divided into two groups. The experimental group (N=20) received 15 µg/uL of colchicine bilaterally into the dentate gyrus of the hippocampus **and the control group (N=9) received 1 µL of physiological saline. The animals were trained for six days (36 trials) in the water maze. The lesioned animals were significantly impaired in their ability to locate the goal in comparison to the control animals. Furthermore, the lesioned group itself exhibited marked differences in goal-finding behavior. The moderately impaired lesioned group failed to find the platform 40% of the time in comparison to the severely impaired group that failed to locate the platform 90% of the time. It is suggested that the behavioral impairment of the moderately impaired lesioned group mimics the spatial disorientation of the goal-directed wandering** observed in the Alzheimer patient. The hyperactive, motor-disinhibited behavior of the severely impaired group mimics the nongoal-directed wanderer.

555.6

CYTOCHROME OXIDASE INHIBITION IMPAIRS LEARNING AND HIPPOCAMPAL PLASTICITY: IMPLICATIONS FOR ALZHEIMER'S DISEASE. M.C. Bennett, D.M. Diamond, S.L. Stryker*, J.K. Parks* and W.P. Parker. Departments of Neurology and Pharmacology, UCHSC & VAMC, Denver, CO 80262

In recent work, Parker et al., (*Neurol.*, in press) reported a selective deficiency in the respiratory enzyme cytochrome oxidase (Complex IV) in blood platelets of Alzheimer's (AD) patients. This finding raises the possibility that a defect in the electron transport chain may play a role in the etiology of AD. Therefore, we tested the hypothesis that selective depletion of cytochrome oxidase impairs learning and physiological plasticity.

Adult male rats were each implanted with an Alzet minipump (2ML4) containing saline (CONTROL) or 160 mg/ml azide (AZIDE). On a shuttle avoidance task, AZIDE rats implanted 6-9 days prior to training did not show a learning curve and had longer escape latencies than did CONTROLS. This learning deficit could not be attributed to a sensory or a motor impairment. Further, in an 8-arm radial maze task, long-term (7 day) but not short-term (2 day) AZIDE treatment slowed the rate of acquisition. Finally, AZIDE rats were significantly impaired in their capacity to develop hippocampal LTP.

These data indicate that chronic, selective depletion of cytochrome oxidase by azide produces deficits in learning and hippocampal plasticity. We suggest that the azide-induced inhibition of cytochrome oxidase in rats constitutes a novel animal model of AD.

555.7

ALUMINUM-INDUCED NEURITE OUTGROWTH IN CULTURED HIPPOCAMPAL NEURONS RESEMBLES NEURITE SPROUTING SEEN IN AGING AND ALZHEIMER'S DISEASE. E. Uemura and R.K. Lartius. Department of Veterinary Anatomy, Iowa State University, Ames, IA 50011.

It has been shown that the aluminum content in the human brain increases with age (up to 25 μM), and it is particularly high in those with Alzheimer's disease (up to 910 μM). we found that 100 μM aluminum in culture media can induce extensive neurite outgrowth (i.e., elongation and branching of neurites) and sprouting (i.e., outgrowth of filiform-like processes from neurite varicosities) in some hippocampal neurons derived from brazilian short-tailed opossum. Such neurite changes occured within 24 hours of aluminum exposure. Neurites exposed to aluminum appeared to grow with no clear direction. Further, there was no statistical difference in neurite length between neurons exposed to aluminum for 24 hours versus four days. Some neurons also displayed sprouting of neurites. Such sprouting always originated from a globular enlargement at the focal area of the neurite along the neurite shaft and at terminal end of the neurite. It appears that brief exposure to low level aluminum is sufficient to promote extensive neurite elongation and sprouting in some hippocampal neurons.

PERSISTENT CHOLINERGIC INNERVATION OF CEREBRAL CORTEX DESPITE DEPLETION OF CORTICAL NEURONS. S.L. Minger & P. Davies*.
Dept. of Pathology, Albert Einstein College of Medicine, Bronx, NY 10461

A controversial theory in Alzheimer's disease research posits that degeneration of the basal forebrain cholinergic nuclei is due to the loss of trophic factors secondary to a reduction in the number of cortical neurons. We have used the in utero application of methylazoxymethanol acetate (MAM) to directly probe this relationship. MAM (15mg/kg,i.p.) or 0.9% NaCl (1.0ml/kg) was administered to pregnant Sprague-Dawley rats on gestational days 14+15. Brains of the offspring of MAM-treated and control animals were utilized for morphological analysis at 2 months of age, and for neurochemical studies at 2 and 6 months. Anatomically matched sections through the anterior to posterior extent of the brains were rigorously analyzed. The MAM-treated animals demonstrated a 25-35% reduction in cortical cross-sectional area, a 40-65% reduction in cortical volume, and a 50-70% reduction in total cortical neurons in layers II/III, as compared to age and sex matched controls (all values $p<.001$). In contrast to this extensive cortical lesion, in the 2 month old MAM-treated rats cholinergic markers (ChAT and AchE) were significantly increased in each of the four neocortical regions analyzed. The increases in ChAT levels ranged from 25% to 56% in the neocortex, with significant increases also found in the striatum and hippocampus. Furthermore, this relative, global cholinergic hyperinnervation of the MAM-treated brain was found to be sustained at 6 months of age in all regions examined. It will be of interest to determine if the hypocellular cortex can maintain a cholinergic hyperinnervation over the life span of the MAM-treated rat.

555.9

ORGANIZATION OF NEUROPEPTIDERGIC SYSTEMS AFTER CHOLINERGIC LESIONS OF THE NUCLEUS BASALIS IN RATS. J.W. Unger and W. Lange*. Department of Anatomy, University of Munich, FRG.

Despite the presence of a number of neurochemical alterations, the cholinergic deficit is a consistent finding in brains of patients with Alzheimer's disease (AD). Since previous studies have shown quantitative changes of cortical somatostatin concentrations in AD patients, as well as rats after lesions of the basal forebrain, our investigation evaluates the response of peptidergic networks after cholinergic deafferentation of several brain regions. 4 weeks and 3 months after bilateral lesions of the nucleus basalis, cell sizes, morphology and density of fibers or terminals are investigated by immunohistochemistry. The distribution of somatostatin and neuropeptide Y neurons in cortex and amygdala remains unchanged after 4 weeks; only minor atrophy of these cells is seen. In addition, galanin fibers in the basal forebrain are spared in lesioned animals. So far, our findings support the hypothesis that cholinergic deafferentation may present only part of the factors that cause widespread neurochemical changes in AD.

MOUSE TRISOMY 16 NEURONS MAINTAINED BY NEURAL TRANSPLANTATION: A POSSIBLE MODEL OF NEUROPATHOLOGY IN ALZHEIMER'S DISEASE. B. Ault, A. Fine & S.I. Rapoport. Lab. Neurosciences, NIH, Bethesda, MD 20892 and Dept. Physiology & Biophysics, Dalhousie Univ., Canada B3H 4H7.

Because of homology between regions of mouse chromosome 16 and human chromosome 21, the trisomy 16 mouse is considered a model of human trisomy 21 (Down syndrome). All trisomy 21 individuals develop neuropathology indistinguishable from Alzheimer's disease after the third decade of life. It would therefore be of great interest to examine trisomy 16 tissue at various periods of survival for any markers of Alzheimer's-like neurodegeneration. However, trisomy 16 fetuses die in utero or shortly after birth. We have attempted to maintain trisomy 16 and control tissue by the use of neural grafting techniques.
Hippocampal and neocortical areas were dissected from brains of trisomy 16 and littermate control fetuses after 14-15 days gestation. After incubation with 0.05% trypsin, the tissue was dissociated in a minimum volume of medium. Viability was better than 90% as assessed by ethidium bromide exclusion. 1 uL of tissue suspension was ejected into the right striatum of young adult sibling hosts. Operated mice were perfused after 2 weeks to 6 months survival. 7 mice with trisomy 16 grafts and 8 mice with control grafts were examined. Cresyl violet staining showed surviving grafted tissue in all animals except one (trisomy 16 graft; 3 week survival) which was well integrated with the host brain. Trisomy 16 grafts were smaller than corresponding control grafts on average, but no obvious neuropathology was observed. However, in trisomy 16 grafts at 4 and 6 month survival times selective expression of some Alzheimer's-associated markers was noted.

555.11

GRAFTING OF FETAL HIPPOCAMPUS IN A RODENT EXCITOTOXIC MODEL OF ALZHEIMER'S DISEASE. D.A.Turner, W.-Q.Dong and D.L.Deupree. Neurosurgery, Duke Univ. Med. Ctr. and Research Service, Durham VAMC, Durham, NC, 27710.

Since many of the early pathological and behavioral changes associated with Alzheimer's disease may be linked to hippocampal damage, we have developed an excitotoxic lesion of bilateral hippocampal dysfunction as a model. Lesion induction involved a slow infusion of N-methyl-D-aspartate (NMDA) into the lateral cerebral ventricles over 2 weeks, to a total dose of 1 mg NMDA. The animals were behaviorally analyzed using a water maze test (using an index of cumulative escape time - CEM) and then underwent neural grafting of 17-18 day fetal hippocampus as chunks into the lateral ventricles. At time points after the grafting procedure the animals were again behaviorally tested, and physiological recordings were performed *in vitro* on the grafts, to assess synaptic integration of the tissue. The goal of the grafts as a treatment paradigm was to partially reconstruct the CA1 circuitry.

Histological analysis of the lesion showed bilateral CA1 cell loss, with moderate accompanying dentate granule damage. Behavioral analysis at the 1 mg NMDA dose showed a subset of lesioned animals with behavioral abnormalities (n=13/24; CEM = 1784 ± 307 s; mean ± SD), compared to control animals (n = 12; CEM = 1003 ± 405 s; $P < 0.05$ by t-test). At one year this behavioral abnormality was persistent in a subset of animals (n= 7/13; CEM = 1764 ± 294 s). The effects of the grafts on the behavioral abnormality were mixed, with a subset showing an improvement (n=6/10; CEM = 650 ± 217 s; $P < 0.01$ by t-test). Physiological recordings from the grafts in slices showed some synaptic connectivity to the host, but the grafts were in general not well integrated into the host hippocampus.

Thus, the integration of the grafts into the host hippocampus and behavioral effects were only moderate. Further characterization will include long-term anatomical and behavioral analysis and improved graft integration with suspension grafts. This model may have considerable relevance for the analysis of fetal grafting paradigms in Alzheimer's disease. Supported by grants from ADRDA, VAMC and B.S. Turner.

556.1

SACCADIC EYE MOVEMENTS IN SCHIZOPHRENIA: EVIDENCE FOR IMPAIRED SENSORIMOTOR GATING OF INTERNAL REPRESENTATIONS. D. Hommer, A. Radant* and S. Nickoloff*. GRECC, VAMC, Seattle, WA 98108.

To investigate the proposal that schizophrenia is a disorder affecting the utilization of representational knowledge, we used infra-red oculography to measure both visually and internally guided saccades during a task in which, initially, the target stepped 20° between two points at unpredictable intervals. Next, it moved in a completely predictable pattern. Finally, the target resumed the initial pattern of predictable location but unpredictable timing. Horizontal eye movements were recorded from 26 neuroleptic-treated and 8 drug-free schizophrenics, 25 normals and 8 patients with obsessive compulsive disorder. Latency and accuracy of visually-guided saccades and the frequency of adaptive predictive saccades did not differ among the groups. However, when the target motion switched from predictable to unpredictable schizophrenics made significantly more premature saccades directed towards the next target. The frequency of these maladaptive anticipatory saccades significantly correlated with thought disorder. These saccades may result from a failure in the inhibitory gating of premotor commands derived from cortical representations of target motion.

556.2

IMPLICIT MEMORY IN SCHIZOPHRENIA. B.L. Schwartz, R.B. Rosse*, and S.I. Deutsch. Psychiatry, VA Medical Center, Washington DC, 20422.

Schizophrenic patients are impaired on explicit recall tests, which depend on higher-order or conceptual cognitive processes. The question in this research was whether schizophrenic patients would be impaired on an implicit memory test that also depends on conceptual processes. We examined this issue in two experiments. In Experiment 1, we replicated the deficit in recall in schizophrenic patients. In Experiment 2, we examined implicit memory in schizophrenic patients using two tests, one that depended on conceptual processes (category production) and one that did not (word identification). The results of Experiment 2 showed that performance for schizophrenic patients did not differ from the performance of control subjects in either the category production or word identification tests. Implicit memory was unaffected in schizophrenia, irrespective of the nature of the cognitive processes involved in the test. These results suggest that conceptual processes in implicit memory tests may differ from those in explicit memory tests.

556.3

SCHIZOPHRENIA PSYCHOPATHOLOGY FOR THE NEUROSCIENTISTS. W.T. Carpenter, R.W. Buchanan* and B. Kirkpatrick. Maryland Psychiatric Research Center, P.O. Box 21247, Baltimore, MD 21228.

Current approaches to diagnosis, proven reliable and valid for many clinical and administrative purposes, are grossly inadequate for the neuroscience-based investigation of schizophrenia. Multiple criteria drawn from divergent aspects of behavior are poorly suited guides for developing animal models. An alternative approach to the use of diagnoses is to subdivide schizophrenia into discrete domains of psychopathology. Five such domains have been defined: expressive symptoms, cognitive symptoms, incongruity of affect, deficit functions, and neurologic manifestations. The neuroscience application of domains can be illustrated in two areas: 1) defining the phenotype for linkage studies; 2) establishing animal models for specific psychopathologic attributes. The authors believe that this shift in focus from diagnosis to domains will facilitate neuroscience investigations of schizophrenia by providing more relevant and applicable psychopathologic targets. This approach may diminish the false negative ascertainment in pedigree-based studies and decrease the speculative inference of animal models to schizophrenia. An animal model of social affiliation, anhedonia, or attentional dysfunction will require less speculative inference, and the relevance to schizophrenia will be more straightforward.

556.4

CORTICAL FOLDING IN THE TEMPORAL LOBE OF SCHIZOPHRENICS. E. Armstrong. Yakovlev Collection, Amer. Regis. Pathol., A.F.I.P., Washington, D.C. 20306.

The degree of cortical folding, as measured by the gyrification index (GI), was used to test the hypothesis that sulcal/gyral patterns in the temporal lobe differed between schizophrenic and normal brains. The GI was measured separately for the pole, dorsal, medial and lateral regions of the temporal lobe of 10 normal, 7 schizophrenic brains with leukotomies and 6 nonschizophrenic brains with leukotomies. The brains come from the Yakovlev Collection.

Both sets of leukotomized brains had a decrease in folding in the dorsal (Sylvian) region compared to normals, but an increase in relative amount of folding in the left medial cortex at the level of the anterior hippocampus. The GI's in the schizophrenic brains differed from the others in having a decreased degree of folding in the left medial cortex at the level of the amygdala, suggesting specific anomalies in this region. The medial cortex is from the amygdala to the medial bank of the occipito-temporal sulcus and includes much of the entorhinal cortex.

AGE-RELATED CT MEASURES IN SUB-GROUPS OF SCHIZOPHRENIC PATIENTS. Arthur Kling, Alan Steinberg, Peter Lucas, Neena Sachinvala, Ken Tachiki, Harald von Scotti, R. F. Ritzmann. Sepulveda VAMC, UCLA, Los Angeles, CA 91343.

Seventy-two schizophrenic patients and 41 controls had head CT scans. Patients were subtyped according to DSM III-R criteria. Measures were made of the area of the lateral ventricles and the amount of cortical atrophy in various brain regions. VBR differentiates between paranoid and residual/undifferentiated schizophrenic subgroups between the ages of 30-49. Total brain atrophy differentiates residual/undifferentiated schizophrenics from paranoid schizophrenics and/or controls after the age of 50. After the age of 40, atrophy in the sylvian region differentiates between schizophrenics and controls, regardless of sub-classification. To assess the possibility that alternative diagnostic classification systems would yield more robust CT differences, a subgroup of patients was classified according to three alternative typologies: Positive/Negative; Type I/Type II; Deficit/Nondeficit. No significant regrouping of patients emerged. Therefore, no change in CT findings was generated via these alternative classification methods. Supported by the Research Service, Sepulveda VAMC.

556.6

REGIONAL VARIATION OF NEUROANATOMICAL BRAIN ABNORMALITIES IN SCHIZOPHRENIA M. S. Myslobodsky, R. Coppola, E. F. Torrey*, D. R. Weinberger, NIMH Neuroscience Center, St. Elizabeths, Washington, DC 20032

Structural brain pathology encountered in schizophrenic patients poses a question whether the abnormalities are centered predominately at the limbic-prefrontal system. We answered this question by comparing the size of the septum with the size of the cuneus and the sucal pattern of the occipital lobe. The latter remains a unique brain province in that it has not been implicated in schizophrenia. Subjects were 19 pairs of monozygotic twins discordant for schizophrenia (range of discordance period was 4-24 yr.). For all pairs MR images (1.5 Tesla GE scanner) were obtained using identical T1 weighted spin echo pulse sequences (TR/TE=800/20). Sagittal cuts (5 mm thick) were analyzed to compare the size of the septum, cuneus, and the course of the medial occipital sulci. The 'variance zone' for the parieto-occipital and retrocalcarine sulci, the slopes of the right and left retrocalcarine sulci, and the the size of the cunei were practically identical between hemispheres and between the two groups. There was a small (11.4%) increase of the size of the septum in the impaired group. Two-sample sign test confirmed a high significance of this difference (p=.002). Thus, the impaired twin could be differentiated by increased septal area, but not by the anatomy of the occipital lobes within the same geometrical space of the brain.

EVIDENCE FOR DIFFUSE GRAY MATTER ABNORMALITIES IN SCHIZOPHRENIA R.B. Zipursky*, K.O. Lim*, A. Pfefferbaum Department of Psychiatry and Behavioral Sciences, Stanford University School of Medicine and VA Medical Center, Palo Alto, CA 94304.

A Magnetic Resonance Imaging (MRI) study was undertaken to determine the extent to which the greater ventricular and sulcal volume found in schizophrenic patients is due to differences in gray matter versus white matter volume.

Axial MRI scans were obtained using a GE Signa 1.5 T scanner from 22 patients meeting DSM-III-R criteria for schizophrenia and 20 healthy community volunteers. All subjects were right-handed male veterans, 20 to 45 years of age. Cerebrospinal fluid volume, gray matter volume and white matter volume were determined for eight 5mm thick sections per subject using a modification of the semiautomated approach described by Lim and Pfefferbaum (J Comput Assist Tomogr, Vol.13, No.4, 1989). Cortical areas were subdivided into multiple subregions in order to determine whether differences could be localized.

Within the cerebral cortex of the community volunteers, percentage gray matter volume but not percentage white matter volume was significantly correlated with age ($r = -.76$, $P < 0.001$). After correcting for the effect of age, the schizophrenic group was found to have significantly lower cortical gray matter volume than the control group (mean $Z = -1.88$, $P < 0.001$). Significant differences in percentage gray matter were found in all regions. No significant differences were found in percentage white matter in the cortex as a whole or in any of the cortical subregions.

These results are consistent with the view that relative gray matter volume is abnormally low throughout the brain in patients with schizophrenia as a group. It remains to be established whether specific regions are disproportionately affected.

Supported by MH 30854, NARSAD and the Department of Veterans Affairs.

GROWTH PROMOTING AGENT FOUND IN SCHIZOPHRENIC CSF CHANGES NEUROBLASTOMA CELL PROPERTIES. S.Shirabe*[1,2], J.P.Schwartz[2], and J.R.Stevens[1]. 1) NIMH, St. Elizabeths Hosp., Washington DC 20032, & 2) CNB, NINDS, NIH, Bethesda MD 20892.

This study was undertaken to look for a transmissible agent involved in the etiology of schizophrenia. The human neuroblastoma cell line SH-EP (NB) was incubated for 5 days with cerebrospinal fluid (CSF) from patients with schizophrenia (Sch) of 2-22 years duration (mean 8.9 yr) from St. Elizabeths Hosp., Washington DC, or various types of control CSF, after which cells were passaged at 2 week intervals. After 2-6 months culture, NB cells which had been treated with fresh CSF from 12/12 Sch patients showed 30-210% higher density growth than 15 control CSF-treated NB cell cultures ($p<.01$). The growth promotion could be transmitted by cell-free media from Sch CSF-treated cells. Seven of 9 Sch CSF- but only 1 of 13 control CSF-treated cultures showed increased size and/or number of colonies upon growth in soft agar. NB cells treated with Sch CSF showed changes in their intracellular neurofilament distribution by immunocytochemistry, using several different antibodies. Experiments are underway to identify the agent responsible for the cell transformation.

PARANOID SCHIZOPHRENIA: FREE AMINO ACIDS IN CEREBROSPINAL FLUID. E. Bonilla, D. Prieto-Rincón*, L. Piñerúa-Shuhaibar*, A.L.N. Prasad*, A. Arrieta*. Instituto de Investigaciones Clínicas, Universidad del Zulia and Inbiomed-Fundacite, Apartado 1151, Maracaibo, Venezuela.

Few publications have appeared regarding the levels of free amino acids in cerebrospinal fluid (CSF) of schizophrenic patients. We now report the results of the determination of 21 free amino acids levels in CSF of five non psychiatric controls (3 women, 2 men; mean age $\pm$ S.D., 41 ± 11.3 years) and seven paranoid schizophrenic patients (4 women, 3 men; mean age, 26.7 ± 8.1).

The samples of CSF were taken between 8 and 11 a.m., after patients and controls had been at bed rest for at least 8 hours and fasting for 14 hours. Lumbar puncture was made between L4 and L5. The amino acids analysis was performed by HPLC. The schizophrenic patients had higher ($p < 0.05$) CSF concentrations of glutamine than controls (547.4 ± 81.4 and 354.5 ± 118.7 µmole/liter, respectively). The levels of the remaining 20 free amino acids did not differ from control values. No significant correlation was detected between age, sex, and content of amino acids in CSF.

We could not confirm the findings of Bjerkenstedt et al (Br.J.Psychiat. 147: 276, 1985) that CSF levels of histidine were elevated in schizophrenic patients. Similarly we did not find any significant increase in the concentrations of CSF alanine, glycine, leucine, and phenylalanine as reported by Reveley et al (Biol.Psychiat. 22: 413, 1987).

DIFFERENTIAL NEURAL CIRCUITS IN SCHIZOPHRENIA. R.W. Buchanan*, W.T. Carpenter, F. Wood, G. Thaker, C. Tamminga. Md Psych Res Ctr, Baltimore, MD 21228

Subclassification of schizophrenic symptoms leads to the identification of discrete neural circuits associated with specific domains of psychopathology. We have studied two of these domains, positive psychotic symptoms and primary, enduring negative or deficit symptoms for discriminating neuroanatomical, neuropsychological, and electrophysiological characteristics. Substantial evidence now exists to suggest that different neural circuits are involved in the production of these symptoms. Limbic circuits appear to mediate positive symptoms and distinguish schizophrenic patients from controls. In contrast, deficit is distinguished from non-deficit schizophrenia by significantly reduced regional glucose utilization (mg glucose/100 gm tissue/min) in the thalamus (deficit: 8.1 ± 0.8; non-deficit: 10.4 ± 0.7) and in multiple regions of the frontal and parietal cortices. Deficit patients also exhibit significantly increased impairment on neurological measures of parietal lobe function (deficit: 3.29 ± 1.10; non-deficit: 1.47 ± 1.12) and significantly increased volitional saccadic latency (secs) (deficit: 441 ± 94; non-deficit 351 ± 70), an eye-tracking measure sensitive to frontal and/or parietal lobe impairment. These data implicate the involvement of the thalamus and frontal and parietal cortices in the production of deficit symptoms.

PET/FDG LOCALIZATION OF METABOLIC CHANGES IN SCHIZOPHRENIA. G.K. Thaker, A. Summerfelt*, M.B. Yablonski*, T.N. Chase, C.A. Tamminga, Maryland Psychiatric Research Center, University of Maryland at Baltimore, Baltimore, MD 21228

Regional analysis of cerebral glucose utilization may serve to localize areas of psychopathology in schizophrenic brain. PET/FDG studies were carried out in drug-free schizophrenic patients to test the hypothesis that areas of altered metabolism would parallel those brain areas in animals affected by the psychotomimetic PCP. Twelve young schizophrenic subjects with mixed florid psychotic symptoms and matched normals were scanned using ^{18}F-2-deoxyglucose on the NeuroPET scanner; five transverse planes in each subject were analyzed blindly using ROIs matched to a human brain atlas. Results showed no differences between schizophrenics and normals in neocortical or extrapyramidal areas, but a significant decrease in glucose metabolism in limbic cortex in subjects with schizophrenia. Specifically, metabolic rates of patients were reduced in hippocampus and anterior cingulate. This distribution of metabolic changes parallels the metabolic alterations in rat brain following PCP and MK801. Differences in schizophrenic subgroups will be reported.

556.12

THE COADMINISTRATION OF AMPHETAMINE AND HALOPERIDOL IN SCHIZOPHRENIA. T. E. Goldberg*, L. B. Bigelow, D. G. Daniel, J. E. Kleinman*, D. R. Weinberger*. Clinical Brain Disorders Branch, NIMH Washington, D.C. 20032

In this study, we attempted to determine if an acute dose of dextroamphetamine might have positive effects on affect and cognition in schizophrenic patients maintained on haloperidol. We based this premise on the rationale that dopamine type I receptors in frontal cortex might be indirectly stimulated by amphetamine, resulting in improved affect and cognition, while the potential psychotogenic effects of amphetamine stimulation of subcortical type II receptor sites would be prevented by haloperidol blockade. In a double-blind placebo crossover study, 21 patients with chronic schizophrenia received a single oral dose of amphetamine at .25 mg/kg. All patients were receiving .4 mg/kg daily of haloperidol. Six patients were judged by clinical rating systems to have improved in terms of affect and engagement with the environment. Improvement was associated with enlarged cerebral ventricles and also with increases in blink rate from placebo to active drug condition. Amphetamine also improved some parameters of performance on the Wisconsin Card Sorting test of concept formation and set shifting, though it did not result in changes in tests of memory or attention. The possibility that a dopamine agonist in conjunction with a dopamine type II receptor antagonist might prove efficacious in schizophrenia may have implications for understanding the neural systems involved in this disease.

[^{3}H]PAROXETINE BINDING IN POSTMORTEM BRAINS OF SCHIZOPHRENICS, SUICIDES, COCAINE ADDICTS AND CONTROLS. M. Laruelle, M. F. Casanova*, D. R. Weinberger and J. E. Kleinman, CBDB, NIMH Neuroscience center, Washington D.C. 20032.

[^{3}H]Paroxetine is the ligand of choice to label the serotonergic uptake sites in human brain (Laruelle, M., Biol. Psychiatry, 24:299, 1988). Because of the implication of the serotonergic system in schizophrenia and suicide, we performed post mortem saturation analysis of [^{3}H]paroxetine (0.065 to 2nM) specific binding (defined as the binding displacable by 1µM citalopram) in the frontal pole of patients suffering from schizophrenia (n=10), chronic schizoaffecive illness (n=5), non psychotic suicide (n=8) and matched controls (n=10). Samples from cocaine addicts were also analysed (n=9), due to the reported toxicity of chronic cocaine administration for serotonin uptake sites in rats (Terry L.M., Soc. Neurosc. Abst., 322.11, 1989). Kd values did not exhibit significant differences between the groups. Bmax values were significantly differents (Anova,p<0.05): controls 84±13 fmol/mg of protein (mean±SEM), schizoaffectives 81±8 fmol/mgP, schizophrenics 48±5 fmol/mgP, suicides 48±2 fmol/mgP and cocaine addicts 64±10 fmol/mgP. Post-hoc analysis showed a significantly lower Bmax in schizophrenics and suicides compared to controls. These results suggest an abnormality of the serotonergic presynaptic system in schizophrenia and suicide but fail to support in human the notion of toxicity of cocaine toward these terminals as described in rats.

Abstract Title: A COMPARISON OF CHRONIC SCHIZOPHRENICS WITH INTERICTAL PSYCHOTICS

Author(s) Name: Estelle Toby Goldstein, M.D., Sheldon H. Preskorn, M.D., Beryl Silkey, ScM., Linda Haug

Patients with the interictal psychosis of partial complex epilepsy (n=18) were compared with patients with chronic schizophrenia (n=17). The patients had been followed in the inpatient and outpatient units of the Wichita Veterans Administration Medical Center Psychiatry Service. Epileptic patients did not significantly differ from schizophrenics in age at index hospitalization (Mean ± SD = 45.4 ± 9.4 yrs vs. 43.4 ± 10.8 yrs, respectively; t=0.58, df=33, N.S.). Schizophrenic patients were about ten years younger at age of DSM-IIIR diagnosis than the epileptic patients, and the latter had a broader range of ages at which diagnosis was made (Mean ± SD = 23.2 ± 6.6 yrs,; 32.5 ± 12.5 yrs, respectively, t=2.54, df=28, p<.01). Schizophrenic patients became psychotic at an earlier age than epileptic patients (Mean ± SD=22.6 ± 6.8 vs. 33.2 ± 10.8; Student's t=3.05, 27df, p<.005).

The epileptic group was more likely to have had a documented history of head injury (X^2=8.31, 3df,p<.05) than the schizophrenic group. Documentation of other major injuries, however, did not differ significantly between the two groups (X^2=.55, 3df, N.S.).

The medical histories of these two groups were not notably different. Two patients in the chronic schizophrenic group had a family history of schizophrenia (maternal side),compared to no family history in the epileptic group. Family history for non-psychotic psychiatric illness (alcohol abuse, depression, other) was equally represented in both groups (five in each group).

Additional comparisons of these syndromes are made, with special reference to clinical features of the psychosis, other behavior disturbances and treatment response.

ELEVATED D2 DOPAMINE RECEPTOR DENSITY IN 26 SCHIZOPHRENIC PATIENTS: L. Tune, D.F. Wong, H.N. Wagner, R.F. Dannals, The Johns Hopkins Hospital Medical Institutions, Baltimore, MD 21205

Utilizing 11-C-N-methylspiperone positron emission tomography (PET) striatal D2 dopamine receptor density (Bmax) was compared in 26 chronic schizophrenic subjects, 21 of whom were drug-naive at the time of scan (and an additional 5 with minimal neuroleptic exposure and 14 controls). All patients satisfied DSM-IIIR criteria for chronic schizophrenic illness. The average age was 37.65 +/- 3.5 years. The average duration of illness was 4.63 +/- .89 years (without prodrome) and 7.22 +/- 1.29 years with prodrome. Dopamine receptor density (Bmax) in schizophrenic subjects (32.35 +/- 17.89) was significantly elevated when compared to control subjects (15.46 +/- 9.26). Bmax overlapped with normal controls in 11 of 26 subjects. Clinical and neuropsychological test results were then compared with Bmax values and will be presented.

POSTMORTEM STUDY OF DOPAMINE AND ITS METABOLITES IN BILATERAL AMYGDALAS OF SCHIZOPHRENICS, COCAINE ADDICTS AND CONTROLS. B.S. Kolachana, M. Laruelle, M. F. Casanova* and J.E. Kleinman. NIMH Neuroscience Center at St Elizabeths, Washington D.C., 20032

Previous studies (Reynolds G.P., Nature, 305:527, 1983) have reported a higher concentration of dopamine (DA) and, to a lesser extent, homovanillic acid (HVA), in the left compared to right amygdalas of patients with schizophrenia. In an attempt to replicate these findings, we measured DA, HVA and DOPAC in the right and the left amygdalas of schizophrenics (n=4), cocaine addicts (n=5) and matched controls (n=6). For DA, results were (Means±SEM) as follows: controls: right 0.83±0.36ng/mg of protein, left 0.43±0.09ng/mgP; schizophrenics: right 0.66±0.37ng/mgP, left 1.46±0.94;ng/mgP; cocaine addicts: right 1.70±1.1ng/mgP, left 1.04±0.49ng/mgP. Neither the diagnosis factor, the hemispheric side factor, nor the diagnosis x hemispheric side interaction showed a significant effect when analysed with a 2 factor repeated measure Anova. Results of HVA and DOPAC levels were also negative. Nevertheless, the schizophrenic group was the only group that showed higher DA levels in the left side compared to the right. This was also true for HVA. More samples should be studied before a conclusion could be reached.

PCP-INDUCED DOPAMINE RELEASE IN VITRO: TACHYPHYLAXIS AND RECOVERY OF RESPONSE. L.P. Dwoskin, L.L. Leibee, S.T. Buxton and J.M. Carney. Div. Pharmacol. Exp. Ther., Col. Pharmacy and Dept. Pharmacol., Col. Med., Univ. Kentucky, Lexington, KY 40536.

Abuse of phencyclidine (PCP) produces behavioral effects resembling schizophrenia, which may be due to activation of CNS dopaminergic systems. Using HPLC-EC, endogenous dopamine (DA) and dihydroxyphenylacetic acid (DOPAC) were measured in superfusates from striatal slices taken from DBA/2J mice. Two slices were placed in each of two superfusion chambers and were superfused (1 ml/min) with Krebs' buffer for 60 min. Subsequently, chambers were superfused for 60 min with control buffer or with buffer containing PCP ($3x10^{-5}$M), followed by control buffer for a variable period (0, 30, 60 and 120 min) followed by a second, 60-min exposure to PCP ($3x10^{-4}$M). Initial exposure to PCP resulted in a peak increase in the concentration of DA and DOPAC (190 and 450 pg/ml/mg, respectively). Despite the continued presence of PCP, DA and DOPAC concentrations returned to basal levels, indicating rapid desensitization. Preexposure to PCP diminished the subsequent response to PCP (70% of control for DA, 40% for DOPAC). However, DA and DOPAC concentrations were not different from control when superfusion for 30 or 60 min period, respectively, was interposed between PCP exposures. Therefore, the diminshed response was not due to depletion of the releaseable pool of DA, but rather to a dynamic adaptive response of the dopaminergic neuron. Supported by NIMH MH42934, UKMC Fund and NIDA Contract 271-87-8133).

POSSIBLE MESOPONTINE CHOLINERGIC HYPERPLASIA IN SCHIZOPHRENIA. C. Karson, E. Garcia-Rill, J. Biedermann*, J. Smith*, R. Skinner, R. Mrak and M. Husain*. Dept. of Anatomy, Univ. of Arkansas for Med. Sci., Little Rock and V.A. Hospital, North Little Rock, AR.

Pedunculopontine nucleus (PPN) neurons, along with adjacent catecholaminergic nuclei, have been implicated in the modulation of sleep and movement. This cholinergic cell group appears to be the generator of the P1 auditory evoked potential (Buchwald et al., 1990) which in turn fails to habituate in schizophrenia (Freedman et al. 1983). Cholinomimetics produce sleep pattern and affective disturbances similar to schizophrenia and a role for cholinergic hyperactivity has been proposed in this disorder. Human brain tissue was obtained from four diagnosed schizophrenics (age 63±10) and from five control subjects (age 60±9). One half of the mesopontine brainstem was fixed and frozen sections processed for NADPH diaphorase histochemistry (which labels cholinergic mesopontine cells) and tyrosine hydroxylase immunocytochemistry (which labels catecholaminergic cells). The cell number and size of cholinergic PPN and laterodorsal tegmental (LDT) nuclei, as well as the nonadrenergic locus coeruleus (LC) were measured. Wilcoxon Test P<0.05 = ***

Cell Number	PPN	LC	LDT
Control	8,500±1621	11,353±4,791	6,268±3,526
Schizophrenia	18,275±8220***	11,496±2,956	12,266±7774
Cell Size (sq. um)	PPN	LC	LDT
Control	517±67	1032±105	625±37
Schizophrenia	517±44	761±106***	553±58

These preliminary findings suggest the presence of a greater number of cholinergic PPN neurons in the brains of schizophrenics. Such a hyperplasia appears consistent with the proposed fault in programmed cell death in this disease (Feinberg 1982), perhaps leading to cholinergic hyperactivity. The reduced cell size present in LC could be a result of neuroleptic treatment, and may contribute further to the disinhibition of PPN in this illness.

THREE BRAIN ANTIGENS IN SCHIZOPHRENIA

W.G. Honer, C.A. Kaufmann, J.E. Kleinman, M.F. Casanova*, J. Gleeson, P. Davies* Dept. of Pathology, Albert Einstein College of Medicine, Bronx, NY 10461

We have described a panel of monoclonal antibodies for schizophrenia brain studies (Brain Res 1989;500:379). Detailed results with 3 of these antibodies are now reported. Antibody EP10 binding to schizophrenia (sch) brain homogenates was increased compared to controls (con) (U=18, p=.007, n=11 sch, 11 con). This increase appeared to be globally distributed in 5 brain regions. Tissue staining with EP10 indicated a pattern typical for synaptic antigens. Immunoblotting revealed an EP10 reactive band at about 38 kd. A similar protein band immunoprecipitated by EP10 was reactive with an antibody against synaptophysin. This, or a similar synaptic molecule may be elevated in the brain in schizophrenia. Antibody EP1 binding to sch caudate was decreased compared to con (U=2, p=.01, n=7 sch, 5 con). Tissue staining showed neuronal cell bodies as well as apical and basilar dendrites. Antibody EP7 binding to temporal cortex from male cases of sch was reduced compared to male con (U=3, p=.05, n=8 sch, 4 con). In tissue sections EP7 appeared to stain distal axonal profiles. Biochemical studies on the EP1 and EP7 antigens are in progress. These preliminary results using the EP antibodies indicate that several distinct molecular abnormalities may be present in the schizophrenia brain.

ABNORMAL GROWTH OF FIBROBLASTS FROM SCHIZOPHRENIC PATIENTS IS NOT DUE TO ACUTE NEUROLEPTIC EFFECT.

H. LAEV, R. REDDY,* S. MUKHERJEE* AND S.P. MAHADIK. Division of Neuroscience, NYSPI & Columbia Univ., N.Y., N.Y.

We have observed abnormal growth and morphology of skin fibroblasts from schizophrenic patients compared with normal controls. Cultures were established from skin biopsies of 14 schizophrenic patients and 12 age-matched normal subjects. Fibroblast cultures from these patients showed differences on the following growth parameters. Initial growth: fibroblasts from schizophrenic patients took considerably longer to establish than those from controls. Established cultures were obtained from most normals at <1 month as compared to 2-4 months for schizophrenic patients. Rate of growth: doubling time for fibroblasts from schizophrenics was markedly longer than that of normals. Morphological differences: fibroblasts from normals showed typical uniform, long, spindle-like appearance and unidirectional orientation; fibroblasts from schizophrenics exhibited random sizes (shorter, flatter) and orientation. Since all of these patients were on neuroleptic treatment, confounding effects of acute neuroleptics on these growth characteristics are difficult to resolve. To address this issue, fibroblast cultures from skin biopsies of patients (N=6) off-drug at the time of biopsy, normals (N=6) challenged in culture with haloperidol and, normal established cultures (N=4) challenged with haloperidol in culture were studied. The initial growth of fibroblasts from off-drug was improved but was not identical to normals. Rate of growth and morphology were still abnormal. There was no effect of haloperidol challenge of skin biopsy of normals or normal fibroblast culture on any of the growth parameters. Data indicate that acute haloperidol has marginal effect on initial growth only and abnormalities observed in patient fibroblasts are probably related primarily to disease process. Further studies with skin biopsies from never medicated patients will help to understand interaction of treatment with disease process.

RESPONSE LATENCY STRUCTURE IN SCHIZOPHRENIA AS RELATED TO DA OVERSTIMULATION THEORY.

M. Lyon and N. Lyon, Center for Schizophrenia Research, Department of Psychiatry, University of Arkansas for Medical Sciences, Little Rock, AR 72205.

Prior investigations have shown the presence of increased switching between responses and increasing stereotypy of responses in schizophrenic patients responding on a two-choice decisional task (Lyon et al., 1986; Lyon and Gerlach, 1988). This was interpreted as support for the effects of dopaminergic overstimulation effects on response sequencing as predicted by Lyon and Robbins (1975) and Robbins and Watson (1981). If this interpretation is correct then the response latency structure should also be more consistently patterned in schizophrenic patients, with resulting increases in number of fixed patterns and in the variety of patterns found to be repeated.

The present study examines the structure of response latency patterns between two-choice decisional responses produced by schizophrenic patients (N=17) and age, sex, and educationally matched normal control subjects (N=17) from the same sample used by Lyon et al. (1986). Sequential time range patterns in the latencies were screened by a computer program (Magnusson, M.S., Revue des Conditions de Travail, 1988) which selected only patterns which occurred at least 3 times with a variability of interresponse latencies having a probability of $P<0.0001$.

Results showed that schizophrenic patients had significantly more ($P=0.025$) total patterns than control subjects, and also a greater variety of significant ($P<0.0001$) individual response patterns. This occurred despite the fact that schizophrenic subjects had a greater number of individual "outlier" latencies that prevented some patterns from being significant. These results give further support to the twin principles of increased switching and final stage stereotypy as important markers in schizophrenic behavior.

EFFECTS OF INTRAVENTRICULAR KAINIC ACID ON SENSORY GATING OF THE RAT N40 AUDITORY EVOKED POTENTIAL.

H.T. Nagamoto, K.E. Stevens, L.L. Fuller*, S. Bernal*, R. Johnson*, and G.M. Rose Depts. of Pharmacology and Psychiatry, UCHSC, & VAMC, Denver, Colo. 80262

The N40 auditory evoked potential recorded in response to the second of a closely spaced pair of stimuli is reduced compared to the first. This gating phenomenon is attenuated in schizophrenic humans, and can be disrupted by amphetamine in humans and rats. This study evaluated the effects of intraventricular (i.c.v.) kainic acid administration on N40 gating in unanesthetized Sprague-Dawley rats. Gating mechanisms were assessed by measuring the suppression of the N40 response to a 71 dB test click stimulus following an identical conditioning stimulus given 0.5 sec earlier. In control rats, N40 showed a significant reduction to the second stimulus. Amphetamine interfered with this decrement; subsequent haloperidol administration restored normal gating. Similar results have been seen in anesthetized rats recorded from both vertex and the CA3 region of hippocampus. Ten male Sprague-Dawley rats received bilateral i.c.v. injections of 0.5-0.7 μl kainic acid. Vertex recordings were obtained 2 weeks to 4 months after infusion, and results were compared with 15 unlesioned rats. The kainic acid treated rats had significantly lower mean conditioning N40 amplitudes and higher conditioning-testing ratios. These parameters did not vary over time in either lesioned or unlesioned animals. Pyramidal cell loss in region CA3 of the lesioned rats varied between 41-88%. However, the extent of the damage to CA3 did not correlate with any N40 parameter. (Supported by P50 MH44212-01.)

DOPAMINE D1, BUT NOT D2, RECEPTOR BLOCKADE REVERSES AMPHETAMINE-INDUCED CHANGES IN AUDITORY GATING.

K.E. Stevens, L.L. Fuller* and G.M. Rose. Dept. of Pharmacology, UCHSC; and VAMC, Denver, CO 80262

The N40 auditory evoked potential recorded in response to the second of a closely spaced pair of stimuli is reduced compared to the first. This gating phenomenon is disrupted by administration of amphetamine. In addition, both conditioning and test evoked potential amplitudes are reduced compared to unmedicated trials. These changes are reversed by haloperidol. Here we report the results of selective dopamine receptor blockade on the amphetamine-induced changes. Rats were chronically implanted with a recording electrode at the vertex. Following recovery, the N40 potentials in response to paired, 71 dB click stimuli (presented 0.5 s apart, every 15 s) were assessed repeatedly over several days. Animals with normal gating were then given amphetamine (1.83 mg/kg, i.p.) to confirm drug-induced disruption of gating. Following this, animals were given either the D1 antagonist, SCH 23390 (0.5 mg/kg, i.p.), or the D2 antagonist, ±sulpiride (40 mg/kg, i.p.), and the effects on N40 observed. Blockade of D1 receptors reversed the amphetamine-induced changes in N40, yielding responses not different from the unmedicated state. In contrast, D2 receptor antagonism had no effect on amphetamine-induced alterations in N40. Administration of the antagonists alone had no effect on normal responses. Thus, changes in N40 amplitude, and the concomitant disruption of gating, induced by amphetamine appear to be mediated through a dopaminergic, D1 receptor mediated, mechanism. (Supported by P50 MH44212-01.)

PARTIAL HIPPOCAMPAL DAMAGE ABOLISHES FACILITATIVE EFFECT OF STRESS ON SIMPLE LEARNING: FURTHER ANALYSIS OF AN ANIMAL MODEL OF SCHIZOPHRENIA.

K.S. Seybold, M. Campion*, J. Kendall* and R.L. Port. Depts of Psychology, Grove City College, Grove City, PA 16127 and Slippery Rock University, Slippery Rock, PA, 16057.

A putative animal model of schizophrenia has been developed based on hippocampal neuropathy described in humans (Jeste & Lohr, 1989). Preliminary analyses (Seybold, et al, 1989) revealed that slight hippocampal damage in rats produced a facilitation of simple learning similar to the effects found in schizophrenic humans. The present experiment evaluated the effects of stress, which facilitates performance in normal subjects but may have deleterious effects on schizophrenic subjects, on simple learning. Adult hooded rats received bilateral intraventricular injections of saline (CONT), 0.5m kainic acid (EXP-L) or 1.5m kainic acid (EXP-H). After recovery, half of the animals were exposed to a cold-water swim (5° C, 3.5 min) and all were trained in shuttlebox avoidance for 30 trials on the following three days. Stress facilitated acquisition in the CONT group but not in the EXP-L or EXP-H groups.
