High levels of protein tyrosine kinase activity are expressed in the hippocampus and cerebellum, two brain regions important in learning and memory. We therefore investigated whether tyrosine kinase activity is required for long-term potentiation (LTP), a form of synaptic plasticity thought to contribute to memory formation. Using in vitro assays of protein kinase activity we found that two compounds, genistein and lavendustin A, selectively inhibited pp60^{c-src}(+), a tyrosine kinase present in hippocampal neurons. These inhibitors blocked LTP in the hippocampal slice when bath applied prior to tetanic stimulation but had no effect on established LTP, on normal synaptic transmission, or on neurotransmitter actions mediated by PKA or PKC. LTP was also blocked when lavendustin A was injected into the postsynaptic CA1 pyramidal cells via an intracellular recording electrode. These data suggest that tyrosine kinase activity is required postsynaptically for the induction of LTP. Since CamKII and PKC also seem to be essential our data suggest that the induction of LTP requires a network of protein kinase activity that includes tyrosine as well as serine/threonine kinases.

ARACHIDONIC ACID AND 1-OLEOYL-2-ACETYL GLYCEROL INDUCE LONG-TERM POTENTIATION IN HIPPOCAMPAL CA1 NEURONS IN LOW MAGNESIUM SOLUTION. K.Kato*, K.Urino*, K.Saito*, H.Kato*, C.F.Zorumski*. Dep. Psychiatry, Washington Univ. Sch. Med., St. Louis, Mo 63110, U.S.A., *Dep. Physiol., Yamagata Univ. Sch. Med., Yamagata 990-23, JAPAN.

To evaluate the role of protein kinase C (PKC) and arachidonic acid (AA) on the maintenance of long-term potentiation (LTP), we examined the effects of phospholipase blockers on tetanus-induced LTP and of diacylglycerol (DG) and AA on synaptic transmission in CA1 neurons of guinea pig hippocampal slices.

Neomycin (1 mM) or 2-nitro-4-carboxyphenyl-N,N-diphenylcarbamate (NCDC, 0.1 mM), blockers of phospholipase, suppressed the maintenance of tetanus-induced LTP. Perfusion of 1-oleoyl-2-acetyl-glycerol (OAG, 100 μ g/ml) or AA (100 μ M) produced a temporary increase in both the amplitude of the population spike (PS) and the slope of the field excitatory postsynaptic potentials (EPSPs) but failed to produce LTP. However, administration of OAG or AA in low-Mg²⁺ (0.1 mM) solution induced LTP. Both OAG- and AA-induced LTP were blocked by di-2-amino-phosphonopentanoic acid (AP5; 50 μ M). The administration of a potent PKC activator, phorbol-12,13-dibutyrate (PDBu), in low-Mg²⁺ (0.1 mM) solution enhanced the PS and EPSPs for two or three hrs, but this enhancement was not sustained. Coapplication of PDBu with AA had no effect on the magnitude of AA-induced potentiation in low Mg²⁺ solutions.

These results suggest that PKC activation itself is not as critical as AA for the maintenance of LTP and that DG and AA coupled with the influx of Ca²⁺ through NMDA receptor-gated channels play important roles in the prolonged nature of LTP.

PROTEIN KINASE C EXPRESSION AND FUNCTION IN NEURONS OF THE HIPPOCAMPUS. K.Kruger, H.Boswell, & S.A.DeRiemer. Dept. Biological Sciences, Columbia Univ., New York, N.Y. 10027

We are investigating the physiological roles of isozymes of protein kinase C (PKC) in the rat hippocampus. The hippocampus was chosen because PKC activity is highest in this area of the brain and the activation of PKC has been shown to enhance synaptic transmission in CA1 pyramidal neurons (Baraban et al.1985). PKC appears also to be important for the induction and expression of long term potentiation in the hippocampus. There are seven isozymes of PKC that have been identified by cDNA cloning and sequencing. We are studying the alpha, beta, and gamma isoforms which are members of the class that require calcium as well as diacylglycerol for activation. We examined the localization of the isozymes in rat embryonic hippocampal neurons in cell culture and in brain slices with antibodies to regions that are highly variable between isoforms (Makowski et al. 1988). The isozymes are coexpressed in all the neurons in cultures from day 19 embryos. Expression of the enzyme is significantly lower in glial cells. The intensity of staining varied between the cytoplasm, perikaryon, and the dendrites for the different isozymes. Marked staining of varicosities and growth cones was seen with the gamma isozyme. Immunohistochemical analysis of cryostat sections from the brain of young animals showed these isozymes to be coexpressed. The gamma isozyme is the most widely distributed, seen in CA1 and CA3 pyramidal cells and dentate granule cells. We are using the whole cell patch technique to look at the effects of PKC isozymes on the electrical properties of hippocampal neurons. Research supported by NIH grant# NS-08614 to KK.

LOW CONCENTRATIONS OF ARACHIDONIC ACID PRODUCE AN ACTIVITY-DEPENDENT ENHANCEMENT OF SYNAPTIC TRANSMISSION IN HIPPOCAMPAL SLICES PRELOADED WITH A DIACYLGLYCEROL ANALOG. C.R. Bramham*, D.S. Lester*, D.L. Alkon. Section on Neural Systems, NIH, Bethesda, MD 20892.

Liberation of arachidonic acid (AA) and activation of protein kinase C are both implicated in long-term potentiation. AA, when applied at 50 μ M and combined with weak afferent stimulation, leads to an increase in synaptic transmission. Recently it was found that AA and diacylglycerol, both lipid activators of protein kinase C, work synergistically to activate this enzyme in a model membrane bilayer system, and in a cellular model of associative learning (see Etcheberrygaray et al. this meeting).

Population EPSPs evoked by Schaffer-collateral stimulation were recorded in stratum radiatum of rat hippocampal slices perfused with standard ACSF. Averaged EPSPs (6 test pulses at 0.1 Hz) were obtained at regular intervals. Oleoylacetyl-glycerol (OAG 5 μ g/ml), a diacylglycerol analog, was perfused for 15 min followed by 15 min of AA (5 μ M) perfusion during which time stimulus pulses were applied every 4 s. This procedure consistently led to an increase in EPSP amplitude which reached a stable plateau after about 30 min. The combination of AA and repetitive afferent stimulation was ineffective without OAG pretreatment, as was sequential perfusion of OAG/AA without afferent stimulation. These results suggest that arachidonic acid-induced potentiation depends not only repetitive synaptic activity but also on the membrane concentration of diacylglycerol.

PHOSPHOINOSITIDE HYDROLYSIS INDUCED BY HIGH FREQUENCY ELECTRICAL STIMULATION IN THE DENTATE GYRUS OF RAT HIPPOCAMPAL SLICE. M.J. Bonner, E.C. Burdard and J.M. Sarvey. Department of Pharmacology, Uniformed Services University of the Health Sciences, Bethesda, MD 20814.

High frequency electrical stimulation in the hippocampus results in long-term potentiation (LTP), a form of synaptic plasticity. Activation of second messenger systems is implicated in the induction and maintenance of LTP. Stimulation of phosphoinositide (PI) hydrolysis by a high frequency train (HFT; 100Hz, 2 sec) to the perforant path in the dentate gyrus was studied *in vitro* in hippocampal slices. HFT increased total PI hydrolysis 1 min post-stimulation by as much as 200% (n=15 slices/gp) of non-HFT exposed (controls) slices. The PI metabolism induced by HFT was antagonized by the NMDA-antagonist CPP (10 μ M). Increased PI turnover was detected over a time course from less than 1 min up to 60 min after HFT. PI turnover increases were also reflected in increases in IP1, IP2, and IP3 at 1 min and 30 min post-HFT. HFT that was subthreshold for LTP did not significantly affect PI hydrolysis. The membrane-bound portion of the PI cycle was affected similarly. This study shows that *in vitro* HFT stimulation of the perforant path in the dentate gyrus of the rat hippocampal slice can induce sustained increases in PI hydrolysis. These results suggest that PI hydrolysis is involved in the expression of LTP in the dentate gyrus.

NMDA RECEPTORS CAUSE Ca^{2+} -DEPENDENT INCREASES IN cAMP LEVELS AND Ca^{2+} -CHANNEL ACTIVITY. D.M. Chetkovich, R. Gray, D. Johnston and J.D. Sweatt. Div. Neurosci., Baylor Coll. of Med., Houston, TX.

We have previously reported that LTP-inducing tetanic stimulation in area CA1 of rat hippocampus leads to an APV-sensitive increase in cAMP. We now have found that a 10 min bath application of NMDA to hippocampal slices produced concentration-dependent increases in cAMP in area CA1, with maximal stimulation at 1 mM NMDA and an EC_{50} of 55 μ M. The effect of NMDA (100 μ M) was blocked by the NMDA receptor antagonist, APV (50 μ M) ($327 \pm 38\%$ of control cAMP without APV, $n=5$; $87 \pm 15\%$ of control cAMP with APV, $n=3$). IBMX (100 μ M) did not attenuate the effect of NMDA (400 μ M) ($393 \pm 46\%$ of control without IBMX, $n=9$; $352 \pm 24\%$ of control with IBMX, $n=6$), suggesting that the effect of NMDA on cAMP is not due to an alteration in phosphodiesterase activity. We examined whether NMDA receptors couple to adenylyl cyclase (AC) directly via a G-protein. AC activity in membranes prepared from area CA1 was stimulated by both forskolin (1 μ M) ($1314 \pm 45\%$ control AC activity, $n=5$) and GTP (10 μ M) ($146 \pm 7\%$ control AC activity, $n=4$); however, NMDA did not affect membrane AC either in the presence or absence of GTP ($n=4$). Thus NMDA receptors apparently do not couple directly to AC via G-protein activation. NMDA receptor activation is known to cause Ca^{2+} influx. Removal of extracellular Ca^{2+} (1 mM EGTA, 0 Ca^{2+}) blocked the NMDA effect ($98 \pm 11\%$ control cAMP with 100 μ M NMDA, no Ca^{2+} , $n=4$). We have previously reported that brief coapplication of NMDA (1 mM) and Ca^{2+} (2 mM) to CA1 pyramidal cells (bathed in high K^+ and 0 Ca^{2+}) increased the activity of voltage-gated Ca^{2+} channels. This effect could be mimicked with 8-bromo-cAMP, but not with NMDA or Ca^{2+} alone. These results, taken together, suggest that NMDA receptor-mediated increases in cAMP occur secondary to Ca^{2+} influx, perhaps through Ca^{2+} /CaM stimulation of AC. Supported by a C. Bell Pearce Award (D.C.), USPHA RR-05425 (D.S. and R.G.), MH 44754 (D.J.), AFAR and McKnight (D.S.).

CYCLIC AMP CAUSES SHORT-LASTING DEPRESSION AND LONG-LASTING POTENTIATION IN CA1. S. Pockett and J.R. Slack*. Dept. of Physiology, University of Auckland, Private Bag, Auckland, New Zealand.

The effect on synaptic transmission of superfusing hippocampal slices with membrane-permeable analogues of cyclic AMP or with the adenylyl cyclase activator forskolin was studied, using extracellular recording techniques. The Schaffer collateral/commissural pathway was stimulated at 0.05 Hz and population spike amplitude measured. The population spike in area CA1 was affected in a biphasic manner by addition of dibutyl cyclic AMP: during the presence of dbcAMP the population spike was depressed and after wash-out of dbcAMP the population spike was potentiated. The depression lasted only as long as the dbcAMP was in the bath and the potentiation lasted unchanged for at least 3 hours after wash-out of dbcAMP. With 200 μ M dbcAMP the depression was to $22\% \pm 11\%$ S.E.M. ($n=7$) of the baseline population spike amplitude and the potentiation was to $137\% \pm 8\%$ ($n=7$) of baseline. Similar results were obtained with 8-bromo cyclic AMP and forskolin. The presence of picrotoxin (10 μ M) in the recording chamber had no significant effect on the depression caused by 200 μ M dbcAMP but significantly decreased the potentiation to $116\% \pm 6\%$ ($n=7$) of baseline. These findings suggest that cyclic AMP may play a role in long-term potentiation.

160.19

CYCLIC GMP POTENTIATION OF NICOTINIC TRANSMISSION IN THE RAT SUPERIOR CERVICAL GANGLION (SCG). Clark A. Briggs. Neuroscience Research, Abbott Laboratories, Abbott Park, IL 60064.

Nicotinic transmission in the SCG is potentiated by 1 mM 8-bromo-cyclic GMP (8-Br-cGMP; Briggs *et al.* (1988), *Br. J. Pharmacol.* 93: 399). However, the lack of effect of dibutyl-cGMP and the ability of dibutyl- as well as 8-Br-cAMP to potentiate nicotinic transmission questioned the specific involvement of a cGMP-mediated process. This hypothesis and the potential involvement of nitric oxide (NO), an agent that can stimulate the synthesis of cGMP, was further investigated. The methods were similar to those previously described. Briefly, rat SCG were isolated and superfused *in vitro* at ambient temperature (25°C) with oxygenated Locke's solution, and the postganglionic compound action potential response to stimulation of the preganglionic nerve at a slow rate (1/60 seconds) was used as a measure of nicotinic synaptic efficacy.

At low concentrations (0.3 μ M - 100 μ M applied for 30 minutes), 8-Br-cGMP caused dose-dependent potentiations of 5% - 80%. While 8-Br-cAMP also caused a potentiation of ganglionic transmission, it appeared to be about 5x less potent than 8-Br-cGMP. Nitroprusside and azide potentiated ganglionic transmission at concentrations known to stimulate cGMP formation in the rat SCG (0.1 μ M - 1 mM applied for 30 minutes). Nitroprusside caused a $24 \pm 2\%$ potentiation at 10 μ M ($n=10$), and was more effective than azide ($11 \pm 2\%$ potentiation at 10 μ M, $n=3$). Ferricyanide (10 μ M) had no effect, as would be expected if nitroprusside acted through the release of NO. Simultaneous addition of 8-Br-cGMP and 8-Br-cAMP did not cause a supra-additive potentiation. The data are consistent with the concept that cGMP may mediate a potentiation of nicotinic transmission that may be related to NO formation. However, additional studies are needed to evaluate the possibility of a physiological role for an 'EDRF'/NO system regulating synaptic transmission in the SCG.

CYCLIC AMP AS THE RESPONSE REGULATOR FOR LONG- AND SHORT-TERM POTENTIATION OF SECRETION. B.H. Morimoto* and D.E. Koshland, Jr. Dept. Molecular and Cell Biology, Division of Biochemistry and Molecular Biology, University of California, Berkeley, CA 94720

The HT4 neural cell line serves as a model for memory by exhibiting short- and long-term potentiation of neurotransmitter secretion. Membrane depolarization elicits secretion and this response can be potentiated. The extent of potentiation correlates with the elevation of cAMP levels. The direct elevation of cAMP by forskolin, or the addition of dibutyl cAMP, induces potentiation, suggesting cAMP levels are responsible for potentiation. The temporal relationship between potentiation and cAMP levels provide further evidence that cAMP is the response regulator for potentiation. Additionally, adrenergic and adenosine receptors which are coupled to adenylylase can also induce potentiation. Long-term potentiation appears to require that cAMP levels exceed a threshold, which is prevented by the adaptation of the β -adrenergic receptor and achieved by other non-adapting stimuli.

160.18

MECHANISM OF SHORT-LASTING DEPRESSION CAUSED BY CYCLIC AMP IN CA1. J.R. Slack*, S. Pockett and R. Milne. Dept of Physiology, University of Auckland, Private Bag, Auckland, New Zealand.

Bath application of 200 μ M dibutyl cyclic AMP to hippocampal slices caused a depression of CA1 population spike amplitude in response to 0.05 Hz stimulation. The depression lasted only as long as dbcAMP was present and was followed by long-lasting potentiation after washout of dbcAMP. We hypothesized that the depression was caused by action of dbcAMP on adenosine receptors. Many adenosine receptor blockers have numerous intracellular actions in addition to their receptor blockade, but 8-p-sulphophenyltheophylline (8PSPT) does not enter cells and hence has only adenosine receptor-blocking actions (Daly, J.W., *in Purines in Cellular Signalling*, Springer-Verlag 1989). Bath application of 10 μ M 8PSPT caused a large increase in population spike amplitude, which was completely reversible on washout. This implies that endogenous adenosine in the slice preparation is tonically active to depress population spike amplitude. Application of 200 μ M dbcAMP during the presence of 8PSPT caused no depression. The long-lasting potentiation caused by dbcAMP was still seen, however, when the dbcAMP and 8PSPT were washed out. Thus the short-lasting depression caused by dbcAMP is probably due to its action on adenosine receptors.

COMPUTER SIMULATIONS OF E-S POTENTIATION IN HIPPOCAMPAL CA1 PYRAMIDAL CELLS. J.C. Wathey, S. Chattarji, W.W. Lytton, J.M. Jester and T.J. Sejnowski. The Salk Institute, La Jolla, CA 92037.

Long-term potentiation (LTP) of hippocampal excitatory synapses is often accompanied by E-S potentiation (i.e., an increase in the probability of spiking to an EPSP of fixed strength). We used computer simulations of a CA1 pyramidal cell to test the plausibility of the hypothesis that changes in dendritic excitability contribute to E-S potentiation. These changes were simulated by adding "hot spots" of voltage-sensitive Ca^{++} conductance to various dendritic compartments. This typically caused spiking in response to previously subthreshold synaptic inputs. The magnitude of the simulated E-S potentiation depended on the passive electrical properties of the cell, the excitability of the soma, and the relative locations on the dendrites of the synaptic inputs and hot spots. The specificity of the simulated E-S potentiation was quantified by co-localizing the hot spots with a subset (40/80) of the synaptic contacts, denoted "tetanized", and then comparing the effects of the hot spots on these and the remaining (untetanized) synaptic contacts. The simulated E-S potentiation tended to be specific to the tetanized input if the untetanized contacts were, on average, electrically closer to the soma than the tetanized contacts. Specificity was also high if the two inputs were segregated to different primary dendrites. The results also predict, however, that E-S potentiation by this mechanism will appear to be nonspecific (i.e., heterosynaptic) if the synapses of the untetanized input are sufficiently far from the soma relative to the tetanized synapses.

To test this hypothesis we recorded field EPSP and population spikes from area CA1 in rat hippocampal slices. Tetanization of a proximal Schaffer collateral input induced LTP at that input and potentiated population spikes evoked via a more distal untetanized perforant path input. This suggests that postsynaptic excitability changes can contribute to E-S potentiation.

Quantal Analysis and Model Discrimination A.C. Greenwood¹, E.M. Landaw², E.W. Kairiss³, T.H. Brown³. Depts. of Physiology¹ & Psychology², Yale Univ., New Haven, CT 06520; Dept. of Biomathematics³, U. of Calif. Los Angeles, CA 90024.

There is growing interest in the quantal basis of synaptic plasticity and modulation in the CNS - including hippocampal long-term potentiation (LTP). A fairly general quantal model includes (i) either a Poisson or binomial distribution to describe quantal release; (ii) a Gaussian or gamma density function describing the single-quantal amplitude distribution; and (iii) Gaussian noise. In this model, plasticity affects quantal size and/or release parameters. We developed a maximum likelihood (ML) estimation procedure to fit two sets of model parameters to a pair of response data sets (from before and after synapse modification). One can fix any parameter to a measured or hypothetical value. Likelihood ratio tests are used to test hypotheses about quantal parameters or mechanisms of synaptic plasticity. Standard errors and confidence intervals of estimated parameters are derived from the likelihood surface and from Monte Carlo (MC) simulations. For various conditions, we estimated the *a priori* probability that an experiment will permit the rejection of a hypothesized locus of plasticity. The chance of success was found to depend on the potentiation factor (F) and the ratio of pre-LTP quantal size to noise (Q/N). Initial work assumed 200 samples before and 200 after LTP induction. Plots of $mean^2/variance$ vs $mean$ (M^2/V) are also used to discriminate among possible loci of LTP. We explored this method analytically and in MC studies, and compared it to our ML method of model discrimination. The results suggest the use of both methods and the optimization of Q/N and F. MC simulations based on independent estimates of Q/N and noise can endow the M^2/V method with estimates of confidence. Both methods are unreliable for Q/N = 1.25 and F = 1.3. For any F, reliability decreases with Q/N. When either method is used near the limit of its reliability, an increase in the size of each quantum can be identified more confidently than can an increase in the number released. For F = 1.3 and Q/N = 20, the M^2/V method performs the latter task less reliably than the ML method. We are studying nonstationarity, to which the M^2/V method is most easily adapted. INDIVIDUAL DIFFERENCES IN EMERGENCE NEOPHOBIA PREDICT HIPPOCAMPAL LONG-TERM POTENTIATION (LTP). D. Mitchell, K. Patel, and S. Maren. Department of Psychology and Neurosciences Program, University of Southern California, Los Angeles, CA 90089-1061.

Rats show a great deal of individual variability in behavioral neophobia (avoidance of novelty) that can powerfully influence both associative and nonassociative learning. Long-term potentiation in the hippocampus, which is thought to modulate learning, also shows considerable within and between strain variability. We compared individual differences in reluctance to explore a novel environment with individual differences in *in vivo* hippocampal LTP.

Fourteen male Long-Evans rats individually housed in a start box with ad lib food and water for 24 hrs were subsequently permitted to explore an adjacent novel alley during a 6 hr videotaped emergence test. Two to four weeks following behavioral testing the rats were anesthetized and implanted stereotaxically with a recording electrode in the hilus of the dentate gyrus and a bipolar stimulating electrode in the medial perforant pathway. Each animal was administered 5 consecutive stimulation trains separated by 20 min (10 40 ms bursts at 5 Hz; intraburst frequencies 25, 50, 100, 200, and 400 Hz). LTP of the excitatory postsynaptic potential (EPSP) slope and population spike (PS) amplitude was assessed 30 min following the last train from input/output functions generated at the beginning and end of the experiment. The animals were ordinarily ranked for both emergence (time spent exploring alley) and LTP scores. LTP of EPSP slope, but not PS amplitude, was negatively correlated ($r = -.87, p < .0001$) with behavioral emergence. This correlation could not be attributed to differences in baseline magnitude of the perforant path evoked response as there were no significant differences between neophobic and non-neophobic animals on this measure. These data suggest that individual differences in behavioral habituation that are frequently used to quantify neophobia may reflect individual differences in hippocampal plasticity.

161.2

QUANTAL ANALYSIS OF SUPERIMPOSED EXCITATORY POSTSYNAPTIC POTENTIALS FROM MULTIPLE SYNAPSES. Paul C. Bush, Shaolin Li* and Terrence J. Sejnowski Salk Institute, La Jolla, CA 92138-9216 USA.

Extracellular stimulating electrodes in hippocampal slices typically activate multiple synaptic boutons, even at minimal levels of stimulation, each of which could have a different quantal size and release probability. The superposition of these EPSPs make conventional quantal analysis problematic. We have developed a method for analysing such data that is capable of separating a small number of release sites. This method relies on the differences in the time courses of EPSPs from different locations in the dendritic tree as measured at the soma.

Our method begins with an estimation of the attenuation factor of the dendritic tree for each synapse by applying a maximum likelihood estimator to the Fourier transform of individual EPSP traces. This produces a time integral of the voltage of the EPSP at the synapse. An inverse filter is then used to produce histograms of quantal amplitudes for each synapse. We have tested our method on randomly generated multiple-synaptic quantal amplitude histograms, generated from α -function EPSPs with noise added at the level observed in microelectrode recording (approximately 3:1 signal:noise power ratio). The algorithm accurately recovered the individual quantal amplitude histograms, from which parameters for the appropriate statistical model are easy to extract.

TEMPORAL SEQUENCES ENCODED AND RECOGNIZED USING LTP INDUCTION AND EXPRESSION RULES. J. Larson, J. Whitson*, R. Granger, & G. Lynch. CNLM, Univ. of Calif., Irvine, CA 92717.

If LTP represents a memory storage mechanism, its induction and expression characteristics may constitute rules governing encoding and read-out of memory in cortical circuitry. Stimulation patterns based on the 4-7 Hz theta EEG rhythm have been shown to be ideally suited for producing robust and stable LTP (Larson & Lynch, *Science*, 232: 985, 1986); these repetitive stimulation cycles have been shown to give rise to unique learning and recognition rules in computational simulations (Ambros-Ingerson, Granger & Lynch, *Science*, 247: 1344, 1990). Sensory cues often consist of sequential elements, raising the question of how LTP induction and expression rules relate to encoding and retrieval of temporal sequences. It has been shown that the sequence in which synapses are stimulated determines the degree to which they potentiate (Larson & Lynch, *Brain Res.*, 489: 49, 1989), thereby yielding a physiological rule for LTP induction using temporal sequences: the greatest LTP is induced in the earliest input and smallest LTP in the last input.

Physiological simulations of synaptic responses predicted an LTP expression rule for temporal sequences; this was supported by physiological tests using sequential stimulation of two afferents (S1 and S2) in field CA1 of the hippocampal slice. Before potentiation, the sequences S1-S2 and S2-S1 gave equal responses; after potentiation of S1, the sequence S1-S2 yielded a significantly larger response than the reverse sequence. Thus, the optimal sequence for depolarization of the postsynaptic cell is the sequence in which synapses are activated from strongest to weakest. The functional consequences of these findings were investigated with a network simulation, using the LTP induction rule to train on cues consisting of temporal sequences, and testing for recognition of the cues using the LTP expression rule. The network showed a high capacity for encoding and accurately recognizing temporally-patterned cue sequences, e.g., 10,000 cues in a network of 1,000 cells. (Supported by ONR N00014-89-J-1255 and N00014-89-J-3179).

161.6

LONG-TERM POTENTIATION OF PERFORANT PATH AND MOSSY FIBER INPUT TO CA3 PYRAMIDAL CELLS: AN *in vivo* COMPARISON OF OPTIMAL TETANIZATION PARAMETERS. Mark F. Yeckel and Theodore W. Berger. Departments of Behavioral Neuroscience and Psychiatry, University of Pittsburgh, Pittsburgh, PA 15260.

Pyramidal cells of the hippocampal CA3 region receive direct monosynaptic excitatory input from entorhinal cortical cells, as well as an indirect disynaptic input via mossy fiber axons of dentate granule cells. We have recently demonstrated, *in vivo*, that a given subpopulation of CA3 pyramidal cells can express different forms of long-term potentiation (LTP) for different subsets of synapses: perforant path LTP is NMDA dependent and specific to the tetanized fibers (i.e., homosynaptic); mossy fiber LTP is not dependent upon NMDA receptor activation and LTP is also expressed for non-tetanized commissural input (heterosynaptic). We have investigated further the expression of LTP by these convergent pathways, more specifically, whether or not their optimal LTP induction parameters may differ.

Stimulating electrodes were placed in 1-3 afferent pathways of halothane anesthetized rabbits: the ipsilateral angular bundle, the ipsilateral hilus, and the contralateral CA3 cell layer. Tetanizing stimuli of 400 Hz (10 trains of 10 impulses; 1 train/10s), followed 45 min later by 100 Hz (1-3 trains of 100 impulses; 1 train/10 s), or 100 Hz followed by 400 Hz, were delivered to the either the perforant path or to mossy fibers. Analysis of input/output functions for monosynaptic population responses recorded in the CA3 pyramidal cell region revealed that 100 Hz delivered to the mossy fibers induced a greater magnitude increase in the number of cells activated than 400 Hz, irrespective of the order in which the tetanizing stimuli were given (n=7). In contrast, the number of CA3 cells evoked by perforant path input was greater after LTP was induced with 400 Hz vs. 100 Hz (n=10). Because it appears that the optimal induction parameters may differ for these pathways, the possibility exists that different patterns of afferent activity could lead to the selective induction of homosynaptic or heterosynaptic LTP (in different pathways), and thus have fundamentally different consequences for global functional properties of the hippocampal system. 161.7

NONLINEAR RESPONSE PROPERTIES OF HIPPOCAMPAL GRANULE CELL POPULATION EPSP'S BEFORE AND AFTER THE INDUCTION OF LONG-TERM POTENTIATION. Jeffrey R. Balzer, Robert J. Sciallasi and Theodore W. Berger. Depts. of Behavioral Neuroscience, Neurosurgery and Psychiatry, Univ. of Pittsburgh, Pittsburgh, PA 15260.

In a previous series of experiments, using an *in vivo* rabbit preparation, nonlinear systems analysis was used to characterize the transformational properties of hippocampal dentate granule cell responses to perforant path input before and after the induction of long-term potentiation (LTP). Perforant path fibers were stimulated with a train of impulses having randomly varying inter-impulse intervals and first, second and third order kernels were computed by cross-correlating the intervals of the random impulse train with amplitudes of the evoked granule cell population spikes. Results showed that second and third order nonlinearities decreased significantly after the induction of LTP. That is, the magnitude of granule cell responses were less dependent on the temporal characteristics of perforant path input after the induction of LTP.

In the experiments reported here we investigated the effect of LTP on the nonlinear response properties of granule cell synaptic potentials as measured using the population EPSP. Prior to the induction of LTP, nonlinear response properties of the EPSP were highly nonlinear, i.e., the slope and magnitude of the EPSP depended significantly on inter-impulse interval. Unlike for the population spike, however, the induction of LTP did not alter either second or third order nonlinear response properties of the EPSP. These results show that LTP-induced changes in nonlinear response properties of granule cell output cannot be accounted for on the basis of changes in perforant path synaptic input. Supported by ONR, AFOSR, MH45156 and MH00343.

161.9

DRAMATIC DIFFERENCES IN THE MAGNITUDE AND TEMPORAL DEVELOPMENT OF LONG-TERM POTENTIATION (LTP) IN RAT HIPPOCAMPAL AREA CA1 AT POSTNATAL DAYS 11 AND 16. P.S. Jackson, T. Suppes, and K.M. Harris. Children's Hospital and Harvard Medical School, Boston, MA 02115 and McLean Hospital, Belmont, MA 02178.

The ontogeny of long-term potentiation (LTP) is largely unstudied (Harris and Teyler, 1984). We examined the magnitude, temporal development and duration of LTP in hippocampal slices from 11 and 15 day old rats. Remarkable differences were found in the LTP seen at these two ages. In addition, the LTP at both immature ages differed from the LTP that has been reported from adult animals.

Electrophysiological recordings of the field EPSP were made with extracellular electrodes placed in s. radium of hippocampal field CA1 while the Schaffer collaterals were regularly stimulated (1-2/min). LTP was induced with tetanic stimulation (2X @ 100Hz for 1 sec) and recordings were continued for 3-20 hours. LTP in slices from day 15 animals increased in the first 30 min post-tetanus, plateaued for 2-3 hours, and then declined over the next hour (n=7). LTP then remained constant at this lower, but still potentiated level for as long as the slices survived. LTP in slices from day 11 animals was maximal immediately post-tetanus and gradually declined to baseline over the next ~2.5 hrs (n=7). In slices which were re-tetaned following return to baseline, LTP could be re-induced (n=3). We also confirmed that LTP is APV sensitive at both of these immature ages.

Thus the expression of LTP in immature animals contrasts with the adult in a number of regards: at day 11 LTP is not persistent but can be re-evoked, and at day 15 there is an exaggerated early phase of the LTP. By correlating biochemical and physiological development during this dynamic period, we may be able to understand the different components which underlie the adult response. Alternatively, understanding LTP in the immature animal may shed light on processes involved in synapse formation and selection which are not present in the adult animal.

DURATION OF LTP IN PIRIFORM CORTEX IN VIVO IS INCREASED AFTER EPILEPTIFORM BURSTING. A. Kapur and L.B. Haberly. Neuroscience Training Program and Dept. of Anatomy, Univ. of Wisconsin, Madison, WI 53706.

Stimulation with trains of 4 or 5 shocks repeated at 200 ms intervals (theta burst stimulation) induces long term potentiation (LTP) at afferent fiber synapses in the piriform cortex slice (Jung et al, *Synapse* 6: 279, 1990; Kanter & Haberly, *Brain Res.* 525: 175, 1990). In the present study, it was found that theta burst stimulation also induces LTP at afferent fiber synapses in urethane anesthetized rats (1.4-1.8 g/kg, IP). However, in contrast to findings in the slice where LTP persisted for the duration of experiments (up to 4 hours), in intact animals LTP decreased by 80% or more within 1-2.5 hr in 7/11 animals. Induction of LTP was blocked by APV (1-3.5mM, topically applied) or MK-801 (0.5-1mg/kg), indicating NMDA dependence as in the slice.

When theta burst stimulation was delivered to afferent fibers in the lateral olfactory tract (LOT) after recovery from a period of epileptiform bursting, LTP was induced that persisted with little or no decrement for the duration of experiments (up to 6 hours) (n=5/5). In these experiments, interictal-like bursts were evoked at 0.2 - 1 Hz by LOT shocks following topical application of a drop of saturated picrotoxin solution; theta burst stimulation was applied after responses had returned to normal waveform. To determine if this effect was: (a) due to residual disinhibition at the time of train delivery, or (b) the result of a change induced by epileptiform activity, theta burst stimulation was applied during disinhibition restricted to the vicinity of the recording site that did not induce epileptiform activity. This local disinhibition was accomplished by diffusion or iontophoresis of bicuculline (10mM) through the recording micropipette. Tip diameters (10-16 μ m) and iontophoretic parameters (0.50 nA) were adjusted so that the number of action potentials evoked by stimuli was markedly increased, but no epileptiform (all-or-none) field potential components were evoked. In the presence of local disinhibition, LTP was decremental (n=7/8) as in control experiments, suggesting that the increased duration after disinhibition was a consequence of a change induced by the epileptiform activity. Supported by grant NS 19865 from NINDS.

Isolated NMDA receptor-mediated synaptic responses in hippocampus can express both LTP and LTD. X. Xie, T.W. Berger and G. Barrionuevo. Departments of Behavioral Neuroscience & Psychiatry, University of Pittsburgh, Pittsburgh, PA 15260.

Tetanic stimulation of hippocampal glutamatergic pathways can result in either long-term potentiation (LTP) or long-term depression (LTD) of AMPA receptor-mediated responses. However, there are conflicting reports as to whether NMDA receptor-mediated activity expresses LTP, and it is not known if NMDA receptors express LTD. Here we demonstrate both LTP and LTD of pharmacologically (CNQX 10 μ M in medium) isolated NMDA receptor-mediated EPSPs recorded from granule cells of the hippocampal dentate gyrus. Brief 50-Hz tetanic activation (3 bursts of 20 pulses with 5 sec interval) of perforant path afferent fibers resulted in substantial LTP of NMDA receptor-mediated EPSPs, either when slices were perfused with low Mg²⁺ (100 μ M) medium or when impaled granule cells were depolarized to -50mV in normal Mg²⁺ (2mM). The average amplitude increase in both normal (n=8) or low Mg²⁺ (n=10) was 75% and 60% respectively measured 30 min posttetanus. Hyperpolarization (-100mV) of the postsynaptic cell during delivery of the same tetani reversibly blocked the induction of LTP (-6%, n=6). Furthermore, by hyperpolarizing the postsynaptic cell during 10-Hz tetanic stimulation of the afferent fibers, we demonstrate that the level of postsynaptic voltage determines whether the same tetanic stimulation induces LTP or LTD: pairing of four 10-Hz tetani with hyperpolarization elicited LTD of the EPSPs (-34%, n=8). When delivered alone, the 10-Hz tetani induced robust LTP (+43%, n=3). Taken together, these findings provide evidence that the induction of use-dependent, NMDA receptor-mediated synaptic plasticity is under the control of postsynaptic mechanisms. EVIDENCE FOR DIFFERING MECHANISMS OF SHORT- AND LONG-TERM POTENTIATION EXPRESSION. P.E. Schultz & D. Johnston. Department of Neurology & Division of Neuroscience, Baylor College of Medicine, Houston, Tx 77030.

It has been suggested that tetanus induced potentiation has several components including: a brief APV-insensitive post-tetanic potentiation, a decremental component of about 10 minutes duration, and a sustained component of greater than 15 minutes duration. The decremental and sustained components, which we will operationally term short- and long-term potentiation (STP and LTP), have not previously been shown to be expressed differently. We tested the hypothesis that STP and LTP are expressed via the same mechanism reasoning that if they are: (1) saturating LTP should decrease STP, and (2) STP and LTP should vary similarly under different induction conditions. Rat hippocampal slices, 375 μ m thick, were perfused with saline containing (in mM): NaCl 120, KCl 3, MgCl₂ 1.2, NaHCO₃ 23, CaCl₂ 1.5, and dextrose 11. Field recordings of pEPSPs were made in CA1. Slices were repeatedly tetanized at stimulus intensities initially yielding pEPSPs of 1.3mV, 2.6mV, or in an additional group 2.6mV in the presence of 10 μ M picrotoxin and altered divalent cation concentrations. Four slices that had potentiated the most by LTP saturation were examined from each of the three groups reasoning that these slices would show the greatest decrease in STP. The findings were: (1) within each group the magnitude of STP remained similar for each tetanus from the first through post LTP saturation; (2) across the three groups the STP magnitude was different despite the induction of similar LTP magnitudes; and, (3) STP was APV-sensitive both for tetanus one and after LTP saturation. These findings suggest different mechanisms for STP and LTP expression despite a similar induction requirement of NMDA receptor activation. (AG00432, AG08664, MH44754)

ASSOCIATIVE LONG-TERM POTENTIATION IN PIRIFORM CORTEX SLICES REQUIRES GABA_A BLOCKADE. E.D. Kanter and L.B. Haberly. Neurosci. Training Prog. and Dept. of Anat., Univ. of Wisc., Madison, WI 53706

Pyramidal neurons in piriform cortex receive two excitatory inputs on adjacent segments of their apical dendrites: afferent fibers from the lateral olfactory tract synapse distally in layer Ia and intrinsic association fibers synapse more proximally in layer Ib. This anatomical configuration suggests the possibility of associative interactions based on coincident inputs from the two fiber systems. Potentiating stimuli (4-pulse trains repeated at theta frequency) were delivered to either Ia afferents or Ib association fibers and single weak shocks were delivered to the other pathway. Neither trains to the first pathway alone nor weak shocks to the second pathway alone produced potentiation in the second pathway. LTP was produced only when the stimuli were given simultaneously and only when the GABA_A antagonist bicuculline, which blocks the fast, Cl⁻-mediated IPSP, was used to block inhibition. Initially, bicuculline (2-5 μ M) was added to a bathing medium in which Ca²⁺ was raised to 10 mM to prevent epileptiform (all-or-none) responses. In later experiments focal, iontophoretic application of bicuculline from either the recording pipette or from a second pipette inserted near the recording site allowed the use of standard medium. Using this method robust associative LTP was consistently observed without epileptiform activity. The magnitude of associative LTP in each pathway was similar to that of homosynaptically induced LTP (approx. 15% in Ia and 40% in Ib; Kanter and Haberly, *Brain Res.* 525:175, 1990). Bicuculline did not increase the magnitude of homosynaptically induced LTP in either pathway. The GABA_B antagonist phaclofen, at a concentration that completely blocks the slow, K⁺-mediated IPSP in piriform cortex, did not facilitate the induction of associative LTP. Induction in both directions was blocked by 15 μ M D-APV, indicating that the potentiation is dependent on NMDA receptors. These results suggest that GABA_A receptor blockade increases the spread of depolarization along pyramidal dendrites sufficiently to allow induction of associative LTP. Supported by NIH grant NS 19865.

Lesions of the medial septum which produce deficits in working/spatial memory do not impair long-term potentiation in the rat hippocampus. K.J. Feasey-Truger*, B. Li*, J. Röhrenbeck*, G. ten Bruggencate. Physiology Dept., University of Munich, 8000 Munich 2, Germany.

Long-term potentiation (LTP) of hippocampal synaptic transmission is of interest as a possible mechanism for memory and learning in the mammalian brain. We have investigated whether impairment of working/spatial memory through medial septum (MS) lesions influences the ability to induce LTP in rat hippocampus *in vivo* and *in vitro*.

MS lesions (1 mA, dc, 40s) were made under Equithesin anaesthesia. After recovery, the working/spatial memory of lesioned and control rats was assessed as the number of correct arm entries made in an 8-arm radial maze. After at least 15 training sessions, the mean score obtained by lesioned rats was 5.8 ± 0.1 (n=8), which was significantly lower than the mean score obtained by control rats (7.84 ± 0.05 , n=11, $p < 0.001$).

The rats were then anaesthetized with urethane, and LTP inducibility examined in the fimbria to CA3 and mossy fibre to CA3 pathways *in vivo*. High-frequency (HF) stimulation induced LTP of the evoked CA3 field response in each pathway. There was no significant difference in the magnitude of potentiation observed in control and lesioned rats, although in both groups the LTP induced by HF fimbrial stimulation was greater than that induced by mossy fibre HF stimulation. LTP could also be induced in the CA1 region of hippocampal slices prepared from lesioned rats.

Acetylcholinesterase activity was severely reduced in the hippocampi of lesioned rats, indicating that the septal cholinergic input to the hippocampus was effectively destroyed. The results demonstrate that the induction of hippocampal LTP is not affected by MS lesions which impair working/spatial memory, and severely disrupt the septal cholinergic input to the hippocampus. THE EFFECT OF LOCALLY APPLIED CHOLINERGIC DRUGS ON PRIMED BURST POTENTIATION. D.A. Engstrom and G.M. Rose. Department of Pharmacology, UCHSC, and Medical Research, VAMC, Denver, CO 80262

Both acetylcholine (ACh) and the hippocampus have been implicated in learning and memory processes. Hence, ACh might be expected to modulate hippocampal synaptic plasticity (a physiological memory model). Primed burst potentiation (PB), a threshold form of LTP, was challenged with locally applied cholinergic drugs in area CA1 of the hippocampus. Drugs were administered via pressure micro-ejection from multibarrel glass micropipettes. The PB train, consisting of a priming pulse followed 170 msec later by a burst of 4 pulses at 200 Hz, was given concurrent with the peak excitation of a CA1 pyramidal cell induced by a locally applied agonist (within 5-10 sec of onset of drug application), or after a 3 min application of an antagonist. PB was defined as the mean percent change from baseline population spike amplitude, 11-20 min post-train. MANOVA of all drug treatments revealed a significant overall drug effect ($F_{19,42} = 2.65$, $p = 0.016$); *a posteriori* analysis showed that PB was attenuated in nicotine- and scopolamine-treated groups compared to saline controls; muscarine had no effect on PB. Nicotine's attenuation of PB was reversed in the presence of mecamylamine and hexamethonium. In summary, locally applied cholinergic drugs affect threshold hippocampal plasticity. However, it appears that muscarine and nicotine exert qualitatively different actions.

161.17

HETEROSYNAPTIC LTP IN THE RAT SUPERIOR CERVICAL GANGLION. Rulin Wu* and Donald A. McAfee, Dept. of Pharmacology, University of California, Irvine, CA 92717

Brief tetanic preganglionic stimulation results in potentiation of cholinergic transmission for hours. The mechanism is presynaptic in origin, producing a long-term potentiation (LTP) of evoked acetylcholine release. We now have evidence that tetany in one group of presynaptic terminals can cause LTP in a smaller population of non-tetanized terminals.

Sympathetic ganglia were isolated and superfused *in vitro* (24°C). The preganglionic nerve was dissected into two bundles and each sucked into separate bipolar stimulating electrodes. Single test stimuli (1/min) were delivered to each bundle, and the amplitude of the compound action potentials in the postganglionic nerve was measured. Care was taken to prevent spread of the stimulus current from one bundle to the other. When, in 10 of 13 preparations, a brief tetany (20Hz/20sec) was delivered to one bundle, the test responses (homosynaptic) in that bundle exhibited PTP followed by LTP. Test stimuli in the non-tetanized bundle (heterosynaptic) exhibited only LTP. Homosynaptic LTP was about 2.5 fold greater than heterosynaptic LTP. Perhaps an endogenous factor released during tetany feeds back to homosynaptic and nearby heterosynaptic terminals to activate a mechanism that induces LTP. (This work was supported by PHS grant NS-22470.)

SEPTAL LESIONS IMPAIR HIPPOCAMPAL PRIMED BURST POTENTIATION AND LTP. G.M. Rose and A. Humphreys*. Medical Research, VAMC, and Dept. Pharmacology, UCHSC, Denver, CO 80262

Acetylcholine (ACh) has long been implicated in memory function. However, the mechanism by which ACh acts to influence memory is unknown. Hippocampal connections show long lasting use dependent changes in strength; it has been suggested that such alterations represent a mechanism for memory encoding. Since lesions of the ACh-containing afferents to the hippocampus profoundly disrupt many types of learning, we decided to investigate the effects of cholinergic deafferentation upon hippocampal synaptic plasticity. Cholinergic deafferentation of the hippocampus was accomplished by making bilateral electrolytic lesions of the medial septum/diagonal band complex under pentobarbital anesthesia. Five to 30 days later, the rats were reanesthetized and prepared for acute recording. Field potential responses to commissural stimulation were recorded in the CA1 pyramidal cell layer of the dorsal hippocampus. A 1 + 4 patterned stimulus train was used to induce PB potentiation. Twenty minutes later, a 100 Hz/1 sec train was used to induce LTP. Septal lesions reduced the magnitude of both PB potentiation and LTP by $\approx 40\%$. The relationship between PB potentiation and LTP was unaltered. AChE histochemistry verified a major reduction in cholinergic input following septal lesions, suggesting that reductions in ACh could affect hippocampal plasticity. However, more specific manipulations of hippocampal cholinergic pharmacology will be required to verify this possibility.

Inverted-U Relationship Between Corticosterone and Hippocampal Primed Burst Potentiation in Urethane-Treated Rats.

D.M. Diamond, M.C. Bennett, J. Meltzer, M. Fleshner and G.M. Rose. Dept. of Pharmacology, UCHSC and VAMC, Denver, Colorado

Stress blocks hippocampal LTP *in vivo* (*Psychobiol.*, 18:273, 1990) and *in vitro* (*BNB.*, 48:138, 1987). The stress effect may result, in part, from an inhibitory effect of elevated levels of corticosterone (CORT) on hippocampal plasticity. For example, we recently reported that there is a negative linear correlation between primed burst potentiation (PB-LTP), a low threshold form of LTP, and elevated levels of serum CORT (*Psychobiol.*, in press). In the present report, we characterize the relationship between PB-LTP and a broad range of CORT levels in urethane-treated animals.

We recorded CA1 population spikes from acute and chronically-prepared rats. Urethane produced a dose-dependent increase in CORT levels; doses of 0.1-1.8 g/kg produced CORT levels of 5-93 $\mu\text{g}/\text{dl}$. There was an "inverted-U" relationship between CORT and PB-LTP: The peak magnitude of PB-LTP occurred at 9-20 $\mu\text{g}/\text{dl}$; the magnitude of PB-LTP was smaller in animals with lower (0-8 $\mu\text{g}/\text{dl}$) and higher (21-93 $\mu\text{g}/\text{dl}$) levels of CORT. Adrenalectomized rats with CORT pellet implants exhibited a similar inverted-U relationship.

These data indicate that CORT exerts a concentration-dependent modulation of hippocampal plasticity. The findings may provide a neuroendocrine basis for the well-described inverted-U relationship between arousal and learning.

161.18

EVIDENCE THAT THE MATRIX RECOGNITION MOLECULE F55 IS PRESENT IN SYNAPSES AND CONTRIBUTES TO THE STABILIZATION OF LTP. B.A. Bahr, P. Xiao* & G. Lynch, Center for the Neurobiology of Learning and Memory, University of California, Irvine, CA 92717

Matrix recognition molecules organize cell-substratum connections given their localization to regions of contact. Recent work (Bahr *et al.*, *NeuroReport* 2:13, 1991) identified a candidate molecule (F55) possibly involved in the focal contacts responsible for synapses, the dominant class of intercellular junctions in brain. Assembly of adhesive contacts via newly exposed matrix receptors conceivably could stabilize synaptic shapes and hence properties. Accordingly, we tested whether matrix recognition is necessary for the stable expression of long-term potentiation (LTP), a lasting increase in synaptic strength in hippocampal CA1. To do this, slices of hippocampus were bathed in solutions containing Arg-Gly-Asp (RGD) peptides known to block members of the integrin superfamily of receptors which mediate a broad spectrum of adhesive interactions. Though the peptides produced no detectable difference in the amount of LTP expressed 1 to 2 min after induction, RGD-specific peptides did produce a reversible, dose dependent reduction in LTP over a period of 40 min. To screen for synaptic adhesion molecules perhaps involved in LTP, synaptic plasma membranes (SPMs) were seeded onto microtitre plates coated with the matrix protein fibronectin (Fn). Hippocampal SPMs consistently displayed 40 to 50% more SPM-Fn adhesion over that displayed by SPMs isolated from whole brain. This adhesive interaction was reduced either by the presence of RGD peptides or by pre-coating the plates with a modified Fn lacking the RGD sequence. Solubilized SPM proteins that were eluted from Fn-agarose with RGD peptides consisted of a 55 / 51 kDa doublet. The doublet bound to a second 'fresh' Fn-agarose column and was the only species RGD-eluted as evident on double silver-stained PAGE. The eluted material ran as a 50 kDa species on a size exclusion column, thus suggesting it is monomeric in nature. This RGD-binding protein was identified as the F55 molecule due to its immunological similarity with a subclass of integrins. This study implicates unique adhesion molecules in the stabilization of LTP. (AFOSR #89-0383 supported.)

RELEASE OF ASPARTATE AND GLUTAMATE FROM HIPPOCAMPAL SLICES: Implications for the expression of long-term potentiation. M. W. Fleck, A. M. Palmer, & G. Barrionuevo, *Departments of Behavioral Neuroscience & Psychiatry, University of Pittsburgh, Pittsburgh, PA 15260.*

We investigated the possible co-release of aspartate (Asp) and glutamate (Glu) to determine whether LTP could result from an increase in the release of Glu relative to Asp. Both amino acids are released from hippocampal area CA1 in a Ca^{2+} -dependent manner and are potent agonists at excitatory amino acid receptors with different affinities: Asp primarily activates NMDA receptors while Glu activates both NMDA and non-NMDA receptors. A decrease in the ratio of transmitter Asp/Glu could account for LTP by increasing non-NMDA receptor activation with little or no change in NMDA receptor activation. Potassium-evoked amino acid release was measured by HPLC with fluorometric detection from hippocampal slices perfused with glutamine (0.5 mM) containing, normal-glucose (10 mM) or low-glucose (0.2 mM) medium. The ratio of evoked Asp/Glu increased from 0.35±0.1 in normal medium to 0.67±0.2 in low-glucose medium (p<0.01). In separate slices, reducing glucose in the perfusion medium resulted in the persistent decrease in initial slope and peak amplitude of Schaffer-CA1 population EPSPs after approximately 30-minute delay. Such a change in EPSP shape is consistent with a shift in the relative activation of NMDA and non-NMDA receptors. These results are consistent with the view that Asp and Glu are co-released from Schaffer collateral/ commissural terminals but act on disparate populations of post-synaptic receptors. Supported by NS01196, NS24288, and an Andrew Mellon Predoctoral fellowship.

161.20

INDUCTION OF LONG-TERM POTENTIATION IN VIVO IS ACCOMPANIED BY CHANGES IN THE INCORPORATION OF ^{35}S -METHIONINE INTO SPECIFIC PROTEINS: M.S. Fazeli, J.M. Corbett, M.J. Dunn*, A.C. Dolphin, T.V.P. Bliss*, Department of Pharmacology, Royal Free Hospital School of Medicine, London, NW3 2PF, UK; *NIMR, Mill Hill, London, NW7 1AA, UK; *Department of Cardiothoracic Surgery, NHLI, London, SW3, UK.

High-frequency stimulation of perforant path fibres induces an increase in synaptic transmission, sustained for several hours. The longevity of the effect indicates that changes in gene expression and protein synthesis may be involved. We have tested this hypothesis by analyzing the *in vivo* incorporation of ^{35}S -methionine into hippocampal proteins following the induction of LTP in the anaesthetized rat dentate gyrus.

Urethane anaesthetized rats were implanted with stimulating and recording electrodes in the angular bundle and the dorsal dentate cell body layer respectively. A cannula was then inserted into the third ventricle through the midline, through which 500µCi of ^{35}S -methionine was infused at 1µl/min. LTP was induced unilaterally (250Hz, 200msec), one hour after the start of infusion and was followed for one and three hours. Dorsal hippocampi were then removed and homogenized in O'Farrell sample buffer. Labelled proteins were separated by two-dimensional electrophoresis and the resulting gels were subjected to autoradiography. Quantitative analysis of the autoradiograms using the PDQuest system (Protein Databases Inc) revealed reductions in the incorporation of 3 proteins one hour after LTP. These were (approximate kD and pI): 4204 (28, 5.8), 1104 (13, 5.2) and 13 (13, 5). At three hours after induction these were no longer significant. However, two other proteins (5307 (20, pI 6.4) and 1606 (75, pI 5.1)) were found to have increased and decreased incorporation, respectively. These and other observed changes are currently being investigated.

ACETYLCHOLINE RECEPTORS: MUSCARINIC I

162.1

NOVEL AMINO TERMINALLY MODIFIED DERIVATIVES OF OXOTREMORINE ARE MORE EFFICACIOUS AGONISTS AT CORTICAL MUSCARINIC RECEPTORS OF THE M-1 SUBTYPE. D.S. Garvey, J. Y.-L. Chung*, Y. K. Shue*, E. Cadman, D. Anderson, S. Armer, and M. Williams. Neuroscience Research Division, Pharmaceutical Discovery, Abbott Laboratories, Abbott Park, IL 60064.

In recent years there has been considerable interest in the development of centrally active agents capable of enhancing cortical cholinergic neurotransmission since such agents may act as a palliative therapy for the amelioration of the symptoms of dementia associated with Alzheimer's disease. Although a number of muscarinic receptor subtypes have been identified in the brain via molecular biological approaches, it is still believed that the pirenzepine-sensitive M-1 site in the cortex, stimulation of which is coupled to phosphatidylinositol (PI) hydrolysis, is that which is most clearly associated with cognitive function. Other central effects linked to muscarinic receptor activation such as tremor and hypothermia are believed to be M-2 receptor mediated.

Oxotremorine, long known as a potent centrally active muscarinic agonist, is a weak partial agonist at the cortical M-1 receptor (14±4% agonist response of carbachol). Efforts to enhance the M-1 agonist efficacy of this compound have resulted in the discovery of a series of novel differentially constrained amino-terminally modified analogs of oxotremorine which incorporate 2-substituted pyrrolidine or piperidine rings. The (R)-enantiomer of the pyrrolidine modification was found to be most efficacious producing a maximal PI response of 43±4% that of carbachol. The *in vitro* pharmacological profiles of these novel muscarinic agonists will be presented.

162.3

SELECTIVE SIGNAL TRANSDUCTION BY THE M1 AGONIST, AF102B, IN CELLS EXPRESSING VARIOUS mAChR SUBTYPES. D. Gurwitz, R. Haring*, C.M. Fraser*, E. Heldman and A. Fisher, Israel Inst. Biological Research, Ness-Ziona 70450, Israel, and *NIAAA, Rockville, MD 20852, USA.

AF102B, a rigid M1-selective cholinergic agonist, is currently evaluated for treatment of Alzheimer's disease (AD). AF102B stimulated PI hydrolysis (25% vs. CCh) in CHO cells transfected with the m1AChR subtype; this was atropine-sensitive. Unlike CCh, AF102B failed to stimulate PI hydrolysis in CHO cells transfected with the m3AChR subtype, or in SK-N-SH human neuroblastoma cells (mostly m3AChR). CCh selectively increased both basal and forskolin-stimulated cAMP accumulation in m1AChR but not m3AChR-transfected cells. In contrast, AF102B attenuated forskolin-induced cAMP accumulation in m1AChR-transfected cells. In PC12 cells (mostly m4AChR) CCh attenuated forskolin-stimulated cAMP accumulation; AF102B mimicked CCh (40% vs. CCh). However, following treatment of PC12 cells with pertussis toxin, which did not affect receptor expression, CCh increased forskolin-induced cAMP accumulation, yet AF102B had no effect on cAMP levels. Thus, the M1 selectivity of AF102B (m1 and m4 AChRs) may reach beyond the mAChRs ligand recognition site, imposing activation of distinct G protein subset(s); this is probably dictated by the rigidity of AF102B. This may contribute to the potential value of AF102B for AD patients. Supported by Snow Brand, Japan.

162.2

AF150 AND AF151: NOVEL EFFICACIOUS M1 MUSCARINIC AGONISTS. A. Fisher, Y. Segall*, H. Meshulam*, E. Shirin*, D. Gurwitz, R. Haring*, R. Brandeis*, M. Segal#, H. Markram**, Z. Pittel*, C.M. Fraser#, E. Heldman and Y. Karton*, IIBR, Ness-Ziona, #The Weizmann Inst, ISRAEL & @NIAAA, USA.

Two new rigid oxazoline-piperidine analogs, AF150 and AF151 (Fisher et al, US Pat Appl, April, 1990), are selective and efficacious agonists for mAChRs in rat cortex (CT) vs cerebellum (CER) (binding of 3H -pirenzepine + GppNHp (Gp) vs 3H -QNB, respectively; e.g. for AF150 in CT: K_{i-Gp} =0.11µM (21%), K_{i-QNB} =11µM; K_{i-Gp} =19µM (100%); in CER: K_{i-Gp} =5.1µM (62%), K_{i-QNB} =81µM). In CHO cells transfected with mAChR, AF150 and AF151 are full agonists in stimulating PI hydrolysis, yet partial agonists (20% vs carbachol, CCh) in elevation of cAMP levels. AF150 and AF151 are partial agonists (25% vs CCh) in CHO cells transfected with m3AChR and in SK-N-SH cells (>m3AChRs), (PI hydrolysis), but full agonists in PC12 cells (>m4AChR), (inhibition of forskolin-stimulated cAMP levels). In CA1 neurons of rat hippocampal slices AF150 appears to be an M1>M2 agonist, but is more effective than AF102B (an M1 agonist). AF150 produced a depolarization and a reduction of the slow AHP, M1 effects, but had little effects on EPSPs or on input resistance. In AF64A (3nmole/2ul/side, icv)-treated rats, AF150 (0.1-1mg/kg, ip) restored cognitive impairments in a passive avoidance test without side-effects at low doses. Due to their unique profile at mAChRs and activation of only distinct G protein subset(s), AF150 and AF151 can be considered as candidate drugs for Alzheimer's disease.

162.4

FUNCTIONAL CHARACTERIZATION (PI-TURNOVER) OF SDZ ENS 163, A MUSCARINIC AGENT WITH A NOVEL PHARMACOLOGICAL PROFILE. A. Enz, A. Sauter*, M. Rudin* and M. Lichtsteiner*, Preclinical Research SANDOZ Pharma Ltd. *Psych.Univ.Clinic CH-4002 Basle, Switzerland

SDZ ENS 163, a pilocarpine derivative, is a drug with a favourable pharmacological profile, presently in clinical development for the symptomatic treatment of Alzheimer's Disease. It acts both *in vitro* and *in vivo* as a postsynaptic agonist (m1/m3) and as a presynaptic antagonists (m2) at muscarinic receptors. The selectivity of this drug for m1 and m3 receptors was investigated by binding and functional studies *in vitro*. Using CHO cells, expressing either m1 or m3 receptors, and 3H -NMS as ligand, no selectivity was found (K_i 1.8 and 3.2 µM). Using A9L cells expressing either receptor and measuring PI-turnover, SDZ ENS 163 was a relatively unselective, partial agonists of both m1 and m3 receptors (pD₂ 5.5 and 5.1, efficacy 45% and 7%, carbachol = 100%). SDZ ENS 163 acts more like an agonist in the rat brain with an accelerated PI-turnover, as measured *in vivo* non-invasively by ^{31}P magnetic resonance spectroscopy and post-mortem by gas chromatography. These findings are compatible with the presynaptic antagonistic and postsynaptic agonistic properties of this muscarinic drug.

162.5

ACTIVITY AND STEREOSELECTIVITY OF AGONIST QUINUCLIDINE ANALOGS IN PROPOSED IN VIVO MODELS FOR MUSCARINIC RECEPTORS. F. P. Bymaster, C. H. Mitch, D. O. Calligaro, H. E. Shannon*, and J. S. Ward*. Lilly Research Laboratories, Eli Lilly and Company., Indianapolis, IN 46285.

The enantiomers of the muscarinic (M) agonist aceclidine (AC, 3-acetoxy-quinuclidine) and \pm 3-(3-methyl-1,2,4-oxadiazol-5-yl)-1-azabicyclo[2.2.2]octane (LY231844, L658903, L) were studied on models for M₁, M₂, and M₃ receptors in vivo in rats. The IC₅₀'s for in vitro 3H-oxotremorine-M binding for S-AC and R-AC were 110 and 1050 nM, thus showing 10 fold stereoselectivity. L, with the ester bioisostere-oxadiazole, had an IC₅₀ of 11 nM. The ED₅₀'s for ex vivo binding of L, S-AC and R-AC were 0.24, >50, >50 mg/kg sc. The t_{1/2} was 2.7 and 0.25 hr for L and S-AC. In the proposed M₁ model, striatal dihydroxy-phenylacetic acid (DOPAC) levels were increased by L, S-AC, R-AC with ED₅₀'s of 0.14, 10, >50 mg/kg sc, presumably via M₁ heteroreceptors on dopamine terminals. L, S-AC, and R-AC decreased M₂ acetylcholine (ACh) release with ED₅₀'s of 0.05, 13 and >50mg/kg. The ED₅₀ for M₃ salivation was 0.05, 5, and >50 mg/kg for L, S-AC, and R-AC. Scopolamine blocked all L- and S-AC-induced changes; whereas, n-methylscopolamine blocked only salivation. Trihexyphenidyl (0.3mg/kg) and pirenzepine (100mg/kg) partially blocked L on DOPAC, but not on ACh. S-AC was more potent than the R-AC in vitro and in vivo models and was non-selective. The analog of aceclidine, L, was quite efficacious, longer-lived, and non-selective.

162.7

ACTIVITY AND SELECTIVITY OF BM 5 ENANTIOMERS FOR MUSCARINIC RECEPTOR SUBTYPES IN RAT BRAIN. W.S. Messer, Jr., L.A. Dokas, U. Hacksell*, P.G. Dunbar* and W. Hoss. Department of Medicinal & Biological Chemistry, College of Pharmacy, Univ. of Toledo, Toledo, OH 43606; Department of Biochemistry, Medical College of Ohio, Toledo, OH 43699; Uppsala Biomedicinska Centrum, Biomedicum, S-75223 Uppsala, Sweden.

The activities of the enantiomers of BM 5 were examined using several paradigms designed to measure muscarinic cholinergic activity in the central nervous system. Receptor autoradiographic methods were utilized to localize muscarinic receptors with a high affinity for each enantiomer. The enantiomers also were examined for their ability to inhibit adenylate cyclase in the cerebral cortex and neostriatum.

In autoradiographic studies, the inhibition of [³H]-1-quinuclidinyl benzilate ([³H]-1-QNB) binding to muscarinic receptors in rat brain sections was measured for each enantiomer. R-(+) BM 5 inhibited [³H]-1-QNB binding at concentrations below 1.0 μ M, while much higher concentrations of S-(-) BM 5 were required to produce a comparable level of inhibition. Analysis of the autoradiograms indicated that both stereoisomers had similar binding patterns with high affinity for receptors in the midbrain and brainstem and lower affinity for the cerebral cortex and hippocampus.

The ability of the enantiomers of BM 5 to inhibit adenylate cyclase activity was examined in the cerebral cortex and the neostriatum. In the cerebral cortex, R-(+) BM 5 was more potent inhibitor of adenylate cyclase than S-(-) BM 5. S-(-) BM 5 was approximately 100-fold less active than the R-(+) enantiomer. The differential effects of the enantiomers of BM 5 were more readily apparent in the cerebral cortex than in the neostriatum. It should be noted that the oxalate salts of BM 5 were utilized and that oxalate alone inhibited adenylate cyclase at higher concentrations.

In summary, R-(+) BM 5 is a potent muscarinic agonist in the adenylate cyclase assay, particularly in the cerebral cortex. The selectivity of R-(+) BM 5 for muscarinic receptors appears to be comparable to that found for other muscarinic agonists. In addition, the 100-fold difference in activity of the two enantiomers indicates a remarkable stereochemical selectivity for muscarinic receptors in both receptor binding and adenylate cyclase activity. The data provide a strong foundation for further studies of the molecular requirements for muscarinic receptor activity. Supported by NS 23929, NS 25765, and NS 23598.

162.9

CARAMIPHEN, IODOCARAMIPHEN AND NITROCARAMIPHEN ARE COMPETITIVE M₁ SELECTIVE COMPOUNDS. Robert L. Hudkins¹, James F. Stubbins*,¹ and Diane L. DeHaven-Hudkins². ¹Department of Medicinal Chemistry, Medical College of Virginia, Virginia Commonwealth University, Richmond, VA 23298-0540 and ²Department of Enzymology and Receptor Biochemistry, Sterling Research Group, Malvern, PA 19355-1314.

Caramiphen is an antimuscarinic agent which is a more effective antidote to organophosphate acetylcholinesterase poisoning than atropine. Because of the structural similarity of caramiphen to the M₁ selective ligand dicyclomine, we examined the M₁/M₂ selectivity of this compound in receptor binding assays and report that caramiphen binds with high affinity (K_i = 1.2 nM) and selectivity (26-fold) for the M₁ subtype. An examination of the effect of aromatic substituent parameters (i.e. σ , π) on the binding affinity and receptor subtype selectivity led to the discovery of the M₁ selectivity of the p-iodo and p-nitro caramiphen derivatives. Iodocaramiphen binds with high affinity at the M₁ site (K_i = 2.1 nM) and displays a 58-fold greater preference for the M₁ than the M₂ site. Nitrocaramiphen binds with equally high affinity at M₁ sites (K_i = 5.5 nM) but with a 71-fold M₁ selectivity. All three compounds interacted with the M₁ binding site in a competitive manner. The nitro and iodocaramiphen derivatives were as potent and showed a greater selectivity of M₁ over M₂ binding than the prototypical agent pirenzepine (M₁ K_i = 5.2 nM, 51-fold selectivity).

162.6

EFFECTS OF BM-5 ON REGIONAL ACETYLCHOLINE TURNOVER AND MUSCARINIC RECEPTOR BINDING IN RAT BRAIN. H.M. VARGAS and T. CHU*. Department of Pharmacology and the Brain Research Institute, UCLA School of Medicine, Los Angeles, CA 90024-1735.

The muscarinic agent BM-5 (N-methyl-N-(1-methyl-4-pyrrolidino-2-butynyl)acetamide) has attracted interest because of its presynaptic antagonist-postsynaptic agonist profile *in vitro* and its ability to produce site selective effects within brain *in vivo*. This study assessed the effects of BM-5 on acetylcholine (ACh) turnover and [³H]-methylscopolamine binding in three brain areas. Endogenous (unlabelled) ACh levels and [³H]ACh specific activity (i.e., turnover) were determined one minute after i.v. tracer [³H]choline injection. In saline controls, ACh levels (nmol/g) in the striatum, cortex and hippocampus were 86 \pm 2, 20 \pm 1, 33 \pm 2, respectively, corresponding mole ratios (x10⁻³) of [³H]ACh/ACh_{TOTAL} were 92 \pm 2, 279 \pm 21, 165 \pm 15, respectively. Fifteen minutes after administration, BM-5 (1, 50 μ mol/kg, s.c.) did not elevate or decrease ACh levels or [³H]ACh ratios in any area. However, an intermediate dose (5 μ mol/kg) did selectively reduce striatal ACh content by 23% and increase specific activity 37%, thus behaving as an antagonist. In comparison, oxotremorine (0.5 μ mol/kg, s.c.) raised regional ACh levels (44, 18, 32%, respectively) and decreased [³H]ACh mole ratios (12, 68, 60%, respectively). Competition binding studies ([³H]NMS, 0.3 nM) indicated that BM-5 had K_i values of 87, 57 and 55 nM in the three regions, respectively. The results suggest that BM-5 exhibits comparable affinity for muscarinic receptors in these regions, but displays differential presynaptic activity in these same areas. The pharmacological agonist/antagonist profile of BM-5, therefore, will vary according to dose and brain region. (Supported by GM37816 and MH17691).

ANTAGONISM OF MUSCARINIC M₁ RECEPTOR MEDIATED CALCIUM RELEASE BY MCN-A-343 AND THE NOVEL ANALOG, BN228.

C. Mathes, S. S.-H. Wang, H. M. Vargas*, and S. H. Thompson. Hopkins Marine Station, Stanford University, Pacific Grove, CA 93950 and Dept. of Pharmacology and BRI, UCLA, LA, CA 90024.

Activation of muscarinic receptors by carbachol causes Ca release from internal stores in N1E-115 neuroblastoma cells. Ca release was measured using fura-2 following exposure to 1 mM carbachol. The response is blocked by pirenzepine, a high affinity M₁ receptor antagonist. McN-A-343 and its novel analog, BN228 (4-[N-(4-chlorophenyl)carbamoyloxy]-pent-2-ynyltrimethylammonium Br; B. Niellson, Uppsala) inhibit Ca release in response to carbachol. The IC₅₀'s for McN-A-343 and BN228 as M₁ antagonists are 9 and 4 μ M, respectively. Although McN-A-343 has been called a "selective M₁ agonist", neither McN-A-343 nor BN228 elicit Ca release when applied in the absence of carbachol. Our results demonstrate that McN-A-343 does not act as an agonist but as an M₁ antagonist in N1E-115 cells. (Supported by NSF BNS-9021217 to SHT and NIH GM317816).

"m1-TOXIN": ISOLATION, CHARACTERIZATION AND SELECTIVITY FOR m1 MUSCARINIC RECEPTORS. S.J. Max, J.S. Liang* and L.T. Potter. Molecular and Cellular Pharmacology, University of Miami School of Medicine, Miami, FL 33101.

Adem et al. (Biochim. Biophys. Acta 968, 340) observed that toxins from the venom of the green mamba, *Dendroaspis angusticeps*, could block 55% of the binding sites for ³H-QNB in rat brain synaptosomal membranes. We purified the principal antimuscarinic component from this venom by gel filtration on Sephadex G-50, and reverse-phase HPLC. The isolated protein has a formula weight of about 7700 D, no alanine or proline residues, and a unique sequence. Its specificity was tested using CHO cells expressing m1-m5 muscarinic receptors individually. One hundred ng/ml toxin blocks 50% of m1 receptors, and full blockade is observed with 200 ng/ml. Concentrations 100-fold higher block 50% of m4 sites but have no effect on m2, m3 or m5 receptors. Hence, we have named this toxin, "m1-toxin". The toxin is selective in fresh or frozen tissue, membranes or solution. It blocks 40-60% of the ³H-NMS sites in the hippocampus, cortex, striatum and whole brain, about 10% of the sites in glands, and less than 5% in heart or brainstem. Furthermore, it blocks 75% of the agonist-activated phosphoinositide hydrolysis in rat hippocampal slices. m1-Toxin is clearly the antagonist of choice for studies of m1 receptors.

162.11

USE OF m1-TOXIN TO FACILITATE THE STUDY OF m1 AND m4 MUSCARINIC RECEPTORS IN THE STRIATUM. S.L. Purkerson*, J.S. Liang*, S.I. Max and L.T. Potter. Molecular and Cellular Pharmacology, University of Miami School of Medicine, Miami, FL 33101.

The striatum expresses mRNA primarily for m1 and m4 receptors, with much less for m2 receptors. Both the m1 and m4 subtypes are blocked by anticholinergic therapy for Parkinson's disease, which may be counterproductive, since m1 receptors are coupled to phosphoinositide hydrolysis and cellular excitation, whereas m4 receptors are coupled to decreased cAMP and inhibition. Little is known about the numbers, locations and functions of m1 and m4 receptors in the striatum, because existing ligands are not very selective; e.g. the present gold standard for m1 receptors, pirenzepine, shows only 5-6 fold higher affinity for m1 than m4. To go further, we have fully blocked m1 sites in the rat striatum with 0.8 µg/ml m1-toxin, with no effect on m4 sites. To judge from binding curves (toxin vs. ³H-QNB or ³H-pirenzepine; pirenzepine and other antagonists vs. ³H-NMS before and after toxin), 40% of the striatal muscarinic receptors are m1, 55% are m4 and 5% are m2. Competition curves between agonists and ³H-NMS show the affinities and K_i/K_H ratios for different agonists at m4 receptors coupled to their native G-proteins. It is therefore possible to use binding assays to screen new m4 agonists and antagonists for functional studies and as potential anti-Parkinson agents. Autoradiographs demonstrate the different distribution of m1 and m4 receptors. Physiological studies of toxin-spared m4 receptors are now possible. It is evident that m1-toxin represents a powerful new tool for studying the striatum.

162.13

Point-mutated muscarinic M1 receptors bind the M2-selective antagonist methoctramine with high-affinity. T.-V. Dam, P. Bouchard*, P. Payette, M. Dennis and F. Gossard. National Research Council of Canada, Biotechnology Research Institute, Montréal, Québec, CANADA. H4P 2R2.

Five genes coding for acetylcholine muscarinic receptors have been found so far by cloning techniques. Pharmacological methods have defined three subtypes of muscarinic receptors that can be discriminated by their binding affinities for specific antagonists. The muscarinic receptor of the subtype 2 (M2) has high affinity, among others, for compounds of the polyethylene tetraamines family of which methoctramine is the prime representative. These antagonists are bound with lower affinity by other members of the muscarinic receptor family in particular by the subtype 1 (M1). Methoctramine has been proposed to bind to M2 by ionic interactions between the charged amine functions and the negatively charged amino acids in the second extracellular loop of the receptor. These charged amino acids are not found in M1. In order to test this model, we have introduced by site-directed mutagenesis, one to three negatively charged amino acids in the second external loop of the M1 receptor. The human M1 gene (Hm1) was introduced in an expression vector downstream of the SV40 late promoter. The construct was then modified using a mutagenesis technique on double-stranded DNA. Wild-type HM1 and mutant genes were introduced into CHO cells and stable cell lines established. The binding characteristics especially for methoctramine of these receptors were determined as well as the intracellular response by the binding of agonists.

162.15

CHARACTERIZATION OF THE EFFECTS OF CHOLINERGIC AGENTS ON EITHER *IN VIVO* ³H-QNB BINDING OR *EX VIVO* HACHT. C.E. Tedford, V.B. Ruperto*, B.A. Duffy* and B.D. McQuade. Schering-Plough Research, Bloomfield, New Jersey, 07003.

Two measurements of cholinergic activity were used to characterize the *in vivo* muscarinic actions of several standard agents. The ability of a compound to displace the *in vivo* binding of ³H-QNB to rat cerebral cortex was investigated as a marker of central muscarinic receptor activity. Furthermore, *ex vivo* modulation of rat hippocampal high affinity choline transport (HACHT) was studied as a potential marker of presynaptic M2 muscarinic receptor activity.

Rats were administered (sc) 10 µCi of ³H-QNB at various times prior to sacrifice. ³H-QNB produced specific binding to cortical muscarinic receptors which was maximal at 1 hr. The centrally acting muscarinic antagonists, scopolamine (IC₅₀ = 0.3 mg/kg) and atropine (IC₅₀ = 17.5 mg/kg) produced a dose-dependent inhibition of ³H-QNB binding, when coadministered (sc) with ³H-QNB.

HACHT was measured in rat hippocampal synaptosomes following *in vivo* sc administration of various cholinergic agents. A dose-dependent reduction in HACHT was observed following treatment with various centrally-acting muscarinic agonists; arecoline, oxotremorine and Merck's (L-658,903). In contrast, the quaternary amine agonists, carbachol and oxotremorine-M did not reduce hippocampal HACHT. Antagonists such as atropine and scopolamine did not increase HACHT alone, but did block agonist-induced inhibition of HACHT. Finally, putative M1 receptor agonists (AF102B, SR 95639A) and ACh releasers (DuP 996) were ineffective in inhibiting HACHT, suggesting that presynaptic modulation of HACHT is primarily through M2 receptors.

In conclusion, two different approaches have been taken to demonstrate centrally mediated actions of known and putative muscarinic agents. These tests have proven useful in describing the possible mechanism of action of muscarinic agents as well as their ability to enter the central nervous system.

162.12

β-HYDROXYETHYLAPROPHEN: A METABOLITE OF APROPHEN WITH ANTIMUSCARINIC ACTIVITIES.

N. D. Brown*, H. Leader*, R. M. Smejkal*, R. K. Gordon*, and P. K. Chiang. Walter Reed Army Institute of Research, Applied Biochemistry Branch, Washington DC 20307-5100.

β-Hydroxyethylapropfen is a metabolite found in the urine of rats after administration of the antimuscarinic drug aprophen. Synthetic β-hydroxyethylapropfen also possessed potent antimuscarinic activities in (1) blocking the contraction of guinea pig ileum with a K_B = 2.5 x 10⁻⁷ M, (2) inhibiting the release of α-amylase from pancreatic acinar cells stimulated by carbachol (K_i = 1.6 x 10⁻⁹ M), and (3) competing for the binding of [³H-N-methyl]scopolamine to muscarinic receptors of N4TG1 neuroblastoma cells (K_i = 4.5 x 10⁻⁸ M). The inhibition constants (M) for aprophen were K_B = 3.1 x 10⁻⁹, K_i = 1.7 x 10⁻⁹, K_i = 5.1 x 10⁻⁸, and atropine were K_B = 2.0 x 10⁻⁹, K_i = 1.6 x 10⁻⁹, K_i = 2.4 x 10⁻⁹, respectively. Thus, β-hydroxyethylapropfen was approximately 80-fold less potent an antimuscarinic compound in the ileum contraction assay than either the parent compound, aprophen, or atropine. However, all three compounds exhibited about the same potency in the pancreas assay. In the binding assay, β-hydroxyethylapropfen was equipotent to aprophen, and both compounds were 10-fold less potent than atropine. Because β-hydroxyethylapropfen is less hydrophobic than aprophen, it may be of interesting therapeutic value for organophosphate poisoning.

162.14

A NOVEL M2-SELECTIVE MUSCARINIC ANTAGONIST. M.S. Gitler, V.I. Cohen, B. Jin, R.C. Reba, W.J. Rzeszutarski, and J. Baumgold. Dept. of Radiology, The George Washington University Medical Center, Washington, DC 20037.

Although several m2-selective antagonists have been described, they are not particularly potent. Thus, the development of potent m2-selective compounds remains an important goal. We now report that a bio-isoster of AQ-RA 741, is one order of magnitude more potent than previously described compounds and is slightly more selective. DIBA, the di-benzo derivative of AQ-RA 741 in which the pyridine of the tricycle was replaced with a benzene, had K_i values of 4, 0.3, 11 and 2 nM at m1 through m4 receptors, respectively. These values were from competition studies with [³H]NMS in membranes from transfected A9 L cells (m1 and m3), rat heart (m2) and NG108-15 cells (m4). AQ-RA 741 had K_i values of 34, 4.86 and 15 nM at each of these receptors. The autoradiographic distribution of DIBA binding sites was determined by displacement of [³H]NMS in rat brain. At low concentration, DIBA displaced [³H]NMS from superior colliculi, thalamus, hypothalamus and pontine nuclei, but not appreciably from caudate, superficial cortex, or CA1 and CA2, consistent with its binding to m2 receptors. These data indicate that DIBA is the most potent, m2-selective muscarinic antagonist yet described. DIBA should therefore become a useful probe in future studies of muscarinic function.

162.16

CHIMERIC m2/m5 MUSCARINIC RECEPTORS: IDENTIFICATION OF RECEPTOR DOMAINS CONFERRING ANTAGONIST BINDING SELECTIVITY. J. Wess, D. Gdula*, and Mark R. Brann*. National Institute

of Neurological Disorders and Stroke, Lab. of Mol. Biology, Bethesda, MD 20892.

The five muscarinic receptors (m1-m5) can be discriminated by the use of several subtype-selective antagonists. We have previously shown that various tricyclic compounds including the AF-DX derivative AQ-RA 741 and the alkaloid himbacine show up to 200-fold higher affinities for m2 and m4 than for m5 receptors (Dörje et al., J. Pharmacol. Exp. Ther. 256, 727, 1991). To explore the structural basis underlying this selectivity, we have created a variety of chimeric m2/m5 muscarinic receptors in which regions of the m5 receptor were systematically replaced by the homologous regions of the m2 receptor. Following their transient expression in COS-7 cells, the antagonist binding properties of the various receptors were studied. The affinity profiles of AQ-RA 741 and himbacine suggest that multiple receptor domains contribute to their higher affinity for m2 receptors. A completely different pattern was observed for the pirenzepine derivative UH-AH 37, which binds to m5 receptors with about 10-fold higher affinity than for m2 receptors. The subtype-selectivity of this antagonist is almost entirely dependent on a short receptor domain comprising most of transmembrane region VI and the third extracellular loop. Our data indicate that different structural epitopes are involved in conferring binding selectivity on different selective muscarinic antagonists.

162.17

ANTAGONISM OF MUSCARINIC AGONIST STIMULATED PHOSPHATIDYL-INOSITOL HYDROLYSIS BY 1-METHYL-(5-ALKOXY-4-ALKYLOXAZOL-2-YL)-1,2,5,6-TETRAHYDRO-PYRIDINES. Charles H. Mitch, David Calligaro, Frank Bymaster, Harlan Shannon, Barry Sawyer, Steve Quimby. Lilly Research Laboratories, Eli Lilly and Co., Indianapolis, IN 46285.

Blockade of muscarinic agonist induced stimulation of phosphatidyl-inositol hydrolysis was used to evaluate antagonist potencies of a series of 1-methyl-(5-alkoxy-4-alkyloxazol-2-yl)-1,2,5,6-tetrahydropyridines. Inhibition of 100 μ M acetyl choline in cortical slices was measured to determine M1 antagonist activity. Inhibition of 1mM carbachol in SK-N-SH cells was measured to determine M3 antagonist activity. Receptor affinity was determined using 3H-pirenzepine and 3H-oxotremorine-M as radioligands. As representative examples 1-Methyl-(5-propoxy-4-(sec-butyl)-oxazol-2-yl)-1,2,5,6-tetrahydropyridine was found to have IC₅₀'s of 81.0 nM and 340 nM respectively for antagonism of agonist stimulated PI turnover in cortical slices and SK-N-SH cells respectively, while it had receptor binding IC₅₀'s of 1 nM and 26 nM for 3H-PZ and 3H-Oxo-M respectively. 1-Methyl-(5-(2-propoxy)-4-(iso-butyl)-oxazol-2-yl)-1,2,5,6-tetrahydro-pyridine was found to have IC₅₀'s of 5630 nM and 2320 nM for agonist stimulated PI turnover in cortical slices and SK-N-SH cells respectively, while it had receptor binding IC₅₀'s of 56 nM and 472 nM for 3H-PZ and 3H-Oxo-M respectively. Selected compounds were also evaluated for their ability to block agonist activity in smooth muscle preparations such as the rabbit vas deferens.

162.18

PHARMACOLOGICAL CHARACTERIZATION OF THE M4 MUSCARINIC RECEPTOR SUBTYPE. M.A. Buck*, W. Billard*, H. Binch III* and R.D. McQuade. Schering-Plough Research, Bloomfield, New Jersey, 07003.

Pharmacologically distinguishable subtypes of the muscarinic acetylcholine receptor have been classified into M1, M2, and M3 primarily on the basis of differential selectivity of the antagonists, pirenzepine (PZ) and AFDX-116. Transfection and stable expression of individual cloned muscarinic receptor genes (m1-m5) into HeLa cells lacking such receptors have allowed for a more detailed comparison of their pharmacological and biochemical properties. The binding and second messenger profiles of the m4 receptor were compared with those for the m1 and m2 receptors. The cloned human m4 muscarinic receptor displays saturable high affinity binding of ³H-PZ (K_D=11.1 nM), similar to m1 receptors, albeit 10-fold less potent (K_D=1.5 nM). In contrast, m2 receptors display low affinity for PZ (K_i=241 nM). Competition studies with atropine demonstrate its equivalent potency at m4 and m1 sites (K_i=0.15 nM). At m2 receptors, however, atropine was 8-fold less potent. Conversely, competition displacement with AFDX-116 demonstrates the similarity between the m4 and m2 receptors; both exhibit K_i's of approximately 40 nM, while the drug was 10-fold less potent at m1 sites. Analysis of second messenger coupling indicates that the m4 receptor is similar to the m2 subtype; both inhibit adenylate cyclase and thymidine incorporation in the transfected HeLa cells.

Characterization of rat cortical tissues indicates the presence of M4 and M1 sites, with little evidence of M2 receptors. Saturation studies of ³H-PZ reveal two high affinity sites, with K_D values of 1 and 11 nM, which correspond to the K_D values obtained for cloned m1 and m4 receptors, respectively. Atropine exhibits a single class of sites with high affinity, indicating the absence of m2 receptors. These data support the existence of an M4 pharmacological subtype characterized by high affinity for PZ, AFDX-116 and atropine and negative coupling to adenylate cyclase and thymidine incorporation.

EXCITATORY AMINO ACIDS: PHARMACOLOGY III

163.1

RILUZOLE INHIBITS RELEASE OF L-GLU AND L-ASP FROM SLICES OF HIPPOCAMPAL AREA CA1. D.Martin, M.A.Thompson* and J.V.Nadler. Dept. Pharmacol. and Neurobiol., Duke Univ. Med. Ctr., Durham, NC 27710.

Riluzole possesses anticonvulsant and neuroprotective activity in animal models. It is believed to exert its effects by reducing glutamate release. This study examined the effects of riluzole on the release of glutamate (L-glu) and aspartate (L-asp) from the Schaffer collateral-commissural-ipsilateral associational (SCCIA) pathway in area CA1 of the rat hippocampus. Transmitter release was evoked from superfused slices of the CA1 area (excluding stratum lacunosum-moleculare) by exposing the slices to 1-min pulses of 50 mM K⁺. Under these conditions nearly all the release of L-glu, L-asp and GABA is Ca²⁺-dependent and it originates predominantly from SCCIA pathway.

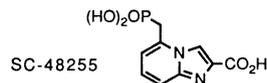

Riluzole (10-100 μ M), in the absence or presence of 1.2 mM Mg²⁺ significantly inhibited the release of both L-glu and L-asp in a concentration-dependent manner. It depressed the release of these amino acids about equally and by as much as 40%. Only the highest concentration of riluzole inhibited GABA release. TTX (0.1 μ M) reduced the K⁺-evoked release of L-glu and L-asp by about 40%, suggesting that a portion of the release depended on the generation of action potentials as the K⁺-concentration within the tissue was rising. The action of riluzole (30 μ M) was not confined to the TTX-sensitive component of the release. In general, the actions of riluzole resembled those of NMDA receptor antagonists and inhibitors of arachidonic acid metabolism that act upon the lipoxygenase pathways.

Therefore the anticonvulsant and neuroprotective properties of riluzole may be at least partly explained by its ability to inhibit L-glu/L-asp release from synaptic terminals. One possibility is that riluzole either inhibits the breakdown of arachidonic acid by lipoxygenases or interferes with the up regulation of L-glu/L-asp release by lipoxygenase products. (Supported by NIH grant NS16064).

163.2

NMDA SELECTIVE EXCITATORY AMINO ACID ANTAGONISTS FROM ACID FUNCTIONALIZED IMIDAZOPYRIDINES. Don W. Hansen Jr., Karen B. Peterson, Sofya Tsymbalov, Joseph B. Monahan, William F. Hood, Robert P. Compton, Thomas H. Lanthorn, Diane H. Ragan, and Gerald B. Watson. Searle Research and Development, CNS Diseases Research Department, 4901 Searle Parkway, Skokie, IL 60077.

Our efforts to design and synthesize antagonists selective for the NMDA site on the EAA receptor complex has led us to explore the use of carboxy-imidazoles as the nucleus for NMDA antagonists. We have now developed phosphonate-carboxylate functionalized imidazopyridine based NMDA antagonists. This poster will describe the synthetic exploitation, the in-vitro pharmacology, and the neuro protective properties in this series. A significant compound in the area, SC-48255, bound selectively to the NMDA site with a K_i of 2 μ M, was determined to be an antagonist by modulation of TCP binding, antagonized NMDA induced inward currents, and was found to be neuro protective in a gerbil ischemia assay.

163.3

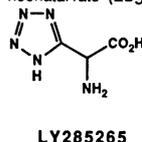

FPL 12495, A METABOLITE OF REMACEMIDE, IS A NONCOMPETITIVE NMDA ANTAGONIST. R. Ray*, R. Julien*, J. Gordon & J. Blosser. Fisons Pharmaceuticals, P.O. Box 1710, Roch., NY 14623

Remacemide (2-amino-N-[1-methyl-1,2-diphenylethyl] acetamide) has been identified as an anticonvulsant and antiischemic agent in various animal models of epilepsy and cerebral ischemia. The major metabolite of remacemide in rat is a desglycine analog (FPL 12495) which structurally resembles known noncompetitive NMDA receptor antagonists. In vitro biochemical receptor binding studies using the noncompetitive antagonist [3H]MK801 demonstrated that remacemide had low affinity for NMDA receptors while FPL 12495 had submicromolar affinity. The affinity of FPL 12495 was not affected by glycine, glutamate or by spermine suggesting that it interacted at the NMDA channel (MK801/PCP) site. FPL 12495 and remacemide demonstrated weak activity at other receptor sites to which non-competitive antagonists have been reported to interact. Thus, 10 to 200 times higher concentrations of FPL 12495 were required to antagonize nicotinic and sigma receptors and only weak inhibition (IC₅₀=10 μ M) of norepinephrine and dopamine transporters was seen. Potent antagonism of the latter site by phencyclidine has been implicated in its psychotomimetic effects. Taken together, these results suggest that FPL 12495 has selective affinity for the non-competitive NMDA binding site. This activity may explain in part the antiischemic properties of remacemide.

163.4

IN VITRO AND IN VIVO PHARMACOLOGY OF D,L-(TETRAZOL-5-YL)GLYCINE: A HIGHLY POTENT AND STRUCTURALLY NOVEL NMDA RECEPTOR AGONIST. W.H. Lunn, D. Lodge*, J.D. Leander, A.J. Saccan and D.D. Schoepp. Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, Indiana 46285 and Royal Veterinary College, Univ. of London, United Kingdom.

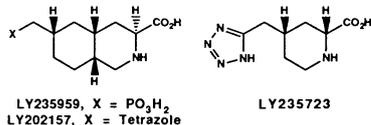

This work describes the pharmacological activity of D,L-(tetrazol-5-yl)glycine (LY285265), a structurally novel and highly potent agonist at the NMDA subtype of excitatory amino acid receptor. D,L-(tetrazol-5-yl)glycine potently displaced rat brain membrane [³H]GCS19755 (10 nM) binding (IC₅₀ = 98 \pm 7 nM) and NMDA-specific ³H-glutamate (10nM) binding (IC₅₀ = 36 \pm 18 nM), but did not appreciably affect the binding of [³H]AMPA, [³H]kainate, or [³H]glycine (IC₅₀s > 30,000 nM). D,L-(tetrazol-5-yl)glycine is more potent than NMDA or *cis*-methanoglutamate as a depolarizing agent in the rat cortical slice, and unlike these other agents induced rapid receptor-mediated neurotoxicity. Depolarization by D,L-(tetrazol-5-yl)glycine can be antagonized by LY233053, a selective NMDA receptor antagonist. D,L-(tetrazol-5-yl)glycine is a very potent convulsant when administered to neonatal rats (ED₅₀=0.071 mg/kg i.p.). Convulsions in neonatal rats or lethality in mice induced by D,L-(tetrazol-5-yl)glycine were selectively antagonized by competitive and non-competitive NMDA receptor antagonists. D,L-(tetrazol-5-yl)glycine is a highly potent and selective NMDA receptor agonist, that could be used to further probe NMDA receptors *in vitro* and *in vivo*.

CHARACTERIZATION OF (-)-LY235959, (-)-LY202157 AND (-)-LY235723 AS THE ACTIVE ISOMERS OF THE RACEMIC COMPETITIVE NMDA ANTAGONISTS LY274614, LY233536 AND LY233053, RESPECTIVELY. P.L. Ornstein, M.B. Arnold*, N.K. Augenstein*, J.D. Leander, D. Lodge, and D.D. Schoepp, Lilly Research Labs, Eli Lilly and Co., Indianapolis, IN 46285 and Royal Veterinary College, London, NW10TU, UK.

Competitive NMDA antagonists show promise as novel therapeutic agents for the treatment of acute and chronic neurodegenerative disorders such as cerebral ischemia, Huntington's Chorea, Parkinson's disease, amyotrophic lateral sclerosis and Alzheimer's disease. We recently described the characterization of LY274614, LY233536 and LY233053 as potent and selective competitive NMDA antagonists. We subsequently resolved these phosphonate and tetrazole substituted amino acids and found that the activity of the racemates resides with the (-)-isomer. (-)-LY235959, (-)-LY202157 and (-)-LY235723 selectively displace [³H]CGS19755 binding with IC₅₀'s of 25 ± 11, 415 ± 122 and 67 ± 6 nM, respectively. At relatively high concentrations, these compounds did not appreciably inhibit [³H]AMPA and [³H]kainic acid receptor binding (IC₅₀'s >10,000 nM). These compounds also potently block NMDA-induced lethality in mice, with minimum effective doses of 0.625, 1.25 and 2.5 mg/kg (i.p.), respectively.

163.7

INFLUENCE OF VOLATILE ANESTHETICS ON NMDA-STIMULATED ⁴⁵Ca UPTAKE IN RAT BRAIN. D.C. Martin, R.L. Denison, M.K. Baumgartner and R.S. Aronstam, Departments of Anesthesiology and Pharmacology & Toxicology, Medical College of Georgia, Augusta, GA.

Volatile anesthetics inhibit glutamate-stimulated [³H]MK-801 binding to the ionophore of NMDA receptor complexes in rat brain (FASEB J. 5:A408, 1991). In the present study, we examined the influence of several anesthetics on NMDA-stimulated ⁴⁵Ca uptake in rat brain. Calcium flux measurements were performed using a microvesicle preparation containing synaptosomes and membrane fragments which reseal and maintain electrical and ionic gradients. To measure ⁴⁵Ca influx, 50 µl of microvesicles (=100 µg protein) was added to a tube containing 800 µl of a physiological salt solution and 50 µl ⁴⁵Ca (=50 nM, 90-100,000 cpm) at 37°C. Uptake was initiated by addition of NMDA. After an appropriate incubation (typically 30 sec), uptake was terminated by filtration through glass fiber filters, and the radioactivity content of the filters was determined by liquid scintillation counting. Nonspecific uptake was measured in the absence of NMDA.

NMDA stimulated ⁴⁵Ca uptake (30 sec) by rat brain microvesicles by 48 ± 9% (mean ± S.D.; N = 6) with an EC₅₀ of 1.4 ± 0.5 µM. The NMDA-stimulated ⁴⁵Ca uptake was inhibited by MK-801 with an IC₅₀ of = 10 µM. Uptake stimulated by 100 µM NMDA was inhibited 60-85% by enflurane, isoflurane, and halothane with IC₅₀'s of 0.1-2.1 mM. Thus, significant inhibition of NMDA receptor-mediated Ca²⁺ flux was produced by anesthetics at concentrations achieved during routine clinical use. Preincubation of brain microvesicles with NMDA resulted in a rapid desensitization of NMDA-stimulated ⁴⁵Ca uptake, with a t_{1/2} of less than 1 min. Each of the anesthetics diminished both the extent and rate of development of this desensitization. These findings further support the notion that anesthetics interfere with neurotransmission at NMDA receptor complexes. (Supported by USPHS grant AA-07698).

163.9

INHIBITION OF HIPPOCAMPAL PATHWAYS BY A CYCLOBUTYLENE ANALOGUE OF 2-AMINO-4-PHOSPHONOBUTANOIC ACID (AP4). J.E. Koerner, N.L. Peterson, H.B. Kroona, R.L. Johnson, Dept. of Biochem., Dept. of Med. Chem. and Neurosci. Grad. Program, Univ. of Minnesota, Minneapolis, MN 55455.

Previously, E- and Z-2,3-methano-4-phosphonobutanoic acid, two cyclopropyl analogues of 2-amino-4-phosphonobutanoic acid (AP4), were synthesized and tested for bioactivity at L-AP4 receptors. Modelling studies indicate that the biologically active conformations of these analogues, and therefore L-AP4, are in an extended form. In an attempt to further define this bioactive conformation, we synthesized the extended, rigid AP4 analogue 1-amino-3-(phosphonomethylene)-cyclobutane-1-carboxylic acid. This cyclobutylene compound was tested for its ability to inhibit evoked responses in the lateral perforant path (LPP) and medial perforant path (MPP) of the hippocampal slice with extracellular techniques. Concentration-response data were collected and IC₅₀'s determined. The cyclobutylene analogue showed pathway specificity giving an IC₅₀ of 41 µM in the LPP and 215 µM in the MPP. Paired pulse potentiation (PPP) studies in the LPP suggest that the analogue may have both pre- and postsynaptic activity (the PPP was increased 1.26 times the normal compared to L-AP4 which was 1.43 times the normal). This mixed response could be due to the analogue acting at postsynaptic glutamate receptors in the LPP in addition to the presynaptic L-AP4 receptors. However, much of the inhibition can be attributed to a presynaptic mechanism. Therefore, we conclude that this analogue is acting at the presynaptic L-AP4 receptor. Moreover, its relative potency in the LPP compared to other synthetic L-AP4 analogues is further evidence that L-AP4 assumes an extended conformation at the L-AP4 receptor of the LPP. [During our study, Allan, R. D. *et al* described a synthesis and tested the cyclobutylene analogue at NMDA receptors (*J. Med. Chem.* 1990, 33, 2905-2915).] Supported by NIH NS17944.

163.6

INHIBITION OF [³H]-MK801 BINDING AND PROTECTION AGAINST NMDA-INDUCED LETHALITY WITH A SERIES OF IMIPRAMINE ANALOGS. L. A. McQuaid, J. D. Leander, L. G. Mendelsohn, N. R. Mason, R. R. Lawson* and E. C. R. Smith, Central Nervous System Research, Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, IN 46285.

We have evaluated a series of imipramine analogs to further explore the structure-activity relationships involved in their inhibition of [³H]-MK801 binding and their ability to prevent N-methyl-D-aspartate (NMDA) induced lethality in mice. The [³H]-MK801 binding assay was carried out using well washed rat forebrain membranes in the presence of glycine (1 µM). The SAR for inhibition of [³H]-MK801 binding indicated that primary amines on short tethers were optimum. The primary amine on a two carbon tether was found to be the most potent imipramine analog with respect to inhibition of [³H]-MK801 binding with an IC₅₀ of 0.36±0.03 µM. The ring nitrogen-carbon portion of imipramine could be replaced with either a carbon-sulfur linkage or a carbon-carbon double bond. The minimally effective dose (MED) was determined for each of the imipramine analogs as that concentration which protected against NMDA lethality (200 mg/kg, i.p.) in greater than 50% of the mice tested. For protection against NMDA lethality, compounds containing a carbon-carbon double bond linkage to a cyclic amine were the most efficacious tricyclics tested. Possible explanations for the lack of correlation between the two assays will be discussed.

163.8

ANTICONVULSANT EFFECTS OF MEMANTINE AND MK-801 IN GUINEA PIG HIPPOCAMPAL NEURONS. J.P. Aplan and F.J. Cann*, Neurotoxicology Branch, U.S. Army Medical Research Institute of Chemical Defense, Aberdeen Proving Ground, MD 21010.

Memantine (1-amino-3,5-dimethyladamantane) is used in treatment of Parkinsonism and movement disorders. Recent work has demonstrated that memantine (Mem) displaces MK-801 from its binding sites (Kornhuber *et al.*, 1989), blocks NMDA receptor channels as potently as MK-801 (Bormann, 1989), and possesses neuroprotective properties (el Nasr *et al.*, 1990). We compared the anticonvulsant properties of Mem to MK-801 and to centrally acting antitussives.

Extracellular recordings were obtained from area CA1 of guinea pig hippocampal slices in a total submersion chamber at 32° C in normal oxygenated artificial cerebrospinal fluid (ACSF). Drugs were applied by bath perfusion. Evoked responses were elicited by stimulation of the Schaffer collaterals. Pretreatment of slices for 16-20 min with 100 µM Mem blocked epileptiform afterdischarges following evoked responses in both Mg²⁺-free ACSF and NMDA-containing ACSF. At this concentration Mem alone had no discernible effect on evoked responses when perfused for up to 50 min. Epileptiform afterdischarges in response to reapplication of NMDA did not fully recover after over 2 hr of washing with normal ACSF. MK-801 was effective at 10 µM and required application for over 1 hr for full suppression of afterdischarges. Mem also reversed epileptiform activity when applied after such activity was induced by NMDA or Mg²⁺-free ACSF, but was more effective against afterdischarges induced by NMDA.

163.10

CHARACTERIZATION OF RETINAL AND HIPPOCAMPAL L-AP4 RECEPTORS USING CONFORMATIONALLY CONSTRAINED AP4 ANALOGUES. N.L. Peterson, W.B. Thoreson, R.L. Johnson, J.E. Koerner, R.E. Miller, Dept. of Biochem., Dept. of Physiol., Dept. of Med. Chem. and Neurosci. Grad. Program, Univ. of Minnesota, Minneapolis, MN 55455.

Several conformationally constrained AP4 analogues (E- and Z-1-amino-3-phosphonocyclopentane-1-carboxylic acid, E- and Z-1-amino-3-phosphonocyclohexane-1-carboxylic acid, and E- and Z-2-amino-2,3-methano-4-phosphonobutanoic acid) made it possible to study and compare four different systems which are sensitive to L-AP4: two retinal (mudpuppy, rabbit) and two hippocampal slice (rat lateral perforant path; guinea pig mossy fiber-CA3) preparations. In addition, the pharmacology of three KAIN/AMPA pathways and one NMDA pathway in the hippocampus was examined. All experiments were done using extracellular recording techniques. Concentration-response data were collected and IC₅₀'s determined (noted in parentheses). The rank order potency of the L-AP4 sensitive systems was similar, though not identical. In these systems, the cyclopropyl analogues and L-AP4 were the most potent (1-35 µM), followed by the cyclopentyl analogues (130-960 µM), with the cyclohexyl analogues being the least potent (1735-5800 µM). The non-L-AP4 systems did not follow this general rank order potency. The KAIN/AMPA systems differed most notably in the potency of L-AP4 and the E-cyclopentyl analogue where E-cyclopentyl AP4 was more potent than L-AP4 in two of the three systems and nearly equipotent in the third. The NMDA system pharmacology differed from both the L-AP4 systems and the KAIN/AMPA systems. The constrained analogues may be able to probe subtle differences in tertiary structure of the four L-AP4 sensitive receptor proteins. Therefore, although the rank order potencies are not identical, the similarities are consistent with the possibility that the L-AP4 receptors may comprise a family of receptor proteins. Supported by NIH NS17944, EY03014, and EY06213.

JSTX (JORO SPIDER TOXIN) SELECTIVELY BLOCKS QUISQUALATE (QUIS)-INDUCED SEIZURE IN RATS: BEHAVIORAL AND ELECTROPHYSIOLOGICAL ASSESSMENTS.

H. Kanai*, N. Ishida*, A. Masui, M. Sadamatsu*, T. Ueno*, T. Nakajima* and N. Kato. Dept. of Psychiatry, Shiga Univ. Med. Science, Otsu 520-21, Japan.

JSTX inhibits QUIS-evoked responses in the rat hippocampus in vitro. QUIS/AMPA receptors are rich in the hippocampus and the seizure by icv QUIS administration is similar to the temporal lobe epilepsy in humans. Anticonvulsant effects of JSTX were evaluated in freely-moving rats against QUIS/AMPA-induced seizures and compared with the effects of CPP, a NMDA antagonist, on the seizures induced by quinolinate (QUIN), a NMDA agonist. Rats were implanted with the electrode into dorsal hippocampus and the icv cannula. QUIS (30µg) elicited spiking EEG with mean latency time (LT) 7.7 min and evoked generalized seizures (GS) with 16 min LT. Mortality rate was 67%. JSTX (20µg) prolonged LT to spiking discharge to 102 min and completely blocked GS in 80% rats. None of the rats pretreated with JSTX died. JSTX failed to antagonize QUIN, while CPP blocked QUIN-induced seizures as expected. Though preliminary, JSTX seemed to suppress AMPA-seizures. CNQX appeared to be effective as well, but to act differently from JSTX.

163.13

INHIBITION OF THE GLUTAMATE TRANSPORTER IN ASTROCYTES BY L-trans-2,4-PYRROLIDINE DICARBOXYLATE. R.J. Bridges, S.N. Shim* and A.R. Chamberlin, Depts of Neurol. and Chem., Univ. of CA., Irvine, CA 92717.

Transport of L-glutamate into astrocytes and neurons is thought to be a key step in the termination of the excitatory signal and the prevention of excitotoxic damage. In previous studies, we synthesized L-trans-2,4-pyrrolidine dicarboxylate (L-trans-2,4-PDC) and identified it as a potent competitive inhibitor of the Na-dependent synaptosomal glutamate uptake system. In the present study we examined the ability of L-trans-2,4-PDC to inhibit this transport system in cultures of rat astrocytes. Type I astrocytes were prepared from the cortices of 4 day old rats. Oligodendrocytes and type II astrocytes were removed by shaking and the purified astrocytes were replated into 6 and 12 well plates, where they were allowed to reach confluency (14-21 days) before being used in the uptake studies. The activity of the Na-dependent transport system was assayed by quantitating the uptake of ³H-D-ASP into the astrocytes for 3 min at 30°C. L-trans-2,4-PDC was found to inhibit the uptake ³H-D-ASP in a competitive manner with a Ki value comparable to that of the Km of D-aspartate (~50 µM). The findings demonstrate that L-trans-2,4-PDC is a potent inhibitor of both the synaptosomal and astrocytic uptake systems. Considering that the inhibitor does not appear to potentially bind to any of the EAA receptors, the results suggest that L-trans-2,4-PDC will be useful in examining the role of glutamate uptake in complex preparations (e.g., co-cultures, tissue slices, *in vivo*) that contain both neuronal and glial components.

163.15

THE KAPPA OPIATE AGONIST CI-977 DOES NOT BLOCK GLUTAMATE-OR HYPOXIA-INDUCED LDH RELEASE AND ⁴⁵Ca⁺⁺ UPTAKE IN CULTURED CORTICAL NEURONS. G. Campbell, A. Probert, D. Rock, and F.W. Marcoux. Dept. of Pharmacology, Parke Davis Pharmaceutical Research Division, Warner-Lambert Company, Ann Arbor, MI 48105.

CI-977 is an agonist at opiate receptors with selectivity for the kappa subtype. It has been shown to be analgesic in animal models as well as neuroprotective in animal models of focal ischemia. The following studies were done to evaluate the effect of CI-977 on glutamate- and hypoxia-induced neuronal cell death or ⁴⁵Ca⁺⁺ flux in cultured cortical neurons to determine if the neuroprotective effects of CI-977 might be due to an interaction with the NMDA receptor ion-channel complex.

CI-977 (10-100nM) caused a slight (10%) reduction in glutamate-induced neuronal death (LDH release). These effects were neither concentration-dependent nor reversed by the addition of 1 µM naloxone. CI-977 was also evaluated as an inhibitor of combined hypoxia/hypoglycemia-induced increases in intracellular Ca⁺⁺ (⁴⁵Ca⁺⁺) and neuronal neuroprotective effects. At higher concentrations, there was a naloxone-insensitive decrease in the response. The competitive NMDA antagonist CPP was completely effective in both assays blocking LDH release and ⁴⁵Ca⁺⁺ influx.

These studies indicate that CI-977 blocks neither glutamate-nor hypoxia-induced neuronal cell death in cultured neurons and suggests that the neuroprotective effects of CI-977 seen in animal models may not be accounted for by a direct interaction with the NMDA receptor complex.

163.12

GLYCINE ANTAGONIST, (+)HA-966, BLOCKS STRESS-INDUCED RISE IN DOPAMINE METABOLISM IN THE RAT MEDIAL PREFRONTAL CORTEX. B.A. Morrow*, W.A. Clark, and R.H. Roth, Department of Pharmacology, Yale University School of Medicine, New Haven, CT 06510.

Restraint stress selectively activates the dopamine (DA) neurons in the prefrontal cortex (PFC) and nucleus accumbens septi (NAS), compared to the striatum (CP), as assessed by postmortem tissue measurements of DA and 3,4-dihydroxyphenylacetic acid (DOPAC) (Roth et al. *Ann. N.Y. Acad. Sci.* 537:138-147, 1988). Kalivas et al. proposed the A10 DA neurons terminating in the PFC have N-methyl-D-aspartate (NMDA) receptors while those terminating in the NAS are regulated by a different glutamate receptor (*J. Pharmacol. Exp. Ther.* 251:378-387, 1989). The current study examines the involvement of glycine's allosteric agonist site on the NMDA receptor in the response of midbrain DA neurons to restraint stress. Rats, treated i.p. with 15 mg/kg (+)HA-966 (+1-hydroxy-3-aminopyrrolidinone-2), a glycine antagonist, or saline, were restrained in wire cages for 30 min, then decapitated and the brains removed and dissected. Brain samples were homogenized, purified over alumina columns and assayed for DOPAC and DA using high performance liquid chromatography with electrochemical detection. (+)HA-966 completely blocked the stress-induced rise in DA metabolism in the PFC, but not the NAS. These data suggest that NMDA receptors are involved in the stress induced metabolic activation of DA neurons in the PFC and not the NAS.

DOPAC/DA Ratios, in percent control ± SEM; n=8 or 9

AMITRIPTYLINE PROTECTS AGAINST NMDA-INDUCED TOXICITY AND AUGMENTS KAINATE AND QUISQUALATE-INDUCED RELEASE OF GLUTAMATE IN NEURONAL CULTURES P.P. McCaslin and X. Z. Yu*, Dept. Pharmacol. & Toxicol., UMC, Jackson, MS, 39216.

It has recently been reported that tricyclic antidepressants inhibit the binding of MK-801 to the N-methyl-D-aspartate (NMDA) receptor complex, cause a voltage-dependent equilibrium block of the NMDA receptor responses, and prevent NMDA-induced convulsions in vivo. In this report, the effect of amitriptyline on the excitatory amino acid (EAA)-induced toxicity and the EAA-induced release of several amino acids were determined in cerebellar granule neurons. Amitriptyline (25 µM) prevented the rapid toxicity induced by 100 µM NMDA in high calcium concentrations (10mM) but had no protective effect against the kainate-induced toxicity in these neurons even when amitriptyline was administered in much higher dosages. In fact, in higher dosages amitriptyline, alone, was toxic to the neurons. Quisqualate, kainate, or NMDA all produced an increase in the release of several amino acids (especially glutamate and taurine) when these EAA were incubated with neurons for one hour. Amitriptyline augmented the kainate- and quisqualate-induced release of glutamate and taurine but had no significant effect on the NMDA-induced release of these amino acids. In conclusion, these findings confirm the reports of others that tricyclic antidepressants have effects on the NMDA receptor and extend that work by showing that amitriptyline also has a selective interaction with kainate/quisqualate in augmenting the EAA-induced release of glutamate and taurine from cerebellar granule neurons. Supported by NIDA grant DA 64841.

ON CENTRAL MUSCLE RELAXANTS, GLYCINE RECEPTORS AND TWO OLD DRUGS: ZOXAZOLAMINE AND HA-966. B.A. McMillen, H. L. Williams*, H.L. Romeyn* and P.D. Shepard, Dept. of Pharmacol., Sch. of Med., E. Carolina Univ., Greenville, NC 27858; Maryland Psych. Res. Ctr., Baltimore, MD 21228.

Zoxazolamine (Zox) is in the centrally acting muscle relaxant class of drugs, which reportedly act by decreasing CNS interneuronal activity. These drugs, but not anxiolytics, decreased dopaminergic (DA) turnover and induced a 'pacemaker' discharge pattern in DA neurons. A mechanism for these effects was not found. We observed that (+)-HA-966, an inhibitor of the glycine modulatory site on the NMDA receptor, has a similar effect on DA impulse flow, but (-)-HA-966 completely inhibits DA impulse flow. Binding of 20 nM [³H]-glycine to cortical synaptosomal membranes was inhibited by (+)-HA-966, IC50 = 3.16 µM, but only poorly by ZOX, IC50 = 474 µM, and chlorzoxazone, a related drug, caused no displacement. Neither 50 mg/kg Zox nor 30 mg/kg (+)-HA-966 prevented amphetamine (0.1 mM/kg plus 10 mg/kg iprindole) depletion of striatal DA, but 3.0 mg/kg of MK-801, a non-competitive NMDA receptor antagonist, did protect DA content. Since baclofen induces a regular firing rate in DA neurons, Zox and (+)-HA-966 were tested for displacement of 10 nM [³H]-l-baclofen from cortical synaptosomal GABA-b receptors, but were ineffective. Thus, the effects of these muscle relaxants on DA neurons are mediated by a mechanism other than glycine or GABA-b receptors.

163.17

DIPYRONE ACTIVATES N-METHYL-D-ASPARTATE (NMDA) RECEPTORS ON HIPPOCAMPAL NEURONS. A.M.N. Costa*, Y. Aracava, E.S. Rocha and E.X. Albuquerque. Lab. Mol. Pharmacol. II, IBCCF, UFRJ, Rio de Janeiro, RJ, Brazil, 21941; Dept. Pharmacol. Exp. Ther., Univ. Maryland Sch. of Med., Baltimore, MD, 21201.

It has been shown that NMDA receptors may be implicated in the transmission of nociceptive inputs in mammalian central nervous system (*TPS*, 11:307, 1990). Recently, we have demonstrated that pyrazole is able to activate NMDA receptors on hippocampal neurons (*Neurosci. Abstr.*, 16:86, 1990). In light of these findings, we decided to evaluate the actions of dipyrone, a pyrazolon derivative with analgesic properties, on NMDA receptor activation. Single channel currents were recorded from outside-out patches excised from rat hippocampal neurons kept in cultures for 5-15 days. When the outside-out configuration was achieved, the patch was placed inside a glass mini-pipe connected to a perfusion system. Nominally-Mg²⁺ free external solution containing the drugs to be tested was delivered via this system. Dipyrone (1-50 μM) activated single channel currents similar to those activated by NMDA. These currents were blocked by APV, a competitive antagonist of NMDA receptor. Single channel conductance was about 50 pS, a value similar to that reported for NMDA- and pyrazole-activated currents. Open-channel currents fluctuated between on and off states giving rise to a burst-like activity. Hyperpolarization increased the number of openings per burst and decreased the intraburst open times. No sign of channel blockade was observed with dipyrone up to 50 μM. The activation of NMDA receptors by dipyrone suggests that these receptors could be involved in the analgesic action of dipyrone. PREFERENTIAL INHIBITORY EFFECTS OF ARYLAMINE SPIDER TOXINS ON NMDA RECEPTOR-MEDIATED INCREASES IN CYTOSOLIC CALCIUM. L.D. Arntman*, T.N. Parks, H. Jackson and E.F. Nemeth. Natural Product Sciences, Inc., 420 Chipeta Way, Salt Lake City, UT 84108.

Low molecular weight arylamine spider toxins such as Joro spider toxin (JSTX) and argitoxin-636 (Arg636) have been reported to be effective glutamate antagonists in a variety of invertebrate and vertebrate preparations. The ability of several synthetic arylamines to block NMDA- and non-NMDA-receptor-mediated increases in intracellular calcium ([Ca²⁺]_i) was examined in cultures of neonatal rat cerebellar granule cells (RCGCs) loaded with fura-2. Rapid and sustained increases in [Ca²⁺]_i were elicited by NMDA (50 μM) plus glycine (1 μM) in 6-8 day old cultures, or by AMPA (30 μM) or kainate (KA, 100 μM) in 5 day old cultures. These increases in [Ca²⁺]_i were abolished in the absence of extracellular Ca²⁺. Responses to NMDA/gly (100-300 nM increase over basal [Ca²⁺]_i) were completely blocked by the addition of 1 mM Mg²⁺. Responses to KA (100-300 nM increase over basal [Ca²⁺]_i) or AMPA (20-30 nM increase over basal [Ca²⁺]_i) were obtained in the presence of 1 mM Mg²⁺ and 1 μM nifedipine. CNQX (2 μM) produced a 50% blockade of KA- or AMPA-induced increases in [Ca²⁺]_i. The synthetic arylamine toxins AG489 and AG505 (α-agatoxins from *Agelenopsis aperta*) blocked increases in [Ca²⁺]_i evoked by NMDA/glycine, AMPA or KA with widely varying potencies. IC₅₀ values for AG489 were 245 nM, 38 μM, and 201 μM, respectively. IC₅₀ values for AG505 were 229 nM, 14 μM, and 20 μM, respectively. Other arylamine toxins such as Arg636 and JSTX3 showed a 10-100 fold selectivity for NMDA- vs. non-NMDA-receptor-mediated increases in [Ca²⁺]_i. These data show that arylamine spider toxins are preferential antagonists of NMDA receptor-mediated responses in RCGCs and perhaps throughout the mammalian CNS.

THE ANTIHYPERTENSIVE DRUGS NITROPRUSSIDE AND NITROGLYCERIN INHIBIT EXCITATORY AMINO ACID (EAA) RESPONSES. Peter K. Kaiser, Sizheng Z. Lei, Sanjay Aggarwal and Stuart A. Lipton. Dept. of Neurology, Children's Hosp & Progr in Neurosci, Harvard Med Sch, Boston, MA

NMDA receptor-mediated increases in [Ca²⁺]_i were monitored with digital imaging techniques using the dye fura-2 in primary cultures of rat neonatal cortical neurons. Bath application of nitroglycerin (NTG; 10-100 μM) or nitroprusside (NP; 1-100 μM) inhibited NMDA (50 μM)-evoked responses. Since the active species of each of these drugs is nitric oxide (NO), we suspected that NO might, at least in part, down-regulate NMDA responses by oxidation of the redox modulatory site of the NMDA receptor-channel complex (Aizenman, Lipton & Loring, *Neuron* 1989;2:1257). In fact, consistent with this notion, the reducing agent dithiothreitol (DTT; 2 mM) reversed the effects by ~90%. However, in some cultures part of the inhibitory effect reversed spontaneously with several min of continued washout. Such reversibility would not be expected of a sulfhydryl oxidizing reagent until introduction of a chemical reductant. Further, NP (but not NTG) inhibited [Ca²⁺]_i responses to K⁺ (50 mM) or kainate (50 μM) in the presence of 1 μM TTX; after pre-treatment with the strong oxidant DTNB (500 μM), NTG or NP produced an additional degree of blockade of the NMDA response. These effects would not have been expected of an agent acting solely at the redox modulatory site. Thus, NTG/NP may possibly act at the redox modulatory site but other effects are also implicated and will require further study. Meanwhile, these clinically-tested agents are being evaluated for the treatment of EAA receptor-mediated neurotoxicity.

POTENTIATION OF DEPRESSED NMDA-MEDIATED TRANSMISSION BY THE PARTIAL GLYCINE AGONIST, D-CYCLOSERINE. P.L. Wood, M. Li* and R. Ryan*. Biological Research, Hoechst-Roussel Pharmaceuticals, Somerville, NJ 08876.

Partial agonists of the NMDA-associated glycine receptor are potential clinical candidates for improving cognitive function. To assess this potential further, we examined the actions of the partial glycine agonist, D-cycloserine on pharmacologically depressed NMDA-mediated neurotransmission in the mouse cerebellum, as assessed by changes in the second messenger, cGMP.

Using this paradigm, D-cycloserine was found to reverse the depressant actions of the competitive NMDA antagonist, CPP. In contrast, the depressant actions of the non-competitive NMDA antagonists, MK-801, PCP and magnesium, were not altered by pretreatment with D-cycloserine.

These data therefore support the potential clinical utility of partial glycine agonists in augmenting NMDA-mediated transmission except under conditions where a non-competitive blockade of the receptor complex is in effect.

PEPTIDES: BIOSYNTHESIS, METABOLISM AND BIOCHEMICAL CHARACTERIZATION I

164.1

NON-RADIOACTIVE SOLUTION HYBRIDIZATION OF BRAIN mRNA. E. Robbins, M.E. Lewis, E.M. Reilly* and E. Baldino, Jr., Cephalon, Inc., 145 Brandywine Pkwy., W. Chester, PA 19380.

We have developed a method for the rapid non-radioactive detection of hybridization of specific cRNA probes to their target mRNA using hapten-conjugated probes. In order to achieve maximum sensitivity, this method employs solution rather than solid phase hybridization. A digoxigenin-labeled cRNA probe complementary to preproenkephalin mRNA and the sense complement of this probe were hybridized to striatal RNA in our solution hybridization assay.

Total striatal RNA (1-2 μg) was aliquoted into a sterile, RNase-free tube to which 2x TES hybridization buffer containing probe was added. After a 4-hour incubation at 75°C, RNase buffer was added to each sample to digest unhybridized probe. Hybrids were then collected on a Whatman GF/C glass fiber filter. After blocking filters in blotto, detection of probe hybridized to striatal mRNA was carried out enzymatically following complex formation with anti-digoxigenin alkaline phosphatase (AP) conjugated antibody at a concentration of 1:1000 in 1x TBS. Unbound antibody was removed by successive washes in TBS, and AP substrate containing 1 mg/ml p-nitrophenyl phosphate in diethanolamine buffer was added. Color development was allowed to proceed in the dark until staining could be detected by eye in background samples (10-15 mins). Color intensity was determined by spectrophotometric analysis of optical density at 405-420 nm. While nearly undetectable (background) amounts of sense RNA probe hybridized to cellular mRNA, substantial specific hybridization was observed using the preproenkephalin-specific cRNA probe.

This new method should provide a valuable tool for the study of other RNA species, such as those related to the study of altered gene expression in development, pathology or due to physiological or pharmacological manipulations.

164.2

LOCALIZATION OF ENKEPHALIN-SYNTHESIZING CELLS IN RAT, GUINEA PIG AND CHINCHILLA BRAINSTEM BY *IN SITU* HYBRIDIZATION. DW Hoffman, PD Gardner and WM Waldron. Departments of Psychiatry, Pharmacology and Biochemistry, Dartmouth Medical School, Hanover, NH 03756.

In situ hybridization has been used to map the distribution of mRNAs encoding enkephalin precursor in superior olivary and periolivary cells of the rat, guinea pig and chinchilla auditory brainstem which innervate auditory nerve dendrites at cochlear inner hair cells. Sense and antisense cRNA probes (935 bases) corresponding to the entire coding region of the preproenkephalin gene (gift of Dr. Steven Sabol) are generated using the SP6 RNA polymerase promoter. Brainstem sections are exposed to Hyperfilm after hybridization, and the density of 35-S-labelled probe binding in the autoradiograms is digitized and quantified using an image analysis system and grain counting program. More recently, probes synthesized with digoxigenin-UTP have been used, with anti-digoxigenin-alkaline phosphatase visualization of localization. Hybridization is seen in the rat in dorsal tegmental nucleus, dorsal parabrachial area, raphe nucleus and lateral superior olivary region, especially in the lateral nucleus of the trapezoid body. Enkephalin cell bodies are seen in the periolivary region in the rat, in comparison to their localization within the lateral superior olive in the guinea pig, as has been reported using immunochemical techniques. The distribution of enkephalin-synthesizing cell bodies in the auditory brainstem of the chinchilla more closely resembles that of the guinea pig than the rat. [Supported by the Henry Heyl Fund of the Hitchcock Foundation].

164.3

EFFECT OF PGE₂ ON THE SECRETION OF MET⁵-ENKEPHALIN (ME) AND THE EXPRESSION OF PROENKEPHALIN A (PROENK) GENE IN BOVINE ADRENAL MEDULLARY (BAM) CELLS. H.H. Suh, K. Pennypacker, X.P. He*, M. McMillian, R. Fannin*, E.C. Mar*, P. Hudson and J.S. Hong, LMIN/NIEHS/NIH, RESEARCH TRIANGLE PARK, NC, 27709.

We previously reported that long-term (24 hrs) stimulation of BAM cells with PGE₂ increased secretion of ME as well as proENK gene expression. The primary goal of the present study was to further characterize the effect of PGE₂ on regulation of proENK gene expression in BAM cells. The onset of secretion of ME and expression of proENK gene induced by PGE₂ began 3 and 6 hrs, respectively, after the treatment. Cycloheximide, a protein synthesis inhibitor inhibited both the secretion of ME as well as the expression of proENK gene induced by PGE₂. The increases in secretion of ME and expression of proENK gene induced by PGE₂ were effectively inhibited by nitrendipine and nimodipine, selective L-type calcium channel blockers but not by ω -conotoxin, a N-type calcium channel blocker. In addition, calmidazolium, a calmodulin antagonist, effectively inhibited both secretion of ME and expression of proENK gene induced by PGE₂. FURA-2 studies showed that PGE₂ produced a prolonged increase in intracellular free Ca²⁺ level. In the gel shift DNA binding assays PGE₂ increased the AP-1 binding activity up to 3 hrs. Our results indicate that increases in secretion of ME and proENK gene expression induced by long-term PGE₂ in BAM cells may require the de novo synthesis of proteins. PGE₂-induced increase of Ca²⁺ through L-type calcium channels may lead to increased formation of Ca²⁺/calmodulin complex which may increase AP-1 binding activity mediating the increasing in proENK gene expression. Utilizing a nuclear run-on assay, we are currently examining the effect of PGE₂ on the rate of transcription of the proENK gene.

164.5

PERFORANT PATH DEAFFERENTATION ALTERS HIPPOCAMPAL DYNORPHIN AND ENKEPHALIN CONTENT IN RATS. L. Thai, J.S. Hong and M. Gallagher, NIEHS/NIH, RTP, NC, 27709, Curriculum in Neurobiology, Univ. of N. Carolina, Chapel Hill, NC, 27599.

The perforant path (PP) innervates dentate granule cells which contain dynorphin and enkephalin. Stimulation of this pathway has been shown to inhibit dynorphin peptide levels and mRNA expression in the hippocampus of young rats. In contrast, basal hippocampal dynorphin content and prodynorphin mRNA are increased in the aged rat brain (PNAS, **86**, 2948, 1989). We examined whether loss of PP input to dynorphin-containing cells in the dentate gyrus of young rats would mimic the effects of aging.

Radioimmunoassays (RIA) showed that a bilateral knife cut of the PP at the level of the angular bundle reliably increased dynorphin (15%) and decreased Met-enkephalin (15%) in the whole hippocampus of young adult Long-Evans rats. In a second study, the dissected dentate gyrus was assayed for high-affinity glutamate uptake (HAGU) and the CA3 region of hippocampus was assayed for dynorphin immunoreactivity. Bilateral PP lesions significantly decreased HAGU and produced a parallel increase in CA3 dynorphin content. Immunocytochemistry also revealed enhanced dynorphin immunoreactivity in the mossy fibers one month after lesioning. The effect of PP lesions on dynorphin mRNA is currently under study using *in-situ* hybridization. We conclude that removal of the PP elevates dynorphin in the hippocampus and may model the effects of aging on the regulation of this peptide.

MASS SPECTROMETRIC MEASUREMENT OF β -ENDORPHIN AND METHIONINE ENKEPHALIN IN HUMAN PITUITARIES. D.M. Desiderio, J.L. Lovelace*, J.J. Kusmierz* and C. Dass*, University of Tennessee, Memphis, Tennessee.

Two opioid neuropeptides, β -endorphin (BE) and methionine enkephalin (ME) were quantified with fast atom bombardment mass spectrometry (FAB-MS) in individual human pituitaries (post-mortem) and in tumor pituitaries (post surgery) in a study to clarify the molecular processes that occur in tumor formation. FAB-MS in the multiple reaction monitoring (MRM) mode was used to link the precursor ion (the protonated molecular ion, MH⁺) of the peptide with a fragment ion that was unique to each neuropeptide. ME was quantified as the intact pentapeptide, and BE₁₋₃₁ was quantified via its tryptic fragment BE₂₀₋₂₄ (NALIK). Two corresponding stable isotope-incorporated peptides, [¹⁵N₄-Phe]-ME and [¹⁴C₄-²²Le]-BE₁₋₃₁, human, respectively, were used as internal standards. The amount of each neuropeptide quantified in control post-mortem pituitaries (n=6) was 75.2±29.6 (s.e.m.) pmol ME mg⁻¹ protein and 132.5±22.3 (s.e.m.) pmol BE mg⁻¹ protein, and in the pituitary tumor samples (n=5), 25.0±7.6 pmol ME mg⁻¹ protein and 36.0±14.8 pmol BE mg⁻¹ protein. The difference in the BE content between the control and tumor pituitaries was significant (p<0.004), and reflected an aberrant metabolism of the POMC system in those human pituitary tumor tissues. The measurements from FAB-MS methods (MH⁺ ion monitoring and MRM mode) were compared to measurements from radioreceptor assay and RIA by analyzing the amount of endogenous ME extracted from five human post-mortem pituitary samples. ME-like receptor activity (ME-LR) was 116±27 pmol mg⁻¹ protein (s.e.m.); ME-like immunoreactivity (ME-LI) was 18.3±9.5 pmol mg⁻¹ protein; MH⁺ data were 42.9±9.5 pmol ME mg⁻¹ protein; and the MRM data were 47.7±12.7 pmol ME mg⁻¹ protein.

164.4

DEVELOPMENTAL DECREASE IN PROENKEPHALIN:Met-ENKEPHALIN RATIO IN THE RAT ADRENAL. P.M. Hudson, M.K. McMillian, D.Y. Lee, L. Thai and J.S. Hong LMIN/NIEHS/NIH RTP NC 27709. Enkephalins are co-localized with catecholamines in adrenal chromaffin cells. Although enkephalin levels are generally co-regulated with catecholamine levels, denervation results in a pronounced and increase in proenkephalin (PPE) mRNA and opiate peptide levels in rat adrenals, while catecholamine-synthesizing enzymes do not increase. The predominant opiate peptide which accumulates after denervation is proenkephalin. We have examined developmental changes in the levels of immunoreactive Met-enkephalin (ME) and proenkephalin (ME-RF). The rat adrenal becomes functionally innervated postnatally, and we hypothesized a fall in enkephalin levels and ME-RF:ME ratio would occur due to developmental increases in splanchnic nerve activity. ME content per mg protein decreased 2-fold between days 10 and 21. There was a more striking 4-fold decrease in ME-RF during the same period, as the ME-RF:ME ratio fell from 2.0 to the adult level of 1.0. Repeated nicotine injections, mimicking increased splanchnic nerve activity, produced a precocious fall in the ME-RF:ME ratio by day 10. *In situ* hybridization studies indicate that PPE mRNA levels are higher in adult than in 10 day old rat adrenal, suggesting that the higher proenkephalin levels observed in the 10 day old are associated with deficient processing to ME rather than increased opiate peptide production.

164.6

CHARACTERIZATION OF cAMP-RESPONSE ELEMENT-BINDING PROTEINS FROM NG108-15 CELLS CHRONICALLY EXPOSED TO MORPHINE AND ETHANOL. N. Miki, T. Osugi, M. Ikemoto and H. Taniura, Dept. of Pharmacology, Osaka Univ. Med. Sch., Suita, Osaka 565, Japan.

The gel retardation assay with a single stranded oligo-DNA of cAMP-response element (CRE) was employed to examine the possibility of transcriptional regulation of cAMP-inducible genes by chronic morphine or ethanol treatment of NG108-15 cells. When the nuclear extracts from the cells treated with morphine or ethanol for several days were provided for the assay, the amounts of DNA-protein complex were decreased about 30-40% of the control and recovered by 1-2 days after morphine withdrawal. Naloxone prevented the reduction of the DNA-protein complex by morphine. One hour treatment did not change the amount of the DNA-protein complex. The nuclear factors that specifically bind to a single stranded CRE and change the binding ability to CRE by morphine or ethanol treatment are being partially purified and characterized. Morphine and ethanol may modulate the expression of cAMP-inducible genes through which tolerance and dependence may develop.

164.8

PRO-OPIOMELANOCORTIN-DERIVED PEPTIDES AND FEEDING BEHAVIOR OF DUNGENESS CRABS. C.W. Wilkinson, E.A. Colasurdo*, S.A. Galt*, and D.D. Jorgensen*, GRECC, VA Med. Ctr., Tacoma, WA 98493; Biology Dept., Univ. of Puget Sound, Tacoma, WA 98416; and Dept. of Psychiatry and Behav. Sci., Univ. of Washington, Seattle, WA 98195.

Microinjections of peptides derived from pro-opiomelanocortin (POMC) affect feeding behavior in mammals, and opiate receptor agonists and antagonists alter food intake in several classes of invertebrates. However, it is not known whether a POMC-like precursor is prevalent in invertebrate nervous systems, whether POMC-derived peptides play physiological roles in the regulation of food intake, or whether any such actions are evolutionarily conserved. We used gel chromatography, high pressure liquid chromatography (HPLC), and radioimmunoassays to determine if peptides similar in size and immunoreactivity to mammalian POMC-derived peptides exist in the nervous system of the Dungeness crab (*Cancer magister*). We also determined whether concentrations and molecular forms of these peptides were altered by the feeding state of the crab. Immunoreactive forms of endorphins, α -MSH, and ACTH were found in extracts of the nervous system of the Dungeness crab. Some of these peptides co-eluted with mammalian forms, and some were apparently novel forms. The relative proportions of immunoreactive peptides in extracts from food-deprived and satiated crabs differed markedly. In general, ACTH- and MSH-like forms were decreased and endorphin-like forms were increased by food deprivation.

164.9

CHARACTERIZATION OF POMC-DERIVED PEPTIDES IN RAT HEART. V.R. Evans¹, L.J. Forman² and W.R. Millington¹. ¹Sch. of Basic Life Sciences, Univ. Missouri-Kansas City, Kansas City, MO 64108. ²Univ. Medicine and Dentistry of NJ-SOM, Camden, NJ 08103.

Pro-opiomelanocortin (POMC) is post-translationally processed to several bioactive peptides, including β -endorphin (β -END), β -lipotropin (β -LPH), α -MSH and ACTH, not only in the brain and pituitary, but in a variety of peripheral tissues as well. Previous studies have localized β -END as well as other opioid peptides, in rat heart, which is consistent with the known effects of opiates on cardiac function. In the present study, we identified the individual molecular forms of β -END in rat heart extracts and further demonstrated that other POMC-derived peptides, ACTH and α -MSH, are also present. Gel filtration analysis revealed that β -LPH and ACTH were almost entirely cleaved to β -END and α -MSH; ratios of β -END: β -LPH and α -MSH:ACTH were 4.6:1 and 6.1:1, respectively. Further analysis of β -END sized peptides by ion exchange HPLC revealed that β -END-1-31 was the predominant form, constituting 49.6% of total immunoreactivity. N-acetylated (N-Ac) and/or C-terminally shortened forms, including N-Ac- β -END-1-31 (15.1%), N-Ac- β -END-1-27 (8.4%), N-Ac- β -END-1-26 (4.7%), β -END-1-27 (14.3%) and β -END-1-26 (7.9%), were also present, albeit in smaller proportional amounts. These results confirm the presence of β -END in rat heart and further show that other POMC-derived peptides are also expressed. β -END undergoes extensive post-translational processing to non-opioid forms in the heart although opioid active β -END-1-31 is the predominant form.

164.11

EFFECTS OF CHRONIC NALTREXONE TREATMENT ON β -ENDORPHIN PEPTIDE LEVELS AND POMC mRNA IN RAT CNS. D.M. Bronstein, N.C. Day, H.B. Gutstein, K.A. Trujillo and H. Akil. Mental Health Research Institute, University of Michigan, Ann Arbor, MI 48109.

An understanding of how the endogenous opioid peptide β -endorphin (β E) is regulated is critical for determining its functional significance. For example, we recently found that chronic morphine pelleting caused brain region-specific and time-dependent changes in β E-ir peptides and in mRNA levels coding for its precursor protein pro-opiomelanocortin (POMC) (Bronstein et al., *Brain Res.* 519:102, 1990), suggesting a possible involvement of β E in the expression of opiate tolerance and/or dependence. In the present studies, we investigated the effects of chronic opiate antagonist treatment on different parameters of β E biosynthesis in discrete regions of the CNS. Following 8 days of pelleting with either 10 or 30 mg naltrexone pellets, concentrations of total β E-ir decreased by 20-50% in the arcuate nucleus, thalamus, hypothalamus, midbrain, and septum compared to placebo animals. At the same time, the ratio of full length β E (β E₁₋₃₁) to more processed β E-ir forms (e.g., β E₁₋₂₇, β E₁₋₂₆) increased in a dose-dependent manner. In caudal POMC systems (i.e., the NTS and spinal cord), β E-ir peptide levels did not change. POMC mRNA levels in the arcuate nucleus were elevated in naltrexone-treated animals compared to placebo controls. These data have been interpreted as evidence of up-regulation of the rostral POMC system-- peptide levels decrease as a result of increased release and mRNA levels increase due to a compensatory induction of POMC biosynthesis. The finding that naltrexone altered the relative amounts of opioid-active (i.e., β E₁₋₃₁) and opioid-antagonistic (i.e., β E₁₋₂₇) peptides suggests another way in which POMC neurons can regulate the signal transmitted across a synapse. (Supported by NIDA DA02265.)

ALTERED PITUITARY PRO-ACTH/ENDORPHIN EXPRESSION IN HYPERACTIVE AND HYPERTENSIVE RATS. K.M. Braas, E.D. Hendley, G.S. Wand*, and V. May. Departments of Anatomy and Neurobiology and Physiology and Biophysics, University of Vermont College of Medicine, Burlington, VT 05405, and Endocrine Division, The Johns Hopkins School of Medicine, Baltimore, MD 21205.

The hypothalamic-pituitary-adrenal axis, including altered pro-ACTH/endorphin (PAE) expression, has been implicated as one of the processes initiating and sustaining the hypertensive process. PAE expression is altered in pituitary gland from spontaneously hypertensive rats (SHR) compared with normotensive Wistar Kyoto (WKY) animals. To determine whether altered PAE expression is associated with the hypertensive or hyperactive trait of the SHR, we examined the WKHT strain, which is hypertensive but not hyperactive, and the WKHA strain, which is hyperactive but normotensive. Neurointermediate pituitary lobe β -endorphin and α -MSH levels were elevated 150 to 200% in the SHR and WKHA strains compared with WKY, but not in the WKHT strain, suggesting a specific association with hyperactivity (WKY α -MSH = 890 pmol/lobe; SHR and WKHA significantly different than WKY by ANOVA, Newman-Keuls, $p < 0.05$). In contrast, anterior pituitary lobe β -endorphin and ACTH content was decreased 30-50% in the SHR and WKHT strains (WKY ACTH = 320 pmol/lobe; $p < 0.05$), suggesting an association with the hypertensive trait. Morphological studies will help define the cellular basis for these tissue-specific alterations in PAE expression associated with the hypertensive and hyperactivity traits. Supported by PHS F07RR05429, NS26390, and NSF9010044.

PROOPIOMELANOCORTIN (POMC) PROCESSING AND CELLULAR ORIGINS IN RAT SPINAL CORD HB. Gutstein, DM Bronstein, and H Akil. Dept. of Anes. and MHRI, U. of Mich., Ann Arbor, MI

While enkephalin and dynorphin peptides have been well characterized in the spinal cord, the anatomic localization of β -endorphin (β E) and the processing of POMC to β E and other non-opioid peptides in the cord has not been extensively investigated. This study characterizes POMC processing in the spinal cord and suggests the presence of an intrinsic POMC/endorphinergic neuronal system in the spinal cord.

Eight rats were sacrificed, and spinal cords sectioned and frozen on dry ice. β E, N-acetyl β E, ACTH, and α -MSH IR was determined by RIA. To look for intrinsic POMC cells, eight rats anesthetized with chloral hydrate underwent complete excision of the spinal cord at two upper thoracic segments. Three days after surgery, the animals were sacrificed, lesions were verified in situ, and the cords were immediately dissected and frozen on dry ice. β E IR was determined above and below the level of the lesions by RIA. Control and sham-operated groups were also studied.

Our data show that the proportion of acetylated β E appears to increase caudally, while the degree of processing appears greater in the cervical cord than in other areas. After spinal cord lesioning, we found persistence of about 1/3 of the total β E IR below the level of the lesions. Molecular sieving of this β E IR revealed high relative proportions of POMC and β -LPH to β E. The β E peak consisted almost exclusively of the highly opioid active β E 1-31 form. Preliminary studies also show persistence of a somewhat higher proportion of ACTH-IR (1/2-2/3 of control levels) below the level of the lesion. Our data suggest that the spinal cord has a different POMC processing pattern from that observed in other areas of the CNS. As one progresses caudally, the degree of processing appears to decrease while the proportion of acetylation appears to increase. This complex pattern may result from a combination of two sources of POMC in the cord - caudal projections of NTS POMC cells, and, as our data suggest, intrinsic POMC cells in the spinal cord. Additional studies will be necessary to further define this intrinsic system and its possible physiologic functions.

METHYLAZOXYMETHANOL (MAM) INHIBITS PRO-OPIOMELANOCORTIN (POMC) TRANSCRIPTION AND SECRETION OF POMC-DERIVED PEPTIDES IN AIT-20 CELLS. R. G. Allen, J. Parker* and P. S. Spencer. Center for Research on Occupational and Environmental Toxicology, and Departments of Biochemistry and Molecular Biology, and Neurology, Oregon Health Sciences University, Portland, OR 97201.

MAM, the aglycone of cycasin, is a potent cytotoxin with neurotoxic potential. By alkylating DNA, RNA, and protein, MAM is potentially able to interfere with a variety of cell functions. Vulnerable sites were studied in pituitary-derived AIT-20 neuroendocrine cell lines treated with increasing concentrations of MAM-acetate (0-500nM) for 48 hr. Treated cells were harvested and POMC mRNA quantitated by Northern analysis followed by densitometry. In parallel experiments, secretion of β -endorphin, a POMC-derived opioid peptide, was quantitated by radioimmunoassay. MAM (100-250 nM) inhibited basal POMC transcription (in a concentration-dependent manner) to 20% of control values. β -Endorphin secretion was reduced to 50% in the same time period, at the same concentration of MAM. Preliminary studies indicate these effects are reversible. We conclude that MAM is a potent inhibitor of actively transcribed genes and also interferes with secretion of peptide hormones. Studies are in progress to understand the mechanisms of these effects. Other studies will determine whether MAM alters post-translational processing of POMC-derived peptides and interferes with regulation of POMC gene expression by glucocorticoids, neurotransmitters and G-protein coupled processes. [Supported by NS 19611]

CREATION OF TRANSGENIC MICE TO STUDY REGULATION OF THE PRODYNORPHIN PROMOTER. S.L. Sanders*¹, C.L. Christensen*¹, J. Douglass*², D.P. Wolf*¹, and M.H. Melner¹. Div. of Neuroscience and Reproductive Biology 1, Oregon Regional Primate Research Center, Beaverton, OR 97006, and Vollum Institute², Portland, OR 97201.

Dynorphin has important regulatory effects in the CNS and reproductive system; however, little is known about the mechanisms which regulate its expression. The goals of this study were to create transgenic mouse lines expressing the reporter gene chloramphenicol acetyltransferase (CAT) under control of the rat prodynorphin (DYN) promoter, and to examine regulation of this promoter *in vivo*. Pronuclear stage embryos of B6D2 mice were injected with a DYN-CAT gene construct containing 1.7 kb of 5' flanking sequence and 151 bp of exon 1 (-1700 to +151). Of the resulting pups (100), 31% were identified as founder lines by incorporation of the DYN-CAT gene as analyzed by PCR. Initial screening of 4 of these lines for expression of the CAT enzyme indicated one positive line. Thin-layer chromatographic analysis of a CAT assay performed on tissue extracts of this DYN-CAT founder mouse showed high levels of CAT activity in the placenta, and to a lesser extent, in the uterus and cerebral cortex. CAT activity was undetectable in other tissues, although this may be due to the expression level being below the sensitivity of the assay. An unexpected finding in this analysis was the relatively high expression in the placenta and the uterus. Northern blot analysis of normal mice and rats for prodynorphin mRNA did not indicate high levels of expression in these tissues. This may indicate aberrant expression in this line or integration near a placental-specific element. However, this line could have appropriate expression in the brain as indicated by expression in the cortical region. Screening of the remaining mouse lines for expression of the CAT enzyme is continuing in order to identify other lines for comparison and verification of the results. With the relatively large number of founder mice, there is a high probability that additional expressing lines will be identified. Further studies are also being carried out to determine regional localization of expression in the brain. Supported in part by NIH DK41035, RR00163-30, and T32 HD07133.

IMMUNOCYTOCHEMICAL CHARACTERIZATION OF PROTEIN KINASE C- β AND C-FOS IN DIFFERENTIATED AND UNDIFFERENTIATED SH-SY5Y CELLS. M. M. Garcia and R. E. Harlan. Dept. of Anatomy, Tulane Univ. School of Med., New Orleans, LA 70112.

Of neural crest origin, the SH-SY5Y neuroblastoma cell line can be induced to differentiate by retinoic acid (RA) into a cholinergic phenotype and by phorbol ester (TPA) into an adrenergic phenotype. These cells also express the μ opiate receptor, with receptor density increased by RA and decreased by PMA. Activation of this receptor has been reported to increase c-Fos in the CNS, by an intracellular mechanism which is unclear. As the c-fos promoter has a TPA response element, we studied differentiation-induced changes in PKC and c-Fos in SH-SY5Y cells with immunocytochemistry.

Compared to undifferentiated controls, both RA- and PMA-treated cells show increased levels of PKC β I and β II immunoreactivity (IR). Both treatments also increase basal levels of c-Fos IR. Cells treated with the PKC inhibitor staurosporine (ST) show an altered phenotype vs. both RA and PMA, along with decreased PKC β I IR and markedly decreased c-Fos IR. Cells treated with chronic morphine (MOR) or with the PKC inhibitor H-7 show similar phenotypic changes and PKC IR, but the MOR treated cells show increased c-Fos IR and the H-7 treated cells show a decrease. In response to acute MOR, the RA treated cells showed decreased c-Fos IR, while the PMA treated cells showed an increase. The ST and H-7 treated cells showed no change in c-Fos IR in response to MOR. RA + ST or H-7 did not block the MOR induced decrease in c-Fos IR, while treatment with PMA+ST or H-7 prevented the MOR-induced rise in c-Fos IR. We conclude that the regulation of c-Fos by MOR is cell specific and may be mediated by both PKC-dependent and independent pathways. (Supported by NS-24148, DA-06194 [REH], DA-05411, IN-133), and the PMA Foundation [MMG].)

DETECTION OF NEUROPEPTIDE Y (NPY) IN VERTEBRATES AND INVERTEBRATES BY USING THE POLYMERASE CHAIN REACTION (PCR). A. G. Blomqvist and D. Larhammar. Dept. of Medical Genetics, Uppsala University, S-751 23 Uppsala, Sweden.

The NPY family consists of several 36-amino-acid peptides including also peptide YY (PYY) and pancreatic polypeptide (PP) as well as the fish pancreatic peptide PY. NPY in higher vertebrates is involved in a number of functions such as food intake, sexual behaviour, and cardiovascular mechanisms. In order to investigate NPY's functions in an evolutionary perspective, we are in the process of deducing the NPY sequences of a number of vertebrate and invertebrate species. Through DNA cloning, we have already shown that NPY is present and extremely well conserved in several vertebrates (see Evolution of the Neuropeptide Y family of Peptides. In "Neuropeptide Y and Related Peptides", Contemporary Neuroscience Series, Ed.: C. Wahlestedt and W.F. Colmers, Humana Press, in press). We are now extending these studies by using the polymerase chain reaction (PCR).

Two degenerate oligonucleotides have been constructed based on known NPY and PY nucleotide and peptide sequences from several species of fish and lamprey (see abstract by C. Söderberg et al.). Total genomic DNA and cDNA libraries were used as DNA templates. PCR gave a product of expected size, 121 bp, in cayman, salmon, anglerfish, and hagfish. The obtained products will be sequenced to confirm their identities and for evolutionary comparisons. Preliminary results show products of similar size also in different groups of invertebrates.

PEPTIDES: BIOSYNTHESIS, METABOLISM AND BIOCHEMICAL CHARACTERIZATION II

IN SITU HYBRIDIZATION USING OLIGONUCLEOTIDE PROBES SPECIFIC FOR THE BETA AND GAMMA FORMS OF PREPROTACHYKININ mRNA. J.E. Marchand, C.S. Connelly, and R.M. Kream. Anesth. Res. Lab., Tufts University School of Medicine, Boston, MA 02111.

The primary transcript of the gene, PPT 1, which codes for substance P and related tachykinins, is alternatively spliced to yield three different mRNA species, alpha, beta, and gamma, which differ in their protein coding regions. In the rat CNS, beta and gamma are the predominant forms of PPT 1 mRNA, as determined by solution hybridization analyses. We have developed oligonucleotide probes which are complementary to and which bind specifically to the beta and gamma PPT mRNA. The beta probe is a 36 mer complementary to bases 224-259 of the rat beta PPT mRNA, corresponding to the major portion of exon 4. The gamma probe is a 30 mer complementary to bases 205-220 and 266-279 of the beta mRNA which spans the splice site comprising contiguous regions of exon 3 and exon 5. The specificity of the hybridization analysis was determined by using selective absorptions with several non-radioactive oligonucleotides. In general, in situ hybridization patterns using the gamma probe yielded patterns of labeling consistent with previous studies. Consistent with solution hybridization analyses, in situ labeling using the beta probe was markedly lower in intensity than gamma labeling. Neuronal labeling patterns suggest coexpression of both forms of PPT 1 mRNA in all regions of the CNS examined.

TWO NPY-LIKE PEPTIDES IN THE RIVER LAMPREY MAY CORRESPOND TO NPY AND PYY. C. Söderberg*, J. Dahlstrand*#, L. Brodin*#, G. Andersson, and D. Larhammar. Department of Medical Genetics, Uppsala University, Box 589, S-751 23 Uppsala, Sweden #) Department of Neurophysiology, Karolinska Institute, Stockholm, Sweden.

Neuropeptide Y (NPY) is an abundant and widely distributed neuropeptide in the CNS and PNS of all mammals investigated. NPY increases blood pressure and food intake and influences several other physiological parameters. NPY is a member of a peptide family which also includes the gut peptide PYY, pancreatic polypeptide (PP), and the fish pancreatic peptide PY.

We have previously isolated DNA clones encoding NPY from rat, chicken, goldfish, ray, and shark. Sequence comparisons show that NPY is one of the most highly conserved neuroendocrine peptides known (see Larhammar, Söderberg and Blomqvist, in "Neuropeptide Y and Related Peptides", Humana Press, in press).

By low-stringency hybridization with a shark NPY probe we have now isolated two cDNA clones with distinct NPY-like sequences from a library made from river lamprey (*Lampetra fluviatilis*) brain mRNA. Studies are in progress to see whether the expression patterns of these two NPY-like peptides correlate with the two previously identified cell populations in lamprey brain stem and spinal cord which exhibit distinct NPY-like immunoreactivities (L. Brodin et al., J. Neurosci 9, 3428-3442, 1989). The complete sequences of the lamprey peptide precursors and their genes may clarify their relationships to mammalian NPY and PYY.

EFFECTS OF HERPES SIMPLEX VIRUS (HSV) INFECTION ON THE NEUROPEPTIDES CALCITONIN GENE-RELATED PEPTIDE (CGRP) AND GALANIN (GAL) IN MOUSE DORSAL ROOT GANGLIA (DRG). D.B. Henken & J.R. Martin, NIH, NINDS, Lab. of Exp. Neuropathology, Bethesda, MD, USA, 20892.

HSV is neurotropic and shows a preference for infecting and establishing latency in neurons of sensory ganglia. In a time course study, we examine how HSV-2 infection affects host neuropeptide expression in mouse DRG. The right hind footpads of anesthetized female BALB/c mice were inoculated with 10 μ l of MS strain HSV-2 (9.3×10^6 pfu/ml). Five, 14, 21 or 28 days later, groups (n=4) of infected and sham-inoculated mice were perfusion-fixed. Spinal columns were decalcified and adjacent paraffin sections were immunoreacted to detect HSV, CGRP or GAL antigen. Somal areas for all labelled and unlabelled neurons in the infected and the contralateral uninfected DRG in each mouse were compared. HSV-positive neurons were small. HSV antigen was present in neurons at D 5, by D 14 the antigen had disappeared. GAL positivity was not seen until D 14, remained high at D 21 and was decreasing by D 28. The mean soma size of the labelled population was small to medium. GAL antigen was not seen in DRG at any interval following sham inoculation. At all times after infection, equal numbers of CGRP-positive neurons were seen in infected and uninfected ganglia and in sham-operated mice. These results suggest that HSV-2 infection differentially affects host neuropeptide production.

EFFECTS OF CAPSAICIN AND RESINIFERATOXIN ON PEPTIDERGIC NEURONS IN CULTURED DORSAL ROOT GANGLION. E. Liu, S. K. Jettiniia, L. Urban and S. Jettiniia. Department of Veterinary Anatomy and Neuroscience Program, Iowa State University, Ames, IA 50011, USA. Sandoz Institute for Medical Research, Gower Place, London WC1E 6BN, UK

The neurotoxic effect of capsaicin has been shown to be selective on a subpopulation of C-type dorsal root ganglion neurons in newborn animals. The aim of this study was to provide evidence of the effect of capsaicin and its ultrapotent analog RTX on sensory peptidergic neurons maintained in organotypic cultures. Effects of two irritants were examined on neurons that contain substance P (SP) and calcitonin gene-related peptide (CGRP). Exposure of the cultures to 10 μ M capsaicin and 10nM RTX for period of 2 days or longer resulted in complete elimination of SP-immunoreactive (IR) neurites and reduction, but not elimination, of CGRP-IR neurites. In addition, both 10 μ M capsaicin and 10nM RTX significantly reduced the number of SP- and CGRP-IR cell bodies within DRG explants. Capsaicin in 100 μ M and RTX in 100nM concentration produced complete elimination of SP-IR fibers, greater decrease of number of CGRP-IR fibers but failed to completely eliminate IR cell bodies. Exposure of the cultures to irritants for 90 min did not produce a noticeable effect on SP- or CGRP-IR neurons. It is important to establish that the effect of capsaicin and RTX on cultured neurons is of long duration (longer than 4 days) and is therefore different from depletion of peptides.

These findings demonstrate that SP-IR processes of cultured sensory neurons are much more sensitive to irritants than cell bodies. Furthermore, our results show that SP-IR neuronal elements are more sensitive to capsaicin than CGRP-IR elements. These data suggest that relatively early in development cultured sensory neurons express functional properties of differentiated pain sensory neurons. Work was supported by NIH grant NS27751 and USDA grant PL95-113.

THYROTROPIN-RELEASING HORMONE (TRH) mRNA IS INCREASED IN SPECIFIC LIMBIC SUBREGIONS FOLLOWING ONE, TWO, OR THREE ELECTROCONVULSIVE SEIZURES (ECS). S.M. Knoblach, S.R. Keim and M.J. Kubek. Depts. of Anatomy, Psychiatry and Program in Medical Neurobiology, Indiana Univ. & VA Med. Ctrs., Indianapolis, IN 46202.

Prepro-TRH mRNA is significantly increased in specific limbic regions after 3 ECS. We examined whether TRH mRNA may increase after only 1 ECS and if further augmentations are produced by multiple treatments. Rats received either 1, 2 or 3 ECS or sham ECS. Six hours after the last treatment brains were removed and sectioned. A 35S-CTP labelled 548bp riboprobe transcribed from a prepro-TRH cDNA was incubated with brain sections for 20 Hrs at 60°C. X-ray film was evaluated via computer image analysis. Average grey values were increased in the hippocampal dentate gyrus (ventral 53+/-3, dorsal 43+/-6), amygdala (26+/-4), and pyriform (41+/-3) and entorhinal (26+/-6) cortices (each region vs. corresponding sham, $p < 0.05$) after 1 ECS. TRH mRNA was undetectable in these same regions in sham controls. In the ventral hippocampus, an additional increase in TRH mRNA occurred from 1 to 2 seizures (2x ECS 81+/-5, $p < 0.05$). The third ECS resulted in no further elevation. In conclusion, a single generalized seizure is sufficient to augment TRH mRNA in limbic regions where we have previously observed increases in TRH. Certain areas respond progressively to additional seizures. Supported by NS25661 & VA.

DIFFERENTIAL EFFECTS OF CLOZAPINE AND HALOPERIDOL ON STRIATAL NEUROTENSIN SYSTEMS IN RATS. S.P. Gygi*, L.G. Bush*, J.W. Gibb and G.R. Hanson. Dept. Pharmacol. and Toxicol., Univ. of Utah, Salt Lake City, UT 84112.

Clozapine (CLOZ) and Haloperidol (HAL) are anti-psychotic drugs with unique therapeutical features. CLOZ is an atypical neuroleptic whereas HAL is a typical neuroleptic. We compared the effects of HAL and CLOZ on striatal neurotensin (NT) systems because they are selectively mediated by dopamine (DA) receptors. HAL and CLOZ were given alone and in combination with methamphetamine (METH), and the NT responses were assessed. In whole caudate HAL, CLOZ, and METH alone caused 278, 340, and 260% increases, respectively. HAL and METH in combination interacted synergistically to increase NT levels ten-fold. In contrast, CLOZ and METH in combination caused increases in NT like CLOZ or METH alone (307%). In preliminary experiments, there were substantial differences in NT responses to these drugs alone and in combination when comparing medial-lateral and rostral-caudal segments of the caudate nucleus. These data suggest that NT systems respond differentially to HAL and CLOZ which may account for some of clozapine's unique clinical properties. (Supported by USPHS grants DA 00869 and DA 04222).

165.4

THE EFFECTS OF ELECTRICAL FIELD STIMULATION AND INFLAMMATORY SUBSTANCES ON THE RELEASE OF CGRP FROM THE RAT TRACHEA. X.-Y. Hua and T.L. Yaksh. Department of Anesthesiology, University of California, San Diego, La Jolla, CA 92093-0818 U.S.A.

Calcitonin gene-related peptides (CGRP) exists in the peripheral terminals of sensory C-fibers in the trachea. The present study is to investigate the effect of electrical field stimulation (EFS) and some inflammatory mediators e.g. bradykinin, serotonin and histamine, which are known to activate or sensitize a population of primary afferents, on the release of CGRP. The rat trachea (below larynx to carina) was dissected and perfused intraluminally with Krebs buffer (0.2ml/min). After lyophilization, the perfusates were subjected to RIA for determining CGRP. Under baseline condition, a resting release of CGRP was observed: 14 \pm 4 fmol/fraction. EFS (0.2 to 20Hz, 10V, 1ms, 10min) caused a frequency-dependent increase of CGRP release, e.g. 0.2Hz: 64 \pm 19; 5Hz: 175 \pm 36; 20Hz: 450 \pm 158 fmol/fraction. High frequency (20Hz) EFS desensitized the release evoked by a second stimulation. Bradykinin (10 $^{-6}$ to 10 $^{-4}$ M) induced a clear-cut release of CGRP in a concentration-dependent manner, while histamine or serotonin did not cause any release of the peptide. Serotonin 10 $^{-6}$ M significantly enhanced CGRP efflux evoked by capsaicin 10 $^{-6}$ M. In summary, CGRP in the rat trachea can be released upon EFS. The terminals from which the depolarization evoked release of CGRP occurs, is subject to local influence by agents known to excite or facilitate C-fiber activity. (This work is supported by Tobacco Related Disease Program, University of California.)

FORSKOLIN AND PHORBOL ESTER INDUCTION OF NEUROPEPTIDE Y (NPY) PRODUCTION BY AGGREGATING FETAL BRAIN CELLS IN CULTURE: A PROCESS REQUIRING INFLUX OF EXTRACELLULAR CALCIUM. Paolo Magni* and Ayalla Barnea. Depts. OB-GYN & Physiology, UT Southwestern, Dallas, TX 75235

NPY is one of the most abundant peptides in the brain. We addressed the question: Does activation of the cAMP or protein kinase C (PKC) pathway induce production of NPY and is there cross-talk between the two pathways? Aggregate cultures, formed from dissociated cells obtained from the hypothalamus-olfactory tubercle area of 17-day-old fetuses, were cultured in serum-free medium for 12 days. A 24 h exposure to forskolin (F; 10 μ M) or phorbol 12-myristate 13-acetate (PMA; 20 nM) resulted in a 2-3-fold increase in the total NPY content (aggregate + medium) and exposure to both F + PMA resulted in an additive response. Inhibition of protein synthesis by cycloheximide (75 μ M) dramatically reduced NPY content of the controls and prevented F and PMA stimulation of NPY accumulation. A 24-h inhibition of RNA synthesis by actinomycin D (5 μ g/ml) did not alter the NPY content of control cultures but it totally abolished F/PMA induced accumulation of NPY; however, a shorter period of inhibition of RNA synthesis (12 h) did not affect F/PMA induction of NPY accumulation. Moreover, inhibition of influx of extracellular calcium by verapamil (100 μ M) did not alter NPY content of control cultures but it drastically inhibited F and PMA action (by 100 and \approx 60%, respectively). These results indicate that: i) NPY is synthesized by the cultured aggregates; ii) NPY-mRNA has a relatively long half-life; iii) F and PMA both induce synthesis of NPY by acting at a transcriptional and post-transcriptional level; iv) there is no evidence for cross-talk between the cAMP and PKC pathways and v) influx of extracellular Ca $^{+2}$ is required for F/PMA induction of NPY synthesis.

TTX-BLOCKADE OF THE NEURONAL ACTIVITY CAUSES TEMPORAL INCREASE OF GALANIN EXPRESSION IN CHOLINERGIC NEURONS.

D.V. Agoston¹, S. Komoly², A. Rókeaus³, R.D. Fields¹ and M. Palkovits⁴. LDN, NICHD,NIH¹; LBNP, NINDS,NIH²; Karolinska Institutet, Stockholm, Sweden³ and LCB, NIMH, NIH⁴, Bethesda, MD 20892.

Neuronal activity regulates the establishment as well as maintenance of neurotransmitter phenotype including galanin (GAL) (J. Neurosci. Res. 28:140, 1991; Science, 236:1268, 1987; Endocrinology, 127: 3096, 1990). Galanin co-exists with choline acetyltransferase (ChAT) in the septum-basal forebrain (Brain Res. 360: 130, 1985). The goal of our studies was to test the involvement of neuronal activity in the altered GAL expression of the basal cholinergic system originally observed following axotomy (P.N.A.S. 87: 7742, 1990). Transection of the diagonal band resulted in a transient (max. at 4th p.o. day) accumulation of GAL IR in numerous neuronal perikarya in the nucleus of the diagonal band. In a second series of experiments, neuronal activity was blocked by injecting tetrodotoxin (TTX) into the vertical limb of the nucleus of the diagonal band. Control animals received identical volume (0.1 μ l) injections of the vehicle solution, while a third group received intrathecal colchicine. In some experiments, TTX was co-injected with the retrograde tracer, cholera-toxin β -subunit, to assess the adequate locations of injections. Animals were sacrificed at different intervals between 1 and 14 day post-injections and processed for GAL and ChAT immunohistochemistry, in situ hybridization, radioimmunoassay and enzyme activity. TTX-induced blockade of neuronal activity dramatically increased GAL expression in neurons of nucleus of tractus diagonalis, whereas no change was observed in ChAT immunohistochemistry up to 14 day. This increase in GAL expression was first seen at day 1 post-injection and found to be maximal at day 4 post-injection followed by a complete return to control levels by day 7. Unilateral injection caused ipsilateral changes, whereas bilateral injection induced bilateral increases in GAL expression. These changes mimicked the effect of the transection of the diagonal band. We conclude that, perturbation of the neuronal activity alone can lead to temporal up-regulation of GAL expression in the basal forebrain cholinergic system.

VASOPRESSIN AND 7B2 ARE ABSENT BUT SPONTANEOUSLY REAPPEAR IN POST-MITOTIC SOLITARY HYPOTHALAMIC NEURONS OF THE HOMOZYGOUS BRATTLEBORO RAT F.W. Van Leeuwen, B.A.Th.F. Gabreëls and N.G. Seidah*, Neth. Inst. for Brain Res., Amsterdam, The Netherlands, and *Clin. Res. Inst. of Montreal, Canada.

The homozygous Brattleboro rat (di/di) synthesizes a vasopressin (VP) precursor with a different C-terminus, of which the passage from the endoplasmic reticulum (ER) towards the Golgi apparatus and further to neurosecretory granules is impaired. In addition, the phenotypic expression of coexisting peptides is disturbed (angiotensin II (Ang II), F8F amide (F8Fa) and secretory protein 7B2) or not affected (dynorphin, NPY and galanin).

During postnatal life a small but increasing number of solitary hypothalamic VP neurons of the di/di rat undergoes a switch to a genuine heterozygous phenotype. They also express Ang II. We report here on the reappearance of 7B2 in these heterozygous cells, indicating that also for 7B2 expression a normal VP precursor is required. The impaired passage of VP precursor in di/di rat VP cells may also disturb that of 7B2 transport. In heterozygous cells VP and 7B2 passage may be partly recovered. It is proposed that within the ER a compartmentalization of precursor synthesis takes place, i.e. within VP cells some precursors (VP, Ang II, F8Fa and 7B2) may be synthesized at different sites of the ER than others (dynorphin, NPY and galanin). Thus the ER may also be one of the sites where the specific contents of a secretory granule, which may change under different physiological conditions, can be regulated.

Vasopressin mRNA and Neurophysin-Related Cell-Surface Antigen (NRSA) of Small-Cell Carcinoma (SCCL). William G. North and XiaoMing Yu*, Department of Physiology, Dartmouth Medical School, Hanover, NH 03756.

We have previously shown immunoreactive vasopressin and neurophysin are produced by SCCL, and that some neurophysin-related protein become associated with the cell membrane as NRSA. We now report on the expression of an abnormal vasopressin mRNA by a long-term culture of SCCL, by a tumor removed from a patient at biopsy, and by small-cell tumors raised in athymic mice. This mRNA is 900 bases in size (human vasopressin mRNA of neurons is 750 bases) and hybridizes with cDNA probes representing the exon A and exon B regions of the vasopressin gene, but fails to hybridize with cDNA probes representing the exon C region of the gene.

Protein extracts of SCCL were subjected to SDS-electrophoresis followed by Western blot analysis using mouse monoclonal and rabbit polyclonal antibodies to vasopressin-associated human neurophysin. This evaluation revealed the presence of two immunoreactive proteins with molecular weights of 30,000 daltons and 20,000 daltons in extracts from all three SCCL sources. Both of these proteins appear to be glycosylated and both are present in the cell membrane fraction of tumor cells. Our data therefore demonstrate that NRSA of small-cell tumors is translated by an abnormal vasopressin mRNA and most probably comprises two neurophysin-related proteins of 30,000 daltons and 20,000 daltons.

DIETARY SODIUM DEPLETION DECREASES THE LEVEL OF THE OXYTOCIN mRNA IN THE PARAVENTRICULAR AND SUPRAOPTIC NUCLEI OF THE RAT BRAIN. F. Riftinga, R. Sakai, B.S. McEwen, Lab. of Neuroendocrinology, The Rockefeller University, New York, NY 10021.

The present study examined the role of oxytocin in arousal of salt appetite in the rat by dietary sodium depletion. The level of oxytocin mRNA in the PVN and SON was determined by quantitative *in situ* hybridization with ¹²⁵I-labeled oligonucleotide probe. Male Sprague-Dawley rats were injected with diuretic furosemide and placed on a sodium deficient diet for 3 days. Control rats received injections of 0.9% NaCl and were maintained on a regular diet. Water intake was recorded daily in both groups. On the fourth day the brains were removed and immediately placed on dry ice for detection of oxytocin mRNA. Trunk blood was collected for a determination of serum sodium concentration and osmolality. Rats maintained on sodium restricted diet consumed on average 10 ml less water than control animals and appeared to be hyperosmotic. Serum sodium concentration remained within normal range. The level of the oxytocin mRNA in the magnocellular neurons of the PVN and SON decreased by 25%. The *in situ* hybridization data indicate that inhibition of oxytocin biosynthesis occurs during dietary sodium depletion and may contribute to the expression of salt appetite in rat. (NIMH grant MH43787).

165.10

VASOPRESSIN CONTENT AND MESSAGE EXPRESSION IN DISCRETE AREAS OF THE RAT HYPOTHALAMUS FOLLOWING REMOVAL OF THE NEUROINTERMEDIATE PITUITARY LOBE. C. A. Johnson, C. D. Refsdal¹, J. B. Gelineau-van Waas² and D. M. Dorsa¹. School of Pharmacy, Univ. of Montana, Missoula, MT 59812-1075 and ¹GRECC, VA Med. Ctr., Seattle, WA 98108.

The influence of the neurointermediate pituitary (NIL) on anterior pituitary hormone secretion is well documented. Our laboratory has demonstrated that surgical removal of the NIL (NIL-X) differentially affects arginine vasopressin (AVP) and oxytocin (OXY) neurons in the rat brain (Neurosci. Lett. 120: 256, 1990). Central AVP neurons play an important role in the neuroendocrine regulation of a variety of anterior pituitary hormones whose secretion is affected by NIL-X, raising the possibility that some of the NIL-X induced hormonal changes may result from alterations in the synthesis and release of central neuropeptides. The present study evaluated AVP concentrations and mRNA levels in discrete areas of the male rat brain 13 days following NIL-X or visualization (SHAM) of the NIL. Following decapitation, brains were either frozen at -80 C until analyzed by *in situ* hybridization for AVP mRNA or were sliced and processed by micropunch analysis and radioimmunoassay for AVP content. The data demonstrate that removal of the NIL results in a decreased expression of AVP message and content in discrete areas of the brain containing AVP cell bodies at a time when AVP concentrations in the hypophyseal portal blood and daily water intake have normalized. This work was supported by MH48228 (CAJ) and NS 20311 (DMD).

MEASUREMENT OF OXYTOCIN AND OXYTOCIN MESSENGER RNA IN A SINGLE MICRODISSECTED HYPOTHALAMIC NUCLEUS OF THE LACTATING RAT. DK Sundberg*, Clara Thore, Miklos Palkovits and RE Eskay*. Department of Physiology and Pharmacology, Wake Forest University, Bowman Gray School of Medicine, Winston Salem NC, 27103 and the National Institute of Health (NIMH and NIAAA), Bethesda, MD.

The neuropeptide, oxytocin (OT), is synthesized in certain discrete hypothalamic nuclei and transported to the neurohypophysis where it is released into peripheral blood. In addition, oxytocin neurons from the paraventricular nucleus (PVN) appear to project to areas throughout the brain. Plasma levels of this peptide increase during lactation and late pregnancy, however, the brain areas that contribute to these changes are not entirely understood.

In the following study we took advantage of the specific solubilities of the peptide and mRNA in alcohol to measure changes in both of these parameters in the same microdissected nucleus. Tissues were microdissected from early pregnant (seven days to avoid estrous cyclicity) and lactating female Sprague-Dawley rats. Tissues were extracted with acidified 98% methanol and the supernatant aliquoted and dried for measurement of OT by RIA. The alcohol insoluble pellet was extracted with 5M guanidium isothiocyanate for OT mRNA which was blotted on Nitran filters and hybridized to a ribonucleic acid probe to exon-C of the OT gene.

Results showed a significant increase in OT mRNA in the PVN, but not in the supraoptic nucleus (SON), the accessory hypothalamic nuclei (AN, anterior commissural nucleus and nucleus circularis) or the neurohypophysis during lactation. OT content, as measured by RIA, however, was found to be decreased in the neurohypophysis and SON but was unchanged in the PVN and AN. Peptide levels were also measured in spinal cord and brain stem areas and showed a general increase associated with lactation. (Supported in part by NIH grant NS 24723).

LOCAL EFFECTS OF AN ANTIESTROGEN AND TESTOSTERONE ON THE EXPRESSION OF VASOPRESSIN mRNA IN THE BED NUCLEUS OF THE STRIA TERMINALIS. M.D. Brot and D.M. Dorsa, Departments of Psychology, Pharmacology and Medicine, Univ. of Washington, and GRECC, VA Medical Ctr., Seattle, WA 98108.

The expression of vasopressin (VP) neurons and mRNA in the bed nucleus of the stria terminalis (BNST) has been demonstrated to be androgen dependent. Male rats have a greater density of VP fibers and higher levels of VP mRNA than female or castrated male rats. Thus, plasma testosterone (T), and in the case of fiber density, central T as well, has been shown to regulate this system.

In this study we used microimplants to investigate the role of central T on VP message expression in the BNST, in addition to trying to block circulating T's effects by local implantation of an antiestrogen. Male rats were castrated and then T or sham replaced peripherally. Unilateral cannula implants containing T, the antiestrogen Keoxifene (K), or nothing were stereotactically placed in the brain targeting the BNST. All animals were sacrificed after 10 days and their brains were frozen and later sectioned. Using *in situ* hybridization methodology, the slides were processed, emulsion coated, developed, and then analyzed for the number of labeled cells in the BNST for each animal over a series of 4 atlas-matched sections.

The results indicate that the removal of T by castration was effective in reducing the number of VP mRNA expressing cells in the BNST as compared to the T-replaced group. Conversely, the castrated, central T implanted group showed an increased number of hybridization-positive cells in the BNST on the side that contained the T when compared with the side that had no implant. Centrally administered K in T-replaced rats significantly reduced the number of cells in the BNST in relation to the T-replaced rats with sham implants, although some reduction of cell number was also noted on the opposite side with no implant. These data suggest that T, through conversion to E₂, may act locally within the BNST to induce expression of the VP gene.

ADRENAL GLUCOCORTICOIDS REGULATE THE ANGIOTENSINOGEN GENE EXPRESSION IN THE RAT BRAIN: *IN VIVO* AND *IN SITU* HYBRIDIZATION STUDIES. J. Angulo, F. Riffina, M. Ledoux*, and B.S. McEwen. Lab. of Neuroendocrinology, The Rockefeller University, New York, NY 10021.

Renin-Angiotensin system is present in the brain and participates in regulation of electrolyte-fluid homeostasis. Three groups of male Sprague-Dawley rats were studied: adrenalectomized (ADX); ADX given Type II selective glucocorticoid agonist RU 28362; and sham-operated rats. The level of Angiotensinogen (ANG) mRNA was detected by quantitative autoradiography after *in situ* hybridization with a synthetic ³²P-labeled oligonucleotide probe. Six days postADX ANG mRNA in the preoptic area (POA) and OVL1 in the ADX rats decreased by 50-60%. RU 28362 (10ug/h in Alzet pumps for 6 days) elevated the level of the ANG mRNA to that of the sham-operated rats. The data indicate that the expression of the ANG gene in the POA is under control of adrenal glucocorticoids. (MH43787).

INCREASES IN VASOACTIVE INTESTINAL PEPTIDE (VIP)- AND PEPTIDE HISTIDINE ISOLEUCINE AMIDE (PHI)-LIKE IMMUNOREACTIVITY (IR) AND VIP/PHI mRNA IN THE ADULT SUPERIOR CERVICAL GANGLION (SCG) MAINTAINED IN ORGAN CULTURE R.E. Zigmond, H. Hyatt-Sachs, C. Baldwin*, X.M. Qu*, T.W. McKeon, R. Schreiber*, and U. Vaidyanathan*. Dept. of Neurosci., Case Western Reserve University, School of Medicine, Cleveland, OH 44106

The adult rat SCG contains ca. 10 pg of VIP-IR. Immunohistochemically, the ganglion has neural processes exhibiting VIP-IR and IR for the related peptide PHI, but very few immunostained cell bodies. After placing the SCG in organ culture for 24 or 48 h with BGJ₃ medium supplemented with fetal calf serum, VIP-IR increased by 6 and 30-fold, respectively. This IR coeluted with synthetic VIP on HPLC. There was also a dramatic increase in the number of neuronal cell bodies and processes showing VIP-IR and PHI-IR. However, cultured ganglia exhibited no change in tyrosine hydroxylase activity or in total ganglion protein. Levels of NPY-IR were found to increase 2.5-fold after 24 h in culture.

The increase in VIP-IR measured after 24 h in culture could be completely blocked by including actinomycin D (1 μg/ml) or anisomycin (100 μM) in the culture medium. The increase in NPY-IR was totally blocked by anisomycin, but was blocked only by about 50% by actinomycin D. Northern blot analysis using a riboprobe complementary to rat VIP/PHI mRNA showed that, although only a faint band was seen in blots of RNA from SCG that had not been cultured, dark bands corresponding to the size of VIP/PHI mRNA were seen in blots of RNA from ganglia after 24 or 48 h in culture.

We have previously shown that VIP- and PHI-IR are present in a population of preganglionic sympathetic but only in very few postganglionic neurons in the SCG. The number of postganglionic neurons expressing VIP and PHI-IR increases dramatically in organ culture due to an increase in the level of VIP/PHI mRNA.

165.19

AN APPROACH TO IDENTIFY PEPTIDE MARKERS IN NEUROENDOCRINE TUMORS. R. Benoit, S. Lavielle* and N. Ling*. Dept. of Medicine, McGill Univ., Montreal, Canada; Lab. of Organic and Biol. Chemistry, Univ. P. and M. Curie, Paris, France² and the Whittier Institute, San Diego, CA¹.

We are looking for specific markers present in high concentration in secretory granules of neuroendocrine tumors, namely basic peptides between 1 000 and 8 000 mol. wt. We think that these peptides can also be found in neurons in normal tissue. Our initial studies were performed with 2.2 G of an acid extract of the most frequent neuroendocrine tumor of the gut in humans, the carcinoid tumor. Sephadex G-75 gel filtration was performed first and five pools of fractions were made based on Substance P and Neurokinin A-like immunoreactivity peaks measured in the column eluate. One pool contained the largest amount of both protachykinin-derived peptides and showed minimal absorbance at 280 nm. It was fractionated by chromatography on carboxymethyl cellulose (CMC). Fractions which contained most of the Substance P immunoreactivity were selected first and further purification was done by reversed-phase HPLC on C18.

Three preponderant peptides contained in the Substance P zone observed on HPLC were purified to homogeneity and sequenced. So far, the most abundant one is a peptide derived from the C-terminal end of human Secretogranin-I precisely after cleavage at LYS³⁶⁶ and ARG³⁶⁷ of the protein. Conclusion: our purification scheme can lead rapidly to identification of neuroendocrine peptides.

165.16

EFFECTS OF DECENTRALIZATION AND AXOTOMY ON VASOACTIVE INTESTINAL PEPTIDE (VIP)- AND NEUROPEPTIDE Y (NPY)-LIKE IMMUNOREACTIVITY (IR) IN THE SUPERIOR CERVICAL GANGLION (SCG). H. Hyatt-Sachs, T.W. McKeon, R. Schreiber*, S. Piszczkiewicz, Y. Sun, M.R. Bachoo* and R.E. Zigmond. Dept Neurosci, Case West Res U, Cleveland, OH

The adult rat SCG contains low levels of VIP-IR detected by radioimmunoassay (RIA) and some immunoreactive neural processes, but very few immunoreactive neuronal cell bodies, detected by immunohistochemistry. The level of VIP-IR and the number of VIP-IR fibers was increased by about 2-fold at both 2 and 7 days after the preganglionic cervical sympathetic trunk (CST) was cut (Hyatt-Sachs et al., Soc. Neurosci. Abstr. 16: 1029, 1990). In contrast, we find that the levels of NPY-IR did not change 2 days after CST section and decreased by 30% after 7 days. To determine whether preganglionic nerve stimulation could block the increase in VIP-IR produced by preganglionic deafferentation, the CST was stimulated unilaterally with 40 Hz trains (250 msec on, 500 msec off) for 90 min immediately after the two CST were cut. Stimulation did not prevent the increase in VIP-IR measured 2 days later. After postganglionic nerve section, VIP- and NPY-IR also changed, but the changes differed qualitatively and quantitatively from those reported above. Two days after the internal carotid nerve (ICN) was cut, VIP-IR increased in the ganglion 12-fold and there was a large increase in the number of immunostained neuronal cell bodies and fibers. NPY-IR increased 2-fold. There was no change in total ganglion protein. When the CST, ICN, and external carotid nerve were all cut, VIP-IR increased 25-fold and there were large increases in immunostained cells and fibers. NPY-IR only increased 2-fold and, again, total protein was unchanged.

These results indicate that adult sympathetic neurons that do not normally express VIP can do so after axotomy. Whether the changes in VIP-IR after axotomy differ from those after decentralization only quantitatively or whether different mechanisms are involved remains to be determined. (NS12651 and MH00162)

MODULATION OF THE INCREASE IN VASOACTIVE INTESTINAL PEPTIDE-LIKE IMMUNOREACTIVITY (VIP-IR) IN ADULT SUPERIOR CERVICAL GANGLIA (SCG) MAINTAINED IN ORGAN CULTURE. Y. Sun, H. Hyatt-Sachs, X.M. Qu*, and R.E. Zigmond. Dept. of Neurosci., Case Western Reserve University, School of Medicine, Cleveland, OH 44106

Maintaining adult SCG in organ culture for 24 or 48 h in BGJ₃ medium with fetal calf serum produces a 6- and 30-fold increase, respectively, in their content of VIP-IR (Zigmond et al., this volume). Placing ganglia in organ culture causes 3 major changes. The neurons are (1) placed in a different humoral milieu than found *in vivo*, (2) deafferented, and (3) axotomized. Since a similar increase in VIP-IR was seen when SCG were cultured in a defined medium, stimulatory factors in serum are not required for this change. Inclusion of dexamethasone (10⁻⁷ M) inhibited the increase in VIP-IR by about 40%, raising the possibility that glucocorticoids *in vivo* might suppress the expression of this IR. One effect of deafferentation is to eliminate, or at least greatly reduce, action potential firing in postganglionic neurons. Interestingly, depolarization of the cultured ganglia with veratridine (5 x 10⁻² M) completely blocked the normal increase in VIP-IR, and this effect was reversed by tetrodotoxin (10⁻⁷ M). While these data raise the possibility that the principal reason expression of VIP-IR is suppressed *in vivo* is impulse activity, our finding that cutting the cervical sympathetic trunk produced only a 2-fold increase in VIP-IR *in vivo* makes this hypothesis unlikely. Axotomy produces a larger increase in VIP-IR *in vivo* and a large increase in the number of immunostained principal neurons (Hyatt-Sachs et al., this volume). Since NGF is not normally included in the culture medium and since both cultured ganglia and axotomized ganglia would be deprived of target-derived NGF, we examined the effect of including 100 ng/ml NGF in our medium. Ganglia cultured in the presence of NGF had about a 2-fold larger increase in VIP-IR than did ganglia cultured in its absence. Thus, deprivation of NGF seems unlikely to cause the increase in VIP-IR either in culture or after axotomy.

165.20

STOICHIOMETRY AND IDENTIFICATION OF BIOTINYLATED RESIDUES IN NEUROPEPTIDES AND PROTEINS. S. L. Knock, J. S. Smith*, B. T. Miller, and A. Kurosky*. Marine Biomed. Inst., Depts. of Human Biol. Chem. & Genetics and of Anat. & Neurosci., Univ. Texas Med. Br., Galveston, TX 77550

The widespread application of the biotin-avidin system and its increasing use has directed more inquiry toward a better understanding of the chemical properties of biotinylating reagents and their reactions. Using neuropeptide Y and lysozyme as models, we have developed a method for the determination of the stoichiometry of biotinylation of peptides and proteins after reaction with an N-hydroxysuccinimide ester of biotin containing the extended spacer arm 6-aminohexanoic acid. The method of analysis, based on the quantification of phenylthiocarbonyl derivatives of 6-aminohexanoic acid, is able to measure low picomolar amounts of biotinyl derivative. Analyses were performed using an automated on-line hydrolyzer followed by HPLC. Compositional analyses determined for known peptides were in excellent agreement with analyses obtained by mass spectrometry. A detailed study of the biotinylated lysine-4 of neuropeptide Y was conducted by automated sequence analysis. Confirmation of the structure of the phenylthiohydantoin derivatives of Nε biotinylated lysine was achieved by mass spectrometry. The advantages of the analytical approach described include: 1) the same assay yields quantitative results for both biotin and protein or peptide content; 2) the biotin label containing the spacer arm may be important for reducing the steric hindrance associated with the binding of biotinylated peptides to both avidin and membrane receptors; and 3) the combination of amino acid compositional analysis and automated sequence analysis can allow identification of the specific residues to which biotin is attached. Since several different biotinylated species can be generated during the course of one reaction, such information is valuable for the consistent production of biotinylated probes. (Support: NIH NS29261, NS07185, and the Robert A. Welch Foundation)

DEVELOPMENT OF N- AND C-TERMINAL DIRECTED IMMUNOLOGICAL PROBES TO A 1745-DA PYROGLUTAMYL PEPTIDE DERIVED FROM CHROMOGRANIN B.

M. de Serres*, J. D. McDermed*, T. Flanagan*, O. H. Viveros, and E. J. Diliberto Jr.*. Division of Pharmacology and of Organic Chemistry, Burroughs Wellcome Co., 3030 Cornwallis Road, R.T.P., NC 27709.

Specific antisera and a competitive homogeneous RIA were developed to detect the presence of a recently described pyroglutamyl 1745-da peptide (BAM-1745) derived from the endogenous processing of chromogranin B by bovine adrenal medulla chromaffin cells. Antisera directed to either end of BAM-1745 were obtained using analogs of BAM-1745 extended by KCGG or GGCK at the amino- or the carboxy-terminal end, respectively, coupled through the cysteinyl residue to multichain Poly-DL-Alanyl-Poly-L-Lysine by sulfosuccinimidyl 4-(N-maleimidomethyl) cyclohexane-1-carboxylate. The resulting directed antisera were found to have markedly disparate epitope requirements when tested for immunological reactivity in a competitive homogeneous RIA against various synthetic analogs of this peptide. Immunoreactivity in micro-pig tissues was examined by RIA using an amino terminal directed antiserum. BAM-1745-like immunoreactivity was found in many of the tissues examined, the highest levels were associated with the pituitary and whole adrenal extracts (12 and 7 nmol/g tissue wet wt, respectively). The highest levels of BAM-1745 like immunoreactivity in brain regions were found to range from 0.4 to 0.2 nmole/g tissue wet wt in cerebellum, hippocampus, striatum, cortex, and septum.

PEPTIDES: BIOSYNTHESIS, METABOLISM AND BIOCHEMICAL CHARACTERIZATION III

166.1

CLONING AND REGIONAL EXPRESSION OF A PUTATIVE PROCESSING ENDOPEPTIDASE FROM RAT BRAIN. D.L. Kilpatrick*, N.D. Mehta*, Z. Galcheva-Gargova*, M. Jacob, J. Marchand, R. Kream*, R.K. Agarwal* and M.S.A. Kumar*. Neurobiology Group, Worcester Foundation For Experimental Biology, Shrewsbury, MA 01545, Dept. of Anesthesia, Tufts Medical Center, Boston MA 02111, and Dept. of Anatomy and Cell Biology, Tufts Univ. Vet. School, N. Grafton, MA 01536.

Recent studies have identified at least three distinct endoproteases in mammals that are related to Kex2, a yeast enzyme involved in the initial proteolytic processing of the precursor of yeast pheromone: furin, PC1/PC3 and PC2. These enzymes all exhibit properties consistent with roles as processing endoproteases: (1) specificity towards paired basic amino acids, typical recognition signals for proteolytic processing found within a variety of protein precursors, and (2) appropriate processing of one or more precursor proteins when co-expressed in transfected cells. Using a cDNA probe for human PC2, we have isolated multiple clones from a rat brain cDNA library that appear to contain a rat homologue of PC2. Partial sequencing shows high homology in the protein coding sequence with those for mouse and human PC2. A major transcript approximately 2.8 kb in size was detected in rat brain RNA using the rat cDNA, consistent with recent reports using mouse and human PC2. Transcripts were much lower or absent in other tissues so far examined using this probe (muscle, liver, kidney, skin, lung). Preliminary Northern blot analysis indicated a widespread regional distribution of rat PC2 mRNA in brain, suggesting this endoprotease may be involved in the processing of multiple neuropeptide precursors within the rat CNS. Data will be presented on the cellular expression and possible regulation of this PC2-like endoprotease in rat brain.

166.3

PUTATIVE ROLE OF PROHORMONE ENDOPEPTIDASES (PEPs) *PC1*, *PC2*, AND *FURIN* IN THE PROCESSING OF PRO-SOMATOSTATIN (PSS). A. Galanopoulou*, G. Kent*, S. Rabbani*, N. G. Seidah*, and Y.C. Patel. Fraser Laboratories, McGill University, and Clinical Research Institute of Montreal, Montreal, Quebec, Canada.

Mammalian PSS is endogenously processed at dibasic and monobasic cleavage sites to generate respectively SS-14 and SS-28. In the present study we have investigated the putative roles of the recently cloned mammalian PEPs *PC1*, *PC2*, and *furin* in mediating these cleavages. We have correlated the endogenous expression of these enzymes with cellular SS-14 and SS-28 in rat islet SS-producing tumor cells (1027 B₂) and in 2 non SS-expressing cells (AtT-20, PC12) acutely transfected with PKS5 (prePSS expression vector - gift of K. Sevarino). The relative abundance of *PC1*, *PC2*, and *furin* mRNA (by Northern analyses with cRNA probes) was compared with percent processed SS-14 and SS-28 (by HPLC analysis followed by RIA) (Table). COS 7 cells transfected with PKS5 constit-

	<i>PC1</i>	<i>PC2</i>	<i>Furin</i>	% SS-14	% SS-28
1027 B ₂	++	-	++	60	40
PC12	-	-	+	100	0
AtT-20	+++	-	-	75	25

tively secreted SS-14 and SS-28 (ratio 48%:52%). These data show absence of *PC2* in 1027 B₂, PC12 and AtT-20 cells and suggest a random distribution of *PC1* and *furin* in these neuroendocrine cells. Although processing by unidentified PEPs cannot be excluded, our results provide indirect evidence that (1) *furin*, expressed alone in PC12 cells, can process PSS to SS-14 but not SS-28. (2) *PC1*, abundantly expressed in AtT-20 cells may process at both dibasic (SS-14) and monobasic (SS-28) sites.

166.2

CLONING AND CHARACTERIZATION OF A cDNA ENCODING A DIPEPTIDYL AMINOPEPTIDASE-LIKE PROTEIN FROM BOVINE, RAT AND HUMAN BRAIN. N. Yokotani*, C. Hunter, S. Shimasaki**, K. Doi, R.J. Wenthold and K. Wada. Lab. of Neurochemistry, NIDCD, NIH, Bethesda, MD 20892, and *Lab. of Molecular Endocrinology, The Whittier Institute, La Jolla, CA 92037.

We showed previously the purification of an AMPA subtype of a glutamate receptor from bovine brain (Hunter and Wenthold, *Soc. Neurosci. Abstr.*, 16, 543, 1990). Several peptide sequences were obtained by microsequencing of the protease-digested fragments of the purified protein. Screening of bovine brain cDNA libraries and sequencing of positive phage clones revealed that some of the chemically obtained peptide sequences were encoded by a cDNA unrelated to AMPA receptor cDNAs. The cDNA encodes a new dipeptidyl aminopeptidase-like protein which shares 27% and 33% amino acid identity to yeast and rat liver dipeptidyl aminopeptidases (DAPs), respectively. The predicted protein has a membrane topology similar to those of other membrane-bound peptidases. Northern hybridization using a rat homologue cDNA on mRNAs from various rat tissues showed that only brain expressed the transcripts of 3.8 and 4.5 kb. Further analysis using the rat and human homologue cDNAs as well as bovine cDNA showed that all of the three species probably express two different forms of the protein due to an alternative splicing of RNA (803 and 863 aa, respectively, in bovine brain). Expression studies using mammalian cell transfection are currently under way to characterize the enzyme activity of the DAP-like protein.

166.4

IN VIVO CHARACTERIZATION OF THE CLEAVAGE SITE SPECIFICITY OF Neuro 2A, Rin m5F AND AtT20 PROHORMONE PROCESSING ENZYMES. N. C. Day, H-L. Lin* and H. Akil. Mental Health Res. Inst., University of Michigan, Ann Arbor, MI 48109.

Many peptide hormones and neurotransmitters are synthesized as larger precursor proteins which are endoproteolytically processed at specific cleavage sites to produce the biologically active peptide(s). Endoproteolytic cleavage usually occurs at dibasic amino acid residues in the peptide precursor. An indirect way to characterize the enzymes responsible for endoproteolysis is to examine prohormone processing in heterologous cell lines, known to process endogenous or transfected precursors. In this study, we have assessed the ability of Neuro 2A, Rin m5F and AtT20 cells to process the β Endorphin/ACTH precursor, proopiomelanocortin (POMC). Wild-type and mutated monkey POMC cDNAs were subcloned into an expression vector employing the cytomegalovirus immediate early gene promoter, and the resulting plasmids transfected into the cell lines. Following extraction and molecular sieving, peptide products were assayed by radioimmunoassay. In AtT20 cells, endogenous mouse POMC was distinguished from transfected monkey POMC by a radioimmunoassay specific for monkey β MSH. Results showed that wild-type POMC is processed to different extents in the different cell lines: Neuro 2A cells processed the least, whilst Rin m5F cells processed POMC the most extensively. The effect of mutating specific cleavage sites on processing of monkey POMC is being examined in terms of a) sequence specificity and b) cellular milieu. The results will be discussed in relation to expression of PC1 and PC2 (Seidah et al., *DNA and Cell Biology* 2:415, 1990), two recently cloned putative processing enzymes, in the different cell lines.

166.5

REGULATION OF A NEUROPEPTIDE PROCESSING ENDOPEPTIDASE IN THE RAT ANTERIOR PITUITARY LACTOTROPHIC CELL LINE, GH₄C₁. L. Greco,* L. Daly,* S. Kim,* L.D. Fricker* and L. Devi.* Dept. of Pharmacology,* New York Univ. Med. Center, New York 10016; *Dept. of Mol. Pharmacology, Albert Einstein College of Medicine, Bronx, NY 10461.

Several peptide hormones and neurotransmitters are produced by cleavage at the monobasic processing sites. An endopeptidase capable of cleaving a dynorphin peptide at the monobasic processing site is secreted from the rat anterior pituitary cell line, GH₄C₁. When characterized by chromatography on FPLC using an ion-exchange column, the majority of the endopeptidase activity elutes as a single symmetrical peak around 0.3 M NaCl. The protease inhibitor profile suggests that the activity is due to a thiol protease. These enzymatic properties are similar to a monobasic processing enzyme previously found in bovine pituitary and in the rat brain. The secretory pathway which contains the enzyme activity in GH₄C₁ cells was characterized by stimulation of secretion by thyrotropin releasing hormone, forskolin, phorbol ester, or potassium chloride. The secretion of the enzyme activity was substantially increased by these compounds suggesting that the GH₄C₁ cells secrete the activity via regulated pathway. A hormonal treatment of the GH₄C₁ cells which has been previously shown to produce a substantial increase in the number of secretory granules and ir-prolactin, has been found in this study to elevate the peptide processing enzyme activity 2-fold. This increase is similar to that seen in the carboxypeptidase E activity; another putative peptide hormone processing enzyme activity. These data suggest that the peptide processing activity is regulated to a small but significant extent and is coordinately regulated with carboxypeptidase E activity.

DIRECT MEASUREMENT OF PROENKEPHALIN PROCESSING IN ADRENAL CHROMAFFIN CELLS. S.P. Wilson, A.P. Rostovtsev, and B.A. Spruce*. Dept. of Pharmacology, USC Sch. of Med., Columbia, SC 29208 and *Dept. of Biochemistry, Univ. of Dundee, Scotland

The processing of proenkephalin (PE) was examined using pulse-chase radiolabeling of bovine adrenal medullary chromaffin cells. PE and PE-derived peptides of > 10 kDa were purified by incubation of cell extracts with an immunoaffinity matrix containing equal portions of the monoclonal antibodies PE-1 and PE-2 directed against PE (*J. Biol. Chem.* 263, 19788; 1988). The purified peptides were then separated by SDS polyacrylamide gel electrophoresis, blotted to polyvinylidene difluoride membranes, and localized by immunostaining. PE (31/33 kDa) and major PE-derived peptides of 13, 15, 18, 22, and 28 kDa were found on the blots and were analyzed for incorporation of [³H]Leu. After 30 and 60 min of labeling, > 75% of the label was found in PE. Radioactivity in PE disappeared with a half-time of about 1 h. Appearance of radiolabel in the PE-derived peptides occurred in parallel with the decrease in PE labeling. No loss in the [³H]PE-derived peptides occurred over times up to 6 h, indicating that these peptides are final products of the PE-processing pathway. Addition of the secretagogue nicotine or the phosphodiesterase inhibitor 3-isobutyl-1-methyl-xanthine during radiolabeling and chase had no effect on PE processing. This work was supported by NSF Grant BNS-8719149.

166.9

ENDOPEPTIDASE 22.19 (EC 3.4.22.19), A PUTATIVE ENKEPHALIN-GENERATING ENZYME, IN THE VERTEBRATE RETINA. E.S. Ferro*, D.E. Hamasaki*, J.C. Bittencourt, A.C.M. Camargo* and L.R.G. Britto. Institute of Biomedical Sciences, University of Sao Paulo, Sao Paulo, SP 05508, Brazil.

In this study we used both biochemical and immunohistochemical procedures to investigate the possibility of endopeptidase 22.19 to convert enkephalins *in vivo*. The specific activity of endopeptidase 22.19 found in pigeon retinae (30.3 ± 7.3 mU/mg) was four times higher as compared to rabbit retinae (7.0 ± 1.1 mU/mg). The enzyme activity was not modified by EDTA, but it was enhanced by dithiothreitol and inhibited by zinc, 5,5'-Dithiobis-(2-nitrobenzoic acid) and dynorphin A₁₋₁₃. The immunohistochemical experiments revealed labeled neurons in both the inner nuclear layer and the ganglion cell layer of pigeon and rabbit retinae. Double-labeling immunofluorescence experiments demonstrated that about 90% of neurons containing endopeptidase 22.19-like-immunoreactivity contained also leucine-enkephalin-like-immunoreactivity. These results represent an important step towards the demonstration of the possible involvement of endopeptidase 22.19 in enkephalin generation *in vivo*.

166.6

TRANSFECTION AND PROCESSING OF PRO-ACTH/ENDORPHIN IN GH4C1 CELLS. E.I. Cullen and F. Lin*. Dept. of Pharmacology, New York Medical College, Valhalla, NY 10595

GC and GH3 cells can endoproteolytically process pro-ACTH/endorphin (PAE or POMC) derived from a transfected cDNA (Cullen and Mains, 1989 *Endocrinology* 125: 1774). Other laboratories have found GH4C1 cells do not process PAE. To facilitate comparison of GC, GH3, and GH4C1 cell processing capabilities, we transfected GH4C1 cells with the same vector and assayed for processing as in earlier work. After incubating transfected cells in medium containing CdCl₂, cells were washed three times in serum-free medium, and extracted in 50% acetic acid. Soluble extracts were subjected to Sephadex G-75 chromatography in 10% formic acid, and aliquots of the fractions were dried and assayed by radioimmunoassay using materials generously provided by Dr. R.E. Mains. In contrast to the results obtained in transfected GC cells, the only amidated joining peptide immunoreactivity (JP-IR) detected in transfected GH4C1 cells displayed a K_D of 0.27 ± 0.02, indicating an apparent molecular weight larger than that of the PAE(1-94)NH₂ found in transfected GC cells. No amidated JP-IR the size of JP(1-18)NH₂ was detected. Thus, processing is less complete in GH4C1 cells than in GC cells, and the ability to cleave at Arg(75)Arg(76) may be absent. Supported by the Pharmaceutical Manufacturer's Association Foundation.

166.8

STABILITY OF EXOGENOUSLY ADDED PROENKEPHALIN IN TRANSFECTION EXPERIMENTS. J.P. Mathis and I. Lindberg*. Dept. of Biochem. and Mol. Bio., Louisiana State University Med. Ctr., New Orleans, LA 70112.

Tissue culture cell lines transfected with neuropeptide precursor cDNA are widely used for investigating the proteolytic processing of neuropeptide precursor molecules. A potential problem with this method is non-specific proteolytic cleavage of the precursor molecule in culture medium. Therefore, the stability of ³⁵S-radiolabelled proenkephalin added to the medium of transfected and non-transfected cells was measured in order to determine the occurrence and extent of non-specific degradation.

The stability of proenkephalin was measured in the following way. Medium containing 4 - 20 x 10⁴ cpm/ml of ³⁵S-radiolabelled, HPLC-purified, exogenous proenkephalin was added to cells. Medium samples were collected at 48h and breakdown of the exogenous proenkephalin was analyzed by gel filtration chromatography or SDS-PAGE. ³⁵S-radiolabelled proenkephalin incubated in the absence of cells did not break down.

The effects of cell density, percent of fetal bovine serum (FBS) in the medium and transient and stable transfection methods on stability of proenkephalin were examined in AtT-20, Cos-1, SK-N-MC and CHO DG44 cell lines. The breakdown of exogenous proenkephalin was increased by 50% at 4 x 10⁵ cells/60mm dish when compared with 2.5 x 10⁵ cells/60mm dish. Degradation of exogenous proenkephalin was reduced by 50% in 5% FBS medium as compared to serum-free medium. Transfection of cells by the calcium phosphate method *per se* did not affect stability of the exogenous proenkephalin. In SK-N-MC cells, breakdown of proenkephalin was mediated by soluble rather than cell-bound proteases. Therefore, non-specific degradation of precursor molecules does occur in cell culture medium and should be taken into account during studies of neuropeptide precursor processing.

166.10

A NOVEL THIOL PROTEASE INVOLVED IN PROCESSING ENKEPHALIN AND TACHYKININ PRECURSORS IS INHIBITED BY α₁-ANTICHYMOTRYPSIN, A COMPONENT OF ALZHEIMER'S AMYLOID DEPOSITS. V.Y.H. Hook, G. Hubbard* and T.J. Krieger* Dept. of Biochemistry, Uniformed Services University, Bethesda, MD. 20814

The protease inhibitor α₁-antichymotrypsin (α₁-AC) is a normal component of the human nervous system. Identification of the endogenous neuronal protease(s) normally regulated by α₁-AC is important to understanding its role in brain function. In this study, we demonstrate that α₁-AC inhibits a novel thiol protease (purified from bovine chromaffin granules, *J. Biol. Chem.*, in press, 1991), cleaving at Lys-Arg and Lys-Lys sites, that is involved in processing enkephalin and perhaps tachykinin precursors. This protease was inhibited *in vitro* by human plasma α₁-AC, and α₁-AC immunoreactivity was colocalized with the enzyme in bovine secretory vesicles from adrenal medulla and pituitary. Purification of the endogenous bovine α₁-AC from pituitary by DEAE-Sepharose, chromatofocusing, butyl-Sepharose, and Sephacryl S200 resulted in a 60 kDa bovine α₁-AC protein that was a potent inhibitor of the thiol protease, possessing an IC₅₀ value (concentration for 50% inhibition) of 12 nM. It also inhibited chymotrypsin and trypsin with IC₅₀ values of 42 and 12 nM, respectively. This is the first demonstration that a neuropeptide precursor processing enzyme is regulated by an endogenous protease inhibitor. Also, these results and recent findings (Abraham et al., *Cell*:52,487) of α₁-AC localization in amyloid deposits of Alzheimer's Disease suggests a possible role for α₁-AC inhibition of neuropeptide production in neurologic disease.

166.11

A LIGHT AND ELECTRON MICROSCOPIC STUDY OF IMMUNOREACTIVE (IR) CORTICOTROPHIN-RELEASING HORMONE (CRH) CONTAINING NEURONES IN THE RAT NEOCORTEX. P.R.Lowenstein¹, A.F.Shering¹, J.L.James¹, P.J.Lowry², L.Linton³ and M.G.Castro⁴. ¹Dept. Anat./Physiol., Dundee University, Dundee DD1 4HN, ²Dept. Biochem./Physiol., Reading University, Reading RG6 2AJ and ³Dept. Molec. Life Sci., Dundee Inst. Technol., Dundee DD1 1HG, United Kingdom.

CRH is the main secretagogue of anterior pituitary ACTH. In CRH, as well as CRH receptors have been identified throughout the CNS. In addition to its neuroendocrine function CRH could act as neurotransmitter in extrahypothalamic areas. To provide the anatomical basis for its role in cortical physiology we have characterised CRH ir neurones in the rat neocortex using light and electron microscopical immunocytochemical techniques. The primary antibodies used were:3B3 and rC70 (Dr.W.Vale), diluted 1:1000. The ABC (Vector) method was used to detect the primary antibodies. Unexpectedly, three different types of ir neurones were encountered: bipolar neurones were found mainly in layers II-III, multipolar sparsely spiny neurones were found mainly in layers V-VI, and smooth dendritic multipolar neurones were located in the white matter. Very few immunoreactive fibres were seen crossing the white matter. Axonal processes originating from bipolar neurones could be followed for long distances and tended to arborize near the cell body. Preliminary examination of the synaptic organization of ir boutons in layers II-III indicates that some CRH boutons establish asymmetric synapses. Our results show that, contrary to previous descriptions, CRH ir neurones in the rat neocortex constitute a heterogeneous neuronal group, some of which may establish excitatory synaptic connections.

DEVELOPMENTAL PATTERN OF THE TYROSYL PROTEIN SULFOTRANSFERASE IN RAT BRAIN

F. Vargas, O. Frerot, M. Trung-Tuong, J.C. Schwartz and F. Brion.

Unité de Neurobiologie et Pharmacologie, Centre Paul Broca de l'INSERM, 75014 Paris - France.

Cholecystokinin (CCK) is a major hormone and neurotransmitter in the central nervous system. Previous studies revealed the important role of a tyrosine protein sulfotransferase (TPS), in the activation of CCK e.g. tyrosine sulfation (Vargas et al., *Biochemistry*, 1985, 24: 5938; Niehrs et al., *J. Biol. Chem.*, 1990, 265: 8525).

In this report we analyzed the developmental pattern of TPS in rat brain. Ontogenic studies showed that TPS is present in the fetal brain and, also, the PAPS synthesizing system. TPS activity was surprisingly 2.5 fold higher in the newborn rat brain tissue than the mature. The Michaelis affinity constants for PAPS and BocCCK-8(ns) for the TPS activity were similar for newborn and adult membranes, Vmax decreased, however from 0.83 ± 0.05 to 0.31 ± 0.02 pmol/mg protein/min in brain membranes from newborn and adult brain respectively.

These results suggest that TPS may play a role in embryogenesis and development as suggested, also, by the presence of CCK-8 in the aerosomal granule of spermatides (Persson et al., *Proc. Natl. Acad. Sci., USA*, 1989, 86: 6166).

PEPTIDES: BIOSYNTHESIS, METABOLISM AND BIOCHEMICAL CHARACTERIZATION IV

167.1

CHARACTERISTICS OF A CCK CLEAVING ENDOPROTEASE PURIFIED FROM RAT BRAIN SYNAPTOSOMES. J.C.Viereck and M.C.Beinfeld. Dept. of Pharmacology, St. Louis Univ. Sch. of Med., St. Louis, MO 63104.

An endoproteolytic activity which specifically cleaves CCK-33 producing CCK-8 has been purified from a rat brain synaptosome preparation. This activity was assayed by incubating with substrate and separating the product on DEAE Sephadex ion exchanger. The assay product co-eluted with authentic CCK-8 on reverse phase HPLC. Steps including DEAE anion exchange, chromatofocusing, hydroxyapatite chromatography and gel filtration resulted in a several hundred fold increase in specific activity. The endoprotease apparently exists as a 90 kDal molecular weight dimer, which can be dissociated into active 45 kDal subunits. The endoprotease has no activity against several specific substrates for other proteases (trypsin, kallikrein, enteropeptidase) as assayed using fluorogenic probes, nor does it display proteolytic activity against analogs of monobasic cleavage sites of several other prohormones. Non sulfated analogs of the cleavage site are also not cleaved by the endoprotease. Thus the amino acid sequence around the cleavage site and sulfation appear to be important in substrate recognition. The specificity and subcellular localization of the endoprotease make it a good candidate for a CCK converting enzyme. Supported by NIH-NS18667

BIOSYNTHETIC PATHWAY AND INTRACELLULAR COMPARTMENTALISATION OF CORTICOTROPHIN-RELEASING HORMONE (CRH). 1.M.G. Castro, 3.P.R. Lowenstein, 2.B. Glynn, 2.A. Perkins, 2.E. Linton and 2.P.J. Lowry. ¹ Dept. Molec. Life Sci., Dundee Inst. Technol., Dundee DD11HG, ²Dept. Biochem. Physiol., Reading Univ., Reading RG62AJ, ³Dept. Anat. Physiol., Dundee Univ., Dundee, DD14HN, U.K.

CRH is cleaved from a larger precursor (proCRH) by endopeptidases. We have used AtT20 cells transfected with the human (h) proCRH gene (R1 and R4 clones; provided by Drs G. Adler and J. Majzoub) to study post-translational processing and intracellular compartmentalisation of proCRH. The levels of intracellular and secreted ACTH and CRH were determined using immunoradiometric assays (IRMA) and/or radio-immunoassays (RIAs). Norepinephrine (0.1mM) caused a several-fold stimulation of CRH release in R1 and R4 cells (basal CRH released: 0.05ng/ml/3h for both R1 and R4 cells; stimulated CRH released: 0.44 ± 0.11 ng/ml/3h for R1 cells and 0.19 ± 0.01 ng/ml/3h for R4 cells). These results indicate that CRH is targeted into the secretory pathway in the transfected cells. Using gel filtration chromatography and HPLC followed by specific IRMA and RIAs on the eluted fractions, we have demonstrated that the CRH precursor is proteolytically processed in the transfected cells to yield CRH(1-41) and proCRH(125-151), suggesting that these peptides may be the end products of the biosynthetic pathway of the hCRH prohormone.

IN VITRO METABOLISM OF RAT GROWTH HORMONE-RELEASING FACTOR(1-29) AMIDE IN RAT PITUITARY AND HYPOTHALAMUS. L. Boulanger, C. Lazure and P. Gaudreau. Neuroendocrinology Laboratory, Notre-Dame Hospital Research Center and Montreal Clinical Research Institute, Montreal, Canada, H2L 4M1.

Previous reports showed that in addition to the stimulation of growth hormone (GH) secretion, GH-releasing factor (GRF) may exert a specific negative feedback on its own hypothalamic secretion. The metabolism of GRF in pituitary and hypothalamus has not been documented yet. However, to design peptide analogs exhibiting a longer duration of action than native GRF, vulnerable peptide bonds must be secured from peptidase action, in both tissues. The kinetic of disappearance of rGRF(1-29)NH₂ and the identification of its metabolites were therefore studied in pituitary (237 ± 51 µg prot./ml) and hypothalamus homogenates (576 ± 27 µg prot./ml). Analytical HPLC revealed an apparent half-life of 22 ± 3 min and 25 ± 4 min respectively. The disappearance of GRF was associated with the successive appearance of 3 major, less hydrophobic, peptides. These degradation products were isolated by preparative HPLC and their identity revealed by amino acids analysis, sequencing and co-chromatography with synthetic fragments. Proteolysis of GRF produced, in both tissues, the fragments 1-21, 1-14 and 1-10. These results show that the main cleavages of rGRF(1-29)NH₂, occur at Lys²¹-Leu²², Leu¹⁴, Gly¹⁵ and Tyr¹⁰-Arg¹¹. Chemical modifications at these critical sites may result in GRF agonists with a greater efficacy.

PEPTIDASE ACTIVITIES AGAINST N-ACETYLASPARTYLGLUTAMATE ACROSS 50 DISCRETE REGIONS WITHIN THE RAT NERVOUS SYSTEM. S. Fuhrman¹, M. Palkovits², and J. H. Neale¹. ¹Dept. of Biology, Georgetown University, Washington, DC. ²Lab. of Cell Biol., National Institute of Mental Health, Bethesda, MD.

The dipeptide N-acetylaspartylglutamate (NAAG), which is found in millimolar concentrations in brain tissue, may function in synaptic communication. NAAG is hydrolyzed to N-acetylaspartate and glutamate by membrane-bound peptidase activities, which appear to be extracellular in brain cell culture. These peptidase activities may be involved in the inactivation of NAAG. Alternatively, NAAG could be acting as a sequestered form of glutamate.

The objective of this project is to determine the anatomical relationship between NAAG and peptidase activities which hydrolyze it. Initially, micropunched samples from 50 rat brain nuclei (incl. spinal cord) were assayed to determine the distribution of the NAAG-hydrolyzing peptidase activity. The results indicate a positive correlation between [NAAG] previously identified by immunohistochemistry and NAAG-hydrolyzing enzyme activity; for example, the caudate nucleus and various regions of cerebral cortex are all low in [NAAG] and in the peptidase activity, while the interpeduncular nucleus and locus coeruleus show high levels of the peptidase activity as well as high [NAAG].

Quisqualate is reported to be a non-competitive inhibitor of one peptidase activity against NAAG. The correlations between these enzyme activities and NAAG in control and lesioned rat CNS will be explored.

CORTICOTROPIN RELEASING FACTOR METABOLISM IN THE RAT HYPOTHALAMUS. J.C. Ritchie, M.J. Owens, C.B. Nemeroff. Depts. Psychiat. and Pharmacol., Duke Univ. Med. Ctr., Durham, NC 27710.

The metabolism of neuropeptides may be of great importance in the termination of their actions in the synapse. In order to study the metabolism of corticotropin releasing factor (CRF) we have developed and characterized an HPLC gradient fractionation for r/h CRF₁₋₄₁ and its available synthetic fragments. In an attempt to elucidate CRF₁₋₄₁ metabolism in the rat hypothalamus we prepared 10,000XG homogenate extracts. These extracts were then incubated at 37°C for varying time periods in the presence of excess CRF₁₋₄₁. Additionally, incubations were carried out in the presence of a wide variety of specific peptidase inhibitors. Fractionation of the enzyme digests showed an attenuation of the CRF₁₋₄₁ peak at all time points and the generation of multiple new peaks. Incubation with specific protease inhibitors altered the pattern of peak generation but did not block completely the degradation of whole CRF. Analysis of the chromatograms reveals that the breakdown of CRF in the rat hypothalamus results in the formation of CRF₃₇₋₄₁ and several other yet unidentified peptide fragments. SUBSTANCE P RELEASE INVESTIGATED IN BOTH THE RAT SUBSTANTIA NIGRA AND SPINAL CORD, USING ANTIBODY MICROPROBES. P. J. Hope*, A.K. Wright*, H.M. Brace*, G. W. Arbuthnott. Department of Preclinical Veterinary Sciences, University of Edinburgh, Edinburgh, EH9 1QH.

Antibody-coated microprobes have been used, for the first time, to study the release of substance P (SP) in two regions of the rat CNS.

Microprobes coated with anti-SP antibodies were inserted sequentially for 10-20 mins either (a) along the mediolateral axis of the substantia nigra (SN) (6 rats) or (b) transversely into the lumbar spinal cord (8 rats). In the region of the SN SP-release was detected following i.p. amphetamine (4 mg/kg). In 2 other rats in which probes had missed the SN by 300µ, no SP release was detected. The origin of this increase in nigral SP may be striatal cells, that contain SP and project to the SN, and which may be excited by amphetamine.

In the lumbar spinal cord SP release was detected in the region of the substantia gelatinosa (SG) following both tibial nerve stimulation (2 min x 50 threshold) and pinch.

These results demonstrate that the antibody microprobe technique can be utilised to detect neuropeptide release in restricted regions of the rat CNS, in both electrophysiological and neuropharmacological studies.

167.4

PROTEOLYTIC CONVERSION OF OXYTOCIN BY RAT BRAIN SYNAPTIC MEMBRANES: ROLE OF AMINOPEPTIDASES AND ENDOPEPTIDASES. A. Argiolas, M.R. Melis and R. Stancampiano*. B.B. Brodie Dept. of Neurosciences, Univ. of Cagliari, 09124 Cagliari (Italy).

The proteolytic conversion of oxytocin (OXY) and vasopressin (VP) by purified rat brain synaptic membranes was studied at 37°C and pH 7.4. The formed peptide fragments were isolated by HPLC and characterized by amino acid analysis. When OXY was incubated, both C- or N-terminal fragments were found. The most abundant were Cyt⁶-OXY 4-9, Cyt⁶-OXY 3-9, Cyt⁶-OXY 2-9, OXY 1-8 and OXY 1-7. In contrast, only C-terminal fragments, Cyt⁶-Arg⁸-VP 4-9, Cyt⁶-Arg⁸-VP 3-9 and Cyt⁶-Arg⁸-VP 2-9, were found by incubating Arg⁸-VP. The formation of C-terminal OXY and VP fragments was prevented by the aminopeptidase inhibitors amastatin and bestatin, while the formation of OXY 1-7 and OXY 1-8 was inhibited by Hg²⁺ and Zn²⁺ ions. The formation of OXY 1-7 was also partially prevented by the endopeptidase inhibitor phosphoramidon. The formation of both C- and N-terminal fragments was inhibited by o-phenanthroline. The results suggest that, unlike VP, OXY is metabolized by both membrane-bound aminopeptidases and endopeptidases.

167.6

SUBSTANCE P-METABOLISM *IN VIVO* BY MICRODIALYSIS AND ON-LINE CONTINUOUS FLOW-FAST ATOM BOMBARDMENT MASS SPECTROMETRY. P.E. Andrén and R.M. Caprioli*. Department of Psychiatry at Ulleråker, University of Uppsala, S-750 17 Uppsala, Sweden and Analytical Chemistry Center, University of Texas Medical School, P.O. Box 20708, Houston, TX 77225

The putative role of substance P (SP) as a neurotransmitter has focused interest on the mechanisms of its inactivation. Many purified enzymes have been shown to hydrolyse the SP-molecule *in vitro* at a variety of peptide bonds. However, it is not known how these enzymes function *in vivo*. The combination of microdialysis and continuous flow-fast atom bombardment (CF-FAB) mass spectrometry allows endogenous aqueous samples to be introduced directly into the mass spectrometer, so that direct and on-line monitoring capabilities can be effectively used. The purpose of the present study was to assess the feasibility of *in vivo* microdialysis as a technique coupled on-line to a mass spectrometer, which enables continuous monitoring of biochemical events in brain extracellular space, and to study SP-metabolism *in vivo*.

Sprague-Dawley rats, anesthetized with pentobarbital, were fixed in a stereotaxic frame and a microdialysis probe with membrane length of 4 mm was implanted unilaterally in the striatum. The microdialysis probe was used to both introduce a bolus of SP (2.5 nmol/5 µL) as well as collect dialysate to measure reaction products. The perfusate from the microdialysis probe was connected directly onto the CF-FAB interface on the mass spectrometer. The present results showed that the SP-fragments 8-11, 9-11, 5-9 and 1-6 were the main metabolites formed when SP was infused into the striatum of the living rat. The SP-infusion also yielded the fragment 1-7, but in a smaller amount. It is concluded that the combination of microdialysis and CF-FAB mass spectrometry provides a useful technique for assay of *in vivo* protease activity.

DIFFERENTIAL EXPRESSION OF NEUTRAL ENDOPEPTIDASE-24.11 (NEP; "ENKEPHALINASE") IN NORMAL, TRANSPLANTED, AND MALIGNANT ASTROCYTES S.A. Back, M. Colon*, C.Y. Endo*, James H. Fallon, F. L. Meyskens, Jr.* and S. Loughlin. Departments of Pediatrics, Medicine, and Anatomy and Neurobiology, University of California, Irvine, CA 92717.

In the CNS of normal animals, NEP is largely expressed by neurons. However, primary human glioma cultures express NEP, suggesting a role for the enzyme in malignant states. We examined the expression of NEP in normal, transplanted and malignant astrocytes using histochemical localization of NEP combined with immunocytochemical localization of the glial marker GFAP.

In normal rat forebrain, little NEP label localized to GFAP-labeled astrocytes, except for occasional cells or processes in layer 1 of neocortex. No astrocytes contained NEP in the striatum. A separate group of animals was examined 5 weeks after receiving transplants of a mixed population of fetal cortical cells (ED 14) into the striatum. At the transplant site, a large encapsulated mixed tumor formed which caused a pronounced mass effect with compression of the lateral ventricle. The tumor contained several distinct populations of cellular elements which co-localized GFAP and NEP. NEP staining in the tumor was markedly greater than in the striatum or cortex on the transplanted or contralateral sides. This suggests that NEP expression is enhanced in glial elements in the tumor relative to normal striatal or cortical neurons. The human astrocytoma cell line U-373 was also used as a glial tumor model to study NEP expression. NEP localized to the cell surface and thin cellular processes suggesting that NEP is membrane-associated. The presence of NEP activity in these cells was confirmed by a colorimetric assay using glutaryl-L-ala-L-ala-phe-4-methoxy-2-naphthylamide as substrate. The cleavage of this substrate by NEP was confirmed by the potent blockade of substrate cleavage by two selective NEP inhibitors, phosphoramidon and JHF-26, with an ID 50 of 3nM and 1nM, respectively.

These studies support our previous work indicating that in the normal adult rat, NEP is almost exclusively localized to neurons. However, astrocytes show markedly enhanced levels of NEP when they display features of deregulated growth and differentiation. SPECIES DIFFERENCES IN THE PHARMACOLOGY OF 5-HT₂ BINDING SITES. D.L. Nelson, V.L. Lucaites*, and D.B. Wainscott*. Lilly Res. Labs., Lilly Corporate Center, Indianapolis, IN 46285, U.S.A.

Both functional (1) and binding (2) assays have suggested species differences in the pharmacology of the 5-HT₂ receptor. Based on this, the objective of the present study was to examine structural features that allow compounds to discriminate between 5-HT₂ receptors from different species. The 5-HT₂ receptors were measured by [³H]ketanserin binding to cerebral cortical membranes from rat, pig, and monkey. Initial studies were carried out to verify that there was no significant binding of [³H]ketanserin to tetrabenazine-sensitive sites in these tissues and to establish conditions to block [³H]ketanserin binding to α -adrenergic receptors. When these conditions were met, it was found that certain ergoline-containing structures could differentially discriminate between 5-HT₂ sites from different species and that this was based, in part, on differences in substituents at the N1 position. Compounds with an N1 isopropyl substituent (LY53857 and LY237733) showed 4-6 fold higher affinity at 5-HT₂ sites in rat membranes than in pig and monkey. Even an N1 substituent as small as methyl produced selectivity for the rat. In contrast, homologs containing an N1 hydrogen (LY86057 and LY193525) had an approximately 10-fold greater affinity for the pig and monkey 5-HT₂ binding sites than for the rat. These data emphasize that species differences in receptor pharmacology must be considered when developing subtype-selective agents and that the rat, though commonly used, is not necessarily the best species on which to base drug design.

CLONING AND NUCLEOTIDE SEQUENCE OF HUMAN(5-HT) TYPE 2 RECEPTOR. Radonna J. Tritch*, Deborah L. Robinson*, Barbara G. Sahagan, Robert A. Horlick*. The DuPont Merck Pharmaceutical Co., Biotechnology and CNS Research, Wilmington De.,19880-0400.

Serotonin (5-HT) is a neurotransmitter that interacts with a family of distinct receptors and mediates diverse physiological responses. The sequence of the rat and Chinese hamster 5HT₂ receptors have been reported (Julius et al. (1990) PNAS 87, 928-932; Chambard et al. (1990) NAR 18, 5282). Here we report the nucleotide sequence of the human 5HT₂ receptor. Using oligonucleotide primers derived from the rat sequence, we have been able to use Polymerase Chain Reaction (PCR) technology to amplify the cDNA for the human 5HT₂ receptor. The human amino acid sequence shares an overall 91% identity to both the rat and Chinese hamster sequences.

168.5

HUMAN 5-HT₂ RECEPTOR ENCODED BY A MULTIPLE INTRON-EXON CONTAINING GENE. W. Yang, K. Chen*, J. Grimsby* and J.C. Shih, Dept. of Mol. Pharm. and Tox., Sch. of Pharm., Univ. of South. Calif., L.A. Ca. 90033.

We have recently cloned a human 5-HT₂ receptor gene. Since the 5-HT₂ receptor gene has been assigned on the human chromosome 13 (Sparks et al., Genomes 9:461, 1991) two human chromosome 13 specific lambda phage libraries (ATCC) were screened. From the library containing EcoRI digested genomic DNA, two positive clones with an insert size of 8.5 and 7.0 kb were isolated. Extensive subcloning and sequencing of these clones showed that the 8.5 kb insert contained exons 1 and 2 of 5-HT₂ receptor gene and the 7.0 kb insert contained a part of the third exon. Using the positive fragment in the third exon as a probe, another lambda phage library constructed by HindIII digested genomic DNA was screened. A positive clone which contained a 9 kb insert was isolated and contained the rest of the coding region in exon 3. Sequencing analysis revealed that this human 5-HT₂ receptor also consisted of 471 amino acid as in the rat and mouse. The deduced amino acid sequence in these three species shares about 90% identity. The intron and exon organization of human and mouse 5-HT₂ receptor gene are identical: they span at least 20Kb and consists of 3 exons. 168.2

BINDING OF TYPICAL AND ATYPICAL ANTIPSYCHOTIC AGENTS TO 5-HT_{1C} RECEPTORS. B.L. Roth**, H.Y. Meltzer** and R.D. Ciaranello*. *Nancy Pritzker Laboratory, Department of Psychiatry, Stanford University and **Department of Psychiatry, Case Western Reserve University School of Medicine, Cleveland, OH 44106.

Clozapine and similar atypical antipsychotic agents are characterized by their relative preferences for 5-HT₂, as opposed to D₂ receptors (Meltzer et al, JPET, 1989). Because of the close structural, pharmacologic and functional similarities between the 5-HT₂ and 5-HT_{1C} receptors, we determined whether a number of putative atypical antipsychotic agents bind to 5-HT_{1C} receptors as well.

For these experiments 5-HT_{1C} and 5-HT₂ radioligand binding was performed as previously detailed (Roth et al, 1987; 1991) on rat brain membranes under site-specific conditions or in COS-7 cells transiently transfected with a 5-HT_{1C} cDNA using the vector pSVK3-5HT1c. 12 different atypical agents were studied: setoperone, clozapine, ritanserin, risperidone, tenilapine, rilapine, tiosperone, fluperlapine, SCH23390, amperozide and melperone. Although some of the agents tested showed high affinities for the 5-HT_{1C} receptors (K_d's < 50 nM: clozapine, ritanserin, SCH23390) many did not (K_d's > 50 nM: setoperone, risperidone, tenilapine, tiosperone, fluperlapine, amperozide, melperone). The atypical nature of these compounds appeared to be better predicted by their binding to 5-HT₂ rather than 5-HT_{1C} receptors.

DIFFERENTIAL RADIOLIGAND BINDING PROPERTIES OF [³H]-5-HYDROXYTRYPTAMINE AND [³H]-MESULERGINE IN A CLONAL 5-HYDROXYTRYPTAMINE CELL LINE. S. Havlik and S.J. Peroutka. Department of Neurology, Stanford University, Stanford, CA 94305.

[³H]-5-HT and [³H]-mesulergine were used to label 5-HT_{1C} receptors expressed in NIH 3T3 mouse fibroblast cells. Saturation analysis of the radioligand data indicate that [³H]-5-HT binding is biphasic. A 2-site model of radioligand binding is significantly more consistent with the data than a 1-site model (p < 0.01). The K_D values of [³H]-5-HT for 2 populations were 0.5 ± 0.1 nM and 8.8 ± 1 nM, while the B_{max} values were 400 ± 100 pmol/g protein and 3700 ± 800 pmol/g protein, respectively. Saturation analysis of [³H]-mesulergine is monophasic with K_D = 4.2 ± 0.4 nM and B_{max} = 8800 ± 600 pmol/g protein. Similar significant differences in apparent B_{max} values were obtained by "cold" saturation analysis. Drug competition studies confirm that both [³H]-5-HT and [³H]-mesulergine label at least 2 subpopulations of 5-HT_{1C} receptors in NIH 3T3 cells. These data demonstrate that at least 3 distinct populations of 5-HT_{1C} receptors in NIH 3T3 cells can be differentiated by radioligand binding techniques.

168.6

CLONED SEROTONIN 5HT₂ RECEPTOR: PHOSPHOINOSITIDE TURNOVER AND GTP INSENSITIVE DOB BINDING. E.G. Szele, J. Zhong, and D.B. Pritchett Children's Seashore House, and Department of Pharmacology, Univ. of PA, Philadelphia, PA, 19104.

Serotonin-2 (5-HT₂) receptors are thought to mediate phosphoinositide turnover by interaction with a GTP binding protein. Addition of non-hydrolysable GTP analogues have been shown to convert the receptor to a low affinity state. We transfected mammalian 293 cells, which normally do not express serotonin receptors, with DNA encoding the 5-HT₂ receptor to assess the binding of ligands and the effect of GTP analogues on that binding. After transfection, Scatchard transformation of saturation binding to cell membranes with [³H]-Ketanserin (a 5-HT₂ receptor specific antagonist) revealed a linear, single-site with a K_d of 0.4 ± 0.01 nM and a B_{max} of 557 ± 80 fmol/mg protein. [³H]-1-(4-Bromo-2,5-dimethoxyphenyl)-2-amino-propane ([³H]-DOB) (a 5-HT₂ receptor specific agonist) saturation binding generated curvilinear Scatchard plots which were best fit by a two-site model with a high affinity K_d of 0.5 nM (B_{max}=40 fmol/mg protein) and a low affinity K_d of 3.0 nM (B_{max}=122 fmol/mg protein). Concentrations of GTPγS or GppNHp as high as 10⁻⁴ M decreased [³H]-DOB by less than 10% and had negligible effects on [³H]-Ketanserin binding. ATPγS had no effect on binding of either compound. However, 5-HT and DOI were effective in stimulating transfected 5-HT₂ receptors to increase phosphoinositide (PI) hydrolysis 5 fold and 8 fold, respectively. These results show that the cloned serotonin receptor is capable of binding agonists as well as antagonists and that it has two affinity states for [³H]-DOB. The lack of non-hydrolysable GTP analogue effects together with the robust PI turnover indicates that these receptors couple to a novel G protein possibly G_q which is insensitive to these compounds.

168.7

EFFECT OF ANTIDEPRESSANT TREATMENT ON SEROTONIN₂ RECEPTOR-MEDIATED CALCIUM MOBILIZATION IN RAT GLIOMA C6BU-1 CELLS. S. Muraoka*, M. Mikuni, A. Kagaya, K. Saitoh*, M. Ikeda and K. Takahashi. Div. Mental Disorder Res., Natl. Inst. Neurosci. NCNP. Kodaira Tokyo, 187 Japan.

It is known that there exists serotonin₂ receptors to couple to phosphoinositide hydrolysis in rat glioma C6BU-1 cells. We have now characterized serotonin₂ receptor-stimulated intracellular calcium mobilization and investigated an effect of antidepressants on the calcium movement in C6-BU-1. Serotonin increased intracellular calcium in a dose dependent manner and it was antagonized by ketanserin (KET) with an IC₅₀ of 1nM, indicating the response was mediated by serotonin₂ receptors. In the presence of clomipramine (CMI), it inhibited 10uM serotonin-induced response with an IC₅₀ of 800nM, and haloperidol (HPD) had similar effect. When C6BU-1 was pretreated with CMI, HPD or KET for 2hr followed by washing, they inhibited the response to 30, 80 or 80%, respectively. Coexposure of KET and CMI showed the similar inhibitory effect as CMI alone. These results indicate that CMI can inhibit serotonin-induced calcium movement by affecting intracellular signaling system, rather than receptor blocking action.

168.9

ENHANCEMENT OF SEROTONIN₂ RECEPTOR-STIMULATED INTRACELLULAR CALCIUM MOBILIZATION IN HUMAN PLATELETS. A. Kagaya, M. Mikuni, S. Yamawaki*, and K. Takahashi. Div. Mental Disorder Res., Natl. Inst. Neurosci., NCNP. Tokyo, 187 and Dept. Neurol. Psychiat. Hiroshima Univ. Sch. Med. Hiroshima, 734 Japan.

We recently investigated serotonin₂ receptor-mediated calcium mobilization in human platelets. To make the mechanism of the receptor function clear, we have studied the modulation of serotonin₂ receptor-mediated calcium movement using fura-2. An alpha₂-adrenergic agonist norepinephrine, when pretreated 3 min prior, enhanced the response to serotonin up to 120%. This enhancement was not abolished by treatment with 2mM EGTA, indicating that this facilitation was from internal storage sites. W-7, one of naphthalenesulfonamide derivatives also potentiated the serotonin-induced calcium response up to 145%, and the potentiation was inhibited by chelating extracellular calcium, suggesting that the W-7-induced enhancement was influx from extracellular calcium. Thus, serotonin₂ receptor can be enhanced from different pathways to the same effector system.

168.11

EFFECTS OF VARIOUS SEROTONIN RECEPTOR SUBTYPE SELECTIVE ANTAGONISTS ON m-CPP-INDUCED INCREASES IN PLASMA PROLACTIN AND CORTICOSTERONE LEVELS IN RATS. T. Tolliver*, C. S. Aulakh*, J. L. Hill*, J. Tolliver, and D. L. Murphy*. Lab. of Clinical Science, National Institute of Mental Health, Bethesda, MD 20892.

Administration of m-CPP (a post synaptic 5-HT receptor agonist) to rats increases plasma concentrations of prolactin and corticosterone. In the present study, we investigated the role of various 5-HT receptor subtypes in mediating m-CPP-induced increases in plasma prolactin and corticosterone in male Wistar rats. Saline or various doses of each antagonist were injected intraperitoneally (i.p.) 15 min prior to administering saline or m-CPP. Animals were sacrificed 30 min after injection of saline or m-CPP. Administration of m-CPP (2.5 mg/kg) significantly increased plasma concentrations of prolactin and corticosterone compared to saline treatment. Pretreatment with nonselective 5-HT antagonist metergoline, and with the partially selective 5-HT_{1C} antagonists mesulergine and mianserin attenuated m-CPP-induced increases in plasma prolactin but not corticosterone. On the other hand, pretreatment with 5-HT_{1B} antagonists iocyanopindolol and CG361, the 5-HT_{1A} antagonist spiperone, the 5-HT_{1A} and 5-HT_{1B} antagonist propranolol, the 5-HT₂ antagonist ritanserin, and the 5-HT₃ antagonists ICS 205930 and MDL-72222 did not affect m-CPP-induced increases in either plasma prolactin or corticosterone levels. These findings suggest that m-CPP-induced increases in plasma prolactin are mediated by stimulation of 5-HT_{1C} receptors while non-serotonergic mechanisms may be involved in m-CPP's effects on plasma corticosterone.

168.8

RESPONSIVENESS OF 5-HT-2 RECEPTOR-MEDIATED CALCIUM MOBILIZATION IS INCREASED IN PLATELETS OF DEPRESSED PATIENTS AND IN C6 GLIOMA CELLS PRETREATED WITH DEXAMETHASONE. M. Mikuni, A. Kagaya, S. Muraoka* and K. Takahashi. Div. Mental Disorder Res., Natl. Inst. Neurosci., NCNP, Tokyo, Japan.

The increase in intracellular Ca concentration induced by 10uM 5-HT in platelets from 11 normal controls was 105±6nM, while that from 11 depressed patients was 129±4nM. This result is consistent with our previous observation that 5-HT-stimulated inositol phospholipid hydrolysis in platelets from depressed patients is greater than that of normal controls, suggesting that 5-HT-2 receptor function in platelets is enhanced in patients with affective disorders. On the other hand, we found that 5-HT-2 receptors were responsible for activating Ca mobilization in C6 glioma cells, and that 48-hour treatment with 100nM dexamethasone enhanced 5-HT-induced Ca mobilization in this clonal cells. Co-treatment with 1uM Ru38486 and dexamethasone inhibited this dexamethasone-induced enhancement, whereas Ru alone did not alter 5-HT-induced Ca mobilization in C6 cells. Taken together, these results suggest that the disinhibition of HPA axis may be in part, responsible for enhancing 5-HT-2 receptor function in affective disorders.

168.10

INVOLVEMENT OF 5-HT₂ RECEPTORS IN PHARMACOLOGICAL EFFECTS OF NAFTIDROFURYL OXALATE

T. Nabeshima¹, K. Niwa², M. Hiramatsu², K. Fujii² and T. Kameyama². ¹Dept. Hospital Pharmacy, Nagoya Univ. Sch. Med., Nagoya 466, Japan and ²Dept. Chem. Pharmacol., Meijo Univ., Nagoya 468, Japan.

Naftidrofuryl oxalate (LS-121) has been used as a therapeutic drug for improving cerebral circulation. In behavioral studies, LS-121 has been reported to have anti-amnesic effects on several animal models. We have suggested the involvement of serotonergic neuronal systems in the anti-amnesic action of LS-121 against the amnesia induced by 5-hydroxytryptophan (5-HTP) and cycloheximide, since LS-121 has affinity only for 5-HT₂ receptors among several receptors in the rat synaptic membrane. In the present experiment to confirm the effects of LS-121 on 5-HT₂ receptors, the effects of LS-121 on 5-HT₂ receptors in the discrete brain areas by using quantitative autoradiography and on (5-HTP + pargyline)-induced head-twitch response were investigated. LS-121 inhibited the [³H] ketanserin binding in the frontal cortex (IC₅₀: 1.53x10⁻⁷ M), cingulate cortex, nucleus accumbens, caudate-putamen and hippocampus. The potency of LS-121 was less than those of methysergide (9.13x10⁻⁹ M) and ritanserin (2.69x10⁻⁹ M). LS-121 inhibited (5-HTP + pargyline)-induced head-twitch response in a dose dependent fashion. These results suggested that LS-121 affects the 5-HT₂ receptors as an antagonist and these effects may be responsible for its pharmacological effects.

168.12

PROTEIN KINASE C AND 5-HT₂ RECEPTORS IN THE SECRETION AND ACTION OF THYROID 5-HT. H. Tamir, K. P. Liu*, M. Adlersberg*, S.H. Hsiung*, P.Y. Yu*, and M.D. Gershon. Div. Neurosci., N.Y. State Psych. Inst. and Dept. Anat. and Cell Biol. Columbia University, P&S, N.Y., NY 10032.

Thyroid follicles are comprised of follicular (F) and parafollicular (PF) cells. Thyrotropin (TSH) or ↑ [Ca²⁺]_e induce PF cells to secrete 5-HT, which activates F cells. 5-HT secretion was studied in MTC cells, a PF-derived cell line. Ca²⁺-dependent secretion of 5-HT was induced by forskolin, dibutyryl (db)-cAMP, or cholera toxin; however, neither TSH nor ↑ [Ca²⁺]_e increased cAMP. Instead, TSH and ↑ [Ca²⁺]_e increased [Ca²⁺]_i. Acute treatment with phorbol esters stimulated 5-HT secretion; staurosporin (0.1 nM) and down-regulation of protein kinase C (PKC) by chronic exposure to phorbol ester antagonized the TSH-induced secretion of 5-HT (but not that due to ↑ [Ca²⁺]_e or db-cAMP). The actions of 5-HT were investigated on FRTL-5 cells, a F-derived cell line. Membranes from FRTL-5 cells bound the 5-HT₂ probe, [¹²⁵I]-DOI, specifically, saturably, and with high affinity; [¹²⁵I]-DOI binding was inhibited by GTP-γ-S. 5-HT increased cAMP, phosphoinositide (PI) turnover, and [Ca²⁺]_i in FRTL-5 cells; these actions were blocked by ketanserin, spiperone, and (except ↑ cAMP) pertussis toxin (PTx). Immunostaining with an anti-idiotypic antibody confirmed the presence of 5-HT₂ receptors on FRTL-5 cells. It is concluded that 5-HT is released from MTC cells by PKC-dependent and PKC-independent mechanisms. 5-HT activates FRTL-5 cell 5-HT₂ receptors, which are coupled via a PTx-sensitive G protein to PI turnover. The 5-HT₂ effect of 5-HT on cAMP is probably indirect. Supported by NIMH grant 37575 and NIH grant NS 12969.

MEDIATION OF ENHANCED SKF 38393-INDUCED ORAL ACTIVITY BY A SEROTONIN SYSTEM. L. Gong*, E.A. Daigneault and R.M. Kostrzewa. Dept. of Pharmacology, College of Medicine, East Tennessee State Univ., Johnson City, TN 37614.

A neonatal 6-hydroxydopamine (6-OHDA) lesion of nigro-striatal dopamine (DA) neurons is accompanied by serotonin (5-HT) fiber hyperinnervation of the striatum. This study was done, to test whether the 5-HT system could mediate supersensitization of DA D1 agonist-induced oral activity. Rats received 6-OHDA (134 µg, half in each lateral ventricle) at 3d after birth and were studied as adults. An enhanced oral response to the 5-HT_{1C} receptor agonist, m-chlorophenylpiperazine (mCPP) was noted in lesioned vs. control rats. Neither 8-hydroxy-2-(di-n-propyl-amino)tetralin (8-OH-DPAT) nor CGS-12066B, respective 5-HT_{1A} and 1B agonists, induced oral activity. The mCPP-induced oral response was attenuated by mianserin, a 5-HT_{1C} receptor antagonist, but not by ketanserin or MDL 72222, 5-HT₂ and 5-HT₃ receptor antagonists, respectively. The DA D1 receptor antagonist, SCH 23390, failed to attenuate mCPP-induced oral activity, but mianserin effectively attenuated the oral response to SKF 38393, a DA D1 receptor agonist. These findings demonstrate concurrent supersensitization of a 5-HT system after lesion of a DA system. Also, this 5-HT system is found to mediate the supersensitized response of DA D1 receptors. (Supported by the Scottish Rite Schizophrenia Research Foundation)

5-HT_{1C} MEDIATED EFFECTS ON APOMORPHINE-INDUCED LOCOMOTOR ACTIVITY. P.B. Hicks, R.J. Zavadny* and K.A. Young. Department of Psychiatry, Scott & White Hospital/Foundation; Departments of Medical Pharmacology and Medical Anatomy and Neurobiology, Texas A&M College of Medicine, Temple, Texas, 76708.

Serotonin (5-HT) neurotransmission, mediated by various 5-HT receptor subtypes, modifies certain aspects of behavior associated with dopamine (DA) neurotransmission. We determined the effect of the 5-HT_{1C/2} agonist DOI and the 5-HT_{1C/2} antagonist mesulergine on apomorphine-induced locomotor activity (AILA) in the rat and compared the results to the AILA effects of ketanserin, a 5-HT₂ antagonist. Serotonergic compounds and apomorphine (0.25 mg/kg) were administered SC and locomotor activities (line crossings) were monitored by videotape in 5 min intervals for 30 min. The 5-HT₂ antagonist ketanserin suppressed AILA. The 5-HT_{1C/2} antagonist mesulergine potentiated AILA at a low dose (0.1 mg/kg) that had no effect on spontaneous locomotor activity. It is expected that at this dose, mesulergine would be more active at 5-HT_{1C} receptors. At higher doses of mesulergine (0.5-1.0 mg/kg), a 5-HT₂ antagonist effect to depress locomotor activity predominates (as demonstrated by ketanserin-induced suppression of AILA). The 5-HT_{1C/2} agonist DOI (1.0 mg/kg), which has a higher affinity for 5-HT_{1C} than 5-HT₂ receptors, blocked the AILA stimulation produced by low-doses of the 5-HT_{1C/2} antagonist mesulergine. This combination treatment resulted in locomotor activity similar to the control group which received apomorphine only. Therefore, the AILA potentiation of low-dose mesulergine is most likely mediated by 5-HT_{1C} receptors. These findings suggest a prominent role for 5-HT_{1C} receptors in the modulation of behaviors associated with DA neurotransmission in the nucleus accumbens.

5-HT₂ RECEPTORS ARE LINKED TO PHOSPHATIDYLINOSITOL TURNOVER IN A NOVEL CELL LINE DERIVED FROM RAT CORTEX. B.J. Ebersole¹, K.A. Berg¹, R. McKay³, and S. Maayani^{1,2}. ¹Depts. of Anesthesiology and ²Pharmacology, Mt. Sinai School of Medicine of CUNY, NY, NY 10029 and ³ Dept. of Biology and Brain & Cognitive Science, MIT, Cambridge, MA 02139.

A novel cell line, A1A1, derived from embryonic rat cortex, was used as a model to study signal transduction systems associated with receptors for 5-hydroxytryptamine (5-HT) in the CNS. Cells were placed in serum-free medium two days before use to minimize effects of the serum present in the growth medium. In cells prelabeled for 48 hrs. with [³H]-myo-inositol, exposure to 5-HT (EC₅₀ = 700 nM) for 10 min. resulted in a 3-fold increase in the amount of [³H]-inositol phosphates ([³H]IPs) accumulated in the presence of 20 mM LiCl. The response to 1 µM 5-HT was blocked by 10 nM spiperone and 10 nM ketanserin, indicating a response mediated by 5-HT₂, rather than 5-HT_{1C}, receptors. Both quipazine and DOI were partial agonists, with intrinsic activities of 0.15 and 0.4, respectively. Pre-treating the cultures for 24 hrs. with 1 µM phorbol 12-myristate 13-acetate (PMA), a condition that promotes down-regulation of protein kinase C (PKC), resulted in a greatly enhanced response to 5-HT (7-fold stimulation), while a 15 min. pre-treatment with PMA, a condition that activates PKC, resulted in a complete loss of 5-HT-stimulated accumulation of [³H]IPs. These results indicate that the 5-HT₂ receptor linked to phosphatidylinositol turnover in A1A1 cells can be modulated by PKC. (Supported by GM34852, DA06620, and NS21991).

THE PLATELET SHAPE CHANGE REACTION: CHARACTERIZATION AND POTENTIAL USEFULNESS AS A MARKER OF AFFECTIVE DISORDERS. J.R. Magliozzi, D.W. Gietzen, and R.J. Maddock*. Depts. of Psychiatry, University of California, Davis Sch. of Med., Sacramento, CA and University of New Mexico Sch. of Med., Albuquerque, NM.

Blood platelets possess a number of attributes of neuronal cells which may be amenable to investigation in neuropsychiatric disease. Among these is a receptor for serotonin which resembles the brain 5HT₂ receptor. In normal human subjects, this receptor mediates a shape transition from discoid to spheroid which can be monitored by light scattering, using slight modifications of standard platelet aggregometry methods. The shape change reaction is characterized by inhibition by ketanserin and spiperone at low nanomolar concentrations, but not by the 5HT₃ inhibitors ICS-205930 and MDL-72222. The reaction was not affected by extracellular EGTA at a concentration range of 0.01-1.0 mM or EDTA at a concentration range of 0.01-170 mM. In a series of 10 patients with unipolar major depression and 10 normal control subjects the velocity of the phase transition one second after addition of 1 micromolar 5HT was affected by age (b' = -0.62; p = 0.004), with a trend noted for the effect of diagnostic group (unipolar major depression vs. control subject; 1.0 ± 0.45 (S.E.M.) mv s⁻¹ vs. 3.0 ± 0.71 mv s⁻¹). These preliminary data suggest the platelet shape change reaction may be a useful marker for the 5HT₂ receptor and its associated effector system function in human affective disorders.

168.16

REGULATION OF cAMP FORMATION BY 5-HT₂ RECEPTOR ACTIVATION IN THE A1A1 CELL LINE. K.A. Berg¹, B.J. Ebersole¹, W.P. Clarke², R. McKay³, and S. Maayani^{1,2}. Depts. of ¹Anesthesiology and ²Pharmacology, Mt. Sinai School of Medicine, CUNY, NY, NY 10029 and ³Dept. of Biology and Brain & Cognitive Sciences, MIT, Cambridge, MA 02139.

The effects of 5-HT₂ receptor activation on cAMP formation were studied in a cell line derived from embryonic rat cortex (A1A1). 5-HT (EC₅₀ = 350 nM) enhanced the amount of cAMP (2.5-6 fold) formed in response to 1 µM forskolin (FSK) after 15 min of co-incubation in the presence of a PDE inhibitor. The effect of 5-HT was blocked by 10 nM ketanserin and 10 nM spiperone indicating a response mediated by the 5-HT₂ receptor subtype. Similarly, 5-HT potentiated the amount of cAMP accumulated in response to cholera toxin and 5'-N-ethylcarboxamidoadenosine (NECA; an adenosine A₂ receptor agonist). After a 15 min co-incubation, the PKC activator phorbol 12-myristate 13-acetate (PMA) increased cAMP formed in response to FSK and NECA. After a 15 min pre-incubation with PMA, a condition which results in a loss of 5-HT stimulated PI turnover in these cells (Ebersole et al., this volume), 5-HT increased forskolin- and NECA-stimulated cAMP levels. Following exposure to PMA for 24 hrs, a condition which promotes PKC down-regulation, 5-HT still enhanced cAMP formation in response to FSK and NECA while the potentiating effects of PMA were reduced or abolished. These data suggest that 5-HT₂ receptor activation regulates cAMP formation in A1A1 cells by a mechanism(s) in addition to PI turnover and PKC activation. (Support: GM34852 and NS21991)

ELEVATION OF CATECHOLAMINERGIC METABOLITE LEVELS IN THE RAT HYPOTHALAMUS BY AN AGONIST OF SEROTONIN 1C/2 RECEPTORS, MK212 (6-chloro-2-(1-piperazinyl) pyrazine). D.A. Mayle*, D.W. Robertson and D.T. Wong. Lilly Research Laboratories, Eli Lilly and Company, Lilly Corporate Center, Indianapolis, IN 46285

MK212, an agonist at both the 5HT_{1C} and the 5HT₂ serotonin receptor subtypes (1), was injected intraperitoneally into male Harlan Sprague Dawley rats (130-160g), and levels of norepinephrine (NE), serotonin (5HT), dopamine (DA) and their metabolites were measured in the rat hypothalamus. MK212 (0; 0.5; 1.0; 2.0; 4.0; 6.0; 10.0 mg/kg i.p.), administered 30 minutes before sacrifice, caused dose-dependent increases in dopamine (DA), its metabolite, 3,4-dihydroxyphenylacetic acid, and the metabolite of NE, 3-methoxy-4-hydroxy-phenylglycol sulfate. The time course of MK212 revealed a peak in DA and metabolite levels between 15 and 30 minutes after injection, with a return to control levels two hours after injection. These increases were effectively attenuated by prior administration of serotonergic antagonists, such as metergoline (0.1-0.6 mg/kg i.p.), mianserin (1.0-10.0 mg/kg i.p.), LY53857 (0.3-3.0 mg/kg i.p.), and ketanserin (ineffective at 0.1-0.3 mg/kg, but effective at 1.0 mg/kg i.p.). These indices implicate either an increase in both NE turnover in noradrenergic neurons and DA turnover in dopaminergic neurons, or simply an increase in NE turnover in noradrenergic neurons (2), due to the activation of serotonin receptors. Serotonergic modulation of NE from rat hypothalamic slices has been demonstrated *in vitro* (3); moreover, the present study supports the possibility of serotonergic modulation of noradrenergic and/or dopaminergic neurons, mediated by the activation of 5HT_{1C} / 5HT₂ receptors, *in vivo*.

RADIOIODINATED (R)-DOI AS AN *IN VIVO* LIGAND FOR BRAIN SEROTONIN RECEPTORS. C.A. Mathis and A. Biegon, Lawrence Berkeley Laboratory, University of California, Berkeley, CA 94720.

The feasibility of using radioiodinated (R)-2,5-dimethoxy-4-iodoamphetamine ((R)-DOI) as an *in vivo* SPECT imaging agent for brain serotonin receptors was examined with *in vivo* autoradiography in the rat and *in vitro* autoradiography in postmortem human brain. Following the tail vein injection of (R)-[¹²⁵I]DOI (specific activity 2175 Ci/mmol), the ligand readily crossed the blood-brain-barrier and accumulated in the rat brain, with cortex-to-blood ratios of ~5:1 at 1 h. The percent of the injected dose found in the brain at 5 min and 1 h were 0.7% and 0.4%, respectively. The distribution of radioactivity at 1 h following injection of 60-250 μCi/kg was similar to the distribution of serotonin 5-HT₂ and 5-HT_{1C} receptors. High levels were found in the cortex, known to be enriched in 5-HT₂ receptors, and in the choroid plexus which has high concentrations of 5-HT_{1C} receptors. Ketanserin, a selective 5-HT₂ antagonist, injected 10 min before (R)-[¹²⁵I]DOI, produced a dose dependent reduction in brain radioactivity *in vivo*. At doses around 500 μCi/kg, (R)-[¹²⁵I]DOI appeared to lose its specificity, as a high density of radiolabeling appeared over the thalamus which equaled or exceeded cortical binding. In the postmortem human brain, (R)-[¹²⁵I]DOI binding was fully displaceable by excess ketanserin. Specific binding was highest in human cortex, particularly occipital cortex. Only moderate to low levels were found in subcortical regions. This pattern is in good agreement with the known autoradiographic distribution of 5-HT₂ receptors in the human brain postmortem. The above results indicate that (R)-[¹²⁵I]DOI may be a useful agent for imaging 5-HT receptors *in vivo*, albeit within a limited dose/concentration range.

AGONIST-INDUCED DESENSITIZATION OF 5-HT₂ RECEPTOR-MEDIATED PHOSPHOINOSITIDE TURNOVER IN CEREBELLAR NEURONS. J. Akiyoshi¹ and D.-M. Chuang, Biological Psychiatry Branch, NIMH, Bethesda, MD 20892

We have previously shown that cerebellar granule cells express 5-HT₂ receptor-mediated phosphoinositide (PI) hydrolysis. The maximal stimulation of 5-HT-induced inositol phosphate accumulation was about 700% of the control and occurred at 10 μM of this agonist. In the study, we investigated agonist-induced desensitization and changes in 5-HT₂ receptor binding sites. Prestimulation of granule cells with 10 μM 5-HT induced a time-dependent decrease of 5-HT-induced PI hydrolysis. This desensitization was evident at 0.5 hr and reached its maximum (about 90% decrease) at 8 hr. Similar time-dependent desensitization of the PI response to 5-HT was observed when DOI (1-(2,5)-dimethoxy-4-iodophenyl-2-aminopropane) was used as the prestimulating receptor agonist; however, DOI appeared to have considerable toxicity for these cerebellar neurons, after more than 8-hr pretreatment. Unexpectedly, 5-HT-induced desensitization was not associated with a decrease in [³H]-ketanserin binding. In fact, a small but significant increase in [³H]-ketanserin binding occurred after 5-HT pretreatment. This observation is in contrast to that found in carbachol-induced homologous desensitization of the PI response in which marked loss of muscarinic receptor sites occurred after treatment with carbachol for more than 2 hr and progressed with the pretreatment time. Molecular events underlying 5-HT-induced desensitization and changes in receptor binding are under investigation.

RADIOLABELLING OF MULTIPLE AGONIST AFFINITY STATES OF BRAIN AND CLONED 5HT_{1C} SEROTONIN RECEPTORS. S. Leonhardt and M. Teitler, Dept. of Pharmacology & Toxicology, Albany Medical College, 47 New Scotland Avenue, Albany, New York 12208.

5HT_{1C} receptors have been detected with radioligand binding assays using various radioligands (1) and have been cloned and expressed in transfected cells (2). Although this receptor is functionally, pharmacologically and structurally closely related to 5HT₂ receptors, there are some striking differences in radiolabelling properties. For instance, 5HT_{1C} receptors can be labelled with [³H]-serotonin, while 5HT₂ receptors cannot. Detailed studies of the molecular and pharmacological properties of brain and cloned 5HT_{1C} receptors using both antagonist and agonist radioligands were conducted in order to investigate the presence, properties, and levels of different agonist affinity states. Saturation studies with [³H]-mesulergine and [¹²⁵I]-DOI revealed a lower B_{max} value for specific [¹²⁵I]-DOI binding to 5HT_{1C} receptors than for [³H]-mesulergine binding in membranes prepared from pig choroid plexus and NIH-3T3 cells expressing 5HT_{1C} receptors derived from transfection with a 5HT_{1C} cDNA. Binding assays in brain and transfected cell membrane homogenates revealed the presence of two agonist affinity states. These and other studies to be presented reveal molecular similarities and some intriguing differences between radiolabelled 5HT_{1C} and 5HT₂ receptors. The differences may be helpful in designing 5HT_{1C} specific agonist and antagonist ligands for studies aimed at determining the functionality of the brain 5HT_{1C} receptor.

EFFECTS OF AGONISTS, PARTIAL AGONISTS AND ANTAGONISTS ON 5-HT₂ RECEPTORS IN P11 CELLS R. C. Ferry, C. D. Unsworth* and P. B. Molinoff, Dept. of Pharm., Univ. of Pennsylvania Sch. of Med., Phila., PA 19104.

Central 5-HT₂ receptors fail to exhibit traditional adaptive/compensatory mechanisms. Although administration of agonists *in vivo* leads to a decrease in 5-HT₂ receptor levels, 5-HT₂ receptors fail to up-regulate following removal of synaptic input or depletion of 5-HT stores. Administration of antagonists leads to a paradoxical decrease in the density of 5-HT₂ receptors. It is not known whether the anomalous behavior of the 5-HT₂ receptor is due to a unique regulatory mechanism or is the result of complexities inherent in the use of *in vivo* models. P11 cells, which express a high density of 5-HT₂ receptors coupled to PI hydrolysis, were used as a model system to study the regulation of 5-HT₂ receptors on cultured cells. Treatment of P11 cells with 1 or 10 μM 5-HT resulted in a 50% reduction in the number of 5-HT₂ receptors as measured by binding of [³H]-ketanserin or [¹²⁵I]-LSD. Following removal of 5-HT, the density of receptors returned to control levels within 24 hr. P11 cells were also treated with the partial agonists LSD and DOI. Scatchard analyses of the binding of [³H]-ketanserin revealed that exposure to 100 nM LSD or 100 nM DOI led to a reduction in the density of receptors on P11 cells of 30 to 40%, which is comparable to the effect of the full agonist 5-HT. In contrast to studies carried out *in vivo*, the 5-HT₂ receptor antagonist ketanserin failed to elicit a change in the density of 5-HT₂ receptors. No change in the apparent affinity of the receptors for [³H]-ketanserin or [¹²⁵I]-LSD was observed following any of the above treatment regimens, indicating that the observed change in B_{max} was not a consequence of residual drug. P11 cells represent a useful model system with which to study the regulation of 5-HT₂ receptors. (USPHS Grant MH 48125)

168.22

COMPARISON OF THE MOLECULAR REGULATION AND PHARMACOLOGY OF 5-HT₂ RECEPTORS IN BRAIN AND SMOOTH MUSCLE CELLS. L. Rydelek-Fitzgerald¹, B.D. Wilcox², M. Teitler¹, and J.J. Jeffrey², ¹Dept. of Pharm/Tox and ²Dept. of Medicine, Albany Medical College Albany, NY 12208

Recently, serotonin was found to be necessary for collagenase production in rat and human uterine smooth muscle cells. Preliminary pharmacological studies suggested that serotonin may be mediating this effect through the 5-HT₂ receptor. In order to definitively establish the presence and functionality of uterine smooth muscle 5-HT₂ receptors, radioligand binding studies were performed in primary cultures of rat uterine smooth muscle cells. Competition of serotonergic agonists and antagonists for the 5-HT₂ receptor agonist radioligand [¹²⁵I]DOI demonstrated that the uterine receptor has the same pharmacology as the 5-HT₂ receptor in the rat brain. Further, 5-HT₂ receptor mRNA transcripts from rat uterine smooth muscle cell cultures were similar in size to those found in the rat brain. Dose-response relationships with 5-HT₂ agonists in the uterine smooth muscle cell cultures were determined using an ELISA to measure collagenase production. Serotonin and DOI stimulate collagenase production in a dose-dependent manner, indicating these cells should prove valuable in determining 5-HT₂ receptor agonist potency and efficacy. 5-HT₂ receptor agonists (5-HT, DOI, quipazine) induced collagenase mRNA in rat uterine smooth muscle cell cultures. In addition, the agonists increased 5-HT₂ receptor mRNA. The changes in collagenase and 5-HT₂ receptor mRNA were blocked by the antagonists, ketanserin and spiperone. Thus, this *in vitro* culture system represents a unique model for the study of the molecular biology of 5-HT₂ receptor regulation. Future studies will assess the levels of 5-HT₂ receptors in cell cultures and *in vivo* to determine whether these levels are regulated to control collagenase production.

HISTAMINE RELEASES NOREPINEPHRINE FROM THE PARAVENTRICULAR NUCLEUS/ANTERIOR HYPOTHALAMUS REGION IN THE CONSCIOUS RAT. S. L. Bealer, Dept. Physiol., Univ. Tennessee, Memphis, TN 38163

Histamine (HA) increases norepinephrine (NE) release from brain slices and synaptosomes. The present study determined if HA also increases extracellular concentrations of NE in the paraventricular/ anterior hypothalamic region (PV/AH) of the conscious rat. A microdialysis probe was positioned adjacent to the PV/AH 24 hr prior to the experiment. During testing, microdialysis probes were perfused with artificial cerebrospinal fluid (ACSF) and dialysate was collected during two 45-minute control periods. ACSF containing HA was then perfused for two 45-min periods followed by one 45-min recovery period. Dialysate NE concentrations were subsequently measured using radioenzymatic assay. Control dialysate NE concentration (23 ± 5 pg/ml) was significantly increased during dialysis with ACSF containing 1, 3, and 10 μ g/ml HA (120 ± 15 pg NE/ml; 560 ± 25 pg NE/ml; and 1575 ± 175 pg NE/ml, respectively). Dialysate NE concentration returned to control levels during the recovery period. These data demonstrate that HA increases extracellular concentrations of NE in the PV/AH region of the brain, possibly through release of neuronal stores. (Supported by USPHS Grant HL-25877 and American Heart Association Grant 88-1103)

H₃-HISTAMINE RECEPTORS ACTIVATE K⁺ CHANNELS TO HYPERPOLARIZE MAGNOCELLULAR HISTAMINERGIC NEURONS OF RAT POSTERIOR HYPOTHALAMUS. Q.Z. Yang and G.I. Hatton, Neuroscience Program, Michigan State Univ., East Lansing, MI 48824.

Brain neuronal histamine (HA) emanates from the magnocellular neurons of the tuberomammillary (TM) nuclei in the posterior hypothalamus. This relatively small group of neurons projects to almost all brain areas, in some of which evidence exists for HA autoreceptors. We have investigated the possibility that HA receptors play a role in the control of the HAergic neurons themselves. Intracellular recordings were made of 30 magnocellular neurons in hypothalamic slices containing the rostral portion of the ventral TM subnucleus (TMVr), virtually all of which have been shown immunocytochemically to be HAergic. Bath-applied HA (10^{-6} M) depressed both spontaneous and current evoked spikes and hyperpolarized TMVr cells. These effects were selectively mimicked by α -methylHA (H₃ agonist) and selectively antagonized by imipridine (H₃ antagonist). With synaptic transmission blocked by 9.3 mM Mg²⁺, 0.05 mM Ca²⁺, HA produced a hyperpolarization (5-40 mV) which was antagonized by the K⁺ channel blocker 4-aminopyridine. Na⁺ channel blockade with TTX (1μ M) revealed Ca²⁺ spikes which broadened when TEA (5mM) was added to the medium. TEA prevented the hyperpolarizing effects of HA or α -methylHA that were seen in TTX or control medium. Lucifer Yellow injections of some cells confirmed their magnocellular morphology and TMVr location. We conclude that HAergic neurons have H₃ receptors linked to K⁺ channels and that these may serve a negative feedback function. Whether activation of these receptors is normally accomplished by recurrent axon collaterals or by inputs from nearby HAergic neurons is not known. Research supported by NIH grant NS16942.

169.5

INHIBITION OF HISTAMINE METHYLTRANSFERASE IN BRAIN ELEVATES LEVELS OF HISTAMINE AND PROMOTES ITS OXIDATION TO IMIDAZOLEACETIC ACID. G.D. Prell, A.M. Morrishow* and J.P. Green, Dept. Pharmacology, Mount Sinai Medical Center, CUNY, New York, New York, 10029

In the periphery, endogenous histamine is metabolized by two pathways: (a) oxidation by diamine oxidase, then aldehyde dehydrogenase (AldDH), to form imidazoleacetic acid (IAA), and (b) methylation by histamine methyltransferase (HMT) to form *tele*-methylhistamine (t-MH), which is oxidized by MAO-B, then AldDH, to *tele*-methylimidazoleacetic acid (t-MIAA). Under normal physiological conditions, histamine in brain is mainly, if not solely, methylated by HMT.

Since we discovered IAA present endogenously in brain using GC-MS, we re-investigated the possibility that IAA in brain derives from histamine. In rats injected (icv) with small, physiological amounts of ³H-histamine, radioactivity was recovered mainly as unchanged histamine or as t-MH or t-MIAA, confirming that, in brain, histamine is normally methylated. In rats infused (>4 weeks using osmotic minipumps) with α -fluoromethylhistidine (>7.5 mg/kg/day), the irreversible inhibitor of histamine's synthetic enzyme, histidine decarboxylase, brain levels of HA, t-MH and t-MIAA were reduced up to 90%, compared to rats infused with saline. Levels of IAA were unchanged, indicating that histamine is not a physiological precursor for IAA in brain. However, 2h after rats were injected (i.p.) with inhibitors of HMT (e.g. metoprine, or drugs used in Alzheimer's disease: THA, 1-hydroxyTHA or physostigmine), cortical levels of histamine's methylated metabolites declined, while levels of histamine and IAA increased. Also, ³H-histamine (icv), in large, non-physiological quantities, was converted to labelled IAA, t-MH and t-MIAA. It appeared that as quantities of histamine increased, so did the extent of oxidation. These results confirm that under normal conditions, histamine does not form IAA in brain. But when HMT is inhibited, or when histamine is present in large quantities, IAA can derive from histamine through an alternative metabolic pathway. Since IAA is a potent GABA_A agonist, the consequences of inhibition of HMT may not be confined to the histaminergic system. [Research supported by NINDS NS-28012]

ADRENAL HORMONES AND CIRCADIAN VARIATION ON THE HYPOTHALAMIC HISTAMINE ACTIVITY IN RATS. A. Gillich & M. J. Meaney, Douglas Hospital Res. Ctr., Depts. of Neurology and Neurosurgery & Psychiatry, McGill Univ., Montreal H4H 1R3, Canada.

Histaminergic cell bodies, found within the posterior hypothalamus, appear to be involved in the regulation of CRF release from neurons within the paraventricular nucleus (PVN). In these studies, we examined the diurnal variation in histamine content in relation to plasma glucocorticoid levels in several brain regions. Long Evans rats were sacrificed at 8PM, 12AM, and 8AM. The PVN, the periventricular nucleus, median eminence, supraoptic nucleus, suprachiasmatic nucleus, mammillary nucleus, and the posterior hypo-thalamus were isolated by the punch technique and assayed for histamine using a single label radioenzymatic technique. We found that the highest histamine levels occurred in all areas during the early AM periods except for the posterior hypothalamus. Long Evans rats were then either adrenalectomized (ADX) or sham operated. After 7 days of treatment with various levels of corticosterone replacement, the ADX animals were sacrificed and histamine levels were measured in the same brain regions. The results showed that 1) ADX caused a decreased histamine levels in all areas examined, and 2) these effects could not be totally reversed by corticosterone replacement even with the administration of high stress levels of corticosterone. These findings suggest that the diurnal variation in hypothalamic histamine activity occurs independently of glucocorticoid influences. Current studies are underway to examine other substances which may influence histamine activity.

169.4

MODULATION OF TSH SECRETION BY MANIPULATION OF HYPOTHALAMIC HISTAMINE LEVELS. L. Tuomisto¹, R. Tuominen² and P. Männistö^{1,2}, Dept. of Pharmacol. and Toxicol., ¹Univ. of Kuopio, P.O.B. 1627, SF-70211 Kuopio, and ²Univ. of Helsinki, Helsinki, Finland.

There is some indication of inhibitory but indirect influence of histaminergic systems in the regulation of thyrotropin (TSH) secretion. In this study histamine synthesis inhibitor α -fluoro-methylhistidine (FMH, 100 mg/kg 24 h and 50 mg/kg 4 h before, i.p.) and catabolism inhibitor metoprine (20 mg/kg 5 h before, i.p.), were given to male rats. After a cold-stress (60 min at +4°C), hypothalamic histamine was measured by HPLC post-column derivatization method, and hypothalamic TRH and plasma TSH and prolactin by radioimmunoassay. Hypothalamic histamine was significantly decreased by FMH and increased by metoprine. TRH was decreased by cold stimulation, and this decrease was prevented by metoprine. TSH was increased about fivefold by cold-stimulation, and neither FMH nor metoprine significantly influenced the cold response, although there was a facilitatory trend after FMH. Also prolactin increased after cold-stimulation. Both FMH and metoprine inhibited this response. Metoprine also decreased basal prolactin level. The results do not disagree with the previous data that the overall role of histamine in the cold-response of TSH may be inhibitory, but the net effect is not marked. However, the discrepancy between TRH and TSH suggests that factors other than histaminergic inhibition of TRH release are also involved.

THE EFFECT OF THIOPERAMIDE ON *EX VIVO* [³H](R)- α -METHYLHISTAMINE BINDING TO BRAIN HISTAMINE H₃ RECEPTORS. S.J. Taylor and G.J. Kilpatrick. Glaxo Group Research, Park Road, Ware, Herts SG12 0DP, U.K.

The selective histamine H₃ receptor agonist [³H](R)- α -methylhistamine ([³H]RAMH) has been shown to label H₃ receptors in brain tissue homogenates (Arrang et al., 1987; Kilpatrick and Michel, 1991). Using the *ex vivo* binding approach we have examined the effect of prior treatment with the H₃ receptor antagonist thioperamide on this binding.

Rats (male, Lister Hooded, 250-300g) were pretreated with thioperamide (0.02-10 mg/kg i.p.) at various times before being anaesthetised and transcardially perfused with HEPES buffer. Cerebral cortices were dissected and [³H]RAMH binding assessed as previously described (Kilpatrick and Michel, 1991) except that the tissue washing stage was omitted.

Thioperamide pretreatment markedly inhibited specific [³H]RAMH binding, peak inhibition was observed 30min after dosing. Significant inhibition was apparent at doses of 0.2 mg/kg and above. At 30min, the apparent ED₅₀ for thioperamide was 1.5 mg/kg. At doses of 2.5 and 10 mg/kg significant inhibition was evident for at least 4 hours. These values were not corrected for the 75 fold tissue dilution that was necessary for the binding assay.

We conclude that *ex vivo* [³H]RAMH binding may be useful in determining the central penetration and time course of agents which interact with the H₃ receptor.

HISTAMINERGIC MODULATION OF HIPPOCAMPAL ACETYLCHOLINE RELEASE. T. Mochizuki, A. Yamatodani, K. Okakura, A. Horii* and H. Wada*. Dept. Pharmacol.II & Dept. *Otolaryngol., Faculty of Med., Osaka Univ., Osaka 530, Japan

In the rat, a dense accumulation of histaminergic fibers is found in the diagonal band and medial septal nucleus, where cholinergic neurons with projections to the hippocampus are located. For examination of the modulatory effects of histaminergic inputs on this cholinergic system, hippocampal acetylcholine (ACh) release was determined by *in vivo* microdialysis after electrical stimulation of the tuberomammillary nucleus (TM), where the cell bodies of the histaminergic neurons are situated. Male Wistar rats were anesthetized with urethane, a microdialysis probe was implanted into the CA1-CA3 region. The mean basal ACh release was 0.98±0.04 pmol/20min. Electrical stimulation (200µA) of the TM resulted in a 1.8-fold increase of the release. This enhancement was dependent on the current intensity and was suppressed significantly after administration of α -fluoromethylhistidine (100mg/kg, i.p.), a specific and irreversible inhibitor of histidine decarboxylase. An H₁-receptor blocker, pyrilamine (5mg/kg, i.p.) also decreased this enhanced release. On the other hand, hippocampal ACh release increased after administration of thioperamide (5mg/kg, i.p.), a specific H₃-autoreceptor blocker. These results indicate that hippocampal ACh release is modulated by the central histaminergic system, possibly through H₁-receptors.

INHERITED IMPAIRMENT OF PURINE RECYCLING IN THE MOUSE: CONSEQUENCES FOR BRAIN PURINE AND DOPAMINE SYSTEMS. H.A. Jinnah, T. Page, and T. Friedmann*. Depts of Neurosciences and Pediatrics, Center for Molecular Genetics, UCSD School of Medicine, La Jolla, CA 92093.

Hypoxanthine-guanine phosphoribosyltransferase (HPRT) is an enzyme required for recycling the purine bases hypoxanthine and guanine into utilizable purine nucleotides. Strains of mice carrying mutations of the HPRT gene offer a unique tool for studying the biologic consequences of reduced purine recycling in the brain. One of these mouse strains carries a deletion in the HPRT gene and has been maintained congenic with the C57BL/6J strain for 10 generations. A second strain carries a retrovirally-induced disruption of the HPRT gene on an inbred 129/SvEv background. Total purine pools measured by HPLC-UV after microwave irradiation were significantly reduced in brains of both HPRT-deficient mouse strains. For example, ATP and GTP levels were reduced by 36.0% and 32.2% in the HPRT-deficient C57BL/6J mice, and by 49.3% and 51.3% in the HPRT-deficient 129/SvEv mice. HPLC-EC analysis revealed brain dopamine levels were reduced by 30-40%, while the levels of norepinephrine, serotonin, and monoamine metabolites were unaffected in whole brain extracts. Regional analysis revealed dopamine levels were most severely reduced in the caudoputamen. These data show that impairment of purine salvage leads to a reduction in brain purines as well as a potential deficit in dopamine-mediated neurotransmission in the brain. These abnormalities are similar to those which are thought to occur in HPRT-deficient human patients with Lesch-Nyhan syndrome.

169.10

MODULATION OF EXTRACELLULAR ATP⁴⁺ (P₂)_U PURINOCEPTOR RESPONSES: ROLE OF PROTEIN KINASE. L. Tennen* and B.R. Talamo. Neuroscience Program; Tufts Univ. School of Medicine, Boston, MA 02111.

ATP is stored and cosecreted with many neurotransmitters and may itself act as a neurotransmitter or modulator. In rat parotid acinar cells, extracellular ATP elevates intracellular calcium (Ca_i) by activating influx of extracellular Ca, probably through a non-selective cation channel. Previous studies have identified this receptor as a P₂-purinoceptor for ATP⁴⁺. Evidence for modulation of these P₂-purinoceptor responses was obtained in studies with inhibitors of protein kinases. Preincubation with the catalytic-site inhibitors K252a and staurosporine, as well as the regulatory domain inhibitor sphingosine, specifically potentiated the elevation in Ca_i mediated by extracellular ATP but had no effect on the Ca_i elevation mediated by muscarinic receptors through phospholipase C activation. The lag time for the potentiation, coupled with the observation that K252a, a membrane impermeant analog of K252a, failed to alter the ATP response suggests that intracellular kinases are involved. Neither the peak intracellular Ca_i²⁺ mobilization nor the sustained Ca_i²⁺ entry in response to carbachol or to a Ca_i²⁺ ionophore (BrA23187) were altered by these inhibitors of kinases, supporting the idea that the effect on the ATP⁴⁺ response was due to enhanced Ca_i²⁺ influx through a P₂-specific route. Studies showing that ATP⁴⁺ increases Mn²⁺ influx support this interpretation. Neither H-7, which potently inhibits protein kinase C (PKC), nor phorbol dibutyrate (PDBu), which activates PKC, had any modulatory effect on ATP-mediated Ca_i²⁺ influx. These observations, coupled with the fact that PDBu did not reverse the effects of sphingosine, argue against the involvement of PKC. Furthermore W-7, a potent inhibitor of Ca/Calmodulin kinase, was ineffective. These results strongly suggest for the first time that P₂-responses (or purinoceptors) can be modulated and that a novel purinoceptor-associated kinase may alter the response to ATP⁴⁺ in parotid cells.

CURRENTS EVOKED BY ADENOSINE 5'-TRIPHOSPHATE IN GUINEA PIG CELIAC GANGLION CELLS. V. Gerzanich, S. Matsumoto¹, R.A. North and E.M. Silinsky². Vollum Institute and ¹Department of Anatomy, Dental School, Oregon Health Sciences University, Portland, OR97201 and ²Department of Pharmacology, Northwestern University, Chicago, IL60611.

Currents activated by ATP (0.2 - 30 µM) in cultured celiac neurons were measured using whole-cell and outside-out patch-clamp technique; pipets contained mostly cesium gluconate, and no ATP or GTP. Whole-cell currents were inward at negative potential and reversed at 0 mV; conductance for inward currents was three times less than for outward. Currents evoked by ATP were reduced by reactive blue 2 or by prior exposure to desensitizing concentrations of α , β -methylene-ATP; they were unaffected by hexamethonium, (+)-tubocurarine or ondansetron at concentrations that blocked similar currents evoked by acetylcholine or 5-hydroxytryptamine (5-HT). The potency of adenosine analogs was 2-methylthio-ATP >ATP \geq α , β -methylene-ATP > β , γ -methylene-ATP >ADP >AMP >>adenosine. Channels in excised patches showed very flickery openings and had a conductance of 22 pS at -50 mV; outward currents were not seen. Channel activity was not affected by nicotinic and 5-HT₃ selective antagonists. It is concluded that ATP opens ligand-gated cation channels in guinea pig celiac neurons; the receptor is pharmacologically most like the P_{2Y} subtype.

ACCUMULATION OF EXOGENOUS POLYAMINES IN THE BRAIN AFTER ISCHEMIA. V.H. Gilad, G.M. Gilad and R.J. Wyatt. NPB, NIMH Neuroscience Center at St. Elizabeths, Washington, DC 20032.

Brain ischemia leads to increased putrescine (Put) synthesis and content while spermidine (Spd) and spermine (Spm) remain unchanged. Nevertheless, extracellular levels of all polyamines (PA) remain unchanged at levels lower than 1 µM. Injections of PA to gerbils after ischemia can protect forebrain neurons from degeneration. Now we sought to determine if PA accumulation from the circulation into the brain and then into brain cells is increased after ischemia. When [³H]-Put was injected (i.v.) 5 h after transient global ischemia its accumulation in the hippocampus increased within 1 h to 174% of control. Auto-radiography after [³H]-Spd injections also demonstrated increased accumulation in brain parenchyma. In hippocampal slices a temperature-dependent uptake was observed only for Spm and it was transiently increased after ischemia, peaking (150% of control) at 12-13 h and subsiding at 24 h. We conclude that after ischemia, accumulation of exogenous PA is increased both via the (compromised) blood brain barrier and by active cellular uptake mechanisms.

Brain Family of Aromatic Amine N-Acetyltransferases
S. J. Gauger and M. A. Nambodiri, Molecular
Neurobiology Laboratory, Department of Biology,
Georgetown University, Washington, DC 20057

The purification of the N-acetyltransferase (NAT) activity from the rat brain has elucidated a family of NATs. A spectrum of NAT activity is observed from arylamine to arylalkylamine specificity. Using an affinity column composed of methotrexate, we have observed different species of NATs based upon their chromatographic behavior. A NAT which is characterized as an arylalkylamine NAT, based upon its specificity towards arylalkylamine substrates, is observed in the effluent of the affinity step, while the arylamine NAT, so called due to its preference towards arylamine substrates, is only observed following soluble methotrexate elution. A third species of NAT is also detected. This NAT also is observed in the effluent and demonstrates affinity for both classes of aromatic amine substrates. These species of NAT can be distinguished by employing other physical parameters as well. The arylalkylamine NAT found in the affinity effluent demonstrates a similar size exclusion HPLC pattern as that seen in the pineal. Two arylalkylamine NAT peaks are observed having apparent molecular weights of 100-KDa and 10-KDa, while a third peak corresponding to 30-KDa demonstrates broad aromatic amine substrate specificity. The other two NATs have an apparent molecular weight around 40-KDa using three size exclusion HPLC columns in series. These two NATs can be further distinguished by their sensitivity to methotrexate inhibition. The NAT which is specifically eluted from the affinity column has a methotrexate IC_{50} value of 62.5 μ M, while the other NAT appears insensitive to methotrexate inhibition in the high micromolar range. Further studies will continue to examine the physiological significance of these NAT activities in the brain as well as the possible interrelationship between these NAT proteins.

COPPER DISTINGUISHES TWO FORMS OF THE HALOPERIDOL-SENSITIVE SIGMA RECEPTOR. Mark Connor* and Charles Chavkin, Dept of Pharmacology, Univ of Washington, Seattle WA 98195

Two subtypes of the haloperidol-sensitive sigma receptor have recently been characterized in guinea pig and rat brain membranes by radioligand binding assays. We now report that radioligand binding to the sigma-1 site (characterized by a high affinity for haloperidol, (+)pentazocine and (+)3-PPP) is also highly sensitive to Cu^{2+} (as $CuSO_4$), whereas the sigma-2 site is relatively insensitive to Cu^{2+} . Cu^{2+} displaced 3 nM [3H]-DTG in a biphasic manner from both rat and guinea pig brain membranes with an IC_{50} of approximately 20 μ M at sigma-1 sites and greater than 10 mM at sigma 2 sites. Zn^{2+} (as SO_4 and Cl_2) has a similar potency to Cu^{2+} at the sigma-1 site but did not discriminate well between the sites. None of the other divalent cations tested (Co^{2+} , Cd^{2+} , Mg^{2+} , Mn^{2+} , Ca^{2+}) were as potent or as selective as Cu^{2+} in displacing [3H]-DTG from haloperidol-sensitive sigma receptors. A fixed concentration of 100 μ M Cu^{2+} blocks the ability of haloperidol, (+)3-PPP and (+)pentazocine to compete with [3H]-DTG for binding to the high affinity sigma site in both rat and guinea pig membranes. The IC_{50} values for (+)3-PPP and (+)pentazocine displacing 3 nM [3H]-DTG from the copper sensitive site in guinea pig are about 13 nM and 4 nM respectively, which are in agreement with previously published values for these drugs at the sigma-1 receptor. In rat, DTG has an IC_{50} value vs 3 nM [3H]-DTG at the high affinity site of 12 nM, which also corresponds well with previously published values. These results suggest that the haloperidol-sensitive sigma binding site which is sensitive to the presence of Cu^{2+} corresponds to the sigma-1 site identified previously. Supported by MH 46501.

NEUROTRANSMITTER MODULATION: EXCITATORY AND INHIBITORY TRANSMITTERS

170.1

MODULATION OF SOMATIC GLYCINE-LIKE IMMUNOREACTIVITY IN PRESUMED GLYCINERGIC NEURONS
R. Wickesberg¹, D. Whitton² and D. Oertel¹, ¹Department of Neurophysiology, ²Waisman Center, University of Wisconsin, Madison, WI 53706.

Intracellular recordings have shown that the projection from the dorsal to the ventral cochlear nucleus is inhibitory. Because the inhibition is blocked by 0.5 μ M strychnine, it is probably glycinergic. In brain slices from mice, the cell bodies of origin for this projection lose their glycine-like immunoreactivity after being maintained *in vitro* for 7 or 8 hrs without electrical stimulation. The loss of immunoreactivity is prevented by continuous stimulation of the auditory nerve (100 μ s shocks, 2/sec), axotomy, or the presence of 0.8 μ M tetrodotoxin, 1 μ M strychnine, 50 μ M colchicine, or 50 μ M β -lumlcolchicine in the bathing saline. The presence of only 5 μ M colchicine does not prevent the loss. After 7 hours *in vitro* without stimulation, the somatic immunoreactivity can be regained by stimulating the auditory nerve for 20 min. The other neurons in the cochlear nuclei, even those that may be glycinergic, respond differently to these manipulations or not at all, and no signs of deterioration were observed. The immunostaining of puncta, which resemble synaptic terminals, appears unaffected by these experiments. These results indicate that in presumably glycinergic neurons, glycine is transferred out of the immunoreactive somatic pool in the absence of synaptic input and that this transfer is blocked by various toxins.

COMPARISON OF CENTRAL AND PERIPHERAL 2-[^{125}I]-I-DOMELATONIN BINDING SITES. M. Viswanathan, J.T. Laitinen, A.M. Seltzer, and J.M. Saavedra. Section on Pharmacology, Laboratory of Clinical Science, National Institute of Mental Health, Bethesda, MD 20892

Quantitative autoradiography was used to compare certain biochemical and pharmacological characteristics of 2-[^{125}I]-iodomelatonin binding in the following tissues: chick retina, pituitary of 10 days-old Sprague-Dawley rats, and suprachiasmatic nuclei, area postrema, anterior cerebral artery, and caudal artery of adult rats. Sections of respective tissues were cut in a cryostat at -17 $^{\circ}C$, thaw-mounted onto gelatin-coated slides, and dried. Tissue sections were incubated with 2-[^{125}I]-iodomelatonin (100 pM) in the presence or absence of melatonin (1 μ M) for 60 min in 50 mM Tris-HCl buffer (pH 7.4) containing 4 mM $CaCl_2$. The effects of dithiothreitol (DTT) which reduces disulfide bridges of proteins or N-ethylmaleimide (NEM) which alkylates sulphhydryl groups of the G-protein alpha-subunit were examined. Low concentrations of DTT (0.1 - 2 mM) in the incubation medium had very little effect on 2-[^{125}I]-iodomelatonin binding at all sites except in the anterior pituitary where the amount of binding was significantly increased. Conversely, NEM (0.5 mM) reduced the amount of 2-[^{125}I]-iodomelatonin binding (33-58% of control) in all tissues. The affinities of various serotonin and melatonin analogues for binding sites in all the tissues studied were also similar. We conclude that the biochemical and pharmacological characteristics of the binding sites studied were not distinctly different from one another when compared under the same assay conditions.

169.16

DEPOLARIZATION-INDUCED RELEASE OF AN ENDOGENOUS LIGAND FOR THE HALOPERIDOL-SENSITIVE SIGMA RECEPTOR FROM RAT BRAIN. Charles Chavkin, Mark Connor* and John Neumaier¹, Dept of Pharmacology and Dept of Psychiatry and Behavioral Sciences², University of Washington, Seattle, WA 98195.

The haloperidol-sensitive sigma receptor is a membrane binding site for a group of psychotomimetic and potentially antipsychotic drugs. Endogenous factors that bind to the haloperidol-sensitive sigma receptor have been detected in brain extracts, and radioligand displacement assays have provided indirect evidence of the presence of an endogenous transmitter for the sigma receptor in brain. We now report that depolarization of rat brain slices releases an endogenous sigma factor into the superfusion buffer. Fresh rat brain slices (200 μ m) were perfused with oxygenated Krebs-bicarbonate buffer (ACSF) and the perfusate was desalted, concentrated and resolved by C18-HPLC. Sigma activity present was quantified by competition binding assay utilizing rat brain membranes and [3H]-DTG. Depolarization of the tissue slices by perfusion with 50 mM KCl caused a 270 \pm 28% increase in the amount of sigma activity recovered (n=4). The sigma activity released co-eluted with a small, nonpeptide factor purified from guinea pig brain extracts. When Mg^{2+} was substituted for Ca^{2+} in the ACSF, depolarization by high potassium failed to induce release of the putative factor (the amount recovered was 89 \pm 12% of control, n=4). The depolarization-induced, calcium-dependent release of a sigma factor supports the hypothesis that the molecule purified from brain extracts may be an endogenous neurotransmitter at the haloperidol-sensitive sigma receptor. Supported by MH46501.

170.2

DEVELOPMENT AND USE OF AN *IN VITRO* PUSH-PULL PERFUSION TECHNIQUE TO MEASURE NEUROTRANSMITTER RELEASE FROM RESTRICTED PERFUSED AREAS OF THE BRAIN SLICE PREPARATION.
B. Anton, M.S. Levine and N. Buchwald. Mental Retardation Research Center, UCLA School of Medicine, Los Angeles, CA 90024.

The present research describes the use of an *in vitro* push-pull perfusion technique that allows measurements of neurotransmitter release from the surface of brain slices (500 μ m). The technique employs a tip-modified concentric push-pull cannula similar to that designed by Philippu et al. (Naunyn-Schmiedeberg's Arch. Pharm. 276, 1973) in which the inner tube (liquid infusion) is shielded within the outer pull tubing in order to minimize tissue erosion during perfusion. The probe is coupled through sylistic tubes to a peristaltic (manostat) liquid pumping system in which the pull system opens to the atmospheric pressure, thus avoiding tissue resistance changes that induce tissue damage and decrease viability of perfused tissue (Neuouillon et al. J. Neurochem. 28, 1977). The slice is placed in a perfused liquid-gas interface chamber. The probe is placed on the surface of the slice to allow administration and sampling of chemicals into a defined area. In an application of the methodology, the resting and K^{+} -stimulated (50mM) 3H -GABA release profiles during extended perfusion periods (up to 3 hr) were characterized in rat and cat brain slices. Two areas of the brain were assessed, the neostriatum and the frontal cortex. In both structures, the K^{+} -evoked 3H -GABA release was partially dependent on the presence of external Ca^{2+} (up to 80%), suggesting a neuronal origin of the releasable amino acid. Additionally, in both species 3H -GABA uptake and K^{+} -evoked release was increased by up to 100% in neostriatum compared to prefrontal cortex. These regional differences in both 3H -GABA release parameters may result from increased GABAergic synaptic density in neostriatum compared to the prefrontal cortex. In summary, this perfusion method may have applications in correlative studies of neurotransmitter release and neuronal firing during specific physiologic and/or drug-altered conditions in the brain slice preparation. Supported by USPHS HD05958.

170.3

N-ACETYLASPARTATE UPTAKE AND METABOLISM BY RAT CEREBELLAR PRIMARY CELL CULTURES. O.H.Saab and J.H.Neale. Department of Biology, Georgetown University, Washington, DC 20057.

The function of N-Acetylaspartate (NAA), which is present in very high concentrations in the central nervous system, has not been elucidated. However, highly elevated levels of NAA have been found in the blood and urine of individuals with certain neurological disorders, such as Canavan disease, the apparent result of a deficiency in aspartoacylase. Immunohistochemical and other methods have indicated a predominantly neuronal localization of NAA in the adult rat brain. The objective of this study was to compare glial and neuronal cells from the rat cerebellum in terms of their uptake and metabolism of NAA. Rat cerebellar cells were maintained in dissociated culture for 9-24 days. The cells were incubated with ³H-NAA under different conditions. While glial cells demonstrated substantial uptake and rapid metabolism of exogenous NAA, granule cells did not show detectible uptake or metabolism. Thus, only the glial uptake of NAA was characterized. These data suggest a differential role between neurons and glia in the metabolism of NAA.

170.5

A TECHNIQUE FOR CONTINUOUSLY SAMPLING RELEASE OF AMINO ACIDS FROM BRAINSTEM SLICES DURING NEURON RECORDINGS. H. J. Waller and D. A. Godfrey, Depts. of Neurological Surgery¹, Otolaryngology², Anatomy³, and Physiology and Biophysics^{1,2}, Medical College of Ohio, Toledo, OH 43699.

We have developed a simple procedure that permits continuous sampling of perfusate in an interface slice chamber and which does not interfere with concurrent recordings of action potentials from rat dorsal cochlear nucleus. Approximately 1% of the perfusion effluent is diverted by means of a microsiphon, and droplets (e.g., 9.4 μ L) can be collected for subsequent measurements. Concentrations of several amino acids have been measured using HPLC. The tip of the microsiphon (polyethylene tubing, 0.61 mm. o.d.) is placed adjacent to but not in contact with the slice, downstream from the region under study. The tubing is supported at intake and collection ends by metal sleeves (20 ga. hypodermic tubing), and can be moved easily without interrupting fluid flow. Measurements were taken at various downstream and lateral positions to provide information about the sampling characteristics of the siphon.

Rates of release of measured amino acids were highest initially and decreased during an experiment. The release of some amino acids (e.g. glycine, serine) was sustained throughout the experiment, whereas that of others (e.g. glutamate, GABA) declined rapidly to low levels. (Supported by NIH grant DC00172.)

170.7

UPTAKE OF EXOGENOUS N-ACETYLSPARTYL-³H-GLUTAMATE AND ³H-GLUTAMATE BY MURINE BRAIN CELLS IN CULTURE. M. Cassidy and J. H. Neale. Department of Biology, Georgetown University, Washington, DC 20057

N-Acetylspartylglutamate (NAAG) is an acidic neuropeptide found in high concentration in the mammalian brain. It has been localized to synaptic vesicles and is released by depolarizing stimuli. Peptidase activities which hydrolyze NAAG to glutamate and N-acetylaspartate provide a mechanism of inactivation of the putative neurotransmitter NAAG, or synaptic activation of neurotransmitter glutamate, or both. Intact NAAG, however, is also taken up into cells in both pure glial cultures and mixed neuronal/glial cultures. ³H-NAAG and ³H-glutamate uptake in cultured murine cells were quantitated and partially characterized. Initial results indicate that the NAAG peptidase activity present in both types of cell cultures is not linked to ³H-glutamate uptake. These data support the hypothesis that a substantial portion of the glutamate released from NAAG in the extracellular space is transiently available for activation of acidic amino acid receptors.

HPLC-EC ASSAY FOR "FREE" GABA IN HUMAN CEREBROSPINAL FLUID. E. Vontzidou, A. Naini, and L.J. Cole. Columbia University, Dept of Neurology, New York, N.Y. 10032

Less than 2% of the total GABA in the CSF is "free" GABA, the remaining source of GABA is in bound form e.g. homocarnosine, homoanserine, and several other unknown conjugates. Most of the chromatographic techniques (isocratic or ion exchange) employed for the measurement of GABA in tissue extract or physiological fluids, use pre or post column derivatization of GABA with o-Phthalaldehyde (OPA) in the presence of β -mercaptoethanol (β -ME). We found that GABA-OPA- β -ME derivative is unstable and could not be used for the assay of GABA in CSF. In contrast, GABA forms a highly stable derivative with OPA (20mM) in the presence of t-butylthiol (40mM) at pH 9.5. Based on this finding, we have developed an isocratic HPLC-EC assay for GABA in the CSF. The derivative of GABA was separated on reversed phase C18 column with a mobile phase of 0.05M potassium phosphate containing 36% methanol and 5% ethyl acetate adjusted to pH of 6.75. GABA was detected using a Coulchem 5100A electrochemical detector (ESA) operating in an oxidative screening mode (detector 1; +0.25, detector 2; +0.60 volt). Concentrations as low as 0.5 pmoles could be accurately measured in 20 μ l injection volume. Recovery studies indicated an accuracy of close to 100% with high precision (between runs CV < 2%).

170.6

KAINIC ACID CAUSES A DISSOCIATION BETWEEN THE STEADY-STATE CONCENTRATION AND THE KCl-EVOKED RELEASE OF DYNORPHIN B AND GLUTAMATE FROM RAT HIPPOCAMPAL MOSSY FIBER SYNAPTOSOMES. J.N. Simpson, R.L. Gannon, J.F. McGinty, and D.M. Terrian. Dept. of Anatomy and Cell Biol., School of Medicine, East Carolina University, Greenville, NC 27858-4354.

In this experiment, the effects of intracerebroventricularly (ICV) administered kainic acid (KA) on the subsequent *in vitro* release of L-glutamate (GLU) and dynorphin B (dyn B) from isolated rat hippocampal mossy fiber synaptosomes were examined. Hippocampal mossy fiber synaptosomes were immediately prepared at 4.5 hrs, 20 hrs, or 48 hrs after ICV administration of 0.5 μ g/ μ l KA. A 35 mM KCl stimulus was applied to the synaptosomal preparation and the quantity of GLU and dyn B-like immunoreactivity released from the synaptosomes was measured fluorometrically and by radioimmunoassay (RIA), respectively. Hippocampal mossy fiber synaptosomal dyn B concentration was also measured by RIA. At 4.5 hrs, KA caused a 69% decrease in KCl-evoked release of dyn B as compared to control levels when the dyn B concentration in the synaptosomal fraction was decreased by 39%. At 20 hrs, the KCl-evoked release of dyn B remained 34% below control levels when the dyn B concentration in the synaptosomal fraction had increased to 46% above control levels. At 48 hrs, there continued to be a 41% decrease in the KCl-evoked release of dyn B when the dyn B concentration of the synaptosomal fraction remained elevated at 47% above control levels. In contrast, KA caused no change in the KCl-evoked release of GLU at 4.5 hrs as compared to control levels. However, there was a 40% decrease in the KCl-evoked release of GLU from mossy fiber synaptosomes at both the 20 and 48 hr time points. These data indicate a prolonged effect of ICV KA on neurotransmission at mossy fiber synapses in the rat hippocampus, resulting in a depression of the release of GLU as well as the opioid peptide, dyn B. The depression in dyn B release, coupled with increased preprodynorphin synthesis (Lason *et al.*, submitted), may both contribute to the elevated dyn B content in the mossy fiber synaptosomes observed at 20 and 48 hrs after KA injection. Supported by DA 03982 (J.F.M.) and AFOSR 89-0531 (D.M.T.)

170.8

GLUTAMATERGIC TRANSMISSION IN A MODEL OF ABSENCE SEIZURES. M.L. Cordero*, A.E. Negrón*, J.G. Ortiz, G. Santiago*, S. Cardona*, and M.T. García*. Dept. of Pharmacology, UPR School of Medicine, San Juan, Puerto Rico 00936-5067

GABAergic neurotransmission is altered in the C57BL/10Bg sps/sps mouse mutant; a model of generalized absence seizures (Ortiz *et al.*, 1990). In addition, glutamate dehydrogenase (GDH), and glutaminase (GLNase) activities are reduced in these mice. The apparent K_m for the high affinity ¹⁴C-GLU uptake (GLU) in the crude synaptosomal (P₂) fraction of adult (2 months old) normal SPS/SPS vs. sps/sps (absence seizure susceptible) mice (38.56 \pm 3.59 and 53.66 \pm 9.8 μ M, respectively) is not altered. In contrast, the U_{max} is increased in sps/sps mice (6.22 \pm 0.34 vs 15.98 \pm 1.99 nmoles/mg protein, $p < 0.05$). The regional binding of ³H-AP-7, ³H-kainic acid, and ³H proline to crude synaptosomal fraction is decreased in this mouse mutant. The reductions in (1) GDH and GLNase activities; (2) in the binding of the above mentioned ligands; and the increase in U_{max} for GLU uptake are consistent with increased EAA neurotransmission in this model of epilepsy. (Supported by the institutional MBRS/NIH and RCMI programs)

GLUTAMINE SYNTHETASE HOMEOSTASIS IN CULTURED ASTROCYTES. S.E. Farinelli* and W.J. Nicklas. UMDNJ-Robert Wood Johnson Medical School, Piscataway, NJ 08854.

Previously we have demonstrated that in cultured astrocytes, the metabolism of exogenous glutamate through both oxidative and glutamine synthetic pathways is dependent on the functional glutamine synthetase (GS) activity in the cells. In the present study we have determined the turnover rate of GS enzyme in the astrocyte coupled with measurements of GS mRNA levels. By pulsing cultures with methionine sulfoximine (MSO), an irreversible inhibitor of GS, and monitoring the timecourse of recovery of enzymatic activity it is possible to determine the rate of synthesis of new GS enzyme. We examined three conditions previously shown to increase the steady-state level of GS activity in astrocytes: maintaining cells in medium containing no glutamine (Gln), and treatment of the cultures with either hydrocortisone (HC, 1 μ M) or dibutyryl cAMP (dbcAMP, 0.5 mM). Elimination of Gln from the medium resulted in a two-fold increase in GS activity compared with those grown in medium containing 5 mM Gln. Both HC and dbcAMP treatment resulted in a 2-3 fold increase in GS activity. Following a pulse of MSO (1 mM for 2 hours) GS enzyme activity rebounded from zero to one-half its steady state level in approximately 2.5 days under all the conditions examined. GS mRNA levels were unaffected by MSO treatment and remained virtually constant throughout the 5 day recovery period. Elimination of Gln from the medium does not result in increased GS mRNA levels whereas in HC and dbcAMP treated cultures GS mRNA levels are elevated when compared with control cultures. This suggests alternative mechanisms of regulating GS activity, ones mediated by hormones and second messengers which act at the transcriptional level and another mediated by Gln, which acts at the translational or post-translational level.

DIFFERENTIAL EFFECTS OF TETANUS TOXIN ON INHIBITORY AND EXCITATORY NEUROTRANSMITTER RELEASE IN SPINAL CORD CELL CULTURES. L.C. Williamson, S.C. Fitzgerald*, and E. A. Neale. Laboratory of Developmental Neurobiology, NICHD, NIH, Bethesda, MD 20892.

Tetanus toxin is a potent neurotoxin which acts in the central nervous system to cause spastic paralysis, likely through disinhibition at the level of the motor neuron. Electrophysiologic analysis of toxin action in murine spinal cord neurons in cell culture demonstrated a short latent period followed by a phase of paroxysmal depolarizing events (PDE) associated with a gradual loss of inhibitory postsynaptic potentials. At greater than 10^{-11} g/ml toxin, the period of convulsant activity is followed by a loss of both spontaneous and evoked excitatory and inhibitory synaptic activity (Bergey et al., J. Neurosci. 3: 2310, 1983). This study examined the effect of tetanus toxin on stimulated and spontaneous release of glycine, GABA and glutamate during the course of toxin action, particularly during PDE. Cell cultures were labeled with 3 H-glycine, 3 H-GABA or 3 H-glutamate; the identity of released radiolabeled molecules was confirmed by TLC. Neurotransmitter release was stimulated by 56 mM K^+ in the presence of 2 mM Ca^{++} at various times after exposure to 10^{-7} g/ml (10^{-10} M) tetanus toxin. Stimulated release of glycine and GABA was blocked completely within 90 min; the stimulated release of glutamate was only partially blocked at this time, with a complete block by 6 hr. Spontaneously released neurotransmitter was measured at 30 min intervals after toxin exposure and examined relative to the radioactivity released from cultures in the presence of 1 μ M tetrodotoxin. The spontaneous synaptic release of GABA was blocked totally within 30 min and glycine, within 90 min. In contrast, the synaptic release of glutamate in toxin-exposed cultures was elevated to twice that of controls for 150 min. These studies indicate that toxin-induced convulsant activity can be defined by a reduction in the release of inhibitory neurotransmitters and a concomitant increase in the release of glutamate.

NOREPINEPHRINE AND DOPAMINE DIFFERENTIALLY MODULATE RESPONSES INDUCED BY EXCITATORY AMINO ACIDS IN DEVELOPING HUMAN CORTEX. Z. Radisavljevic, C. Cepeda, M.S. Levine and N.A. Buchwald. MRRC, UCLA-School of Medicine, Los Angeles, California 90024.

The human cerebral cortex is innervated richly by the neuromodulators norepinephrine (NE) and dopamine (DA). These catecholamines alter cortical excitability, at least in part, by modifying responses of cortical neurons to amino acid neurotransmitters. Experiments were performed to study the effects of NE and DA on cortical tissue resected surgically in cases of intractable childhood epilepsy. Tissue was obtained from patients of 7 months to 7 years of age. Brain slices (400 μ m) obtained from the cortical samples were maintained in physiological solutions using standard procedures. In these slices the effects of NE, its β -receptor agonist, isoproterenol and DA on responses evoked by iontophoretic application of excitatory amino acids (glutamate (GLU) and N-methyl-D-aspartate (NMDA)) were assessed. In different experiments GLU (0.2M, pH=8), NMDA (0.1M, pH=8), NE (0.2M, pH=5), isoproterenol (0.2M, pH=5) and DA (0.1M, pH=4.5) were applied iontophoretically in the vicinity of the recorded neuron (n=17). Iontophoretic application of GLU (Average current -155 ± 24 nA (S.E.)), and NMDA (-127 ± 22 nA) evoked membrane depolarizations and action potentials in cortical neurons. Simultaneous iontophoretic application of NE ($+142 \pm 25$ nA) or isoproterenol ($+125 \pm 25$ nA) enhanced responses (increased the frequency of action potentials and the duration of the response) evoked by GLU and NMDA. In contrast, application of DA ($+197 \pm 20$ nA) enhanced responses to NMDA (increased the frequency of evoked action potentials and the duration of the response), but decreased or eliminated responses to GLU. The differential effects of the two catecholamines may be important in assessing their possible roles in epileptogenic cortex.

ALPHA-KETOGLUTARATE TRANSPORT: A MECHANISM FOR REPLENISHING AND REGULATING THE TRANSMITTER POOL OF GLUTAMATE. R.P. Shank and D.J. Bennett*. CNS Research, The R. W. Johnson Pharmaceutical Research Institute, Spring House, PA 19477-0776

Alpha-ketoglutarate (α -KG) is avidly accumulated by synaptosomes, which represents one step in a putative metabolic pathway in which α -KG is supplied by astrocytes to neurons. The uptake of α -KG is mediated by a Na^+ -dependent transport process that exhibits complex kinetics. The results of a variety of experiments suggest that uptake is mediated primarily by a single system that exhibits negative cooperativity. This transport process is differentially affected by glutamate, glutamine, malate, membrane depolarization, and a soluble heat-labile substance in rat CNS extracts. Our results suggest that the α -KG transporter possesses two allosteric sites that regulate uptake. One of these is a negative modulatory site that reduces the affinity between α -KG and the transport binding site. Glutamate, malate, and α -KG itself interact with this site. The second site serves to positively modulate uptake by increasing the V_{max} . Glutamine and glutamate interact with this site. Glutamate at concentrations $\leq 3 \mu$ M enhances α -KG uptake, but at higher concentrations it inhibits uptake. Hence, glutamate appears to have a dual regulatory effect on the synaptic concentration of α -KG, one of its two primary immediate precursors. Our results indicate that at extracellular concentrations below 3 μ M glutamate can promote its own synthesis by increasing the accumulation of α -KG, whereas at higher concentrations glutamate inhibits its own synthesis by reducing the accumulation of α -KG. From a physiological perspective these modulatory effects are equivalent to the functional expression of glutamate autoreceptors.

HETEROGENEITY OF BRAIN L-GLUTAMATE DECARBOXYLASE. J.-Y. Wu, B. Nathan and J. Bao. Department of Physiology & Cell Biology, Univ. of Kansas, Lawrence, KS 66045-2106

Previously we as well as others have reported the presence of multiple forms of soluble L-glutamate decarboxylase (GAD) in mammalian brain, differing in its affinity for pyridoxal phosphate (PLP) [Denner and Wu, J. Neurochem. 44, 957 (1985)], kinetic properties [Spink et al., Brain Res. 421, 235 (1987)] and gene structure [Kobayashi et al.; J. Neurosci. 7, 2768 (1987); Huang et al.; Proc. Natl. Acad. Sci. US 87, 8491 (1990)]. In addition to soluble GAD, we have also isolated, purified and characterized a new form of membrane GAD. The membrane GAD was first isolated from P2 membrane, followed by solubilization with Triton X-100, and purified by a combination of column chromatographies on ion exchange (DE-52), gel filtration (ACA34 and Sephadex G-200), hydroxylapatite and preparative gel electrophoresis. The membrane associated GAD thus purified differs greatly from soluble GAD in molecular size, electrophoretic mobility in non-denaturing PAGE immunochemical properties, and PLP dependency [Wu et al., (Neurochem. Res. in press).] Eventually, we would like to purify membrane GAD to homogeneity and to determine its specific physiological role in GABAergic transmission. [Supported by grants NS 20978 (NIH) and BNS-8820581 (NSF)].

COMPARATIVE ANATOMICAL DISTRIBUTION OF 5HT1A RECEPTOR mRNA AND 5HT1A BINDING IN RAT BRAIN

D.T. Chalmers, C. Caamaño and S.J. Watson. Mental Health Research Institute, Univ. of Michigan, MI 48109.

The development of selective molecules for the 5HT1A receptor has allowed identification of this site as both a putative inhibitory somatodendritic autoreceptor on raphe serotonergic cells and as a postsynaptic receptor in selective serotonergic terminal fields. The recent cloning and functional characterization of the rat 5HT1A receptor gene (Albert et al 1990) indicates features characteristic of the G protein coupled receptor family. Here we describe the anatomical distribution of cells in rat brain expressing 5HT1A mRNA using *in situ* hybridisation histochemistry and compare this distribution to that of radiolabelled 5HT1A receptor sites.

In general terms, there was a complementary distribution of cells expressing 5HT1A receptor mRNA and 5HT1A receptor sites. High levels of both 5HT1A mRNA and 5HT1A receptors were evident in the hippocampal formation (CA1, CA3, dentate gyrus), entorhinal cortex and raphe nuclei and lower levels in neocortex and thalamus. Although 5HT1A mRNA was not expressed in any regions which did not also exhibit 5HT1A receptors, within both the diagonal band and medial septal nucleus mRNA levels were proportionately higher than 5HT1A receptor levels, possibly reflecting receptor transport or heterogeneity of 5HT1A receptor turnover mechanisms. 5HT1A receptor mRNA and 5HT1A binding sites were undetectable in caudate/putamen and cerebellar regions. The present data indicate the synthesis of 5HT1A receptors both in raphe serotonergic cells and in anatomically specific serotonergic projection areas.

171.3

EFFECT OF IBOTENIC ACID AND AF64A LESIONS OF CAUDATE PUTAMEN ON D₂ RECEPTOR mRNA IN RAT BRAIN.

N. Narang, M.A. Hunt, L.L. Longlet, M.E. Alburges and J.K. Wamsley. Neuropsychiatric Research Institute, 700 First Avenue South, Fargo, ND 58103.

Dopamine (DA) containing neurons project from substantia nigra compacta (SNc) to terminate on cholinergic (ACh) interneurons in the caudate-putamen (CPU). D₂ receptors are known to mediate the influence of DA on striatal ACh neurons. D₂ receptors are presynaptic on nigrostriatal terminals and postsynaptic on striatal neurons. We examined the changes in D₂ receptor mRNA after AF64A or ibotenic acid (IA) lesions in CPU. One group of male Long-Evans rats were stereotaxically injected with saline, IA (20 µg/2µl), or AF64A (0.34 µg/2µl) on the left side of the brain. After 15 days, *in situ* hybridization was performed using a [³⁵S]dATP radiolabeled dopamine D₂ receptor oligonucleotide (48 base pair) probe. The results show a large decrease in the D₂ message in the CPU with the IA lesion and a smaller decrease with the AF64A lesion as compared to controls. A very small decrease was also seen in the D₂ message in the SNc in both groups. The data indicate that mRNA encoding postsynaptic D₂ receptors in the CPU occurs in ACh containing neurons.

171.5

RAPID RADIOIODINATION OF SCH-23390, A POTENT D1 DOPAMINE RECEPTOR IMAGING AGENT. R.H. Sexton III, K.S. Lee*, M. Sassaman*, A. Braun, K. Vlodavac* and D. Weinberger. National Institute of Mental Health/Neuroscience Center at St. Elizabeths, Washington, DC. 20032.

In recent years, there has been an increasing interest in developing a radiopharmaceutical method of selectively evaluating the concentration of dopamine D1 and D2 receptors in the basal ganglia in order to study the pathology of the central nervous system using SPECT and PET imaging.

One such agent is the iodinated Schering compound, SCH-23390, developed by Kung's research group. 7-Chloro-8-hydroxy-1-(4'-iodophenyl)-3-methyl-2,3,4,5-tetrahydro-1H-3-benzazepine (FISCH) is prepared from 7-chloro-8-methoxy-1-[(4'-tri-n-butylstannyl)phenyl]-3-methyl-2,3,4,5-tetrahydro-1H-3-benzazepine by iodination with Na¹²⁵I and H₂O₂ followed by demethylation with BBr₃.

The original procedure required 2 hours to effect radioiodination. We have developed a modification which reduces the reaction time to 3 minutes: Aqueous peroxyacetic acid (100 µL, 3.2% w/v) is added to a mixture of the tri-n-butylstannane [50 µL (100 mg/mL)], 200 µL EtOH, 40 mL 1N HCl and carrier-free Na¹²⁵I in a sealed vial. The reaction is allowed to stand 3 minutes at room temperature and quenched by the addition of 40% NaHSO₃ (to reduce excess peracid). The solution is made basic by the addition of sat'd Na₂CO₃ and extracted with EtOAc. The organic layer is dried over Na₂SO₄ and evaporated to dryness under a stream of N₂.

The radiochemical yield after subsequent demethylation is 50%. *In vivo* autoradiographic studies in the rat demonstrate a binding pattern consistent with the regional distribution and relative density of D1 receptors.

171.2

IN VIVO LABELING OF DOPAMINE AND SEROTONIN UPTAKE SITES IN THE RAT BRAIN WITH [¹²³I]-RTI-55. U. Scheffel, R.F. Dannals*,

E.J. Cline, Marigo Stathis*, Christine Steinert*, F.I. Carroll*¹ and M.J. Kuhar. Dept. of Radiology, The Johns Hopkins Med. Institutions, Baltimore, MD 21205, NIDA/ARC, Baltimore, MD 21224 and ¹Research Triangle Inst., Research Triangle Park, N.C. 27709.

[¹²³I]-RTI-55, a new cocaine analogue, has been found to label central serotonin (5-HT) and dopamine (DA) transporters with high affinity. In this study, the precursor of RTI-55 was labeled with [¹²³I] and the compound evaluated for its *in vivo* binding in the rat brain. High-specific [¹²³I]-RTI-55 was synthesized from the corresponding stannyl analog and [¹²³I] using chloramine-T as an oxidant (yield = 85%). Rats were injected i.v. with 50 µCi [¹²³I]-RTI-55. Highest accumulation occurred in DA transporter rich regions: Specific to nonspecific (cerebellar) ratios reached 22 in the striatum, 11 in the olfactory tubercles 5 hours p.i. Binding was also high in 5-HT uptake site rich regions: In hypothalamus and pre-frontal cortex, the ratios were 6.5 and 4.1, respectively. Pre-injected paroxetine (5mg/kg) dramatically decreased [¹²³I]-RTI-55 binding in areas rich in 5-HT, but not in those rich in DA uptake sites. Chronic treatment of rats with MDMA significantly reduced [¹²³I]-RTI-55 uptake in regions known to be affected by MDMA neurotoxicity. The results indicate that [¹²³I]-RTI-55 should be useful for SPECT imaging of both, DA and 5-HT uptake sites.

171.4

CHANGES IN DOPAMINE RECEPTOR BINDING AND NEUROPEPTIDE mRNA FOLLOWING A RETROGRADE LESION OF STRIATOPALLIDAL NEURONS. M.B. Harrison, R.G. Wiley* and G.F. Wooten. Dept. of Neurology, Univ. of Virginia, Charlottesville, VA 22908; #Depts. of Neurology and Pharmacology, Vanderbilt Univ., Nashville, TN 37232.

We have previously used the retrogradely transported neurotoxin, volkensin, to study changes in D1 and D2 receptors as well as preproenkephalin (PPE) and preprotachykinin (PPT) mRNA after a lesion of striatonigral neurons. In this study, we have used an immunotoxin, OX7/saporin (OX7), to selectively lesion striatopallidal neurons. Three rats were examined 5 days after an injection of 0.5 µg of OX7 in the external segment of the left globus pallidus (GPe). Serial 20 µm striatal sections were examined for receptor binding with [³H]-SCH 23390 (D1) and [³H]-raclopride (D2) and *in situ* hybridization with [³⁵S] labelled oligonucleotide probes for PPE and PPT mRNA. Specific binding or optical density (OD) was compared contra- and ipsilateral to the lesion using a paired t-test. Specific D1 binding was unchanged (184.1 fmol/mg ± 4.8 (mean ± SE) vs. 181.3 ± 5.4 ns.) while D2 showed a 14% decrease (131.6 ± 7.0 vs 113.3 ± 9.4 p < .01). PPE mRNA expression decreased 27% (OD 0.555 ± 0.043 vs. 0.405 ± 0.037 p < .01); PPT mRNA did not show a significant decrease (OD 0.154 ± 0.01 vs 0.129 ± 0.01 ns). These results suggest that D2 but not D1 receptors are selectively expressed by striatopallidal neurons and are consistent with the previous observation that PPE and D2 receptor mRNA are colocalized in a subpopulation of striatal neurons. The absence of an effect of this lesion on D1 receptor binding or PPT mRNA strongly suggests that the lesion is specific for striatal neurons projecting to GPe. These data are the first demonstration of selective expression of D2 receptor binding sites by striatopallidal neurons.

171.6

Differences in Dopamine D2 Receptor Distribution in Hippocampal Formation and Temporal Cortex in Human, Rat and Cat. S. Goldsmith, P.A. Frohna and J.N. Joyce. Dept Psychiatry, Sch. Med, Univ Penn, Philadelphia, PA 19104.

The medial temporal lobe, including the hippocampus and parahippocampus, is importantly involved in dementia associated with a number of disorders. While there is low density of tyrosine hydroxylase fibers reported in this area (Gaspar et al., JCN., 279: 249, 1989), there is a high density of D2 receptor binding in certain regions of the medial temporal lobe in human (Joyce et al., JPET, 1991). Analysis of the cellular and laminar distribution of the D2 receptor was accomplished by autoradiography with [¹²⁵I]epidepride (Epid). Neurons expressing the receptor were also identified immunocytochemically (IHC) with anti-peptide polyclonal antibodies (McVittie et al., PNAS, 1991) in the temporal lobe of the rat, cat and human. Unlike frontal cortex where binding is low with the densest in deep layers, temporal cortex demonstrates a higher density of binding, with highest binding in external (I-III) and internal layers (V, VI). The pattern changes in areas 35 and 36 where binding was densest in layers I-III and low in layers IV and VI. Epid binding and IHC stained cells were conspicuously absent in the entorhinal cortex (area 28) in all three species. Epid binding was high in subregions of hpc in human and cat: CA3, dentate gyrus (DG) and subiculum. Low binding was observed in the rat. IHC staining in human revealed D2 cells in CA3, subiculum, piriform cortex and areas 35-36, but none in DG. In rat, IHC revealed a pattern of specific staining in hpc formation. In dorsal hpc, some pyramidal and basket cells were labeled, as well as in CA1 and CA2 with occasional cell staining in CA3. There were numerous cells stained in the hilus (CA4), but no cells stained in the dorsal DG in the rat. In ventral hpc, large numbers of DG cells were stained, as well as in CA1 and CA3. Piriform cortex showed IHC positive cells. Staining with preimmune sera was negative. Funded by MH43852, MH 43880, AG 09215.

171.7

DOPAMINE D₁ AND D₂ RECEPTORS COLOCALIZE TO THE SAME CELLS IN RAT MEDIAL PREFRONTAL CORTEX. S.L. Vincent, Y. Khan* and F.M. Benes, Department of Psychiatry and Program in Neuroscience, Harvard Medical School and Mailman Research Center, McLean Hospital, Belmont, MA 02178.

The neuronal localization of dopamine D₁ and D₂ receptor subtypes was investigated in rat medial prefrontal cortex (mPFC) using simultaneous binding of fluorescent derivatives of the antagonists SCH-23390-BODIPY (100 nM) and N-(p-aminophenethyl)piperone-Texas Red (100 nM), respectively. Fresh-frozen, 10-µm-thick glass-mounted sections were incubated in a solution containing labeled antagonists alone or in combination and then viewed with epifluorescence optics. Specificity of binding for the labeled D₁ and D₂ probes was determined by inhibition with unlabeled SCH-23390 (100nM) or (+)-butaclamol (100 nM), respectively. In addition, because spiperone and its derivatives have a high affinity for serotonin 5-HT₂ sites, mianserin (100 nM) was also used to inhibit binding to this receptor. Low-power, photomicrographic montages through the depth of mPFC were analyzed for the presence of fluorochrome-labeled neurons. The greatest number of neurons labeled with either D₁ or D₂ ligand were found in layers V and VI, and there was nearly complete overlap for the two ligands. Tissue sections incubated with mianserin showed a similar distribution of D₁ and D₂-positive neurons, although fewer cells with intense fluorescence were found in the upper layers of mPFC. These data suggest that D₁ and D₂ dopamine receptor subtypes are colocalized on the same neurons and show a distribution that is similar to that of the mesocortical dopamine projection to mPFC in rat. Supported by MH00423, MH42261 and the Scottish Rite Foundation.

DISTRIBUTION OF DOPAMINE D₁ AND D₂ RECEPTOR SUBTYPES IN RAT CENTRAL NERVOUS SYSTEM: AN IMMUNOCYTOCHEMICAL STUDY. C.A. Kitt, A.I. Levey, D.L. Price, R. Maggio*, W. Kao* and M.R. Brann*. Neuropathol. Lab., Dept. Pathol., The Johns Hopkins Univ. Sch. of Med., Balto., MD 21205; NINDS, NIH, Bethesda, MD 20892; University of Vermont, Burlington, Vermont 05405.

Five distinct genes have been identified that encode dopamine receptors (D₁-5). To characterize receptor proteins in brain, we made antibodies to fusion proteins (pGEX2T bacterial expression vector) containing sequences unique to D₁ and D₂ but not in the other subtypes. Antisera reacted specifically with respective fusion proteins on immunoblots; receptor subtypes expressed in transfected cells were specifically immunoprecipitated. Immunocytochemistry revealed intense, complementary patches of D₁ and D₂ proteins in striatum and olfactory tubercle. In substantia nigra, D₁ was located in neuropil and D₂ in cells. D₁-immunostained cells were seen in layers II/III and V of cortex, hippocampal CA1 pyramidal layer, bed nucleus of the stria terminalis, and portions of amygdala and cerebellum. Thus, antibodies provide cellular and subcellular localization of D₁ and D₂ gene products with sensitivity and specificity not achievable using autoradiographic techniques. These reagents should be useful for identifying the normal distribution of receptors in brain and alterations in disease.

171.11

LOCALIZATION OF DOPAMINE D₂ RECEPTOR PROTEIN IN RAT BRAIN USING POLYCLONAL ANTIBODY. J. Brock, S. Farooqui, K. Ross*, and C. Prasad. Lab. Neurosci., Pennington Biomed. Res. C, Baton Rouge; Dept. Med., LSU-MC, New Orleans, LA 70112.

The precise distribution of the dopamine type D₂ receptor (D₂) has been mapped for the first time, using an antibody to D₂ receptor protein. Polyclonal antisera were collected from rabbits inoculated with an undecapeptide identical to residues 24-34 of the D₂ protein sequence. Rat brain slices 40 µm in thickness were incubated with either primary antiserum, the antiserum plus free peptide antigen, or pre-immune serum. Antibody binding was visualized by peroxidase-antiperoxidase (PAP) and light microscopy. PAP complex was seen in discrete areas consistent with the binding of D₂ radioligands and known expression of D₂ receptor mRNA. Staining was heavy in the striatum, frontal and parietal cortices; staining was more diffuse throughout the medial forebrain bundle and hypothalamus. Unexpectedly, PAP was seen in lateral thalamic nuclei, also in the superior and inferior colliculi. These data suggest that D₂ protein was recognizable at all levels of the dopaminergic systems (target tissue, axons, and cell bodies of origin). (Supported by Dept. of Army)

171.8

DOPAMINE RECEPTOR GENE EXPRESSION IN RAT AND HUMAN NIGROSTRIATAL COMPLEX: A NEUROANATOMICAL STUDY. C. Le Moine, E. Normand, V. Bernard, R. Guenoun, F. Tison, J. Aubert, M. Jaber, B. Bloch, URA CNRS 1200, Laboratoire d'Histologie-Embryologie, Université de Bordeaux II, 146 rue Léo Saignat, 33076 Bordeaux Cedex, France.

Dopamine receptor mRNAs (D₁, D₂, D₃, D₄, D₅) were detected by in situ hybridization using radioactive and biotinylated oligonucleotides, in rat and human striatum and substantia nigra. Special attention was devoted to the phenotypical identification of the neurons expressing the dopamine receptor genes. In rat, the D₁ gene is expressed in substance P neurons, and in a small number of cholinergic and somatostatinergic neurons. The D₂ gene is expressed in encephalineric neurons, in 80% of cholinergic neurons and in dopaminergic neurons. All striatal neurons expressing the D₂ gene contain the D₂⁴⁴⁴ mRNA isoform and express increased levels of D₂ mRNA after haloperidol treatment (55% and 148% in encephalineric and cholinergic neurons, respectively). During ontogeny, D₁ and D₂ mRNAs appear, respectively, at gestational days 17 and 14, and DARPP-32 mRNA is present in 66% of the medium-sized neurons and in some cholinergic neurons. Experiments in progress demonstrate D₁ and D₂ mRNAs in human caudate and putamen neurons as well as D₃, D₄ and D₅ mRNAs in rat striatal neurons. The abundance of neurons labelled with each specific probe suggests co-localization of several receptors within the same neurons. These results demonstrate a neurochemical complexity for dopamine receptor gene expression far more important than previously suspected on the basis of autoradiographic binding studies.

171.10

IMMUNOCYTOCHEMICAL LOCALIZATION OF MUSCARINIC RECEPTOR PROTEINS IN RAT AND PRIMATE BRAIN AND COLOCALIZATION IN CHOLINERGIC NEURONS. A.I. Levey, C.A. Kitt, C. Heilman*, H. Fedor*, S.M. Edmunds*, D.L. Price and M.R. Brann*. Neuropathology Laboratory, The Johns Hopkins University School of Medicine, Balto., MD 21205; NINDS and NIH, Bethesda, MD 20892; and University of Vermont, Burlington, VT 05405.

Native muscarinic receptor proteins (m₁-m₅) in the brain were studied using subtype-specific antibodies, previously generated to their i₃ loops. By immunoprecipitation and immunocytochemistry, three receptor proteins (m₁, m₂, and m₄) accounted for the vast majority of total solubilized muscarinic binding sites and showed marked differences in regional and cellular localization in rat. m₁ was present in most neurons in cortex and striatum; m₂ receptor was abundant in cortex, basal forebrain, scattered striatal neurons, and was enriched in thalamus and brainstem. m₂ and ChAT immunoreactivity colocalized in striatal neurons; however, in basal forebrain, m₂ was present in many noncholinergic neurons. m₄ receptor was enriched in neostriatum and olfactory tubercle and in patches in neocortex. Similar localization of m₁, m₂, and m₄ was observed in monkeys. These studies indicate that the major receptor subtypes in rat and primate brain have important differences in cellular localization that help clarify their functions.

171.12

DOPAMINE D₂ RECEPTOR CIRCUITS IN HUMAN CORTEX. J.N. Joyce. Departments of Psychiatry and Pharmacology, University of Pennsylvania School of Medicine, Philadelphia, PA

The primate cortex shows an expanded dopamine (DA) innervation to motor (agranular) and limbic (medial temporal lobe) regions as compared to other species. Comparison with the DA D₂ receptor was examined in human postmortem material. The distribution of binding sites for the D₂ receptor was visualized by autoradiography with [¹²⁵I]pepideptide (Joyce et al., JPET, 1991). Neurons expressing the receptor were also identified immunocytochemically with anti-peptide polyclonal antibodies. Prefrontal cortex showed low binding in the deep laminae and few D₂ positive neurons, but the primary sensory regions examined showed very low binding in all laminae. The agranular cortices (motor, cingulate) showed significantly higher densities of binding sites in the external and internal laminae. Pyramidal neurons in layers II, III, and VI were positively stained for the D₂ antibodies. The temporal cortex, except for primary auditory cortex, showed 3-fold higher numbers of binding sites than prefrontal cortex. In the middle and inferior temporal cortex the predominant patterning was of D₂ receptors in the deep laminae. At the border of the collateral sulcus this pattern changed such that [¹²⁵I]pepideptide binding sites and D₂-positive neurons were located in the upper and lower laminae. The lateral occipito-temporal (LOT) cortex showed dense binding in the external laminae only, whereas the entorhinal cortex (EC) showed very low binding. D₂ positive neurons were visible in the LOT but few in the EC. The projection zone of the LOT within the dentate gyrus exhibited D₂ binding sites but no D₂-positive neurons. In contrast, D₂ binding sites and D₂-positive neurons were located in the CA3 and subicular fields of the hippocampus and the basolateral nuclei of the amygdala. These data suggest that the D₂ receptor is an important mediator of the actions of DA in motor and limbic cortex. **Funded by MH43852, MH 43880, AG 09215.**

GLUTAMIC ACID DECARBOXYLASE (GAD) IMMUNOREACTIVITY OF MAUTHNER CELLS AND HOMOLOGOUS NEURONS IN GOLDFISH. R. K. K. Lee¹, T. E. Finger² and R. C. Eaton¹. ¹Center for Neuroscience, Univ. Colorado, Boulder, CO 80309-0334, and ²Dept. Cell and Struct. Biol., Univ. Colorado Med. Cr., 4200 East 9th Ave., Denver, CO 80262.

The hindbrain is partitioned into a series of 7 segments or rhombomeres. In goldfish, each rhombomere contains distinct clusters of reticulospinal (RS) neurons, some of which are reiterated across adjacent segments. The Mauthner cells and two pairs of segmentally homologous neurons are large and individually identifiable. We have studied the distribution of inhibitory synapses on these neurons using GAD (synthetic enzyme for GABA) immunocytochemistry in conjunction with retrograde labelling (fluorogold or fluorescein dextran) from the spinal cord. Immunoreactive punctate reaction product, presumably synaptic terminals, is present throughout the neuropil of the reticular formation in the vicinity of the Mauthner cells. The lateral dendrites of the Mauthner cells are densely covered by relatively large puncta. There is also a somato-dendritic gradient of GAD-positive terminations on the Mauthner cells. The highest density of immunoreactive puncta appears at the lateral and ventral dendrites; a much lower density is present on the soma. In contrast, GAD immunoreactive terminals are sparser and distributed uniformly across the dendrites and cell bodies of Mauthner cell homologues. These findings suggest that, in spite of developmental and morphological similarities between the Mauthner cell and its homologous counterparts, these neurons may exhibit different functional properties. LOCALIZATION OF mRNAs ENCODING TWO FORMS OF GLUTAMATE DECARBOXYLASE IN THE HIPPOCAMPAL FORMATION. C.R. Houser and M. Esclapez*. Dept. of Anatomy and Cell Biology and Brain Research Institute, UCLA, and VA Medical Center, Los Angeles, CA 90024.

Neurons containing mRNAs for two forms of glutamic acid decarboxylase (GAD) have been localized in the rat hippocampal formation by *in situ* hybridization histochemistry using digoxigenin labeled cRNA probes. The goals were to determine if the two GAD mRNAs were differentially localized among subpopulations of GABA neurons in the hippocampal formation and to clarify the distribution of GABA neurons in the polymorph or deep hilar regions of the dentate gyrus. The findings indicated that both GAD mRNAs were present in all subpopulations of hippocampal GABA neurons. However, mRNA labeling for the lower molecular weight form of GAD (GAD₆₅) appeared to be slightly greater than that for the higher molecular weight form (GAD₆₇) in many neurons of the polymorph region. This pattern was consistent with preferential labeling of the somata of some deep hilar neurons with an antibody to GAD₆₅. These studies confirm the presence of numerous GABA neurons in the deep hilus of the dentate gyrus that have proved difficult to label consistently with some immunocytochemical methods. Supported by VA Medical Research Funds, NIH grant NS21908, and Del Duca and Philippe Foundations.

FLUORESCENCE IMAGING OF BENZODIAZEPINE BINDING SITES IN LIVING RAT CORTEX SLICES USING CONFOCAL MICROSCOPY.

Q. Gu and M. Cynader, Department of Ophthalmology, University of British Columbia, Vancouver, British Columbia, Canada, V5Z 3N9.

Benzodiazepines are a class of CNS-depressant drugs that have strong anticonvulsant, anxiolytic and hypnotic effects, and function by activating GABA_A receptors to increase permeability of chloride ion channels. In the present study, benzodiazepine binding sites in living rat cortex slices were labelled with the fluorescent benzodiazepine derivative N-(7-nitrobenz-2-oxa-1,3-diazol-4-yl)-desdiethyl-fluorazepam (NBD-Ro-1986, MOLECULAR PROBES), and visualized with a confocal laser scanning fluorescence microscope. The cortex slices were prepared as for standard electrophysiological slice experiments. Extracellular (field potential) and intracellular recordings were applied to make sure that cortical cells were healthy. After incubation with the NBD-Ro-1986, fluorescent clusters and spots, representing binding sites, were seen and analysed with three-dimensional reconstruction. The binding sites were clearly localized to the surface of cell bodies and processes, and could be displaced by competition with the non-fluorescent benzodiazepine lorazepam, indicating specific labelling. The size of labelled cell bodies varied widely, and cell bodies in the frontal cortex tended to show more intense fluorescence than those in the occipital cortex. These results indicate that various cell populations in the cortex can be differentially affected by benzodiazepines. This technique can also be used to label other membrane receptors or ion channels in living tissues, and the distribution and regulation of these binding sites can be studied at the single cell level.

DETECTION OF TWO FORMS OF GAD AND THEIR mRNAs IN RAT BRAIN BY IMMUNOHISTOCHEMISTRY AND NON-RADIOACTIVE *IN SITU* HYBRIDIZATION. M. Esclapez*, N.J.K. Tillakaratne, A.J. Tobin, and C.R. Houser. Brain Research Institute, UCLA, Los Angeles, CA 90024.

We have studied the localization of mRNAs encoding two forms of glutamic acid decarboxylase (GAD₆₅ and GAD₆₇) using digoxigenin-labeled cRNA probes and, in adjacent sections, the immunohistochemical distribution of these forms using specific antibodies. Both GAD mRNAs were present in all subpopulations of GABA neurons examined, but patterns of labeling varied among brain regions. Strong labeling of the two GAD mRNAs was observed in several brain regions including the substantia nigra pars reticulata and reticular nucleus of the thalamus. Lighter but comparable mRNA labeling for both forms was present in many neurons of the superior colliculus and striatum. Other neurons were labeled heavily for only GAD₆₇ mRNA, and these included neurons of the globus pallidus, a small population of neurons in the striatum and granule cells of the olfactory bulb. Most neurons that showed heavy labeling for either GAD mRNA also showed immunocytochemical cell body staining for that form of GAD. Due to the cellular resolution and minimal background obtained with the present non-radioactive *in situ* hybridization methods, our findings emphasize the different levels of GAD mRNA labeling among GABA neurons. Supported by Del Duca and Philippe Foundations, VA Medical Research Funds and NS21908.

DEMONSTRATION OF GAD IMMUNOREACTIVITY IN RAT HIPPOCAMPAL CELLS IN CULTURE. C.A. Levesque, J.M.R. Harrison*, H.R. Brashear. Depts. of Neurology and Neuroscience, Univ. of Virginia, Charlottesville, VA 22908

The major inhibitory neurotransmitter in the hippocampus is gamma-aminobutyric acid (GABA). GABA-ergic cells and their projections were identified in a well-characterized rat hippocampal pyramidal cell culture (Banker et al. Brain Res. 1977; 126:397) using glutamic acid decarboxylase (GAD) immunohistochemistry. After 16-23 days in culture, living cells on coverslips were fixed with 4% paraformaldehyde, 0.5% zinc salicylate in 0.5 M NaCl, and permeabilized with 0.1% Triton. Coverslips were incubated with sheep anti-GAD antibody (kindly provided by Dr. D. Schmeckel) followed by biotinylated anti-sheep IgG, processed with avidin-biotin-peroxidase complex, and counterstained with ethidium bromide. Strong immunoreactivity without nonspecific staining occurred at an antibody dilution of 1:6000. Approximately 11% of cells showed classical GAD immunoreactivity with marked or moderate cytoplasmic staining. About 9% of cells showed equivocal staining and the remainder were clearly negative. Cell processes exhibited punctate labeling consistent with boutons. Many neurites appeared to make synaptic contacts with GAD-negative cells. Although flat astrocytes are rarely seen in this culture system, those observed were GAD-negative. A subpopulation of cultured hippocampal neurons exhibit a range of GAD immunoreactivity.

PENTOBARBITAL (PB) DECREASES THE DISSOCIATION CONSTANT (K_D) FOR [³H]FLUNITRAZEPAM ([³H]FLU) DIFFERENTIALLY ACROSS BRAIN REGIONS. B.X. Carlson and H.A. Baghdoyan. Department of Anesthesia, Penn State University, College of Medicine, Hershey, PA 17033.

The mechanisms by which hypnotic barbiturates and benzodiazepines (BDZ) induce sedation are not well understood. These pharmacological agents have binding sites on the gamma amino-butyric acid/BDZ (GABA/BDZ) receptor, and it is thought that barbiturate-induced sedation may be produced, in part, by enhancing the actions of BDZ at the GABA/BDZ receptor. Our preliminary data suggested that PB alters the K_D for [³H]FLU differentially across brain regions (Neurosci. Ab., 16: 689, 1990). We now present further evidence supporting the hypothesis that PB alters the K_D for [³H]FLU differentially throughout the brain.

Using standard receptor binding assays, tissue homogenates from six brain regions (cortex, diencephalon, midbrain, pons, medulla, cerebellum) were incubated with [³H]FLU in the absence or presence of PB (0.5mM). Saturation analyses revealed that PB significantly decreased the K_D (p<0.05; paired t-test) within each brain region. The decreases in K_D were significantly different between the six regions (F=7.1; df=5,23; p=0.0004), and the largest PB-induced decrease in the K_D occurred in the medulla (-42%). There was no significant effect of PB on the B_{max} (F=3.0; df=1,46; p=0.09). These data are consistent with the hypothesis that PB may produce sedation, in part, by increasing the affinity of the GABA/BDZ receptor for BDZ differentially within the brain.

PERIPHERAL-TYPE BENZODIAZEPINE (τ) RECEPTOR CHARACTERISTICS IN BOVINE PROSTATE: A STEROID DEPENDENT ORGAN. H.L. Grandel*, P.F. Consroe, H.E. Laird II, Univ. of Arizona, College of Pharmacy, Dept. of Pharm/Tox, Tucson, Arizona 85721.

Bovine prostate mitochondria were isolated using subcellular fractionation techniques. Using the isoquinoline carboxamide, PK11195, which is specific for the peripheral-type benzodiazepine receptor (τ), the τ receptor in the bovine prostate mitochondrial and microsomal fractions were characterized. The purified mitochondrial membrane preparation contained the greatest density of τ receptors. Non-linear analyses of data obtained from saturation experiments, revealed that the τ receptor in the bovine prostate mitochondria had a $K_D = 0.324 \pm 0.033$ nM and a $B_{max} = 1.64 \pm 0.018$ pmol/mg protein. In comparison to previous work done in this laboratory, (Parola & Laird, *Life Sci.* 48:757, 1991), the prostate contains fewer numbers of τ sites than the adrenal cortex and testes, but is similar to the number of τ receptors found in the kidney and brain. Competition experiments revealed that the rank order of binding potency for τ receptor ligands to the bovine prostate mitochondria was PK11195>Alpidem>>>>>RO5 4864>Clonazepam. The bovine τ receptor has low affinity for benzodiazepine ligands which is consistent with previous reports in this species. To date, the prostate τ receptor has been reported in only one other species, rat. (Katz, et al., *Biochem. Pharmacol.* 40:817, 1990). (Supported by Ariz. Dis. Con. Res. Comm. #82-1685, HEL)

REGIONAL LOCALIZATION OF RECEPTORS AND TRANSMITTERS II

ALKYLATION OF MELATONIN RECEPTOR UNCOUPLES SIGNAL TRANSDUCTION IN CHICK BRAIN. S.-W. Ying and L.P. Niles, Dept. Biomedical Sciences, Division of Neuroscience, McMaster University, Hamilton, Ontario, Canada, L8S 3Z5.

In order to determine whether the melatonin receptor is sensitive to sulfhydryl (-SH) group alkylation as reported for other G_i coupled receptors, the effects of the irreversible alkylating agent, N-ethylmaleimide (NEM) were investigated. NEM caused a concentration-dependent inhibition of [125 I]MEL binding. At least two -SH groups were involved, one of which was highly (50-fold more) sensitive to NEM. Alkylation of the sensitive -SH group by a low concentration of NEM abolished the high-affinity state of the melatonin receptor and led to a complete loss of sensitivity to GTP. In addition, pre-treatment of membranes with a low concentration of NEM uncoupled melatonin receptor-mediated inhibition of adenylate cyclase activity in chick brain. These findings show that the melatonin receptor is coupled to an inhibitory G protein and sulfhydryl groups play an important role in melatonin signal transduction.

CHARACTERIZATION OF MUSCARINIC RECEPTOR SUBTYPE OF RAT ECCRINE SWEAT GLAND BY AUTORADIOGRAPHY. N. E. Torres*, P. J. Zollman*, P. J. Dyck, and P. A. Low, Neurophysiol. Lab., Dept. Neurology, Mayo Clinic, Rochester, MN 55905.

The muscarinic cholinergic receptor of rat eccrine sweat gland was characterized using quantitative autoradiography and [3 H]-QNB as radioligand. The distribution of radioligand was maximal in the secretory coil. Autoradiographic competition binding studies were performed using selective antagonists to M_1 (pirenzepine), M_2 (AF-DX 116) and M_3 (4-DAMP) and the classical nonselective antagonist atropine. pK_i for pirenzepine, AF-DX 116, 4-DAMP and atropine were 6.58, 5.47, 8.50 and 8.66 respectively indicating that the eccrine sweat gland muscarinic receptor was predominantly M_3 (Table).

Antagonist	pIC_{50}	Hill Coefficient	Regression Coefficient	pK_i^a
Atropine	8.08 \pm 0.06	0.97 \pm 0.07	0.9698	8.66
4-DAMP	7.92 \pm 0.04	0.79 \pm 0.04	0.9854	8.50
Pirenzepine	6.00 \pm 0.04	1.02 \pm 0.03	0.9927	6.58
AF-DX 116	4.89 \pm 0.04	1.04 \pm 0.05	0.9816	5.47

^a Inhibition constants were converted from the IC_{50} values using the Cheng and Prusoff (1973) equation.

GLYCINE RECEPTOR AND GLYCINE BOUTON CORRESPONDENCE IN THE DEEP CEREBELLAR NUCLEI. S. Chen and D. Hillman, Dept. Physiol. and Biophys., NYU Med. Cr., New York, NY 10016.

Glycine is recognized as a prominent and powerful inhibitory transmitter in the brainstem and spinal cord while, in the cerebellum, the glycine content is relatively low and GABA is high. The role of glycine in cerebellar signal-transmission has been questioned because of: 1) the coexistence of glycine and GABA in the same neurons and terminals, 2) non-matching of glycine positive terminals to glycine receptors, and 3) the difficulty in distinguishing between the "transmitter" and "metabolic" pools. Our glycine immunohistochemistry revealed positive small DCN cells (presumed interneurons) throughout all parts of the DCN. Semithin plastic sectioning showed extensive labeling of glycine fibers and terminals around large DCN cells. Additionally, numerous positive, large neurons (presumed projection cells) were limited to the fastigial nuclei. The GlyR was found along dendrites and around the soma surface of medium and large sized DCN cells in all three nuclear groups. A small dorsal part of the dentate nucleus had an especially dense labeling. The close correspondence between the glycine terminals and glycine postsynaptic sites (GlyR) favors a neurotransmitter role for glycine in these nuclei. Supported by USPHS NS-13742.

172.4

CHARACTERIZATION OF THE CHOLINERGIC INNERVATION OF THE HIPPOCAMPUS IN THE RAT FOLLOWING FORNIX TRANSECTION. B. W. Fenton*, M. B. Moss, and D. L. Rosene, Department of Anatomy and Neurobiology, Boston University School of Medicine, Boston, MA 02118

Three different markers of cholinergic fibers: hemicholinium (HC), acetylcholinesterase (AChE) and oxotremorine were used to quantify the effect of fornix transection in rat hippocampal subfields. Radioactively labeled HC binds the high affinity choline uptake (HACU) sites on cholinergic axon terminals. Radioactive oxotremorine labels the M_2 muscarinic receptor. The Tago AChE method provides quantifiable assessment of cholinergic fibers and diffuse AChE. Unilateral or bilateral lesions of the fornix were made behind the septum with a Scouten wire knife, completely severing the fornix without damaging cingulate cortex. After 35 days the animals' brains were frozen at -70° C, cut on a cryostat and adjacent sections processed with the three methods and analyzed on an imaging system. Unilateral fornix lesions reduced AChE by 78% in all ipsilateral subfields but bilateral lesions reduced it by 85%. Unilateral cases had less depletion in all subfields of the temporal pole, accounting for the greater loss in bilateral lesions. In the unilateral cases HACU density was reduced by 40% overall, but like AChE, the reduction was smaller in the temporal hippocampus. In both bilateral and control cases both AChE and HACU density were uniform from the dorsal to the temporal pole. The gradients of AChE and HACU in the unilateral cases may reflect either sprouting or normal bilateral innervation of the temporal hippocampus through the hippocampal commissure. AChE in the molecular layer of CA1 was largely preserved after either fornix lesion but HACU density was reduced to the same extent as other subfields, indicating that the preserved AChE may be non-cholinergic. Thus AChE is generally useful for localization of cholinergic afferents but may overestimate their loss. In contrast to the reductions of AChE and HACU density, oxotremorine binding showed an 8% loss, suggesting that the majority of M_2 receptors are not localized on cholinergic afferents. "Supported by NIH grants AG04321, NS16841, and NS07152, and an Alzheimer's Association grant."

CELLULAR MAPPING OF m1-m5 MUSCARINIC RECEPTOR mRNA'S IN RAT BRAIN. D. M. Weiner, A. I. Levey, and M. R. Brann* HHMI-NIH Res. Schol. Prog; Dept. of Neurology and Neuropathology, JHU; and LMB-NINDS, Bethesda MD., 20814.

We have used a series of subtype specific oligodeoxynucleotide probes to localize, with cellular resolution, the pattern of mRNA expression of the m1-m5 muscarinic acetylcholine receptors. In cortex, the m1 and m4 are found in all layers, in ~90% and ~75% of neurons respectively. The m2 was localized to layers 3-6, the m3 to layers 2,3 and 6, while no cortical expression of m5 was observed. The m1, m3, and m4 are expressed by most neurons in the hippocampal formation. The m2 is seen mainly in the polymorphic layer of the dentate gyrus, as well as in the pyramidal cells in the Ca fields of Ammon's horn. The m5 is restricted to the pyramidal cells in Ca1 and Ca2. The m2 and m3 are widely expressed in the thalamus, predominately in the anterior, intralaminar, and midline groups, where they display overlapping yet distinct patterns of expression. In the hypothalamus, the m3 is observed in various mammillary nuclei, while m5 is found in the ventromedial nucleus. The m2 and m3 are the predominant receptors expressed throughout various brainstem nuclei. The m2 is widely expressed by cholinergic neurons, however some of these neurons also express other receptor subtypes. These mRNA data, along with data about the distribution of receptor proteins, may help to determine the functional roles these subtypes subserv.

[³H]-1,25-DIHYDROXYVITAMIN D₃ (SOLTRIO) BINDING IN THE MIDLINE AND INTRALAMINAR THALAMUS OF THE SIBIRIAN HAMSTER.

J. M. Musiol*, W. E. Stumpf, H. Bidmon*, and Ch. Pilgrim. Dept. of Cell Biology and Anatomy, University of North Carolina at Chapel Hill, Chapel Hill, NC 27599 and Abteilung für Anatomie und Zellbiologie, Universität Ulm, D-7900 Ulm, Germany.

Autoradiographic studies revealed receptors for Vitamin D in the brain of rats and mice. In the present study, six month old Sibirian hamsters (*Phodopus sungorus*) were sc injected with tritiated 1,25-dihydroxyvitamin D₃ (1,25-D₃, vitamin D, soltrio) in two pulses of 0.2 ug/100 g bw each in one hour interval, and sacrificed four hours after the first pulse. Thousand-fold excess of unlabeled ligand injected 30 min before and with the first pulse (50% each) prevented nuclear labeling. Autoradiograms were processed according to the thaw-mount method. Neurons with nuclear concentration of labeled hormone are found in most midline and intralaminar nuclei (n). Strongest nuclear labeling exists in the n. reunions, n. rhomboideus, n. gelatinosus, and an extended group dorsal to the zona incerta. Nuclear labeling is also present in the n. paraventricularis, n. parataenialis, n. intermediodorsalis, a portion of the n. mediodorsalis, and in the region of n. centromedialis and centrolateralis. The extensive presence of vitamin D-soltrio receptors in the limbic thalamus of a strongly seasonally adjusted species like the Sibirian hamster, suggests a regulatory role and seasonal modulation of soltrio on thalamic nuclei that receive afferents from the hypothalamus and the reticular formation of the lower brainstem and project to various cortical regions.

172.9

TACHYKININ IMMUNOREACTIVE CELLS IN THE RAT VENTRAL PREMAMMILLARY NUCLEUS: SEX DIFFERENCES, CASTRATION EFFECTS, AND GONADAL STEROID BINDING. T.R. Akesson and P.E. Micevych, Dept of VCAPP, Wash State Univ, Pullman, WA and Dept of Anat & Cell Biol and Lab of Neuroendocrinol, UCLA Sch Med, LA, CA.

The ventral premammillary nucleus (PMv) in the caudal hypothalamus has reciprocal connections with sexually dimorphic nuclei such as the medial preoptic nucleus, the bed nucleus of the stria terminalis, and the medial nucleus of the amygdala. Lesions of the PMv in female rats block the surge of gonadotropin that normally occurs on proestrus, but other roles of this nucleus have yet to be elucidated. We present several new anatomical observations that suggest the PMv may also participate in neural mechanisms that regulate sexual behavior.

Males have more tachykinin containing cells than do females, and in both sexes, numbers were unaffected by the steroid milieu.

Sex	N	Treatment	# Tachykinin-positive cells
♂	4	Intact	1337 ± 58
♂	4	Castrate	1222 ± 67
♀	4	Ovx - 2 wks	524 ± 77
♀	4	Ovx - E capsule	574 ± 108
♀	3	Ovx - E injection	623 ± 41

We have previously reported a small population of E-concentrating cells along the ventrolateral edge of the PMv and a small proportion of these E-accumulating cells also contain tachykinin. However, using ³H-dihydrotestosterone or R1881, a much higher number of steroid-concentrating cells are seen throughout the PMv. Androgen-concentrating cells that contain immunoreactive tachykinin are common. These results suggest that androgen-receptive tachykinin-containing neurons may form a component of the neural network controlling reproductive function. Supported by HD22869 and NS21220.

172.6

THE DISTRIBUTION OF CALBINDIN CONTAINING CELL BODIES AND FIBERS IN THE CORTEX OF PRIMATES. S.Iritani, K.Kase, K.Kobayashi* and T.Kaneko*. Tokyo Metropolitan Matsuzawa Hospital, 2-1-1 Kamikitazawa Setagaya Tokyo 156 Japan

Calcium ions play a key role in many aspects of neuronal behavior and certain calcium binding proteins may influence this behavior. We have studied distribution of calbindin 28K immunoreactive cell bodies and fibers in the cerebral cortex of macaque monkey and of post-mortem human brain by immunohistochemical technique. Many immunoreactive cell bodies were seen mainly in layer II, III and V, and some cell bodies stained heavily and others stained lightly. Immunoreactive fibers were also observed mostly in layers II, III and V, and many of fibers run perpendicular to the surface. Immunopositive granular deposits were seen among fibers. These immunoreactive structures were seen as two bands within the cortex. The physiological function of this protein has not been clarified yet, but this characteristic pattern of distribution of calbindin 28K suggests that this protein has significant role in the primate cerebral cortex.

172.8

LOCALIZATION OF TRH RECEPTOR mRNA IN THE CAUDAL BRAINSTEM AND SPINAL CORD OF RAT. W. Wu¹, R. Eldred^{1,2}, M.W. Wessendorf¹ and T. Hökfelt² Dept. Cell Biol. & Neuroanat., Univ. Minnesota¹, Minneapolis, MN 55455, and Dept. Histology and Neurobiology, Karolinska Institute², S-104 01 Stockholm, Sweden.

Thyrotropin-releasing hormone (TRH) is expressed in some serotonergic, bulbospinal neurons and has a facilitatory effect on motor neurons in the spinal cord of rat. Although TRH binding has been demonstrated in spinal cord, the identity of cells which produce TRH receptors has not been determined. Four, 48-mer oligonucleotides complementary to selected regions of the cDNA for mouse pituitary TRH receptor (Straub et al., PNAS 87: 9514, 1990) were individually 3'-end labeled, mixed and applied to cryostat sections of spinal cord and caudal brainstem of rat. Both film and emulsion-dipped autoradiograms were developed.

Hybridization signals were observed over large motor neurons in the facial nuclei in the brainstem. Clusters of grains were also observed over large motor neurons in the ventral horn and over small- to medium-sized neurons in the intermediate gray of the spinal cord. These findings suggest that neurons which are synaptic targets of bulbospinal TRH neurons express TRH receptor mRNA, and that these G-protein linked receptors are post-synaptic structures.

[LEU³¹, PRO³⁴] NEUROPEPTIDE Y IDENTIFIES NEUROPEPTIDE Y RECEPTOR SUBTYPES IN THE RAT BRAIN. D.A. Schober, S.L. Gackenheim and D.R. Gehlert. CNS Research, Lilly Research Labs, Eli Lilly and Company, Indianapolis, IN 46285

Receptor subtypes for neuropeptide Y (NPY) have been previously differentiated into Y₁ and Y₂ subtypes based upon the binding profiles of long C-terminal fragments of NPY, especially the fragment NPY 13-36 which binds Y₂. In this study, our objective was to evaluate the analog [Leu³¹, Pro³⁴]NPY (LP-NPY) for its potential use in the identification of NPY receptor subtypes. LP-NPY has been reported in the literature to be highly selective for the Y₁ receptor subtype. [¹²⁵I]-peptide YY (PYY) binding to rat brain homogenates and tissue slices were performed to determine the binding characteristics of LP-NPY. Results were analyzed using Lundo software for ligand binding and an image analysis system for the autoradiographic studies.

The Y₁ receptor selective analog LP-NPY was found to produce a partial inhibition of [¹²⁵I]-PYY binding in rat whole brain homogenates. Displacement curves using this analog were biphasic with K_d values of 1.01 nM and 13.46 μM. Saturation experiments revealed multiple binding sites for [¹²⁵I]-PYY alone, however, when [¹²⁵I]-PYY was incubated in the presence of 100 nM LP-NPY, the low affinity binding component was eliminated. Two-site analysis of [¹²⁵I]-PYY binding resulted in plots with K_d values of 55.11 pM and 715.6 pM with B_{max} values of 28.64 fmol/mg protein and 131.4 fmol/mg protein, respectively. One-site analysis of [¹²⁵I]-PYY + 100 nM LP-NPY binding yielded a K_d value of 67.8 pM and a B_{max} of 10.12 fmol/mg protein.

Autoradiographic analysis using [¹²⁵I]-PYY in the presence and absence of 100 nM LP-NPY revealed a selective binding pattern in distinct brain regions. Areas that displayed almost complete displacement by 100 nM LP-NPY (Y₁) were the anterior olfactory nucleus, lamina 1-3 of the cerebral cortex, and ventrolateral thalamic nucleus. Those brain regions that were relatively resistant to LP-NPY displacement and appeared to be mainly Y₂ were the lateral septum, globus pallidus, and paraventricular hypothalamic nucleus. Areas where binding to the two sites were evenly distributed include the olfactory tubercle, nucleus accumbens, and gracile nucleus.

[¹²⁵I]-PYY was found to label the Y₁ binding site with lower affinity than the high affinity component which appeared to be Y₂. Furthermore, it appears the LP-NPY can be used as a useful tool to reveal the distribution of NPY subtypes in the rat brain.

172.11

IMMUNOREACTIVE-NEUROTENSIN AND -GALANIN IN THE PITUITARY GLAND AND BRAIN OF TWO SPECIES OF *Xiphophorus*. L. Cepriano and M. P. Schreiber. Department of Biology, Brooklyn College, C.U.N.Y., Brooklyn, New York 11210.

The distribution of neurotensin (NT) and galanin (GAL) in the brain and pituitary gland of *Xiphophorus maculatus*, the platyfish, and *Xiphophorus helleri*, the swordtail, was studied by employing immunocytochemistry on Bouin's-fixed, polyfin embedded material. Immunoreactive- (ir-) NT was localized in the neurohypophysis and in the three regions of the adenohypophysis. In young animals, NT was not observed in the pars intermedia of the adenohypophysis. Ir-Gal was localized in perikarya and fibers of the nucleus lateralis tuberis of the *Xiphophorus* brain and in the neurohypophysis and the three regions of the adenohypophysis. The localization of ir-NT and -GAL in the NLT, a brain nuclei previously implicated in pituitary function, and pituitary glands of these animals suggests that these peptides are involved in the regulation of pituitary function. [Supported by NASA (NAGW-1704), AID, and PSC-CUNY.]

DIFFERENTIAL EXPRESSION OF ESTROGEN RECEPTOR AND ITS mRNA IN HIPPOCAMPUS AND HYPOTHALAMUS OF MOUSE AND RAT. E. Combatsiaris¹, M.D. Bergman¹, W. Schneider², G. Shyamala², E.R. DeSombre³, B.A. Brooks¹ and J.F. Nelson¹. ¹Dept. of Physiology, U. of Texas Health Science Center, San Antonio, TX 78284-7756, ²Lady Davis Research Inst., Montreal, Canada, ³Ben May Laboratory of Cancer Research, U. of Chicago.

A recent study of the distribution of estrogen receptor (ER) immunoreactivity in the female rat brain gave evidence of unprecedentedly high levels of ER in the hippocampus (Mol Endocrinol 3:1165). Contrary to results from earlier ligand-binding assays, levels of immunoreactive ER in the hippocampus were similar to those in the hypothalamus. The present study was designed to examine this question further by evaluating the distribution of both ER and its messenger RNA in the brains of mice and rats. Brain regions from ovariectomized C57BL/6J mice and Sprague-Dawley rats were dissected and 1) homogenized immediately for ER measurements either by ligand binding or by immunoprecipitation and western blotting with a monoclonal antibody to ER (H222) or 2) frozen for ER mRNA determinations by solution hybridization/RNase protection assay using a cRNA probe complementary to a transcribed portion of the mouse ER gene. In both mice and rats the amount of radiolabeled estradiol specifically bound (cytosolic + nuclear ER) in hippocampi was 13% of that bound in hypothalami. Western analysis revealed significant ER immunoreactivity in the hypothalamus but negligible ER immunoreactivity in the hippocampus. Furthermore, the amount of ER mRNA in mouse hippocampus was only 24% of that in mouse hypothalamus. These observations do not support the results of the previous study of ER immunoreactivity, but confirm and extend those of earlier ligand binding studies by showing in both mice and rats that concentrations of ER and ER mRNA are markedly lower in the hippocampus than in the hypothalamus.

172.15

REGIONAL DISTRIBUTION OF MINERALOCORTICOID RECEPTOR IN RAT BRAIN BY WESTERN BLOT ANALYSIS. B.S. McEwen, R.R. Sakai, T.K. Akompong and Z. Krozowski* The Rockefeller Univ., 1230 York Ave., NY, NY 10021 USA and Prince Henry's Hospital, Monash Medical Centre, Melbourne, Australia, 3004.

Regional localization of mineralocorticoid receptor was measured by Western blot analysis in micro-punched rat brain tissue. Cytosolic brain mineralocorticoid receptor content in various brain regions was determined with the polyclonal antibody, MINREC IV, which was raised against a 167 amino acid sequence of the human mineralocorticoid receptor.

Mineralocorticoid receptor protein was present in hippocampus, cortex, preoptic area, bed nucleus of the stria terminalis and amygdala. Cytosolic levels of mineralocorticoid receptor protein were increased in 3 day adrenalectomized rats and correlated with decreased nuclear labelling of both mineralocorticoid (MINREC IV) and glucocorticoid (BuGR) receptors visualized by immunocytochemistry.

These results provide a means by which immunocytochemical labelling of mineralocorticoid receptors may be semi-quantitated with concurrent Western blot analysis. Supported by MH43787 (BSM).

THE DISTRIBUTION OF ESTROGEN RECEPTORS IN THE PIG HYPOTHALAMUS. F.J.C.M. van Eerdenburg, S. Chouham*, J.F. Axelson**, D.F. Swaab*** and F.W. van Leeuwen***. Univ. Utrecht, 3508 TD Utrecht, The Netherlands; *Univ. Hassan-II, Casablanca, Morocco; **Holy Cross College, Worcester, MA, USA; ***Neth. Inst. Brain Res., Amsterdam.

The recently described vasopressin and oxytocin containing nucleus (VON) in the pig hypothalamus contains three times as many cells in the adult female as that of the male, which is due to a sexually differential increase in neuron number starting at puberty (Van Eerdenburg et al., J. Comp. Neurol. 301, 138, '90). Since the neuronal number of the VON is influenced by gonadal steroids, a study was initiated to find out whether the VON contains estrogen receptors (ER) and to describe their distribution in the hypothalamus. Using antibodies against the human ER (#H222, Abbott), hypothalami of intact post-pubertal female and male pigs were incubated according to Axelson and Van Leeuwen (J. Neuroend. 2, 209, '90). Nuclear ER staining was found in many areas. The density was more intense in females, e.g. in the medial preoptic area, the area resembling the rat sexually dimorphic nucleus (SDN) of the preoptic area, the bed nucleus of the stria terminalis and the ventromedial hypothalamus. The VON, although surrounded by cells with ER, showed a complete absence of ER. No clear sex differences were observed, except for the SDN which contained more ER cells in females. In conclusion, the distribution of ER in the pig hypothalamus resembles that found in other mammals. Gonadal steroids seem to affect the VON indirectly.

172.14

ESTROGEN RECEPTORS IN DOPAMINERGIC AND PEPTIDERGIC NEURONS IN THE HYPOTHALAMUS OF THE PRAIRIE VOLE. A.A. Gerall, L. Givon, and D.T. Outlaw*. Dept. of Psych., Tulane Univ., New Orleans, LA 70118.

In the rat, whose ovulation is triggered cyclically by estrogen, autoradiographic assays have demonstrated that ³H-estrogen accumulates in subsets of dopaminergic and beta-endorphin- but not in gonadotropin releasing hormone (GnRH)-immunoreactive (ir) neurons. Using immunocytochemistry, we examined whether the estrogen receptor (ER) is present in similar subsets of neurons in the prairie vole whose ovulation is evoked by copulation. Also, colocalization of ER with oxytocin-ir neurons was determined in the rat.

First, the endogenous neuroactive substances were labelled using a modified Sternberger peroxidase-anti-peroxidase procedure and the chromogen diaminobenzidine. ERs were visualized using the H222spr monoclonal antibody (courtesy of Abbott Laboratories), the ABC method (Vector Laboratories) and benzidine dihydrochloride as the second chromogen.

GnRH-ir neurons in the vole's brain did not contain ER-ir. A subset of TH-ir neurons in the periventricular and arcuate nuclei but none in the zona incerta had ER-ir. A small proportion of beta-endorphin-ir neurons in the arcuate nucleus colocalized ER-ir. In the above neurons, ER-ir was confined to their nuclei. ER-ir was most evident in oxytocin-containing neurons in the anterior commissural and paraventricular nuclei of the rat. Although the rat and vole have different ovulatory mechanisms, their ER appear to be colocalized in similar neuronal systems.

PLACENTAL LACTOGEN BINDING SITES IN THE PREGNANT RABBIT CNS. L.P. Mangurian and R.J. Walsh. Department of Biological Sciences, Towson State University, Towson, MD and Department of Anatomy, George Washington University, Washington, DC.

The highest concentrations of prolactin receptors in the CNS reside within the hypothalamus and choroid plexus. In an effort to evaluate these areas for potential sites of action of placental lactogens (PL), in vitro autoradiography was used to localize PL binding sites in the brain of pregnant New Zealand White rabbits. Frozen brain and liver sections were incubated in a medium containing ¹²⁵I human PL (hPL) alone (total binding) or with a 500-fold excess of unlabelled hPL (non-specific binding). Specificity was assessed with excess unlabelled hGH and oLH. An intense autoradiographic reaction occurred over the choroid plexus and liver sections. Excess unlabelled hPL and hGH caused a significant reduction (p<.001) in the binding of the ¹²⁵I hPL while unlabelled oLH had no effect. In contrast, the hypothalamus exhibited a weak autoradiographic reaction that was not affected by any excess unlabelled hormones. The results support a role for the choroid plexus in PL to brain interactions but do not define a hypothalamic site of action.

172.17

DISTRIBUTION OF CANNABINOID RECEPTOR mRNA IN RAT BRAIN. L. M. Console-Bram¹, J.G. McElligott¹ and S.G. Fitzpatrick-McElligott². Temple University, Pharmacology Dept., Phila., PA 19140¹ and E.I. Du Pont, Medical Products, Glasgow, DE 19702².

Histological distribution of cannabinoid receptor mRNA was determined in the brains of both adult and neonatal rats. A 30-base oligonucleotide, complementary to the mRNA, was synthesized from the known cDNA cannabinoid receptor sequence (Matsuda et al., 1990). The oligonucleotide was radiolabelled and used to probe sections of rat brain tissue according to *in situ* hybridization methodology. From these experiments, cannabinoid receptor mRNA in the adult rat brain was found to be localized to the granule cell layer and deep nuclei of the cerebellum, granule and pyramidal cells of the hippocampus, the habenula, diagonal band of Broca, mitral layer of the olfactory bulb, basal ganglia and cerebral cortical layers. Brainstem nuclei expressing receptor mRNA include, the inferior olive, pons and the superior and inferior colliculi. Results from preliminary developmental studies indicate that the pattern of expression of mRNA in the neonatal rat brain (first two postnatal weeks) is similar to that of adult rat brain. The presence of cannabinoid receptor mRNA in the cerebellum, basal ganglia and hippocampus support the involvement of these brain regions in the production of adverse effects such as, difficulty in motor coordination (ataxia) and memory acquisition as a consequence of cannabinoid usage. The localization of cannabinoid receptor mRNA in these brain structures is in agreement with the distribution of receptor protein as reported by Herkenham et al. (1991).

AUTORADIOGRAPHIC DISTRIBUTION OF SIGMA RECEPTORS IN HUMAN NEOCORTEX, HIPPOCAMPUS, BASAL GANGLIA, CEREBELLUM & PINEAL. K.L.R. Jansen¹, R.L.M. Faull², M. Dragunow³, R.A. Leslie⁴

¹Clinical Pharmacology⁴Oxford University-Smith Kline Beecham Centre, Radcliffe Infirmary, Woodstock Rd, Oxford, OX2 6HE
²Anatomy, ³Pharmacology, Auckland University, P.B., New Zealand

The distribution of σ receptors in selected regions of human brain was studied using autoradiography. Sections from 8 brains (5 males, 3 females), average age 52 (range 26-70) were labelled with 6nM [³H]diorthotolyl guanidine ([³H]DTG) as previously described (Jansen et al., *Brain Res.*, 507, 158-160). The highest densities among the areas examined were in the substantia nigra pars compacta and over the cerebellar Purkinje cell layer. Pineal levels were modest compared to rat where they are very dense. This may reflect the age of the sample. In cerebral cortex, binding was enhanced in the superficial laminae (II-IVA) and attenuated over a band in the midzone of the gray matter in several areas, especially visual cortex where the band of attenuation corresponded to lamina IVB-IVC α and was followed by a dense band corresponding to IVC β . There was slight enhancement over the granular layer of the hippocampal dentate gyrus. Binding was modest in caudate and putamen, with less binding in the globus pallidus. The high density over the cerebellar Purkinje and molecular layers was similar to the pattern in rodents. The results of this study support the proposition that σ receptors may be involved in the control of movement and mental status. Supported by NZMRC, NZ Neurological Foundation.

G-PROTEIN COUPLING INFIDELITY BY THE MELATONIN RECEPTOR AFTER EXPRESSION IN *XENOPUS* OOCYTES. P. Barrett¹, P.J. Morgan¹, S.P. Fraser² and M.B.A. Diamgoz². ¹Rowett Research Institute, Aberdeen, AB2 9SB and ²Department of Pure and Applied Biology, Imperial College, London, U.K. Melatonin receptors inhibit forskolin-stimulated cAMP accumulation via inhibitory G-proteins in *pars tuberalis* (PT) cells. In an attempt to clone the gene for the melatonin receptor this tissue has been used as a source of RNA for microinjection into *Xenopus* oocytes.

Total RNA was extracted from the PT and either used for selection of poly A⁺ RNA on an oligo dT column or size fractionated on a 5-20% sucrose gradient. RNA solution (70 nl) was microinjected into oocytes (stage VI) and incubated in modified Barths for 4-10 days. Recordings were made under voltage clamp conditions, whilst oocytes were perfused with frog ringer with or without drugs.

Aluminium fluoride (AlF₄⁻) made by mixing 10 mM NaF and 0.1 mM AlCl₃ induced a slow inward oscillatory current with a reversal potential of -24 mV. This response resembles the Ca²⁺-dependent Cl⁻ current seen in *Xenopus* oocytes with a variety of stimulants including carbachol which induces these currents through the muscarinic acetylcholine receptor. Using AlF₄⁻ or carbachol to stimulate oocytes, melatonin (1 mM) blocked the oscillatory current in oocytes which had been injected with poly A⁺ RNA or size fractionated total RNA extracted from the PT. However, melatonin had no effect on non-injected oocytes. The dose-dependency and pharmacology of the response were consistent for the melatonin receptor. The response to AlF₄⁻ and subsequent inhibition by melatonin was not altered by the addition of EGTA to the incubation medium, implicating the internal calcium stores in the response to AlF₄⁻.

These results demonstrate the expression of a functional melatonin receptor linked to the inhibition of the IP₃/Ca²⁺ signal transduction pathway. Therefore the expressed receptor lacks the G-protein coupling fidelity of its native PT cell.

173.3

STIMULATION OF TRANSCRIPTIONAL REGULATORY FACTOR ACTIVITY BY SUBSTANCE P (SP). Y. Ohashi^{*}, C. Christian^{*}, M. Gilbert^{*}, and D.G. Payan. University of California, San Francisco and the Howard Hughes Medical Institute, U-426, San Francisco, CA 94143.

We have established stably transfected cell lines expressing functional rat SP receptors (KNRK-SPR). When stimulated by SP, KNRK-SPR cells respond by simultaneously mobilizing intracellular Ca²⁺ and increasing cAMP levels. Our results further demonstrate the independent activation of the PKC and PKA pathways. In order to examine if SP stimulation results in the activation of transcriptional regulatory factors, we have transfected KNRK-SPR cells with plasmids containing the AP-1 and CRE-enhancer elements coupled to the chloramphenicol acetyltransferase (CAT) reporter gene. Stimulation with 10nM SP results in an approximate 2-fold increase in CAT activity both in AP-1/CAT and CRE/CAT transfected cells. These results suggest that SP binding to its receptor stimulates AP-1 and CRE-enhancer activity through PKC and PKA activation respectively, and thus may elucidate the complex cellular responses mediated via the SPR receptor.

173.2

DIFFERENCES IN THE FUNCTIONAL RESPONSES OF TWO CELL LINES EACH EXPRESSING PLC-COUPLED MUSCARINIC RECEPTORS. J. Baumgold and R. Paek. Dept. of Radiology, The George Washington University Medical Center, Washington, DC 20037

Stimulation of the m1, m3 and m5 muscarinic receptors results in activation of phospholipase C (PLC) and A, increase in intracellular calcium and activation of protein kinase C. Herein we show that these biochemical responses do not always result in the same functional responses.

Fluorescent oxonol dyes were used to measure changes in the membrane potential of two cell lines each expressing PLC-coupled muscarinic receptors. Both SK-N-SH cells (expressing m3 receptors) and m1-transfected A9 L cells express muscarinic receptors which, when stimulated, elicit a large increase in intracellular calcium and release of inositol phosphates. Despite the similarity in this second messenger response, muscarinic stimulation resulted in hyperpolarization of the A9 L cells and depolarization of the SK-N-SH cells. The hyperpolarizing response could be mimicked in the A9 L cells by treatment with the calcium ionophore A23187, suggesting that in these cells, the hyperpolarization is mediated by calcium activation of potassium channels. This ionophore had no effect in the SK-N-SH cells, suggesting that the depolarization was not mediated by intracellular calcium. These studies demonstrate that the functional response of cells may vary considerably, despite being mediated by a similar second messenger response.

173.4

MUTATIONS IN THE THIRD CYTOPLASMIC LOOP OF THE MOUSE M1 MUSCARINIC ACETYLCHOLINE RECEPTOR WHICH AFFECT G-PROTEIN INTERACTION AND AGONIST AFFINITY. R. A. Shapiro and T. Cislo^{*}. Bristol-Meyers Squibb Pharmaceutical Research Institute, Seattle, WA 98121

Mutations were constructed in the highly conserved carboxy-terminal region of the third cytoplasmic loop of the mouse m1 muscarinic acetylcholine receptor (mAChR) by site-directed mutagenesis. The effects of these mutations on ligand binding and on mAChR coupling to phosphoinositide turnover have been examined following expression in mouse Y1 adrenal carcinoma cells. Antagonist binding affinity was unchanged while agonist binding increased. Those mutations which increased agonist binding also resulted in increased agonist potency. These data suggest that G-protein binding to receptor can significantly alter the potency of agonists to couple to physiological responses.

173.5

TRANSMEMBRANE SIGNALING THROUGH THE PHOSPHOINOSITIDE PATHWAY IN HUMAN CORTICAL MEMBRANES (BRODMANN'S AREA 9). M.A. Wallace and E. Claro,* Dept. of Biochemistry, University of Tennessee, Memphis, TN 38163.

Exogenously supplied substrate was used to measure regulation of phosphoinositide-specific phospholipase C (PLC) in membranes prepared from prefrontal cortex frozen in liquid N₂ at autopsy. Homicide victims, schizophrenic, Parkinson's and Alzheimer's patients were analyzed. Guanosine 3'-o-thiotriphosphate (GTPγS) stimulated PLC activity which was synergistically enhanced by muscarinic cholinergic, serotonergic or dopaminergic agonists. Muscarinic agonists shifted to lower concentrations the EC₅₀ value for GTPγS and this shift was reversed by dopamine for homicide victims, schizophrenics and Alzheimer's patients, but the dopamine effect was not apparent in Parkinson's membranes. Results indicate that: 1) there is a reduction of muscarinic response in Alzheimer's patients which cannot be overcome by supplying agonist to the membranes, 2) there is an altered PLC response to dopamine in Parkinson's patients due to the disease process or l-dopa therapy, and 3) there is a reduced PLC response to serotonin in schizophrenics relative to other neurotransmitters. The usefulness of the PLC assay with exogenous substrate is thus demonstrated for studying transmembrane signaling in human brains.

173.7

CHARACTERIZATION OF COMPENSATORY CHANGES IN RECEPTOR-STIMULATED PHOSPHOINOSITIDE (PI) HYDROLYSIS FOLLOWING COLCHICINE ADMINISTRATION IN THE RAT HIPPOCAMPUS. P. Tandon¹, S. Barone Jr.² and H.A. Tilson³, ¹Center for Environ. Med. and Lung Biol. UNC, Chapel Hill and ²U.S. EPA and ³MEI, RTP, NC 27709.

Compensatory changes in receptor-stimulated PI hydrolysis occur in response to intradentate administration of colchicine (Tandon et al., 1989, *J. Neurochem* 53: 1117). To characterize these changes further, bilateral injections of colchicine (2.5 ug/site) were made in the hippocampus of adult male Fischer-344 rats (9 rats/group). The rats were sacrificed 12 weeks later and carbachol-stimulated IP-release measured in the hippocampus. The cholinergic muscarinic receptor is linked to the IP second messenger system via GTP-binding proteins. To observe the involvement of G-proteins in this response, non hydrolyzable analogues of GTP and NaF were used to stimulate PI hydrolysis without stimulating the receptor: a decrease in non-receptor-stimulated IP-release was observed in the hippocampus from colchicine-treated animals. This suggests that G-proteins were not involved in the colchicine-induced increase of carbachol-stimulated IP release. A separate study evaluated membrane function by depolarizing the membrane with increasing concentrations of K⁺ and simultaneously stimulating IP release with carbachol. A greater increase in receptor-stimulated IP release was observed in hippocampal slices from colchicine-treated rats, suggesting that colchicine-induced alterations in membrane function and structure affect receptor-mediated IP hydrolysis. Further work is needed to study these membrane changes and their effects on cholinergic-muscarinic receptor function.

173.9

INOSITOL PHOSPHATE (IP) ACCUMULATION IN RAT NEOSTRIAL SLICES UNDER CONDITIONS USED TO MONITOR NEUROTRANSMITTER RELEASE. M. H. Weiler, D. Katz*, H. Lee*, N. V. Cozzi*, and K. DasGupta¹. School of Pharmacy and ¹Dept. of Psychiatry, University of Wisconsin, Madison, WI 53706.

To determine whether accumulation of IP is altered by manipulations that significantly alter neurotransmitter release, inositol phospholipid metabolism was examined under experimental conditions used to study acetylcholine (ACh) and dopamine (DA) release from rat neostriatal slices. Slices from Fischer 344 rats (3-mo.) were labelled with myo[2-³H]-inositol, and IP accumulation was determined in the presence of LiCl (10 mM). Effects of nondepolarizing and depolarizing conditions, acetylcholinesterase (AChE) inhibition, and muscarinic agents were tested. Under nondepolarizing conditions, IP accumulation (% of total ³H-inositol incorporation) was 2.4 ± 0.1% (n=3) during a 25 min incubation. If the slices were depolarized an additional 5 min following the nondepolarizing incubation, IP accumulation increased another 78% (4.28 ± 0.28%; n=3, p<0.05), indicating that conditions used to stimulate neurotransmitter release also increase IP accumulation. In the presence of physostigmine (PHY), an AChE inhibitor, IP accumulation following a 25 min nondepolarizing/5 min depolarizing incubation was 3.3-fold greater (p<0.05) than in its absence. Oxotremorine-M (OXO-M), a muscarinic agonist, enhanced IP accumulation 5-fold (5μM) and 9-fold (100μM) during a 25 min nondepolarizing incubation, and 29% and 14% more during an additional 5 min depolarization. Pirenzepine (50 μM), a muscarinic antagonist, decreased IP accumulation in the presence of OXO-M and PHY by 74% (p<0.01) and 68% (p<0.01), respectively. These manipulations also significantly affected ACh and DA release, indicating that IP accumulation in neostriatal slices is significantly altered during manipulations used to study neurotransmitter release.

173.6

NORADRENALINE AND CARBACHOL STIMULATED INOSITOL PHOSPHATE ACCUMULATION IN CEREBRAL ENDOTHELIAL CELLS REGULATED BY PHORBOL ESTER, PERTUSSIS TOXIN, AND CA²⁺. J. Xu, Z. X. Qu* and E. L. Hogan, Dept. of Neurology, Med. Univ. of SC, Charleston, SC 29425.

It has been reported that noradrenaline (NE) and carbachol stimulated inositol phosphate (IP) accumulation in confluent murine cerebral endothelial cells (MCEC) maintained in culture. Treatment of MCEC with phorbol 12,13-dibutyrate (PMA) 0.1, 1, and 10 μM for 10 min decreased NE-induced IP accumulation to 58%, 68% and 100% and decreased carbachol-induced IP to 85%, 88%, and 88% respectively. Pretreatment of MCEC with pertussis toxin, IAP 0.01, 0.1, and 1 μg/ml for 18 hr inhibited NE-induced IP in a dose-dependent manner (3%, 32% and 72%) but had little inhibitory effect on carbachol stimulation of IP. NE and carbachol-induced IP accumulations were decreased to 67% when calcium was absent in the medium during incubation of MCEC with agonists. IP responses to NE and carbachol were much less in the absence of calcium and the presence of 1mM EGTA. These results suggest that NE and carbachol induced IP accumulations are regulated by protein kinase C. These responses are dependent on physiological calcium concentration. G_i protein is involved in adrenergic receptor mediated PI turnover, but not in muscarinic receptor response. Supported by NS-11066.

173.8

LITHIUM INDEPENDENT MUSCARINIC RECEPTOR ACTIVATED ACCUMULATION OF CDP-DIACYLGLYCEROL IN HUMAN NEUROBLASTOMA CELLS. E.B. Stubbs, Jr., A.M. Heacock, E.B. Seguin* and B.W. Agranoff, Mental Health Research Institute, Departments of Psychiatry and Biological Chemistry, Neuroscience Laboratory Building, University of Michigan, Ann Arbor, MI 48104-1687.

A lithium-dependent accumulation of CDP-diacylglycerol (CDP-DG), the immediate precursor of phosphatidylinositol (PI), following muscarinic receptor activation in cerebral cortical slices has recently been described. Evidence suggests that lithium perturbs the phosphoinositide signal transduction pathway in the CNS by depleting intracellular levels of myo-inositol through the inhibition of inositol monophosphatase, thereby limiting substrate availability for the resynthesis of PI. In the present study, we describe a stimulated accumulation of CDP-DG independent of lithium treatment in cultured human SK-N-SH neuroblastoma cells. Activation of [³H]cytidine prelabeled cells with full muscarinic agonists results in a rapid 4-5 fold accumulation of a single labeled band comigrating on thin layer chromatography with authentic CDP-DG standard. Carbachol-stimulated accumulation of [³H]CDP-DG was dose- (EC₅₀ = 6 mM) and time-dependent, with maximal accumulation occurring within 10 min, sustained for at least 90 min and completely reversed by the subsequent addition of atropine (10 μM). Oxotremorine-M was as efficacious as carbachol at stimulating [³H]CDP-DG accumulation, whereas oxotremorine, arecoline, pilocarpine and bethanechol were only partially effective. Preincubation of labeled cells with LiCl or inositol had no effect on either the basal or stimulated accumulation of [³H]CDP-DG. The resting intracellular mass of myo-inositol was 129 ± 12 nmol/mg protein, approximately 20 x greater than has previously been reported for cultured neuroblastoma cells or peripheral nerve. Culturing cells in a myo-inositol free chemically defined medium substantially reduced the intracellular content of myo-inositol. Under these conditions, lithium and inositol sensitivity are observed. These results indicate that in some cells, lithium-induced substrate limitation of PI synthase may not regulate stimulated phosphoinositide turnover. (Supported by grant NIMH PO1 MH42652.)

173.10

ANGIOTENSIN II INCREASES PHOSPHOINOSITIDE HYDROLYSIS IN RAT SUPERIOR CERVICAL GANGLION THROUGH AT₁-RECEPTORS. C. Stromberg, K. Tsutsumi, M. Viswanathan and J.M. Saavedra, Section on Pharmacology, Laboratory of Clinical Science, National Institute of Mental Health, Bethesda, MD 20892

Angiotensin II (AII) interacts with the sympathetic nervous system in maintaining vascular tone. Our preliminary autoradiographic studies have shown, that the sympathetic superior cervical ganglion (SCG) has AII receptors, and that these are mainly of AT₁ type. In this study we wanted to clarify whether these receptors are coupled to the intracellular phosphoinositide (PI) cycle. Ganglia were taken from 8-week-old male Sprague-Dawley rats, labeled for 2 h with ³H-myoinositol, and stimulated for 45 min with AII in the presence of 10 mM LiCl. When used, the antagonists were added 10 min before AII. The IP₁-fractions were separated by anion exchange chromatography and the radioactivity was measured in a liquid scintillation counter. The results were corrected for the total incorporation of label. AII elicited a dose-responsive increase in IP₁ accumulation with a maximum effect of 101.3% over control obtained with the dose 10⁻⁶ M. The EC₅₀ was 2.3 nM. The effect of AII was completely inhibited in a dose-responsive manner by the AT₁-selective antagonist DuP 753, but not by the AT₂-selective displacer PD 123177. The results indicate that SCG contains angiotensin AT₁ receptors and these receptors are coupled to the intracellular PI cycle.

173.11

INOSITOL TRISPHOSPHATE GENERATION IS MEDIATED BY A B2 BRADYKININ RECEPTOR IN NG108-15 NEUROBLASTOMA - GLIOMA HYBRID CELLS. J.E. Rubinstein, M.A. Raio Jr., and R.J. Hitzemann. Dept. Psychiatry and Behavioral Sci., Health Sciences Center T-10, SUNY, Stony Brook, NY 11794-8101.

Selective analogs of bradykinin (BK) were used in order to pharmacologically characterize bradykinin-induced phosphoinositide hydrolysis in NG108-15 cells. NG108-15 cells were grown in DMEM with HAT, 10% FBS and 5 μ Ci [³H]inositol for 2 days in order to prelabel inositol phospholipids. The media was removed and the cells preincubated for 15 min in Ringer-HEPES buffer. Lithium was not used in the buffer. BK or analogs were then added and after various times the reaction terminated with perchloric acid. BK receptor antagonists, when used, were added 5 min prior to BK. Inositol phosphates were separated by ion-exchange chromatography.

BK produced a robust concentration- and time-dependent increase in inositol trisphosphate (IP3) as well as IP2 and IP4. The B1 selective agonist [des-Arg⁷]BK (BK₁) was totally inactive. The B1, B2 antagonist [Arg¹,Thi^{5,8},Phe⁷]BK (Antag2) inhibited BK action in a dose-responsive fashion. The response of 1 μ M BK was totally abolished by 30 μ M Antag2. [Thi^{5,8},Phe⁷]BK also antagonized the BK response but was less potent than Antag2. Kallidin (Lys-BK) had agonist properties as expected, and was slightly more potent than BK itself. These results indicate that it is the B2 BK receptor subtype that is linked to Phospholipase C-mediated phosphoinositide hydrolysis in this cell line.

173.13

ETHANOL ENHANCES NEUROTENSIN-INDUCED STIMULATION OF INOSITOL PHOSPHOLIPID METABOLISM. Radcliffe, R.A. and Erwin, V.G. Alcohol Research Center, School of Pharmacy, University of Colorado, Boulder, Colorado, USA 80309-0297

Ongoing work in this laboratory suggests that neurotensin (NT), a tridecapeptide, mediates in part, ethanol related behaviors including the differential hypnotic and hypothermic sensitivity to ethanol seen in long-sleep (LS) and short-sleep (SS) mice. NT administered i.c.v. causes SS to become significantly more sensitive to the hypothermic and anesthetic effects of ethanol while virtually no effect is seen in LS. The density of NT receptors in forebrain is greater in SS compared to LS. Endogenous levels of NT in various brain regions are generally higher in LS compared to SS. Both lines of mice show a decrease in NT after acute ethanol administration and an increase in NT after chronic ethanol administration with LS showing greater sensitivity in both cases. It has been shown that NT stimulates the formation of the second messenger inositol-trisphosphate in N1E-115 cells, rat brain slices, and mouse brain slices. Studies have been initiated to investigate the possibility that ethanol alters the NT receptor coupled process of PI metabolism in LS and SS brain slices. Stimulation of PI metabolism by carbachol, a muscarinic agonist which has been shown to be effective in eliciting a PI response, was not affected by the addition of 100-200 mM ethanol in either LS or SS. Ethanol, however, increased the effect of NT on PI metabolism by as much as two fold. Furthermore, enhancement of the NT response was greater in SS than in LS. These observations lend support to the hypothesis that NT receptor coupled processes are modulated by ethanol and that there is a genetic influence on this effect of ethanol. (Supported by NIAAA Grants Number 003527, 00079 and 07330)

CAFFEINE AND DOPAMINE MOBILIZE CALCIUM FROM INTRACELLULAR STORES IN ISOLATED CATFISH HORIZONTAL CELLS. C.L. Linn and B.N. Christensen. Dept. of Physiology & Biophysics, University of Texas Medical Branch, Galveston, TX, 77550.

Catfish cone horizontal depolarize to glutamate (GLU) and the glutamate analogs kainate (KA), quisqualate (QA) and N-methyl-D-aspartate (NMDA). In fura-2 loaded cells and with the cell membrane potential controlled with a voltage clamp, application of these agonists result in significant increases in intracellular Ca²⁺ as a result of influx and Ca²⁺-induced-Ca²⁺ release.

Caffeine (10 Mm) normally produces a rapid single transient increase in intracellular Ca²⁺. Dopamine (20 μ M) has a similar effect except that the Ca²⁺ transient is only about 25% of the caffeine-induced Ca²⁺ transient. Caffeine mobilizes intracellular Ca²⁺ by its direct effect on the Ca²⁺ store. Dopamine produces no membrane current, presumably does not cross the cell membrane and therefore, unlike caffeine must release Ca²⁺ via a second messenger system.

In some cells, caffeine can trigger Ca²⁺ oscillations. The exact conditions that are necessary for Ca²⁺ oscillations are not clear however, we believe that the cell must undergo a period of cytoplasmic Ca²⁺ load before caffeine is effective in triggering oscillations. Ca²⁺ loading can be readily produced by prior repetitive challenges with one of the GLU analogs. Supported by NRSA grant to C.L.L. and NEI EY-01897 to B.N.C.

POLYAMINE - STIMULATED PHOSPHOINOSITIDE TURNOVER IN CORTICAL MEMBRANES OF RAT BRAIN. S. Periyasamy and W. Hoss. Dept. of Medicinal and Biological Chemistry, Univ. of Toledo, Toledo, OH 43606.

The polyamines, spermidine and spermine, and their precursor, putrescine are present in virtually all cells. Although the physiological role of these amines is not well understood, studies have demonstrated that normal cellular growth and differentiation require polyamines. Behavioral studies have shown that polyamines produce sedation, hypothermia and convulsions in the laboratory animals. Recently, it has been demonstrated that there are specific binding sites for spermidine in membranes of rat brain. In the present study, we investigated the effects of polyamines on phosphoinositide (PI) turnover in rat brain cortical membranes. Cortical slices from rat brains were prelabelled for 2 hr at 37°C with [³H]-inositol and a membrane fraction was prepared by homogenization and centrifugation. Release of [³H]-inositol phosphates as a measure of PI turnover was determined using ACCELL QMA anion-exchange SEP-PAK's cartridges. The polyamines, spermine and spermidine produced concentration-dependent increases in PI turnover response in the presence of GTP- γ -S (10 μ M) and deoxycholate (1.5 mM) with the EC₅₀ values of 40 \pm 15 and 60 \pm 10 μ M, respectively. Spermidine produced maximal stimulation (200% above basal) at 1 mM whereas spermine produced maximal stimulation (130% above basal) at 300 μ M. Putrescine also produced an increase in PI turnover, but only at the higher concentrations. Our study clearly demonstrated a stimulatory effect of polyamines on PI turnover. We propose that the increased PI turnover response induced by polyamines is mediated by their specific receptors based on the following observations: 1) the stimulatory effect of the polyamines is dose-dependent and saturable; 2) the effect is GTP-dependent; and 3) specific binding sites for polyamines have been identified. The data suggest that at least some of the cellular effects of the polyamines might be initiated through the phosphoinositide cascade. The work was supported by NIH grants DA06258 and DA04068.

PROGESTERONE STIMULATES PHOSPHATIDYLIOSITOL METABOLISM IN SPECIFIC CNS STRUCTURES OF THE FEMALE RAT. S.A. Tischkau, G.S. Panjwani, J.W. Wright and V.D. Ramirez. Dept. of Physiology, University of Illinois, Urbana, Illinois, 61801.

The rapidity of onset of many of the actions of progesterone (P) suggests that these effects may not be mediated through the classical genomic mechanism for steroid hormone action. Recently, our laboratory has shown that P binds to specific sites in neuronal tissue plasma membranes. This study was undertaken to determine if the phosphatidylinositol (PI) pathway is a mechanism by which the nongenomic action of P occurs and if this action is specific to areas of the brain which are known target sites for P. The ability of P to activate the PI pathway was determined by incubating various concentrations of P with crude membrane fractions (P₂) prepared from cortex, hypothalamus, corpus striatum, and cerebellum to which [³H]-myo-inositol had previously been incorporated. Li⁺ was included to block reutilization of the myo-inositol. P stimulated PI metabolism in the corpus striatum in a dose-dependent manner. 10ng and 100ng P resulted in statistically significant increases (P<.001) in the PI response (796 \pm 219 CPM, n=8 and 947 \pm 154 CPM, n=7, respectively) as compared to basal levels (290 \pm 84 CPM, n=16). Similarly, P appears to stimulate the PI response from P₂ fractions prepared from medial basal hypothalamus. 2ng P resulted in a two-fold increase (519 \pm 4 CPM, n=2) over basal release (233 \pm 38, n=9). The effect of P on the PI response in the cerebellum is more complex. 10ng of P appears to stimulate the PI pathway, (876 \pm 53 CPM, n=2) as compared to control values (440 \pm 124 CPM, n=5), while, 100ng P (809 \pm 231, n=4) is neither stimulatory nor inhibitory. Finally, P has no effect on PI hydrolysis in P₂ fractions derived from cortical tissue. Curiously, basal PI release from the cortex was somewhat higher than other tissues (580 \pm 114, n=4). These data suggest that upon binding to a membrane site in the hypothalamus, corpus striatum, and cerebellum, progesterone stimulates the metabolism of phosphatidylinositol. The variation in response between neural tissues may indicate different functions for P in these tissues.

GLUTAMATE AND TRANS-ACPD INDUCE FORMATION OF INOSITOL 1,4,5-TRIPHOSPHATE IN RAT HIPPOCAMPAL SLICES: INTERACTION BETWEEN IONOTROPIC AND METABOTROPIC GLUTAMATE RECEPTORS. G. Lonart and K.M. Johnson. Department of Pharmacology and Toxicology, University of Texas Medical Branch, Galveston, TX 77550

We are currently investigating the possible influence of ionotropic glutamate receptors on the glutamate stimulated inositol 1,4,5-triphosphate (1,4,5-InsP₃) formation. Cross-chopped hippocampal slices (350 X 350 μ m) were prepared from male Sprague-Dawley rats, washed and incubated for 60 min in Krebs bicarbonate buffer, saturated with O₂/CO₂ (95:5). Gravity packed slices (50 μ l) were added to 220 μ l Krebs buffer. Additions of agonists/antagonists were made in a volume of 30 μ l. Incubation (5 min) was terminated by addition of 700 μ l of 1 M TCA. Generation of 1,4,5-InsP₃ was assessed using a radioreceptor assay. Glutamate (1 mM) induced a 58 \pm 8% increase in the basal 1,4,5-InsP₃ level (33.1 \pm 1.8 pmol/mg of protein). This was not blocked by the AMPA or NMDA receptor antagonists, CNQX (10 μ M) or CGS 19755 (10 μ M). AP-3 (300 μ M), a proposed antagonist of the metabotropic glutamate receptor, produced a 43 \pm 5% increase in the 1,4,5-InsP₃ formation alone. This response was not further increased by adding glutamate (1 mM), suggesting a possible agonistic effect of AP-3. However, trans-ACPD (100 μ M), an agonist of the metabotropic receptor, stimulated the basal 1,4,5-InsP₃ level by 54 \pm 8% in a manner that was antagonized by AP-3. Ongoing experiments are being carried out to test the effect of the ionotropic glutamate receptor agonists AMPA and NMDA on the trans-ACPD stimulated 1,4,5-InsP₃ formation. Supported by DA-02073.

INOSITOL PHOSPHATES (IP) BREAKDOWN IN CHICKEN BRAIN: EFFECTS OF MELATONIN (MEL) ANALOGUES, SUBSTANCE P (SP) AND TRH. J.S. Popova* and M.L. Dubocovich, Dept. Pharmacol., Northwestern University Medical School, Chicago, IL 60611.

The direct effect of various agents on phosphatidylinositol (PI) breakdown (lithium 10 μ M) was examined in chick striatum (E) and optic lobes (OL). Chicks (1-2 weeks old) maintained on a 14:10 L:D cycle were sacrificed 4 hours after lights on. Slices were prelabeled with 0.53 μ M myo-[2- 3 H]-inositol. IP were separated (IP₃, IP₂, IP₁) by Dowex ion exchange chromatography. In control OL slices following 30 min incubation with Li, the accumulation of IP₃, IP₂ and IP₁ was 1.09%, 1.7% and 5.05% of total tissue radioactivity, respectively. Exposure to 1-100 μ M melatonin analogues (MEL, 6-Cl-MEL, 2-IMEL, N-Acetylserotonin), SP (10 μ M) or TRH (10 μ M) during 5 min increased IP₁ accumulation by 10-35%. Exposure to 6-Cl-MEL (10 μ M) for 20 sec induced transient increases in IP₃ and IP₂ levels (30% and 37%, respectively), while IP₁ levels increased in a time dependent manner from 1% at 1 min to 30% at 30 min. The increased in IP breakdown elicited by 6-Cl-MEL was identical in slices from S and OL, and was not modified by sacrificing the chicks 12 h after lights on. Methysergide (10 μ M), a non-selective serotonin (5-HT) antagonist, inhibited 5-HT-induced (10 μ M) but not 6-Cl-MEL-induced (10 μ M) IP₁ accumulation, suggesting that the effects of melatonin analogues on PI breakdown may not be mediated through activation of 5-HT-1c or 5-HT-2 receptor.

173.19

BERYLLIUM IS A POTENT INHIBITOR OF BRAIN *myo*-INOSITOL-1-PHOSPHATASE, BUT UNLIKE LITHIUM DOES NOT POTENTIATE AGONIST INDUCED PI TURNOVER. S.H. Zom, W.S. Faraci*, A.V. Bakker*, K.G. Pratt*, Department of Neuroscience, Central Research Division, Pfizer Inc., Groton, CT 06340.

Lithium is the drug of choice for the treatment of bipolar depression although it has some limiting side effects. Its action may be due in part to its ability to dampen phosphatidylinositol turnover (PI) by inhibiting *myo*-inositol-1-monophosphatase (IP1ase). The present study was undertaken to examine the properties of BeCl₂ as a lithium mimetic agent. BeCl₂ is at least three orders of magnitude more potent than LiCl (K_i = 0.5-0.8 mM) as an inhibitor of partially purified IP1ase isolated from rat brain (K_i = 150 nM), bovine brain (K_i = 35 nM), and from the human neuroblastoma cell line SK-N-SH (K_i = 100 nM). Kinetic analysis revealed that BeCl₂ is a competitive inhibitor of IP1ase, in contrast to that of lithium (uncompetitive). Inhibition of exogenous [3 H]-1-(1)-P breakdown by BeCl₂ (IC₅₀ = 100-200 nM) was observed to the same maximal extent as that seen with lithium (10nM) in permeabilized SK-N-SH cells reflecting inhibition of cellular IP1ase. In contrast to lithium's potentiation of agonist induced PI turnover in intact and permeabilized SK-N-SH cells and in rat brain slices, BeCl₂ was completely inactive in this regard at concentrations up to 0.5 mM. These studies indicate that BeCl₂ is a potent competitive inhibitor of brain *myo*-inositol-1-monophosphatase *in vitro*. The disparity in the actions of BeCl₂ and Lithium may suggest that either selective inhibition of IP1ase does not completely explain the action of lithium on the PI cycle, or that uncompetitive inhibition of IP1ase is a necessary requirement to observe functional lithium mimetic activity.

173.21

PHOTOAFFINITY LABELING OF THE INOSITOL-1,4,5-TRISPHOSPHATE RECEPTOR BINDING SITE. B.J. Mourey, V.A. Estevez*, J.F. Marecek*, G.D. Prestwich* and S.H. Snyder, Depts. of Pharmacology and Neuroscience, Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205; Dept. of Chemistry, SUNY, Stony Brook, NY 11794.

The inositol-1,4,5-trisphosphate (InsP₃) binding site is believed to be located in the amino terminal quarter of the InsP₃ receptor. To address where in this region InsP₃ is binding, we have synthesized an InsP₃ photoaffinity ligand, [125I]1-O-[N-(4-azidosalicyloxy)-3-aminopropyl-1-phospho] myo-inositol 4,5-bisphosphate (Prestwich, G.D., *et al.* *JACS*, 113:1822, 1991). This ligand binds to the InsP₃ receptor with high affinity and specificity, i.e., InsP₄ and InsP₆ are weak competitors while other inositol phosphates are inactive.

In crude rat cerebellar membrane fractions, only the InsP₃ receptor is specifically labeled, i.e., completely displaced by high concentrations of unlabeled InsP₃. Two-dimensional peptide maps prepared from enzymatic (trypsin, thermolysin, St. aureus V8) or chemical (cyanogen bromide) digestion of purified photolabeled InsP₃ receptor all yield a single labeled spot which is very acidic. In the published amino acid sequence of the InsP₃ receptor, there exists only one very acidic region (a.a. 317-330) in the amino terminal quarter of the receptor. We hypothesize that InsP₃ may bind basic residues near this region. Based on the amino acid sequence, we would predict a labeled cyanogen bromide peptide of approximately 14 kDa and a N-chlorosuccinamide peptide of 10.9 kDa. Interestingly, we do resolve a photolabeled peptide of the predicted sizes using a tricine-SDS-PAGE system.

173.18

LITHIUM INHIBITION OF NORADRENALIN STIMULATED CYCLIC AMP ACCUMULATION AND AGONIST STIMULATED MASS INOSITOL PHOSPHATE DETERMINATION IN WISTAR RAT CEREBRAL CORTEX SLICES. SILLENCE D.J and DOWNES C.P.* Department of Biochemistry University of Dundee UK

One theory for the mechanism of action of lithium in the treatment of affective disorders is that lithium inhibits specific adenylyl cyclases perhaps by inhibiting G-protein function, another is that lithium attenuates the production of inositol phosphates by inducing inositol depletion in hyperactive neurons. NA acting on the alpha-1 receptor potentiates cyclic AMP accumulation and stimulates inositol phosphate production. Data is presented comparing the inositol reversibility of CMPPA accumulation, Inositol phosphate mass and cyclic AMP accumulation. The concentration of lithium required to incur these effects are compared to elucidate which is the therapeutically relevant target for lithium's action.

173.20

FUSION PROTEIN ANTIBODIES DIRECTED AGAINST TOPOGRAPHICALLY DISTINCT REGIONS OF THE CEREBELLAR INOSITOL-1,4,5-TRISPHOSPHATE RECEPTOR. D. Lin and W.S. Agnew, Dept. of Cellular and Molecular Physiology and Program in Neuroscience, Yale Univ. Sch. of Med., New Haven, CT 06510. cDNA fragments were prepared by PCR from mouse cerebellar mRNA with primers specific for coding sequences near the N-terminus (5'), middle (M), and carboxyl terminal membrane spanning segments (3 α , 3 β). These were cloned, sequenced and spliced into pGEX expression vectors to form fusion protein recombinants with glutathione S-transferase. Preparative amounts of antigens were grown in *E.coli*, isolated by affinity purification or by electroelution, and used to raise rabbit polyclonal antisera. Antigen-specific antibodies were then characterized for their utility in western blots, immunoprecipitation, and immunocytochemical labeling.

All four antibodies reacted strongly in western blots performed with a high affinity (K_d = 4 nM) IP₃ receptor purified from rat cerebellum, or with unpurified receptor in cerebellar microsomes. Antibodies M and 3 β efficiently precipitated the native receptor, while 5' was less effective. Antibodies M and 3 α provided sensitive immunocytochemical markers; strong labeling was observed in the soma, dendrites and dendritic spines of cerebellar Purkinje neurons. Axonal staining of these cells, previously not reported, was also clearly visible. Other novel findings included labeling of relatively rare cerebellar Lugaro cells, hippocampal neurons, as well as pyramidal cells in the cerebral cortex. These antibodies provide useful biochemical and immunocytochemical reagents for studies of receptor structure, expression, and localization.

IP₃-SENSITIVE CALCIUM STORES ARE REFILLED BY A PLASMALEMAL CALCIUM LEAK. T.M. Lo and S.A. Thayer, Dept. of Pharmacology, Univ. of Minnesota, Minneapolis, MN 55455.

The refilling mechanism for IP₃-sensitive calcium stores in single NG108-15 hybridoma cells was examined by indo-1 based microfluorimetry. IP₃-sensitive calcium stores were depleted by a single 1 minute exposure to bradykinin (30nM). The stores were refilled completely in 20 minutes (t_{1/2} = 2 minutes). Thapsigargin produced a transient release of calcium from the store and inhibited refilling with an EC₅₀ of 3nM indicating mediation by the microsomal Ca-ATPase. This effect was partially reversible at submaximal thapsigargin concentrations. The refilling of these stores was also blocked by the removal of extracellular calcium. Verapamil (10uM), diltiazem (10uM), flunarizine (10uM), and nickel (0.2mM) did not effect the refilling of IP₃-sensitive calcium stores. However, nifedipine (10uM) and lanthanum (10uM) blocked refilling of these stores suggesting involvement of a specific channel in replenishing intracellular IP₃-sensitive calcium stores. Exposing NG108-15 cells to 10mM Ca²⁺ following Ca²⁺-free (1mM EGTA) treatment caused a transient increase in calcium. The amplitude of this [Ca²⁺]_i transient was not altered by depleting the store with bradykinin prior to the calcium challenge suggesting that an additional influx was not recruited during refilling of IP₃-sensitive calcium stores. These results suggest that the IP₃-sensitive calcium stores in NG108-15 cells are refilled by a plasmalemmal calcium leak channel.

173.23

SUBSECOND KINETICS AND REGULATION OF IP3-INDUCED Ca^{2+} RELEASE BY ATP. E.A. Finch^{1,3}, T.J. Turner², and S.M. Goldin^{2,3}.

¹Program in Neuroscience and ²Biol. Chem. Dept., Harvard Med. Sch., Boston, MA 02115; ³Cambridge Neuroscience Research, Inc., Cambridge, MA 02139.

We have previously reported that extravesicular Ca^{2+} (Ca^{2+}_e) rapidly potentiates and more slowly inactivates IP3-induced $^{45}Ca^{2+}$ release (Finch et al., *Science* 252:443, 1991). The finding that Ca^{2+}_e is a coagonist for the IP3 receptor suggests functional homology with the structurally homologous ryanodine receptor of sarcoplasmic reticulum. ATP has been reported to allosterically regulate both the IP3 receptor and the ryanodine receptor. We have examined the effects of ATP on the subsecond kinetics of IP3-mediated $^{45}Ca^{2+}$ release from synaptosome-derived microsomes using a rapid superfusion system.

Both Na_2ATP and $MgATP$ rapidly potentiated IP3-induced $^{45}Ca^{2+}$ release (within 100 ms after introduction of ATP). The maximum rate of $^{45}Ca^{2+}$ release was increased at all $[Ca^{2+}_e]$ examined (0.1 - 100 M). The rapid potentiation by Ca^{2+}_e and the biphasic Ca^{2+}_e -dependence of IP3-induced $^{45}Ca^{2+}$ release observed by Finch et al. remained apparent in the presence of ATP, but the amplitude of the $^{45}Ca^{2+}$ release was increased. At 10 μM Ca^{2+}_e , 0.1 - 3 mM Na_2ATP produced an ≈ 2 -fold increase in the maximum rate of IP3-induced $^{45}Ca^{2+}$ release. The potentiation was also observed with AMP-PNP and ATP βS , indicating that ATP hydrolysis was not required. These results suggest that Ca^{2+}_e and ATP synergistically potentiate IP3-induced $^{45}Ca^{2+}$ release. They further suggest that rapid changes in ATP levels may modulate IP3-induced $^{45}Ca^{2+}$ release. Finally, in the presence of IP3 and ATP changes in cytosolic $[Ca^{2+}]_i$ are likely to dynamically regulate IP3-induced $^{45}Ca^{2+}$ release.

173.24

LOCALIZATION OF INOSITOL TRISPHOSPHATE RECEPTOR IN NEURONAL CELL BODIES, DENDRITES AND TERMINALS IN THE RAT CENTRAL NERVOUS SYSTEM.

A.H. Sharp, C.A. Ross, T.M. Dawson and S.H. Snyder. Dept. of Neuroscience, The Johns Hopkins University School of Medicine, Baltimore, MD 21205

The inositol trisphosphate receptor (IP3R) releases Ca^{2+} from intracellular stores in response to stimulation of IP3 production by neurotransmitters and hormones and has been previously localized to the endoplasmic reticulum of cerebellar Purkinje cells. To help elucidate the function of the IP3R, we have now determined the localization of the IP3R throughout the rat brain and spinal cord by an immunoperoxidase method using affinity purified antibodies against the rat cerebellar IP3R and by *in situ* hybridization. Among the structures labeled, cell bodies and dendrites were intensely stained in the hippocampus, cortex, dorsal cochlear nucleus and olfactory tubercle. A number of the circumventricular organs were strongly stained suggesting a role for IP3 as a second messenger in regulation of water and salt balance. Other labeled areas included the striatum, olfactory bulb and various nuclei in the thalamus, hypothalamus and brainstem. Nerve terminals were prominently labeled in a number of areas including the deep cerebellar and vestibular nuclei and the substantia nigra reticulata suggesting a role for IP3 in modulation of neurotransmitter release.

174.1

THE ANXIOLYTIC EFFECTS OF AHR14042, A NOVEL AZETIDINE, ARE NOT MEDIATED BY BENZODIAZEPINE RECEPTORS. D.J. Bill, A. Fletcher, C.A. Boast, H. Morris, R. Tasse, and D.N. Johnson. Wyeth Research (U.K.), Taplow, Maidenhead SL6 0PH, U.K. and Wyeth-Ayerst Research, CN 8000, Princeton, NJ, 08543-8000.

AHR14042 is a novel azetidone molecule [3(4-chlorophenoxy)-N-(2-propenyl)-1-azetidonecarboxamide]. We have examined the activity of this compound in two animal models of anxiety, i.e. the rat Geller-Seifter paradigm and the mouse two-compartment light:dark box model. AHR14042 was also examined in several seizure models in the mouse.

AHR14042 was active in both models of anxiety, inducing effects similar to those of benzodiazepine positive controls. In the mouse light:dark box, AHR14042 significantly increased light compartment rearing and motor activity at doses (0.1-1.5mg/kg sc) which did not modify dark compartment behaviour. AHR14042 significantly increased punished responding in the rat Geller-Seifter paradigm at a dose of 10mg/kg i.p. In both models, the benzodiazepine receptor antagonist, flumazenil (10mg/kg), blocked the effects of diazepam or lorazepam, but not those of AHR14042. When administered up to high dose levels (25mg/kg sc) in mice, AHR14042 had no significant effect on pentylenetetrazol-induced clonic seizures. AHR14042 exerted a weak anticonvulsant effect at high doses in mice challenged with picrotoxin, bicuculline or electroshock. This effect was accompanied by marked sedation/ataxia, suggesting that the compound was inducing a general non-specific effect at these doses. A wide receptor binding profile of AHR14042 did not reveal a significant binding affinity of this compound for any of the major central monoamine, amino-acid, benzodiazepine or opioid receptors. AHR14042 also did not interact with calcium, potassium or chloride channels, or with the adenylyl cyclase or protein kinase C second messenger systems. Further work will be focussed on ascertaining the mechanism of action of this novel and interesting anxiolytic.

174.3

MEDIAL HYPOTHALAMIC FACILITATION OF FELINE DEFENSIVE RAGE FROM THE PERIAQUEDUCTAL GRAY IS MEDIATED THROUGH NMDA RECEPTORS. A. Siegel, C.L. Lu* and M.B. Shaikh. Dept. of Neurosciences, N.J. Medical School, Newark, NJ 07103.

The principal excitatory input to the midbrain periaqueductal gray (PAG) with respect to defensive rage behavior (DR) arises from the medial hypothalamus (MH). The present study was designed to test the hypothesis that this pathway utilizes excitatory amino acids (EAA) as a transmitter. Cannula electrodes were implanted into PAG sites for elicitation of DR as well as for infusion of EAA antagonists and NMDA, and stimulating electrodes were placed into sites within the MH from which facilitation of DR could be obtained. Concurrent stimulation of the MH and PAG facilitated DR when compared to single stimulation of the PAG. Then, this dual stimulation paradigm was repeated following microinjections of EAA antagonists into PAG DR sites: kynurenic acid (KYN, non-specific) [0.1-2.0 nM], DAP-7 (NMDA) [0.1-2.0 nM], CNQX (non-NMDA) [4.0 nM]. The results indicated that both KYN and DAP-7 blocked the facilitatory effects of MH stimulation upon DR in a dose and time dependent manner. In contrast, infusion of CNQX failed to alter the facilitatory effects of MH stimulation. Moreover, infusion of NMDA into PAG DR sites mimicked the facilitatory effects of MH stimulation in a dose and time dependent manner. The results indicate that EAA is a transmitter involved in MH facilitation of PAG elicited DR in which NMDA receptors are utilized. [Supported by NIH Grant NS 07941-21].

174.2

EFFECTS OF ALLOSTERIC AGONISTS FOR NMDA RECEPTOR COMPLEX ON METHAMPHETAMINE-INDUCED LOCOMOTOR STIMULATION IN RATS. A. Hashimoto*, T. Nishikawa*, T. Oka*, T. Higuchi and K. Takahashi. Div. of Mental Disorder Res., Natl. Inst. of Neurosci., NINP, Tokyo, 187, Japan and Tsukuba Res. Lab., Nippon Oil & Fats Co., Ltd. Ibaraki, Japan.

The findings indicating that destruction of cortico-fugal glutamatergic pathways augments amphetamine-induced hyperactivity and stereotyped behaviors have suggested the possible involvement of reduced excitatory amino acidergic transmission in these abnormal behaviors. We have investigated the effects of intracerebroventricular (i.c.v.) injection of allosteric agonists for the NMDA receptor. I.c.v. injection of D-Ser and D-Ala reduced the ability of methamphetamine (MAP) to induce hyperactivity (1.0 mg/kg, s.c.) in a dose-dependent manner without affecting MAP-induced stereotyped behaviors. In contrast, the L-isomer of Ala failed to affect the MAP-induced hyperactivity. This stereospecificity suggests that the antagonism of locomotor stimulatory effects of MAP may be due to stimulation of strychnine-insensitive glycine binding site, since the D-forms are more potent than L-forms as agonists for the allosteric regulation site of NMDA receptor complex.

174.4

ACQUISITION OF DRUG DISCRIMINATION LEARNING WITH CHOLECYSTOKININ. P.M. Melton & A.L. Riley. The American University, Washington, D.C. 20016.

Recently, the conditioned taste aversion procedure has been demonstrated to be a viable behavioral baseline to examine control by drug states, i.e., drug discrimination learning (Mastroianni et al., *Pharmacol. Biochem. Behav.*, 32: 1-8, 1989). The sensitivity of the procedure is indexed by the rapid acquisition of drug discriminations using this design and by the variety of compounds for which a discrimination has been established, including the opiate antagonists (Kautz et al., *Drug Dev. Res.*, 16: 317-326, 1989). The present study examined the ability of cholecystokinin (CCK) to serve as a discriminative cue, a compound for which discrimination learning has heretofore been hard to establish. Specifically, every fourth day experimental rats were injected with 13 $\mu g/kg$ of CCK 5 min before saccharin-lithium chloride pairings and control rats were injected with 13 $\mu g/kg$ of CCK before saccharin-distilled water pairings. On recovery days, all animals were injected with the CCK vehicle prior to saccharin exposure with no post injection. After 10 CCK-saccharin-lithium trials, 7 of 12 experimental animals acquired the discrimination. In subsequent generalization tests, 10, 18, and 32 $\mu g/kg$ of CCK resulted in drug-appropriate responding, whereas doses lower than 10 $\mu g/kg$ did not. Neither the opiate antagonists naloxone (0.56, 1.0, 3.2 mg/kg) nor diprenorphine (1.0, 3.2, 5.6 mg/kg) substituted for the CCK cue.

174.5

EFFECTS OF CHRONIC CAFFEINE EXPOSURE IN MICE ON LOCOMOTOR ACTIVITY AND THE RESPONSE TO ADENOSINE AGONISTS AND ANTAGONISTS. O. Nikodijevic, K. A. Jacobson, and J. W. Daly. NIDDK, NIH, Bethesda, MD 20892.

Chronic caffeine treatment results in an upregulation of central adenosine receptors, but the role of such receptors in tolerance to caffeine is unclear. In mice ingesting caffeine (1 g per liter in drinking water), the locomotor activity relative to vehicle control was greater during the first 24 hours (increasing gradually to 48% stimulation), and then decreased (gradually to 45%) for 5 days, after which time activity stabilized slightly (15-20%) lower than control levels. After stabilization, the A₁-selective adenosine agonist N⁶-cyclohexyladenosine (i.p.) was less effective than in controls in decreasing locomotor activity, while caffeine (i.p.) caused a slight stimulation to about the level of locomotor activity in controls. The bell-shaped dose response curve for the locomotor effects of caffeine (i.p.) in mice chronically ingesting caffeine appeared shifted to the left, and the maximum effect was diminished compared to controls. This suggests that multiple processes underlie caffeine habituation, and that adenosine receptor regulation is only in part involved.

174.7

DIFFERENCES AMONG NEUROLEPTICS IN INHIBITING METHYLPHENIDATE-INDUCED STEREOTYPED BEHAVIORS: POSSIBLE RELATIONSHIP WITH VARYING CLINICAL EFFICACY. W. Koek and F.C. Colpaert. FONDAX, Groupe de Recherche SERVIER, Puteaux, FRANCE.

Methylphenidate (MPD) increased in rats the incidence of sniffing, rearing and locomotion, and, at higher doses, exclusively induced stereotyped gnawing. Neuroleptics inhibited gnawing induced by 40 mg/kg of MPD; however, as gnawing was inhibited in a dose-dependent manner, other responses (i.e., sniffing, rearing and locomotion) appeared. Higher doses of neuroleptics also inhibited these latter responses, so that the behavior of the MPD-treated animals became similar to that of normal controls. Only neuroleptics appeared able to normalize the behavior of MPD-treated rats, i.e., to inhibit all of MPD's effects at doses that induced neither complete behavioral suppression nor adverse effects. The neuroleptics differed markedly, however, in terms of the relative doses at which they 1) inhibited gnawing, 2) inhibited the other effects of MPD, and 3) induced complete behavioral suppression or adverse effects. These differences among neuroleptics seem to be compatible with their relative efficacy in suppressing the productive symptoms of schizophrenia.

MICROIONTOPHORETICALLY APPLIED ACETYLCHOLINE, MORPHINE AND NOREPINEPHRINE MODULATE BED NUCLEUS OF STRIA TERMINALIS NEURONS. N. Dafny and J.H. Casada. Department of Neurobiology and Anatomy, The University of Texas Medical School at Houston, Houston, TX 77225.

The bed nucleus of the stria terminalis (BNST) has been implicated in the production of several of the components of the stress response including endocrine, autonomic and behavioral changes. Because of the ability of BNST to regulate several components of the stress response, a study of the effects of neurotransmitters found in BNST may lead to an understanding of physiological coping mechanisms or provide a basis for the pharmacological control of the stress response. The present experiment was designed to determine the effects of three neurotransmitter systems in rats (N=4) anesthetized with 1.25 g/kg urethane. The following drugs were administered via a 6 barrel glass electrode: glutamate, morphine (MS), norepinephrine (NE), acetylcholine (ACh), and a vehicle carrier. Forty-five single BNST neurons were tested with each drug. 52% of BNST neurons responded to MS with increases and decreases in firing rate observed with equal frequency. 72% of BNST neurons responded to NE, predominantly with decreases in firing rate. Finally, 46% of BNST neurons responded to ACh, predominantly with increases in firing rate. The typical BNST neuron responded to more than one drug; 30% of these neurons responded to all three drugs which were tested. Thus NE, ACh, and opiates appear to be important in modulating the firing rate of BNST neurons.

174.6

HORMONAL MODULATION OF MUSCIMOL-INDUCED CATATONIA: A NEW MODEL FOR CHANGES IN DRUG SENSITIVITY? L.C. Kaufman, M.M. McCarthy, D.W. Pfaff and S. Schwartz-Giblin. Rockefeller University, 1230 York Ave, NY, NY. 10021.

The specific GABA-A receptor agonist, muscimol, has been shown to induce catatonia when infused into the lateral hypothalamus or zona incerta of male rats (Wardas et al., Brain Res. 1988). In the present experiments, female rats implanted with 23 g cannulae directed at the ventromedial hypothalamus were tested for catatonia beginning one week post-surgery. Catatonia was determined by placing the animals forepaws on a 9cm high block and timing the latency to descent, with a cut-off time of 5 min. After a pretest, muscimol (25ng) or saline was bilaterally infused (0.25 µl/side) and the animal tested for catatonia at 5, 10, 20, 30, 60 and 120 min post-infusion. Ovariectomized (OVX) rats infused and tested daily for five days showed a significant catatonia after muscimol vs. saline with a peak in catatonia being observed at 60 min post-infusion and increasing catatonia over the 5 day period (two-way ANOVA; p<.001). In a separate experiment, hormonally-treated females were infused with muscimol and tested for catatonia. When OVX, estrogen-treated (E-treated; 10 µg for 2 days prior) and progesterone-treated females (P-treated; 1mg 4 hr prior) were infused with muscimol there was significantly higher catatonia in the OVX and E-treated females as compared to P-treated females (ANOVA; p<.05). These E- and P-treated females tested at weekly intervals exhibited different patterns of sensitization to muscimol. Catatonia induced by muscimol in E-treated females did not change over the 3 weeks but in P-treated females catatonia was significantly greater at 3 weeks than 1 or 2 weeks (p<.05). These results indicate an increasing sensitivity to muscimol when given daily for 5 days and changes in drug sensitivity after weekly administration which are dependent on the hormonal milieu. It is proposed that catatonia testing may serve as a useful index of changes in drug sensitivity after repeated exposure.

IMPLICATION OF ACETYLCHOLINE IN THE INITIATION OF 22 kHz ULTRASONIC VOCALIZATION IN THE RAT. S.M. Brudzynski and D. Ociepa. Dept of Clinical Neurological Sciences, University of Western Ontario, London, Ontario, N6A 5A5 Canada.

It has been recently reported that direct application of carbachol into the rat's basal forebrain can induce 22 kHz ultrasonic vocalization suggesting that the central cholinergic system is involved in initiation of ultrasonic calls. The aim of the present study was to demonstrate that endogenous acetylcholine is implicated in the generation of ultrasonic vocalization in rats. Ultrasonic calls were induced by a mild footshock (max. 1 mA for 1 s) in 17 rats. Bilateral intracerebral injection of physostigmine (10 µg/0.2 µl) into the anterior hypothalamic/preoptic area potentiated and prolonged, by 3.5 times, the duration of ultrasonic vocalization induced by footshock. Local pretreatment with atropine (0.5 µg/0.2 µl) decreased, by 3.7 times, the duration of the footshock-induced vocalization. These results were significant as compared to saline pretreated controls. It is concluded that endogenous acetylcholine is involved in the initiation of 22 kHz ultrasonic calls in rats.

ENVIRONMENTAL DETERMINANTS OF THE RELATIVE REINFORCING EFFICACY OF NICOTINE. S.I. Dworin, J. Broadbent, R. Guarino, and J. Robinson. Dept. of Physiology and Pharmacology, Wake Forest University, The Bowman Gray School of Medicine, Winston-Salem, NC 27157.

Male Fisher-344 rats were used to determine conditions under which animals could be trained to self-administer nicotine. For these investigations three behavioral paradigms were utilized to assess the relative reinforcing efficacy of nicotine compared to cocaine. The three paradigms included a fixed-ratio schedule of drug presentation, a schedule-induction paradigm using a fixed-time 1 min schedule of food delivery and a concurrent chained schedule of food, water and nicotine delivery. Lever presses under all three procedures resulted in a 0.2ml infusion of nicotine (3-10 µg/infusion) delivered over 5.6 sec. Under both the fixed-ratio and concurrent chained schedule the initial rates of nicotine self-administration (2-24 infusions) diminished over the first three to five sessions to comparatively low levels (2-6 infusions). Twenty-four hour food extinction probes increased nicotine self-administration under the concurrent chained schedule. Substitutions of cocaine for nicotine resulted in higher rates of self-administration by rats under the fixed-ratio procedure. Single infusions of nicotine to rats that self-administered cocaine but not nicotine under the fixed-ratio procedure, resulted in a decrease in cocaine self-administration. The schedule-induction paradigm produced relatively high rates of responding that resulted in nicotine infusions. However, saline substitutions did not immediately diminish responding by these rats. These data indicate it is more difficult to engender and maintain nicotine self-administration compared to cocaine self-administration, which suggest that cocaine has a greater reinforcing efficacy than nicotine. (Supported by a contract from the R.J. Reynolds Tobacco Co.)

EVALUATION OF CENTRAL EFFECTS OF NICOTINE IN A DRUG DISCRIMINATION PARADIGM USING MICRODIALYSIS TECHNIQUES IN RATS. H.F. Villanueva, J.H. Johnson, S. Arezo, J.R. James, and J.A. Rosecrans. Depts. of Pharmacology/Toxicology & Anatomy, Virginia Commonwealth Univ., Richmond VA 23298.

It has previously been shown that rats trained to discriminate peripherally administered nicotine in a two-lever operant drug discrimination procedure will generalize to nicotine injected directly into the dorsal hippocampus and the reticular formation (PBB 15:21-26, 1981). Current research in this laboratory is examining the use of microdialysis techniques to administer nicotine intracerebrally. Nicotine bitartrate or buffered vehicle was delivered via a microdialysis probe inserted through a guide cannula 1-6 hours prior to testing. Brain areas tested include the mesencephalic reticular formation, dorsal hippocampus and nucleus accumbens. Preliminary studies involving the infusion of radioactive nicotine indicate that 2% of the nicotine infused through the probe reached the tissue, resulting in approximately 2.4 µg nicotine reaching the tissue over a 10 minute period of infusion with 25µl of a 30 mmolar nicotine solution. FAGERSTROM TOLERANCE QUESTIONNAIRE (FTQ) SCORE, PLASMA COTININE, CAFFEINE AND SMOKING-INDUCED MOOD CHANGES. C.J. Meliska & D.G. Gilbert*. Psych. Dept., Southern Ill. Univ. at Carbondale, Carbondale, IL 62901

Plasma nicotine, cotinine (COT), and caffeine (CAF) were assayed before and after 2 and 5 cigarettes, in 8 male and 8 female, overnight smoking-deprived smokers. Before testing, subjects completed the FTQ, an instrument purporting to differentiate smokers based on physical dependence. Mood was assessed before and after smoking. Partial correlation coefficients (controlling for gender and, where appropriate, nicotine boost and nicotine-free baseline values) showed that, prior to smoking: (1) FTQ scores were marginally correlated with plasma COT levels ($r = .400$, $P = .07$) and with unpleasant feelings ($r = .61$, $P = .028$); (2) plasma COT correlated with negative affect ($r = .61$, $P = .048$) and malaise (nausea + sick + unpleasant; $r = .70$, $P = .016$); (3) CAF correlated positively with drowsiness ($r = .70$, $P = .016$). After 2 cigarettes: (1) FTQ correlated negatively with arousal (Energy + Alert - Drowsy, $r = -.75$, $P = .008$) and positively with negative affect ($r = .91$, $P = .001$); (2) COT correlated with positive affect ($r = .71$, $P = .050$) and reduced anger ($r = -.79$, $P = .020$); (3) CAF correlated with reduced anger ($r = -.76$, $P = .040$) and malaise ($r = -.80$, $P = .030$). After 5 cigarettes COT correlated negatively with arousal ($r = -.86$, $P = .006$). Results suggest that plasma COT and CAF levels modulate the mood-influencing effects of smoking.

THE EFFECTS OF SCOPOLAMINE ON VACUOUS CHEWING INDUCED BY SUB-CHRONIC HALOPERIDOL IN THE RAT. R. E. Steingreis and J. D. Salamone. Dept. of Psychology, Univ. of Connecticut, Storrs, CT 06269-1020.

Long and short term administration of neuroleptic drugs produces debilitating extrapyramidal side effects in humans. In rats, neuroleptics produce involuntary movements including vacuous chewing. In the present study, rats were given daily IP injections of either vehicle, 0.4 mg/kg haloperidol (HP) alone, 0.4 mg/kg HP with 0.25 mg/kg scopolamine (SC), or 0.4 mg/kg HP with 0.5 mg/kg SC. Rats were observed in daily 5-min blocks, over a two week period. Observation periods began 50 min after injection. Sub-chronic HP produced a syndrome of vacuous chewing movements in rats that was present in the first few days. Repeated daily co-administration of 0.5 mg/kg SC with HP from the first day resulted in a partial attenuation of the emergence of the syndrome, while co-administration of the lower dose of SC with HP did not. Rats continuing on HP alone after SC was withdrawn demonstrated a rebound increase, showing the highest number of vacuous chewing movements of all groups. In rats previously treated with HP alone, co-administration of 0.5 mg/kg SC with HP after the tenth day did not reduce vacuous chewing responses. These findings have implications for the efficacy and timing of anticholinergic reversal of acute-onset extrapyramidal side effects.

THE DISCRIMINATIVE STIMULUS PROPERTIES OF AN ETHANOL-NICOTINE MIXTURE IN RATS. B.D. Youngblood, D.V. Gauvin, and F.A. Holloway. Dept. of Psychiatry & Behavioral Sciences, University of Oklahoma Health Sciences Center, Oklahoma City, OK 73190-3000.

Very little is known about the factors or "rules" that govern the perception of drugs in mixtures. This laboratory has previously reported results of drug discriminations (DD) based on a number of legal stimulant mixtures. We now report the results of an "AND" drug discrimination (Stolerman & Mariathasan, *Psychopharmacology*, 102, 557-560, 1990) between an ethanol-nicotine mixture and saline (SAL). Twelve Sprague-Dawley rats were trained to discriminate between SAL and an ethanol-nicotine mixture (1.0 g/kg ethanol + .3 mg/kg nicotine) administered i.p. 15 min prior to a 15 min DD task under a FR10 schedule of food maintained lever-press responding. The elements of the compound stimulus, when tested singly, engendered approx. 50-50 responding on the SAL- and mixture-appropriate levers. A full range of ethanol and nicotine doses were tested in combination with SAL; both drugs failed to engender >90% mixture-appropriate responding up to doses that suppressed rates of responding. However, when the training doses of either ethanol or nicotine were held constant and various doses of the alternate drug element were added in combination, a graded dose-dependent increase in mixture-appropriate responding resulted. These data, in conjunction with Stolerman (*Psychopharmacology*, 101, S74, 1990), suggest that 1) drug mixtures are not normally perceived as new entities distinct from their component elements; 2) training dose-ratio may influence the characteristics of mixture discriminations; and 3) overshadowing of one drug by another may be an important factor determining the characteristics of cues produced by drug mixtures.

174.14

EFFECTS OF ANTICHOLINERGICS ON ELEVATED PLUS-MAZE BEHAVIOUR IN THE RAT. C. P. S. Smith, A. Chape* and G. W. Bennett*. (SPON: Brain Research Association). Dept. of Phys. & Pharm.-Med. Sch., Q. M. C., Nottingham, NG7 2UH, UK

The Elevated Plus-Maze (EPM) has recently been used as a test paradigm for the evaluation of learning and memory in mice. The present study assessed the effects of two muscarinic cholinergic antagonists, atropine (ATR) and scopolamine (SCOP) on EPM performance in the rat. Male, Hooded Lister rats (250-450 g) received single daily injections of either saline (SAL; 1 ml/kg i.p. n=8 and 10), SCOP (0.15 mg/kg i.p. n=8) or ATR (2.0 mg/kg i.p. n=9) 30 min prior to testing on three consecutive days. On day 1, both ATR and SCOP treated animals exhibited a reduced transfer latency (TL-time taken to reach centre of closed arm from end of open arm) and increased residence latency (RL-time spent within closed arm) compared to SAL controls (Mann-Whitney U test; TL $p < 0.01-0.05$, RL $p < 0.001-0.05$). On days 2 and 3, SAL TL scores were reduced ($P < 0.001$) compared to day 1, whereas ATR and SCOP TL scores were not. The results indicate that ATR and SCOP have both anxiogenic and learning effects in this test.

C. P. S. Smith is a SERC CASE student in conjunction with SmithKline Beecham.

174.16

THE DISCRIMINATIVE STIMULUS PROPERTIES OF ACUTE ETHANOL WITHDRAWAL (HANGOVER) IN RATS. D.V. Gauvin and F.A. Holloway, Dept. of Psychiatry & Behavioral Sciences, University of Oklahoma Health Sciences Center, Oklahoma City, Oklahoma 73190-3000

We have previously reported that acute high dose pretreatments of ethanol produced a rebound "anxiety"-like state in rats trained to discriminate between pentylenetetrazole (PTZ) and chlordiazepoxide in a Drug 1 - Drug 2 discrimination (DD) task (Gauvin *et al.*, *Drug & Alcohol Dep.*, 24, 103-113, 1989). The ethanol rebound effect was both time and dose dependent. The present study was designed to re-assess this acute ethanol rebound in rats trained in a more typical Drug - No Drug discrimination task. Twenty male Sprague-Dawley rats were trained to discriminate between 15 mg/kg PTZ and saline (SAL) in a two choice DD task under a FR10 schedule of food motivated operant responding. Test sessions were conducted on a randomized subsample of 10 subjects per dose. Ethanol, administered i.p. 15 min. before test sessions, failed to generalize to the PTZ discriminative cue up to doses that totally suppressed responding. However, acute high dose ethanol pretreatments of 2, 3, & 4 g/kg produced a graded dose- and time-dependent shift from SAL- to PTZ-appropriate responding; the peak of PTZ-appropriate responding engendered by these high dose pretreatments were 40%, 76%, and 84% which occurred at 8, 11, and 13 hrs, respectively. This dose- and time-dependent "anxiety"-like rebound produced by high dose ethanol pretreatments is similar to our previously published results and those of Benjamin *et al.* (*Neuropharm.*, 26, 1727-1731, 1987) after chronic ethanol exposure. Taken together, these data support D.B. Goldstein's (*Pharmacology of Alcohol*, 1983, pp 106) and McQuarrie & Fingl's (*JPET*, 124, 264-271, 1958) suggestion that the delayed effects of a single high dose of ethanol (hangover) are qualitatively similar to those elicited by chronic exposure and may differ only in magnitude and time course. LUTEINIZING HORMONE-RELEASING HORMONE (LHRH) NEURONS MIGRATE ALONG VOMERONASAL AND OLFACTORY AXONS WHICH EXPRESS CC2 GLYCO-CONJUGATES IN RATS. G.A. Schwarting, D.L. Drinkwater*, J.E. Crandall, and S.A. Tobet EK Shriver Ctr, Waltham, MA 02254; and Program in Neuroscience, Harvard Medical School, Boston, MA

LHRH neurons migrate from the epithelium of the medial olfactory placode, across the nasal cavity and cribiform plate to the forebrain, in a wide variety of species. The CC2 monoclonal antibody reacts with the terminal alpha-galactose and alpha-fucose residues of one glycolipid and two glycoproteins (Schwarting and Crandall, *Brain Res.*, in press) which are expressed selectively in the olfactory system of rats. At the ages examined in the present study (E13-15), CC2-immunoreactive glycoconjugates (CC2ir) were demonstrated on vomeronasal cells and axons and also on a dorsomedial subset of main olfactory neurons and axons. At E15, CC2ir was detectable on fibers which run both dorsally and ventrally along the surface of the developing forebrain and also on some fibers which extended directly into the rostral forebrain. In adjacent sections, LHRH-immunoreactive neurons (LR-1, gift of Dr. R. Benoit) were seen at E14 and E15 in the nose adjacent to the vomeronasal organ, across the cribiform plate, and in the rostral and ventral forebrain. Double-label immunocytochemical analysis revealed LHRH neurons in close association with CC2ir vomeronasal and olfactory nerve bundles, and with a complex network of CC2ir fibers across the cribiform plate. LHRH neurons in the nose were associated with CC2ir fibers. By E15, many LHRH neurons had migrated into the rostral forebrain, in some cases maintaining association with CC2ir. These studies raise the possibility that CC2ir glycoconjugates provide a specific chemical guide for a subset of migrating LHRH neurons or their migratory pathways.

ONTOGENY OF GONADOTROPIN-RELEASING HORMONE (GNRH) NEURONS IN THE CHICK. K.A. Sullivan, A.J. Silverman, Dept. Anat. & Cell Biol., Columbia Univ., NY, NY 10032.

GnRH neurons originate in the olfactory placode and migrate into the forebrain (Schwanzel-Fukuda and Pfaff, 1990; Wray, et al., 1990). The current study was undertaken to delineate the time course of the phenomenon, describe the cytology of the developing cells and determine the migratory route. Chicks, ages E3 to E21 (hatching), were fixed by immersion, frozen sections were cut and processed by standard immunocytochemical techniques (Benoit). GnRH+ cells first appeared on E4 in the olfactory epithelium and distributed throughout the midline, along the nasal septum by E5 and E6. By E7, cells had reached the anterior pole of the telencephalon. In these early stages, GnRH+ neurons had large vesicular nuclei and a thin rim of cytoplasm. By E21, they had acquired their characteristic fusiform shape. From E9 to E21, following a dorsal and caudal route over the telencephalon, they turn ventral at the level of the lateral ventricles and distribute to their adult positions. This pathway differs from the ventral route taken by GnRH neurons in the mammal. Studies are currently in progress to examine the substrate for migration. HD 10665 T32HD07093-15.

LUTEINIZING HORMONE - RELEASING HORMONE IMMUNOREACTIVITY IN THE ADULT AND FETAL HUMAN OLFACTORY SYSTEM. LS Patel¹, EG Stopa¹, R Chorsky¹, B Rubin², J King². Dept. of Pathology¹ SUNY-HSC, Syracuse, NY 13210; Dept. of Anat. & Cell. Bio.² Tufts Hlth Sci. Schls., Boston, MA 02111

Recent studies in fetal brain tissue of rodents, nonhuman primates and birds have demonstrated that cells containing luteinizing hormone-releasing hormone (LHRH) migrate from the olfactory placode across the nasal septum into the forebrain. The purpose of this study was to examine LHRH neurons in components of the adult and fetal human olfactory system. Brain tissues were fixed by immersion in Zamboni's fixative (14 hours), sunk in 30% sucrose, and cut with a cryostat at 40 microns. The immunocytochemical procedures incorporated the use of CR11B73 antibody and the avidin-biotin-peroxidase method on free floating tissues. In the adult human brain (n=3), immunoreactive LHRH was localized in diffusely scattered cell bodies and processes observed in the olfactory bulb, olfactory nerve, olfactory cortex, and nervus terminalis located on the inferior surface of the gyrus rectus. LHRH immunoreactive structures showed a similar distribution in 20 week human fetal brains (n=2), indicating that the migration of LHRH neurons is near completion at this time. These data are consistent with observations made in other species, and suggest that LHRH neurons migrate into the brain after originating in the olfactory placode. Additional studies of human fetal brains obtained earlier in development are presently underway. (AG09301; HD19803)

175.2

ANTIBODY TO NEURAL CELL ADHESION MOLECULE (NCAM) CAN DISRUPT THE MIGRATION OF LUTEINIZING HORMONE-RELEASING HORMONE (LHRH) NEURONS INTO THE MOUSE BRAIN. M. Schwanzel-Fukuda, S. Abraham, G.R. Reinhard, K.L. Crossin, G.M. Edelman, D.W. Pfaff. The Rockefeller University, New York, New York. We examined the effects of antiserum to NCAM (A-NCAM) on the migration of LHRH neurons from the epithelium of the olfactory pit into the forebrain, since NCAM appears to be a major component of the migration route (Soc. Neurosci. Abstr. 398, '90). Swiss mice, on day 10 of pregnancy, were laparotomized and 1 ul of A-NCAM (10 mg/ml) injected into the area of the olfactory pit of each embryo of one uterine horn. Embryos of the second uterine horn served as uninjected controls. Each embryo of one uterine horn of control animals received 1 ul injection of rabbit IgG (10 mg/ml) into the olfactory pit, or mechanical damage to the olfactory pit. On day 11 or 12, the embryos were collected, fixed in Bouin's solution, and embedded in paraffin. Serial 8 um sections were examined by immunocytochemistry for LHRH, NCAM or IgG. Injection into the olfactory pit was counted as successful only when uptake of A-NCAM or IgG was detected in the epithelium of the olfactory pit. Animals at 12 E that showed such uptake of A-NCAM, had few or no LHRH-immunoreactive cells along the migration route on the nasal septum, or at the entrance to the medial basal forebrain, as is seen in normal 12 E mice. No disruption of the NCAM "scaffolding" resulted from this A-NCAM, but it was sufficient to retard migration of LHRH cells out of the epithelium of the olfactory pit. Untreated control animals, animals injected with IgG or with A-NCAM but that did not show uptake of the antibody, or those which had mechanical damage, showed at 12 E a normal distribution of LHRH cells along the NCAM fascicles on the migration route. These results with A-NCAM provide support for our thesis (Nature, 338:161; '89) that LHRH cells migrate from the olfactory placode to the brain. Supported by NIH grant DC00880 (MSF).

175.4

PRIMARY CULTURES OF LHRH NEURONS FROM FETAL RAT AND MONKEY OLFACTORY PLACODE. P. Claude¹, C.A. Schulz², L.L. Luchansky¹ and E. Terasawa¹. Wisc. Reg. Primate Res. Ctr. and ¹Neuroscience Training Program, UW-Madison 53715.

Recent reports indicate that hypothalamic LHRH neurons arise in fetal olfactory placode and migrate into the brain before birth, in rodents (Schwanzel-Fukuda and Pfaff, 1989; Wray et al., 1989), and monkey (Ronnekleiv and Resko, 1990). To obtain primary LHRH neurons for further study, we cultured olfactory placode tissue from rhesus monkey (E36) and rat (E12.5) fetuses. The olfactory placode area was cut into small pieces (<1 mm²), and plated onto collagen-coated glass coverslips in medium M199 supplemented with 10% charcoal-stripped fetal calf serum. Cultures were maintained for up to 35 days, and medium was assayed by RIA for LHRH. Cultures were immunostained for LHRH, gonadotropin-associated peptide (GAP), neurofilament protein (NF), neuron-specific enolase (NSE) and glial fibrillary acidic protein (GFAP). Results: There were no glial (GFAP-staining) cells in the cultures. Two types of neuron (NF and NSE-positive) migrated out of the explants: LHRH-negative neurons were round and small (5-8 μm) had short neurites, and tended to form dense clusters. LHRH-positive neurons were large (up to 25 μm in rat placode cultures) and also GAP-positive. They initially stained lightly for LHRH, but with time in culture, staining intensity increased. They usually associated with each other in chains or networks, and extended long, varicose neurites (up to 800 μm). In monkey cultures there were few LHRH-negative cells, LHRH neurons were larger than in rat cultures, and took longer to mature. Cultured cells released LHRH into the medium, and responded to challenge with high K⁺. These cultures contain primary LHRH neurons that migrate and mature in culture and are accessible for study using electrophysiological and microscopic techniques. (Support: NIH grants HD11355, HD15433 & RR00167.)

175.6

REGULATION OF LHRH AND OXYTOCIN GENE EXPRESSION IN ORGANOTYPIC CNS SLICE-EXPLANT CULTURES: EFFECTS OF K⁺ AND ESTRADIOL. S. Wray, S. Key and H. Gainer. Lab. of Neurochemistry, NINDS, NIH, Bethesda, MD 20892.

Examination of the regulation of cell-specific neuropeptide gene expression in luteinizing hormone releasing hormone (LHRH) and oxytocin (OT) neurons has been difficult due to the absence of an *in vitro* system which maintains these CNS neuroendocrine cells in primary cultures. We have found that a wide variety of postnatal neuroendocrine cells survive and express specific neuropeptide genes in organotypic slice-explant cultures. Utilizing this model system, we examined the effects of potassium (K⁺) and estradiol treatment on peptide mRNA levels in LHRH and OT neurons using semi-quantitative *in situ* hybridization histochemistry. Brain slices from postnatal day 5 rats were cultured in serum-containing media to allow thinning, maintained in defined media (serum-free) for 4-6 days, and exposed to either 40 mM K⁺ (4 hrs) or 10 nM estradiol (8 or 24 hrs). To determine if the effect of estradiol on peptide gene expression in LHRH and OT cell subtypes was direct or via interneurons, the cultures were examined under 'normal' synaptic activity and tetrodotoxin activity blockade. Analyses of the OT cultures was performed using X-ray film, providing a density value/culture which corresponds to mRNA levels. Comparisons of these values showed that OT mRNA levels ~doubled after exposure to 40 mM K⁺ (p < 0.01). Densitometric single cell analyses of LHRH and OT neuronal mRNA levels are currently in progress. Single cell analyses will determine if either of these neuroendocrine cell types contain subpopulations which differentially respond to depolarization and estradiol treatment.

175.7

SUBGROUPS OF LHRH NEURONS PROJECT TO DEFINED REGIONS OF THE MEDIAN EMINENCE IN RATS. J.C. King, B.S. Rubin and C.E. Lupini. Dept. of Anatomy and Cellular Biology, Tufts University Health Sciences Campus, Boston, MA 02111.

We have demonstrated that the distribution of LHRH neurons detected by the high threshold PAP technique, i.e. neurons with high abundance of LHRH precursors and intermediates, vary in detection as a function of endocrine state in male and female rats. Three-dimensional analyses of the differences in distribution have revealed a basic microarchitecture of LHRH subgroups. We have postulated that these subgroups receive different afferent inputs and project to distinct selective regions of the median eminence. It was the purpose of this study to test the hypothesis of distinctive projections to the median eminence [ME] using neuro tracing techniques. We delivered PHA-L by iontophoresis with a micropipette tip of 10 μ to anesthetized females in a stereotaxic apparatus. Positive current 5 μ Amp was pulsed on/off for 7 sec for a total of 20 minutes. Hypothalamic neuronal cell bodies incorporated the PHA-L and fibers could be traced to the ME in animals perfused with either 4% paraformaldehyde in 0.1M Borate Buffer, pH 11 or 3% acrolein in 0.1M Sorensen's phosphate Buffer, pH 7.2. PHA-L was localized using peroxidase-antiperoxidase or avidin-biotin protocols. Neurons located in the rostral preoptic area in the midline just superior to the organum vasculosum of the lamina terminalis projected primarily to midline regions of the ME. The restricted ME projection of neurons in this area, which is within the boundaries of one subgroup of LHRH neurons, is consistent with the hypothesis of an organized projection to selected regions of the ME. This study is one in a series of studies directed to elucidating the functional organization of LHRH subgroups. DCB-9004498 (JCK) and HD 19174 (BSR).

175.9

THE NUMBER OF LHRH-CONTAINING NEURONS DECREASES SELECTIVELY IN THE ARCULATE NUCLEUS DURING PUBERTY IN MALE FERRETS. Y.P. Tang and C.L. Sisk, Neuroscience Program & Dept. of Psychology, Michigan State University, East Lansing, MI 48824.

The neuropeptide luteinizing hormone releasing hormone (LHRH) controls gonadotropin secretion from the pituitary gland. Pubertal maturation is characterized by more frequent release of LHRH and the gonadotropic hormones. In order to determine whether a change in the number of LHRH-producing neurons is correlated with enhanced hormone release at puberty, LHRH-containing neurons were identified immunocytochemically in male ferrets at various ages spanning puberty. Intracerebroventricular administration of colchicine, a blocker of axonal transport, to anesthetized ferrets 24 hr prior to sacrifice did not reveal additional numbers of immunopositive LHRH (iLHRH) cell bodies in any brain area in either pre- or postpubertal ferrets. There were significantly fewer iLHRH somata within the arcuate nucleus in peri- and postpubertal ferrets compared to prepubertal ferrets. A 50% reduction in the number of iLHRH neurons in the arcuate was observed both in ferrets in which puberty onset was induced by a transition from short to long daylengths, and in ferrets which experienced spontaneous puberty in the absence of a change in daylength. The fact that the number of iLHRH neurons is reduced selectively in the arcuate nucleus at a time of more frequent LHRH release suggests that, in the prepubertal ferret, LHRH from arcuate neurons provides an ultrashortloop negative feedback signal that inhibits release of LHRH into the median eminence from non-arcuate LHRH neurons. The decrease in the number of arcuate LHRH-producing neurons at puberty may reduce this negative feedback signal and permit more frequent release of LHRH. Supported by HD26483.

SEASONAL REPRODUCTION IN THE SYRIAN HAMSTER AND THE INFLUENCE OF EXCITATORY AMINO ACIDS. H.F. Urbanski, M. Pierce* and P.M. Collins*. Division of Neuroscience, Oregon Regional Primate Research Center, Beaverton, OR 97006.

Melatonin is known to play a key role in mediating the suppressive effects of short days on the reproductive axis of Syrian hamsters but the link between this indole and the neuronal circuitry controlling LHRH secretion is poorly understood. Recently, we showed that administration of the excitatory amino acid (EAA), *N*-methyl-D-aspartate (NMDA), to male hamsters could overcome the inhibitory effects of short days by stimulating gonadotropin secretion and causing testicular recrudescence. We now sought to test whether activation of EAA receptors could overcome the anti-gonadotropic action of melatonin. Male hamsters were transferred from short to long days (i.e., from 6L:18D to 14L:10D), in order to stimulate testicular recrudescence, and given daily sc injections of melatonin (25 μ g) either in the mornings (AM) or afternoons (PM) for 4 weeks. As expected, only the PM injections blocked the stimulatory action of long days on pituitary gonadotropin content, serum gonadotropin and testosterone levels, and on testicular weight. Interestingly, this inhibitory effect of PM melatonin treatment could be overcome by concomitant sc injections of kainate (6.5 mg/kg BW), an EAA that activates non-NMDA receptors. In contrast, concomitant sc injections of NMDA (25 mg/kg BW - a dose that can completely suppress the inhibitory effects of short days) was largely ineffective. These results indicate that endogenous EAAs most likely exert their influence on the hamster's reproductive axis by acting through both NMDA and non-NMDA receptors and, furthermore, they suggest that different EAA receptor subtypes are integrated at different sites along the photo-neuroendocrine pathway that regulates LHRH secretion.

LUTEINIZING HORMONE RELEASING HORMONE (LHRH) NEURONS WHICH UPTAKE FLUORO-GOLD FROM THE VASCULATURE IN THE MALE FERRET. L.A. Berglund and C.L. Sisk, Neuroscience Program & Department of Psychology, Michigan State University, East Lansing, MI 48824.

LHRH-producing neurons are diffusely distributed from rostral forebrain through caudal diencephalon in the ferret. About 70% of the LHRH cell bodies are located in retrochiasmatic hypothalamus in this species. In order to determine whether a distinct subpopulation of LHRH neurons is responsible for LHRH secretion into the vasculature, prepubertal male ferrets received two systemic injections, 5 days apart, of the retrograde tracer Fluoro-Gold (FG). After an additional 5 day post-injection survival period, ferrets were anesthetized and perfused with saline and 4% paraformaldehyde. Immunocytochemistry for LHRH was performed on brain sections using a secondary antibody tagged with tetramethylrhodamine isothiocyanate. LHRH-producing neurons with axon terminals in regions containing fenestrated capillaries were defined as cell bodies which demonstrated both immunofluorescence for LHRH and localization of FG. Double-labelled neurons were scattered throughout the entire population of immunoreactive LHRH (iLHRH) cell bodies. However, less than 30% of iLHRH neurons also contained Fluoro-Gold, and most of these cells contained very faint FG labelling. In contrast, when a matching set of sections from these brains was immunoreacted for neurophysin (NP), a majority of the NP cell bodies in supraoptic and paraventricular nuclei were heavily labelled with FG. The lesser degree of FG uptake in iLHRH cells suggests relative inactivity of the LHRH neurons projecting outside the blood-brain barrier in prepubertal ferrets. Supported by HD26483.

DETECTABILITY OF LHRH IN SPECIFIC SUBGROUPS IS CORRELATED WITH THE PROESTRUS LH SURGE. B.S. Rubin, J.C. King, S.D. Vath*, and R.A. Strauss*. Department of Anatomy and Cellular Biology, Tufts Health Science Schools, Boston MA 02111.

We have previously reported an increase in the number of LHRH neurons detected by the PAP technique on the evening of proestrus, after the peak of the LH surge, compared to the number detected earlier that afternoon, prior to the surge. We have analyzed the distribution of the detectable LHRH neurons at these two time points by counting LHRH neurons immunoreactive with antiserum 1076 (R.P. Millar) in each section throughout the basal diencephalon. The sections were assigned to one of 4 areas. Area 1 includes the region through the Diagonal Band of Broca, area 2 includes the Organum Vasculosum of the Lamina Terminalis, area 3 includes the Preoptic Area and Anterior Hypothalamus and area 4 encompasses the Medial Basal Hypothalamus. The data suggest that the increase in perikarya number is not randomly localized throughout the entire LHRH neuronal population. Whereas no change in the number of LHRH perikarya was observed in the area of the Diagonal Band of Broca on proestrus, the number of LHRH neurons counted in the Preoptic-Anterior Hypothalamic area on the evening of proestrus was 175% of the number detected in that same region during the early afternoon. Three dimensional mapping of the LHRH neuronal system at these two time points is currently underway to enable a more precise identification of the subgroups in which LHRH detectability varies above/below the threshold for detection with PAP on proestrus. We hypothesize that precise localization of the LHRH subgroup(s) that vary in detectability between early and late proestrus will yield valuable insight regarding the specific LHRH neurons that are involved in the LH surge. PHOTOPERIOD REGULATES THE LH RESPONSE TO CENTRAL GLUTAMATERGIC STIMULATION IN THE MALE SYRIAN HAMSTER. Francis J.P. Ebling, Yui Hui*, Elizabeth S. Maywood* and Michael H. Hastings. Department of Anatomy, University of Cambridge, Cambridge CB2 3DY, UK.

This study investigated whether a change in glutamatergic function might underlie photoperiod-induced changes in luteinizing hormone (LH) secretion. The experimental approach was to compare the effects of glutamate agonists on LH secretion in reproductively active hamsters kept in long days (LD) with those in photoinhibited hamsters kept in short days (SD) for 6 weeks having regressed testes. Agonists were delivered via a cannula into the III ventricle of freely moving hamsters. In Exp 1, a high dose of NMDA (3 nmole) induced significant ($P < 0.01$) increases in serum LH 15 min later in both photoperiods (SD 0.7 ± 0.2 pretreatment increased to 2.8 ± 0.5 ng/ml; LD 1.2 ± 0.1 pretreatment increased to 2.4 ± 0.2 ng/ml). The magnitude of the LH response in SD was twice that in LD. In Exp 2, a lower dose of NMDA (0.3 nmole) revealed a difference in sensitivity. Hamsters in SD responded to this dose (1.6 ± 0.4 ng/ml vs vehicle controls 0.7 ± 0.1 , $P < 0.05$) whereas those in LD did not (1.6 ± 0.3 ng/ml vs controls 1.4 ± 0.2). In Exp 2, hamsters were also treated with AMPA. This non-NMDA agonist induced a two-fold increase ($P < 0.05$ vs controls above) in serum LH in both photoperiods (SD to 1.5 ± 0.3 ng/ml; LD to 2.5 ± 0.6 ng/ml). To investigate the site of action of NMDA, the expression of the *c-fos* gene was used as a marker of neuronal activation. Although NMDA induced widespread *c-fos* expression in many periventricular regions including the medial preoptic area (POA), dual ICC revealed that in neither photoperiod was *c-fos* product induced in GnRH-positive neurons 1 h after 3 nmole NMDA, despite the increases in LH secretion. This observation is consistent with a site of action of NMDA in the median eminence rather than a direct effect on GnRH perikarya in the basal forebrain and POA. In conclusion, these results show that both NMDA and non-NMDA glutamatergic pathways could potentially regulate LH secretion in the Syrian hamster. The increased sensitivity and responsiveness to NMDA in hamsters in SD is consistent with the hypothesis that photoperiod-induced seasonal infertility reflects decreased glutamatergic drive to GnRH neurons. CONSPECIFIC MALE ODOR ENHANCES SYNTHESIS OF LUTEINIZING HORMONE IN THE PITUITARY GLAND OF FEMALE RATS: EFFECT MEDIATED THROUGH THE VOMERONASAL ORGAN. G. Rajendren*, R.N. Rosenberg, C.A. Dudley and R.L. Moss. Dept. of Physiology and Neurology, The Univ. Texas Southwestern Med. Ctr. at Dallas, Dallas, TX 75325.

The influence of male rat odor and the effect of removal of the vomeronasal organ (VNO) on the content of luteinizing hormone (LH) in the pituitary gland of regularly cycling female rats was investigated. VNO-removed (VNX), VNO-sham (VNS) or VNO intact (VNI) females were individually housed, and were exposed to clean bedding or male-soiled bedding. Exposure of the females to bedding began on the day of estrus and continued until they were sacrificed on the day of proestrus of the following cycle. On the day of sacrifice, the females were injected with pentobarbital (35 mg/Kg of body weight) to block the preovulatory LH surge. Three to four hours later they were sacrificed by decapitation. The anterior lobe of the pituitary gland was dissected on dry ice, homogenized and the content of LH was determined by radioimmunoassay. The content of LH in the pituitary was not significantly different in the VNX, VNS or VNI females exposed to clean bedding. However, of the females exposed to male-soiled bedding the pituitary content of LH in the VNS and VNI females was significantly higher as compared to the VNX group. The results suggest that male-originating cues can enhance the synthesis of LH in the pituitary and that the effect is mediated through the vomeronasal system. Supported by NIH grant MH41784.

EVIDENCE THAT NMA INCREASES LH SECRETION BY ACTING INDIRECTLY ON LHRH NEURONS. W.-S. Lee, R. Abbud, G.E. Hoffman, and M.S. Smith. Department of Physiology, University of Pittsburgh, School of Medicine, Pittsburgh, PA 15261.

NMA stimulates the secretion of LH by increasing the release of LHRH. To determine whether LHRH neurons are activated in association with NMA treatment, we used expression of cFos as a marker of LHRH neuronal activation. During proestrus, LHRH neurons express cFos in association with the LH surge. Treatment with the NMDA receptor antagonist, MK-801, (0.2 mg/kg, s.c.) at 1130 h blocked both the LH surge and cFos induction in LHRH neurons. These data suggest that NMDA receptors are involved in the regulation of LHRH neuronal activation during the LH surge. However, neither systemic (40 mg/kg, 4 injections, 10 min apart) nor intraventricular (2 µg/2 µl, 4 injections, 10 min apart) administration of NMA induced cFos expression in LHRH neurons in female rats, indicating that NMA may act directly on LHRH terminals or on afferent neuronal projections which impinge on LHRH neurons, or both. To differentiate between these possible mechanisms, proestrous rats were treated with pentobarbital (40 mg/kg i.p.) at 1200 h to block neuronal transmission, followed by either saline or NMA (i.v.) administration between 1500-1600 h. Pentobarbital treatment blocked the proestrous LH surge and cFos induction in LHRH neurons in saline-treated animals. NMA treatment of pentobarbital-blocked rats resulted in no increase in LH secretion, suggesting there were no direct effects of NMA on LHRH neurons. These results demonstrate that although NMDA receptor activation appears to be necessary for LHRH neuronal activation during proestrus, NMA appears to act indirectly on LHRH neurons, perhaps activating afferent neuronal projections to the LHRH neuron. Supported by NIH grants NS 28730 and the Samuel and Emma Winters Foundation.

HYPERPROLACTINEMIA SUPPRESSES THE LH RESPONSES TO N-METHYL-D-ASPARTATE AND NEUROPEPTIDE Y IN MALE RATS. M. Selmanoff and S.-K. Park*, Department of Physiology, University of Maryland, School of Medicine, Baltimore, MD 21201.

This study further characterizes the response of LHRH neurons to N-methyl-D-aspartate (NMDA) and neuropeptide Y (NPY) and determines whether neurons utilizing these compounds are involved in mediating hyperprolactinemic (HP) suppression of LH release. Male Sprague-Dawley rats (250-300g BW) were orchidectomized, adrenalectomized, implanted with a testosterone silastic capsule and a 50% corticosterone pellet and with third cerebroventricular and right atrial cannulae at time 0. Rats received either subcutaneously injected oPRL (2,400 µg/0.25 ml) in a polyvinylpyrrolidone depot or vehicle every 12h. The mean maximal LH increments (ΔLH) to two doses of LHRH (0.4 and 0.8 ng/100g BW) were not altered in HP rats. NMDA (20 mg/kg BW iv)-induced LH release peaked 5 min after injection. The ΔLH (0-5 min) in HP rats (0.16 ± 0.05 ng/ml) was suppressed compared with controls (0.33 ± 0.06 ng/ml). Two doses of NPY (2 and 10 µg/2µl icv) produced dose-dependent LH increments which peaked at 10 min. In HP rats the ΔLH (0-10 min) in response to 10 µg/2µl NPY was suppressed (0.12 ± 0.03 ng/ml) compared with controls (0.25 ± 0.03 ng/ml). Hence, the LH responses to both NMDA and NPY were inhibited in HP rats. This suggests that PRL either acts directly on LHRH neurons to decrease their responsiveness to all stimuli, and/or, that PRL acts indirectly to inhibit glutamatergic and NPYergic neurons that are stimulatory to LHRH release. (Supported by NIH grant HD21351).

HYPOTHALAMIC RELEASE OF LHRH IS REDUCED AFTER MATING OR GONAECTOMY IN BREEDING FEMALE, BUT NOT IN MALE, FERRETS. G.M. Lambert, B.S. Rubin, M.J. Baum. Dept. of Biology, Boston Univ., Boston MA 02215 and Dept. of Anatomy and Cellular Biology, Tufts Univ., Boston MA 02111.

Mediobasal hypothalami were collected from male and female ferrets which were gonadectomized, or which were in breeding condition and had either achieved or received an intromission with a sexual partner or were left unpaired. LHRH was measured in effluents collected at 10-minute intervals from *in vitro* perfusion chambers containing the MBH tissues. Estrous female ferrets which had received an intromission 14 minutes prior to sacrifice and ovariectomized females released significantly less LHRH than estrous females which had not been paired; no such effects occurred in females 1 or 2 1/2 hours after mating. The release of LHRH from MBH collected from males was not affected by mating or castration. These data suggest: 1) the post-coital surge of LH in the female ferret is preceded by a release of LHRH that initially depletes neuronal terminals, while LHRH, like LH, is minimally affected by mating in males, and 2) the feedback regulation of LHRH secretion by endogenous gonadal steroids differs between male and female ferrets. (Supported by RO1 HD21094, RO2 MH00392, and MH09812).

GABA-B MEDIATION OF NMDA-STIMULATED LH RELEASE IN FEMALE MICE. G.M. Miller and M.J. Gibson. Div. Endocr. Mount Sinai School of Med., New York, N.Y. 10029.

Our recent findings suggest central inhibitory mediation of GnRH secretion to NMDA challenges, resulting in differential release of LH in male and female hypogonadal mice with preoptic area brain grafts (HPG/POA). As GABA blocks NMDA-induced LH release in pubertal rats, we evaluated the role of the GABA-B receptor in modulating NMDA effects in normal female mice. Five days after ovariectomy, mice were fitted with jugular cannulae and tested the following day. Two NMDA challenges (20mg/kg, iv) were given 2h apart. Ten min before the 2nd NMDA challenge, mice received the GABA-B receptor agonist baclofen (Bac, 5mg/kg, iv) or saline (Sal). Blood samples (0.1 ml) were taken at 10 min intervals before and after each challenge. Resuspended red blood cells were returned following the next sample withdrawn, and plasma duplicates (25ul) were assayed for LH. Bac-pretreatment attenuated the LH response to the 2nd NMDA challenge: 1: 2.21±0.36 ng/ml, p<0.01; 2: 1.28±0.22ng/ml, ns. In Sal-treated mice, LH increased significantly to both NMDA challenges: 1: 3.04±0.38ng/ml, 2: 3.06±0.38ng/ml, both p<0.01. HPG/POA female mice are being tested. These studies implicate GABA-B receptors in GABAergic control over NMDA-induced LH release in female mice. Support: NIH Grants T32DK07645 (GM) & HD19077 (MJG).

IMMUNOCYTOCHEMICAL DETECTION OF A CHICKEN-LHRH-II-LIKE PEPTIDE IN THE RAT HYPOTHALAMO-HYPOPHYSAL SYSTEM.

F. Vandesande, J. van Gils* and F. Bijtebier*. Lab. Neuroendocrinologie, Zoölogisch Instituut, Naamsestraat 59, B-3000, Leuven, Belgium.

Two polyclonal rabbit antisera were prepared against Lys-His-Gly-Trp-Tyr-Pro-Gly-NH₂ conjugated to thyroglobulin. This sequence corresponds to c-LHRH II(5-10). Both antisera recognize c-LHRH II in an immunospotting test and do not cross-react with any other known neuropeptide present in the rat hypothalamo-hypophyseal system. Three groups of adult rats of both sexes were used. (1) six normal rats, (2) six rats sacrificed 48 hours after an intracisternal injection of 50 µg colchicine and (3) two Brattleboro rats. Sections of their hypothalamo-hypophyseal system were stained with the antisera in combination with the PAP technique. In all animals, immunoreactive (ir) perikarya were found in the paraventricular nuclei, the nuclei accessorii, the supraoptic nuclei and the supraoptic retrochiasmatic nuclei. An intense staining was also observed in both the external region of the median eminence and the posterior lobe, where the ir-fibres appeared to accumulate around the blood-capillaries. In the colchicine-treated animals, the staining intensity of the perikarya was much stronger, while the ir in the nerve fibres had decreased. Double staining with anti-vasopressin, anti-oxytocin and antisomatostatin showed that 100 % of the c-LHRH-II-ir perikarya contained vasopressin, but only 50 to 60 % of the vasopressinergic cells were also ir for c-LHRH-II.

BRAIN LHRH IMMUNOREACTIVITY IS RETAINED FOLLOWING NEURAL LESIONS THAT ABOLISH THE PHOTOPERIODIC, REPRODUCTIVE RESPONSE IN JAPANESE QUAIL.

T.S. Juss*, B.K. Follett and Dilys M. Parry*, AFRC Research Group, Dept of Zoology, Univ. of Bristol, Bristol BS8 1UG, U.K.

Seasonal reproduction in Japanese Quail is triggered by long days (LD), resulting in secretion of LHRH and consequently LH. Using ablation techniques several regions in the bird brain have been identified that influence this response, but their physiological role remains equivocal. We have tested the possibility that lesions in the posterodorsal area of the infundibular nucleus (p.d.-i.n.c.) in the tuberal hypothalamus prevent photoinduction by causing a deficit in the LHRH system.

Following lesions, male quail were transferred from short days (8L:16D) to LD (18L:16D). After 4-5 weeks, birds whose reproductive response was blocked by the lesions (terminal testicular weight $11 \pm 2(8)$ [Mean \pm S.E.M.(n)] mg) and those which exhibited normal testicular growth ($2687 \pm 100(8)$ mg) were subjected to immunocytochemical analysis for LHRH. The total number of LHRH immunopositive perikarya (blocked birds; $436 \pm 80(5)$, normal birds; $387 \pm 50(5)$, in $90 \mu\text{m}$ sections) and their regional distribution was similar, with the median eminence staining intensely, in both groups.

It is concluded that the LHRH neuroendocrine system is intact after lesioning and that the p.d.-i.n.c. is probably involved in mechanisms that mediate photoperiodic information.

HYPOTHALAMIC-PITUITARY-GONADAL REGULATION: STEROIDS

ESTROGEN RECEPTOR mRNA IN FEMALE RAT BRAIN DURING THE ESTRUS CYCLE: A COMPARISON WITH OVARIECTOMIZED FEMALES AND INTACT MALES. P.J. Shughrue, C.D. Refsdal* and D.M. Dorsa. University of Washington, Department of Pharmacology, and GRECC, VA Medical Center., Seattle, WA 98108.

Estrogen action in the preoptic area and basal hypothalamus induces female reproductive behavior and facilitates cyclic release of gonadotropins from the pituitary. Autoradiographic, immunocytochemical and *in situ* hybridization studies have detected estrogen receptor (ER) in preoptic/ hypothalamic regions and revealed hormone dependent changes in receptor number and topography. Since dramatic changes in hormonal milieu occur in the cycling female brain, the present study investigated ER mRNA expression during the estrus cycle. Female Wistar rats (200g) were sacrificed during estrus, metestrus, diestrus, proestrus, or 72 hrs after ovariectomy. Additional intact male rats were also sacrificed. Brains were frozen and $20 \mu\text{m}$ cryostat sections thaw-mounted and hybridized with a ^{35}S -labeled probe for ER mRNA. Section-mounted slides were processed, apposed to x-ray film, and then dipped in liquid emulsion and quantified by computer. After exposure, ER mRNA was detected in brain regions including the medial preoptic area (MPO), arcuate (ARC), and ventromedial nucleus (VMH) of the hypothalamus. At the level of the MPO, ER mRNA levels were highest on metestrus, attenuated at diestrus, and low on proestrus and estrus. In contrast, ER mRNA levels in the VMH increased from metestrus to diestrus and peaked during proestrus, then declined on estrus. However, ER mRNA in the ARC was unchanged during the estrus cycle. When females were ovariectomized message expression was elevated, while levels in the intact male were low. The results indicate that expression of ER mRNA is sexually dimorphic, varies during the estrus cycle, and increased after ovariectomy. These data further suggest that ER mRNA is differentially regulated in nuclei of preoptic and hypothalamic regions of the brain. Supported by NS20311 and NS07332.

ANDROGEN RECEPTOR-LIKE IMMUNOHISTOCHEMICAL LABELING OF NEURONS IN MOUSE AND RAT BRAIN. A.N. Clancy, R.W. Bonsall and R.P. Michael. Department of Psychiatry, Emory University School of Medicine, Atlanta, Georgia 30322 and the Georgia Mental Health Institute, Atlanta, Georgia 30306.

To locate neurons containing androgen receptor-like (AR) proteins, mouse brains were immunohistochemically labeled with a commercially available monoclonal antibody (Affinity BioReagents MA1) raised in rats against protein fragments containing human AR sequences, and rat brains were stained with a polyclonal antibody (Affinity BioReagents PA1-110) raised in rabbits against the same fusion proteins. Frozen sections were incubated with antibodies and further processed by the peroxidase avidin-biotin complex method. Similar patterns of labeling occurred in the brains of both species. Labeled cells were widely distributed throughout the brains and were noted in areas previously identified as containing androgen target neurons by autoradiography including: the medial preoptic area, amygdala, hypothalamus, bed nucleus of the stria terminalis, lateral septum, cortex, hippocampus, several brainstem nuclei, and cerebellar Purkinje cells. However, labeling was also observed in a few brain regions (e.g. the supraoptic nucleus) not labeled autoradiographically. Labeling patterns were generally similar in the brains of intact and orchidectomized animals and in male and female rats. To test the specificity of labeling, some sections were incubated in the absence of anti-AR antibodies while others were incubated in monoclonal anti-AR antibodies that had been preabsorbed with cytosol from rat prostate gland, a tissue rich in androgen receptors: no labeling was observed in either case. Supported by USPHS grant MH 19506, Emory University Research Committee and the Georgia Department of Human Resources.

DIFFERENTIAL REGULATION OF ANDROGEN RECEPTORS IN BRAIN AND PROSTATE OF MALE GUINEA PIGS AS SHOWN BY IMMUNOCYTOCHEMISTRY. J.V.A. Choate and J.A. Resko. Dept. of Physiology, Oregon Health Sciences Univ., Portland, OR 97201, Oregon Reg. Primate Res. Ctr., Beaverton, OR 97006.

Androgens affect reproductive behaviors and gonadotropin secretion. These effects are mediated through intracellular receptors which affect gene transcription. We compared androgen receptor (AR) regulation in two androgen dependent tissues, the brain and prostate. We developed polyclonal antibodies, in rabbits, to an AR-specific peptide antigen (a.a. 201-222 of the human AR N-terminal region). Using antigen-purified antibodies, we localized AR by immunocytochemistry. Intact animals possessed specific staining for AR in nuclei of prostatic epithelial and stromal cells. Immunostaining was broadly distributed throughout the brain and localized to neuronal nuclei. Brain areas with positive immunoreactivity included piriform and sensory cortex, amygdala, and several nuclei of the hypothalamus. Castration had little or no effect on the distribution or intensity of immunostaining in the brain, however, positive staining was completely abolished in the prostate. These results suggest differential regulation of AR between androgen dependent target tissues. Supported by NIH grants: T32 HD07133 and HD18196.

176.4

LOCALIZATION OF INHIBIN/ACTIVIN SUBUNIT mRNAs IN RAT BRAIN BY *IN SITU* HYBRIDIZATION. V.J. Roberts, W. Vale, and P.E. Sawchenko. Dept. Repro. Med., UCSD, La Jolla, CA 92093, and The Salk Institute, La Jolla, CA 92037.

The reproductive hormones inhibin ($\alpha/\beta\text{A}$ or $\alpha/\beta\text{B}$ subunit heterodimers) and activin (β/β dimers) have a broad anatomical distribution both peripherally and centrally. We recently described the central distribution of inhibin/activin subunit proteins in neuronal cell bodies, fibers, and nuclei and reported the presence of mRNAs encoding each of these subunits in all major brain regions (determined by S1 protection analysis). In the present study we examined the detailed *in situ* localization of these mRNAs using ^{35}S -RNA probes and found: 1. βA -mRNA signal was in most regions where βA -immunoreactive (IR) nuclei (inf. olive, medial vest. nu., caudate-putamen) cell bodies (vent. medullary ret. formation) or fibers (amygdala) were present. 2. βB -mRNA signal was present in most regions showing βB -IR neurons (vent. medullary ret. formation, substantia nigra) and fibers (various thalamic nu., amygdala), and in some areas with exclusively βA nuclear IR (spinal trigeminal nu., cochlear nu.). 3. Areas with βA - or βB -mRNA signal and no corresponding IR were also seen (deep cerebellar nu., hippocampus). 4. α -mRNA signal was usually found in areas along with βA -mRNA signal (piriform cx., hippocampus) but we have not yet succeeded in localizing α -subunit IR in the brain. These results suggest that inhibin/activin proteins are produced in many brain regions where they may be stored, function as intracellular growth factors, or are transported and may act as intercellular communicators.

NEUROANATOMICAL SPECIFICITY IN THE AUTOREGULATION OF AROMATASE BY ANDROGENS AND ESTROGENS: AN IMMUNOCYTOCHEMICAL STUDY. J. Balthazart, A. Foidart, C. Surlémont*, N. Harada*, and E. Naftolin. Lab. Biochemistry, Univ. Liège, B-4020 Liège, Belgium. Molec. Genetics, Fujita Health Univ., Toyoake, Aichi 470-11, Japan, and Dept. Obstetrics/Gynecology, Yale Univ., New Haven, CT 06510, USA.

Testosterone (T) increases brain aromatase activity (AA) in quail and other avian and mammalian species. It was shown both in quail (C.R. Acad. Sci. 1987, 305:569-574) and in rat (Neuroendocrinol. 1991, 53:79-84) that this enzymatic induction results from a synergistic action of androgens and estrogens. These studies provide little information on possible anatomical or cellular specificity of the effect. Using a polyclonal antiserum against human placental aromatase, we have identified aromatase-immunoreactive (ARO-ir) neurons in the quail brain (J. Comp. Neurol. 1990, 301:276-288) and demonstrated that T increases the number of ARO-ir cells in the quail preoptic area (POA) (Brain Res. 1990, 514:327-333) supporting previous evidence that T increases AA in the brain. However, which T metabolites are involved, the actual mechanism of autoregulation and the possibility of anatomical specificity for these effects are not yet clear. EXPERIMENTAL: We dissociated the effects of androgens and estrogens in aromatase induction by comparing ARO-ir in neurons of quail treated with T alone or T in the presence of a potent aromatase inhibitor (R76713), which has been shown to depress AA levels and to suppress T-activated copulatory behavior (Horm. Behav. 1990, 24:510-531). T increased the number of ARO-ir cells in POA, bed nucleus striae terminalis (BNST) and tuberal hypothalamus (TU). The T effect was inhibited by concurrent treatment with aromatase inhibitor in TU, but not in POA and BNST. CONCLUSIONS: T increases AA and ARO-ir. The T effect is blocked by R76713 in areas where ARO-ir and estrogen receptor-ir are generally co-localized (TU) and is not affected in areas with mainly ARO-ir positive, estrogen receptor-ir negative cells (POA, BNST) (J. Neurobiol. 1991, 22:143-157). This suggests anatomical differences in the expression or clearance of aromatase which may be differentially sensitive to androgens and estrogens and dependent upon the presence of sex steroid receptors. Supported by FRFC (2.9003.91, 9.4601.90) and EEC (SCI-0230-CITT) to JB and NIH HD13587 to FN. R76713 was provided by Dr. R. DeCoster (Janssen Pharmaceutica).

176.7

IMMUNOCYTOCHEMICAL LOCALIZATION OF ESTROGEN RECEPTORS WITHIN NEUROTENSIN NEURONS IN THE FEMALE RAT. J.F. Axelson, F.W. van Leeuwen, W.J. Shannon*, and K.A. O'Shaughnessy*. Psychology Department, Holy Cross College, Worcester, MA 01610 and The Netherlands Institute for Brain Research, Amsterdam, The Netherlands.

In situ hybridization procedures indicate that estrogen selectively increases neurotensin and neuromedin (NT)/N mRNA levels in the anterior medial preoptic nucleus (AMPN) (Alexander et al., 1989). Using the co-localization procedures of Axelson and van Leeuwen (1990), the present study examined whether NT cells in the hypothalamus contained estrogen receptors (ER). Brains from adult ovariectomized, colchicine-treated rats were fixed with 4% paraformaldehyde and 0.5% glutaraldehyde. Vibratome sections were first incubated with estrogen receptor antibody (H222, Abbott) and stained with DAB-Ni⁺ producing a blue-black nucleus. Methanol-hydrogen peroxide washes were used either before or after ER staining. NT anti-sera (HC-8) was used to provide a brown reaction following DAB. The number of NT cells in the AMPN containing ER was shown to be dependent upon a number of factors including colchicine treatment and duration of post-ovariectomy time period. These data support the hypothesis that NT cells in the AMPN that play a role in LH release are, in part, influenced directly by estrogen feedback via nuclear estrogen receptors.

ULTRASTRUCTURAL EVIDENCE FOR ESTROGEN RECEPTOR IMMUNOREACTIVITY IN GLIA, EPENDYMA, AND ENDOTHELIA. M.C. Langub, Jr. and R.E. Watson, Jr. Dept. Anatomy and Neurobiology, Univ. of Kentucky Medical Center, Lexington, KY 40536-0084.

The presence of estrogen receptors (ERs) in non-neural cells in brain, including glia, ependyma, and endothelia, has not previously been documented with electron microscopy. This study was conducted using ultrastructural immunocytochemistry to examine the possibility that ER-immunoreactivity (ER-ir) is present in non-neural cells in brain. Female guinea pigs (Hartley Strain) were perfused with buffered 4% paraformaldehyde and 0.1% glutaraldehyde and 50µm thick sections were cut on a vibrating microtome. Tissue including the anterior pole of the preoptic region and third ventricle was immunostained for ERs with monoclonal antibody H222 (Abbott Labs) using 3,3',5,5'-tetramethylbenzidine (TMB) as the chromogen (Norgren and Lehman, 1989). Thin sections including the periventricular periventricular nucleus (Pep), anterior compact subnucleus of the medial preoptic nucleus (MPNa), and the organum vasculosum of the lamina terminalis (OVLt) revealed many ER-ir cells which were identified ultrastructurally by the presence of distinct spicule-like TMB crystals in their nuclei. While neurons constituted the clear majority of ER-ir cells, labeled astrocytes, ependyma, and endothelia were also present. Distinct intranuclear TMB labeling was present in approximately 1-2% of the astrocytes at this brain level. No labeled oligodendrocytes were observed. Scattered ependymal cells, including both common ependyma and putative tanycytes, were also labeled. Finally, approximately 5% of the vessels in the OVLt, Pep, and MPNa were lined by ER-ir endothelial and vascular smooth muscle cells. Collectively, these results indicate that in addition to regulating the activity of neurons, estrogen may affect brain function through effects exerted on the genome of a subset of astrocytes, ependymal cells, and endothelial cells.

A SEXUALLY DIFFERENTIATED, ESTROGEN-RESPONSIVE POPULATION OF NEUROTENSIN NEURONS IN THE ARCULATE NUCLEUS OF THE RAT. M.J. Alexander and S.E. Leeman, University of Massachusetts Medical Center, Worcester, MA 01655.

Previous studies have indicated that a majority of the neurotensin (NT) neurons in the rat arcuate nucleus are also dopaminergic. NT and dopamine have opposite direct effects on prolactin secretion by the anterior pituitary, and evidence suggests a stimulatory role for NT in female-specific regulation of prolactin secretion (PNAS 85:9866, 1988). We have used *in situ* hybridization histochemistry to detect mRNA encoding NT and neuromedin N (NT/N) in the arcuate nucleus of male and female rats, and we report a pronounced sex difference in NT/N gene expression restricted to the dorsomedial division of the rostral arcuate. In bilateral sections through this region, proestrous females had nearly three times as many labeled cells in the dorsomedial division as did males (20 ± 2 vs. 7 ± 1). In contrast, there was no sex difference in the number of labeled cells in the ventrolateral division. In the dorsomedial division, cell totals for females on diestrus-1 (9 ± 2) differed significantly from those for proestrous females, suggesting that NT/N mRNA abundance in the arcuate nucleus might be regulated by circulating estrogen levels, which are maximal on proestrus. Indeed, in ovariectomized rats estradiol treatment (2 wks) markedly increased the number of labeled cells in the dorsomedial division, but not the ventrolateral division. These results further implicate NT in female-specific regulation of prolactin secretion and raise the possibility that estrogen, which has complex effects on dopamine synthesis and release, differentially regulates the amounts of releasable NT and dopamine in neurons of the dorsomedial arcuate nucleus in the female rat.

COLOCALIZATION OF ATRIAL NATRIURETIC PEPTIDE AND ESTROGEN RECEPTOR IMMUNOREACTIVITY IN SEXUALLY DIMORPHIC NUCLEI IN THE MEDIAL PREOPTIC REGION. R.E. Watson, Jr., R.K. Hutchinson*, J.W. Landis*, and M.C. Langub, Jr. Dept. of Anatomy and Neurobiology, Univ. of Kentucky Medical Center, Lexington, KY 40536-0084.

The medial preoptic region contains a number of distinct sexually dimorphic nuclei, including the anteroventral periventricular nucleus (AVPv), periventricular preoptic nucleus (Pvpo), and medial preoptic nucleus (MPN). These nuclei are characterized by the presence of abundant estrogen receptor- (ER) and atrial natriuretic peptide- (ANP) immunoreactive (ir) neurons. This study was conducted to determine if ER-ir is present in ANP-ir neurons in these nuclei. Young adult female Sprague-Dawley rats were ovariectomized and injected the following day with colchicine (50 µg) intracerebroventricularly. One to two days later, these animals were perfused with Zamboni's fixative. Brain sections (25 µm) were stained for the immunocytochemical localization of ER using monoclonal antibody H222 (kindly provided by Abbott Laboratories) using nickel ammonium sulfate-enhanced DAB as the chromogen, which produced a blue-black reaction product that was confined predominantly to the nuclei of immunopositive cells. ANP-ir was demonstrated using a rabbit polyclonal antiserum against rat ANP (Palm, et al., '89) and DAB which produced the typical reddish-brown reaction product in the cytoplasm of immunopositive cells. Approximately 5-10% of the ANP cells in the AVPv, Pvpo, and MPN were ER-ir. Moreover, single labeled ANP-ir cells frequently appeared to be in direct apposition to ER-ir cells. These results suggest that estrogen is capable of regulating the activity of subsets of ANP-ir neurons in the medial preoptic region, potentially affecting neuroendocrine or cardiovascular function, or the regulation of fluid balance.

ESTROGEN RECEPTORS IN AXON TERMINALS IN GUINEA PIG HYPOTHALAMUS: IMMUNOGOLD LOCALIZATION. J.D. Blaustein, J.C. Turcotte, and M.N. Lehman. Neuroscience and Behavior Program and Psychology Dept., Univ. Mass., Amherst, MA 01003 and Dept. Anat. and Cell. Biol., Univ. Cinc. Coll. Med., Cincinnati, OH 45267

While we have confirmed previously that estrogen receptor-immunoreactivity (ER-IR) in hypothalamic neurons is present most abundantly in cell nuclei, we have also detected dense ER-IR in the perikarya and processes of neurons. We have reported with an immunoperoxidase technique, using diaminobenzidine as a chromogen, that ER-IR was present in numerous extranuclear organelles and sites, including axon terminals and distal dendrites. Because results using diaminobenzidine can be confounded by diffusion of reaction product, we used an immunogold-streptavidin procedure. Ovariectomized guinea pigs were perfused, brains vibratome-sectioned, and estrogen receptors immunostained (with H222 antibody) using a biotinylated secondary antibody followed by streptavidin labeled with 1 nanometer particles of colloidal gold. The gold particles were then visualized by silver intensification. Electron microscopic analysis confirmed the distribution of silver deposits in association with cell nuclei, axon terminals containing predominantly round and flattened clear synaptic vesicles, proximal and distal dendrites, and rough endoplasmic reticulum. In addition to suggesting the endoplasmic reticulum as a site of synthesis of the receptor, these results suggest the axon terminal as a potential intracellular site of action for estradiol in the hypothalamus.

ESTROGENIC REGULATION OF HEAT SHOCK PROTEINS 90Kd AND 70Kd IN THE RAT VENTROMEDIAL HYPOTHALAMUS AND UTERUS. U.E. Olazábal, D.W. Pfaff and C.V. Mobbs. Rockefeller Univ., New York, NY 10021.

Recent evidence indicates that cellular heat shock proteins 90Kd (hsp90) and constitutive 70Kd (hsp70c) may be involved in the steroid hormonal control of target tissues. Therefore, we carried out this study to determine if estrogen regulates hsp90 and hsp70c protein levels in the ventromedial hypothalamus (VMH), a brain region which controls the estrogen-dependent behavior, lordosis, and in the uterus. Ovariectomized female rats received a single injection of estradiol benzoate (E, 10 µg, s.c.). VMH was removed by microdissection from untreated OVX controls and at 6h, 12h, 18h, or 24h following E, prepared in SDS sample buffer, and normalized with respect to total VMH protein content. Hsp90 and hsp70c were detected by 1-D gel electrophoresis followed by immunoblotting using monoclonal antibodies to these hsp's (StressGen). Specific immunoreactive bands were visualized on film using enhanced chemiluminescence (Amersham) and scanned with a laser scanning densitometer. Analysis of hsp's levels in VMH showed a time-dependent increase for females, but not males, in both hsp90 and hsp70c which reached maximum levels at 12h (see table). In subsequent experiments, the hsp90 induction in the VMH was replicated at 12h, and estrogen-induced increases for hsp90 and hsp70c were also demonstrated in the uterus.

E.t-course	0h	6h	12h	18h	24h
hsp90 VMH	-	+15%	+33% **	0%	0%
uterus	-	+45%	+46%	+124% *	+41%
hsp70c VMH	-	+40%	+56% *	+21%	-21%
uterus	-	+24%	+31% *	+53% **	+84% **

Percentage changes from OVX controls; * p<0.05; ** p<0.01

EXPRESSION OF GLUTAMATE-A RECEPTOR mRNA IN GONADOTROPIN-RELEASING HORMONE CONTAINING (GnRH) NEURONS OF THE FEMALE RAT. L. Jennes and E. J. DuPré*, Dept. Anatomy, Wright State University, Dayton, OH 45435.

Glutamate is a major excitatory neurotransmitter which, among many other functions, has been implicated to participate in the regulation of GnRH release. The present study was designed to determine the glutamate receptor subtype(s) which mediate the stimulatory signal to the GnRH neurons. Central and peripheral administration of the glutamate agonist AMPA caused a significant increase in circulating LH by actions inside the brain, since exposure of cultured pituitary cells to AMPA had no effect on LH release. Immunohistochemistry for GnRH was combined with "in situ" hybridization for the detection of mRNAs encoding for the glutamate-A receptors. The results show that most GnRH-immunoreactive neurons in the septum-diagonal band complex express the mRNAs for both, "flip" and "flop" sequences of the glutamate-A receptor. It is concluded that glutamate can directly activate the GnRH neurons, at least in part, through binding to and activating postsynaptic glutamate-A type receptors. Supported by NIH grant HD 24629.

HEAT-SHOCK PROTEINS 90Kd AND 70Kd IN RAT BRAIN AND UTERUS: CELLULAR LOCALIZATION BY IMMUNOCYTOCHEMISTRY AND *IN SITU* HYBRIDIZATION. S.P. Kleopoulos, U.E. Olazábal, A.H. Lauber, D.W. Pfaff and C.V. Mobbs. Rockefeller Univ., New York, NY 10021.

We have shown (Olazábal et al., this meeting) that estrogen increases heat shock 90Kd (hsp90) and constitutive 70Kd (hsp70c) protein in the ventromedial hypothalamus (VMH) and uterus. To determine which cell types may be participating in this regulation, we have examined the cellular localization of hsp90 and hsp70c protein and mRNA in brain and uterus. Protein was detected by immunocytochemistry, entailing an avidin-biotin-peroxidase detection procedure, using monoclonal antibodies to hsp90 and hsp70c (StressGen). Hsp90 mRNA was detected using a modified method of *in situ* hybridization entailing I¹²⁵-labeled cDNA probes to mouse hsp90. Hsp90 and hsp70c immunoreactivity were readily apparent in neurons throughout the brain, including the VMH, but not in glial cells. Hsp90 and hsp70c immunoreactivity was prominent in secretory cells of the uterus (glandular and luminal epithelial cells) from estrogen-treated rats. In these animals, hsp90 and hsp70c immunostaining was considerably less prominent in stromal and myometrial cells. In ovariectomized rats not given estrogen replacement, hsp90 and hsp70c immunoreactivity was also less prominent. Localization of hsp90 mRNA by *in situ* hybridization was similar to that obtained for hsp90 protein by immunocytochemistry. Similar findings have been shown for hsp70c (Mobbs et al., Soc. Neurosci. Abs., 15:1989). These data suggest that in VMH and uterus, the cell types most likely involved in estrogenic regulation of heat-shock proteins are neurons and secretory cells, respectively.

NEUROENDOCRINE REGULATION: 3D ULTRASTRUCTURE OF A MEDIAN EMINENCE MICROVASCULAR MODULE.

LS Hibbard, TL Arnicar-Sulke*, RA Grothe, Jr.*, BJ Dovey-Hartman*, and RB Page. Washington University School of Medicine, St. Louis, MO; Schering-Plough Research, Lafayette, NJ; and The Pennsylvania State University College of Medicine, Hershey, PA.

To study hypothalamic regulation of the anterior pituitary, we are reconstructing discrete portions of the capillary plexus of the median eminence (ME) of the hypothalamus. These capillary modules, imaged at 1650X, were chosen from a 3D reconstruction of a large volume of a single rabbit ME imaged at lower magnification (100X). TEM digital image mosaics of sections, at 1 µ intervals, are aligned by Fourier correlation analyses. The capillary lumens were extracted by region-growing techniques based on the local pixel statistics. The cellular features were extracted by interactive tracing. The reconstruction of one vascular module will be presented, including endothelial cells, pericytes, smooth muscle cells, and the neural-mesenchymal stromal boundary.

ENDOCRINE REGULATION I

177.1

EFFECTS OF HYPOTHALAMO-PITUITARY DISCONNECTION, THYROID HORMONE STATUS AND DIABETES MELLITUS ON INSULIN-LIKE GROWTH FACTOR II (IGF-2), GROWTH HORMONE-RELEASING HORMONE (GRF) AND SOMATOSTATIN (SRIF) mRNA PREVALENCE IN ADULT RAT BRAIN. A. Levy, M.C. Matovelle* and W.S. Young III, National Institute of Mental Health, Bethesda, MD 20814.

We have used hybridization histochemistry to examine changes in transcript levels encoding choroid plexus IGF-2 mRNA, arcuate GRF- and periventricular SRIF-transcripts induced by pituitary stalk transection, hypophysectomy and drug induced thyrotoxicosis, hypothyroidism and diabetes mellitus. Brains were obtained from male rats after 10 days ingestion of a powdered diet containing either 0.5% propylthiouracil (PTU) or 60µg/kg triiodothyronine (T3), or 10 days after trans-oral surgery or a single intraperitoneal injection of 100mg/kg streptozotocin (STZ). The effects of dietary manipulation were confirmed by demonstrating appropriate changes in pituitary TSH mRNA (231±5.6% and 69±3.6% of control respectively) and the effects of STZ and pituitary surgery by measurement of blood glucose (>22mM by stick testing) and water intake (>200mL/kg/day).

Hypophysectomy lead to increased GRF mRNA and decreased SRIF and IGF2 mRNA levels. Stalk transection induced similar but less pronounced changes. T3 lead to a small increase in SRIF and decreased IGF2, leaving GRF unchanged. PTU only increased GRF mRNA. Finally STZ treatment markedly decreased GRF and IGF2 transcript levels.

Our results support the observations that hypothyroidism and hypoglycemia lead to abnormal somatic growth and confirm the effects of pituitary disconnection and hypophysectomy on GRF and SRIF gene expression. Furthermore, although of unknown significance, endocrine manipulations can also effect levels of IGF2 transcripts in the choroid plexus.

177.2

GROWTH HORMONE RECEPTOR MESSENGER RNA IS COLOCALIZED IN SOMATOSTATIN NEURONS IN THE MALE RAT HYPOTHALAMUS. K.A. Burton*, D.K. Clifton, R.A. Steiner. Departments of Physiology and Biophysics and Obstetrics and Gynecology, University of Washington, Seattle, WA 98195.

Growth hormone (GH), either directly or through insulin-like growth factor-1, has been shown to stimulate the release of somatostatin (SS) peptide from the hypothalamus and to stimulate hypothalamic SS messenger RNA (mRNA) levels. We have previously demonstrated that in the adult male rat, the mRNA for the GH receptor is located in areas of the hypothalamus known to be involved in regulating GH secretion, the periventricular (PeN) and arcuate nuclei. We reasoned that if GH negative feedback involves a direct action on SS neurons in the PeN, then SS neurons in the PeN should express the mRNA for the GH receptor. We tested this hypothesis by performing a double-labeling *in situ* hybridization on basal forebrain tissue sections from the male rat. SS mRNA was hybridized with a RNA probe labeled with digoxigenin-UTP, and the GH receptor mRNA was hybridized with a RNA probe labeled with ³⁵S-UTP. SS mRNA-positive cells were visualized by an alkaline phosphatase color reaction, and the GH receptor mRNA-positive cells appeared as silver grains overlying a cell nucleus. We observed that more than 50% of the SS mRNA-positive neurons in the PeN contained the mRNA for the GH receptor.

Conclusion: The GH receptor gene is co-expressed in SS mRNA-containing cells in the hypothalamus. We infer that GH feeds back directly on those SS neurons in the PeN that participate in orchestrating the pulsatile secretion of GH from the pituitary gland.

CORRELATION BETWEEN PROLACTIN (PRL) GENE EXPRESSION AND SECRETION AS ASSESSED BY THE COMBINED REVERSE HEMOLYTIC PLAQUE (RHP)/*IN SITU* HYBRIDIZATION ASSAY: EFFECT OF ESTRADIOL (E2) AND/OR BLOCKADE OF CALCIUM CHANNELS. G.H. Larson and P.M. Wise. Dept. Physiology, Univ. of Maryland Med. Sch., Baltimore, MD 21201.

It has been recently demonstrated that inhibition of calcium entry through voltage-gated channels modulates PRL secretion and mRNA levels in cultured pituitary and GH3 cells. Furthermore, estrogen treatment and/or blockade of these calcium channels enhances the amount or proportion of hormone that is secreted constitutively. The purpose of this study was to assess the effects of nifedipine, an L-type calcium channel blocker, and/or estrogen on PRL secretion and gene expression, and whether either of these treatments influences the coupling of gene expression and hormone secretion at the single cell level. Young rats were ovariectomized (OVX) and after 1 week half of the rats received E2 capsules (180 µg/ml). Three days later pituitary cells were enzymatically dispersed for use in the RHP assay. The cells were incubated with anti-PRL antibody ± nifedipine (10^{-6} M) for 3 hours. Treatment with complement resulted in the lysis of red blood cells in the areas surrounding lactotropes actively secreting hormone. *In situ* hybridization was performed by incubating slides overnight at 53°C with an 35 S-labelled antisense riboprobe (2.1 X 10^8 dpm/µg) transcribed from PRL cDNA. In OVX and E2 rats, 3 hours of exposure to nifedipine suppressed PRL secretion per cell, but did not appear to decrease the level of PRL mRNA per cell. E2 increased PRL secretion and mRNA levels per cell, and resulted in a correlation between the amount of secretory activity and the level of gene expression in individual cells, regardless of treatment with nifedipine. In conclusion, it appears that the ability of E2 to stimulate PRL secretion is coupled to its ability to enhance PRL gene expression within an individual cell. Under these experimental circumstances the blockade of L-type calcium channels does not appear to influence this coupling. (Supported by HD15955 and AG05493)

EFFECTS OF HYPO- OR HYPERTHYROID CONDITIONS ON PREPRO-NPY mRNA AND PRECURSOR-VIP/PHI mRNA LEVELS IN THE SUPERIOR CERVICAL GANGLIA (SCG) AND LOCAL THYROID GANGLIA (TG) OF RATS. L. Huffman*, M. Michalkiewicz*, K.E. Vrana*, and G.A. Hedge. Depts. of Physiology and Biochemistry, West Virginia Univ. Hlth. Sci. Ctr., Morgantown, WV 26506.

Both NPY and VIP are present in thyroid nerves and have been shown to alter thyroid blood flow and hormone secretion. The present study was conducted to determine whether hypo- or hyperthyroidism, induced by propylthiouracil (PTU) or thyroxine (T_4), respectively, is associated with changes in prepro-NPY mRNA or precursor-VIP/PHI mRNA levels in the major ganglia supplying nerves to the thyroid gland. Rats (8/group) were treated for six days with vehicle (0.5 ml 0.01N NaOH/day, ip), PTU (1 mg/100gBW-day, ip), or T_4 (5 µg/100gBW-day, ip). SCG and TG were dissected and total RNA was extracted and size fractionated on a denaturing gel for Northern blot analysis. Prepro-NPY mRNA was assessed using a 32 P-labeled rat cDNA probe and precursor-VIP/PHI mRNA was determined using a 32 P-labeled rat riboprobe. Prepro-NPY mRNA levels detected in the SCG were greater than those in the TG, whereas an opposite pattern was seen for precursor-VIP/PHI mRNA levels. No significant changes in prepro-NPY mRNA or precursor-VIP/PHI mRNA concentrations were detected in the SCG (8/group) or the TG (4/group) in response to either treatment. We conclude that changes in the thyroid axis in response to these hypo- and hyperthyroid conditions do not include alterations in the steady-state prepro-NPY or precursor-VIP/PHI mRNA concentrations in the major ganglia supplying nerves to the thyroid gland (Supported by NSF DCB-8904470).

GONADOTROPIN-RELEASING HORMONE (GnRH) REGULATES RAT MEDIAN EMINENCE TYROSINE HYDROXYLASE (TH) ACTIVITY *IN VITRO*. D.D. Rasmussen and K.E. Greene. Dept. Reprod. Med., UCSD, La Jolla, CA 92093.

GnRH can stimulate dopamine (DA) turnover in the lateral palisade zone of the rat median eminence (Neurosci. Lett. 45:253), suggesting that GnRH autoregulation could be mediated by DA. However, GnRH can also inhibit rat brain DA synthesis (Nature 296:354), suggesting that previously demonstrated correlations between pulsatile LH and prolactin secretion could be in part mediated by GnRH-induced suppression of hypothalamic DA secretion. Accordingly, we investigated the effect of GnRH on *in vitro* TH activity in adult male rat tuberoinfundibular dopaminergic neurons, as reflected by 3,4-dihydroxyphenylalanine (DOPA) accumulation in the medial portion of the median eminence during *in vitro* incubation with the DOPA decarboxylase inhibitor 3-hydroxybenzylhydrazine (NSD-1015). DOPA content was determined by HPLC with electrochemical detection. Addition of 10^{-7} M GnRH to the medium inhibited ($p < 0.002$, $n = 13-15$ /trtmt) medial median eminence TH activity (73.2 ± 6.3 vs 122.0 ± 15.1 pg DOPA/µg protein) whereas 10^{-9} and 10^{-5} M GnRH had no significant effect (97.4 ± 9.6 and 110.0 ± 13.2 pg DOPA/µg protein, respectively). These results demonstrate that GnRH can suppress *in vitro* TH activity in the medial median eminence and that this response is dose-dependent, suggesting that GnRH may stimulate *in vivo* prolactin secretion in part by inhibiting tuberoinfundibular DA secretion. In contrast, preliminary results from experiments including lateral portions of the median eminence appear to be consistent with the previously demonstrated stimulation of DA turnover by GnRH, although more studies are required. Further studies will evaluate whether the regulation of median eminence TH activity by GnRH is mediated by specific GnRH receptors. Supported by NIH HD12303, Unit 4 (DDR) and NSF Graduate Fellowship (KEG).

177.4

LOCALIZATION OF PROLACTIN-RECEPTOR mRNA IN ANTERIOR PITUITARY CELLS. Sufen Chiu* and Phyllis Wise. Department of Physiology, University of Maryland School of Medicine, Baltimore, MD 21201.

Prolactin (PRL) regulates its own secretion and the secretion of other anterior pituitary hormones. Whether it acts directly at the level of the pituitary is controversial. We have previously reported that Prolactin-Receptor (PRL-R) mRNA is detectable in the anterior pituitary gland (Chiu S et al, 1991, Endocrine Society Abstr. 260). Therefore, we initiated studies to determine which pituitary cell types express PRL-R mRNA. The initial experiments used the newly developed combined reverse hemolytic plaque-*in situ* hybridization (Scarbrough K et al, Mol Endo 5:134-142, 1991) to determine specifically whether cells secreting LH or PRL contain PRL-R mRNA.

Anterior pituitary cells from female rats were dispersed with trypsin and combined with protein A-coupled red blood cells. They were incubated for two hours in the presence of LH antibody or for one hour in the presence of PRL antibody. Treatment with complement resulted in plaques surrounding cells actively secreting LH or PRL, respectively. The cells were then fixed in 4% paraformaldehyde and hybridized to an 35 S-labelled riboprobe complementary to PRL-R mRNA (specific activity of 2×10^6 dpm/µg) overnight at 53°C. After a series of washes, the slides were dipped in emulsion and developed within 5 days.

We detected PRL-R mRNA in pituitary cells. However, the mRNA was not localized in cells actively secreting PRL or LH during the experimental period. We speculate that PRL-R mRNA is localized in either non-secreting lactotropes or non-secreting LH gonadotropes or other types of anterior pituitary cells.

NMDA RAPIDLY INCREASES CELLULAR LEVELS OF LHRH mRNA IN PARALLEL WITH INCREASES IN LH RELEASE. S.L. Petersen, S. McCrone*, M. Keller* and E. Gardner*. Dept. of Anatomy and Neurobiology, Univ. Missouri Sch. Med., Columbia, MO 65212.

We have previously demonstrated that LHRH mRNA levels are low before the estrogen-dependent LH surge, then rise. Similarly, LHRH release into the pituitary portal system increases before the LH surge. Because these changes in LHRH mRNA levels are blocked by antiestrogen implants into the MPOA, we believe that they are cellular correlates of the positive feedback effects of estrogen on LHRH neuronal activity. This interpretation is supported by studies in other neuropeptide systems which show that changes in neuronal activity alter levels of biosynthesis and are reflected in changes in mRNA levels. However, most of these studies have used chronic perturbations of the neuropeptide systems in question. To determine whether changes in LHRH mRNA could be used as an index of acute changes in neuronal activity, we infused intact male rats with either NMDA (13 mg/kg iv), a substance which increases LH release by a hypothalamic action, or with saline. We then used *in situ* hybridization to measure changes in cellular levels of LHRH mRNA at 15 and 60 min after the infusions. LHRH mRNA levels in cells of the rostral preoptic region were significantly elevated by NMDA at both 15 and 60 min, as were serum LH concentrations. Thus, LHRH mRNA levels appear to rapidly reflect changes in LHRH release. Because higher doses of NMDA lesion the arcuate nucleus, changes in levels of mRNAs encoding tyrosine hydroxylase and POMC were also examined.

177.8

THE DISTRIBUTION OF PROGESTIN RECEPTOR-IMMUNOREACTIVITY IS SIMILAR TO THAT OF ESTROGEN RECEPTOR-IMMUNOREACTIVITY IN THE MIDDLEBRAIN OF FEMALE GUINEA PIGS. J.C. Turcotte and J.D. Blaustein. Neuroscience and Behavior Program and Psychology Department, University of Massachusetts, Amherst, MA 01003

Estradiol-induced progestin receptor-immunoreactive (PR-IR) neurons in female guinea pigs have been mapped in a number of forebrain areas, including the preoptic area and mediobasal hypothalamus. Using immunocytochemical techniques, we have found that estradiol-induced PR-IR cells are also located in the midbrain central gray (MCG). The distribution of PR-IR cells is similar to that of estrogen receptor-immunoreactive cells in that they are found in the same areas of the MCG, lateral and ventrolateral to the cerebral aqueduct. PR-IR cells, like ER-IR cells, appear to increase in number from rostral to caudal levels before tapering off in the region of the inferior colliculus recess. Midbrain PR-IR cells, however, are far fewer in number than ER-IR cells and seem to be restricted primarily to the MCG, while ER-IR cells are found in other midbrain regions, such as lateral to the MCG. Midbrain PR-IR cells are also more lightly stained than PR-IR cells in other sites, such as the hypothalamus, and have little or no apparent cytoplasmic immunoreactivity. The presence of these cells suggests a role for progestins as well as estrogens in midbrain functions, which may include effects on steroid hormone dependent behaviors such as sexual receptivity.

177.9

SOME OF THE VENTROLATERAL HYPOTHALAMIC NEURONS CONTAINING SUBSTANCE P AND PROGESTIN RECEPTORS PROJECT TO THE MIDBRAIN CENTRAL GRAY IN GUINEA PIGS. K. H. Nielsen and J. D. Blaustein. Neuroscience and Behavior Program and Psychology Department, University of Massachusetts, Amherst, MA 01003

In estradiol-primed, female guinea pigs, up to 50% of the progesterin receptor-immunoreactive (PR-ir) neurons in the ventrolateral hypothalamus are also immunoreactive for substance P (SP-ir). In order to determine the efferent projections of these specific neurons, retrograde tracing was combined with double-label, fluorescent immunocytochemistry. Microinjections of Fluoro-Gold (FG) into the midbrain central gray and adjacent areas labeled neurons in and around the ventrolateral hypothalamus, an area involved in the hormonal control of female sexual behavior. A number of these FG-labeled neurons were SP-ir, and several were PR-ir. Some of the FG-labeled neurons were immunoreactive for both substance P and progesterin receptors. In contrast, FG injection sites in the red nucleus of the midbrain, which included only a small portion of the central gray, labeled very few neurons in the ventrolateral hypothalamus. Therefore, some of the progesterone target neurons in the ventrolateral hypothalamus express substance P and also project to the midbrain central gray.

VIP/PHI NEURONS IN THE RAT MEDIAN EMINENCE: IMMUNOHISTOCHEMICAL AND IN SITU HYBRIDIZATION STUDIES. S. Ceccatelli, M. J. Villar, T. Hökfelt. Dept. of Histology and Neurobiology, Karolinska Institute, Stockholm, Sweden.

Using immunohistochemistry and in situ hybridization we have analyzed the distribution of vasoactive intestinal polypeptide (VIP) and peptide histidine isoleucine (PHI) in hypothalamus of male and female Sprague-Dawley rats under normal and experimental conditions. Precapillary arterioles along the lateral aspect of the median eminence were surrounded by dense networks of VIP/PHI positive fibers, suggesting that these peptides, via their vasodilatory property, may be involved in control of blood flow through portal vessels. Furthermore, a thick VIP/PHI containing nerve bundle of variable size was observed on the surface of the median eminence in coronal, horizontal and sagittal sections. Also this bundle could be of importance for portal circulation, but VIP/PHI released may reach the anterior pituitary level and play a role in, for example, control of prolactin release. Although different lesions were performed, the origin of the VIP/PHI nerves around lateral blood arterioles and the bundle is still unclear, but is in all probability peripheral. After 48 h hypophysectomy a very large number of PHI immunoreactive fibers could be observed in the median eminence, and with in situ hybridization VIPmRNA could be demonstrated in magno- and parvocellular neurons of the paraventricular nucleus, whereas in control rats it was undetectable. These results demonstrate that VIP/PHI are present in systems of direct neuroendocrine importance i. a. in nerves related to the blood vessels in the median eminence and presumably involved in control of blood flow through the portal system. To what extent the VIP/PHI nerve bundle on the surface of the median eminence might be involved in regulation of pituitary function remains to be established.

177.13

GROWTH HORMONE RELEASING HORMONE (GHRH) IMMUNOREACTIVE NEURONS IN THE HYPOTHALAMUS OF PIGS AND CATTLE. L. S. Leshin¹, C. B. Barb¹, D. Slayin^{1*}, E. Taras^{2*}, G. B. Rampacek^{2*}, L. E. Kiser^{2*} and R. R. Kraeling^{1*}. USDA-ARS¹, Athens, GA 30613 and Animal and Dairy Science Dept., University of Georgia², Athens, 30602.

Hypothalamic GHRH neurons were localized in female immature gilts (n=6) and heifers (n=2) to identify anatomical sites involved in regulation of growth hormone secretion. Coronal and sagittal frozen sections (48-60 μ m) of Zamboni's fixed hypothalamic tissue were incubated with GHRH primary antisera (B. D. Schanbacher, USDA-ARS, Clay Center, NB and F. C. Buonomo, Monsanto Co., Chesterfield, MO) for 48 h then visualized by peroxidase-diaminobenzidine or fluorescent immunocytochemistry. Treatment with nonimmune serum lacked specific staining. Incubation of GHRH antisera with GHRH peptides p1-44, b1-44 or h1-29 (2-10 μ g/ml, 24 h) prior to immunocytochemistry greatly reduced or blocked specific staining. Rounded or fusiform, bipolar immunoreactive GHRH perikarya were only in ventrolateral portions of the arcuate nucleus with fibers projecting ventrally into the median eminence. In both species, there was very dense innervation of the external lamina of the median eminence. Immunoreactive GHRH was not observed in other hypothalamic areas, suggesting that these GHRH neurons may have only hypophysiotropic functions in gilts and heifers.

177.10

ABLATION OF THE HYPOTHALAMIC MEDIAN EMINENCE REDUCES THE CONCENTRATION OF VASOACTIVE INTESTINAL PEPTIDE IN THE ANTERIOR PITUITARY GLAND OF MALE RATS. A. J. Carrillo and D. E. DiLuze. Dept. of Anatomy, NEOUCOM, Rootstown, OH 44272.

Recent studies have clearly shown that vasoactive intestinal peptide (VIP) produced in the anterior pituitary gland is regulated by the thyroids, adrenals and perhaps the gonads in a manner similar to that of a pituitary gland-target organ feedback loop. Because the hypothalamus is essential for the functioning of such a feedback loop, this study was designed to determine the influence of this neural center on the anterior pituitary concentration of VIP. To this end, the hypothalamic median eminence (ME) of anesthetized adult male rats was ablated by lowering a triangular shaped knife (2.0 X 1.0 mm) to the base of the hypothalamus and rotating several times. Intact and sham ablated rats served as controls. Fifteen days later all the rats were decapitated (AM) and the anterior pituitary dissected out and frozen for VIP determination using a recently established RIA (Carrillo et al. Endocrinology, 128:131, 1991). In order to evaluate the completeness of the ME ablation, water consumption per 24 hrs. was monitored after surgery and the adrenals and testis were weighed at the time of decapitation. Ablation of the ME resulted in a 211% increase in water consumption and in a reduction of tissue mass of the anterior pituitaries (mg of protein), adrenals and testis (weight) of 59%, 54% and 40% respectively, when compared to controls. Pituitary content of VIP was also significantly ($p < 0.01$) reduced in the ME lesion group (80 ± 13 pg/mg of protein) when compared to sham (518 ± 65) and intact controls (771 ± 162). These data suggest that the hypothalamus is involved in the regulation of pituitary VIP. Supported by Ohio Board of Reagents Research Challenge Program 1989-91.

GALANIN NEURONS INNERVATE ANTERIOR PERIVENTRICULAR SOMATOSTATIN CELLS AND MODULATE SOMATOSTATIN SECRETION FROM ARCULATE NUCLEUS-MEDIAN EMINENCE FRAGMENTS. Zs. Liposits, M.M. Valenca, F.J. López, I. Merchenthaler and A. Negro-Vilar. LMIN, NIEHS, NIH, Research Triangle Park, NC 27709.

It has been reported that galanin (GAL) alters growth hormone (GH) secretion via central hypothalamic mechanisms (Ottlecz et al., PNAS 85:9861-9865, 1985; Maiter et al., Endocrinology 126:1212-1222, 1990). Due to the dual inhibitory and stimulatory influence of the diencephalon upon GH secretion, the effect of GAL might be manifested through both growth hormone-releasing hormone (GHRH) and growth hormone-release inhibiting hormone or somatostatin systems. In order to address the modulation of the hypothalamic somatostatin system by GAL, morphological and pharmacological studies were undertaken in male rats. By means of light and electron microscopic immunocytochemical double labeling techniques, we have found that somatostatin-producing neurons in the anterior periventricular area are heavily contacted by GAL-immunoreactive axons. At the ultrastructural level, axosomatic and axo-dendritic synaptic connections were detected among GAL- and somatostatin-immunoreactive profiles. *In vitro* incubation of arcuate nucleus-median eminence fragments, containing primarily nerve terminals, in the presence of 0.05-1 μ M rat GAL resulted in a significant increase in somatostatin release. These data indicate that the central galanin neuronal system may influence the production and release of somatostatin acting upon both the cell bodies and terminals; thus, the GAL-somatostatin interaction should also be considered as an important step in the mechanisms regulating tonic and pulsatile GH secretion.

IN SITU HYBRIDIZATION FOR CREATINE KINASE-B MESSENGER RNA IN RAT UTERUS AND BRAIN. H.T. Bergen¹, B.T. Pentecost^{2*}, H.W. Dickerman^{2*}, and D.W. Pfaff¹. ¹Lab. of Neurobiology and Behavior, Rockefeller University, New York, NY 10021, and ²Wadsworth Center for Laboratories and Research, Albany, NY 12201.

Creatine kinase-B (CKB) is present in both uterus and brain, and in uterus its synthesis (protein and mRNA) is induced by estrogen (E). Malnick et al. (Endocrinology 113: 1907, 1983) proposed that E induction of CKB also occurs in brain. Preliminary immunocytochemical data in our lab showed E induction of CKB in uterus, but not in brain (Schwanzel-Fukuda et al., unpub.). Thus in the present study we used *in situ* hybridization (ISH), to detect CKB mRNA in uterus and brain, and to examine whether there is site-specific induction of CKB mRNA by E in these tissues. Tissue was taken from ovariectomized (ovx) control rats, and ovx rats that had been injected with E, 2, 8, 24, and 72 hr previously. In the final group (72 hr), the rats also received E at 48 hr. The brains and uteri were removed, frozen, and cryostat-sectioned and processed for ISH by previously published methods employing a ³H-CKB DNA probe complementary to a 3' fragment of CKB mRNA, and a control sense probe identical to the same 3' fragment. Quantification of the results consisted of either counting the autoradiographic grains/unit area (uterus) or the number of grains/cell (brain). In uterine smooth muscle, a 2.5 and 3.5 fold induction of CKB mRNA was observed 2 and 24 hr after E, respectively, and levels approached ovx controls at 72 hr. A smaller induction (1.9 fold, 2 hr) was observed in uterine luminal epithelium, with little induction of CKB mRNA in the stroma. In the brain, CKB mRNA was detected in neurons, but not in clearly identified glia, and only occasionally in ependymal cells. Some brain regions had higher neuronal expression than others, but expression was widespread and not limited to neuroendocrine sites. We have not seen evidence of a significant E effect on CKB mRNA levels in brain.

EFFECTS OF ESTROGEN ON FOS-LIKE IMMUNOREACTIVITY (F-IR) AND ³H-THYMIDINE (³H-THY) INCORPORATION WITHIN UTERINE TISSUES TRANSPLANTED TO THE ADULT RAT CNS. H.J. OKANO, R.B. Gibbs, & D.W. Pfaff. Lab. of Neurobiol. & Behav., Rockefeller University, N.Y., NY 10021

Estradiol (E) stimulates Fos induction and cell division in uterus, but not within E-concentrating neurons in brain (Gibbs et al., Mol. & Cell. Neurosci. 1: 29-40, 1990; Gibbs et al., Mol. & Cell. Neurosci. 1: 250-261, 1990). If uterus were transplanted into brain, would either tissue confer its hormone reactivity upon the other?

Thirty-two adult, ovariectomized, Sprague-Dawley rats were used. Uteri obtained from donor animals were cut into small pieces (~3mm³) and stereotaxically implanted into the third ventricle adjacent to the arcuate, ventromedial, and anterior hypothalamic nuclei. Two to 5 weeks later, animals received a subcutaneous injection of 10 µg estradiol (E) or vehicle (V). Five, 12, and 24h later, animals were sacrificed and the brains and uteri removed for ICC detection of F-IR using a polyclonal anti-Fos antibody generously provided by Dr. M. Iadarola (NIH). In addition, 5 animals received an IP injection of ³H-Thy (5 µCi/g.b.w.) 22h after receiving either E (n=3) or V (n=2). These animals were sacrificed 2h later. The brains and uteri were removed, processed for ICC, and then for RA detection of ³H-Thy incorporation.

Twenty-nine grafts survived, all of which showed signs of a first-set rejection response including vascular cuffing and infiltration by small mononuclear cells. F-IR epithelial cells (ECs) were detected in all E-treated uteri as well as within all E-treated grafts in which ECs could be identified (12/12). F-IR ECs were not detected within non-E-treated uteri, but were detected within 2 of 7 non-E-treated grafts. ³H-Thy-labeled ECs and stromal cells were detected within 3 of 3 E-treated uteri. Many ³H-Thy-labeled ECs and stromal cells were also detected within E-treated grafts; fewer labeled cells were detected within non-E-treated grafts. The uterine grafts did not confer E-stimulated F-IR or DNA synthesis to surrounding areas of the brain. These data demonstrate that E can stimulate F-IR and DNA synthesis in uterine tissues grafted to an environment where comparable effects on E-concentrating neurons are not observed.

PAIN PATHWAYS: HYPERALGESIA

178.1

MOLECULAR SPINAL RESPONSES TO PERIPHERAL NERVE INJURY. J.L. Culbertson, R. Jenkins*, S. Williams* and S.P. Hunt. M.R.C. Molecular Neurobiology Unit, Hills Road, Cambridge CB2 2QH, U.K.

The immediate-early genes *c-fos* and *c-jun* are rapidly and transiently activated in dorsal horn neurons by noxious peripheral stimulation. We have examined the effects of peripheral nerve injury in adult SD rats. The sciatic nerve was exposed surgically (control), and either cut or crushed. In fixed frozen sections of lumbar spinal cord from rats killed two hours after nerve damage, Fos protein-like immunoreactivity appeared (with somatotopic distribution) in many neuronal cell nuclei within the superficial dorsal horn; reactive cells were not seen in motor or dorsal root ganglion neurons. Complimentary localization of central projections was observed in parallel experiments with saphenous nerve lesions. When the survival time was increased from 2 hours to 24 hours, Fos positive neurons were dispersed bilaterally throughout laminae I-VIII and X, but an increase in Jun protein-like immunoreactivity within dorsal root ganglion cells and motor neurons ipsilateral to the injury was seen for the first time. This response was sustained for 7 days, the longest timepoint examined, and was therefore neither rapid nor transient. C-fos induction in second-order sensory neurons may result from injury potentials in the peripheral nerve. C-jun may regulate the long-term response to damage within the injured afferent and efferent neurons themselves.

CHANGES IN PCP BINDING SITES IN RAT SPINAL CORD IN AN EXPERIMENTAL MODEL OF ACUTE, PERIPHERAL INFLAMMATION. S. I. Sloan¹, C.L. Stucky², E.M. Jansen², M.T. Galeazza², V. S. Seybold² and L. Aanonsen¹ ¹Biology Dept., Macalester College, St. Paul, MN 55105 and ²Dept. of Cell Biology & Neuroanat., University of Minnesota, Mpls, MN 55455.

Previous studies reveal that there is modulation of CGRP and SP binding sites in the dorsal horn of the rat spinal cord in a model of peripheral inflammation (Galeazza et al., 1990). The purpose of the present study was to examine changes in PCP receptor binding sites in laminae I/II in this same model. Inflammation was induced by injection of Freund's complete adjuvant (FCA) into the plantar surface of the left hindpaw (75µl, emulsified 1:1 with PBS; s.c.). The thickness of the inflamed paw and the amount of extravasated Evans Blue were significantly increased compared to controls (uninjected rats) at 2 and 4 days after injection (Galeazza et al., 1990). The animal's response to a noxious thermal stimulus was tested 2, 4 and 8 days after FCA injection. A hyperalgesic response was evident ipsilaterally to inflammation on days 2 and 4, and contralateral to inflammation on day 4, when compared to controls. Autoradiographic studies were performed on tissue sections of spinal segment L4. These sections were obtained from control rats and from rats 2, 4 and 8 days after FCA injection. The spinal cord sections were incubated in ³H-TCP (5 nM) which was used to label the PCP binding site (Aanonsen and Seybold, 1989). Nonspecific binding was determined by incubation of adjacent sections in ³H-TCP plus 100 µM PCP. Autoradiographic grain densities in the emulsion overlying laminae I/II were quantified using computerized image processing. Specific binding was determined by subtracting nonspecific binding from total binding in the analyzed region. The analysis revealed a significant decrease in ³H-TCP binding in laminae I/II ipsilaterally to inflammation only on day 2.

The PCP binding site is believed to be associated with the NMDA receptor, an excitatory amino acid receptor subtype. Thus, the apparent modulation of PCP binding sites in this study may reflect changes in release of glutamate from afferents 2 days following inflammation. Supported by USPHS grant NS17702.

EFFECTS OF NEONATAL SCIATIC NERVE LESION ON THE CONTRALATERAL VENTRAL ROOT AFFERENT FIBERS. K. Chung, K. Sheen and J.M. Chung. Sch. Allied Health Sci., Marine Biomed. Inst., Depts. of Anat. & Neurosci. and of Physiol. & Biophys., Univ. Texas Med. Br., Galveston, TX, 77550.

In previous studies, we showed that a lesion of the sciatic nerve during the neonatal stage triggers sprouting of afferent fibers in the ipsilateral ventral root. In this study, we examined the possibility that the same type of lesion triggers sprouting of afferent fibers in the contralateral ventral root.

A total of 18 adult (3 month old) Sprague-Dawley rats was used; 5 neonatal sciatic neurectomized (at the age of 3 days) and 13 control rats (10 unoperated normal and 3 sham operated rats). The animals were perfused and the L5 ventral root on the side contralateral to the sciatic nerve lesion was processed for electron microscopic study. The numbers of both myelinated and unmyelinated fibers were counted in electron photomicrographs.

The average numbers of myelinated fibers in the L5 ventral root contralateral to the sciatic nerve lesion were 1697 and 1700 in control and neurectomized rats, respectively. However, the average numbers of unmyelinated fibers in the same root were 19 and 52 in corresponding rats.

These results suggest that a unilateral peripheral nerve lesion during the neonatal period triggers sprouting of unmyelinated fibers in the contralateral ventral root. (Supported by NIH grants NS21266 and NS11255 and a grant from Bristol-Myers Squibb Co.)

178.4

SPONTANEOUS AND EVOKED EXPRESSION OF C-FOS IN RAT LUMBAR SPINAL CORD DURING THE DEVELOPMENT OF ADJUVANT-INDUCED ARTHRITIS. C. Abbadie*, F. Morain* and J.-M. Besson. INSERM U 161 and EPHE, 2 rue d'Alésia, 75014 Paris, France.

This study evaluated Fos-like immunoreactivity (FLI) in spinal cord neurons during the development of adjuvant-induced arthritis (AIA), at 1, 2, 3 and 11 weeks (W) postinoculation with Freund's adjuvant. Lumbar spinal cord sections (L2 to L6) from injected and control rats were immunostained using Fos antibody. Quantification of the total number of FLI neurons showed that AIA disease correlated with FLI. FLI was absent in control rats and at 1W, moderate at 2W, maximal at 3W and slightly decreased at 11W. At 3W, which is the acute stage of hyperalgesia, FLI distribution was 6% in superficial laminae (I and II), 6% in the nucleus proprius (laminae III and IV), 55% in the neck (laminae V and VI) and 33% in the ventral horn. Maximal staining was found in L4.

At 3W, FLI was then used to test the responsiveness of spinal neurons to moderate pressure at the ankle joint, under ketamine anesthesia. The number of FLI neurons was significantly higher in arthritic than in healthy rats, particularly in the superficial laminae and in the neck of the ipsilateral dorsal horn with maximal staining in L3 and L4. Similar results were obtained with pressure applied to the dorsal paw. The appearance of spontaneous FLI neurons during AIA disease and their increased number relative to healthy rats following stimulation suggesting these neurons are abnormally active and involved in the hyperalgesia of AIA.

INFLUENCES OF LOCAL ANESTHETIC UPON EXPERIMENTAL MODELS OF PERIPHERAL NEUROPATHY. C.J. Garrison, P.M. Dougherty, W.D. Willis, S.M. Carlton. Dept. of Anat. & Neurosci., Marine Biomedical Institute, Univ. Texas Medical Branch, Galveston, TX, 77550-2772

Neuropathic pain remains a major complication following various forms of peripheral nerve injury in humans. Two models of peripheral neuropathy in the rat have recently been described which result in hyperalgesia to thermal stimulation. One model is induced by the placement of 4 loose ligatures around the entire sciatic nerve (Bennett & Xie, 1988); the second model is produced by the placement of a tight ligature around one-third to one-half of the sciatic nerve (Seltzer et al., 1990). It was the purpose of this study to compare the effect of the injuries on time course and magnitude of foot withdrawal latency to radiant heat. In addition, to evaluate the hypothesis that hyperalgesia develops as a result of injury discharge, some injuries were induced following local application of lidocaine to the sciatic nerve. Our results from a total of 120 male Sprague-Dawley rats showed that the hyperalgesia in partial-constriction neuropathy (PCN) develops faster than that produced by the partial-transsection neuropathy (PTN). In addition, lidocaine reduced the duration and magnitude of the hyperalgesia in the PCN (N=52 vs N=43 animals without lidocaine). The PTN failed to show this sensitivity in 14 animals compared to 11 controls. Based on our results, PCN develops and is maintained, at least in part, by lidocaine-sensitive mechanisms. Lidocaine effected the duration and magnitude, but not the onset, of hyperalgesia. These data suggest that injury-related discharge is one factor which contributes to the generation of hyperalgesia in the PCN model. The factors underlying the PTN model result in a slower onset of hyperalgesia and involve mechanisms which may or may not be shared with the PCN model. HISTOCHEMICAL CHANGES IN THE DORSAL HORN OF THE RAT FOLLOWING EXPERIMENTAL PERIPHERAL NEUROPATHY. A.A. Cameron, K.D. Cliffer, P.M. Dougherty, W.D. Willis and S.M. Carlton. Dept. of Anatomy and Neurosciences and Marine Biomedical Institute, Galveston, TX 77550.

An experimental rat model of peripheral neuropathy which produces hyperalgesia has recently been described (Bennett and Xie, 1988). We have investigated some of the neurochemical changes occurring in the dorsal horn as a result of the peripheral neuropathy. Four loose ligatures were tied around the sciatic nerve in anaesthetized rats. All animals demonstrated behavioral hyperalgesia. After 28 days the animals were perfused and 25 μ m sections of L4 and L5 spinal cord were stained with soybean agglutinin and immunostained for the lectin RL-29, the growth associated protein GAP-43 and the neuropeptides substance P and calcitonin gene-related peptide (CGRP). In the superficial dorsal horn the densities of reactivity to soybean agglutinin, RL-29 and GAP-43 were all increased, while those to substance P and CGRP were slightly decreased. We hypothesize that damage to peripheral axons and the consequent central anatomical changes, possibly including regenerative changes, contribute to the hyperalgesia. (Supported by NS11255, NS09743, NS27910, NS08860 and Bristol Myers-Squibb).

NEUROMA FORMATION AND NUMBERS OF AXONS IN AN EXPERIMENTAL PERIPHERAL NEUROPATHY. S.M. Carlton, P.M. Dougherty, C.M. Pover and R.E. Coggeshall. Dept. of Anat. & Neurosci., Marine Biomedical Institute, University of Texas Medical Branch, Galveston, TX 77550.

Chronic partial constriction of the sciatic nerve in the rat produces a neuropathy characterized by hyperalgesia to thermal stimuli (Bennett and Xie, 1988). Some important questions to be investigated in this model are the degree of fiber damage, neuroma formation and whether correlations exist between fiber loss and behavioral changes. Two weeks following chronic sciatic constriction in 5 rats, ultrastructural analysis was performed on the injury site and on the nerve proximal and distal to the injury. At the constriction site, the perineurium was disrupted and a neuroma was present in all cases. Axon counts demonstrated 84-99% and 62-84% decreases in myelinated and unmyelinated axons, respectively, in the distal compared to the proximal segment. The majority of the surviving myelinated axons were A δ fibers. There was considerable disparity in fiber loss from animal to animal, but similar behavioral changes were demonstrated by all animals. We hypothesize that input from the surviving axons will result in increased activity in the neuroma, which in turn will be interpreted as noxious input by the animal. Furthermore, although all fiber populations are decreased, input relayed by unmyelinated axons appears to be crucial in the generation of this model. (Supported by NS11255, NS27910 and Bristol-Myers Squibb).

178.6

HISTOCHEMICAL CHANGES IN GRACILE NUCLEUS FOLLOWING EXPERIMENTAL PERIPHERAL NEUROPATHY IN THE SCIATIC NERVE OF RATS. K.D. Cliffer, A.A. Cameron, P.M. Dougherty, W.D. Willis and S.M. Carlton. Marine Biomedical Institute and Dept. of Anatomy and Neurosciences, Univ. of Texas Medical Branch, Galveston, TX 77550.

Peripheral nerve damage induces changes in the spinal cord hypothesized to be involved in associated sensory disorders. However, effects in another target for primary afferent fibers, the dorsal column nuclei (DCn), have not been extensively characterized. We stained DCn of rats that were subjected to chronic constriction of the sciatic nerve (Bennett and Xie, 1988) unilaterally for 14 or 28 days. Gracile nuclei from each of the 14-day rats (N=8) and the 28-day rats (N=8) exhibited striking increases in immunohistochemical staining for calcitonin gene-related peptide (CGRP) ipsilateral to the injury. Profiles with increased staining included large fibers or fiber bundles. This contrasted to no obvious change in staining for substance P or galanin in the gracile nucleus, and to a slight decrease in staining for CGRP in spinal cord. Increases in staining for growth-associated protein GAP-43 and with soybean agglutinin, a marker for small primary afferent fibers, also occurred in the ipsilateral gracile nucleus. These changes may be involved in modification of sensory processing in the DCn and contribute to sensory disorders associated with peripheral nerve damage.

AN ELECTRON MICROSCOPIC ANALYSIS OF SOYBEAN AGGLUTININ-LABELED PROFILES IN THE RAT DORSAL HORN FOLLOWING EXPERIMENTAL PERIPHERAL NEUROPATHY. E.S. Hayes, P.M. Dougherty and S.M. Carlton. Dept. of Anatomy & Neurosci., Marine Biomed. Institute, Univ. of Texas Med. Branch, Galveston, TX 77550.

The lectin soybean agglutinin (SBA) labels small diameter dorsal root ganglion cells and primary afferent fibers and terminals in the rat dorsal horn. It has been demonstrated that SBA labeling increases in the dorsal horn in rats with experimental peripheral neuropathy (Cameron et al., Soc. Neurosci. '91). It was the aim of this study to determine, at the ultrastructural level, the profile types which label with SBA in both the normal and the neuropathic dorsal horn.

Following the protocol of Bennett and Xie (1988), 4 loose ligatures were tied around one sciatic nerve (n=3) and a sham-operation was performed on the contralateral side. Fourteen days later, the animals were anesthetized and perfused with an EM fixative. Tissue sections (25 μ m) from L4 were labeled for SBA and prepared for EM analysis.

Light level analysis revealed an increase in SBA staining on the operated compared to the sham-operated side. On the sham-operated side, EM analysis demonstrated SBA label concentrated in unmyelinated axons and glomerular terminals with dense core vesicles in LI and II. Although colchicine in one animal failed to show any labeled cells at the light level, EM analysis demonstrated SBA-labeled neuronal cell bodies, dendrites and dendrites containing vesicles. In the dorsal horn on the operated side, similar types of SBA-labeled profiles were observed, however, SBA staining was often seen in extracellular spaces, particularly surrounding neuronal somata. It is this extracellular label observed at the EM level which may be responsible for the increase in the density of SBA staining seen at the light level. (Supported by NS11255, NS27910 and Bristol-Myers Squibb).

ULTRASTRUCTURAL CHANGES IN THE VENTRAL HORN OF THE RAT SPINAL CORD IN EXPERIMENTAL PERIPHERAL NEUROPATHY. H.A. Lekan, P.M. Dougherty, S.M. Carlton. Dept. of Anat. & Neurosci., Marine Biomed. Institute, University of Texas Medical Branch, Galveston, TX 77550.

Animals exhibit hyperalgesia in a rat model of peripheral neuropathy in which the sciatic nerve is unilaterally constricted by ligatures (Bennett and Xie, 1988). The degree of hyperalgesia is determined from paw withdrawal latencies (PWL) from a radiant heat source. All animals exhibit hyperalgesia at post-operative day 14 (14D) with a trend towards recovery by post-operative day 28 (28D). Following testing of PWL, 14D and 28D animals were anesthetized, perfused with an EM fixative and the spinal cords were removed. Tissue sections (40-50 μ m) from L4-L5 were processed for EM. Light level analysis revealed numerous dark profiles (8-15 μ m) in the ventral horn on the experimental side in the areas of the motor neuron pool of the sciatic nerve in both 14D and 28D animals. Analysis at the EM level indicated that the dark profiles resembled glial elements. At 14D, >80% of the large neuronal cell bodies (>40 μ m) were observed to be partially covered by glial processes and had undergone "synaptic stripping". These cells appeared otherwise normal morphologically. No chromatolytic neurons nor degenerating terminals were apparent. At 28D, many of the large cell bodies in this same region were chromatolytic, however glial processes were not observed surrounding the somas. Synaptic contacts were present on these neurons. The ventral horn changes described here parallel those seen following axotomy; however, the changes in the model of peripheral neuropathy are delayed. These morphological changes may lead to alterations in motor function which must be considered when analyzing the results of behavioral testing paradigms. (Supported by NS 11255 and NS 27910 and Bristol-Myers Squibb).

RESPONSES OF SPINOTHALAMIC TRACT (STT) NEURONS TO MECHANICAL AND THERMAL STIMULATION OF SKIN IN RATS. V. Paleckova, J. Palecek, P.M. Dougherty, S.M. Carlton and W.D. Willis Dept. of Anat. & Neurosci. & Mar. Biomed. Inst., UTMB, Galveston, TX - 77550

The STT neurons are thought to play an important role in transmission of nociceptive information from the periphery to the CNS. The aim of this study was to determine responses of STT cells, antidromically activated from VPL thalamus, to standard mechanical (Brush - brushing the skin with a cotton swab, Press - pressing the skin by a arterial clip with a modest grip, Pinch - noxious pinch with a clip with a strong grip) and thermal stimuli (series of 5s heat pulses, 35s apart grading from 37 - 49°C and 51°C produced by a Peltier device). Activity of STT cells was recorded with carbon filament microelectrodes (3 - 6 MΩ) from 20 rats (Sprague -Dawley) under Urethane anesthesia. Recorded cells were 200 - 1000 μm deep from the spinal cord surface with antidromic latencies from the thalamus ranging from 3.2 - 19 ms. Some of the deeper cells were mostly activated from subcutaneous tissues. 90% of the cells with cutaneous receptive fields had low background activity (< 1Hz). Most of the cells responded with graded activity to standard mechanical stimuli, with about 35% showing afterdischarges. Threshold temperature for evoked activity ranged from 37 - 51°C. Discharge frequencies at 49°C ranged from 4 to 45 Hz with about 60% of the cells showing afterdischarges. Our results indicate that rat STT cells have similar properties as those found in primates. (This work was supported by NIH grants NS 11255, NS 09743, NS 27910 and a Bristol - Myers Squibb grant).

INFLAMMATION-INDUCED INCREASE IN PREPROTACHYKININ mRNA IN A SUBPOPULATION OF SPINOMESEPHALIC PROJECTION NEURONS. K. Noguchi and M.A. Buda. Neurobiology and Anesthesiology Branch, NIDR, NIH, Bethesda, MD 20892.

A cascade of molecular, chemical and physiological events have been shown to occur in the spinal cord in a rat model of peripheral inflammation and hyperalgesia. This study investigated the inflammation-induced response of neurons containing preprotachykinin (PPT) mRNA, which codes for substance P and neurokinin A, in dorsal horn projection neurons and local circuit neurons. To identify projection neurons, Fluoro-gold was injected bilaterally into the midbrain parabrachial area. Rats received an injection of complete Freund's adjuvant (CFA) into one hindpaw 10 d later. At 4 d after CFA injection, the animals were killed and the L4,5 spinal cord segments were processed for RNA blot analysis or *in situ* hybridization using a ³²P or ³⁵S-labeled PPT oligonucleotide probe, respectively. RNA blot analysis demonstrated that there was a 60% increase in PPT mRNA ipsilateral to the inflammation. Counts were made of cells labeled with either PPT mRNA, or Fluoro-gold, or both, in laminae I, II and V/VI. The number of neurons exhibiting PPT mRNA was differentially increased in each lamina ipsilateral to inflammation: 80% in lamina I; 30% in lamina II; and 250% in laminae V/VI, although the number of laminae V/VI neurons was less than 10% of the total PPT mRNA neurons. The percentage of lamina I PPT mRNA cells also labeled for Fluoro-gold was 29% ipsilateral and 17% contralateral. The percentage of Fluoro-gold labeled cells also labeled for PPT mRNA in lamina I was 61% ipsilateral and 22% contralateral. These data demonstrate that the induction of PPT mRNA in response to peripheral inflammation and hyperalgesia occurs in both local circuit neurons and spinomesecephalic projection neurons. The identification of spinomesecephalic neurons with inflammation-induced increases in PPT mRNA suggests the participation of tachykinin peptides in nociceptive CNS projection pathways.

INFLAMMATION OF THE SKIN AFFECTS FUNCTIONAL NEURONAL CONNECTIVITY IN THE RAT SPINAL DORSAL HORN. A. Eblen-Zajur and J. Sandkühler. II. Physiologisches Institut, Univ. Heidelberg, Germany.

The functional neuronal network in the spinal dorsal horn is poorly understood. To evaluate the functional connectivity among dorsal horn neurons multiple neuron recordings were made via a single electrode in the lumbar spinal cord of pentobarbital anesthetized rats. Single neuron discharges were identified using a template matching algorithm (Forster et al. J. Neurosci. Method. 31(1990):109) and were analyzed by auto-correlation (AC), cross-correlation (CC) and by joint impulse configuration scatter diagram (JICSD) (bin width 1 ms) after stationarity test. With the skin at the ipsilateral hindpaw intact the CCs at 5/8 (62.5%) dorsal recording sites (depth ≤ 600 μm) and at 14/53 (26.4%) ventral recording sites (depth > 600 μm) had single broad peaks with width of more than 10 ms and zero delays. The CCs at only 2/53 (3.2%) ventral recording sites had bilateral sharp peaks (width < 4 ms and symmetrical delays ≤ 7 ms). The strength and the time of the interaction was the same for dorsal and ventral recordings sites. CCs suggestive of monosynaptic connection were not observed. With the glabrous skin at the ipsilateral hindpaw inflamed by radiant heat CCs with bilateral sharp peaks (width < 4 ms and symmetrical delays of 19.8 ± 9.9 ms \bar{X} ± SD) were found at 9/18 (50%) of the recording sites. These results suggest that under normal conditions there is a predominant common input via interneurons to neurons recorded at the same site either in the dorsal or in the ventral spinal dorsal horn consistent with a parallel cascade processing model. With the skin inflamed signs of reverberating neuronal circuits were found.

RESPONSES OF SPINOTHALAMIC TRACT CELLS TO MECHANICAL AND THERMAL STIMULATION OF SKIN IN RATS WITH EXPERIMENTAL PERIPHERAL NEUROPATHY. J. Palecek, V. Paleckova, P.M. Dougherty, W.D. Willis and S.M. Carlton. Dept. Anat. & Neurosci. & Mar. Biomed. Inst., UTMB, Galveston, TX - 77550

Placing loose ligatures around the sciatic nerve in rats produces hyperalgesia lasting several weeks (Bennett and Xie 1988). Since the spinothalamic tract (STT) is believed to be an essential pathway for the transmission of nociceptive information, our experiments concentrated on the responses of STT cells in rats in which the sciatic nerve was tied 7, 14 or 28 days previously. All rats used in the experiment showed faster withdrawal of hindpaws with sciatic lesion when exposed to radiant heat. Responses of STT cells from 25 neuropathic rats (Sprague-Dawley) were recorded in response to standard mechanical (BRUSH - brushing the skin with a cotton swab, PRESS - a large arterial clip applied to the skin, subthreshold for pain in humans, PINCH - pinching the skin with a clip with strong grip - perceived as painful in humans) and thermal stimuli (5 s heat pulses 35 s apart ranging from 37 - 49°C and 51°C produced by Peltier device). The most profound changes in STT cells responses were found 14 days after inducing the neuropathy. 50% of the STT cells in these animals showed high background frequencies (5 - 62 Hz) and 87% showed afterdischarges following mechanical stimuli. Even though we did not find a significant shift in the threshold to thermal stimulation, those cells responding to lower temperatures of stimuli usually had high background frequencies and afterdischarges. Furthermore, the afterdischarge rate often surpassed those during the stimuli. These data suggest that changes in STT signalling participates in the generation of neuropathic pain. EFFECTS OF LOOSE LIGATION OF THE INFRAORBITAL NERVE ON C-FOS EXPRESSION IN THE MEDULLARY DORSAL HORN OF THE RAT. B.P. Vos, A.M. Strassman and R.J. MacIewicz. Pain Physiology Laboratory, Department of Neurology, Massachusetts General Hospital and the Neuroscience Program, Harvard Medical School, Boston, MA 02114.

Loose constrictive ligation of the rat's infraorbital nerve (IoN) produces behavioral changes which suggest the presence of trigeminal neuropathic pain. In order to identify alterations in patterns of central neuronal activity that may be associated with these behavioral changes, the distribution of fos-like immunoreactivity was determined in the medullary dorsal horn following IoN ligation. Rats received either a unilateral IoN ligation (n=12) or a unilateral sham operation (n=11). The development of changes in facial sensory function was assessed using behavioral testing on post-operative days 3, 6 and 8. Behavioral signs of altered facial somatosensation developed in IoN-ligated rats but not in sham-operated animals. On post-operative day 9, rats were anesthetized with urethane and innocuous or noxious mechanical stimuli (von Frey monofilaments, 2g or 15g; 1.2Hz; 30sec stimulation per min, for 30 min) were applied to the hairy skin of the vibrissal pad (between vibrissae B4-5, C4-5) ipsilateral to the operated side. In order to evaluate c-fos expression related to the IoN ligation alone, 3 rats of each group did not receive stimulation. Animals were perfused 2 hours after stimulation and the caudal medulla was processed for immunocytochemical detection of fos. In the absence of mechanical stimulation, few labelled neurons were found in either the IoN-ligated or the sham-operated animals. In both groups noxious stimulation produced 50% more fos-positive neurons than innocuous stimulation. In IoN-ligated rats, mechanical stimulation produced significantly more fos-positive neurons (for 2g, 180% increase; for 15g, 65% increase), and the labelling was distributed over a larger rostrocaudal distance when compared to sham-operated rats. The increase in labelling in IoN-ligated rats was confined to the superficial dorsal horn, whereas labelling in the deep dorsal horn was similar in IoN-ligated rats and sham-operated rats. These findings indicate that loose constrictive ligation of the IoN that causes behavioral changes consistent with trigeminal neuropathic pain, is accompanied by changes in the pattern of stimulus-induced expression of c-fos in the medullary dorsal horn.

THE HYPERALGESIA INDUCED BY A PERIPHERAL MONONEUROPATHY IS ABOLISHED BY NEONATAL CAPSAICIN TREATMENT. T.J. Maves, S.T. Meller and G.F. Gebhart. Depts. of Anesthesia and Pharmacology, University of Iowa, Iowa City, IA, 52242.

A recently developed model of a peripheral mononeuropathy in the rat (Bennett and Xie, Pain 1988, 33:87-107), produced by loose ligatures tied around the sciatic nerve, has been characterized by a marked hyperalgesia, a reduction in the number of large myelinated fibers and an increase in the number of small myelinated fibers.

In the present study, we examined the role of C-fiber afferents in this peripheral mononeuropathy model. 4 loose chronic gut ligatures (4-0) were tied around the left sciatic nerve above the point where the sciatic nerve trifurcates. Response latencies for withdrawal of the left and right hind-paws from a ramped heat stimulus were measured in neonatal capsaicin- and vehicle-treated rats on the day prior to surgery, and on days 5, 10 and 20 post-surgery. Capsaicin-treated rats had a significantly greater response latency on all days tested compared to vehicle-treated rats. On the day immediately prior to surgery there was no left paw/right paw difference in latencies in either group. However, on days 5 and 10, vehicle-treated rats showed a markedly lesser response latency on the left compared to the right. This left/right difference was not apparent at day 20. In contrast, the capsaicin-treated rats did not show any left/right difference in response latencies on any day tested.

These results are consistent with a significant role for unmyelinated C-fiber afferents in mediating a peripheral mononeuropathy-induced thermal hyperalgesia.

PERIPHERAL INJURY ENHANCES EXTRACELLULAR LABELING IN THE SUBSTANTIA GELATINOSA AFTER INJECTION OF WGA-HRP IN THE SCIATIC NERVE. A. Rustioni, J. Valtschanoff, and R. Weinberg, Dept. of Cell Biology & Anatomy and Dept. of Physiology, U of North Carolina, Chapel Hill, NC 27599.

After injection of WGA-HRP into dorsal root ganglia, reaction product is seen in the extracellular space surrounding synaptic boutons in superficial laminae of the spinal dorsal horn (Weinberg et al., 1990). Intraganglionic injection is inherently traumatic; to assess the possible role of injury in this extracellular labeling, WGA-HRP was injected bilaterally into the sciatic nerve of anesthetized rats. After the injection, the sciatic nerve was crushed or transected distal to the injection on one side. After 2-7 days survival, the animal was anesthetized and perfused with aldehyde fixatives. Fifty μ m Vibratome sections of spinal cord segment L₅ were cut, reacted for TMB with tungstate stabilizer, and processed for light and electron microscopy.

Labeling in the form of electron-dense crystals and amorphous deposits was inside typical primary afferent terminals. In most cases, labeling could also be seen in postsynaptic elements, including dendrites, somata, and glia. Labeling was usually also present in the extracellular space outside primary afferent terminals. It often nearly surrounded these terminals, but characteristically was excluded from the synaptic cleft itself. The degree of extracellular and transneuronal labeling (as assessed by blind scoring) was significantly greater on the injured side, suggesting that injury leads to release of a variety of proteins into the extracellular space near the synapse. We hypothesize that release of some endogenous peptide may play a role in post-traumatic hyperalgesia. Supported by NINDS award #

CONTRIBUTION OF PROTEIN KINASE C TO PERSISTENT PAIN FOLLOWING SUBCUTANEOUS FORMALIN INJECTION. T.J. Coderre, Pain Mechanisms Laboratory, Clinical Research Institute of Montreal, 110 Pine Ave. West, Montreal, P.Q., Canada H2W 1R7.

We have recently suggested that noxious stimulus-induced neuronal plasticity occurring in the early period following s.c. formalin injection contributes to tonic pain in the rat formalin pain model. This study assessed the role of various second messengers in the development of this CNS plasticity. Pain behaviour, in response to a 50 μ l injection of 2.5% formalin into the hindpaw of rats, was assessed following intrathecal injection of agents affecting various second messengers. Formalin pain scores were unaffected by forskolin and H-9, which affect cAMP and cAMP-dependent protein kinase, respectively. Formalin pain scores were also weakly affected by quincarine, which inhibits the conversion of phosphatidylcholine to arachidonic acid, and W-7 which inhibits Ca²⁺/calmodulin-dependent protein kinase. By contrast, formalin pain scores were significantly inhibited by neomycin, which inhibits the hydrolysis of phosphatidylinositol 4,5-bisphosphate (PIP₂) to inositol trisphosphate and diacylglycerol (DAG), and by H-7, which inhibits protein kinase C (PKC). Furthermore, formalin pain scores were significantly enhanced by a phorbol ester (PMA) and SC-10 which stimulate PKC. We hypothesize that formalin produces a release of glutamate and aspartate which by acting at NMDA and quisqualate receptors, respectively, leads to an influx of Ca²⁺ and the stimulation of PIP₂. The breakdown of PIP₂ into DAG leads to the production of PKC, which is activated during high rates of Ca²⁺ influx. By phosphorylating substrate proteins, PKC would produce sustained membrane alterations contributing to tonic pain in the formalin test.

PAIN MODULATION: PERIPHERAL

POST-SYMPATHECTOMY NEURALGIA: THE RESULT OF CONCURRENT DEAFFERENTATION AND SYMPATHETICALLY-MAINTAINED PAIN MECHANISMS? R.C. Kramis*, R.G. Gillette* and W.J. Roberts, R.S.Dow Neurological Sci. Inst., Good Samaritan Hosp. & Med. Ctr., Portland, OR.

Sympathectomy, when used to relieve chronic pain, often induces a new painful condition proximal to the previously painful region. This post-sympathectomy pain may be moderately intense and of limited duration or extremely painful, persistent and resistant to pharmacological intervention.

Our recent investigations and data from the literature support the hypothesis that post-sympathectomy pain occurs because: 1) wide-dynamic-range spinal neurons are sensitized by nociceptive input associated with the painful condition for which sympathectomy is performed, 2) primary afferent axons (both somatic and visceral) traveling in the sympathetic trunk are unavoidably transected by sympathectomy, and 3) this peripheral afferent axotomy produces degenerative and perhaps regenerative central effects which further heighten the responsiveness of the already sensitized WDR spinal neurons.

We have used electrical stimulation of the lumbar paravertebral sympathetic trunk and extracellular single unit recording from the L4-L5 spinal cord of pentobarbital anesthetized cats to demonstrate convergence of "sympathetic" and somatic afferents onto spinal WDR neurons with receptive fields in the anterolateral and anteromedial thigh, the region which becomes painful in patients following lumbar sympathectomy. Often these same neurons also respond to somatic afferent input elicited by stimulation of sympathetic efferents. This sympathetic efferent/somatic afferent/spinal WDR "loop" may explain the relation of "spontaneous" post-sympathectomy pain to sympathetic hyperactivity in the newly painful (non-sympathectomized) region in patients. The proposed "sensitizing" (deafferentation) effects of transecting afferents in the paravertebral sympathetic trunk remain to be investigated.

VAGAL ELECTRO-STIMULATION IN AWAKE RATS PRODUCES SIGNS OF PHYSIOLOGICAL DISTRESS BEFORE ANTINOCICEPTION

D. F. Bossut and W. Maixner, Dept. Physiology and Dental Research Center, University of North Carolina at Chapel Hill.

Several observations made in anesthetized or decerebrated animals indicate that electrical vagal afferent stimulation (VAS) produces antinociception. The goal of the following experiments was to determine whether VAS produces a reduction of nociceptive responses before signs of physiological distress in awake, intact animals.

Thoracic or cervical continuous VAS (1 to 100 Hz and 0 to 3 mA) produced a short lived antinociception (increased tail-flick latency) only at levels of stimulation (10 Hz, 1 mA) also producing signs of physiological distress (gasping, cyanosis, immobility, etc). Under anesthesia, inhibition of the digastric reflex started with 2 mA VAS. Blood pressure and heart rate dropped more as the intensity of VAS increased.

It is concluded that electrical VAS does not produce antinociception before obvious signs of physiological distress occur.

DECREASE IN THE MAGNITUDE OF VAGINOCERVICAL STIMULATION-PRODUCED ANALGESIA IN AGING RATS. S. Chinapen, J.L. Steinman, A. Pierprzyn*, and B.R. Komisaruk, Institute of Animal Behavior, Rutgers-The State University, Newark, NJ 07102.

Vaginal mechanical stimulation (VS) in sexually mature rats produces analgesia as demonstrated by elevations in tail flick latency (TFL) to radiant heat and in vocalization threshold (VOCT) to electrical shock of the tail. A comparison of VS-produced analgesia in rats tested repeatedly at 4-5 months (mo), 8-9 mo, 12-13 mo, 16-17 mo, 20-21 mo, 24-25 mo and 28-29 mo was made using these two behavioral tests (n's > 9 for groups 8-9 mo and older). Rats were ovariectomized at least 1 week before initial testing. VS (100 & 300g) was applied using a force calibrated 1-cc syringe plunger assembly; data were analyzed using correlated t-tests and 1-way ANOVA's.

In each age group, a significant increase above baseline in TFL and VOCT was produced by 100 and 300g VS (t-tests). The baseline levels showed a significant decline from 4 mo to 24 mo of age (.32 to .17 mA for VOCT; 4.21 to 3.06 sec for TFL; p's < .006). There was an overall significant decline in VS-produced analgesia (100g VS) on TFL from 4 to 24 mo (p < .002) which was first observed at 16 mo of age. No further significant change was seen at 28 mo on this measure. During both 100 and 300g VS, VOCT was significantly lower at 24 mo than at all previous ages (p's < .003) and also did not show a further significant change at 28 mo. These results demonstrate that the magnitude of VS-produced analgesia declines with increasing age, with decrements in the analgesic effect on TFL appearing at 16 mo and on VOCT at 24 mo of age. These findings raise the possibility that aging induces changes in the female nervous system that reduce analgesic mechanisms by 24 mo of age. [Supported by NIH RR08223 and the Busch Foundation].

EFFECT OF COLONIC INFLAMMATION ON RESPONSES TO NOXIOUS COLORECTAL DISTENSION. M.B. Burton and G.F. Gebhart, Department of Pharmacology, University of Iowa, Iowa City, IA 52242

Despite growing knowledge about pain and inflammation, little is known regarding the role of inflammation in visceral pain. However, inflammatory mediators are known to sensitize nociceptors. The following experiments were performed to determine whether colonic inflammation alters responses to noxious colorectal distension (CRD).

Intracolonic administration of 25% turpentine in peanut oil (1 ml) was used to induce inflammation in male Sprague-Dawley rats. Evan's Blue dye extravasation in the colon was measured up to 24 hours after turpentine treatment. Colonic tissue was taken from another group of treated rats for determination of leukocyte infiltration over the same time period. Changes in mean arterial pressure and abdominal electromyographic (EMG) activity were measured in response to a 20 sec phasic CRD before and, in a time-dependent manner, after treatment. The visceromotor threshold, determined by an increasing ramped CRD, was measured over the same time course.

Leukocyte infiltration did not increase at any time measured; however, extravasation was apparent beginning 8 hours after treatment. Changes in EMG activity increased at 2 hours after treatment while, in the other experimental group of animals, the visceromotor threshold decreased at this time.

These results indicate that turpentine induces changes in response to noxious CRD before histological changes are apparent.

ANALGESIA PRODUCED BY UTEROCERVICAL MECHANOSTIMULATION IN THE RAT: ROLE OF AFFERENT NERVES AND IMPLICATIONS FOR ANALGESIA OF PREGNANCY AND PARTURITION. B.R. Komisaruk¹ and A.R. Gintzler². Inst. Animal Behavior, Rutgers-The State Univ., Newark, NJ 07102¹ and Dept. Biochem., SUNY Health Science Ctr, Brooklyn, NY 11203².

Uterocervical mechanostimulation was applied to non-pregnant intact rats via a silastic disc (2mm dia.) implanted in the uterus, abutting against the cervix, and attached to a thread that was externalized through the vaginal orifice. Tail flick latency (TFL) was used as the indicator of pain threshold. Mean pre-stimulus TFL's (4.7-5.4 sec) did not differ among groups. Force of 150g but not 100g increased TFL over pre-stimulation levels (n=7, p<0.03). Using 150g force, TFL increased by 110.4±40.6% (n=7; pre- vs during-stimulation) in the sham-operated control group. In the hypogastric neurectomy (HX) group, TFL increased by 136.0 ± 32.7% (n=8), which did not differ from the control group (p>0.05). By contrast, rats in the pelvic neurectomy (PX) group showed a mean increase in TFL of only 1.7 ± 12.5%, which was less than the increase in either the control or the HX groups (p<0.05, n=7). Stimulation of the uterine cervix in rats subjected to HX + PX produced a decrease in TFL of 25.0 ± 9.4% relative to both the control and HX groups (p<0.05; n=9). Thus, the analgesia that occurs during pregnancy and/or parturition may result at least in part from mechanical stimulation of the uterine cervix. Supported by NIH grants NS 19898 (BRK) and HD 18448 (ARG).

A δ AND C FIBER NOCICEPTORS RESPOND DIFFERENTLY TO INJURY. D.L. Tanelian and M.B. MacIver, Pain Research Laboratory, Department of Anesthesia, Stanford University School of Medicine, Stanford, California 94305.

The contribution of A δ and C fiber discharge activity to acute and chronic pain following injury was studied using the *in vitro* rabbit cornea preparation. Extracellular recording electrodes were used to monitor multiple and single unit discharge from corneal nerves, and receptive fields for mechanosensitive fibers were mapped. A corneal abrasion (2 mm²) was produced which involved the receptive field of an identified fiber(s). Both A δ and C fibers responded with high frequency discharge (20 to 50 spikes/s) during injury, but only C fibers continued to discharge tonically (14 ± 3.1 spikes/s; mean ± SD, n=28) following injury. In multiple unit recordings, recruitment of previously silent units were often observed during injury. Responses to mechanical and thermal stimuli were increased by 150 to 300 % compared to control (p < 0.001; ANOVA), for at least 3 hours after injury. Abrasions which completely destroyed the epithelium, and hence the nerve ending portion of fibers, resulted in abolition of all discharge activity. The results indicate that A δ fibers respond phasically during injury, while only C fibers continue to discharge following injury. In addition, it appears that nerve endings are essential for sensory transduction and fiber discharge, since truncated fibers do not exhibit tonic activity, and do not discharge in response to stimulation after destruction of the epithelium. Further studies will investigate mechanisms of nerve fiber sensitization following injury. Supported by NIH grant NS28646-01 A1.

UPREGULATION OF VASOACTIVE INTESTINAL PEPTIDE IN SUBSTANCE P EXPRESSING PRIMARY SENSORY NEURONS AFTER INJURY

T. Hökfelt¹, V.M.K. Verge¹, Z. Wiesenfeld-Hallin³ and M. Eriksson². Dept. of Histology and Neurobiology¹, Pharmacology², Karolinska Institutet, Stockholm, Sweden, 104 01 and Sect. Clin. Neurophysiol.³, 141 86 Huddinge, Sweden.

Peripheral nerve injury leads to downregulation of substance P (SP) and upregulation of vasoactive intestinal peptide (VIP) levels in adult rat primary sensory afferents. The physiological consequences of these changes indicate that the role of SP in mediating C-afferent-induced flexor reflex facilitation is taken over by VIP after axotomy (Neurosci Lett 116(1990)293-298). To examine whether VIP becomes expressed in the same neurons that downregulate SP, the sciatic nerve was sectioned and the co-expression of VIP and SP studied at various time points using *in situ* hybridization with ³⁵S-labelled SP and VIP oligonucleotide probes on adjacent sections of lumbar DRG. At 4 days after axotomy numerous DRG neurons expressed mRNA for both peptides which do not normally coexist in detectable levels in intact neurons.

The above results provide the anatomical substrate in support of the hypothesis that the specific functional consequences associated with axotomy-induced alterations in afferent peptide expression occur within distinct subpopulations of sensory neurons. Supported in part by the Canadian and Swedish MRCs.

179.6

THE CENTRAL PROCESS RESPONSIBLE FOR ABLTM-MEDIATED ALLODYNIA IN SOME PATIENTS WITH RSD IS SENSITIVE TO PERFUSION OF THE MICROENVIRONMENT OF NOCICEPTOR TERMINALS. R.H. Gracely^{*}, S. Lynch and G.J. Bennett. Neurobiology and Anesthesiology Branch, NIDR, NIH, Bethesda, MD 20892.

Mechanical allodynia (touch-evoked pain) is often observed in Reflex Sympathetic Dystrophy (RSD). Increasing evidence indicates that this allodynia can result from perception of normally innocuous tactile input from A δ low threshold mechanoreceptors (ABLTM) as painful. We recently proposed that this misperception is caused by a central process which is dynamically maintained by ongoing nociceptor input.

ABLTM-mediated allodynia is inferred in part from differential ischemic blocks in which circulatory occlusion simultaneously abolishes A δ function and allodynia while A-delta and C-fiber function is intact. However, in certain patients we have observed an unexpected response in which ABLTM allodynia is abolished rapidly (2-6 min) while all neural function is intact. We propose that this effect is due to ischemic modification of the nociceptor activity maintaining the central process.

We tested this hypothesis in two patients with rapid (2-4 min) ischemic block of ABLTM allodynia on the lower leg. Ischemia produced by a tourniquet applied to mid-calf in a patient with an ankle injury resulted in rapid loss of allodynia both above and below the tourniquet, which returned 3 min after the tourniquet was removed. Elevating the leg without a tourniquet produced a similar loss of allodynia which returned when the leg was lowered, but allodynia did not return if an ischemic block was applied mid-calf before lowering. In the second patient, with a knee injury, leg elevation also abolished allodynia until the leg was lowered. However, an ischemic block at mid-calf after elevation did not prevent return of allodynia above the block.

These results indicate that modification of the peripheral nociceptor input from the injury site is sufficient to abolish allodynia. This modification may be due to decreased capillary perfusion, or change in blood pressure or sympathetic tone that follow limb elevation or circulatory occlusion.

179.8

CROSS-EXCITATION OF DORSAL ROOT GANGLION NEURONS IN NERVE INJURED RATS BY NEIGHBORING AFFERENTS AND BY POST-GANGLIONIC SYMPATHETIC EFFERENTS. M. Devor¹, P.D. Wall^{2*} and W. Janig^{3*}, ¹Life Sciences Inst., Hebrew University Jerusalem, Israel; ²Dept. Anatomy and Dev. Biol., Univ. College London, UK; and ³Physiol. Inst., Kiel Univ., FRG.

A small proportion of primary afferent neurons in intact dorsal root ganglia (DRGs) fires spontaneously, and this activity is substantially increased in animals with chronic nerve injury. We now report that such ectopic DRG discharge is augmented by tetanic stimulation of the axons of neighboring afferent neurons that share the same DRG, where the spontaneously active neuron itself has not been stimulated directly. Sensory cross-excitation does not follow stimuli 1:1 like ephaptic coupling, but rather builds up gradually on stimulus onset, decaying gradually after the end of the stimulation. Strong excitations are often followed by afterdepression. Ectopic DRG discharge is also sensitive to sympathetic efferent activity. Repetitive stimulation of postganglionic sympathetic efferents in ventral roots T13 and L1, at frequencies as low as 5 Hz., caused excitation of DRG neurons after a delay of a few seconds. This was sometimes followed by depression. In some DRG neurons, only depression was seen. DRG excitation by sympathetic activity could be mimicked by systemic adrenaline and blocked by phentolamine indicating chemical mediation via α -adrenoceptors. DRG cross-excitation could contribute to ongoing and evoked neuropathic sensory abnormalities.

ALTERATION OF THE SUBSTANCE P CONTENT OF PRIMARY AFFERENT NEURONS BY NOCICEPTIVE STIMULATION. K.E. McCarron and B.D. Goldstein, Department of Pharmacology and Toxicology, Medical College of Georgia, Augusta, GA 30912-2300.

Substance P (SP) has been proposed as a mediator of nociception in the spinal cord. We have shown that noxious mechanical pinch increases SP release into the superficial dorsal horn. Formalin injection into the hindpaw, a known nociceptive stimulus, has been shown to produce a biphasic increase in dorsal horn SP immunostaining, but decreases SP release in a biphasic manner. This study was undertaken to determine if nociceptive activation of primary afferent neurons affects the SP content of dorsal horn, dorsal root, and dorsal root ganglion tissues. The hindpaws of unanesthetized decerebrate/spinal rats received either an injection of 5% formalin or noxious mechanical stimulation (pinch) as the nociceptive stimulus. Saline injected and naive rats served as controls. After various time intervals the lumbar dorsal horn, the L5 dorsal roots, and the L5 dorsal root ganglia were assayed for SP-like immunoreactivity (SPLI) using radioimmunoassay. Formalin injection produced increases in dorsal horn SPLI content at 20 and 80 minutes. Formalin also increased dorsal root ganglion SPLI content 80 minutes after hindpaw treatment. Noxious pinch slightly decreased the SPLI content of both dorsal horn and dorsal root tissues. Dorsal root SPLI was unchanged by any other treatment. Saline injection also increased dorsal horn SPLI at 60 minutes. SPLI changes in the contralateral dorsal horns were similar to those in the dorsal horn ipsilateral to hindpaw treatment, providing indirect evidence for the collateralization of nociceptive information at the segmental level. The results of this study indicate that both processing of SP precursors and SP release may affect the SPLI content of primary afferent neurons. Supported by a grant from the Medical College of Georgia Research Institute, Inc.

Norepinephrine (NE) Acts Indirectly to Sensitize C-Fiber Mechano-Heat (C-MH) Nociceptors in Hairy Skin of the Rat.

Michael S. Gold, Ming Guo*, Deborah M. White, and Jon D. Levine*, *Depts. of Medicine and Oral Surgery, and Division of Neuroscience, UCSF, Box 0452A, San Francisco, CA 94143-0724.*

Intradermal injection of NE, in the presence of the calcium-ionophore A23187, induces mechanical hyperalgesia in the rat by an action at the α_2 -adrenergic receptor (Neurosci. 32: 523, 1990). Since this model of sympathetic dependent hyperalgesia allows characterization of the nociceptor both prior to and after the onset of hyperalgesia, we employed it to study mechanical hyperalgesia induced by NE in C-MH nociceptors in the rat.

45 C-MHs with mechanical thresholds > 2.0 g and thermal thresholds > 42 °C were isolated from the saphenous nerve of pentobarbital (50 mg/kg) anesthetized 200-300 g male, Sprague-Dawley rats; 30 in controls, and 15 in rats one week after surgical sympathectomy (SYMPx). The mechanical thresholds of C-MHs in control and SYMPx rats were 5.8 ± 0.91 and 5.7 ± 1.38 g (mean \pm SEM), respectively. Intradermal injection of neither NE (10 μ g) nor A23187 (1 μ g), adjacent to the mechanical receptive field of 12 C-MHs, affected mechanical threshold. However, a third injection containing NE + A23187 significantly decreased threshold (33.8 ± 4.34 %, $p < 0.01$) sensitizing 9 of the 12 C-MHs. The three C-MHs not sensitized by NE + A23187, were not sensitized by a fourth injection of prostaglandin E₂ (PGE₂) (100 ng). In a separate group of 9 C-MHs, 6 were sensitized by PGE₂.

SYMPx significantly attenuated the hyperalgesic effect of NE + A23187 (28% decrease, $p < 0.01$). In normal rats, co-injection of indomethacin (10 μ g) significantly attenuated the sensitization of C-MHs ($n=9$) induced by NE + A23187 ($p < 0.01$).

Our data are compatible with the suggestion that a local increase in calcium induces a state in which NE can sensitize C-MH nociceptors. This NE-hyperalgesia is indirectly mediated by sympathetic postganglionic neuron terminal-dependent production of hyperalgesic prostaglandins. Supported by NIH grant NS21647

EFFECTS OF SYMPATHECTOMY ON A PERIPHERAL NEUROPATHY MODEL IN THE RAT. S.H. Kim, K. Sheen and J.M. Chung. Marine Biomed. Inst., Depts. of Anat. & Neurosci. and of Physiol. & Biophys., Univ. Texas Med. Br., Galveston, TX, 77550.

Recently we developed an animal model for neuropathic pain which involves a unilateral tight ligation of the L5 and L6 spinal nerves in rats. The model produces signs of neuropathic pain lasting up to several months, which resembles causalgia in humans. The aim of this study was to determine effects of sympathectomy on this animal model.

The neuropathy was produced in a group of 10 rats according to the previously established model. These animals showed a marked increase in occurrence of paw lifting in response to innocuous mechanical stimuli and a shortened latency of paw withdrawal in response to noxious radiant heat stimuli on the affected hind limb. Three weeks after the surgery when these behavioral signs were at the maximum, surgical sympathectomy was performed under sodium pentobarbital anesthesia by removing the sympathetic chain on the affected side from the L2 to L6 levels.

The sympathectomy produced an almost complete reversal of the responses to innocuous mechanical stimuli, but had variable effects on paw withdrawal latency to noxious heat stimuli.

The data suggest that sympathectomy is effective in alleviating allodynia but not hyperalgesia in our neuropathic pain animal model. (Supported by NIH grants NS21266 and NS11255 and a grant from Bristol-Myers Squibb Co.)

CHANGES OF RESPONSE PATTERN OF SENSORY AFFERENTS IN RATS EXPOSED TO SUB-BLOCKING CONCENTRATIONS OF LIDOCAINE.

J.G. Thalhammer, S.A. Raymond, G.R. Strichartz. Anesthesia Research Laboratories, Brigham & Women's Hospital, Harvard Medical School, Boston, MA 02115.

Traditional understanding of the mechanism of anesthesia due to local nerve blocks is based on the assumption that the absence of sensation in the innervated region results from a complete block of impulse traffic across the nerve site exposed to local anesthetics (LAs). However, somatosensory evoked potentials can be elicited from regions perceived as fully anesthetized indicating that perception of a stimulus can be abolished without fully blocking signal propagation along the neuraxis.

Impulse activity is known to affect the threshold and conduction velocity of subsequently elicited impulses in an axon. So do LAs, especially when impulse activity is present.

We studied changes in axonal excitability and in the response pattern to natural stimulation propagated through a region of nerve exposed to different concentrations of lidocaine insufficient to fully block impulse conduction. In rats anesthetized with Nembutal, the sciatic nerve was exposed to lidocaine (0.1 - 0.6mM) over a length of 15 mm. Axonal excitability was monitored by tracking latency of conduction in response to electrical stimulation (0.5 Hz - 500 Hz) of the nerve trunk. Changes in response pattern were monitored by recording action potentials from single afferents responding to natural stimulation of the cutaneous receptive field. Lidocaine concentrations as low as 0.1mM induced frequency-dependent changes in response latencies which were accompanied by changes in response pattern without resulting in a complete block of signal conduction. The changes did not correlate with fiber diameter, but did correlate with fiber modality.

Assuming that sensory information is at least in part encoded in the pattern of discharge, then altering of the pattern may blur the information sufficiently to result in changes of perception without abolishing signal transmission.

ELECTROMYOGRAPHIC (EMG) RESPONSES OF RAT NECK AND JAW MUSCLES TO INFLAMMATORY IRRITANT.

B.J. Sessle, X.-M. Yu, J.W. Hu, H. Vernon* and D.A. Haas. Faculty of Dentistry, University of Toronto, and *Canadian Memorial Chiropractic College, Toronto, Ont. M5G 1G6 Canada.

An EMG study was carried out in 9 anaesthetized rats to determine if the activity of neck and jaw muscles could be influenced by the injection of the inflammatory irritant mustard oil into the deep tissues surrounding the C2 vertebra. EMG baseline activity was recorded bilaterally in the deep neck muscles and ipsilaterally in trapezius, masseter and digastric muscles. Vehicle injection (20 μ l, mineral oil) usually induced a transient (1.5 min) increase in EMG activities of all 5 muscles. In contrast, injection of mustard oil (20 μ l, 20% allyl isothiocyanate) produced an EMG increase in all 5 muscles that was significantly greater in magnitude (50%, $P < 0.05$) and longer in duration (3 min, $P < 0.05$). Furthermore, some muscles often showed a second phase of activation which appeared 3.5 - 20 min after the mustard oil injection and lasted 15 - 20 min. These effects suggest that inflammatory irritants injected in deep periaricular tissues of the neck may reflexly enhance the activity of muscles distant from the injection site. Such effects may be related to increased muscle activity associated with trauma to deep tissues. Supported by NIH grants DE04786 and DE09559.

VISUAL CORTEX: EXTRASTRIATE RESPONSE PROPERTIES

180.1

THE RESPONSE OF CELLS IN AREA MT TO STIMULATION OF BLUE-SENSITIVE CONES. Eliot R. Charles¹, Nikos K. Logothetis¹, and Patrick Cavanagh² ¹Dept. of Brain and Cognitive Sciences, MIT, and ²Dept. of Psychology, Harvard Univ., Cambridge, MA.

The contribution of short-wavelength (S) cones to the luminance channel remains controversial within the psychophysical literature. In addition, physiological studies suggest that the S cones have little input to the spectrally non-opponent retinal ganglion cells. Area MT is a region of extrastriate cortex that is believed to rely heavily on the luminance channel and receives the majority of its input from spectrally non-opponent cells. However, we have previously shown that many cells in area MT respond to isoluminant blue/yellow sinusoidal gratings. To determine the contribution of S cones to area MT we recorded from two alert rhesus monkeys using a stimulus configuration designed to isolate S cones.

We first determined optimal tuning for excitatory receptive fields (s.f., velocity, direction) of single units using a range of luminance contrasts and used these parameters for the S cone stimulation. For the tritanopic stimulus, a sinusoidally modulated grating was presented on a CRT using the blue phosphor. An "equiluminizing" veil was placed in front of the screen and flooded with bright yellow light, reducing the luminance contrast of the grating to less than 0.5 percent. We found that the majority of cells respond to S cone stimulation however the signal is markedly lower than the response to a high contrast luminance grating. In addition, we used a series of S cone modulations and adjusted the luminance of the yellow field using neutral density filters. By generating spike density functions we were able to obtain t.v.i. curves and examine the temporal characteristics of the response for many of the cells.

SIGNALS ENCODING TARGET ACCELERATION IN VISUAL AREA MT OF MACAQUE MONKEYS. S.G. Lisberger and J.A. Movshon. Dept. of Physiology, UCSF, San Francisco, CA 94143 and Howard Hughes Medical Institute, Center for Neural Science, NYU, New York 10003.

Studies of the initiation and maintenance of smooth pursuit eye movements have shown that signals related to both target acceleration and target speed play an important role in the visual guidance of pursuit. We now show that cells in visual area MT discharge in relation to both of these parameters of target motion. We made extracellular recordings from direction selective single units in visual area MT in anesthetized, paralyzed macaque monkeys. Stimuli consisted of random dot textures that moved across an electronic "window" over the cell's receptive field. Motion of the texture provided instantaneous steps or 128-ms ramps of speed in the cell's preferred direction.

Ramps of stimulus speed produced a shaped pulse of firing rate followed by steady firing related to final target speed. Steps of stimulus speed produced a transient that was associated with the onset of motion, followed by a transition to steady-state firing. For each cell we used the steady-state speed tuning curve to calculate the firing rate that could be attributed to stimulus speed, and we subtracted this speed component from the firing recorded during ramps of target speed. In approximately half of the MT cells, this procedure revealed a component of firing rate that could not be attributed to stimulus speed and that appeared as a clear relationship between firing rate and stimulus acceleration. For the remaining 50% of the cells, firing rate could be attributed entirely to stimulus speed. We conclude that the signals carried by neurons in MT can encode all parameters of target motion that are used for the visual guidance of pursuit eye movements. 180.3

NEURONAL SELECTIVITY FOR STIMULUS SPEED AND CONTRAST IN THE PRESTRIATE VISUAL CORTICAL AREAS V4 AND MT OF THE MACAQUE MONKEY.

K. Cheng, K.S. Saleem and K. Tanaka. Laboratory for Neural Information Processing, Frontier Research Program, RIKEN, Wako, 351-01, Japan.

V4 and MT are distinctive areas in the prestriate visual cortex of the macaque monkey: V4 projects mainly to the temporal areas, while MT to the parietal areas; color selective cells are present in V4 but absent in MT, whereas directionally selective cells present in MT but absent in V4. Orientation selective cells, however, are found in both areas. In order to further know the difference and similarity of the two areas, we compared neuronal selectivities for stimulus speed and contrast between V4 and MT.

We recorded neurons in V4 (n=85) and MT (n=34) of the same anesthetized, immobilized monkeys (*M. fuscata*), and examined their responses to a slit moving at 10 speeds (0.5-256 deg/s) and to the slit moving at the preferred speed with 6 contrasts (ranging from 0.03 to 1.0 logarithmic values of the lightness difference between the slit and its background). Distributions of peak speeds for cells in V4 and MT overlapped largely, and both had the median at 32 deg/s. Cells tuned to the very slow speeds (0.5 and 1 deg/s) were only found in V4 (7.5%), and cells were more evenly distributed within the range from 8 to 128 deg/s in MT than in V4, although the two distributions were not statistically different (p>0.05). Distributions of the cut-off contrast at half maximal response in the two areas also considerably overlapped, but the position of the peak appeared at higher contrast in V4 (0.35) than in MT (0.12). The difference in the two distributions was statistically significant (p<0.01). In comparison with the previous data obtained from cells in the lateral geniculate nucleus (LGN), the distributions of cut-off contrast for both V4 and MT cells were in between those for cells in the magnocellular and parvocellular layers of LGN. We suggest that a mostly overlapped range of retinal information is sent to MT and V4 in parallel, but is used differently in these two areas.

A NEURAL NETWORK FOR FLOW-FIELD PROCESSING IN THE VISUAL MOTION PATHWAY OF HIGHER MAMMALS. M. Lappe* and J.P. Rauschecker. NIH Animal Center, NIMH, Poolesville, MD 20837, U.S.A. and Max Planck Institute for Biological Cybernetics, Tübingen, Germany.

Recent neurophysiological findings from cat and monkey suggest that the visual system may be capable of extracting retinal flow-field information: Neurons in cat area PMLS (Rauschecker et al., 1987) and monkey area MT (Albright, 1988) favor stimuli moving away from the area centralis. This centrifugal direction bias in both species is more pronounced in the visual field periphery and is independent of visual experience (Brenner & Rauschecker, 1990). Other results from monkey areas MT and MST additionally suggest that single neurons themselves may be sensitive to expanding, contracting, or rotating visual patterns. We have designed a neural network model based on these findings, which detects the direction of egomotion with high accuracy.

The network consists of two layers with 4,000 cells. Neurons in layer one (PMLS/MT) prefer movement in different directions, but with an overall centrifugal bias. The second layer (MST) consists of 400 neurons with very large receptive fields responding to global expansions. This is achieved with converging excitatory connections. Each layer-two cell encodes a specific 3-D direction. The direction of egomotion is given by the peak of neuronal activity. The network has been tested with synthetic flow fields and different directions of egomotion within the innermost 10° of the visual field. Varying the centrifugal bias revealed an optimal range in which the mean error (1°) is comparable to humans. Best results were obtained with a strong bias in the periphery and no bias in the center. When there is no bias at all, a large number of peripheral neurons become useless for the task. With a strict overall bias the net is insensitive to differences in flow patterns generated by different movements.

Cells in PMLS and MT show varying degrees of directional selectivity. When we varied the broadness of direction tuning in layer one of our network, we found no effect on the location of the activity peak in layer two. More broadly tuned layer-one cells gave only rise to a higher background activity in layer two. Our neural network provides another example of how precise behavioral performance can be achieved with a large set of imprecisely tuned neurons.

180.7

MSTd NEURONAL SENSITIVITY TO HEADING OF MOTION IN OPTIC FLOW FIELDS. C. J. Duffy and R. H. Wurtz. Lab. of Sensorimotor Research, National Eye Institute, Bethesda, MD 20892.

Neurons in cortical area MSTd of the rhesus monkey respond to planar, circular or radial stimuli which simulate the components of optic flow fields. We have combined planar and radial stimuli to determine how these neurons respond to the unique flow fields produced by such combinations. Stimuli were presented to the central 100° of the visual field and combined the preferred radial motion with one of 8 directions of planar motion. The resulting 8 flow fields differ from radial motion chiefly by having the center of the pattern displaced from the middle of the screen by about 35°. The combined radial and planar stimuli simulate flow fields observed during self-movement with straight ahead gaze when this heading is displaced off to the side.

Single component radial neurons responded best to uncombined radial motion, showing the most heading selectivity. The reduced responses to combined stimuli suggests that these neuron's radial selectivity results from active selection against planar responses. Triple component neurons (responsive to planar, and circular, and radial motion) responded to 4 or 5 combined stimuli, showing the least heading selectivity. The width of directional tuning for heading was proportionate to the width of directional tuning for simple planar motion. However, there was great variability in the relationship between the direction of preferred heading and the direction of the preferred planar motion.

Thus, MSTd neurons respond selectively to a variety of combined flow fields and this selectivity differs between the classes of neurons we have described previously (Duffy and Wurtz, *J. Neurophysiol.*, 1991). Differences between the preferred direction of heading and the preferred direction of simple planar motion might be explained by the way in which combined stimuli distribute the directions of motion across the neuron's receptive field.

180.4

RESPONSES OF MACAQUE V4 NEURONS TO PASSIVELY AND SELF-INDUCED RETINAL IMAGE MOTION. R.G. Erickson and P. Thier. Department of Neurology, University Tübingen, 7400 Tübingen, Germany.

The ability to discriminate self-induced visual motion is necessary for proper spatial orientation, and the brain must possess mechanisms for removing self-induced input from that part of the visual system deciphering motion signals. Recent studies have shown that directionally selective visual neurons within a certain part of the motion pathway, area MSTd, do indeed respond only to retinal image motion not caused by pursuit eye movements (Erickson and Thier, *Exp. Brain Res.*, 1991). The contribution of motion signals to alternate functions such as analysis of form would, however, be expected to require responses invariant with respect to the source of motion. To examine this possibility we have tested area V4, a visual area processing color and form but not direction of motion, by comparing the responses of motion-sensitive cells to retinal image motion caused by stimulus movement as opposed to eye movement.

Recordings from two awake monkeys were obtained while the animals attended to a small target that was either held stationary or moved slowly to induce a low velocity smooth pursuit (5-20 deg/sec). Moving stimuli were swept across a stationary receptive field during stable fixation, and receptive fields were swept across stationary stimuli during pursuit eye movements. Of 25 neurons verified by histological reconstruction to be within V4, all responded well to motion of a bar or slit, none were directionally selective, and all responded equally well to similar retinal image motion regardless of whether the eyes were moving or stationary.

The observed invariance with respect to the source of visual motion is in agreement with the proposed role of area V4 in object recognition and underscores the uniqueness of visual-motion processing occurring in area MST.

180.6

HOW POSITION-INDEPENDENT DETECTION OF SENSE OF ROTATION OR DILATION IS LEARNED BY A HEBB RULE. M.E. Sereno*, K. Zhang*, and M.I. Sereno. Cognitive Science Department, University of California San Diego, La Jolla, CA 92093.

Some neurons in MSTd detect the sense of rotation or dilation of a pattern independent of the location of the motion singularity (Saito et al. 1986). We constructed a model of how this sensitivity might be learned using a Hebb rule. Our previous work (M.I. Sereno, 1989) showed that a feedforward network with V1-like first-layer units and a Hebb rule, can develop second layer units that solve the aperture problem for pattern translation when trained on a set of rigidly translating velocity fields. The present work added a third layer to the network receiving input from the second layer of MT-like neurons.

The model was trained and tested on rotating, dilating, and translating patterns of various diameters placed at various retinal locations. With large interlayer divergences, some third-layer units learn to detect one or the other senses of rotation or dilation in a position-independent way (Sereno and Sereno, 1991). One explanation for position-independence suggested by Saito et al. and Duffy and Wurtz (1991) is that rotation (curl) or dilation (divergence) is detected locally and then summed across space in MSTd. However, this is difficult to reconcile with the observation that MT units, which provide a major input to MSTd, are *not* sensitive to senses of rotation and dilation. Our model suggests a simpler explanation.

The best direction at each x-y second-layer input location for trained selective units turned out to be surprisingly position-dependent. Rotation neurons had centered, circularly-organized local direction selectivity while dilation neurons had radially organized direction selectivity. If we assume each x-y point in the input layer contributes an output equal to the dot product of the local stimulus velocity and the local direction-selectivity, then we show that the output of a second layer unit summing over the input layer is independent of the location of the center of the stimulus. If speed and direction tuning interact multiplicatively, the dot product can be calculated exactly by a group of units with cosine tuning curves.

As soon as the initial random weights (or noise) make a unit sensitive to a particular sense of rotation or dilation, we then show that a Hebb rule and our training set makes that weight vector grow the fastest.

RESPONSES OF DEPTH-MOVEMENT-SENSITIVE NEURONS TO SIZE AND DISPARITY CHANGES IN THE PARIETAL CORTEX OF ALERT MONKEYS. M. KUSUNOKI, Y. TANAKA* AND H. SAKATA*. Dept. of Physiology, Nihon Univ. Sch. of Med., Itabashi, Tokyo 173, Japan

There is a group of neurons that are sensitive to depth movement in the parietal association cortex of the monkey. Previously, we found many of them responded to the size change of visual stimuli (Sakata et al., 1985). Since the change of disparity is another important cue of depth movement, we studied the responses of the parietal depth-movement-sensitive neurons to the disparity change, either separately or combined with the size change, by using a pair of polarized filters with orthogonal planes. Two Japanese monkeys (Macaca fuscata) were used for chronic experiments after training the gaze fixation task. The recording sites of these neurons were localized both in the deepest part of the superior temporal sulcus (MST area) and in the fundus of the intraparietal sulcus (VIP area). Most of the neurons sensitive to depth movement of real objects also responded well to the disparity change of visual stimuli and were suppressed by binocular stimuli moving in parallel on a tangential screen. Some neurons showed vigorous responses when size and disparity changes were presented together. Although most of disparity sensitive neurons preferred the direction straight to or away from the midpoint between two eyes, several neurons were found to prefer oblique direction slanted to the right or left side. In such neurons optimal stimuli to the right and left eyes were often the same in direction but different in velocity. Some of depth-movement-sensitive neurons showed more vigorous response in the light than in the dark to depth movement of real objects. Their responses to changes of size and/or disparity were enhanced by a random dot pattern presented in the background. These characters suggest that these neurons are closely related to the perception of object movement in three dimensional space.

AREA 21a IN THE CAT AND THE DETECTION OF BINOCULAR ORIENTATION DISPARITY. G.H.Henry*, E.Wieniawa-Narkiewicz*, B.Wimborne*, and W.R.Levick Centre for Visual Sci., John Curtin School of Med. Res. Australian Nat. Univ., Canberra, 2601.

Visual response properties were examined in 115 cells, recorded extra-cellularly in area 21a of the cerebral cortex of 15 anesthetized and paralyzed cats. Every cell had common response properties and their receptive fields consisted of a single uniform discharge region which fired with composite ON/OFF responses to stationary flashing stimuli. All cells were binocular and all were sharply tuned to stimulus orientation (mean 1/2 width at 1/2 height=15.6°). The optimum orientations favoured the vertical (21%) and horizontal (34%). There was no evidence that area 21a cells were effective detectors of binocular positional disparity. Instead, the sharpness of their orientation tuning together with their binocular drive suggested a possible role in the detection of binocular orientation disparity. Measurements showed that cells in the sample had preferred orientation disparities that ranged over 20° and that the tuning to this form of disparity was extremely sharp. It is concluded that while S cells of the striate cortex are suited for the extraction of positional disparity, the detection of orientation disparity is more effectively served by the cells in area 21a.

COVERT ORIENTING OF ATTENTION IN MACAQUE: I. BEHAVIORAL PARAMETERS. E. M. Bowman, V. J. Brown, U. Schwarz, and D. L. Robinson. Laboratory of Sensorimotor Research, National Eye Institute, Bethesda, MD 20892.

It is well established from studies of humans that reaction times to visual targets are modified by antecedent cues (Posner, 1980). The cues are hypothesized to influence the direction of attention. We trained rhesus monkeys to perform a reaction time task with visual cues and altered various parameters which might modulate performance. We used nonparametric statistics to compare the distributions of responses in different conditions.

Reaction times for visual targets which are preceded by cues at the same location (validly cued) are faster than for targets which follow cues at other locations (invalidly cued). This differential responding (validity effect) diminishes with increasing cue-target intervals. When we used different experimental manipulations to speed or slow the animals' performance, the validity effect remained unchanged except when extremely fast responses were generated. The removal of visual landmarks indicating the locus of the target and cue produced a deterioration of the validity effect. When validly cued targets were most frequent, they were consistently responded to faster by both humans and monkeys. When validly cued targets were rare, humans were substantially slowed in responding to them; monkeys were also slowed but not as profoundly. There was a spatial gradient of the effects of cues on reaction times as the cue-target distance increased.

We conclude from these studies that a visual cue leads to a change in performance at its locus. The mechanisms which generate this effect in monkeys are probably involuntary but nonetheless can be modulated.

180.13

POSTERIOR CINGULATE CORTEX OF RHESUS MONKEY: MECHANISMS OF ORBITAL-POSITION AND POSTSACCADIC SENSITIVITY S. Y. Musil, C.R. Olson, and M. E. Goldberg. Laboratory of Sensorimotor Research, National Eye Institute, Bethesda, MD 20892, and Department of Psychology, George Mason University, Fairfax, VA 22030.

The posterior cingulate cortex (Area 23) of the rhesus monkey is linked to parietal Area 7a by strong reciprocal pathways and so must contribute to visuospatial and attentional processes that depend on the latter area. We have monitored the activity of posterior cingulate neurons in monkeys performing visually guided eye movements with head fixed and have found that the level of tonic firing depends on two task parameters: the angle of the eye in the orbit and the size and amplitude of the immediately antecedent saccade (S.Y. Musil, C.R. Olson and M.E. Goldberg, "Visual and Oculomotor Properties of Single Neurons in Posterior Cingulate Cortex of Rhesus Monkey," Soc. Neurosci. Abstr. 16:1221, 1990). Thus posterior cingulate neurons carry information that could be used for spatial interpretation of visual signals.

Neurons exhibiting dependence on the orbital angle of the eye and on saccade direction and amplitude as described above, might be influenced by a variety of cues including extraocular efference copy and visual reafferent signals. To dissociate the relative contributions of these factors, we carried out experiments in which eye movements and the angle of the eye in the orbit were held constant while visual context was varied. Manipulations included removing the visible target during eye movements and fixation, imposing darkness on the surroundings and rotating the monkey relative to the surroundings. The results demonstrate that posterior cingulate neurons span a continuum with respect to their dependence on extraocular as opposed to visual cues, ranging from exclusive dependence on saccade metrics and orbital position to strong modulation by visual context.

180.10

BINOCULAR INTERACTIONS IN THE ANTERIOR ECTOSYLVIAN CORTEX OF CATS. H. Jiang, F. Lepore, M. Piujo, A. Piujo, and J.-P. Guillemot. Groupe de Rech. en Neurophys. Exp., Université de Montréal and Montréal Neurological Institute, Montréal, Qué., H3C 3J7.

AEC is considered a high order cortical association area. AEC neurons have been found to respond to several sensory modalities. The distribution of these modality specific cells along the anterior ectosylvian sulcus (AES) indicates that visual neurons are mainly concentrated in the ventral bank of AES. These neurons have large receptive fields (RF) and are mostly binocular. In order to test for binocular interactions, extracellular microelectrode recordings were carried out along the ventral and dorsal banks of AES in anesthetized-curarized adult cats. The RF for each eye was first determined using light or dark bars. They were then separated using divergent prisms and stimulated simultaneously (both eyes opened). Results demonstrated that: 1) most of the visual units encountered were binocular; 2) some of these cells responded also to other sensory modalities (e.g. auditory, somatosensory); 3) although most of cells showed some kind of binocular interactions, only about 1/4 of the sample showed clear interaction effects. These results taken in conjunction with previous data obtained in our laboratory point to the complexity of this high order area and indicate that it is probably involved in sensory and sensory-motor integration.

180.12

COVERT ORIENTING OF ATTENTION IN MACAQUE: II. A SIGNAL IN PARIETAL CORTEX TO DISENGAGE ATTENTION. D. L. Robinson, E. M. Bowman, and C. Kertzman. Laboratory of Sensorimotor Research, National Eye Institute, Bethesda, MD 20892.

Damage to parietal cortex in humans leads to neglect and extinction, and Posner et al (1984) have proposed that these patients cannot disengage their attention. We have recorded from neurons within the intraparietal sulcus in monkeys performing a cued reaction time task. Monkeys fixated a central spot of light and responded with a bar release to the appearance of peripheral targets which followed visual cues.

The discharge of a subset of neurons was best when the peripheral cue had directed attention away from the target within their visual receptive field. The differential activity was transient as was the behavioral effect of the cue. This neuronal activity might contribute to an attentional error signal. For the same neurons there was an enhancement of the visual response generated by active discrimination at the central spot when compared to response with simple direction of gaze at the same point. Here the best response was evoked when attention was actively directed toward the fixation point and not toward the receptive field. Modest response levels were also obtained when the monkeys saccaded repeatedly to a target within the receptive field as well as when the animals repetitiously responded with a bar release to a target in the receptive field. In contrast, infrequent and unexpected targets within the receptive field evoked strong responses.

These data suggest that intense activity from these neurons could be part of an attentional error signal contributing to neuronal events which disengage attention from its current focus. It occurs for targets when attention is directed away from the receptive field. The processes which generate this error signal can be evoked by sensory stimuli as well as various cognitive processes.

180.14

SHAPE AND COLOR SELECTIVITY OF INFEROTEMPORAL NEURONS IN THE MACAQUE. H. Komatsu, T. Ideura*, and S. Yamane* Neuroscience Section, Electrotechnical Lab., Tsukuba, Ibaraki, 305, Japan.

Inferotemporal cortex (IT) of the macaque plays an essential role on the visual recognition of objects. Shape and color are both very important parameters for the recognition of objects. Previous studies have shown the existence of neurons that are sensitive to the shape of the visual stimulus and those sensitive to the color. However, no attempt has been made to compare the shape selectivity and the color selectivity of individual neurons systematically. We have tested quantitatively the shape selectivity, and compared it with the color selectivity of the same IT neurons. Monkeys were trained a fixation task, and a visual stimulus was presented at the center of the visual field while the fixation spot was blinked off. Shape selectivity of IT neurons was tested by comparing the responses to seven geometrical shapes. Color selectivity was tested by comparing the responses to 13 or more colors that distributed evenly on the CIE chromaticity diagram. On each test, other parameters were fixed at the optimal values. About 40% of the neurons we have tested were sensitive either to shape or color but not to both. The remaining 60% required a particular combination of shape and color for the maximal activation. These results suggest that color and shape of objects are coded redundantly in IT.

180.15

SELECTIVE NEURONAL RESPONSES TO COMPLEX VISUAL OBJECT-FEATURES ARE ALREADY PRESENT IN POSTERIOR PART OF THE MACAQUE INFEROTEMPORAL CORTEX.

E. Kobatake and K. Tanaka, Neural Information Processing, RIKEN, Japan.

The macaque inferotemporal cortex (IT) is situated at a higher stage of the pathway responsible for object vision, and contains cells that selectively respond to complex visual features of objects. We previously divided IT into the posterior and anterior parts, which probably correspond to cytoarchitectural areas TEO and TE. To better know their functional differences, stimulus selectivities of cells in the two regions were compared by a method more objective than those in previous studies.

Cells were recorded from IT of anesthetized, immobilized monkeys (*M. fuscata*). The critical feature for the activation of each cell was determined by presenting many 3D objects, simplifying the images of effective objects with an image processor, and determining the simplest feature that evoked the maximal response. If the critical feature was more complex than bars or spots, response to it was then compared with responses to a set of simple stimuli including 32 spots and bars with different size, orientation, color, and contrast polarity and those prepared in relation to the individual critical feature.

There were cells that responded only to the particular complex feature (Elaborate cells), cells that showed some responses (25 to 75% of the response to the critical complex feature) to some of the simple stimuli (Intermediate cells), and cells that responded maximally to some of the simple stimuli (Primary cells). Elaborate cells predominated in the anterior IT, whereas all 3 types of cells were intermingled in the posterior IT. The Elaborate cells in the anterior IT had large receptive fields (10 to 25°) including the fovea. The posterior IT cells, regardless of the type, had small receptive fields (1 to 9°), which occupied various positions within 15° from the fovea. We suggest that integration of visual object information takes place serially: selective responses to complex features appear in the posterior IT and the selectivity becomes more precise and positionally invariant in the anterior IT.

180.17

A CODE SIGNIFYING PATTERN RECOGNITION IN THE RESPONSES OF INFERIOR TEMPORAL NEURONS. B. J. Richmond, E. N. Eskandar*, L. M. Optican.

Laboratory of Neuropsychology, National Institute of Mental Health, and Laboratory of Sensorimotor Research, National Eye Institute, Bethesda, Maryland 20892. *HHMI Fellow.

In the preceding abstract we reported that when IT neurons are stimulated during a sequential match-to-sample task, the responses to a stimulus are frequently different across the sample, match, and nonmatch conditions. Thus, the temporally modulated responses convey information about the behavioral context of the stimulus presentation. This suggests that there might be a consistent coding scheme in IT neurons which signals the behavioral significance of visual stimuli.

To examine the response changes related to the behavioral context of the stimuli we quantified the responses according to the coefficients of the first three principal components. The average response to each pattern in each condition was graphed in a three dimensional space defined by the weights of the principal components. We observed that the responses to all of the stimulus patterns presented in one condition, e.g., the match, were restricted to a narrow region which we abstracted as a plane. In each of 15 neurons conveying large amount of information about stimulus condition, the planes representing the responses to the different conditions occupied different positions in the space. In eight of these neurons, the planes representing the responses to two conditions were shifted in position but remained parallel. These planes were not offset along any single axis in the response space, but rather, the offset represented a change along all of the principal components. In the remaining 7 neurons, the differences in the responses were represented by a combination of differing orientations and displacements of the planes. We hypothesize that in the neurons which show a parallel shift in the response planes, the difference vector between the planes could be a code representing the behavioral relevance of visual stimuli.

180.19

A PREDICTIVE WARNING TONE MODULATES ACTIVITY OF TE UNITS IN MACAQUE. James L. Ringo, Dept. of Physiology, U. of Rochester, Rochester, NY 14642.

This study examined nonvisual and indirect influences on cells recorded in inferotemporal (IT) cortex. In order to see these inputs in isolation a fully split-brain, split-chiasm monkey was used and single units were recorded while the ipsilateral eye was covered. The completeness of the split was verified behaviorally by the failure of inter-ocular transfer. Over 300 units were recorded while the monkey was working on a visual discrimination task. Two phenomena have been observed. First, when the trials were separated by a pseudorandom inter-trial-interval (4-15s) over half of the cells showed a response to a warning tone (67 dB SPL) which indicated that the trial was about to begin. Although the identical tone also sounded to indicate the end of the trial, virtually no cells responded to this latter tone. In a second block of experiments, the majority of sessions were run with a fixed (predictable) inter-trial-interval. In this block, only about 10% of the cells showed a response to the warning tone. The second observation is that following the image presentation and despite the fully split condition some cells show an altered discharge rate locked to the stimulus presentation. No units were found responsive to the onset of the reward (a squirt of fruit juice) nor the panel push necessary to obtain the reward.

180.16

INFERIOR TEMPORAL NEURONS CONVEY INFORMATION ABOUT STIMULUS PATTERNS AND THEIR BEHAVIORAL RELEVANCE. E. N. Eskandar, B. J. Richmond, L. M. Optican.

Laboratory of Neuropsychology, National Institute of Mental Health, and Laboratory of Sensorimotor Research, National Eye Institute, Bethesda, Maryland 20892.

Lesions of area TE in the inferior temporal (IT) cortex of monkeys cause a profound deficit in learning pattern recognition tasks. A pattern recognition system must encode a current stimulus, recall a previous stimulus, compare the two, and decide based on the outcome of the comparison. Therefore, neurons in IT cortex ought to carry signals related to one or more of these processes.

To look for such signals, we recorded 50 single IT neurons from two monkeys performing a sequential match-to-sample task. A complete set of 32, black-and-white, 2-D Walsh patterns were presented under the sample, match and nonmatch conditions. The neuronal response waveforms were decomposed into their principal components (PC's). The weights of the PC's were examined by an analysis of variance (ANOVA), and were used to calculate the information transmitted about the spatial patterns and the behavioral conditions of the stimuli. We found that the neuronal response waveforms were significantly modulated by the pattern independent of the condition in 86% of the neurons, and by the condition independent of the pattern in 66% of the neurons (ANOVA, $p < 0.05$). This modulation conveyed information about both the pattern (0.355 bits) and the condition (0.045 bits). Pair-wise comparisons of the various conditions (sample-match, sample-nonmatch, match-nonmatch) revealed that the neurons conveyed significantly more information in each of these than in the control sample-sample pair (t -test, $p < 0.001$). At the 1991 ARVO meeting we reported that IT neurons convey information about recalled stimuli suggesting that some IT neurons perform the comparison step of pattern recognition. The current results suggest that some IT neurons are also involved in the decision step of pattern recognition.

OSCILLATIONS IN THE RESPONSES OF NEURONS IN INFERIOR TEMPORAL CORTEX ARE NOT DRIVEN BY STATIONARY VISUAL STIMULI. T. J. Gawne, E. N. Eskandar*, B. J. Richmond, and L. M. Optican

National Institute of Mental Health, LN, and the National Eye Institute, LSR, Bethesda, MD 20892. (†HHMI Fellow)

Several groups have reported that the electrical activity of visual cortex in anesthetized cats shows oscillations in the range of 30 to 70Hz, in response to moving stimuli. This activity is strongest in the local field potential (LFP), but it can also be seen in the timing of action potentials (APs). Is this activity also present in inferior temporal (IT) cortex, an area known to be important for pattern recognition?

We used eight sites in area TE of IT cortex of monkeys performing a sequential match-to-sample task. At each site we recorded both the APs of visually responsive neurons, and the LFP from the same micro-electrode. The stimulus set consisted of 32 B&W stationary Walsh patterns presented 8 to 12 times each. Spike-triggered averaging of the LFP showed no relationship between the LFP and the APs. Both the number and temporal pattern of APs was significantly related to the stimuli at all 8 sites ($P < 0.05$, ANOVA). In contrast, spectral analysis of the LFP showed that the frequency of the peak between 20 and 74Hz was significantly related to the pattern of the stimulus at only 2 of the 8 sites ($P < 0.05$, ANOVA), and the pattern accounted for only $8.1 \pm 2.3\%$ of the variance of frequency. The magnitude of the peak never showed a significant relationship to the stimulus, even when the frequency did. Therefore, any relationship between oscillations in the LFP and visual stimuli is weak at best. Calculating the information transmitted by the temporal pattern of the APs showed that increasing the bandwidth beyond 22Hz added no new stimulus related information. These results suggest that oscillations in the range beyond 20Hz do not play a role in the processing of information about stationary patterns in IT cortex.

TONOTOPIC MAPPING OF SYNCHRONIZED NEURONAL ACTIVITY IN THE INFERIOR COLLICULUS OF THE RAT.

D.S. Weiss and S. Reinis. Department of Psychology, University of Waterloo, Waterloo, Ontario, Canada, N2L 3G1.

Neuronal activity was recorded from the inferior colliculus (IC) of anaesthetized rats using tungsten microelectrodes. Pure tone continuous and burst stimuli were presented from 0.5 to 20 kHz (60-90 dB SPL). Novel stimuli consisted of mechanically induced impulse noises and mixed frequency tone bursts. One-second epochs of neuronal activity were digitized and stored on floppy disk for later analysis. Spikes of individual units were separated and discriminated into leading cell and mass activity categories. Records of neuronal activity were subjected to spectral analysis (FFT). Frequency histograms of interspike intervals were calculated in order to determine significant interactions between neurons. The most striking finding was that localized cell clusters in the central nucleus (ventrolateral division) and the external nucleus of the IC fired in a synchronized manner to reproduce the signatures of both mechanically and electro-magnetically produced sound stimuli. This effect was present only in specified regions of the auditory tectum and followed the general tonotopic organization of the inferior colliculus. The synchronizing effect did not persist after the animal was euthanized and did not appear in other CNS locations.

181.3

INHIBITION SHAPES RESPONSE TO INTERAURAL TIME DIFFERENCES IN THE INFERIOR COLLICULUS OF THE BARN OWL. J.A. Mazer and R. Adolphs. Div. of Biology 216-76, Caltech, Pasadena, CA 91125.

The barn owl, *Tyto alba*, uses interaural time differences (ITD) to encode sound source location in azimuth. Neurons in several nuclei below the level of the inferior colliculus (IC) are sensitive to interaural phase differences at their best frequency. Only at the level of the external nucleus of the inferior colliculus (ICx) does one find neurons capable of responding selectively to a particular ITD without ambiguity of phase, provided that the sound's spectrum contains more than one frequency. ICx neurons are broadly tuned to frequency, suggesting that one way in which phase ambiguity is resolved at this stage is by combining the responses to ITD across several frequency channels. We investigated the role of nucleus ventralis lemnisci lateralis, pars anterior (VLVa) in generating ITD-tuning in the ICx.

VLVa provides polysynaptic input to the contralateral ICx and contains sharply frequency-tuned neurons that are sensitive to interaural phase differences. We microiontophoretically applied agonists (GABA, muscimol) or antagonists (bicuculline methiodide, BMI) of GABA-A receptors to VLVa neurons and found that agonists decreased, and antagonists increased the evoked response rates. In subsequent experiments, we pressure injected these drugs into VLVa while recording evoked responses to ITD from single neurons in the contralateral ICx. We found that: 1. Increasing neural activity in VLVa with BMI led to a decreased response to ITD in the ICx; 2. Decreasing neural activity in VLVa with GABA or muscimol led to an increased response to ITD in the ICx; 3. These effects were greatest when the best frequencies of the VLVa injection site and the ICx neuron recorded from were matched; 4. In some experiments, VLVa injections differentially affected ICx responses at the real ITD (main peak) and at phase-ambiguous ITDs (side peaks) in response to noise stimuli. These results suggest that VLVa provides functional inhibition to ICx in response to ITD, that the projection from VLVa to the inferior colliculus may be topographically organized in the frequency domain, and that VLVa may contribute to side-peak suppression of responses in the ICx.

CORTICO-CORTICAL CONNECTIONS OF RANGE AND VELOCITY PROCESSING AREAS IN THE AUDITORY CORTEX OF THE MUSTACHED BAT. D.C. Fitzpatrick and N. Suga. Department of Biology, Washington Univ., St. Louis, MO 63130.

In the auditory cortex of the mustached bat, two types of biosonar information are initially processed separately; target range in the FM-FM area, and target velocity in the CF/CF and DSCF areas. Since the initial processing stages of these two types of information are entirely separate, we questioned whether range and velocity information comes together elsewhere in the auditory cortex. Consequently, we made injections of anatomical tracers in these different cortical areas, and looked for common targets.

Injections in the FM-FM area labeled two targets in the AC, the dorsal fringe (DF) area and the ventral fringe (VF) area. Both the DF and VF areas are known to contain target ranging neurons. Injections in the CF/CF area also labeled two AC targets. One of these was in the posterior bank of the Sylvian fossa at a relatively dorsal location, which we have called the dorsal intrafossa (DIF) area. The other was in a part of the ventroanterior (VA) area that contains neurons tuned to the second and third harmonic constant frequency components of the biosonar signal. Injections in the DSCF area resulted in labeling in the DIF and VA areas, but the VA area label was in a location posterior to that from CF/CF area injections, in a part of the VA area that contains neurons facilitated by pulse-echo pairs.

To date, we have not labeled any targets in common following injections in range and velocity processing areas, so these processing systems appear to remain separate throughout the auditory cortex. (Supported by NINCD grants NS08659 and DC00175).

IPSI- AND CONTRALATERAL INTERACTIONS BETWEEN NEURONS RECORDED SIMULTANEOUSLY IN THE AUDITORY CORTEX OF BOTH HEMISPHERE. F. de Ribaupierre, G. Simm*, F. Giovannini*, Y. de Ribaupierre* and E. Rouiller. Inst. de Physiologie, Univ. de Lausanne, Bugnon 7, CH 1005 Lausanne, Switzerland.

Functional significance of interhemispheric connections in the auditory system was approached at the neuronal level. Eight single unit spike trains were recorded simultaneously from 7 microelectrodes placed in the primary (AI) and anterior (AAF) auditory cortices on both sides of a cat anesthetized with nitrous oxide and nembutal. Neuronal interactions were studied by cross-correlation techniques for 256 single unit pairs during spontaneous and acoustically driven activity.

For 116 pairs with both members being located on the same hemisphere, interactions observed were typical for the presence of a shared common input (CI), which was present for 18 % of the pairs. These CI occurred between pair members located within the same (AI-AI) or across different areas (AI-AAF), within the same cortical depth or between superficial and deep layers, and for quite a range of best frequency (BF) separations (with a slight preference for pairs having BFs within one octave).

Surprisingly pairs with members on each cortical side also presented CI for 11 % of them. These CI were also observed for all combination of areas, layers and BFs separations, with a preference for short BFs separations and heterotypic positions (17 % of CI for AI-AAF pairs versus 4 % for AAF-AAF or AI-AI pairs). It is quite significant that these interhemispheric neuronal interactions were only about half less frequent than those within one hemisphere. They could be due to the presence of a local branching, in the hemisphere of origin, of the callosal axons.

181.4

RESPONSE PROPERTIES OF NEURONS IN THE VENTRAL NUCLEUS OF THE LATERAL LEMNISCUS OF THE MUSTACHED BAT. W.E. O'Neill, J.R. Holt, and M.L. Zettel. Dept. of Physiology, Univ. of Rochester Medical Center, Rochester, NY 14642

The ventral nucleus of the lateral lemniscus (VNLL) is highly developed in echolocating animals, but the response properties of cells within it are almost completely unknown. To determine the response properties of VNLL neurons, we recorded single unit activity in awake mustached bats. Recordings were made passing through the inferior colliculus (IC) on the way to the VNLL, allowing comparison of responses to similar stimuli in both nuclei. Stimuli consisted of 30 ms tone bursts, sinusoidal amplitude modulated tones, linear frequency modulations (12 kHz bandwidth), or wide-band noise bursts (WBN). Cells within the columnar VNLL were isolated over unusually small distances (30-50 μ m), and best frequencies varied by as much as an octave from cell to cell. VNLL units were broadly tuned (Q-10dBs from 2 to 11), and often had lower thresholds to WBN. Discharge patterns were of the ON or ONSET type. In contrast to IC cells, latency was invariant with intensity as well as rate of intensity change (rise-time). Thus they resemble "phasic constant latency responders", which are common in FM bats, but rare in the mustached bat IC. Such cells are theoretically important for target range determination and/or fine feature discrimination (Supported by NIDCD R01-DC0267)

181.6

NEURONS IN THE DSCF AREA OF THE AUDITORY CORTEX OF THE MUSTACHED BAT ARE SENSITIVE TO COMBINATIONS OF NON-HARMONIC FREQUENCIES. J.S. Kanwal, D.C. Fitzpatrick and N. Suga. Dept. of Biology, Washington Univ., St. Louis, MO 63130.

The Doppler-shifted constant frequency (DSCF) area includes about 30% of the primary auditory cortex of the mustached bat, *Pteronotus parnellii parnellii*, and overrepresents 60-63 kHz, so that this area is considered to be specialized for processing the second harmonic CF component of a biosonar signal. We unexpectedly found that about 50% of the neurons in this area show facilitative responses to combinations of low (25.05 \pm 1.86 kHz; n=43) and high (61.30 \pm 1.04 kHz) CF tones. The biosonar signal of the mustached bat consists of four harmonics (CF₁-CF₄ and FM₁-FM₄); 61.30 kHz represents the typical CF₂, but 25.1 kHz is lower than the range of CF₁ frequencies and is contained at the end of a downward FM₁ sweep (30.5-24.5 kHz). These neurons also show a facilitative response to combinations of CF₂ and FM₁. To further characterize the basic response properties of the facilitative neurons, we obtained excitatory, facilitatory and inhibitory tuning curves. The facilitative response was tuned sharply to the high frequency component and broadly to the low frequency component. Moreover, the facilitatory tuning curves were sandwiched between inhibitory tuning curves and the facilitative response exhibited lower thresholds to the high frequency component than the low frequency component. These properties can be useful for processing sounds with a complex acoustic structure, such as communication calls which range from 7-80 kHz and contain both CF and FM sounds. This subpopulation of DSCF neurons may, therefore, process non-biosonar as well as biosonar sounds.

181.7

EFFECTS OF INHIBITORY AMINO ACID ANTAGONISTS ON AMPLITUDE TUNING IN THE AUDITORY CORTEX OF THE MUSTACHED BAT

S. Sawaki, T. Shimozawa, J. A. Butman, N. Suga and K. K. Ohlemiller
Dept. of Biology, Washington Univ., St. Louis, MO 63130

Unlike peripheral neurons, the majority of neurons in the Doppler-shifted constant frequency (DSCF) area of the primary auditory cortex of the mustached bat are tuned to particular amplitudes as well as particular frequencies. This amplitude tuning (non-monotonic impulse-count function) is associated with inhibition at high amplitudes (Suga and Manabe, 1982). Since 79% of collicular neurons are tuned in amplitude (O'Neill, 1985), most of the amplitude tuning of DSCF neurons is created by subcortical nuclei. In the cortex, GABAergic endings are abundant. We therefore studied whether amplitude tuning is sharpened by inhibition within the cortex. A multibarreled electrode was inserted into the DSCF area, and inhibitory amino acids and their antagonists were iontophoretically applied. All 40 neurons studied showed non-monotonic impulse-count functions. Of these, 35 showed upper thresholds. Bicuculline methiodide (BMI) increased the response magnitude in 15/17 neurons tested, while strychnine increased the response in 6/16. The amplitude tuning curve at a best frequency became broader in 14/17 of neurons by BMI and in 11/16 of neurons by strychnine. Upper thresholds were eliminated in 5/13 neurons by BMI and 2/16 by strychnine. However, BMI and strychnine did not change the non-monotonic impulse-count function into a monotonic impulse-count function. These data indicate that amplitude tuning created in subcortical nuclei is sharpened in the cortex.

MNTB PROJECTION TO THE MSO IN RODENTS AND BATS. II: TOPOGRAPHICAL PROJECTIONS AND TERMINAL FIELDS. N. Kuwabara, and J.M. Zook. Dept. of Zool. and Biomed. Sci. and COM, Ohio University, Athens, OH 45701.

Previously, we have shown single collateral axons projecting from principal cells of the medial nucleus of the trapezoid body (MNTB) to the medial superior olive (MSO) (Kuwabara et al., *Neurosci. Abstr.* 16:723, 1990). Since MNTB principal cells supply inhibitory input to the lateral superior olive (LSO), their collaterals may provide inhibitory input to the MSO. We are continuing to investigate this projection in the rodent species, *Mus musculus* and *Meriones unguiculatus*, and the bat species, *Eptesicus fuscus* and *Pteronotus parnellii*. MNTB principal cells or their axons were intracellularly labeled with Lucifer Yellow or Lucifer Yellow cadaverine biotin-X in tissue slice preparations of the auditory brainstem.

Here we show that collateral axons of MNTB principal cells project in a topographic pattern to the MSO in all of the species examined. In many cases, the size of the terminal field and the density of axosomatic terminal endings in the MSO were similar to the size and density of the main axon's projection to the LSO. The specific pattern of inputs from the MNTB may play a role in shaping many of the response characteristics of MSO units such as phasic discharge pattern, non-monotonic rate-level function and sharpness of the ITD curve. 181.11

INTRINSIC AND COMMISSURAL CONNECTIONS OF THE RAT INFERIOR COLLICULUS.

E. Saldaña. Dept. of Cell Biology and Pathology, Univ. of Salamanca, 37007-Salamanca, Spain, and Neuromorphology Lab., University of Connecticut, Storrs, CT 06269-4154.

In spite of its importance in the auditory brainstem circuitry, the intrinsic organization of the inferior colliculus (IC) is still poorly understood. Its central nucleus (CN) and dorsal cortex (DC) are tonotopically organized, but the relationships of the CN to the external cortex (EC) and the contralateral IC remain unclear. To analyze the intrinsic and commissural projections of the IC, the anterograde tracer *Phaseolus vulgaris* -leucoagglutinin (PHA-L) was iontophoretically injected at different locations within the CN of adult rats, and visualized immunocytochemically.

Each injection gives rise to four fibrillar, laminar plexuses, two in each IC, that span the IC rostrocaudally. The first ipsilateral plexus, situated in the CN, is parallel to the known isofrequency planes of the IC, and penetrates the DC dorsally. The second plexus is located in the EC, slightly oblique to the pial surface. These two plexuses meet caudally and ventrally. In the contralateral IC, the two plexuses occupy positions symmetrical to those of the ipsilateral side, forming a mirror-like image. The mediolateral and dorsoventral position of the four plexuses changes as the position of the injection site is varied. This systematic variation is especially pronounced when the injection site is displaced along the tonotopic axis of the CN, indicating that the intracollicular projections, both intrinsic and commissural, follow an orderly, tonotopic pattern. The projection from the CN to the EC is tonotopic, thus suggesting the existence of a tonotopic organization for the EC.

181.8

ACUITY IN RANGING BASED UPON NEURAL RESPONSES IN THE FM-FM AREA OF THE MUSTACHED BAT. M. Suzuki* and N. Suga. Dept. of Biology, Washington Univ., St. Louis, MO 63130.

Bats can detect 60-100 μ s differences in echo delay and 0.5 μ s echo jitters (J. A. Simmons, *J. Acoust. Soc. Amer.* 54:157 1973, J. A. Simmons, *Science* 204:1336 1979). In the auditory cortex of the mustached bat, *Pteronotus parnellii parnellii*, neurons tuned to particular echo delays (target ranges) are clustered in three different areas. The FM-FM area is the largest and represents echo delays from 0.4 to 18 ms. Can the acuity in the behavioral data be explained by the neurophysiological data? That is, what level of acuity in ranging can be theoretically derived from neural activity in the FM-FM area? Using the neurophysiological data (e.g. N. Suga, *Neural Networks*, 3:3 1990), the theoretical acuity was computed as just-noticeable changes at 75 % correct level in (1) the position of maximally responding neurons along the range axis in the FM-FM area, (2) the weighted sum of responses of all FM-FM neurons, and (3) the center of neural activity over the FM-FM area. The just-noticeable changes depend upon both the stability of neural response and absolute echo delay (target range). Assuming the response of a single neuron fluctuates with 30 % standard deviation of its mean response, the just-noticeable changes in echo delay at the range of 30-120 cm are 110-305 μ s, 2.2-34 μ s and 2.4-4.0 μ s for (1), (2) and (3), respectively. For 10 % standard deviation, the values are 106-240 μ s, 0.73-11 μ s and 0.80-1.3 μ s for (1), (2) and (3), respectively.

TONOTOPIC SHIFTS IN THE AUDITORY PATHWAY OF THE MUSTACHED BAT: COCHLEAR, NEURAL AND BEHAVIORAL CORRELATES. R.F. Huffman and O.W. Henson, Jr.* Curr. in Neurobiology and Dept. Cell Biology & Anatomy, Univ. N. Carolina, Chapel Hill, NC 27599.

Correlates of markedly sharp tuning in the mustached bat (*Pteronotus parnellii*) include: 1) pronounced cochlear resonance, the frequency (CRF) of which is near the 2nd harmonic, constant frequency component (CF2) of the biosonar pulse; 2) numerous sharply tuned neurons throughout the auditory pathway that collectively over-represent the CF2; and 3) Doppler-shift compensation (DSC), whereby the flying bat adjusts the CF2 to maintain the echo CF2 within a narrow band. Previous studies have shown that the CRF changes with flight, noise exposure and body temperature (BT) (Kössl & Vater, 1985, *Hear. Res.* 19:157; Henson et al., 1990, *Hear. Res.* 50:259; Huffman et al., 1990, *ARO Abstr.* 13:232). The purpose of this study was to determine whether small temperature-dependent shifts in the CRF produce concomitant changes in the response properties of "CF2 neurons" and CF2 biosonar emissions.

Cochlear microphonic (CM) electrodes were chronically implanted in seven bats, one week prior to experiments. CRF was determined from FFT analysis of CM potentials. Shifts in CRF were induced by controlled adjustments of BT (within normal physiological range for active bats, 36-42°C). DSC was examined by swinging bats on a pendulum toward a target and analyzing the spectral content of emitted pulses and echoes. The preferred echo CF2 and the CF2 emitted from stationary bats both shifted in parallel with changing CRF. In four awake bats, 29 CF2 single and multi-units in the cochlear nucleus and inferior colliculus were characterized. In every case, a CRF shift produced a corresponding change in the best-response frequency (BF). Results were the same for single and multi-units in both nuclei. Although BF's changed reliably with CRF shifts, 72% of the units showed no change in threshold or Q-10dB; this suggests a shift in the position of the place code within the sharply tuned segment of the cochlea. It is concluded that labile cochlear tonotopy in the CF2 region causes shifts in central tonotopy and in the frequency of the emitted CF2. (Supported by PHS grant DC00114.)

THE AUDITORY CORTEX INNERVATES THE CENTRAL NUCLEUS OF THE INFERIOR COLLICULUS

M. Feliciano and E. Saldaña. Neuromorphology Lab., University of Connecticut, Storrs, CT 06269-4154.

It has generally been accepted that the descending projection from the auditory cortex to the inferior colliculus (IC) innervates its dorsal (DC) and external (EC) cortices, and that its central nucleus (CN), by contrast, does not receive direct neocortical input (Faye-Lund, 1985, *Anat. Embryol.*, 173:53-70). To study the topography and morphology of the cortico-collicular projection, the anterograde tracer *Phaseolus vulgaris* -leucoagglutinin (PHA-L) was iontophoretically injected at different locations within the primary auditory cortex of adult albino rats.

Each injection gives rise to three fibrillar, laminar plexuses in the IC, two in the ipsilateral and one in the contralateral side, that span the IC rostrocaudally. The plexuses consist of thin fibers with multiple collateral branches, and small *en passant* and terminal boutons. The first ipsilateral plexus, located in the medial half of the IC, has a dorsomedial to ventrolateral orientation, parallel to the isofrequency planes of the IC. This plexus is continuous through the DC and CN, thus proving that the CN receives innervation from the auditory cortex, contrary to the previous tenet. The second plexus is located in the EC, slightly oblique to the pial surface. These two plexuses appear to meet caudally and ventrally. The plexus in the contralateral IC occupies a symmetrical position to that of the first ipsilateral plexus. The mediolateral and dorsoventral position of the three plexuses changes as the injection site is displaced rostrocaudally. These topographic variations conform to a pattern that mimics that of the intracollicular projections (see Saldaña, *Soc. Neurosci. Abstr.*, 1991). (Supported by PHS grant NS-09904, and D.G.I.C.Y.T. of Spain, PB88-0372.)

181.13

FUNCTIONAL ORGANIZATION AND RESPONSE PROPERTIES OF LOW-FREQUENCY, NOISE-SELECTIVE NEURONS IN THE INFERIOR COLLICULUS OF THE PALLID BAT. J. Kennedy and Z.M. Fuzessery. Depts. Psychology and Zoology/Physiology, Univ. of Wyoming, Laramie, WY 82071.

The auditory system of the pallid bat (*Antrozous pallidus*) is specialized for two different spatial tasks. This species emits high-frequency (30-90 kHz) pulses for echolocation, but relies on passive hearing at low frequencies (< 20 kHz) to locate terrestrial prey. This study examines the functional organization and response properties of the low-frequency, noise-selective neurons in the central nucleus of the inferior colliculus (ICC) that may serve passive prey localization.

The tonotopy of the ICC was evaluated through multiunit recording with tungsten electrodes, and recording sites were reconstructed from electrolytic lesions. These studies revealed that the ICC of this bat has a disproportionately large representation (> 50%) of low frequencies (2-25 kHz). In some cases, neurons tuned to frequencies of less than 10 kHz were encountered throughout entire dorsoventral electrode penetrations through the ICC.

Many low-frequency neurons were noise-selective in that their response thresholds for noise were up to 30 dB lower than for tones. They exhibited a high degree of temporal precision in their ability to time-lock to the very short (10 μ sec) components of amplitude-modulated noise, and a high degree of response synchrony to amplitude modulation rates of greater than 2000 Hz. The temporal response properties of these cells likely serve in the localization of walking prey through the resolution of ongoing interaural delays in noise.

ELECTROPHYSIOLOGICAL PROPERTIES OF NEURONS IN THE CHICK NUCLEI MAGNOCELLULARIS AND LAMINARIS. A.D. Reyes, R.L. Hyson, E.W. Rubel. Hearing Development Laboratories, Univ. of Washington, Seattle, WA 98195.

Nucleus magnocellularis (NM) and nucleus laminaris (NL) contain, respectively, the second- and third-order neurons of the chick auditory system. NM receives direct input from the VIIIth nerve and projects ipsilaterally and contralaterally to NL. Characterizing the electrophysiological properties of these neurons is important for understanding how sensory information is transmitted through the auditory system. We performed whole cell recordings from these neurons using an *in vitro* slice preparation. The low resistance electrodes used (5-10M Ω) afforded injection of large current and facilitated application of voltage clamp.

Recordings were made from transverse slices (300 - 450 μ m) of the chick (5-7 days old) brain stem containing the VIIIth nerve, NM, and NL. Patch electrodes were filled with (in mM): KCl (17.5), K-gluconate (65), HEPES (10), NaCl (9), MgCl₂ (5), and Na₂ATP (2). The electrode was slowly driven into the slice while applying positive pressure to prevent clogging. Upon contact with a neuron, negative pressure was applied until a tight seal was formed and the underlying membrane was ruptured.

Neurons in both NM and NL exhibited decreased slope resistance at depolarized levels; voltage response to depolarizing current steps were significantly less than to hyperpolarizing steps. Suprathreshold d.c. stimulation caused a single action potential after which the membrane potential remained below threshold for the duration of the step. In NM, EPSPs evoked at rest by stimulation of VIIIth nerve were brief but broadened when the cells were hyperpolarized. Voltage clamp studies revealed that these effects are due to an outward current that: 1) is persistent; 2) is partially activated at rest (-50 to -60mV); 3) increases activation with depolarization, and 4) reaches steady-state values within 2ms. This ionic conductance, by attenuating depolarizing d.c. potentials, may allow neurons of NL and NM to phase-lock to high frequency stimuli. Various pharmacological blocking agents are currently being used to further characterize this conductance. (Supported by DC00395 and DC00858)

THALAMIC INPUT AND CYTOARCHITECTURE OF AUDITORY NEOSTRIATUM IN ZEBRA FINCH. E.S. Fortune and D. Margoliash. Dept. of Organismal Biol. and Anat. Univ. of Chicago, Chicago, IL, 60637.

Song learning modifies Hvc auditory neurons. Field L (FL) is the recipient of efferents from n. ovoidalis (OV) and is a likely source of auditory input to Hvc. We have examined the cytoarchitecture of FL in celloidin embedded material and the organization of thalamic projections to FL and adjacent neostriatum.

The primary thalamorecipient zone is a plate extending dorsocaudally from the dorsal medullary lamina (LMD) coursing across the neostriatum below the hyperstriatal lamina. This plate, designated L2a, is coextant with the internal capsule. Large and small oblong neurons aligned parallel to the major axis of the plate are visible in L2a of Nissl stained parasagittal sections. Dorsocaudal to L2a is L2b of Wild (1990), which is a cloud of densely packed small neurons. A band of small neurons extends in an arch from L2b caudoventrally towards LMD. L3 is the area bounded by this band of neurons caudally, LMD ventrally, and L2a rostrally, and is composed of large clustered fusiform neurons. L1 is a plate of large and small clustered neurons which lies dorsoanterior to L2a. Axons from OV, as demonstrated by HRP and fluorescent tracers, pierce LMD laterally and travel dorsocaudally through L2a, and to a lesser extent through L1 and L3. Axons in L1 and L3 arch into L2a. These axons have at least three types of specializations: large (~8 μ m) and small (~2 μ m) varicosities, and some axons bifurcate before entering L2a. N. ovoidalis medialis, adjacent to OV, appears to send axons to L2b. Neurons in the tractus ovoidalis project to regions caudal to FL and medial to Hvc. We continue to investigate parallel auditory pathways to the neostriatum and the sources of auditory input to the song system. Supported by NIH grant NS25677 to DM.

181.14

AUDITORY AFFERENT INPUT TO THE INFERIOR COLLICULUS OF THE CHICKEN (GALLUS DOMESTICUS). D.W.F. Schwarz, A. Dezso* and I.E. Schwarz*. The Rotary Hearing Ctr., Univ. of British Columbia, Vancouver, B.C., Canada.

If a temporal analysis of the sound waveform occurs after the combination of the binaural input in the laminar nucleus (NL), one would expect faithful phase locking in inferior colliculus (IC) neurons driven with stimuli from both ears (EE-cells). At optimal interaural delays such cells, recorded extracellularly in the anaesthetized chicken, encode the sound period at least as well as cochlear afferents. At the least favourable delays spike counts tend to be lower than during monaural stimulation of either ear, indicating phase locked inhibition. Candidate sources of such phase matched inhibitory contribution are the superior olive (OS) and lateral lemniscal nuclei (VLVa, VLvP and LLv), all of which can be retrogradely labelled from IC with various tracers. OS and LLv contain a similar proportion of neurons projecting to IC of both sides as the NL (ca 0.5%), as they incorporate different dyes (True Blue and Diamidino Yellow) injected into each IC. Thus several pathways exist which might contribute to the conservation, or perhaps improvement, of the temporal code available at the mesencephalic level.

CONNECTIONIST MODELS OF ZEBRA FINCH AUDITORY NEURONS: DYNAMIC NEURONAL PROPERTIES PREDICT RESPONSES TO COMPLEX STIMULI. S. C. Bankes and D. Margoliash. Rand Corp., Santa Monica, CA and Dept. Organismal Biology and Anatomy, Univ. of Chicago, Chicago, IL.

We constructed parametric models of ovoidalis and Hvc neuronal responses to natural and artificial auditory stimuli in urethane-anesthetized zebra finches. An exploratory modeling approach was employed where a variety of parametric model architectures were trained and evaluated. Connectionist models of time varying (dynamic) responses were explored although some non-connectionist and static models were also tested. Architectural variations included representing time through delay lines vs. recurrence, variations of the input representation (sonogram, sonogram and RMS amplitude, cochlear model) and variations of the numbers of units and tunable parameters.

Explorations were conducted for each architecture to determine the minimum training set required for good performance. For cells from ovoidalis, models trained with dynamic response to tone bursts (instantaneous firing rate) could predict responses to complex stimuli (bird song). This is a significant result, as a quantitative relationship between central neuronal responses to simple artificial and complex natural stimuli has rarely been achieved. Models trained only with average firing rate information did not accurately predict such responses. This suggests that dynamic models of neuronal responses can capture important information missing in models using only average firing rates, even for cells with "classical" response properties. This modeling paradigm can therefore provide a useful tool for neuroscience. Supported by ONR, NIH and the Searle Scholar Program.

AUDITORY RESPONSES IN THE NUCLEUS OVOIDALIS ARE NOT SO SIMPLE. B. Dickamp and D. Margoliash. Department of Organismal Biology and Anatomy, Univ. of Chicago, Chicago, IL, 60637.

Neurons in the thalamic nucleus ovoidalis (OV) have been shown to be largely uniform in their responses to acoustic stimuli (Bigalke-Kunz et al., 1987). OV is tonotopically organized, and neurons typically have high spontaneous activities and tonic discharges. Frequency tuning curves of OV neurons display an excitatory area flanked by inhibitory sidebands. Recent anatomical studies, however, indicate that the OV complex may consist at least of three subdivisions. We are studying the response properties of neurons in OV of male zebra finches, looking for physiologically different, functional zones that might relate to the anatomical data.

We are using the technique of analog spike waveform classification, permitting the isolation of several single cells per recording site and the study of a large sample of OV neurons. A stimulus set consisting of simple and complex stimuli is used to thoroughly characterize response properties. All neurons are tested with tone bursts (250 - 7250 kHz) and white noise at intensities between 10 and 80 dB SPL, linear amplitude-modulated (AM) white noise, frequency-modulated tones, harmonics, the bird's own song (BOS) and songs of four conspecifics. To date, the following observations have been made. Neurons vary considerably in their spontaneous activities, latencies, sensitivity and sharpness of frequency tuning, discharge patterns to simple tone bursts, phase locking to AM noise, and response strengths to the five conspecific songs including BOS. Neurons recorded at the same location have either similar, correlated response properties or show different latencies and discharge patterns (tonic or phasic). Characteristic frequencies of neurons at some recording sites differ by more than one octave suggesting substantial scatter in the tonotopic organization of single neurons in OV. These preliminary data indicate that neurons in OV might belong to physiologically diverse populations. (Supported by NIH grant NS25677 to DM.)

POSSIBLE MECHANISMS OF HIGH FREQUENCY PHASE COMPARISON IN BARN OWLS. W.E. Sullivan, Dept. of E.E. Biology, Princeton Univ., Princeton, N.J. 08544.

Barn owls detect binaural phase differences in high frequency (5 to 9 kHz) sounds for horizontal localization. This involves convergence of phase-locked spikes from the magnocellular cochlear nuclei onto cells in nuc. laminaris. Laminaris neurons fire most strongly when inputs are coherent, suggesting that they act as coincidence detectors.

The present work was designed to understand this process in more detail. It combines an analysis of the synaptic input pattern that would be conveyed by about 100 afferents from each side with a study of spike output mechanisms. Input analysis shows that unitary synaptic conductance changes can be longer than the stimulus period if their shape is asymmetrical. In this case, coherent inputs produce a conductance modulation at the stimulus frequency whereas out-of-phase inputs do not produce this information bearing signal. Both cause modulations at lower frequencies due to random variations in spike arrival.

To explore how laminaris cells could detect rapid conductance changes, a standard spike generation model (Hodgkin and Huxley 1952) was used. Several modifications need to be made to produce maximal selectivity at high frequencies. These include increases in both channel density and gating rate. Increasing the density and gating rate of Na⁺ channels allows the model to respond to rapid conductance modulations. Increasing K⁺ channel density and gating rate reduces the response to slower modulations, characteristic of synaptic noise. The resulting spike generator responds poorly to steady or slowly changing excitatory conductances but strongly to rapid modulations of synaptic input.

LOCALIZATION OF NON-LINEAR TEMPERATURE EFFECTS IN THE FROG AUDITORY SYSTEM. M. B. Carey and R. Zelick, Dept. of Biology, Portland State University, P. O. Box 751, Portland, OR 97207.

Multiunit auditory midbrain recordings in frogs show non-linear temperature effects on threshold (Hubl & Schneider, J. Comp. Physiol. 130:17, 1979), however, recent data show linear changes in VIIIth nerve parameters (van Dijk et al. Hear. Res. 44:231, 1990).

We have examined the effect of temperature on the auditory brainstem response (ABR) in *Rana pipiens*, a technique which provides simultaneous whole-system performance at peripheral and central levels. The ABR was obtained using chronic electrodes, and evoked by 1.0 kHz single-period sinusoids presented at 10/sec. Amplitude and latency of ABR peaks I-IV were measured at a supra-threshold stimulus level (88 dB SPL). Threshold was determined using visual criteria.

Frogs were acclimated to room temperature (19 - 21°C). During recording, temperature was changed from 10 - 32 °C by passing warm or cold water through a copper manifold on which the frog was placed. Cranial temperature was measured by a thermocouple implanted along with ABR electrode.

The temperature Q₁₀ for I-II interpeak latency (VIIIth nerve level) was 1.45, while the Q₁₀ for the III-IV interpeak latency was 1.36 above 16 °C (similar to the periphery), but 3.62 below 16 °C. Peaks III-IV are generated before the midbrain torus semicircularis level. Threshold was more stable at warm temperatures, with a Q₁₀ of 1.00 above 16 °C, but like latency increased markedly (Q₁₀ = 1.83) below 16 °C. This represented a change in threshold, from ~30 dB SPL above 16 °C to 49 dB SPL at 10 °C.

Thus the non-linear temperature dependence in the frog auditory system appears to be localized to the brainstem.

COCHLEAR AXON MORPHOLOGY, COCHLEAR NUCLEUS VOLUMETRIC CHANGES, AND THEIR POTENTIAL ROLE IN DEVELOPMENT OF TUNING IN THE DORSAL COCHLEAR NUCLEUS OF THE HAMSTER. L. Schweitzer and T. Cecil, Department of Anatomical Sciences and Neurobiology, Univ. of Louisville School of Medicine, Louisville, KY 40292

While regressive events (e.g., loss of axonal branches) underlie the development of tuning in some systems, we have determined that axonal morphology in the dorsal cochlear nucleus (DCN) of the hamster is stable after initial ingrowth. WGA-HRP with poly-L-ornithine was iontophoretically injected into the cochlear nerve root of brainstem slices (from hamsters aged PND 2-37) maintained for 4 hours in artificial cerebrospinal fluid (31° C, bubbled with O₂/CO₂). Frozen sections of the slices were reacted with DAB allowing visualization of individual axons in the DCN. On PND 2 the axons are in the deep DCN and reach the top of the fusiform cell layer by PND 10. In addition, topographically-related axons form defined sheets (the anatomical analog of isofrequency planes) by PND 10. After this age, the branching and expansion of the axonal fields changes very little. In contrast to the constancy of the axonal fields, after day 10 the volume of the DCN more than doubles, and the number of large cell bodies within an axon's field decreases by about 30%. Consequently, as development proceeds, each large soma is in the domain of fewer and fewer cochlear axons. These anatomical changes may underlie the successive narrowing of physiological tuning curves reported for auditory cells in developing mammals.

AUDITORY SYSTEM: CENTRAL PATHWAYS IV

182.1

CORTICAL AFFERENTS FROM THE MONKEY MEDIAL GENICULATE COMPLEX: PHA-L TRACING AND CALCIUM BINDING PROTEIN IMMUNOHISTOCHEMISTRY. T. Hashikawa¹, M. Molinali^{1,2} and E. G. Jones^{1,3}. ¹Neural Systems Lab., F.R.P., RIKEN, Wako 351-01, Japan. ²Catholic University, Rome, Italy. ³Dept. of Anatomy and Neurobiology, University of California, Irvine, CA 92717.

Thalamocortical neurons of monkey medial geniculate complex have been shown to contain either parvalbumin or 28 Kd calbindin. These neurons have layer specific cortical projections (Brain Res., 544: 335-341, 1991). In the present study this differential pattern of the geniculate projections was shown by anterograde transport of *Phaseolus vulgaris* leucoagglutinin (PHA-L) combined with immunohistochemistry for the proteins.

Electroporetic injections of PHA-L into small areas about 500 um in diameter, of the ventral and dorsal divisions of the medial geniculate body of *Macaca fuscata* resulted in labeling of geniculocortical fibers, forming plexuses with terminal-like swelling in layers IIIB and IV of primary and neighboring auditory areas. Few fibers projected to other layers. The major plexus in the primary cortex extended several hundred microns in width and continued several millimeters rostrocaudally. Immunohistochemically, most fibers were parvalbumin-positive, and calbindin-positive fibers were rare. These results fit with the previous immunohistochemical findings and also suggest that auditory information from a limited region of the medial geniculate nuclei is distributed along isofrequency bands in primary auditory cortex and in corresponding zones of adjacent areas.

182.2

A METHOD TO COMPUTE THE ORIENTATION AND 3-DIMENSIONAL (3-D) ANATOMY OF LAYERS IN THE INFERIOR COLLICULUS (IC). S. Ahghari^{*}, D.L. Oliver, and T. Ju^{*}, Dept. Anatomy, Center for Neurological Sciences, UCONN Health Center, Farmington CT 06030; Dept. Electrical and Systems Engineering, UCONN, Storrs, CT 06269-3115.

The fibro-dendritic layers in the central nucleus of the IC may provide an important substrate for integration of monaural and binaural inputs. To graphically reconstruct and quantify the 3-D orientation of these layers, we have studied serial Golgi-Cox impregnated sections in low, mid and high frequency regions of the central nucleus. At each site in each 100 um-thick section, an argon laser scanning confocal microscope (Bio-Rad) is used to take a series of images at discrete steps along the Z-axis. These images are processed on a Gould IP8500 by an algorithm to preserve the closely spaced layered dendrites and eliminate the non-layered processes. Four different gradient (directional) filters plus median and low pass filters are used to extract the contours of the layers from each image. After processing, the bit-mapped images are converted to vector lists and the objects that represent layered cells are selected interactively. The 2-D orientation of the layered cells in each image is determined by performing a linear regression analysis. To create a 3-D surface model that represents a single layer at that site, the regression lines from each image in the Z-series are connected. The spatial orientation of the resultant surface is calculated with two vector cross products at two opposite corners of each non-planar polygon. The average direction of the layer at that site is represented as the average of the normal vectors for the surface model. All of the 3-D surface models from a single brain are displayed together with the outline of the IC on a IRIS 4D/310GTX workstation (Silicon Graphics). The results show the central part of the central nucleus has a uniform layering pattern, while more medial and lateral parts have more curvature.

COCHLEAR NUCLEUS INNERVATION OF THE CONTRALATERAL LATERAL SUPERIOR OLIVE IN THE NEONATAL GERBIL. L.M. KITZES, J. KIL and G. KAGEYAMA, Dept. of Anatomy and Neurobiology, University of California Irvine, Irvine, CA 92717

A small projection from the cochlear nucleus (CN) to the contralateral lateral superior olive (LSO) has been described in the adult cat and bat. We have observed this projection in the adult gerbil. As part of our study of the development of efferent projections of CN, we have examined the extent of this projection in the neonatal gerbil.

A crystal of Di-I was placed in the ventral CN of gerbil pups ranging in age from one to 14 days. After maintaining the brains in an oven at 37°, the brains were cut in the coronal plane and the projection from CN to the contralateral LSO evaluated using a fluorescence microscope. Some sections were then prepared for electron microscopic analysis by photo-oxidizing labeled fibers in a solution of DAB.

As in the adult gerbil, in the neonate fascicles of fibers course through the ventro-medial limb of the contralateral LSO to the dorsal hilus. On post-natal day 1 there is a dense confluence of labeled fibers within the LSO. The density of these fibers diminishes progressively over the next week, when it resembles the adult pattern. Synaptic profiles of Di-I labeled fibers have been observed in the contralateral LSO during the first post-natal week. Synaptic profiles were also observed in the contralateral medial nucleus of the trapezoid body (MNTB). No label was observed in cells of MNTB, demonstrating the lack of trans-neuronal transfer of Di-I in this system.

PHYSIOLOGICAL IDENTIFICATION OF DORSAL COCHLEAR NUCLEAR NEURONS OF MICE: INTRACELLULAR RECORDING AND DYE-INJECTION IN SLICES. S. Zhang and D. Oertel, Department of Neurophysiology, Univ. of Wisconsin, Madison, WI 53706.

Detailed physiological studies of cells that were labeled intracellularly with biocytin show that different anatomical cell types in the DCN are distinguishable physiologically. All fusiform cells (18) could be unambiguously identified by their frequent, spontaneous, bursts of IPSPs. Most (6/7) cells that are probably cartwheel cells (the spines were generally not labeled by biocytin), and only those cells, had bursts of action potentials superimposed on slow depolarizations. Tuberculoventral cells (TV) (6) and giant cells (2) lack the aforementioned features and differ from one another in three ways. Giant cells have action potentials with more prominent fast undershoots than TV cells. Second, the synaptic responses of TV cells to shocks of the nerve root consist of prominent monosynaptic excitation and weak polysynaptic inhibition, whereas in giant cells an early, strong IPSP and later trains of regular IPSPs almost mask the underlying excitation. Third, only strong (>60V; 2/2 giant cells) shocks to the VCN evoke action potentials directly in giant cells whereas weak stimulation (<30V; 3/3 cells) suffices to stimulate TV cells whose axons in the VCN are not cut.

NEURON TYPES IN GERBIL DORSAL COCHLEAR NUCLEUS. T.E. Benson, G.T. Gdowski, and H.E. Voigt, Department of Biomedical Engineering, Boston University, Boston, Massachusetts 02215.

In the course of studies on correlated activity of units in the dorsal cochlear nucleus (DCN) and their correlated anatomy/physiology we have labeled four neuron types with horseradish peroxidase (HRP). Dendrites and axons were characterized by light microscopy from 12 female gerbils.

Fusiform cells (n=8) were bifurcated with apical dendrites in the molecular layer (MOL) of DCN in cone-like topology. Basal dendritic trees were simpler, less branched and less spiny in deep DCN (DEEP). There was a range in the spinniness of apical dendrites among fusiform cells. Apical spines were more "stubby" than basal. Recurrent branches were never observed; in 6 cases axons were traced into the dorsal acoustic stria. Giant cells (n=3) had multipolar cell bodies located in DEEP. Spine-sparse dendrites projected extensively in DEEP. A dendrite from each cell terminated in MOL in a complex "tuft" consisting of fine processes. A large diameter, ventrally directed axon emitted two fine branches in DEEP before entering the posteroventral cochlear nucleus (PVCN). Cartwheel cell bodies (n=2) were in the fusiform layer or MOL. Spiny dendrites were restricted to MOL, mostly the surface 2/3. Axons ramified locally, restricted to MOL or fusiform layers. A Golgi cell in MOL had three sparsely branched dendrites restricted to that layer with fine, short appendages and a curving dendrite (Mugnaini et al., 1980). The fine axon of this cell was directed toward the ependyma and it branched like a T.

Neurons were similar, in most respects, to corresponding ones in other species (e.g. Brawer et al., 1974) and to Golgi-staining results in gerbil (Schwartz et al., 1987). A lack of local branches from rodent fusiform cells suggest differences, as compared with cat, in interactions of fusiform and other DCN neurons. Giant cells in gerbil may influence DCN neurons and project through VCN. Their dendrites may be influenced by MOL parallel fibers through their "tuft" as well as deeper input. 182.4

THE EFFECTS OF BARBITURATE AND COCAINE ON THE AMPLITUDE-MODULATION-FOLLOWING RESPONSE (AMFR) OF THE RABBIT: AN INVESTIGATION OF SOURCES. R. Batra, S. Kuwada, N.B. Kluck* and S.J. O'Connor*, Depts. of Anatomy and Psychiatry, Univ. of Conn. Health Center, Farmington, CT 06032.

Since auditory evoked potentials appear to arise from multiple brain sites, they are potentially useful as neurological tools. The AMFR to sinusoidally amplitude modulated tones may be especially advantageous because different generators appear to dominate the response at different modulation frequencies.

In our recordings of the AMFR from the skull of the unanesthetized rabbit, multiple generators are indicated by the way in which the amplitude and latency of the AMFR vary with modulation frequency from ~20-800 Hz. The amplitude shows a sequence of peaks separated by sharp dips, suggesting the summation and cancellation of signals from two or more sources. The latencies, as measured from plots of the phase of the AMFR vs modulation frequency, indicate that different generators dominate the response at different frequencies. The phases lie roughly along three linear segments. The segments at progressively higher frequencies have shallower slopes, indicating progressively shorter latencies.

The responses at different modulation frequencies also differ in their sensitivity to intravenously administered sodium pentobarbital or cocaine. Pentobarbital reduces the amplitude of the AMFR at low frequencies, and the sequence of peaks and dips is abolished. Cocaine enhances the AMFR at low frequencies. In contrast, both pentobarbital and cocaine have much smaller effects on the AMFR at higher frequencies.

Our results suggest that the AMFR may be useful as a neurological tool because different generators might be isolated by varying the modulation frequency. The dominant generators at higher frequencies are consistent with sources in the brainstem, while those at lower frequencies may reside higher in the auditory pathways.

THE TWO MIDBRAIN AUDITORY SPACE MAPS IN THE GUINEA PIG EXHIBIT DIFFERENT SUSCEPTIBILITIES TO SENSORY EXPERIENCE. D.J. Withington, K.E. Binns* and M.J. Keating*, Department of Physiology, Leeds University, LS2 9NQ, U.K. & * N.I.M.R., London NW7 1AA, U.K.

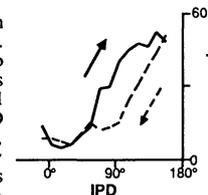

Two separate topographically ordered representations of auditory space are found in the guinea pig brain; in the superior colliculus (SC) and the external nucleus of the inferior colliculus (ICX). Both maps have been examined following experiments in which animals were subjected to sensory deprivation, either by dark raising or placement in a continuous noise environment to perturb directional cues on sound location. Terminal mapping experiments were performed on anaesthetized guinea pigs. Electrophysiological data in the form of multi-unit receptive fields were collected in response to free-field presentation of white noise. We have shown previously that the SC space map is highly susceptible to both auditory and visual deprivation during development. Withholding either modality of experience, particularly during a crucial period before the normal emergence of the map, prevents the normal chronological expression of the SC map. In contrast the ICX map, whilst perturbed by auditory deprivation, is unaffected by visual deprivation. The differing susceptibilities of the SC and ICX maps to sensory experience may reflect different functional roles subserved by the maps in the process of sound localization.

182.8

HYSTERESIS IN RESPONSES OF INFERIOR COLICULUS NEURONS TO DYNAMIC INTERAURAL PHASE STIMULI. M.W. Spitzer, M.N. Semple, Dept. of Anatomy and Neurobiology, University of California, Irvine, CA 92717.

Because an observer's head is normally free to move, binaural difference cues are frequently dynamic. However, little attention has been paid to the influence of dynamic stimulus features on the processing of binaural spatial cues. We studied responses of single inferior colliculus neurons to dynamic interaural phase disparities (IPDs) generated by interaural phase modulation (IPM; Spitzer and Semple, *Soc. Neurosci. Abstr.*, 1990). Digitally-synthesized sounds were presented dichotically to anesthetized gerbils and cats. Responses of single isolated units were recorded extracellularly.

Response profiles for modulation in opposite directions were rarely symmetric. As illustrated by the response of a unit to triangular IPM shown in the Lissajous figure, the increase in firing rate elicited by modulation toward a favorable IPD follows a convex trajectory. In contrast, the decrease in discharge elicited by modulation in the opposite direction follows a concave trajectory (dashed line). Such hysteresis indicates that the encoding of IPD is a nonlinear process. The influence of dynamic stimulus features thus illustrated would impair the ability of neurons to encode absolute, instantaneous IPD. Alternatively, the temporal structure of neuronal discharge may convey information about dynamic features of IPD. Supported by NIDCD grant DC 00364.

182.9

DEVELOPMENT OF EFFERENT CONNECTIONS OF THE COCHLEAR NUCLEUS IN THE RAT. K. Kandler and E. Friauf. Dept. Animal Physiology, Univ. of Tübingen, Fed. Rep. Germany.

To study the ontogeny of the ascending pathways in the auditory brainstem, small crystals of the carbocyanine dye, DiI were implanted into the cochlear nucleus (CN) of embryonic (embryonic age E18 - E21) and postnatal (P0 - P14) formaldehyde-fixed rat brains. After 2-9 months, brains were cut with a vibratome and examined under epifluorescent illumination. In a second set of experiments, coronal brainstem slices containing both the CN and the superior olivary complex (SOC), were prepared and maintained alive *in vitro* for 8-15 hours. Crystals of biocytin applied to the ventral acoustic stria resulted in retrogradely labeled neurons in the CN and anterogradely labeled fibers in the SOC.

As early as E18, labeled fibers could be observed in the lateral part of the ipsilateral SOC (iSOC), in the medial part of the contralateral SOC (cSOC), bilaterally in the lateral lemnisci and in ventrostral aspects of the inferior colliculi. However, collaterals were only observed in the iSOC and in the IC. At E20, collaterals were also present in the cSOC and bilaterally in the ventral nuclei of the lateral lemniscus (VNL). In the contralateral dorsal NLL, collateral sprouting started at E21. Labeled fibers and retrogradely labeled neurons were first observed in the cDCN at P2 and in the cVCN at P3. In the contralateral medial nucleus of the trapezoid body, end bulbs of Held were first found at P3. Since the main afferent pattern to the IC appears adult-like in rat embryos (unpublished), we conclude that the main connections between auditory brainstem nuclei develop in a temporally parallel rather than a serial fashion. Our results also show that there is a time period of about two weeks between the establishment of the main auditory brainstem pathway and the onset of hearing at P12. During this period, spontaneous activity may be necessary for a proper maturation of the auditory system. Supported by DFG Fr 772/1-1

SPATIAL ATTRIBUTES OF PINNA TRANSFORMATIONS IN THE CAT. J.C.K. Chan, A.D. Musicant* and J.E. Hind. Department of Neurophysiology, University of Wisconsin, Madison, WI, 53706.

We have described spectral characteristics of free-field to eardrum acoustic pressure transfer functions that occur as a result of sound interacting primarily with the pinna. One consistent finding was a spectral notch that shifts upward in frequency with increasing source azimuth and/or elevation (Musicant et al., Int. Cong. Acoust., 1986; JASA, 1990). We also described a spatial feature, the acoustic-axis. This is the direction from which a particular frequency component is most amplified relative to other directions. Although the acoustic axis is broadly tuned spatially, binaural psychoacoustic experiments have shown that narrow bands of noise tend to bias judgements towards the acoustic axes.

Another spatial attribute is the presence of a distinct region, for each frequency component in the 8-16 kHz range, where the pinna amplification is low, and usually negative. This region of low amplification often appears as a narrow strip in an isoamplitude contour plot. Each strip is oriented at about 45 degrees with respect to the horizontal axis. Strips for the two ears form mirror images of each other and intersect near the median plane. With increasing signal frequency each strip shifts location systematically in a direction orthogonal to its orientation. For each frequency component in the 8 - 16 kHz range, there is a well defined locus near the median plane where pinna amplification is low in both ears. Physiological experiments in our labs have recently demonstrated that these regions of low amplification are detected by the nervous system at the level of the auditory nerve and the primary auditory cortex (Poon et al., Reale et al., Soc. Neurosci. Abstr., 1991), suggesting that these acoustic features might play a role in sound localization. [Supported by NIH grant DC00116]

182.13

MONAURAL DIRECTION-DEPENDENT RESPONSES OF NEURONS IN CAT PRIMARY AUDITORY (A1) CORTEX. R.A. Reale*, J.E. Brugge, J.C.K. Chan, A. Musicant*, J.E. Hind, and P.W.F. Poon*. Dept. of Neurophysiology and Waisman Center, University of Wisconsin, Madison, WI 53706.

The dichotic simulation of free-field sounds using insert earphones provides a powerful technique to study the direction-dependent responses of single auditory neurons. Earphone reproduction permits independent variation of acoustical properties including sound pressure level and spectrum both of which play a role in sound localization. Our system accurately simulates the direction-dependent pinna transformation of a broad-spectrum sound (click) presented from a free-field source. We refer to this representation of simulated free-field sounds as acoustic virtual space.

The majority of single neurons in the primary auditory (A1) cortex of the barbiturate-anesthetized cat which respond to tones also respond to clicks. Typically, a cell discharges only when a click stimulus corresponds to certain sound source directions in acoustic virtual space. An aggregation of effective directions forms a Virtual Space Receptive Field (VSRF). VSRFs are strongly influenced by changes in sound pressure level. The shapes of VSRFs can vary from a simple unimodal focus to a complicated pattern. A VSRF resulting from monaural stimulation can exhibit a striking correspondence with the direction-dependent amplitudes of spectral components in the click stimulus. Plotting the amplitudes of single spectral components as a function of azimuth and elevation in acoustic virtual space permits direct comparison with shapes of VSRFs. For a subset of neurons, isoamplitude contours derived for the spectral stimulus component near characteristic frequency (CF) can delineate the VSRF for near-threshold intensity levels. Often, the VSRF is delimited by isoamplitude contours representing both local maxima and local minima. Furthermore, the same contours can exhibit a correspondence with the spatial distribution of first-spike latencies comprising the VSRF. In other cells, VSRFs are better matched by isoamplitude contours for stimulus frequencies different from CF or by contours derived from a range of stimulus frequencies.

HYSTERESIS IN RESPONSES OF INFERIOR COLLICULUS NEURONS TO DYNAMIC BINAURAL AMPLITUDE DISPARITY. M.N. Semple. Dept. of Anatomy and Neurobiology, University of California, Irvine, CA 92717.

Most acoustic environments are rich in temporal fluctuations of frequency and amplitude. The two ears are stimulated differently and the stimulus at each ear varies constantly. How do these interaural dynamics contribute to the processing of directional information? Interaural modulation provides a means for examining the neural consequences of dynamic changes in binaural conditions. Dynamic amplitude disparity stimuli (DAD) were generated by modulating the signal amplitude at one or both ears. Stimuli were synthesized digitally and presented dichotically to anesthetized gerbils and cats. Single-unit responses were recorded extracellularly in the central nucleus of the inferior colliculus.

DAD stimuli typically elicit steeper rate/level functions, lower disparity thresholds and greater peak rates than are evoked by static amplitude disparity (SAD) stimuli. Responses to modulation in opposite directions through the same amplitude disparity range exhibit hysteresis (see figure). These properties indicate that the encoding of binaural level is a nonlinear process.

PATTERNS OF RESPONSE OF CAT AUDITORY-NERVE FIBERS TO EARPHONE-REPRODUCED FREE-FIELD CLICKS. P.W.F. Poon*, and J.E. Brugge. Dept. Neurophysiology and Waisman Center, University of Wisconsin, Madison, WI 53706.

Spectral and temporal information about a sound in space is altered by the acoustic properties of the head, pinna and ear canal before being filtered by the transduction mechanisms of the inner ear and relayed to the cochlear nuclei of the brainstem. To assess these transformations, and therefore the input to the brain, responses of single auditory-nerve fibers of anesthetized cats were obtained to a set of digitally-processed free-field clicks delivered via calibrated earphones sealed into the external auditory meatus. The stimulus set was derived from sound-pressure waveforms generated by a loudspeaker at different locations around a cat's head and recorded at the tympanic membrane as part of a related study (Musicant et al., J. Acoust. Soc. Am. 82:757, 1990). The full complement of these signals represents what we refer to as acoustic virtual space, and the azimuth-vs-elevation map of spike activity derived from responses to this stimulus set is termed a Virtual Space Receptive Field (VSRF). Fibers with CF between 0.4 to 40 kHz were studied. The pattern of activity defining a VSRF depended upon the fiber CF, the stimulus level at which the map was obtained, and on spontaneous discharge rate. The isoamplitude contour map plotted for a single frequency in the stimulus spectrum corresponding to the fiber's CF closely matched the VSRF pattern, although for fibers with CF between 15 and 30 kHz a better correspondence was often obtained with isoamplitude contours for frequencies above CF, especially at high stimulus levels. For fibers of the same CF and at similar stimulus level above threshold, the VSRFs were similar in form, but the spatial contrast between evoked and spontaneous activity was higher for low spontaneous fibers. We conclude that, to the first approximation, VSRFs of single auditory-nerve fibers are governed by the filtering properties of the fiber and the spectral contents of the stimulus. This conclusion is further supported by the agreement between experimental data and results from a two-stage model of the auditory-nerve filter.

THE EFFECTS OF NEONATAL AUDITORY CORTICAL LESIONS ON MINIMUM AUDIBLE ANGLES FOR SOUND LOCALIZATION BY THE FERRET. B.J. Rooney and J.B. Kelly. Laboratory of Sensory Neuroscience, Carleton University, Ottawa, Canada, K1S 5B6.

Previous studies have shown that ferrets with unilateral lesions of primary auditory cortex are incapable of localizing sounds within the contralateral field, but experience no difficulty localizing around midline or within the ipsilateral field. The present study was undertaken to determine whether unilateral cortical lesions in neonates would result in the same deficit observed in the adult. The ferret was selected because of the immaturity of its CNS at birth. Unilateral cortical lesions were produced in 4-day old ferrets. As adults, the animals were tested in a two-choice procedure which permitted independent assessment of minimum audible angles around 0, -60 and +60 degrees azimuth. Animals with large cortical lesions showed contralateral deficits similar to those previously reported for adults. Animals with smaller lesions were less impaired than expected whereas those with lesions restricted to the middle ectosylvian gyrus showed no contralateral impairment. Thus, while infant lesions still produced contralateral deficits, there was some indication of functional sparing. (This research was supported by NSERC.)

PROCESSING OF PERIODIC SIGNALS IN THE BRAINSTEM OF THE GUINEA FOWL (NUMIDA MELEAGRIS) R.W. Ward Tomlinson and Gerald Langner. Dept. of Zool., Tech. Univ. Darmstadt, Schnittpahstr. 10, D-6100 Darmstadt, Germany (West)

The lambus call of the Guinea fowl has a strong sinusoidal amplitude-modulated component. Previous investigations have found neurons in its inferior colliculus analogue MLD nucleus showing marked band-pass tuning to modulation frequency in both their discharge rates and synchronicity. To investigate characteristics of the inputs of MLD, responses of 130 single and multi-units were recorded from auditory brainstem of 12 awake Guinea fowl to pure tones and sinusoidally amplitude modulated tones. Histological confirmation revealed recording sites in or near N. angularis, N. laminaris and N. magnocellularis. The spike counts and synchronization coefficients were measured with respect to pure tone frequency, and modulation frequency. Band-pass modulation frequency characteristics were clearer and occurred more frequently when synchrony was used as a measure of response. With discharge rate as a measure, low-pass characteristics and shallow band-pass characteristics were dominant. Since avian auditory nerve demonstrates only low-pass characteristics to modulation frequency, it can be concluded that additional processing of AM signals is occurring at the level of the cochlear nuclei. RESPONSES TO COMPLEX SOUNDS IN THE CAT'S ANTERIOR AUDITORY FIELD. B. Tian, J.P. Rauschecker, M. Korte* and J.E. Olsen. NIH Animal Center, NIMH, Poolesville, MD 20837, U.S.A. and Max Planck Institute for Biological Cybernetics, Tübingen, Germany.

More than two dozen different representations have now been described in the visual cortex of cat and monkey. These maps show functional specializations for the processing of different aspects of the visual world, such as form, motion, and depth (Hubel & Livingstone; Ungerleider & Desimone; Van Essen; Zeki). Much less is known about the functional subdivisions of auditory cortex in higher mammals. This is even more surprising since sounds are very important for communication in these species.

We have started to analyze single unit responses in the auditory cortex outside the primary auditory field AI. Our first target was the cat's anterior auditory field (AAF), which is reported to have tuned responses in a tonotopic map (Phillips & Irvine; Reale & Imig). Our results confirm these earlier findings: most cells show narrow frequency tuning when tested with tone bursts. However, virtually every neuron responded much better, and often with sustained firing, when tested with more complex natural sounds, such as finger snaps, key jingle, hissing or kissing. These sounds were digitized on a 486 workstation by means of the SIGNAL program package (Engineering Design). Parts of these standardized complex sounds were then played back during single unit recording. In addition, we used frequency and amplitude modulated synthetic sounds. Semichronic recordings were performed under light gas anesthesia. Almost every neuron in AAF responded briskly to auditory stimulation. More units preferred transient sounds with sharp onsets, rather than signals with slow amplitude modulation. Frequency sweeps often elicited good responses too. Some units responded best when the stimulus was presented at a specific location in space or when it was moved across this location in a certain direction (c.f. Rauschecker & Harris, 1989, for SC neurons).

At present, we cannot say anything about a columnar arrangement of these response properties across the isofrequency domain. It appears puzzling, however, why there should be less order in the organization of auditory cortex than of visual cortex.

THE FUNCTIONAL ANATOMY OF MIDDLE LATENCY AUDITORY EVOKED POTENTIALS JOSEPH A. KITHAS*, SHI DI and DANIEL S. BARTH Department of Psychology, University of Colorado, Boulder, CO 80309-0345 (U.S.A)

The neural origins of middle latency auditory evoked potentials (MAEP) were studied in rat cortex. MAEP were mapped from the cortical surface with a high spatial resolution electrode array. Spatiotemporal analysis, based on multivariate statistical methods, was then used to relate putative neural generators of the MAEP complex to established cytoarchitectural anatomy. Our data support the hypothesis put forward by others that the MAEP peaks are generated by separate neuronal subpopulations. The topographic distributions of epicortical potentials associated with each peak of the MAEP complex in the present study were different, indicating activation of spatially overlapping but distinct subpopulations of cells within primary and secondary auditory cortex. These data indicate that the MAEP waveform reflects systematic asynchronous activation of both primary and secondary auditory cortex during the processing of simple click stimuli.

CONDITIONING CHANGES FREQUENCY REPRESENTATION IN GERBIL AUDITORY CORTEX.

H. Scheich and C. Simonis*, Zoological Inst., Technical Univ. Darmstadt, 6100 Darmstadt, Germany

The ^{14}C -2-deoxyglucose method was used to investigate the influence of learning on frequency representation in the auditory cortex of gerbils. During classical conditioning 1 kHz tones as CS were paired with a footshock as US. In the mirror imaged tonotopic fields AI and AAF the two labeled frequency band laminae had a larger distance in comparison to unpaired controls suggesting a shift of representation during conditioning. In a second experiment animals were trained in a shuttle-box to avoid the shock before the 2DG session. In trained animals the width of the labeled frequency band laminae was increased compared to controls, suggesting an expansion of the frequency representation in this paradigm. In a third experiment gerbils were trained differentially with 1 and 10 kHz to avoids (CS+) and not avoid the footshock (CS-). In addition to an expansion of CS+ representation the CS- representation was suppressed. Supported by DFG, SFB 45

A SECTOR BASED ANALYSIS OF THE RAT AUDITORY CORTEX. E.L. Moore, M.E. Taylor, E.A. Floyd, and H.K. Rucker. Department of Physiology, Meharry Medical College, Nashville TN 37208.

This study was designed to study the organization of the Sprague-Dawley albino rat temporal cortex by employing the combined techniques of auditory electrophysiology, cytoarchitectonic analysis, and retrograde labeling patterns in medial geniculate nuclei (MG). The parietal-temporal cortex of male rats (300-350 gms) was subdivided into twelve sectors employing a 2mm grid design (for identification: columns=w,x,y,z; rows=1,2,3; e.g. sector z3 is caudal-ventral above the tail of the rhinal sulcus). Results have been obtained from 26 animals. Sectors w1 and w2 are characterized by long latency (20-43msec range) responses. All responsive units exhibited a "build-up" type response and were broadly tuned; no tonotopic organization could be discerned. Somatosensory responses were also observed. No acoustically responsive units were located in sector w3. Nissl stained sections of column w did not reveal a distinct layer 4. Medial geniculate (MG) projections to column W1 and w2 were sparse and originated in dorsal MG (MGD) and magnocellular MG (MGM); on the other hand, no MGB projections were evident to sector w3. X1 and Y1 also exhibited retrograde transport to MGD and MGM. Units were broadly tuned with a rough high to low frequency organization (caudal to rostral). The remaining sectors exhibited the same tonotopic organization. However, layer 4 was variable but distinct and the units were more sharply tuned with reliable short (11-13msec) latency responses. Retrograde label was found mainly in MGv and MGD. Our results suggest that the subdivisions of the rat acoustically responsive cortex are more complex than previously reported. SENSITIVITY TO INTERAURAL TIME DIFFERENCES (ITDs) OF NEURONS IN THE SUPERIOR OLIVARY COMPLEX (SOC) OF THE UNANESTHETIZED RABBIT. S. Kuwada and R. Batra. Department of Anatomy, University of Connecticut Health Center, Farmington, CT 06032.

The SOC is considered to be the chief site for processing ITDs in the fine structure and the envelope of sounds. Cells sensitive to ITDs in the SOC are commonly viewed as coincidence detectors. They receive phase-locked inputs from each ear, which can be excitatory or inhibitory. If a cell receives excitatory inputs from both ears, then it should discharge maximally at a particular ITD, independent of frequency. In contrast, if a cell receives excitatory input from one ear, and inhibitory input from the other ear, then it should discharge minimally at a particular ITD, independent of frequency. The ITD that produces maximal or minimal responses will be determined by the relative latencies of the two inputs from each ear. Thus, each combination of inputs leads to a specific prediction about a cell's behavior to ITDs.

We have found SOC cells that have responses consistent with the above predictions. Some cells were excited by monaural tones presented to either ear. They typically responded maximally at the same ITD, independent of frequency and favored ipsilateral delays. Other cells were excited by tones presented to the ipsilateral ear and inhibited by tones presented to the contralateral ear. They typically responded minimally at the same ITD, independent of frequency and favored contralateral delays.

In sum, we find that both mechanisms for processing ITDs that have been postulated may operate in the SOC of the unanesthetized rabbit. Cells of the medial superior olive may code ITDs by discharging maximally, while those of the lateral superior olive may code ITDs by discharging minimally.

DORSAL COCHLEAR NUCLEUS OF UNANESTHETIZED DECEREBRATE CATS: DISCHARGE REGULARITY OF PAUSE-BUILD UNITS. K. Parham and D.O. Kim. Div. Otolaryng., Dep. Surgery, Surgical Res. Ctr., Ctr. Neurological Sciences, Univ. Conn. Hlth. Ctr., Farmington, CT 06030.

We systematically examined the mean and standard deviation of interspike intervals (ISI) and the coefficient of variation (CV) of ISIs versus time in all of our sample of 87 pause-build (PB) units from the dorsal cochlear nucleus (DCN) of decerebrate unanesthetized cats. The units were characterized using both poststimulus time histograms (PSTH) and excitatory-inhibitory area (EI-area) schemes. The PB units in the present sample were distributed across four different EI-area types: III (51%), I/III (25%), II (15%) and IV (9%). A predominant portion of PB units (80% of 44 units with sufficient number of spikes for CV analysis) exhibited mean CVs less than 0.5 in the 20-40 msec time window in response to 50 msec tone bursts at characteristic frequency at 60 dB SPL re 20 μ Pa; 39% of the 44 units exhibited highly regular discharges (mean CV < 0.35). PB units with mean CVs less than 0.35 were exclusively of types III and I/III. Intracellular depolarizing currents applied to simple-spiking DCN cells *in vitro* produced highly regular discharges (Hirsch & Oertel, 1988; Manis, 1990). The present *in vivo* finding is consistent with the *in vitro* observations in that both indicate regular discharges of certain DCN cells. We suggest that the absence of noticeable chopping in the PSTHs despite the presence of highly regular ISIs of PB units arises from the variability in the absolute latencies of groups of regularly-spaced spikes.

PRENATAL AND EARLY POSTNATAL DEVELOPMENT OF AUDITORY THALAMOCORTICAL AXONS. R.K. deVencencia and N.T. McMullen. Department of Anatomy, University of Arizona College of Medicine, Tucson, AZ 85724

The behavioral onset of hearing in rabbits occurs between 6 and 7 days after birth. Simultaneously, supernumerary dendrites appear on layer III/IV nonpyramidal cells in auditory neocortex, presumptive targets of thalamocortical (TC) axons, suggesting that afferent activity may have a stimulatory effect on cortical dendrogenesis. To examine the ingrowth of auditory TC axons, Dil was used for anterograde axonal labeling. A small crystal of Dil was placed into the medial geniculate body of rabbit brains fixed with 4% paraformaldehyde at successive developmental periods from gestational day (GD) 25 to postnatal day (PD) 6. Serial coronal sections of 100-200 μ m thickness were examined by fluorescence microscopy and TC axons reconstructed from serial photomicrographic slides. At GD-25, axons have entered the cortical mantle and are prominent in the white matter below the presumptive auditory cortex. Growth cones were observed at the tips of the few axons that have entered the grey matter. At birth, axons have penetrated up to layer V where they branch repeatedly. Unbranched axons also extend into the molecular layer but few axons appear to terminate within the cortical plate. However, by PD-3, sparsely branched axons have entered the trisplanar cortical plate. At PD-6, TC axons span the entire extent of the neocortex and branch extensively within the upper layers. From birth until PD-6, the ingrowth of TC axons was most extensive in ventral portions of the auditory cortex where low frequencies are represented tonotopically. These data agree with the appearance of initial behavioral responses to low frequency tones at PD-6.5. Thus, the arrival and ingrowth of TC axons correlates well with previous anatomical, electrophysiological and behavioral data for this sensory neocortex (Arizona Disease Control Research Commission Contract #82-1688).

EXCITOTOXICITY IN THE RAT NUCLEUS TEGMENTI PEDUNCULOPONTINUS, WITH PARTICULAR REFERENCE TO THE LOSS OF CHOLINERGIC NEURONS. P. Winn, E. Rugg*, J. Dunbar*, M. Latimer* and P. Dean. Dept. Psychology, Univ. St Andrews, Fife KY16 9JU, Scotland; Dept. Psychology, Univ. Sheffield, Sheffield S10 2TN, U.K.

The NTPP contains cholinergic neurons which innervate the thalamus, basal ganglia, superior colliculus and other sites. Recent reports suggest that in the basal forebrain certain excitotoxins have selective actions on cholinergic neurons. Various excitotoxins were therefore tested in the NTPP with special reference to loss of cholinergic neurons, identified using ChAT immunohistochemistry. The size of the lesions was computed following examination of cresyl violet stained sections. The largest were made by kainate=AMPA > NMDA=ibotenate > quisqualate=quinolinate. In terms of the number of cholinergic neurons lost the most effective was NMDA > ibotenate=quinolinate=AMPA=quisqualate > kainate. The ratio of cholinergic to general neuronal loss was computed: kainate, both doses of AMPA and the lower dose of ibotenate were relatively non-selective; the higher doses of ibotenate and quinolinate and both doses of quisqualate and NMDA were more selective; and 24nmol quinolinate, with a ratio more than 2X the next best toxin was the most selective. TOH immunohistochemistry showed axons running through the lesioned area indicating that fibers were undamaged. We conclude that in the NTPP different excitotoxins make quantitatively and qualitatively different lesions. Unlike basal forebrain excitotoxic lesions quinolinate not quisqualate made the most selective lesions of cholinergic neurons and unlike septal nuclei lesions ibotenate spared non-myelinated fibres.

CHOLINERGIC STIMULATION OF RAT SUBSTANTIA NIGRA: COMPARISON OF CARBACHOL, NICOTINE, NEOSTIGMINE, AND EFFECTS OF 6-OHDA LESIONS. W. Inglis*, G. Parker* and P. Winn. (SPON: Brain Research Association) Dept. Psychology, Univ. St Andrews, Fife KY16 9JU, Scotland.

Intranasal carbachol increases feeding, drinking and sexual behavior if there is a pre-existing tendency to respond and low baseline rate. The effects of other cholinergic stimulants have not been compared. Groups of 6-12 non-deprived rats received 0.5ul microinjections into SN of 0.1-5.0ug carbachol, 0.1-5.0ug nicotine, and 1.25-5.0ug or 0.1-1.0ug neostigmine (vehicle, artificial CSF) and their effects on feeding, drinking, locomotion, grooming, rearing and sniffing were examined. Carbachol, nicotine and neostigmine stimulated dose-dependently eating of dry macaroni: amount consumed, latency and duration of feeding were not different; other activities were unaffected. These data show that stimulation of nicotinic or muscarinic receptors or inhibition of AChE in SN potentiates behavior. Nigral ACh is thought to activate DA neurons. A second experiment examined whether unilateral 6-OHDA lesions of nigrostriatal DA neurons affected carbachol-elicited eating. Before lesioning 0.5ug/0.5ul carbachol stimulated significantly more eating than vehicle alone. 6-OHDA lesions were made in 14 rats; 6 rats received sham lesions. After lesioning, carbachol elicited no more eating than vehicle in lesioned rats but elicited eating as before in control rats. HPLC analysis showed lesions had reduced DA concentration in caudate-putamen on the lesioned side by 50%, but had not affected accumbens DA; 5HT was not affected. These data show that DA loss from the caudate-putamen but not accumbens abolishes the effects of intranasal carbachol.

LONG-TERM CHANGES IN STRIATAL OPIOID BINDING SITES AFTER 6-HYDROXYDOPAMINE (6OHDA) LESION OF SUBSTANTIA NIGRA.

J. A. M. Smith*, S. E. Loughlin and F. M. Leslie. Dept. of Pharmacology, Univ. of California, Irvine CA 92717.

Striatal mu and delta opioid receptor densities decrease after lesion of the nigrostriatal dopamine (DA) system, consistent with a localisation of these opioid receptors on DA terminals. Recently, however, it has been suggested that mu opioid receptors are localised on intrinsic striatal neurons and that lesion-induced decreases in density are a result of trans-synaptic changes. In the present study quantitative autoradiography was used to correlate changes in opioid binding site density in rat striatum with the extent of DA denervation at different time intervals after unilateral 6OHDA lesion of the substantia nigra. Mu, delta and kappa sites were labelled using [³H]DAGO, [³H]DADLE (in presence of D-Pro⁴, morphiceptin) and [³H]diprenorphine (in presence of D-Pro⁴, morphiceptin and DSLET) respectively. [³H]Mazindol binding to DA uptake sites in the ipsilateral striatum was less than 10% of that in the contralateral side at one week post-lesion, and remained at this level at 24 weeks. Delta binding site density was decreased 25% at both 2 and 24 weeks post-lesion. Mu sites, in both patch and matrix compartments, exhibited a similar change at 2 weeks, but were further decreased to approximately 70% of the contralateral side at 24 weeks. Kappa sites were apparently unchanged at 2 weeks, but a 30% decrease was observed at 24 weeks. The short-term changes in mu and delta opioid binding sites may be consistent with a presynaptic localisation for these receptors. In contrast, the delayed loss of a large proportion of mu and kappa sites suggests the presence of a population of postsynaptic striatal opioid receptors which undergo long-term trans-synaptic changes as result of 6OHDA lesion. Supported by NIH NS19319, NS26761; DC00450; National Parkinson Foundation.

GLUTAMATE RECEPTOR BINDING IN THE HISTOCHEMICALLY DEFINED PATCH-MATRIX MOSAIC IN HUMAN STRIATUM. Leon S. Dure IV, John B. Penney, Anne B. Young. Department of Neurology, University of Michigan, Ann Arbor, MI 48109.

The corpus striatum consists of histochemically defined patches and matrix. These regions have so far been defined by variations in histochemical staining, and by differences in mRNA expression as examined by *in situ* hybridization. The patches and matrix differ anatomically with respect to afferent and efferent connections within the brain, but no functional distinctions between these areas have yet been described. Using quantitative *in vitro* autoradiography in frozen sections of human striatum, we performed radioactive ligand binding to receptors specific for the PCP site, the ionotropic quisqualic acid (AMPA) binding site, and the kainic acid binding site. The pattern of receptor binding was correlated with histochemical staining for the patches and matrix defined by acetylcholinesterase activity. There was a correspondence between the acetylcholinesterase-poor patches and areas of increased binding to the kainate receptor. Conversely, the binding to the AMPA site was greater in areas coincident with the matrix. These findings indicate a difference in glutamate receptor subtype distribution within the patch/matrix mosaic of the striatum. Given the potential neurotoxicity of glutamate, a differential distribution of glutamate receptors within the striatum may help to explain the pathophysiology of processes characterized by inhomogeneous striatal pathology, such as Huntington's disease. This work supported by the Huntington's Disease Society of America (LSD), and USPHS grant NS 15655 (ABY and JBP).

FIBER ARCHITECTONICS OF THE STRIOSOME-MATRIX ORGANIZATION OF PRIMATE CAUDATE-PUTAMEN. B. Quinn & A.M. Graybiel. Dept. of Pathology, UCLA School of Medicine, Los Angeles, CA 90024, and Dept. of Brain and Cognitive Sciences, Massachusetts Institute of Technology, Cambridge, MA 02139.

The striosome and matrix compartments constitute a fundamental organizational system for the neostriatum, and govern heterogeneous distributions of neurotransmitters, receptors, and input-output pathways in this region. This heterogeneity generally remains occult in tissue treated with classical stains such as the Nissl, Luxol Fast Blue, and Weigert, although under certain conditions clusters of striatal neurons can be discerned. We have developed a modification involving hydrogen peroxide catalysis of Schmued's gold chloride fiber stain that reliably demonstrates striosomes as heterogeneous zones clearly delineated by fiber patterns in the caudate-putamen of the squirrel monkey in frozen sections from formalin-perfused brains. Striosomes appeared as zones of reduced fiber impregnation, sometimes surrounded by an annulus of darker-stained fibers. In adjacent tissue sections, the location of striosomes was confirmed by enkephalin immunohistochemistry. These fiber patterns mainly delineated striosomes in the caudal caudoputamen. Under identical conditions, fiber patterns indicating striosomes were not seen in the rat brain. Fiber definition of striosomes may be a valuable adjunct to previously available techniques for the analysis of striosome-matrix architecture in primate brain.

THREE-DIMENSIONAL RECONSTRUCTION AND VOLUME IMAGING OF THE PATCH-MATRIX ORGANIZATION IN NEOSTRIATUM OF RATS USING ³H-NALOXONE RADIOLABELING. D.J. Woodward, J.-Y. Chang, C.R. Gerfen, K.S. Pollan and S.F. Sawyer. Dept. Cell Biology and Neuroscience, UT Southwestern Med. Center, Dallas, TX 75235 & Lab of Cell Biology, NIMH, Bethesda, MD 20892

A principle feature of the structural organization of the mammalian neostriatum is the segregation of afferents and efferents into neurochemically-defined compartments, referred to as the patch (striosomes) and the matrix, with the latter occupying approximately 85% of the volume of the neostriatum. As viewed in single sections, patches have an irregular appearance ranging in diameter from 200-800 μ m. We have investigated the 3-dimensional structure of patch and matrix across serial sections in the rat neostriatum using an opiate receptor probe to label patch regions. Two adult rats were anesthetized and perfused with 0.3% formalin. Serial sections were cut 20 or 50 μ m thick in the coronal plane with a cryostat, mounted on slides and incubated in 5 nM [³H]-naloxone. Sections were apposed to tritium-sensitive film for 2 months to permit visualization of [³H]-naloxone-labeled patches. Autoradiographic images of 130 sections (2.6 mm total thickness) from one animal and 22 sections (1.1 mm total thickness) from the other animal have been digitized, aligned and reconstructed using software from *Biographics*. Volume imaging from different perspectives, aided by rotating views of solid images in video sequences, provided a 3-dimensional view of the organization of the patch system. A "lateral streak" formed a largely continuous shell along the lateral aspect of the neostriatum. Groups of patches observed in multiple serial sections were found to possess a fenestrated and interconnected lamellar organization. This patch-lamellar system was oriented largely parallel to the lateral streak and was most prominent dorsolaterally. The patch-lamellar organization fragments into isolated "islands" in ventromedial regions of the neostriatum. The reconstructed images provide a foundation for integration of data from diverse anatomical and molecular methods. Supported by MH-44337, AFOSR 90-0416 and Biological Humanities Foundation.

NIGRAL AFFERENTS IN RELATION TO DOPAMINERGIC NEURONS M. Damilama and J.M. Tepper. Center for Molecular and Behavioral Neuroscience, Rutgers The State University of New Jersey, Newark, NJ 07102.

The normal functioning of substantia nigra dopaminergic neurons is greatly influenced by their afferent inputs as evidenced by significant differences in their physiological characteristics of *in vivo* vs *in vitro* preparations. Although the source and chemical content of many afferents to the nigra have been characterized, their precise postsynaptic targets remain to be determined both at the light and electron microscopic level. PHA-L anterograde transport was used in combination with tyrosine hydroxylase (TH) immunohistochemistry to visualize nigral afferents and their sites of termination in relation to TH-immunoreactive neurons.

PHA-L was iontophoretically injected into one of the following brain loci: the globus pallidus, neostriatum, and subthalamic nucleus in anesthetized male Sprague-Dawley rats. After 10 days, animals were perfused with 4% paraformaldehyde-0.2% glutaraldehyde. Free floating 40 μ m parasagittal sections were immunolabeled for PHA-L and reacted with nickel-enhanced DAB. Dopaminergic neurons were identified with TH immunocytochemistry, and the reaction product was visualized with DAB. All tissue was processed with Vector ABC reagents.

Following subthalamic injections, large non-varicose axons were seen traversing pars compacta (PC) rostro-caudally with little sign of terminal arborizations. These same injections resulted in finer and more numerous varicose axon terminals coursing both dorso-ventrally and rostro-caudally along the ventral and caudal extent of pars reticulata. There was no clear preferential association with TH immunoreactive neurons or processes; rather, in several cases, labeled axons appeared to cluster around non-immunoreactive nissl-stained cell bodies in pars reticulata. Pallidal injections resulted in a dense network of varicose terminal labeling throughout both the pars compacta and pars reticulata. There did not appear to be a preferential association of pallido-nigral axons with TH immunoreactive dendrites in pars reticulata. Neostriatal injections resulted in a dense network of fine axons and terminal labeling in the ventral pars reticulata with very little labeling within the pars compacta. Supported by MH45286 and Rutgers University Research Council.

5'-NUCLEOTIDASE: A NEW ENZYMATIC MARKER FOR STRIOSOMAL ORGANIZATION IN THE RAT CAUDOPUTAMEN. S.W. Schoen and A.M. Graybiel. Dept. of Brain and Cognitive Sciences, M.I.T., Cambridge, MA 02139.

In the mammalian striatum, patchy compartments, the striosomes, can be distinguished from the surrounding neuropil, the extrastriosomal matrix, by differential distributions of a large number of neurotransmitters and related compounds. With a histochemical lead technique, we demonstrate that the adenosine-producing ecto-enzyme 5'-nucleotidase (5'N) follows a similar compartmentalization in the striatum of the adult rat. Serial-section comparisons of the distribution of 5'N enzymatic activity and the distributions of opioid receptor sites (a marker for striosomes visible by ³H-naloxone ligand binding) or calbindin immunoreactivity (a marker for matrix) show that 5'N is differentially concentrated in striosomes, where it assumes a dense neuropil staining. 5'N follows a striosomal distribution in all but the caudal caudoputamen, including the dorsolateral quadrant in which little calbindin staining appears. In practice, 5'N histochemistry proves an advantageous tool for detecting the striosomal architecture in the rat: it can be performed on both unfixed (cryostat) and perfusion-fixed (vibratome or freezing microtome) sections; it reveals a widespread striosomal organization; and it constitutes an inexpensive and fast (results obtained 2 - 3 hr after tissue collection) procedure. 5'N is predominantly associated with glia in the adult nervous system and thus could reflect a specific glial compartmentalization within striatum. This enzyme has, in addition, been localized in modifiable synapses and thus could also mark striosomes as sites of synaptic plasticity.

NEOSTRIAL AFFERENTS LABELED WITH 5-HYDROXYDOPAMINE: SYNAPTIC ULTRASTRUCTURE AND RECONSTRUCTIONS FROM SERIAL SECTIONS. J.C. Linder, S.J. Young and P.M. Groves. Dept. Psychiatry, Univ. Calif. San Diego, La Jolla, CA 92093

This project analyzed electron micrographs of neostriatum from rats which had been infused intraventricularly with 5-hydroxydopamine (1.5 mg). Serial sections (12-70 / ribbon) were obtained of heavily labeled axons. These axons appeared similar to those presumed to be dopaminergic in previous reports using tyrosine hydroxylase immunocytochemistry. Our sample contained 50 synapses in a total volume 1102.6 μ m³. These were analyzed for presynaptic axon diameter, type and area of synaptic specialization, and post-synaptic target. The morphology of some axons and their postsynaptic targets was visualized by computer-assisted three-dimensional reconstruction. We estimate that labeled axons comprise 3% of the neuropil volume and that at least 5% of all synapses within this striatal region were labeled. Labeled axons were relatively straight, unbranched, and of small diameter (0.06-1.5 μ m). Variations in diameter occurred along an axon. Enlargements were more often associated with mitochondria than with synapses. Diameter at synapses was 0.1-0.77 μ m (mean = 0.26 μ m). Synapses were *en passant*, symmetric, and contacted spine heads (n=15), spine necks (n=13), dendritic shafts (n=21), and an axon (n=1). Axon diameter and synaptic contact area were larger for synapses on dendritic shafts than for those on spines. These tiny synaptic specializations (area: 0.01-0.11; mean = 0.04 μ m²) appeared in only 2-3 adjacent serial sections. Synaptic vesicles were almost obscured by the label but appeared sparse and relatively large. Three-dimensional reconstructions facilitated comparison of the locations of these presumed dopaminergic synapses relative to unlabeled synapses along a dendrite. While labeled synapses often contacted spiny dendrites near the base of spines or on spine necks, unlabeled, asymmetric synapses predominated on spine heads. Some spiny dendrites received labeled synapses at branch points. Reconstructions of individual axons revealed variations in their morphology and the distribution of synapses along their length. A stereo reconstruction of one 10 μ m segment of labeled axon demonstrated that it made 6 symmetric synapses with 6 different postsynaptic dendrites, 4 spiny and 2 aspiny. Other reconstructions showed multiple labeled axons contacting a single dendritic segment. These results further characterize dopaminergic influence within the striatum.

CONTEXT-DEPENDENT BASAL GANGLIA (BG) ACTIVITY MAPPED WITH ¹⁴C DEOXYGLUCOSE AUTORADIOGRAPHY. C. Manetto, T.I. Lidzky, L.L. Brown. Inst. for Basic Research, Staten Island, NY 10314 & Dept. of Neurology, Albert Einstein College of Medicine, Bronx, NY 10461.

It has been suggested that BG activity is dependent on behavioral context. To evaluate this suggestion, BG activation patterns to perioral stimulation were assessed by glucose utilization autoradiography in rats in situations in which trigeminal feedback either was (context group) or was not (control group) important for guiding movement. Controls showed activation of a specific region of the dorsolateral striatum. In contrast, the context group showed greater glucose utilization in this same dorsolateral area. In addition, ventral striatal regions (including part of the nucleus accumbens), and the globus pallidus were activated only in the context rats. These results indicate that the regional specificity of processing of a given sensory stimulus depends on behavioral context. Moreover, since activation of BG output, via the pallidum, only occurred in the context group, the striatum can act as a gate for behaviorally significant stimuli.

SOMATOTOPIC MAPS IN RAT STRIATUM: EVIDENCE THAT THE STRIATUM PLAYS A ROLE IN COORDINATION OF THE TWO SIDES OF THE BODY. L.L. Brown, Dept. of Neurology, Albert Einstein College of Medicine, Bronx, NY 10461.

To determine the organization of somatosensory activity in rat striatum, ¹⁴C deoxyglucose mapping studies were carried out in awake rats receiving tactile stimuli of either the hindlimb, trunk, or forelimb, on the left side. The stimuli were 4/sec sweeps of a nylon bristle (1 mm dia.) which traversed 0.2-2.0 cm of the rat's body anteroposteriorly. Patchy areas of activation were identified using image analysis, and their x,y coordinates were measured at 7 different anterior-posterior striatal levels. The results showed a loose somatotopic organization contralaterally, as previously reported from this laboratory, but also ipsilaterally. The activation of both sides was not in symmetric striatal regions, however. In the posterior striatum, the activation ipsilateral to the stimulus was 300 μ m dorsal to the activation contralateral. Anteriorly, it was 300-500 μ m ventral. The results suggest that each side of the striatum has two separate representations of the body, one from each side, juxtaposed at distances that permit physiological interactions for side-to-side coordination.

VENTRAL PALLIDO-STRIATAL PATHWAY IN THE RAT BRAIN. H. Kuo and H.T. Chang, Dept. of Anatomy and Neurobiology, College of Medicine, The Univ. of Tennessee, Memphis, 875 Monroe Ave., Memphis, TN 38163.

The reciprocal connections between the dorsal striatum and dorsal pallidum have been well established in the rat. Comparable connections between the ventral striatum (VS) and the ventral pallidum (VP) have also been reported. In this study we aimed to further characterize this ventral pathway to determine the morphology and chemical properties of ventral pallido-striatal projection neurons, and to determine the morphology of VP efferents in VS. Fluoro Gold (FG) was injected into VS to retrogradely label VP projection neurons. Enkephalin and substance P immunoreactivity were used as pallidal markers to delineate VP from the neighboring substantia innominata (SI). The results showed that most neurons retrogradely labeled by FG were found in VP, but a few were also found in SI. Additional double labeling experiments showed that none of these FG-labeled cells were cholinergic neurons, however, some were immunoreactive for parvalbumin, a calcium binding protein found in many pallidal neurons. The somatic size of these VS-projecting neurons is very similar to those that project to the medial dorsal thalamus. Electron microscopic (EM) analysis revealed that the long dendrites of these VS-projecting neurons formed many synapses. Injection of PHA-L into VP resulted in many anterogradely labeled fibers in VS. EM analysis revealed that some of these labeled axons were myelinated and they formed either symmetrical or asymmetrical synapses with VS neurons. RESPONSES OF SUBTHALAMIC NEURONS TO STIMULATION OF THE FRONTAL CORTEX. K. Fujimoto and H. Kita, Dept. of Anatomy and Neurobiology, College of Medicine, Univ. of Tennessee, Memphis, 875 Monroe Ave., Memphis, TN 38163

The subthalamic nucleus (STH) receives inputs from the frontal cortex (Cx) via both monosynaptic and polysynaptic pathways. In order to investigate the role of each of these pathways, we assessed the responses of STH neurons to stimulation of the Cx in rats which received various brain area lesions. Male Sprague-Dawley rats were used. Some rats were anesthetized with Ketamine and Xylazine, and received quinolinic acid lesion of the neostriatum, and others received ibotenic acid lesion of the globus pallidus 10-14 days before recording. For recording, the rats were anesthetized with urethane, and stimulus electrodes were placed in the Cx. Responses of the STH to Cx stimulation were recorded extracellularly and intracellularly using glass electrodes. STH neurons exhibited excitations with two peaks and a subsequent long lasting inhibition in response to stimulation of the ipsi- or contralateral Cx. The responses of the STH neurons were not significantly affected by the chronic striatal lesion or the acute knife cut of the brainstem immediately caudal to the substantia nigra. However, after the pallidal lesion, the STH responded with a single peak, broad excitation. The reciprocal circuits between the STH and the globus pallidus seem to play some roles in producing two peaks of the excitation. Responses of the STH evoked by contralateral Cx stimulation basically possessed the same patterns as those evoked by ipsilateral Cx stimulation. However, the former had higher thresholds and longer latencies. Responses to the contralateral stimulation completely disappeared after the corpus callosum was transected. Therefore, contralateral stimulation seems transmitted through the corpus callosum. (Supported by NIH grants NS25783 and NS26473)

RELATIONSHIPS BETWEEN INTERNEURONS IN THE RAT STRIATUM: PARVALBUMIN NEURONS AND CHOLINERGIC NEURONS. H. T. Chang and H. Kita, Department of Anatomy and Neurobiology, College of Medicine, The University of Tennessee, Memphis, 875 Monroe Ave., Memphis, TN 38163

The corpus striatum consists of both projection neurons and interneurons. Several types of striatal interneurons have been identified recently, each containing characteristic neuroactive substances such as acetylcholine, somatostatin, or parvalbumin (a calcium binding protein found in a population of GABAergic striatal interneurons). The present study aims to elucidate the synaptic relationships between cholinergic neurons (ChAT) and the parvalbumin immunoreactive (PV) neurons. A pre-embedding double-labeling immunocytochemical reaction was performed on rat brain sections in which PV neurons were labeled by silver-intensified colloidal gold particles, and the cholinergic neurons by immunoperoxidase reaction products. Our preliminary electron microscopic analysis reveals that both PV and ChAT axon terminals form synapses with unlabeled medium-sized somata with round un-indentated nuclei, a typical characteristic of the medium spiny projection neurons. PV and ChAT axon terminals also form synapses with the somata of PV neurons. The somata of ChAT neurons, however, appear to be not innervated by PV terminals. These observations suggest that PV and ChAT neurons have converging influences on both the striatal projection neurons, and the striatal PV interneurons. Whether PV neurons form synapses directly with ChAT neurons, perhaps on the ChAT dendrites, remains to be determined. (Supported by NIH Grants AG05944, NS25783, NS26473 and a grant from the Alzheimer's Association)

PALLIDO-NEOSTRIATAL PROJECTIONS OF THE RAT.

H. Kita, H. T. Chang and K. Fujimoto, Dept. of Anatomy and Neurobiology, College of Medicine, The Univ. of Tennessee, Memphis, 875 Monroe Ave., Memphis, TN 38163.

Previous studies have shown that the globus pallidus (GP) possesses topographically organized projections to the neostriatum (Str). We have studied these projections in detail using electrophysiological and anatomical techniques. In anesthetized rats, the responses of GP neurons to striatal stimulation were recorded intracellularly. Antidromic responses were evoked from 23 of 68 recorded neurons. The mean antidromic latency was 1.0 ± 0.5 msec. GP neurons projecting to the Str were labeled retrogradely by Fluoro-Gold which was visualized with an immunoperoxidase reaction using anti-Fluoro-Gold serum. Cell count in Nissl stained sections indicated that more than 40% of GP neurons project to the Str. The labeled neurons were seen in all parts of the GP except the caudomedial GP. Most of the GP-Str projection neurons were immunoreactive for parvalbumin, a calcium binding protein which is found in GABAergic GP neurons. PHA-L anterograde labeling revealed that GP-Str fibers formed a moderately dense terminal field within the Str with many boutons en passant. Electron microscopic analysis revealed that the PHA-L labeled boutons form symmetrical synapses mainly with somata and dendritic shafts of spiny neurons. These results suggest that 1) a significant population of GP neurons project to the Str, 2) most of these neurons are GABAergic, and 3) they terminate mainly on striatal spiny projection neurons.

TRANSNEURONAL TRANSPORT OF HSV-1 FROM THE PRIMARY MOTOR CORTEX AND THE SMA: EVIDENCE FOR SEPARATE 'MOTOR' CIRCUITS WITHIN THE BASAL GANGLIA. J.E. Hoover and P.L. Strick, VAMC and Depts. of Neurosurg. & Physiol., SUNY-HSC, Syr., NY 13210.

We have used transneuronal transport of herpes simplex virus type 1 (HSV-1) to examine the 'motor' circuits which link the basal ganglia with 2 cortical motor areas: the primary motor cortex and the supplementary motor area (SMA). We injected the arm area of the primary motor cortex (n=2) or the arm area of the SMA (n=2) of monkeys (*Cebus apella*) with a strain of HSV-1 which is transported transneuronally in the retrograde direction. Animals were sacrificed 24-48 hrs. after the development of myoclonic jerks in the arm contralateral to the injected hemisphere. Following tissue processing, numerous neurons infected with virus were found in regions of the ventrolateral thalamus that are known to project to the primary motor cortex or SMA (e.g., VPLo and VL0). In addition, labeled neurons were found in regions of the internal segment of the globus pallidus (GPi) that are known to project to VL0. Surprisingly, transneuronal transport from the 2 arm areas labeled neurons within different regions of GPi. The neurons labeled by injections into the primary motor cortex were located largely within ventral regions of GPi. The neurons labeled by injections into the SMA were located at the same rostro-caudal level, but in more dorsal regions of GPi. These results support the proposal that the primary motor cortex and the SMA are both targets of pallidal output (Holsapple et al., J. Neurosci. '91). Furthermore, they suggest that the 2 motor areas are components of separate basal ganglia circuits. Perhaps, these circuits are differentially involved in the preparatory (SMA) and execution (primary motor cortex) phases of movement. Support: VA Med. Res. Service.

TOPOGRAPHY AND LAMINAR ORIGIN OF CORTICOCAUDATE PROJECTIONS IN RHESUS MONKEYS. E.H. Yeterian and D.N. Pandya. Dept. of Psychology, Colby College, Waterville, ME 04901, ENRM Veterans Hospital, Bedford, MA 01730, and Boston Univ. Sch. of Med.

Corticocaudate projections were studied by using fluorescent retrograde tracers. The head of the caudate nucleus (HCN) receives projections from the prefrontal cortex, the superior temporal region (STR), the cingulate gyrus, and the ventromedial temporal cortices. The rostral HCN receives projections from medial prefrontal areas 25, 32, 9 and 10, from orbital areas 11, 12, 13 and 14, and from lateral areas 9, 10, 46 and 12. STR projections are derived from the rostral part of the superior temporal gyrus and the upper bank of the superior temporal sulcus as well as the insula. The cingulate projections arise from rostral area 24, caudal area 23, and the retrosplenial cortex. The ventromedial temporal projections originate from the entorhinal cortex, the CA1 sector of the hippocampus, and areas TF, TH and TL of the parahippocampal gyrus. The caudal HCN has similar cortical inputs, but also receives some projections from areas 8 and 6. It receives relatively sparse projections from frontal and temporal preoccipital cortices, the caudal cingulate region, the insula, and the ventral temporal cortices. It appears that cortical areas projecting to a specific region of the HCN are predominantly those that have reciprocal corticocortical connections, and that share similar architectonic features. With regard to laminar origin, the main source of corticocaudate projections is layer V, with relatively few neurons in layers VI and III giving rise to these projections. A GABAergic INPUT FROM THE ZONA INCERTA TO PREDORSAL BUNDLE CELLS IN THE RAT. U. Kim*, E. Gregory and W. C. Hall. Department of Neurobiology, Duke University, Durham N.C. 27710

Predorsal bundle cells give rise to the main efferent pathway from the superior colliculus to brainstem centers concerned with initiating orienting movements of the head and eyes. Previous work has shown that a ventral, GABAergic subdivision of the zona incerta projects to the layer of the superior colliculus which contains the predorsal bundle cells. The present experiments demonstrate that this pathway contributes a monosynaptic input to the predorsal bundle cells. Predorsal bundle cells were labeled by the retrograde transport of HRP following injections in either the decussation of the predorsal bundle or in the paramedian pontine reticular formation. In the same animals, the ventral subdivision of the zona incerta was injected with either PHA-L or HRP for an anterograde tracer. The tissue was then processed for HRP histochemistry and/or PHA-L immunocytochemistry and viewed with the light and electron microscopes. Labeled terminals were found in synaptic contact with the proximal dendrites and somas of labeled predorsal bundle cells. The terminals contained pleomorphic synaptic vesicles and formed symmetric contacts. Further experiments using biocytin as both the anterograde and the retrograde tracer extended the main results. That is, labeled incertotectal terminals were found in close apposition to the somas and proximal dendrites of predorsal bundle cells, but some of the terminals were in apposition to more distal dendrites, at sites as far as 100 μ m from the cell soma. (Supported by NIH grant EY-08233)

PROJECTIONS FROM THE AUDITORY CORTEX TO THE NEOSTRIATUM IN THE ALBINO RAT.

Arévalo, M (1), Herrera, M * (3), García-Méndez, J. A.* (2), and Lanciego, J. L.* (1).

1.- Cátedra de Histología. Fac. de Medicina. Univ. de Salamanca. (España).

2.- Cátedra de Histología. Colegio Universitario de Avila. Univ. de Salamanca. (España).

3.- Dept. de Anatomía. Fac. de Medicina. Univ. de Alicante. (España).

In the present study PHA-L was injected iontophoretically into different zones of the auditory cortex of the rat. Study of the descending ipsilateral projections shows that these course rostrally and curve inwards to penetrate the caudal and lateral regions of the striate body; essentially, the caudate nucleus and putamen. The fibres forming part of the acoustic radiations continue caudally, coursing towards the medial geniculate body and other nuclei of the acoustic pathway. On passing through the striate body the descending fibres give rise to a dense plexus of collaterals forming a right angle and coursing in the dorsoventral direction, occupying the caudate nucleus and the putamen. Among these fine collaterals with numerous terminals there are thicker fibres also with larger terminals. The terminals are found both in the neuronal fields and among the radiations of cortical fibres.

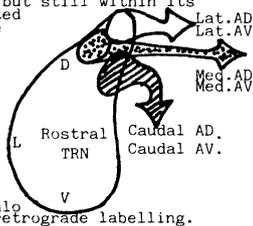

Iontophoretic injection of HRP into the striate body in areas where the above-mentioned striate plexus is present discloses neurones retrograde labelled within the auditory cortex, at the level of layers IV and V. (Supported by Junta de Castilla y León grant N° 1115/90, and by FISS grant N° 88/2040.)

BASAL GANGLIA AND THALAMUS II

184.1

THE ROSTRAL POLE OF THE THALAMIC RETICULAR NUCLEUS (TRN) AND ITS CONNECTIONS WITH THE ANTERIOR THALAMUS OF THE RAT. A. Gonzalo-Ruiz, J.M. Sanz and A.R. Lieberman. Depto. of Anatomy, University College of Soria, Spain and Depto. of Anatomy, University College London, England.

We have investigated the pattern of connections between the rostral portion of the TRN and the anterior nuclei of the thalamus (ATN) in eighteen adult albino rats anaesthetized with Nembutal (45 mg/Kg), by placing small iontophoretic injections of HRP (Sigma) into various subnuclei of the ATN and into different parts of the rostral TRN. One to two days later, the animals were reanaesthetized and killed by cardiac perfusion of fixative. The brains were removed, sectioned serially in the frontal plane and alternate sections processed for visualization of HRP using tetramethylbenzidine. Retrograde cell labelling after injections into ATN revealed three major, essentially non-overlapping regions in the dorsal part of ipsilateral rostral TRN, from which cells project to different parts of the ATN. The most dorsomedial part of rostral TRN projects to the lateral half of rostral anterodorsal nucleus (AD) and to the dorso-lateral part of rostral anteroventral nucleus (AV). Immediately ventral to this part of TRN, but still within its dorsal portion, are medially located neurons which project to the more caudal levels of both AD and AV. The dorsolateral part of rostral TRN projects to the medial parts of rostral AD and AV and to a second region situated laterally within the posterior subnucleus of AV. No label was seen in TRN after injections confined to the anteromedial nucleus. Injections of HRP into TRN produced anterograde terminal labelling in the ATN in a topographic pattern corresponding to that of the reticulo-thalamic projections defined by retrograde labelling.

AFFERENT PROJECTIONS TO THE NUCLEUS ACCUMBENS CORE AND SHELL IN THE RAT. J.S. Brog*, A.Y. Deutch** and D.S. Zahm. Depts. of Anat. and Neurobiol. and *Pharmacol. and Physiol. Sci., St. Louis Univ. Sch. Med., St. Louis, MO, 63104 and **Dept. of Psychiat., Yale Univ. Sch. Med., New Haven, CT, 06508.

In response to recent reports suggesting that topography provides an incomplete explanation for differences in the connections of the core and shell of the nucleus accumbens, a comprehensive evaluation of the afferents of the compartments was undertaken. The distribution of retrogradely labeled cells following iontophoresis of fluorogold in the core or shell is reported here as a basis for subsequent targeting of confirmatory PHA-L injections. Immunohistochemistry sensitively revealed fluorogold labeled neurons. Involvements of core and shell at injection sites were judged with the aid of substance-P staining. **Shell:** bilateral subcortical afferents from the basal forebrain, hypothalamus, medial amygdala and brainstem, were predominant. Cortical afferents were rather sparse, ipsilateral, and almost exclusively in the rostroventral medial prefrontal area and the entorhinal cortex. **Core:** In contrast, bilateral cortical inputs from medial and sulcal prefrontal areas were predominant. Subcortical afferents of the core were less prominent and primarily ipsilateral - in ventral pallidum, VTA, dorsal raphe and the central grey. **Shell and core:** dense aggregates of labeled neurons were present ipsilaterally in midline and intralaminar thalamic nuclei and hippocampus and bilaterally in the basal amygdala. These results show certain similarities in the connectivity of shell and core, but also reveal considerable specificity of connections unrelated to topography and suggestive of separate systemic affiliations. Supported by USPHS NS-23805 and MH-45124.

184.3

TERMINATION PATTERNS AND OVERLAPPING OF THE STRIATONIGRAL FIBERS IN THE NORTH AMERICAN OPOSSUM. O. B. Ghonegun and J. C. Hazlett. Department of Anatomy and Cell Biology, Wayne State University, Detroit, MI 48201.

The opossum striatonigral projection is topographically organized (Ghonegun & Hazlett, 1989). This study further clarifies this organization by paired injections in the striatum using WGA-HRP and ^3H -proline and also determine their termination patterns in the substantia nigra (SN) with striatal PHA-L injections. In the paired injections, eleven animals received twenty-two injections in the rostral, middle, and caudal caudate nucleus, and the putamen. Our results confirm that rostral, middle, and caudal caudate project to medial, middle, and lateral portions of the SN respectively and the putamen projects to lateral portion of the SN. The rostromedial to caudolateral topography is less precise in the caudal one-third of the SN. This feature is related to the SN distribution of tyrosine hydroxylase positive neurons (Hazlett et al., 1991). In the five animals with striatal PHA-L injections, results demonstrate that in SN reticulata (SNr), majority of labeled axon terminals and varicosities appear to contact dendrites, while a smaller component selectively contact cell bodies. This latter contingent involves direct synaptic contact with dopaminergic neurons and the former with GABAergic ones. The cell bodies receiving contacts were interspersed with neuronal somas free from such appositions. Labeled axons were also seen extending medially from SNr into SN compacta cell somas.

184.5

PATTERNS OF PEPTIDERGIC FIBERS IN THE DORSAL MIDLINE AND INTRALAMINAR THALAMUS OF THE RAT. L. J. Freedman and M. D. Cassell. Neuroscience Program and Department of Anatomy, University of Iowa, Iowa City, IA 52242.

The paraventricular thalamus (PV) receives projections from many brainstem and hypothalamic autonomic centers and projects to several structures in the basal forebrain, including nucleus accumbens and central nucleus of the amygdala. Recent studies suggest a dorsoventral topographic arrangement of PV cells projecting to these limbic structures. We have examined the distribution of peptidergic fibers in PV to determine if their is a similar topographic organization of afferents to PV.

Immunocytochemical detection of several peptides was performed using the ABC technique. Three basic patterns were found within PV. Pattern 1, the most common, involves labelling throughout PV, except for a small rostromedial zone, as well as in intermediodorsal nucleus and intralaminar nuclei. Pattern 1 is found using antisera against enkephalin, substance P, neurotensin, cholecystokinin, and somatostatin. Pattern 2 involves labelling in laterodorsal PV and is found using antisera against VIP and αMSH . Pattern 3 involves labelling in ventromedial PV, rostral laterodorsal PV, and intermediodorsal nucleus, and is found using antiserum against vasopressin.

Patterns 2 and 3 resemble the retrograde labelling in PV following injections in amygdala and core of nucleus accumbens, respectively. This suggests that parallel peptidergic inputs may influence outputs to parallel limbic circuits.

184.7

THE STRIATAL COMPARTMENTAL ORGANIZATION IN PRIMATES: LOCALIZATION OF CALBINDIN D-28k AND PARVALBUMIN WITH REFERENCE TO THE STRIOSOMES. P.-Y. Côté and A. Parent. Neurobiology Res. Center, Fac. of Med., Laval Univ., Québec, Canada.

Sections of the striatum of rhesus monkeys (*Macaca mulatta*) were immunohistochemically reacted to reveal the distribution of calbindin D-28k (CaBP) and parvalbumin (PV), two calcium-binding proteins.

Calbindin was heterogeneously distributed in the caudate and the putamen. Small regions where both cell body and neuropil immunostaining was low were encountered mostly in the rostral part of the caudate and putamen. More caudally, these calbindin-poor regions were not found in the putamen and they could not be clearly delineated in the caudate nucleus. Alternate sections stained for the enzyme acetylcholinesterase (AChE) revealed that a striking correspondence exists between the calbindin-poor regions and the striosomes. Most of the striosomes had their counterpart on the alternate sections stained for calbindin. Some calbindin-poor regions, very few in number, did not match the AChE-poor striosomes.

Parvalbumin-positive neurons were distributed in an homogeneous manner in the striatum, but the neuropil showed poorly stained regions that did not match exactly with the striosomal organization. The parvalbumin-positive neurons were disclosed in the striosomes and in the extrastriosomal matrix, whereas the calbindin-positive neurons were confined to the extrastriosomal matrix only. Most calbindin neurons were of medium size, and a few large neurons also displayed calbindin immunoreactivity. The parvalbumin neurons were much less numerous than the calbindin neurons and most of them were aspiny and of medium size although a few larger neurons were noted. These results suggest that calbindin and parvalbumin label different striatal cell populations, namely the medium size projection neurons (CaBP) and a group of aspiny interneurons (PV). We propose that CaBP can be used as a reliable marker of the striosomal organization in primates, as it is the case in rodents, and that PV might be part of a neurochemically distinct subgroup of striatal interneurons in primates. [Supported by FCAR, FRSQ and MRC].

184.4

COMPARTMENTAL DISTRIBUTION OF VENTRAL STRIATAL NEURONS PROJECTING TO THE MESENCEPHALON IN THE RAT. H.W. Berendse, P. Voorn, and H.J. Groenewegen. Dept. Anatomy and Embryology, Vrije Universiteit, 1081 BT Amsterdam, The Netherlands.

The ventral striatum in the rat is characterized by an intricate neurochemical compartmentation that is reflected in the distribution of most of its afferent fibre systems. The objective of the present study was to establish the compartmental relationships of ventral striatal neurons projecting to the mesencephalon by combining retrograde (cholera toxin B) and anterograde (PHA-L) tracing methods with the histochemical localization of leu-enkephalin. Neurons in the "shell" of the nucleus accumbens, that project to the ventral tegmental area, the retrorubral field, the peribrachial region, and possibly the dorsal part of the substantia nigra pars compacta, are located outside areas of high cell density and weak enkephalin immunoreactivity (ENK-IR). In the rostromedial part of the nucleus accumbens, neurons that reside inside the large areas of strong ENK-IR surrounding the anterior commissure project to the dorsomedial part of the substantia nigra pars reticulata. Neurons outside these areas innervate the ventral tegmental area and the medial part of the substantia nigra pars compacta. In the border region between the ventromedial part of the caudate-putamen and the dorsal part of the nucleus accumbens, clusters of neurons that project to the substantia nigra pars compacta coincide with patches of strong ENK-IR, whereas neurons in the surrounding matrix issue fibres to the dorsomedial part of the pars reticulata. These results indicate that distinct sets of ventral striatal neurons project either to the substantia nigra pars reticulata or to the ventral tegmental area, the substantia nigra pars compacta, the retrorubral field, and the peribrachial region. Moreover, these sets of neurons respect previously defined compartmental boundaries in each of the various sectors of the ventral striatum. [Supported by NWO Program Grant #900-550-093]

184.6

MODULAR ORGANIZATION OF THE STRIATOPALLIDAL SYSTEM. L.N. Hazrati and A. Parent. Lab. of Neurobiology, Fac. of Med., Laval Univ., Québec, Canada, G1K 7P4.

Injections of the anterograde tracer *biocytine* (Bio) in the sensorimotor (SM) portion of the putamen in the squirrel monkey (*Saimiri sciureus*) produce anterograde fiber labeling in the two segments of the globus pallidus (GP). These fibers are arranged in the form of elongated bands (thin fiber plexuses) lying parallel to the medullary laminae and remaining strictly confined to the SM territory of the GP. Injections of Bio in the associative (AS) portion of the caudate nucleus lead to anterograde labeling in the AS portion of the two GP segments. The labeled fibers form bands orientated parallel to the internal capsule. The functional significance of the band-like pattern displayed by striatopallidal fibers and terminals is unknown. This pattern most likely correspond to the arrangement of the large and discoidal dendritic arborization of the pallidal neurons, which also lie parallel to the external surface of both GP segments. Perhaps the most intriguing aspect of studies is that each injection produces at least two terminal bands separated by zones devoid of anterograde labeling. This suggest that striatal neurons may arborize profusely upon two distant layers of pallidal cells. Indeed, a dual representation of the striatum at pallidal level has been proposed on the basis of autoradiographic tracing study of the striatopallidal projection in the rat. Studies involving intracellular injections of horseradish peroxidase reveal that single striatopallidal neurons arborize twice within the GP in the rat. On the basis of these findings we propose that the striatopallidal system terminates in the form of multiple adjacent modules, each consisting of the entire terminal arborization that covers a single layer of pallidal cells. These modules would originate from groups of striatal cells whose dimensions, shape and regional distribution remain to be determined, particularly in the light of the heterogeneous matrix organization of the striatum. These striatal cell groups terminating in the form of modules at pallidal level would represent the functional unit of the striatopallidal system. The fact that each functional unit gives rise to at least two modules suggests the existence of a fair amount of redundancy of information at pallidal level.

THE TEGMENTO-NIGRAL PROJECTION IN PRIMATE: CELLULAR ORIGIN AND CHEMOSPECIFICITY. B. Lavoie and A. Parent. Centre de recherche en neurobiologie, Hôpital de L'Enfant-Jésus, Université Laval, Québec, Canada, G1J 1Z4

Recently, the organization of the massive bilateral projection to the substantia nigra (SN) originating from the pedunculopontine nucleus (PPN) has been visualized with the anterograde tracer PHA-L in the squirrel monkey (*Saimiri sciureus*). In the present study the exact cellular origin of this tegmento-nigral projection has been identified following unilateral injections of the fluorescent tracer, fluorogold (FG), in the substantia nigra of squirrel monkey. The results demonstrate that this projection originates mostly from neurons located in the rostral two-thirds of the PPN. At this level retrogradely labeled neurons were bilaterally distributed and were slightly more abundant in the ipsilateral PPN (60%) than in the contralateral PPN (40%). In the caudal third of PPN, only a few neurons were retrogradely labeled and they were mainly localized ipsilaterally. Immunofluorescence (TRICT) studies with antibodies raised against choline acetyltransferase (ChAT) and glutamate (GLU) have revealed that only a few neurons in PPN expressed GLU compared to the large number of neurons expressing ChAT. The study of colocalization of FG and TRICT in PPN neurons showed that a significant proportion of retrogradely labeled neurons were ChAT-positive compared to only a small number that expressed GLU. Further investigations combining WGA-HRP and immunohistochemical procedures should help to determine the distribution and exact proportion of cholinergic and glutamatergic tegmento-nigral neurons in the ipsi- and contralateral PPN. These findings reveal that the PPN exerts a powerful bilateral influence upon the SN and that this influence may, at least in part, be mediated by acetylcholine and, less prominently, by glutamate. SUBSTANTIAL ALTERATIONS IN NEUROCHEMICAL AND METABOLIC INDICES IN SELECT BASAL GANGLIA NEURONS FOLLOW LESIONS OF GLOBUS PALLIDUS NEURONS IN RATS Wm.A. Staines and M.T.C. Hincke*. Department of Anatomy, University of Ottawa, Ottawa, Ontario, Canada K1H 8M5

The globus pallidus (GP) projects massively to the subthalamic nucleus and in an apparently less dense manner to the substantia nigra pars reticulata (SNR) and the matrix compartment of the striatum (CPm). Observations made through visualizing these projections with PHAL transport indicates that select target neurons in all three regions receive equally massive innervation from the GP although the number of fibers/volume tissue is far less in the case of the SNR and the CPm. Experiments were carried out to identify some target neurons of this pathway and to examine the biochemical sequelae to removal of pallidal influence over these cells.

In the striatum, the GP efferents innervated the NPY immunoreactive cell and pallidal deafferentation decreased the number of NPY immunoreactive fibers in the striatum by 99%. A similar decrease was seen in somatostatin positive fibers and NADPH-dependant diaphorase (NADPH-d) staining in striatum but no other CP markers were affected. A mirror image decrease occurred in NADPH-d on the contralateral side. Subsequent to deafferentation of nigral neurons of the pars reticulata there was a near total loss in the cytochrome oxidase immunoreactivity in the cell body and proximal dendrites. These findings are taken to indicate that pallidal efferents exert a great influence over the steady state of their target neurons.

INTRACELLULAR LABELLING OF MEDIUM SPINY NEURONS IN THE PRIMATE CAUDATE NUCLEUS: ANATOMICAL RELATIONSHIP OF DENDRITES TO STRIOSOMAL BORDERS R. H. Walker, ¹G. W. Arbuthnot and A. M. Graybiel. Dept. of Brain and Cognitive Sciences, MIT, Cambridge, MA 02139, and ¹Dept. of Pre-clinical Veterinary Sciences, University of Edinburgh, Scotland.

With the technique of intracellular filling of cells in lightly fixed tissue slices, carried out in combination with staining for striosomes and immunocytochemistry specific to the intracellular dye, we investigated the orientations of dendrites of medium-sized spiny neurons lying near striosomes in the primate caudate nucleus. Slices 400µm thick were cut from lightly fixed squirrel monkey brain. Cells were filled at random using a micropipette filled with an 8% solution of Lucifer Yellow (Sigma). Slices were post-fixed, sectioned at 40µm, and stained for butyrylcholinesterase to demonstrate striosomes. Following this they were incubated overnight with an antibody to Lucifer Yellow (courtesy of Drs Kuwada and Knaf) and processed with diaminobenzidine. This sequence permitted the detailed morphology of the filled cells to be clearly distinguished under the light microscope in the presence of staining for the striosomal compartments. Of 206 filled medium-sized spiny neurons, 170 were in the matrix and 36 in striosomes. The dendrites of a number of neurons near striosomal borders, 17 in matrix, 15 in striosomes, avoided crossing distinct compartmental boundaries, whereas dendrites of 5 matrix cells and 4 striosomal cells clearly crossed between compartments. Thus, although many medium-sized projection neurons observe striosome/matrix borders, a subpopulation have the potential for integrating information from both compartments.

DYE-COUPLING IS DIFFERENTIALLY AFFECTED BY APOMORPHINE IN ACCUMBENS CORE AND SHELL NEURONS. P. O'Donnell and A. A. Grace. Depts. of Behavioral Neuroscience and Psychiatry, Center for Neuroscience, University of Pittsburgh, Pittsburgh, PA 15260.

Dye coupling has been used as an index of electrical coupling in a number of brain regions. Furthermore, coupling between cells in the retina and in the striatum appears to be regulated by dopamine (DA). In this study, we investigate whether dye coupling (DC) occurs between cells in the accumbens (Acc) and its modulation by the DA agonist apomorphine.

Lucifer yellow was injected intracellularly into 70 accumbens neurons in rat brain slices perfused with either control or apomorphine-containing Krebs-Ringer's solutions. In all cases the stained neurons were of the medium spiny type, with 12-20 µm somata giving rise to 3-6 primary dendrites. The axon emerged either from a major dendrite or from the soma, and projected caudally. In control conditions, 10/22 neurons injected in the Acc core exhibited DC, while 5/20 neurons in the Acc shell showed DC to other neurons. Administration of apomorphine (10-100 µM) decreased the incidence of DC only between neurons in the core region (0/11 cells), and this effect was prevented by adding the specific D1 antagonist SCH 23390 (1-3 µM) to the bath (2/7 cells were coupled). In contrast, apomorphine administration caused an apparent increase in dye coupling between neurons located in the shell region (5/10 cells).

The division of the Acc into core and shell has been based largely on differences in their connectivity patterns. These results suggest that DA may exert opposite effects on electrical coupling between cells in different regions of the Acc; decreasing the comparatively high level of electrical coupling between neurons in the core while providing an apparent increase of coupling in the shell. ELECTROPHYSIOLOGY AND MORPHOLOGY OF IDENTIFIED THALAMIC NEURONS USING IN VIVO INTRACELLULAR RECORDING AND STAINING. A. Lavin & A.A. Grace. Depts. Behavioral Neuroscience and Psychiatry, Univ. Pittsburgh, Pittsburgh, PA. 15260.

Anatomical, electrophysiological and clinical evidence indicate that the thalamus plays a major role in the regulation of motor activity. In these studies, we compared the anatomy and physiology of neurons located in motor vs. non-motor regions of the thalamus and their response to stimulation of basal ganglia afferents. Intracellular recording and staining of thalamic neurons were done *in vivo* in chloral hydrate anesthetized rats. Neurons were identified after recording by intracellular injection of Lucifer yellow (n = 10). The somata of thalamic neurons ranged from 12 to 65 µm and gave rise to three distinct fascicles of dendrites, two from each pole of the neuron and one from central regions of the soma. Injection of hyperpolarizing current pulses usually elicited prominent rebound low threshold spikes upon repolarization of the soma. Neurons recorded in the ventral posterior nuclei (n = 5) had 12-65 µm polygonal somata with dense tufts of dendrites. Spontaneous epsps were not observed in these neurons. In contrast, neurons recorded in ventral anterior and in posterior thalamic nuclei (n = 5) had fusiform shaped somata measuring approximately 20 µm in length. These neurons exhibited spontaneous epsps of 17 ± 5 mV amplitude and cortical stimulation elicited long duration epsps (35 ± 6 msec). In contrast, stimulation of the striatum elicited epsps (6 ± 1 mV) followed by ipsps which often triggered rebound low threshold spikes. In contrast to the hypothesized role of LTS in rhythmic neuron firing, these cells often exhibited irregular LTSs that appear to be elicited during the rebound of spontaneous ipsps.

CO-LOCALIZATION OF EXCITATORY AND INHIBITORY TRANSMITTER MARKERS IN STRIATO-PALLIDAL PROJECTION NEURONS IN THE RAT. K.M. Carnes, J.M. Dubinsky, H. Hodges, L.E. White, & J.L. Price. Dept. of Anatomy & Neurobiology, Washington Univ. Sch. Med., St. Louis, MO and Dept. of Physiology, Univ. Texas Health Science Ctr., San Antonio, TX.

The striato-pallidal projection is believed to be inhibitory and to use gamma-aminobutyric acid (GABA) as a neurotransmitter. However, several lines of evidence from our laboratories suggest that a subpopulation of striato-pallidal projection neurons may contain both excitatory and inhibitory neurotransmitters. Recent findings from tissue culture experiments showed that a significant fraction of the synaptic activity recorded from coupled pairs of striatal neurons was excitatory, and could be blocked using the glutamate receptor antagonist, 6-cyano-7-nitroquinoxaline-2,3-dione (CNQX) (Dubinsky, 1989, J. Neurosci. 9:3955-3965). Some of the presynaptic excitatory neurons were labeled with antibodies to glutamic acid decarboxylase (GAD), the synthetic enzyme for GABA. In another study, a portion of the striato-pallidal pathway was labeled *in vivo* with the retrograde tracer, [³H]-D-aspartate, a marker of neurons that possess a high-affinity uptake system for glutamate/aspartate and putatively use these amino acids as neurotransmitters (Carnes et al. 1990, J. Comp. Neurol. 302:824-852).

In this study, we report that some striato-pallidal projection neurons are double-labeled with antibodies against GAD and with retrogradely transported [³H]-D-aspartate. These *in vivo* anatomical findings, taken together with previous *in vitro* physiological results, demonstrate that a subpopulation of striatal neurons use glutamate/aspartate to mediate excitatory effects on pallidal neurons, and that some of these neurons also contain GAD. ULTRASTRUCTURAL LOCALIZATION OF L-BACLOFEN IMMUNOREACTIVITY IN RAT AND MONKEY SUBSTANTIA NIGRA. G.R. Holstein, P. Pasik, M. Skladany* and G. Martinelli. Depts. Neurology, Cell Bio/Anatomy & Surgery, Mount Sinai Sch. Med., CUNY, New York, N.Y. 10029.

The goal of this work was the immunocytochemical visualization of L-baclofen in the rat (Sprague-Dawley) and monkey (*M. fascicularis*) substantia nigra. Experimental animals received an i.m. injection of L-baclofen-HCl (5 mg/kg), controls received an equal volume of saline. Ninety min. post-injection, animals were sacrificed by perfusion. Fifty µm vibratome sections were exposed to a monoclonal antibody raised against L-baclofen (Martinelli et al., 1991; *Neurosci.*). Sections were then processed with the PAP procedure, or the avidin-biotin immunogold method.

Ultrastructural observations of the PAP method revealed large immunoreactive dendritic profiles throughout pars reticulata. Many of these profiles were totally ensheathed by unlabeled axon terminals which formed synapses with the labeled dendrites. Other immunostained dendrites also occupied postsynaptic sites, but were incompletely surrounded by boutons. Small caliber unmyelinated immunoreactive axons were prevalent in the neuropil, and immunostained boutons were occasionally observed. A more restricted immunostain was obtained using pre-embedding immunogold labeling. In general, the silver-enhanced particles were membrane-bound, and formed clusters adherent to outer mitochondrial membranes, cisternae, and the plasma membrane of the neuronal elements, most often visible at synaptic contacts. The deposits were common at points of membrane apposition, both nonsynaptic and synaptic. Identically processed sections from the uninjected animals showed no immunoreactivity.

Baclofen is a specific GABA_B receptor agonist. The present results suggest that the baclofen-sensitive receptors are localized both presynaptically and postsynaptically, and may participate in GABAergic feedback loops in the substantia nigra. Aided by NIH Grants # NS-24656, NS-22953. L-baclofen was generously provided by Ciba-Geigy, Ltd.

NEUROPEPTIDE Y- AND CHOLINE ACETYLTRANSFERASE-CONTAINING INTERNEURONS IN THE RAT STRIATAL NETWORK. L. Kerkerian-Le Goff*, J. Vuillet*, R. Dimova* and A. Nicoullon. Neurochemistry Unit, Lab. of Functional Neuroscience, CNRS, 13402 Marseille cedex 9, France.

This study examined the respective position and synaptic relationships of choline acetyltransferase (ChAT) and neuropeptide Y (NPY)-containing interneurons within the rat striatum using dual immunolabelling methods and combination of immunocytochemistry with degeneration of striatal cortical or nigral neuronal inputs. ChAT-immunoreactive (-Ir) neurons (large aspiny) were found to be prevalent in the dorsolateral areas of the striatum whereas NPY-Ir neurons (medium-sized aspiny) were observed to be preferentially localized in the ventromedial part of the structure. Electron microscopic observations indicated that both ChAT and NPY-Ir neurons receive some nigral dopaminergic and cortical afferents and contact striatal spiny presumably projection neurons. In addition, NPY-Ir neurons were found for some of them to also contain the GABA synthetic enzyme, glutamic acid decarboxylase (GAD), and to be frequently contacted by GAD-Ir terminals. Examination of the relationships between the ChAT and the NPY-containing neuronal systems further showed that the two populations of striatal interneurons have reciprocal synaptic interactions, suggesting that their activities may be functionally linked. All in all, these data indicate that the NPY and the cholinergic interneurons have quite similar patterns of connectivity. The reciprocal interactions between these interneurons may serve as a comparative integrator of striatal afferent information allowing coordinate modulation of striatal projection neurons presumably involved in distinct functional loops.

DEVELOPMENT OF DOPAMINE CELLS IN THE SUBSTANTIA NIGRA STUDIED BY THYROXINE HYDROXYLASE AND BROMODEXYRIDINE DOUBLE LABELING. M. Takada, T. Kono, and S. T. Kitai Dept. of Anat. and Neurobiol., College of Medicine, University of Tennessee, Memphis, Memphis, TN 38163

A double immunofluorescence cytochemical technique was used for identification of transmitter phenotype of the cell by tyrosine hydroxylase (TH) and its birth date by bromodeoxyuridine (BrdU). BrdU was injected intraperitoneally (50mg/kg) to pregnant Wistar rats with gestation days of 11 through 20 and to pups at P3 (N=5 for each day). Pups injected with E11 through 20 were sacrificed on postnatal day 0 (date of birth) and 7 and P3 pups on day 4 under ether anaesthesia and perfused transcardially with 20% formalin in 0.1 phosphate buffer (pH 7.4). The brain was removed and coronal sections (30µ thick) were made through SN for immunocytochemical procedures for TH and BrdU antibody.

SN cells were double labeled for TH and BrdU with injections only at E11 through E14. No cells were labeled with injections at E15 and E16. Only small cells were labeled with BrdU with injections at E16 through E19 and large cells at E18 through E20 and P3. In terms of double labeled neurons, maximal labeling (almost 80%) of SN pars compacta (SNc) cells occurred at E12 and E13 injection while maximal labeling (approximately 65-70%) of SN pars reticulata (SNr) cells took place on E13 and E14. By P7, SNr double labeled neurons were reduced almost by 80% but only about 30% of double labeled neurons were lost in SNc. These data indicate that dopamine neurons were born earlier in SNc than SNr and less dopamine cell loss occurs in SNc than SNr post-natally. Supported by USPHS grant NS20702.

ENK+ STRIATAL NEURONS AND THEIR INPUT FROM NIGRAL DA+ NEURONS AT THE EM LEVEL. E.J. Karle, K.D. Anderson and A. Reiner. Dept. of Anatomy & Neurobiology, Univ. of Tennessee, Memphis, TN.

Although information is available on the synaptic inputs to medium spiny striatal neurons in general, little is specifically known regarding inputs to enkephalin-containing (ENK+) striatal neurons. Therefore, we investigated this issue in pigeons, in whom ENK+ striatal neurons and their dendrites and spines can be readily labeled.

Immunohistochemical labeling using an antibody against leucine-enkephalin revealed abundant ENK+ striatal perikarya and dendrites at the LM and EM levels, particularly in the rostral and medial striatum. The ENK+ dendrites were spine-laden. These spines typically received asymmetric synapses at their tips from large terminals containing numerous round vesicles (presumably of cortical or thalamic origin). ENK+ perikarya and dendritic shafts also received synaptic input from ENK+ terminals and from unlabeled terminals whose origin is uncertain. In addition, ENK+ terminals synapsed with various unlabeled cell bodies and dendrites, including "pallidal" type dendrites that were densely coated with ENK+ and other terminals.

EM double-labeling techniques using immunogold in conjunction with PAP/DAB labeling revealed that dopaminergic (DA+) nigral terminals (labeled using anti-tyrosine hydroxylase) made appositions and synapses with ENK+ neurons.

These results show that ENK+ striatal neurons qualitatively receive the same major types of synaptic input as do striatal medium spiny neurons in general. Supported by NS-19620 & NS-28721 (A.R.)

MORPHOLOGICAL DIVERSITY OF PROJECTION NEURONS IN THE NUCLEUS ACCUMBENS OF THE RAT. G.E. Meredith¹, D.S. Zahm², M. Arts², R. Agolia², and H.J. Groenewegen¹. ¹Dept. Anatomy and Embryology, Faculty of Medicine, Free University, Amsterdam, The Netherlands; ²Dept. of Anatomy and Neurobiology, St. Louis University School of Medicine, St. Louis, MO, USA.

Nucleus accumbens can be subdivided into shell and core regions, each of which is characterized by distinct neurochemical relationships and particular afferent and efferent connections. Within these two accumbal regions, further compartmentation with respect to chemical composition and connectivity, has been described. Inasmuch as striatal outputs are known to come from medium spiny neurons, we have addressed whether the fine morphology of this neuronal subtype varies systematically in the different accumbal compartments. Efferent neurons, identified in nucleus accumbens following injections of Fast Blue in the ventral mesencephalon, were intracellularly injected with Lucifer Yellow (LY) in fixed slices. The tissue was further sectioned and dual-immunostained with antisera against LY and leu-enkephalin (ENK). The ENK immunoreaction was performed to display the accumbal mosaic and the core/shell structure. Computerized (Eutectic) reconstruction and analysis revealed that all neurons were small to medium sized (somal area: 102±26 µm²) and spiny. Shell cells had fewer dendrites, which were longer, thicker and less spiny than those of core cells. Morphological differences distinguishing cells in and out of the ENK patches in the core were not observed.

OCULOMOTOR SYSTEM I

185.1

THE DIRECT CONNECTION BETWEEN THE SUPERIOR COLLICULUS AND OMNIPAUSE NEURONS IN THE CAT. M. Paré and D. Guitton, Montreal Neurol. Inst. and McGill Univ., Montreal H3A 2B4.

Omnipause neurons (OPNs) are tonically active during fixation but cease firing for saccade duration. Their activity inhibits the saccadic pulse generator and controls it as an on-off gate. Raybourn and Keller (1977) established a direct connection between the superior colliculus (SC) and OPNs. This projection was found to be excitatory and therefore could not inhibit OPNs and initiate saccades. An attempt to explain the function of that connection was proposed by Munoz and Guitton (Rev Neurol 1989). In their model, cells of the SC's fixation area project onto, and excite, OPNs and therefore contribute directly to fixation behavior and participate in saccade initiation through disfacilitation. Here we report on the nature of the connection between the deeper layers of the SC and OPNs. We recorded OPNs from two alert cats, implanted with SC stimulating electrodes. The characteristics of the gaze shifts elicited at each site were evaluated with parametric studies and indicated the location of the electrodes on the collicular motor map. We found that OPNs could be orthodromically activated from many different sites in the motor map of the SC. 74% of the neurons were mono-synaptically excited from at least one site; other sites elicited either responses having longer latencies (e.g. disynaptic) or no response at all. 23% of the neurons were not driven by the electrical stimulus from any sites. Electrical stimulation of the fixation area of the SC elicited OPN responses, that had the shortest latencies and lowest threshold intensities. Our results suggest a distributed projection from the SC onto the OPNs. They also support the hypothesis that the fixation area of the SC projects preferentially to OPNs.

185.2

ACTIVITY OF OMNIPAUSE NEURONS DURING GAZE SHIFTS ELICITED BY COLLICULAR STIMULATION IN THE ALERT CAT. D. Guitton, M. Paré and M. Crommelinck, Montreal Neurol. Inst. and McGill Univ., Montreal H3A 2B4.

In the head-fixed cat, electrical stimulation of the superior colliculus (SC) elicits either contraversive fixed-vector or "goal-directed" eye saccades when the stimulating electrode is located in the rostral or caudal parts of the SC, respectively. In the head-free cat, stimulation elicits fixed gaze (eye-head) vectors defined by the site in the motor map being stimulated. Noteworthy, when the caudal portion of the SC is stimulated, the eye movement is still "goal-directed"; the eye trace consists of a saccade followed by a plateau period during which the eye remains immobile at a craniotopic goal location. We have recorded the activity of omnipause neurons (OPNs) during gaze shifts elicited by stimulation of the caudal SC. In the head-free condition, OPNs paused for the gaze duration and not for the duration of the eye saccade. These results concur with our previous report that OPNs exhibit gaze-related activity during visually-guided combined eye-head gaze shifts (Paré and Guitton, Exp Brain Res 1990). In the head-fixed condition, the pause duration corresponded to the eye saccade duration. The pause did not prolong into the plateau period, although the induced gaze error was not nulled by the small eye movement evoked. In addition, OPNs did not pause when the eye motion was ipsiversive or when the eye, already at the craniotopic goal location, did not move when stimulation was applied. We suggest that two mechanisms gate OPNs: (1) a collicular feedback circuit reactivating the SC's fixation area when head motion is permitted, (2) a brainstem circuit that stops both vestibular quick phases and the "goal-directed saccades" we evoked when the head was fixed.

185.3

EFFECT OF FRONTAL EYE FIELD OR SUPERIOR COLLICULUS LESIONS ON STIMULATION-EVOKED SACCADES ELICITED FROM THE PRIMATE DORSOMEDIAL FRONTAL CORTEX. E. J. Tehovnik, K. M. Lee and P. H. Schiller. Department of Brain & Cognitive Sciences, M.I.T., Cambridge MA 02139

Using electrical stimulation, we have shown that there is an organized topographic map in the dorsomedial frontal cortex (DMFC) for the execution of eye movements and for the maintenance of gaze. The evoked movements are always contraversive and the final eye position, or termination zone, is relatively invariant to initial eye position. As the electrode is stepped caudally in the DMFC, the termination zone shifts from the periphery to the midline of craniotopic space along the azimuth. Furthermore, if electrical stimulation is maintained while the eyes are fixating a target situated in a termination zone, all visually-evoked saccades are inhibited and gaze is maintained. We posit that this region harbours a motor map that specifies eye position in head-space coordinates.

It is known that both the frontal eye fields and the superior colliculus receive direct projections from the DMFC. Both these structures innervate the brainstem which contains the saccadic generator. We lesioned either the frontal eye fields or the superior colliculus to determine if the DMFC utilizes either of these channels to gain access to the brainstem. Our preliminary findings suggest that neither of these lesions abolishes saccades evoked from the DMFC; furthermore, the integrity of the motor map is generally preserved suggesting that other channels are used by the DMFC to have access to the brainstem.

185.5

AN UPWARD BIAS OF SACCADES TO REMEMBERED TARGETS IS REFLECTED IN THE MOVEMENT FIELDS OF SACCADE-RELATED BURST NEURONS (SRB's) IN THE SUPERIOR COLLICULUS (SC) OF THE MONKEY. T.R. Stanford, E.G. Freedman, and D.L. Sparks. Dept. of Psychology, Univ. of Pennsylvania, Phila. PA 19104.

Compared to visually-guided saccades, saccades to the remembered location of a visual target are less accurate, more variable, and display a pronounced upward bias (Gnadt et al., *Vis. Res.* 31:693, 1991). In an effort to examine the neural basis for these errors, we recorded from collicular SRB's and compared movement fields obtained for saccades to visual and remembered goals. Each SRB was recorded while the animal performed an alternating sequence of visual and memory trials. Both trial types required the fixation of a central LED after which an eccentric LED was illuminated. The monkey maintained fixation until the central LED was extinguished, at which time a saccade could be initiated. On visual trials, the target remained on, while on memory trials, the target was extinguished 500 ms before the fixation LED.

Movement fields of SRB's for saccades to remembered targets were shifted relative to those for saccades to visual goals. The shift was consistent with the upward bias observed for saccades to remembered targets. For example, a neuron that discharged maximally before horizontal saccades on visual trials discharged maximally prior to oblique, upward saccades on memory trials.

Other authors have suggested that a bias could result from distortion in the sensorimotor transforms required to make saccades to remembered locations (Gnadt et al., *Vis. Res.* 31:693, 1991). An upward shift in preferred direction for neurons in intraparietal cortex (LIP) has been reported and postulated as a neural correlate of this bias (Bracewell et al., *Soc. Neurosci. Abstr.* 16:622, 1990). The movement field shifts that we've observed for collicular SRB's might reflect a distortion that originates in area LIP. Alternatively, the signal responsible for the upward bias may be added at a site downstream to the SC. Addition of such a signal would alter the relationship between discharge rate and saccade metrics for any antecedent neuron. (Supported by NIH EY01189 and F32-EY06320).

185.7

A MODEL FOR TRANSFORMING AUDITORY SIGNALS FROM HEAD-CENTERED TO OCULOMOTOR ERROR COORDINATES. J. M. Groh and D. L. Sparks. Institute of Neurological Sciences and Department of Psychology, Univ. of Pennsylvania, Phila., PA 19104.

The primate superior colliculus (SC) contains an auditory map of space which appears to be encoded in a motor error rather than head-centered frame of reference (Jay and Sparks, *J. Neurophys.* 57:35-55, 1987). The spatial locations of the receptive fields of the cells in this map shift with changes in eye position, thus encoding the direction and amplitude of the eye movement needed to acquire the target.

Such a map cannot be derived directly from the peripheral sensory receptors, but must be computed neurally instead. The location of an auditory target relative to the head can be determined by interaural timing and intensity differences. Then, subtraction of the position of the eyes in the orbit yields the motor error of the auditory target.

A neural architecture for the implementation of the second portion of this computational process is proposed here. The model's inputs are an anatomical map of auditory target position in head-centered coordinates and frequency coded signals of horizontal and vertical eye position. The anatomical code of auditory target location is first decomposed into frequency coded signals of its horizontal and vertical components using synaptic weights. Then, the appropriate eye position signals are subtracted through inhibitory connections, yielding frequency codes of horizontal and vertical motor error. These frequency codes are transformed back into an anatomical code through a combination of differing thresholds and inhibition. This final stage produces a dynamic map analogous to the auditory map found in the SC.

185.4

DIRECTION SELECTIVE SACCADE RELATED MOSSY FIBER ACTIVITY IN THE OCULOMOTOR VERMIS OF MACAQUES. K. Ohtsuka and H. Noda. Dept. of Vis. Sci., Sch of Optometry, Indiana Univ., Bloomington, IN 47405.

The discharge of direction selective mossy fibers was studied during saccades in different directions and amplitudes in the oculomotor vermis of the macaque. Most units did not display background activity, except for a few burst-tonic units, and were located in the white matter. The recording side of units was determined by the direction of horizontal component of evoked saccades during microstimulation. The majority (63%) of units preferred contralateral saccades and they started bursting 23.8 ms (SD 13 ms) prior to the saccade onset. The lead time of the mossy fibers which discharged with ipsilateral saccades was slightly longer; 33.1 ms (SD 16.5 ms). Although the burst duration did not show a high correlation with the saccade amplitude, the burst offset was time locked to the saccades offset. The duration from the peak firing to burst offset was correlated with the saccade duration. Movement field was demonstrated in most units; 60% of these showed the sector type, while 40% showed the vector type. In correlation with the discharge of the previously studied fastigial units, the neural mechanisms subserving the control of saccades by the oculomotor vermis will be discussed (supported by NIH grant EY04063).

185.6

A Class of Collicular Saccade Related Bursters (SRB) specifies the metrics of impending eye movements after target specification but before movement initiation. Paul W. Glimcher and David L. Sparks. Department of Psychology, University of Pennsylvania, Philadelphia, PA 19104.

SRBs have been described whose discharge pattern includes a low frequency component as prelude to a high frequency burst. Only the burst component has shown a temporal correlation with the impending eye movement (Sparks, 1972). We report here that, in a subset of these units, this prelude is correlated with movement selection. The ongoing activity of the prelude appears appropriate to serve as a motor latch, encoding the impending movement.

The prelude was studied by using a multiple target paradigm which independently cues target presentation, selection and movement initiation. Briefly, animals were trained to fixate a yellow LED. While this fixation light was illuminated, two eccentric yellow potential target LEDs were briefly illuminated, one above and one below the horizontal meridian. Several hundred msec after these targets were extinguished, the fixation light was extinguished and a second yellow fixation light illuminated. After the monkey looked to the new fixation light, its color was changed to either red or green, selecting one potential target and deselecting the other. Red signaled that a saccade to the remembered location of the upper target would be rewarded after the fixation light was extinguished. Green similarly specified the lower target. In this manner, the behavior of collicular units can be sampled before, during and after target selection and movement initiation, in both retinal and motor coordinate frameworks. Traditional methods were employed to record the activity of single collicular units.

The class of SRBs reported here become active 300-800 msec after the fixation LED turns red/green if and only if the impending movement is encoded by the SRB's burst component. This prelude activity continues as long as the animal fixates the red/green LED (measured up to 4000 msec) and is almost perfectly correlated with the impending movement. This signal appears appropriate for encoding the metrics of a selected, impending movement.

185.8

ROLE OF HIGH FREQUENCY GROUPED DISCHARGES OF CAT TECTORETICULOSPINAL NEURONS. E.Olivier*, A.Grantyn* and A.Berthoz (SPON: European Brain and Behavior Society). CNRS, Laboratoire de Physiologie Neurosensorielle, Paris, France.

Tectoreticulospinal neurons (TRSN) of the cat exhibit steady state firing of 700-1100 imp/s when strongly depolarized by transmembrane current (Grantyn et al., EBR, 1983). During orienting movements in alert cats, TRSN bursts contain only short grouped discharges (doublets, triplets, etc.) characteristic of firing in the regenerative mode (Grantyn & Berthoz, EBR, 1985). The role of grouped discharges in the control of eye and head movements has been assessed by recording the activity of identified TRSN axons in alert, head-fixed cats during gaze shifts induced by moving visual stimuli.

Grouped discharges (GD) reaching instantaneous rates of 300-800 imp/s are usually present in bursts accompanying orienting in the preferred direction of a given TRSN. GDs generated before saccades often coincide with the onset of a slow eye movement in the direction of the forthcoming gaze shift (pre-saccadic drift). Similarly, GDs appearing during the deceleration phase of the saccade are followed by an increment of saccadic velocity (reacceleration) or by the initiation of a slow eye movement in the same direction (post-saccadic drift). The generation of GDs also correlates with short-lasting EMG increments superimposed on neck muscle activity associated with orienting gaze shift.

The results show that GDs may lead to an augmentation of saccadic eye velocity and induce brief supplementary increments of the ongoing contraction of neck muscles. GDs may also contribute to the triggering of pre- and post-saccadic slow eye movements. These effects could be mediated by direct connections of TRSN with ocular and spinal motoneurons, reinforced by the activity of eye-neck reticulospinal neurons (Grantyn & Berthoz, EBR, 1987).

185.9

EFFECT OF BICUCULLINE INJECTED INTO THE FASTIGIAL OCULOMOTOR REGION UPON VISUALLY-GUIDED SACCADES. H. Sato, H. Noda and R. Noda. Vis. Sci. Dept., Sch. of Optometry, Indiana Univ., Bloomington, IN 47405.

To study the effect of impulses from the oculomotor vermis upon visually-guided saccades, the GABA-mediated synapses were blocked by bicuculline injected into the fastigial oculomotor region (FOR) of the monkey. When bicuculline was injected into the FOR, saccades evoked by stimulation of the oculomotor vermis were suppressed for several hours. The changes in the evoked saccades were used as an indicator of the blocking of oculomotor impulses. Saccades from the center to one of 8 targets, evenly spaced LEDs on the 15° perimetric circle, were recorded and their trajectories were reproduced by computer. When the synapses in the FOR were blocked, evidenced by the suppression of evoked saccades, saccades toward the targets presented on the injected side became hypometric. Saccades in the opposite direction became hypermetric. The strongest effect on saccades appeared in the upper-oblique, horizontal, or lower-oblique direction, depending on the experiment and the initial eye position shifted in the direction opposite to that of the strongest effect on saccades. These effects were reversible and the time course of the recovery was closely related to the changes in the evoked saccades (supported by NIH grant EY04063).

SMOOTH-PURSUIT EYE MOVEMENT RELATED ACTIVITY IN MONKEY NUCLEUS RETICULARIS TEGMENTI PONTIS. D.A. Suzuki, T. Yamada*, K.F. Betelak*, & R.D. Yee. Dept. of Ophthalmology, Indiana Univ. Sch. of Medicine, Indianapolis, IN 46202.

The nucl. reticularis tegmenti pontis (NRTP) may be part of a cortico-ponto-cerebellar pathway involved with regulating smooth-pursuit eye movements (SPEM). A major source of cortical inputs to NRTP is the Frontal Eye Field, where lesions cause pursuit deficits. NRTP activity was recorded in alert monkeys trained to fixate a moving 0.25 deg spot. Eye position was monitored with the scleral search coil technique.

In addition to the saccade-related activity reported earlier by Crandall & Keller, a variety of ocular motor related responses were recorded from NRTP. The most common SPEM-related response was direction selective and encoded pursuit eye velocity. A novel finding was the recording of unit activity that appeared to encode smooth-pursuit eye acceleration. When pursuit direction changed ("turnabout"), these cells exhibited peak firing rates that were not related to eye position. Eye position related activity per se was, however, recorded in a different population of NRTP cells.

These results add to the evidence that implicate a role for NRTP in SPEM control. A Frontal Eye Field-NRTP-cerebellum route would parallel the visual motion (MT/MST)-dorsolateral pontine nucleus-cerebellum pathway. This parallel SPEM circuit could account for the recovery of pursuit ability after forming lesions in dorsolateral pontine nucleus. Supported by a grant and fellowship from RPB Inc., NY, NY.

GABAergic INNERVATION OF ABDUCENS MOTONEURONS RETROGRADELY OR INTRACELLULARLY LABELED WITH HRP. AN ULTRASTRUCTURAL STUDY IN THE RAT. H. Bras*, G. Chazal, A. Barbe* and F. Lahjouji*, CNRS UPR 418, 280 Bd Ste Marguerite, 13009 Marseille (France).

GABAergic innervation of abducens motoneurons was studied using a combination of post-embedding gold-immunocytochemistry with retrograde or intracellular labeling of the motoneurons. 1) For retrograde labeling, HRP was revealed in vibratome sections with TMB stabilized with ammonium molybdate. Ultrathin sections were cut from these blocks and were processed for immunocytochemistry. The retrograde labeling of the motoneurons consisted of needle-like deposits distributed in the cytoplasm of their somata and proximal dendrites. GABAergic axon terminals (ATs) were characterized by the presence of colloidal gold particles. The majority of the labeled ATs were densely packed with ovoid and flat vesicles and mitochondria. They were more numerous on the proximal dendrites than on the somata. 2) To visualize and quantify the GABAergic innervation on the whole dendritic arborization, motoneurons were identified and intracellularly stained with HRP revealed on vibratome sections with DAB intensified with cobalt. The neurons were reconstructed in three dimensions using a computer aided microscope. The visualization of the neurons in different views revealed that the dendrites of each neuron appeared to occupy a definite site. The thick sections were cut in 4 µm serial sections, and the exact location of the observed labeled dendritic profiles were determined referencing the 3D reconstruction before ultrathin sectioning and immunocytochemical staining. The quantitative analysis of GABA ATs distribution is currently under study to determine the percentage of synaptic covering and the packing density on the somata and along the dendrites.

THE EFFECT OF BOTULINUM TOXIN ON SACCADIC EYE MOVEMENTS IN RHESUS MONKEYS. E. J. FitzGibbon, P. Inchingolo, L. M. Optican and M. E. Goldberg. Laboratory of Sensorimotor Research, National Eye Institute, Bethesda, MD 20892, and Dipartimento di Elettrotecnica, Elettronica ed Informatica, Università di Trieste, Trieste, Italy.

Botulinum Toxin (BTX) has been used clinically to realign the positions of the eyes in strabismus. We have studied the effect of BTX in two rhesus monkeys after injections in the horizontal rectus muscles of one eye. In each monkey the medial rectus muscle was affected more than the lateral rectus. We recorded eye position of both eyes simultaneously while animals viewed only through the normal eye, in order to study the open-loop response of the weak eye to normal neural commands.

We noted four unexpected characteristics of saccades made by the weak eye to visual targets seen only by the normal eye: 1) There was a directional hysteresis with orbital position dependency: the static position of the weak eye in relation to the normal eye depended on the direction of the previous eye movement. 2) A reduced saccadic step gain of the weak eye that was dependent on orbital-position. 3) There were post-saccadic ocular drifts, whose amplitudes and time constants were continuous functions of orbital position. The ratio of drift amplitude to antecedent saccade amplitude was a nonlinear function of the time constant of the drift, and varied from positive values in temporal positions to negative values in nasal positions. 4) Saccades were slower, and nasally directed saccades began later, in the weak eye.

These effects of BTX can be viewed in terms of a model of the oculomotor plant with a single nonlinear viscoelastic element. BTX not only decreases the innervation-tension gain of the model, but also increases its effective stiffness and viscosity. These changes depended on both orbital-position and saccade-direction.

INITIAL EYE POSITION DEPENDENCE OF EYE MOVEMENTS EVOKED BY MICROSTIMULATION IN THE MONKEY NUCLEUS RETICULARIS TEGMENTI PONTIS. T. Yamada*, D.A. Suzuki, K.F. Betelak*, and R.D. Yee. Dept. of Ophthalmology, Indiana Univ. Sch. Medicine, Indianapolis, IN 46202.

The characteristics of eye movements elicited by microstimulation in the nucleus reticularis tegmenti pontis (NRTP) were effected by initial eye position. Two monkeys were trained to fixate and track a 0.25° target spot. Pursuit-related neuronal responses were recorded prior to stimulation. The stimulus was delivered through the same recording electrode. 50-400 msec trains of biphasic, 0.3 msec, 10-100 µA pulses were delivered at 100-600 Hz.

Microstimulation elicited "pursuit-like", smooth eye movements. In contrast to stimulation in MT/MST, robust eye movements could be evoked when the animal was in the dark and not fixating, as well as when it fixated a stationary target. The speed of the evoked eye movements depended on initial eye position, even though there was no pre-stimulus neuronal response to eye position per se. The speed of the evoked eye movements did not seem to be related to the speed of the pursuit eye movements. The speed of the evoked, "pursuit-like" eye movements was dependent on (i) initial eye position, (ii) the frequency of the stimulating pulse train, and (iii) the intensity of the stimulating current.

The results support the conclusion that NRTP is involved with the regulation of smooth-pursuit eye movements. Supported by a grant and fellowship from RPB Inc., NY, NY.

CORTICAL CONNECTIONS OF TWO DIFFERENT EYE FIELDS IN THE DORSOMEDIAL FRONTAL CORTEX OF THE MACAQUE MONKEY. R. Camarda*, G. Luppino*, M. Matelli* and G. Rizzolatti* (SPON: European Brain and Behavior Society) Istituto di Fisiologia Umana Università di Parma Via Gramsci 14 I-43100 Parma Italy.

A large sector of the dorsomedial frontal cortex sends projections to the intermediate and deep layers of the superior colliculus. Cytoarchitecturally, this sector corresponds to the dorsal part of area 6aβ and to area 8b of Walker. Physiologically, eye movements can be elicited from the dorsal part of area 6aβ (Supplementary eye field, SEF, Schlag and Schlag-Rey, Exp. Brain Res. 58:208-211, 1985) and from area 8b (Mitz and Godschalk, Neurosci. Lett. 106:157-162, 1989). In this study we examined the possibility that these two cortical sectors may represent two different anatomo-functional areas. Intracortical microstimulation was used to localize the region from which oculomotor responses could be evoked. The caudal and the rostral parts of this region were then separately injected with fluorescent tracers (FB and TB) in the two hemispheres of one Macaca fascicularis. The two injections produced labeling in different prefrontal, limbic, parietal and temporal cortical regions. The caudal injection produced intense labeling in the dorsal and ventral parts of frontal eye fields (FEF), in area 12 and in area 8b. Substantial but less dense labeling was observed in caudal parts of area 9 and area 46. Minor projections originated from area 24, area 7 and from polysensory areas of superior temporal sulcus (STS). The rostral injection produced intense labeling in dorsal and mesial area 10, area 9, dorso-rostral area 46 and in dorsal area 6aβ. Rich projections came also from orbito-frontal cortex as well as from limbic areas 32 and 25. In contrast to the caudal injection, only minor projections were found in the dorsal part of FEF. Finally, few cells were found in the polysensory areas of STS.

In conclusion, architectonic and hodological data suggest that the dorsomedial frontal eye field is composed by two different areas: dorsal area 6aβ, caudally, and area 8b, rostrally. The caudal area is strongly connected with FEF and receives from both visual and auditory-related areas. The rostral one is weakly connected with FEF and receives a robust input from limbic and prefrontal areas.

SMOOTH PURSUIT EYE MOVEMENTS OBEY LISTING'S LAW IN THE MONKEY. Th Haslwanter*, K Hepp*, D Straumann, MR Dürsteler, BJM Hess. Neurology Dept., Univ. Hospital, CH-8091 Zürich, Switzerland.

Listing's law specifies the amount of ocular torsion as a function of the line of sight by stating that all eye-rotation-vectors lie in a plane. It is known to hold true for fixations and saccades, but its validity for smooth pursuit eye movements has been questioned by different authors.

We have tested Listing's law during smooth pursuit in the monkey, and compared the results with recordings during spontaneous eye movements in the light. Two juvenile rhesus monkeys were chronically prepared with a dual search coil for 3-dimensional eye position measurement. They were trained to follow a light spot. The spot made a smooth, quasi-periodic movement covering the oculomotor range up to ± 20 deg. Eye position recordings were taken over 2 min periods, and saccades were removed. The pursuit movements had a standard deviation from Listing's plane of only 0.66 deg. This value was smaller than that for fixations (0.79 deg).

VIOLATIONS OF LISTING'S LAW AND DONDERS' LAW DURING HEAD AND EYE MOVEMENTS. T. Vilis, B. Glenn and D. Tweed. Dept. of Physiology, Univ. of Western Ontario, London, ON CANADA N6A 5C1.

Previous studies of the three dimensional position of the eye in space, during combined head and eye movements, have suggested that its torsional position is confined to a plane and thus obeys Listing's law as does the eye when the head remains stationary. The present study reexamined this question using five normal human subjects instructed to fixate visual targets over a large range ($\pm 70^\circ$ or greater). Static eye position in space, at the end of gaze shifts, was constrained to a surface but this surface exhibited a consistent twist similar to that of a Fick gimbal (with Fick torsion=0). During gaze shifts, eye position moved out of and then back into this surface. This dynamic violation of Donders' law was in part due to the VOR acting to stabilize gaze near the end of the head movement.

The observations that the eye in space violates Listing's law statically and Donders' law dynamically suggest that the perceptual rationale for Listing's law, proposed by Hering, (that it maintains self-congruence of the retinal images of oblique lines in the outside world) should be discarded.

185.16

CONJUGACY OF HUMAN SACCADES. R. Bains, W. Cadera*, T. Vilis. Depts. of Physiology and Ophthalmology, The University of Western Ontario, London, Ontario, Canada, N6A 5C1.

The observation that the saccadic system can undergo asymmetric monocular adaptation raises the question as to how the two eyes are yoked. Are they driven by independent saccade generators, or a common saccade generator? The yoking of the two eyes was examined in five normal human subjects using a three-dimensional scleral search coil technique. Subjects made saccades from a central target to 12 radial targets at 30 degree eccentricity. The eyes were 2 meters from the central target, a distance which produced insignificant changes in vergence during saccades. Saccades to the same target showed considerable trial to trial variation in peak velocity, duration, and curvature (deviation from a linear trajectory). However, variations in one eye were mirrored by similar variations in the other eye with a high positive correlation. The mean correlation coefficients for the five subjects were 0.92 for peak velocity, 0.92 for duration, and 0.85 for curvature. The high correlation between the peak velocities suggest that saccades in the two eyes are driven by a common saccade generator. The high correlation between saccade durations and between saccade curvatures suggests that burst activity is guided by a single feedback loop. Thus, it appears that the site of independent adaptive control is distal to the feedback loop, perhaps at the level of the ocular motor nuclei.

OPTOKINETIC MOVEMENTS AND LISTING'S LAW. D. Tweed, E. Koenig*, D. Fischer*, H. Misslisch*, M. Fetter. Department of Neurology, University of Tuebingen, D7400 Tuebingen, Germany.

Saccades and pursuit follow Listing's law (i.e. they restrict eye position to 2 degrees of freedom by keeping the torsional component = 0). This restriction to 2-D does not hamper these systems, because their job is to control a 2-D variable: gaze direction. But the eye needs all 3 of its degrees of freedom to track en bloc rotation of the visual field: to stabilize the whole field on the retina, eye velocity must be matched to field velocity in all 3 dimensions. Deviations from Listing's law should occur even during horizontal full-field tracking. We used search coils to measure 3-D eye position in 7 human subjects as they tracked a field of light spots which could rotate about any axis. Eye position plots showed ocular torsion restricted to 0 ± 6 deg even during torsional tracking, because each quick phase of nystagmus restores torsion to near 0. To see whether slow phases follow Listing's law, we examined slow phase eye velocities, looking for a particular dependence on eye position characteristic of the law. An analysis program assigned scores to periods of horizontal tracking: 0 when eye velocity was independent of eye position (as required for optimal tracking), .5 for Listing's law. As a control, horizontal sinusoidal pursuit of a single red light spot superimposed on the moving field gave an average score of .50 (range .49 - .52; 3 subjects). For full field tracking, scores averaged .32 (.08 - .53; 7 subjects), i.e. perfect tracking was sacrificed to "partially follow" Listing's law. Scores were $< .5$ ($p < .05$) in all but 1 subject, even for the first 2 s of motion, suggesting that even the initial seconds of tracking are not accomplished by simple pursuit.

A SURVEY ON THE RESPONSE CHARACTERISTICS OF NEURONS LOCATED IN THE PRETECTAL REGION IN THE SQUIRREL MONKEY. J. Kröllner, F. Behrens, O.-J. Grüsser and W. Rüdiger. Physiologisches Institut der Freien Universität, Arnimallee 22, 1000 Berlin 33, Germany

Pretectal nuclei are known to be involved in the pupillary light reflex (OPN, PPN) and in the control of eye movements (NOT). In 2 awake untrained monkeys, recordings of action potentials were obtained from single pretectal neurons of both sides; eye movements were monitored by scleral search coils. The neurons recorded could be tested in 3 paradigms: (a) the monkey was placed inside a rotating drum of vertical black-and-white stripes; (b) a random dot pattern was projected onto a 90x90-degree round screen in front of the monkey which could be moved in any direction or (c) varied in brightness. Within a region of about 1 mm diameter anterior-lateral to the colliculi, we found neurons of the following response characteristics:

(1) Units sensitive to an increase in brightness and (2) units which exhibited an increase in discharge rate to darkening. Sudden steps in intensity elicited a slight overshoot in activity followed by a plateau of high activity. A short phase lead occurred in responses to sinusoidal intensity modulations between 1 and 3 Hz. The response characteristics of neurons sensitive to light or to darkening seem to be similar except for the sign of the response. The units have large uniform receptive fields. (3) Movement-sensitive units appear to respond to the retinal image motion velocity in the ipsiversive direction. There was a wide range of response characteristics to rapid onset of movement. Some transition between groups 1 and 3, and 2 and 3, were observed.

186.2

FIXATION OF A STATIONARY TARGET WITH MOVING PATTERNED BACKGROUNDS BY A MONKEY WITH BILATERAL FOVEAL LESIONS. A.A. Witkovsky, A.A. Skavanski and C.M. Accolla. Psychology Department, Northeastern University, Boston, MA 02115.

Humans and monkeys with macula scotomata readily adapt to the loss by developing a Preferred Retinal Locus (PRL) on intact eccentric retina. Using the PRL, quality of fixation on a small point of light in the dark nearly matches fixation with the fovea. We asked whether this fixation quality would be as robust in the face of prominent moving backgrounds as commonly would be encountered in normal viewing. A macaque monkey was trained to fixate on a small point. After the monkey received bilateral three degree lesions of the fovea, we tested its fixation while a 12 deg arc diameter, checkered background (check sizes of 22, 36 and 48 min arc) moved slowly, horizontally or vertically, in triangle wave motion. The moving background had a small effect on drift direction. But, the directions of the predominate normal drift directions had not changed. The variability of fixation increased only modestly compared to fixation with a dark background. We conclude that the additional stimulation of the eccentric retina had little effect on the effectiveness of slow control during fixation with the PRL.

186.3

SMOOTH PURSUIT EYE MOVEMENTS IN THE PRESENCE OF STRUCTURED BACKGROUND BY A MONKEY WITH BILATERAL FOVEAL LESIONS. C.M. Accolla, A.A. Skavenski, & A.A. Witkowsky. Dept. of Psychology, Northeastern University, Boston, MA 02115.

Loss of central vision due to retinal disease degrades performance of fine visual tasks in humans. Fixation has been shown to adapt rapidly to a new preferred retinal locus (PRL) after elimination of foveae, but saccades adapted incompletely. In the present study, the characteristics of steady-state smooth pursuit performance in the presence of homogeneous or structured backgrounds was examined. A macaque monkey was first trained to smoothly pursue a small target moving with sinusoidal motion. Foveae were then lesioned, leaving a 3 deg bilateral scotoma. Soon after lesions, tracking performance of sinusoidal and pseudorandom motion with the PRL at 2 deg eccentricity was good against dark or homogeneous illuminated backgrounds and dim structured backgrounds. When luminance of the structured background was raised, tracking was marked with frequent saccades and very little smooth component. After practice, however, performance improved dramatically and there was a shift from saccadic tracking back to smooth pursuit. Thus, the smooth pursuit system seems largely unaffected by the loss of foveal vision, and prior reports (e.g. Tamminga, 1983) of the breakdown of peripheral tracking on backgrounds may owe to the subjects' inexperience with the task.

INDUCTION OF BLINK REFLEX HYPEREXCITABILITY BY FACIAL NERVE DAMAGE. A CAUSE OF HEMIFACIAL SPASM? C. Evinger, A.K.E. Horn, J.J. Pellegrini, and M.A. Basso. Dept Neurobiology & Behavior, SUNY Stony Brook, Stony Brook, NY 11794

Excitability of the blink reflex circuit can be assessed by measuring the EMG of the lid closing muscle, the orbicularis oculi (OOemg), elicited by two identical electrical stimuli delivered to the supraorbital branch of the trigeminal nerve. With interstimulus intervals of less than 1 s, the OOemg activity evoked by the second stimulus is less than that elicited by the first stimulus. In diseases characterized by exaggerated blinking and lid closure, e.g. hemifacial spasm, the blink reflex circuit excitability increases. Hemifacial spasm appears to result from compression of the VIIth nerve at the root entry zone. This disease origin suggests that motor damage leads to modification of reflex excitability centrally.

We investigated whether facial nerve damage or partial paralysis of the orbicularis oculi muscle with botulinum toxin would modify the excitability of the blink reflex circuit in chronically prepared, alert rats. We stimulated the supraorbital branch of the trigeminal nerve while recording the evoked OOemg activity. After establishing the magnitude of the suppression of the second response (2nd response/1st response) as a function of interstimulus interval (25 - 990 ms), we removed 3-4 mm of the zygomatic branch of the facial nerve. This procedure enhanced blink reflex circuit excitability by as much as 60% in the first 10 days. Seventy-five days later, this hyperexcitability was still present. The additional observation that injection of botulinum toxin into the orbicularis oculi muscle of guinea pigs also increased blink reflex circuit excitability demonstrated that muscle weakness induced a central modification in the blink reflex circuit. Supported by NEI EY07391 and a NATO fellowship by the DAAD.

186.7

NIROSTRIAL LESIONS MODULATE THE BLINK REFLEX. M.A. Basso, C. Evinger and R.E. Strecker. Depts. Psychology, Neurobiology & Behavior, and Psychiatry, SUNY Stony Brook, Stony Brook, NY 11794

Humans with extrapyramidal movement disorders exhibit blink reflex abnormalities. For example, blink reflex circuit hyperexcitability, as shown by the reflex's resistance to habituation, is characteristic of Parkinson's disease. To investigate whether an animal model of Parkinson's disease showed blink reflex hyperexcitability, we made unilateral lesions of the nigrostriatal dopaminergic system in rats using 6-hydroxydopamine (6-OHDA) and measured blink reflex excitability. The excitability testing paradigm consisted of the presentation of two identical electrical stimuli (ISI < 1 s) to the supraorbital branch of the trigeminal nerve and measuring the evoked EMG of the lid closing muscle, the orbicularis oculi (OOemg) in chronically prepared, alert rats. On the side *contralateral* to the lesion, the OOemg evoked by the second stimulus was less than that elicited by the first stimulus, a result comparable to normal rats. On the side *ipsilateral* to the lesion, however, the OOemg evoked by the second stimulus was frequently larger than the first. This result mimics human Parkinsonism. In addition, the blink reflex ipsilateral to the lesion resisted habituation. Unlike the majority of motor problems which are contralateral to the lesion, unilateral 6-OHDA lesions and hemiparkinsonism most strongly effect the ipsilateral blink reflex. Nevertheless, in one animal, a unilateral 6-OHDA lesion increased blink reflex excitability bilaterally. The presence of vigorous amphetamine induced rotation demonstrated that the lesions were unilateral. Because of its simplicity and reliability, the blink reflex is a valuable counterpart to the more typical measures of motor deficits in models of Parkinson's disease. The paradigm is also amenable for investigating the neural mechanisms by which Parkinson's disease alters reflex excitability. Supported by a Parkinson's Disease Foundation Fellowship and NEI EY07391.

186.4

EFFECTS OF BOTULINUM TOXIN A ON THE PHYSIOLOGY AND MORPHOLOGY OF THE ORBICULARIS OCULI MUSCLE. A.K.E. Horn, J.D. Porter, C. Evinger. Dept. Neurobiol. & Behavior, SUNY Stony Brook, Stony Brook, NY 11794, Dept. Anat. & Neurobiol., Univ. Kentucky, Lexington, KY 40536

Injections of Botulinum Toxin A (BoTA) into the orbicularis oculi muscle (OO) is a treatment for lid spasms in humans. Unfortunately, these treatments must be repeated every 2-3 months to prevent spasms. We studied the time course of BoTA effect on the blink reflex by monitoring blink parameters prior to and after BoTA injection (0.02-0.3 ng) into the OO, and compared the physiological findings with structural changes in the OO. In chronically prepared guinea pigs we measured lid movements with the search coil and the OO-EMG activity during blinks evoked by electrical stimulation of the supraorbital nerve or an air puff. After post injection intervals of 4-42 days, we perfused the animals for histological examination of the OO. Within 2 days of the injection we observed a dramatic decrease of the OO-EMG and blink amplitudes that reached its maximum at 3-4 days (75-80% reduction). Gradual recovery of the blink reflex from BoTA treatment started at day 6, with blink amplitudes that recovered fully only after 42 days. The guinea pig OO muscle fiber composition is predominantly type II with some type I, similar to that of other mammals. At day 4 after BoTA treatment, the morphology of the OO did not exhibit significant pathology. Profound atrophy of both fiber types was evident at day 21, with significant recovery of fiber size by day 42. The presence of neuronal growth cones by 21 days suggested sprouting as a means of recovery from BoTA paralysis. The knowledge obtained from combined physiological and morphological investigations into the recovery from BoTA treatment may expose new strategies to eliminate the necessity for reinjection. Supported by NATO-fellowship by the DAAD, NEI grants EY05464 & EY07391.

STUDIES ON THE MECHANISM OF BLINK REFLEX SUPPRESSION. J.J. Pellegrini & C. Evinger. Dept Neurobiology, SUNY Stony Brook, NY 11794

Reflex blinks, voluntary movements and conditioning stimuli such as tones have all been shown in humans to produce suppression of the blink reflex evoked by a subsequent supraorbital (s.o.) stimulus. The mechanism(s) of these effects are unknown. The suppression caused by a reflex blink could result from the stimulus, the movement, or general arousal. In addition, the suppression could occur at a number of different sites within the reflex arc.

We utilized EMG studies and single unit recordings in a chronic guinea pig preparation to investigate the mechanisms by which a supraorbitally evoked reflex blink diminishes the blink to an impending identical stimulus. In guinea pigs, as in humans, this suppression lasts longer than 1 sec., and the later components of the orbicularis oculi (oo) EMG response show stronger suppression than the earlier ones. Our results show that this effect is not due to forewarning: non-blink evoking tones presented to guinea pigs prior to s.o. shock either facilitate the reflex or have no effect. However, both s.o. stimulation and the movement it evokes appear to contribute to subsequent reflex suppression. S.O. shock at intensities subthreshold for the reflex produces reflex facilitation at very short lead times but suppression at longer intervals. Blinks evoked by stimuli other than s.o. shock suppress the s.o. blink, but not as potently as blinks evoked by s.o. shock. The suppressive effects of the reflex blink appear to be exerted at the afferent limb of the reflex arc. Some rostral trigeminal nucleus neurons which respond to s.o. stimulation at latencies shorter than those of the ooEMG response show a time course of double shock suppression that lasts as long as that seen in the ooEMG. Moreover, the observation that large spontaneous blinks sometimes occur following reflex blinks at delays when reflex blinks are suppressed indicates that oo motor units are not fatigued or inhibited. Supported by grant EY07391.

PUPILLARY AND ACCOMMODATIVE PRE- AND POSTGANGLIONIC NEURONS IN THE MONKEY AND CAT. J.T. Erichsen, C. Evinger and P.J. May. Dept. of Neurobiology & Behavior, SUNY at Stony Brook, NY, and Depts. of Anatomy and Ophthalmology, U. of Mississippi Med. Ctr., Jackson, MS.

These studies represent a continuation of experiments aimed at anatomically defining the pupil and lens accommodation pathways in the nucleus of Edinger-Westphal (EW) and the ciliary ganglion. In cats and old world monkeys, WGA was injected into the anterior chamber of one eye and the vitreous humor of the other eye. Our expectation was that the anterior chamber injections would preferentially label the iridial pre- and postganglionic motoneurons. By contrast, because of the communicating flow from the vitreous into the aqueous, the vitreous injection was expected to label pathways to the iris as well as to the ciliary muscle. Surprisingly, the number and distribution of the transsynaptically labeled preganglionic neurons that resulted from each injection appeared to be similar. Specifically, in the cat, preganglionic neurons were found in and around the midline EW and among the exiting fascicles of NIII. In the monkey, cells were largely restricted to EW, located dorsal to the oculomotor nucleus, and to the dorsal part of the anteromedian nucleus. The proportion of postganglionic cells in the ciliary ganglion labeled by these two injections was also roughly equivalent. One possible explanation of these data is that the vitreous injection results in little or no uptake by the ciliary muscle, perhaps due to tight junctions present in the ciliary epithelium. In addition, numerous WGA-containing bouton-like endings contacted both labeled and unlabeled postganglionic cells in the ciliary ganglion. An ultrastructural analysis of the ciliary ganglion reveals transsynaptically labeled preganglionic terminals and indicates that there are at least two terminal types. In light of these results, the WGA-labeled boutons on unlabeled, possibly accommodative, ganglion cells may be collaterals from axons of either pre- or postganglionic cells. Such arrangements could yoke the firing of postganglionic neurons or mediate the near response. Supported by grants EY04587 (JE), EY07391 (CE) and EY07166 (PM).

EYE AND HEAD MOVEMENTS DURING GAZE SHIFTS TO VISUAL TARGETS ARE GOVERNED BY DIFFERENT CONTROL STRATEGIES. L. Ling*, J.O. Phillips, J.J. Florde*, and A.F. Fuchs, Regional Primate Research Center, Department of Physiology and Biophysics, and Department of Psychology, University of Washington, Seattle, WA 98195

Primates normally use a combination of eye and head movements to acquire visual targets. To determine the contribution of head movements to overall gaze movements, we studied the kinematics of targeted gaze shifts in a monkey free to move his head in the horizontal plane. For the same target step, the variability of gaze and eye trajectories was of a quite different nature. Gaze trajectories, which were relatively stereotyped, differed predominantly in their peak velocities; they saturated for movements of about 25 deg and decreased at larger amplitudes. On the other hand, head trajectories showed a high degree of variability throughout their time course, and the final head contribution at the end of the gaze shift was extremely variable. These data suggest that gaze-associated eye and head movements are controlled differently.

To evaluate this hypothesis, we stimulated the region of the omni-pause neurons (OPNs) during head-free gaze shifts. Stimulation trains of up to 150 msec duration presented randomly during gaze shifts consistently terminated the gaze movement, which then remained fixed in space roughly for the duration of the train; gaze fixation occurred because the eye saccade was terminated and the VOR was turned back on. OPN stimulation, however, did not consistently perturb the associated head movements.

These results suggest that the head and eye movements that comprise a primate gaze shift are controlled separately at the level of the OPNs. We suggest that eye movements may be driven by a gaze signal through a local feedback burst generator, which determines the amplitude of the eye saccade. Head movements, on the other hand, may be controlled by feed forward mechanisms. To ensure the accuracy of the gaze movement, the head velocity must be taken into account by the eye burst generator, which may give rise to the observed decreased peak gaze velocities with large gaze shifts.

This work was supported by NIH grants EY00745, RR00166, EY07991 and a grant from the Virginia Merrill Bloedel Hearing Research Center.

ORGANIZATION OF THE OCULOMOTOR AND EDINGER-WESTPHAL NUCLEI IN THE LESSER GALAGO. Paul J. May and Wensli Sun*, Depts. of Anatomy and Ophthalmology, U. of Mississippi Med. Ctr., Jackson, MS, 39216.

Anthropoid primates have several specializations in the organization of the oculomotor (III) and Edinger-Westphal nuclei (EW). Monkey medial rectus motoneurons are subdivided into three subgroups, the levator palpebrae motoneurons are distributed bilaterally and preganglionic motoneurons are confined within the EW, a pair of cell columns located just dorsal to III. By contrast, the cat III has a unitary medial rectus subdivision, the majority of levator motoneurons are located contralaterally, and the majority of preganglionic motoneurons are located outside the confines of the single midline EW. To determine whether the monkey pattern was general for all primates, we utilized the retrograde tracer, WGA-HRP, to define motoneuron distributions in the nocturnal prosimian, *Galago senegalensis*. Injections of the medial rectus muscle labeled motoneurons ipsilaterally in a distribution suggestive of the monkey subgroups. Levator motoneurons were distributed contralaterally in the caudal central subdivision as in the cat. Trans-synaptic retrograde labelling of the preganglionic population indicates these cells are located within the EW nucleus as in the monkey. But the EW is a single midline nucleus that runs dorsal to the III and then wraps around its rostral end to extend caudally, between the exiting IIIrd nerves, similar to the cat. This analysis was extended to the ciliary ganglion ultrastructure. Postganglionic motoneuron somata are generally devoid of synapses. Most synaptic contacts are in the perisomatic neuropil and the vast majority of presynaptic profiles have pleomorphic vesicles and make asymmetric contacts. The specialized axosomatic synapses and multiple synaptic types present in some monkeys were not observed. In sum, these results suggest that the Galago is intermediate in its development, having both monkey and cat features. Supported by NEI grant EY07166.

ACTIVITY OF MONKEY FRONTAL EYE FIELD NEURONS PROJECTING TO OCULOMOTOR REGIONS OF THE PONS. M. A. Segraves, Dept. of Neurobiology and Physiology, Northwestern Univ., Evanston, IL 60208.

The monkey's frontal eye field projects directly to oculomotor regions of the pons. These projections are an important component of the cortical system involved in the control of saccadic eye movements. I have identified the signals carried from frontal eye field to pons by antidromically exciting 25 corticopontine neurons in 2 behaving rhesus monkeys. Mean threshold and latency were 277 μ A and 2.0 ms. Most pontine stimulation sites were centered within the nucleus raphe interpositus (RIP), the location of omnipause neurons. In a few instances, the lowest thresholds for antidromic excitation were obtained from sites ventrolateral to the RIP corresponding to the location of the nucleus reticularis tegmenti pontis (NRTP) or basal pontine nuclei, both cerebellar relays.

Twenty-eight percent of the corticopontine neurons were most active during fixation and responded to visual stimulation of the fovea. Forty-eight percent had movement related activity, they were active before and during saccades made within a limited contralateral field. Most of the remaining neurons had activity related to static eye position. Cells with purely visual activity were not found. The anatomical complexity of this brainstem region combined with the spread of stimulation current make it difficult to localize the exact site of termination of these cortical neurons. It is clear, however, that the frontal eye field conveys at least two messages to cells just a few synapses away from extraocular motoneurons. The first message signals when it is appropriate to break fixation and make a saccade, the second message conveys the current position of the eyes and the amplitude and direction of the impending eye movement. For the RIP, these signals may provide the trigger to turn off omnipause cells and initiate a saccade. For the NRTP and pontine nuclei, they may help in the generation of a corollary discharge that is transmitted to the cerebellum.

THE TIMING OF THE RESPONSE OF BRAINSTEM OMNI-PAUSE NEURONES RELATIVE TO SACCADIC EYE MOVEMENTS IN RHESUS MONKEYS. A.F. Fuchs, L. Ling*, C.R.S. Kaneko, W. M. King, and Susan D. Usher*, Regional Primate Research Center and Dept of Physiology and Biophysics, University of Washington, Seattle, WA, 98195.

Brain stem omni-pause neurons (OPNs), which discharge at a steady rate during fixation and cease firing (i.e., pause) during all saccades are thought to play a pivotal role in a local feedback loop that controls the time course of saccades. During fixation the discharge of these inhibitory units keeps the saccadic burst generator inactive, whereas the pause in their activity allows burst neurons to be driven by inputs that specify the metrics of the saccade. Despite their putative central role in the control of saccades, there is little quantitative information about their discharge patterns, especially in monkeys. Therefore, we recorded from OPNs in Rhesus monkeys during spontaneous and targeted saccades.

The pause of every OPN began about 10-15 msec before the saccade. For only a few OPNs were pause and saccade duration well correlated ($r > 0.9$) and the slope of the relationship close to one. For most, the slope was less than one and the correlation coefficients ranged between 0.4 and 0.8. Moreover, almost all OPNs exhibited pauses that ended at the time or after the movement had come to rest. These data suggest that OPNs may chiefly be involved in starting the saccade. All OPNs also cease firing during blinks and often remain silent during a glissade at the end of a saccade.

Occasional OPNs have an excitatory visual response, and a few have pauses that depend on saccade direction. The scarcity of these later types suggests that OPNs may still be regarded as a single, qualitatively homogeneous population.

RESPONSE FIELDS OF NEURONS IN THE SUPPLEMENTARY EYE FIELD OF THE RHESUS MONKEY ARE RETINOTOPIC. G. S. Russo and C. J. Bruce, Section of Neurobiology, Yale Univ. Sch. of Med., New Haven, CT 06510.

The trajectory of saccades elicited by electrical stimulation can be affected by the direction of gaze at the time of stimulation. In the supplementary eye field (SEF) this gaze effect has been interpreted as indicating craniotopic coding of saccades (Schlag & Schlag-Rey, *J. Neurophysiol.*, 57: 179, 1987). We recently quantified this gaze effect for saccades elicited from SEF and hypothesized other explanations for this orbital dependence, e.g., summing a population of saccade vectors with orbitally-dependent thresholds (Russo & Bruce, *Soc. Neurosci. Abstr.* 16:899, 1990).

Here, we further studied the coding of saccades in SEF by quantitatively analyzing the effect of gaze direction on response fields of SEF neurons. Of 126 neurons with saccade-related activity, 44 had only visual activity, 24 had only movement activity, and 40 had both. For 38 of these neurons we quantitatively mapped the polar direction of the response field (θ) at three widely-spaced fixation points. The effect of gaze on θ was indexed by the regression (K) of gaze eccentricity upon θ . $K=0$ indicates a perfectly retinotopic response field whereas $K>0$ could indicate a craniotopic field. There was little overall effect of gaze on θ ; the mean K (-0.09) did not significantly differ from zero.

At the sites of 21 of these neurons we subsequently elicited saccadic eye movements with electrical stimulation through the recording electrode and measured the average saccade elicited from each of the fixation points that had been used to plot the neuron's response field. Overall, the directions of the elicited saccades matched the direction of the neuron's response field, the mean absolute difference being only 17.5°. As expected, gaze consistently perturbed the direction of elicited saccades; the analogous K having a mean (+0.52) significantly greater than zero, with all but one K being positive. K values of the corresponding neurons were significantly smaller ($t_{20} = 2.76$). Furthermore, elicited and neuronal K values were uncorrelated across sites ($R = +0.03$).

Thus the effects of gaze direction on the trajectory of electrically elicited saccades are not reflected in analogous perturbations of response fields of SEF neurons, indicating that SEF, like the frontal eye fields and superior colliculus, codes saccadic vectors and that the orbital perturbation of saccades electrically elicited from SEF does not derive from a craniotopic coding of saccades there. PROPERTIES OF VISUAL STIMULI THAT DRIVE COMPLEX SPIKES IN MONKEY FLOCCULUS. D.C. Gillespie*, R.J. Krauzlis, H.M. Bronté-Stewart and S.G. Lisberger, Dept. of Physiology and Neuroscience Graduate Program, UCSF, San Francisco, CA 94143

Complex-spikes (CSs) in the monkey flocculus are known to occur in association with image motion, but their function is unclear. To identify properties of stimuli that elicit CSs, we used small visual perturbations to mimic the image motion that normally precedes CSs. We recorded extracellularly from single Purkinje cells (PCs) in the flocculus of alert monkeys during fixation of a stationary or moving spot. We counted CSs in a 120 ms interval beginning 60 ms after the onset of perturbations that imposed 100 ms of controlled image motion at random times.

We examined the CS activity of PCs in which downward or ipsilateral eye motion caused increases in simple-spike activity. The brief motion of a small spot along a PC's preferred axis was sufficient to evoke CSs with a high probability, but did not cause a measurable eye movement. The probability of evoking a CS was independent of whether image motion was presented during fixation or tracking, and of whether the stimulus was a spot or a large texture. Tests of directionality revealed narrow tuning, with the best direction opposite that for simple spikes. CS responses were direction selective for image speeds ranging from 0.25 to 128 deg/s and exhibited broad velocity tuning between 1 and 32 deg/s. Our data imply that complex-spikes respond to visual motion and that they signal primarily the direction of image motion. (Supported by NSF Grant BNS 8616509)

MIGRATION OF SUPERIOR RECTUS MOTONEURONS TO THE CONTRALATERAL OCULOMOTOR NUCLEUS AS REVEALED WITH Dil IN CHICKEN AND MICE. D. H. Nichols, B. Fritzsche and P. R. Brauer*, Creighton Univ., Div. of Anatomy, Omaha, NE 68178

All vertebrates have oculomotor motoneurons projecting to the superior rectus muscle (SRM) of the contralateral eye. Based on silver stained material it was proposed that these cells selectively migrate over the midline (Heaton, M.B., JCN 198 (1982) 633). Recent experimental analysis in *Xenopus* were not in full agreement with this interpretation (Matesz, C. NSL 116 (1990) 1). We have re-examined this problem in chicken and mice using Dil diffusion in fixed animals. In chicken at E 6% retrograde labelling revealed only cells on the ipsilateral side; anterograde tracing showed a distinct innervation of SRM. At E 7 a population of ocular motoneurons was segregated from the ipsilateral population along the midline. At E 7% a larger ipsilateral and a smaller contralateral population was found. In mice at E 12 only ipsilateral oculomotor neurons were labelled; anterograde tracing showed a distinct innervation of SRM. At E 13 we found a larger population of ipsilateral cells and a smaller population of cells at or close to the midline; the latter cells all had dendrites to the contralateral side. At E 14 a larger ipsilateral and a smaller contralateral population was found. In both omnivorous species examined the developmental pattern is similar and consistent with the suggestion of migration of neuroblasts over the midline. The prior peripheral segregation indicates that contact formation may actually trigger migration.

A NEURAL NETWORK MODEL OF SACCADE PROGRAMMING. David L. Sheinberg*, Gregory J. Zelinsky* & Heinrich H. Bühlhoff, Dept Cog & Ling Sci, Brown University, Box 1978, Providence RI 02912.

Human saccadic programming is subject to bottom-up and top-down influences. A neural network model was developed to show how these two processes may interact to produce eye movements. The model consisted of modules loosely corresponding to presaccadic processing in the superior colliculus (SC) and cortex. Both modules received input from a simulated retina. The collicular module was divided into sensory, intermediate, and motor layers and provided a direct interpretation of the visual scene. The cortical module processed inputs based on task dependent variables such as target / non-target differentiation. Topographic connections between units in the cortical and collicular modules allowed target information to selectively enhance locations within the SC intermediate layer. Winner-take-all competition between these integrated neural images was then used to suggest a specific oculomotor target. The system was dynamic in the sense that ongoing cortical enhancement continued to affect the collicular representation while the network settled.

Psychophysical tests were used to assess the predictive validity of the model. The results indicated a qualitative similarity between human and simulated fixations. In particular, saccades to double target stimuli landed at intermediate positions in both cases. A pronounced interaction between saccadic accuracy and latency was also observed. Actual and simulated eye movements became more accurate with longer saccadic latencies. This correspondence suggests that a top-down component may affect saccadic programming by selectively enhancing target locations within a bottom-up computation.

CATCH-UP SACCADE AMPLITUDE IS RELATED TO SQUARE WAVE JERK RATE. J.A. Jesberger*, L. Friedman, L.A. Abel, L.F. Dell'Osso, H.Y. Meltzer.

A remarkably strong correlation was noted in normal controls (N=20) between square wave jerk (SWJ) rate during pursuit and mean catch-up saccade (CUS) amplitude (Spearman rho = 0.87, p < 0.0001). Eye movements were recorded with IR oculography. Target speed was 5°/s. This correlation was also present in psychiatric patients (N=38) (rho = 0.53, p = 0.0006), although it was significantly weaker than in normals (p < 0.02). The relationship between SWJ rate and CUS amplitude was specific: SWJ rate was not correlated with gain (rho = -0.07) or CUS rate (rho = 0.07). Similar strong correlations between SWJ rate during fixation and mean CUS amplitude were also found for normals (rho = 0.73, p = .0002) and patients (rho = 0.52, p = 0.0009). The rates of SWJ during pursuit and fixation were highly correlated (rho = 0.64 for normals, 0.60 for patients). These findings clearly indicate that one factor that predicts CUS amplitude is SWJ rate. The results suggest that saccadic intrusions during tracking keep the saccade correcting system "busy" and delay correction for the position error that accumulates when gain is less than 1.0.

FINE STRUCTURE OF THE EYE'S CHOROID AND ITS INNERVATION BY CHOROID NEURONS OF THE CILIARY GANGLION IN THE CHICKEN. M.F. De Stefano and E. Mugnaini. Lab. of Neuromorphology, Univ. of Connecticut, Storrs, CT 06269-4154.

The ciliary and the choroid neurons in the avian ciliary ganglion are both cholinergic but only the choroid neurons express the neuropeptide somatostatin. The two types of neuron innervate different targets in the eye. Recent evidence points to an influence of the target on somatostatin expression by the choroid neurons. Thus, a thorough analysis of the fine structure of the choroidal coat is appropriate. This coat is a complex tissue containing blood vessels, lacunae and trabeculae. The blood vessels are lined by an endothelium of the tight variety (continuous endothelial cells with conspicuous tight junctions and scarce plasmalemmal vesicles). Smooth muscle fibers in the vessels' walls contact the endothelial lining at points where the basal lamina is interrupted. The lacunae are limited by a thin mesothelial lining. The trabecular framework consists of smooth muscle fibers, extracellular collagen matrix, fibroblasts and pigmented cells, many of which are apposed to the mesothelial cells and contact their surface at points. Choroid nerves, ensheathed by Schwann cells, run within the trabeculae and innervate the smooth muscles in the vessels' wall and in the trabeculae themselves with similar boutons containing clear round vesicles and dense core vesicles. The choroid fibers have been immunostained for ChAT and somatostatin and the two markers are presumably colocalized in the same boutons. The only cells in physical contact with the choroidal nerve endings are the Schwann cells and the vascular and trabecular smooth muscle. Supported by a fellowship of the Italian M.P.I. and USA NIH grant NS-09904.

HUMAN VISUAL-VESTIBULAR INTERACTION DURING PASSIVE AND ACTIVE VERTICAL HEAD MOVEMENTS (HM). J. L. Demer, J. G. Oas, R. W. Baloh, and L. A. Hovis. Jules Stein Eye Institute and Department of Neurology, University of California at Los Angeles, 90024.

To investigate gaze stabilization during vertical HM, we measured gain (eye velocity/head velocity) of eye movements during passive, as well as voluntary, active pitch HM under several visual conditions.

Eye and head movements of normally sighted subjects were measured using magnetic search coils. Subjects were trained to make active sinusoidal HM (0.4 - 6.0 Hz) in synchrony with an audible tone varying in pitch. Passive, whole-body rotation (0.4 - 3.2 Hz) was obtained using a servo-driven swing rotating about the interaural axis. The vertical vestibulo-ocular reflex (VOR) was tested in darkness. The visually enhanced VOR was tested in light with normal vision (1X) and with 2X binocular telescopic spectacles (2X).

Robust VOR was observed during both active and passive vertical HM, with gain varying slightly from 1.0. During active HM, gain during 1X viewing was 1.0 over the entire spectrum tested. With 2X viewing, gain was ~2.0 at low frequencies, declined with increasing frequency, and remained significantly >1.0 even at maximum frequencies of voluntary HM achieved. During passive HM less 2X gain enhancement occurred than during active HM. Significant relative visual enhancement of gain during 2X viewing was observed up to maximum frequencies of 1.5 - 2.5 Hz, but was absent for higher frequencies.

Since visual and vestibular inputs are identical during active and passive vertical HM, these data suggest that neck proprioception and/or skeletal motor efference copy produce important additional gain modulation in visual-vestibular interaction during active HM at frequencies above the range of the pursuit system.

SEROTONIN DIRECTLY EXCITES NEONATAL HYPOGLOSSAL MOTONEURONS. A.J. Berger, D.A. Bayliss, and F. Viana. Department of Physiology & Biophysics, University of Washington School of Medicine, Seattle, WA 98195.

Serotonin (5-HT)-containing nerve fibers and terminals have been demonstrated in the hypoglossal nucleus (*Brain Res. Bull.* 23: 249-256, 1989) and 5-HT-containing boutons have been observed in close apposition to identified hypoglossal motoneurons (HMs) (*Brain Res.* 538: 215-225, 1991). These anatomical results suggest that 5-HT can directly modulate the excitability of HMs. To test this hypothesis, we investigated the effects of bath-applied 5-HT to neonatal (P3 to P10) rat HMs in two separate *in vitro* brainstem slice preparations.

One preparation employed conventional intracellular microelectrode recording from thick (400 μ m) slices. The other used thin slices (approx. 130 μ m) to record whole-cell currents from visualized HMs with patch type electrodes. In all cases (12 HMs to date), bath-applied 5-HT (10 μ M) caused either reversible depolarization (current-clamp mode) or generation of an inward current (voltage-clamp mode). 5-HT also caused an increase in spontaneous synaptic activity. Bathing the slice in a nominally Ca^{2+} -free solution containing TTX (1 μ M) and 2 mM Mn^{2+} abolished the synaptic effects, but the excitation was maintained.

These results are in contrast to a recent report in which bath-application of 5-HT was found to depress rhythmic hypoglossal nerve activity in the neonatal brainstem-spinal cord preparation (*Neurosci. Letters* 111: 127-132, 1990). Because synaptic effects were not ruled out in that study, we suggest that 5-HT inhibitory effects are probably mediated at a site presynaptic to the HM, and that the direct effects of 5-HT on HMs are excitatory. (Supported by NS 14857).

ONTOGENESIS OF MOTONEURON ELECTRICAL PROPERTIES: ROLE OF CALCIUM AND CALCIUM-ACTIVATED CONDUCTANCES. F. Viana, D. A. Bayliss, and A. J. Berger. Department of Physiology & Biophysics, University of Washington School of Medicine, Seattle, WA 98195.

We examined the membrane and firing properties of rat hypoglossal motoneurons (HMs) during various stages of development (P2 to P12 and adult). Intracellular recordings were performed in brainstem slices (400- μ m) using standard techniques. At P2, HMs were already capable of firing repetitively in response to intracellular current injections. Firing was blocked by TTX.

Firing of young HMs (<P6) differed markedly from that of adult HMs. The action potential of young HMs repolarized less rapidly, was followed by a larger afterdepolarization (ADP) and a longer afterhyperpolarization (AHP). ADP was voltage-dependent, being enhanced in amplitude at negative membrane potentials. The pharmacology of ADP and AHP was similar at all stages. ADP was absent in zero Ca^{2+} solution, enhanced by high Ca^{2+} or Ba^{2+} , and blocked by Mn^{2+} ; ω -conotoxin had no effect. AHP was also Ca -dependent: it was absent in zero Ca^{2+} , enhanced by high Ca^{2+} , blocked by apamin, ω -conotoxin, Ba^{2+} and Mn^{2+} . A functional consequence of this prolonged AHP was lower minimal and maximal firing rates for young HMs. Also, young HMs often showed rebound burst firing after hyperpolarizing current pulses. This burst firing was blocked in zero Ca^{2+} and was not present in adult HMs.

Ca^{2+} currents were studied in isolation (intracellular Cs^{+} , extracellular TEA, TTX and 4-AP) in HMs (P3 to P10) using whole-cell voltage-clamp recordings in a thin-slice preparation. We identified two Ca^{2+} currents: a transient low-voltage-activated (LVA) and a high-voltage-activated (HVA) with inactivating and non-inactivating components. Both LVA and HVA currents were blocked by zero Ca^{2+} or inorganic Ca^{2+} blockers.

Collectively our results suggest a crucial role for Ca^{2+} and Ca^{2+} -activated K^{+} currents in the normal firing of HMs at all postnatal ages, with a more prominent role of the LVA Ca^{2+} current at early stages. (Supported by NS 14857)

5-HT₁ RECEPTORS MEDIATE 5-HT-INDUCED DEPOLARIZATIONS IN IMMATURE MOTONEURONS. B.S. Seebach and L. Ziskind-Conhaim. Dept. Physiol., Univ. of Wisconsin, Madison, WI 53706.

The pharmacological profile of serotonin-mediated potentials was studied in the isolated spinal cord of embryonic (Days 18-21) and neonatal (1-to-3-day-old) rats. Serotonin (5-HT) produced long-lasting depolarizations and high-frequency subthreshold potentials. The subthreshold potentials, but not the long-lasting depolarizations, were blocked by high Mg^{2+} and TTX, indicating that 5-HT affects both motoneurons and interneurons. 5-CT and α -methyl-5-HT were the only agonists that induced motoneuron depolarizations and subthreshold activity. 8-OH-DPAT depolarized motoneurons without generating subthreshold potentials, while DOI and 2-methyl-5-HT had no effect. Methysergide was the only antagonist that completely blocked 5-HT-induced potentials. Ketanserin, spiperone, and MDL 72222 only partially blocked the long-lasting depolarizations and subthreshold potentials. These findings suggest that 5-HT₁ receptors, or an unidentified receptor subtype, mediate 5-HT responses in embryonic spinal cord. Supported by NIH grants NS01314 and NS23808.

187.2

THYROTROPIN-RELEASING HORMONE DECREASES A POTASSIUM CONDUCTANCE IN HYPOGLOSSAL MOTONEURONS *IN VITRO*. Douglas A. Bayliss, Felix Viana and Albert J. Berger. Department of Physiology and Biophysics, University of Washington School of Medicine, Seattle, WA 98195.

The hypoglossal motor nucleus is innervated by fibers containing the neuropeptide thyrotropin-releasing hormone (TRH) and contains TRH binding sites. We therefore investigated the effects of TRH on hypoglossal motoneurons (HMs) in transverse slices of rat brainstem using conventional single-electrode (3 M KCl) recording techniques (i.e., current- and voltage-clamp). TRH (0.1 to 10 μ M), applied either by perfusion or by pressure microinjection, caused a depolarization and/or the development of an inward current in all HMs tested (n=37). These effects were fully reversible, dose-dependent, and showed only modest desensitization with repeated applications. In addition, although TRH increased synaptic activity in most cells, the depolarizing response to TRH was maintained in a tetrodotoxin-containing (0.5 μ M) or in a Ca^{2+} -free perfusate containing 2 mM Mn^{2+} in which synaptic effects were abolished. Thus, TRH directly depolarizes HMs. Constant current or voltage steps applied to the neuron during TRH application revealed that the depolarization (inward current) was associated with an increased input resistance (decreased conductance), suggesting involvement of a K^{+} conductance. Consistent with this hypothesis, extrapolated instantaneous current-voltage relationships obtained before and at the peak of the TRH response intersected at approximately -100 mV, the expected K^{+} equilibrium potential (E_K). Moreover, the TRH-induced depolarization was reversibly diminished when extracellular $[K^{+}]$ was raised from 3 to 12 mM, and enhanced in amplitude from depolarized potentials (i.e., further from E_K). These data are inconsistent with an effect on a Cl^{-} conductance, as E_{Cl} would be displaced to depolarized potentials by the KCl-containing electrodes. Thus, we conclude that TRH directly depolarizes hypoglossal motoneurons by decreasing a resting K^{+} conductance. (Supported by NS 14857)

FREQUENCY MODULATION OF THE NMDA AND NON-NMDA RECEPTOR-MEDIATED EPSPS IN THE NEONATAL RAT SPINAL CORD. M. Pinco and A. Lev-Tov. Dept. of Anatomy, The Hebrew Univ. Sch. of Med., Jerusalem, Israel.

Intracellular recordings of EPSPs generated in α -motoneurons by dorsal root afferents in the neonatal rat spinal cord revealed a slow voltage dependent component as the Mg^{2+} in the bathing medium was reduced to 1/4 of its normal level. The slow component was identified as an NMDA receptor mediated EPSP and could be separated pharmacologically from the predominant non-NMDA component. The present study, characterizes the frequency modulation of the NMDA and non-NMDA EPSP components simultaneously (using time window analysis), and separately (using the specific NMDA and non-NMDA blockers APV and CNQX, respectively). Both components exhibited prolonged EPSP-depression [Lev-Tov et al. *Neurosci. Abs.* 16, 1015, 1990], with similar kinetics and frequency dependence. As the baseline of transmitter release was lowered by application of 2 μ M L(-) baclofen to the bath, the prolonged EPSP depression was virtually abolished and could be transformed into frequency facilitation and potentiation. Again, the time course and frequency dependence of facilitation and potentiation were virtually identical for the NMDA and non-NMDA receptor mediated EPSP components. Our findings suggest that the EPSPs generated by dorsal root afferents in α -motoneurons in the neonatal rat spinal cord are mediated by activation of postsynaptically co-localized NMDA and non NMDA receptor sub-types.

DEPLETION SUPERSENSITIVITY TO SEROTONIN IN SPINAL MOTONEURONS OF RAT EMBRYOS. B.-X. Gao, M.A. Sweet* and L. Ziskind-Conhaim. Dept. Physiol., Univ. of Wisconsin, Madison, WI 53706.

In embryonic motoneurons, the time course of the changes in serotonin-induced depolarizations was correlated with the growth of serotonergic (5-HT) projections into the ventral horn. To determine the functional role of 5-HT in inducing these changes, 5-HT synthesis was blocked by p-chlorophenylalanine (p-CPA). Starting at Days 7-10 of gestation, daily p-CPA injection (100mg/kg) to pregnant rats resulted in a depletion of 5-HT in the spinal cords of 17 to 21-day-old embryos. Injections of control saline solution did not result in significant changes in the growth pattern of 5-HT projections in the ventral horn. In the absence of 5-HT in the nerve terminals, 5-HT responses increased. In Day 19-21 embryos, the amplitude of 5-HT induced motoneuron depolarizations increased from an average of 7 mV in control motoneurons to 14mV in p-CPA-treated spinal cords. This supersensitivity may be due to an increase in the number or binding affinity of 5-HT receptors, or a change in 5-HT receptor type(s) mediating motoneuron depolarizations. Supported by NIH grants NS01314 and NS23808.

MULTIPLE EFFECTS OF HYPOXIA ON NEURONS IN DORSAL MOTOR NUCLEUS (X) AND NUCLEUS TRACTUS SOLITARI (NTS). J.B. Dean, E.A. Gallman, W.H. Zhu* and D.E. Millhorn. Dept. of Physiology, Univ. of N. Carolina, Chapel Hill, NC 27599.

Whole-cell recordings were made in NTS and X neurons in 400µm slices prepared from adult rat. Slices were maintained in a medium-gas interface (35-37°C) aerated with (control) 95%O₂-5%CO₂, (hypoxia) 95%N₂-5%CO₂ or 85%N₂-5%CO₂-10%O₂. Four responses were observed during hypoxia (2-15 min) in NTS and X. 1) 14% of neurons were hyperpolarized, sometimes transiently, accompanied by decreases in synaptic activity, R_{in}, and excitability (spontaneous & evoked spikes) and increased net outward current. 2) 25% of neurons were depolarized and showed increased excitability, spike broadening, increased or unchanged synaptic activity, and increased net inward current. R_{in} was increased, decreased or unchanged. 3) 16% of neurons were depolarized as in 2 but with unchanged or reduced excitability. Both depolarization and hyperpolarization were maintained in TTX or high Mg⁺⁺-low Ca⁺⁺ synaptic blockade. 4) 45% of neurons were insensitive showing no change in excitability, spike waveform, R_{in}, or synaptic activity. We conclude that some neurons respond to hypoxia with multiple ionic mechanisms whereas other neurons are resistant showing no change in excitability. Maintenance of excitability and synaptic integrity by certain neurons in NTS and X during hypoxia may prevent compromised cardiorespiratory function. (NSF, NIH, ALA)

OPIOIDERGIC MODULATION OF REFLEXES EVOKED BY MECHANICAL STIMULATION OF THE HEEL IN THE RABBIT. J. Harris, T.W. Ford & R.W. Clarke* (Spon: Brain Research Association). Dept. Physiology & Env. Sci., Univ. Nottingham, Sutton Bonington, LE12 5RD, U.K.

We have examined the effects of the opioid antagonist quadazocine on reflex responses elicited in the motoneurons of gastrocnemius medialis (GM) by controlled mechanical stimulation of the heel. Five rabbits were decerebrate and spinalized at the lower thoracic level under halothane (2-4%)N₂O anaesthesia. Reflexes were evoked by single pinches of 1s duration applied to the skin of the heel by an electronically-triggered, pressure-driven pinching device. Responses were recorded from the central end of the cut, desheathed GM muscle nerve, and were quantified by integrating the instantaneous firing rate of the whole nerve. Four pinch forces were used: 0.12 ± 0.03, 0.41 ± 0.07, 1.88 ± 0.12 and 4.5 ± 0.12N of which the lowest force was barely perceptible, and only the most intense evoked pain when tested on ourselves. In untreated animals the lowest intensity pinch evoked no response in GM, whereas the strongest pinch elicited a response which had a mean duration of 2.4 ± 0.5s and which consisted of 560 ± 50 spikes during the pinch, and an afterdischarge of 458 ± 165 spikes. (+)-Quadazocine (500µg/kg i.v.) had no effect on reflex responses in GM. (-)-Quadazocine was given i.v. in cumulative doses of 1 to 156µg/kg and caused a dose-dependent increase in reflex responses evoked by all strengths of stimulation. After the top dose of the opioid antagonist, the 0.12N pinch elicited reflexes of mean duration 2.1 ± 0.7s, with 220 ± 73 spikes fired during the pinch and 283 ± 115 afterwards: the corresponding values for the 4.5N pinch were 6.9 ± 0.7s, 690 ± 66 and 1840 ± 441 spikes respectively. These findings show that endogenous opioid peptides tonically and non-selectively inhibit reflex pathways to GM motoneurons from both high- and low-threshold cutaneous afferents.

LONG-TERM EFFECT OF SPINAL CORD HEMISECTION ON GABA_B BINDING IN THE RAT SUBSTANTIA GELATINOSA. J.S. Kroin, G.D. Bianchi, and R.D. Penn. Dept. of Neurosurgery, Rush Medical College, Chicago, IL 60612.

At present, it is not known why a severe spinal cord lesion in humans often leads to the development of spasticity. To study one of the mechanisms that might accompany spinal cord injury in humans, we examined long-term GABA_B receptor changes following a spinal lesion in rats. Midthoracic hemisections were performed in adult female rats and one year later the lumbar spinal cords were analyzed by quantitative autoradiography (Bowery, et al, *Neurosci*, 20:365,1987). On the hemisected side, as compared to the normal side, there was a small increase in density (B_{max} increased 12%) of GABA_B receptors in the substantia gelatinosa of the dorsal horn. In addition, there was a moderate change in affinity (K_d increased 26% on the lesioned side). Therefore, in this model of spinal injury, there are small but statistically significant changes in the GABA_B receptor system.

AGE-DEPENDENT EFFECTS OF BICUCULLINE AND STRYCHNINE ON DORSAL ROOT-EVOKED POTENTIALS. W-L. Wu* and L. Ziskind-Conhain. Dept. Physiol., and Ctr. Neurosci., Univ. of Wisconsin, Madison, WI 53706.

Starting at Day 16 of gestation (birth is at Days 21-22), dorsal root stimulation evoked long-latency excitatory and inhibitory depolarizing potentials in spinal motoneurons of rat embryos. The contribution of the inhibitory inputs to dorsal root-evoked potentials was studied by blocking GABA- and glycine-mediated transmission with bicuculline (20 µM) and strychnine (10 µM). These antagonists affected dorsal root-evoked potentials differently at early and late gestational stages. At Days 16-18 of gestation, either antagonists significantly decreased the amplitude of the long-latency potentials, while at Days 19-21 each potentiated it. These findings suggest that some changes in synaptic transmission occur between Days 17 and 19 of gestation. At the same developmental stages, there was a reduction in motoneuron responses to GABA and glycine. The average amplitude of GABA- and glycine-induced depolarizations (in the presence of TTX and high Mg²⁺) decreased from 9 mV at Day 17 to 5 mV at Day 19. Supported by NIH grants NS 01314 and NS 23808.

PONTOSPINAL ENKEPHALINERGIC PATHWAYS AND THEIR EFFECTS ON SPINAL REFLEX EXCITABILITY OF THE CAT. H. Zhuo*, S.J. Fung and C.D. Barnes. Department of VCAPP, Washington State University, Pullman, WA 99164-6520.

Our previous studies have shown that more than 70% of the noradrenergic coeruleospinal neurons in the locus coeruleus complex (LC) of the cat co-contained enkephalin.

The present experiments, performed on decerebrate cats, were done in order to test the effects of the descending enkephalinergic pathways on spinal monosynaptic reflex (MSR) excitability. The MSR of flexor and extensor motoneuron pools were recorded from the cut L7 or S1 ventral root of the spinal cord when stimulating the peripheral nerves ipsilaterally. The effect of Naloxone, an opioid antagonist, on the LC-induced early facilitation phase and the late inhibition phase of the MSR were studied. Both the early facilitation and late inhibition phases of the MSR response were decreased by systematic injection of Naloxone (0.5-2 mg/Kg). The antagonistic action of Naloxone on the descending enkephalinergic influence was dosage-dependent and reversible. Vehicle (saline) control experiments were without effect on LC-induced MSR changes.

The results of the present study indicated the early facilitation and the late inhibition of the MSR conditioned by stimulation of the LC involved the descending enkephalinergic pathways. (Supported by NIH grants NS24388 and 11H-2940-8751).

ACETYLCHOLINE RELEASE IN THE ATONIA MEDIATING REGIONS OF THE CAT MEDULLA. T. Kodama, Y.-Y. Lai and J.M. Siegel UCLA. Sch. Med. and VAMC, Sepulveda, CA 91343

The medial medullary reticular formation is an area mediating muscle atonia in REM sleep. We reported in previous studies that a rostral medullary region, N.magnocellularis(NMC), is responsive to glutamate and that a caudal region, N. paramedianus(NPM), is responsive to ACh. The present study was designed to investigate endogenous ACh release during the sleep-wake cycle in these two areas.

Twelve samples were obtained from both NMC and NPM during each stage of wake(W), SWS and REM. A two way ANOVA demonstrated that the amount of ACh release across sleep-wake stages was different in NMC and NPM. In NMC, the mean level of ACh release was significantly higher during REM sleep(55.78±2.87 fmole/min perfusate)(p<0.001) and W(54.83±3.67)(p<0.01) than that during SWS(49.67±3.13). However, levels of release in W and REM sleep did not differ. In contrast, the mean levels of ACh release in NPM during REM sleep(31.66±1.75) were 31% higher than those during SWS (24.22±1.25) and 35% higher than those during W(23.45±1.64). These differences were significant(p<0.001). This profile of ACh release in NPM across the sleep-wake cycle resembles that in the dorsal tegmental field, where cholinergic agonists induce muscle atonia. This enhancement of ACh release in NPM during REM sleep supports our hypothesis that cholinergic neurons in NPM mediate REM sleep processes.

GLUTAMATERGIC PROJECTIONS TO PERI-LOCUS COERULEUS α . J.R. Clements, Y.Y. Lai, S.J. Grant and J.M. Siegel. Dept. of Vet. Anatomy and Public Health., Texas A&M Univ., College Station, TX 77843; Dept. of Psychol., Univ. of Delaware, Newark, DE 19716; and Dept. Psychiatry, UCLA, and Neurobiol. Res. VAMC, Sepulveda, CA 91343.

Microinjection of acetylcholine into the dorsolateral pons has long been known to produce a suppression of muscle tone and REM sleep phenomena. The source of cholinergic projections to this region has been identified as the pedunculopontine (PPN) and laterodorsal tegmental (LDT) nuclei. Recently we demonstrated that glutamate microinjection in the same region also produced muscle tone suppression in the decerebrate cat. To determine the source of the glutamatergic projection to this region, we microinjected WGA-HRP at sites where muscle tone suppression was induced by glutamate injection and then labeled neurons containing the retrogradely-transported WGA-HRP with TMB. In tissue sections containing retrogradely-labeled neurons, NADPH-diaphorase histochemistry was used to identify cholinergic cells and an anti-glutamate antibody was used to immunocytochemically label glutamate-like immunoreactive neurons. Glutamate-like immunoreactive cells projecting to the peri-locus coeruleus α were found in the rostral PPN, FTP and ventral pons, including TRC. The glutamate-like immunoreactive neuronal population projecting to the injection sites was largely distinct from the cholinergic projection, however in caudal PPN some retrogradely labeled cells were both glutamate-like immunoreactive and NADPH positive. The coordinated activation of glutamatergic and cholinergic cells in the PPN may be responsible for the suppression of muscle tone in REM sleep.

MEDULLARY CONTROL OF LOCOMOTION AND MYOCLONIC JERKS. Y.Y. Lai and J.M. Siegel. Dept. Psychiatry, UCLA, and Neurobiol. Res. VAMC, Sepulveda, CA 91343.

Myoclonic jerks are a common clinical problem. We have demonstrated that corticotropin-releasing factor (CRF) and non-NMDA agonists microinjected into nucleus magnocellularis (NMC) of the medulla produce muscle atonia, while NMDA agonists produce increased muscle tone and/or locomotion. The present study was designed to determine the effect of glutamate and CRF on spontaneous or mechanically induced increases in muscle activity and myoclonus. Spontaneous locomotion or myoclonic jerks were present after the second day post decerebration and could also be induced by insertion of a microinjection needle into the medulla. Microinjection of CRF (10 nM), kainic acid (0.1-0.2 mM), and quisqualic acid (1 - 10 mM) into NMC blocked locomotion and myoclonic jerks for only 2.6-5.4 min. However, APV (50 mM), an NMDA antagonist, blocked locomotion or myoclonic jerks for more than 3 h. Thus CRF and non-NMDA agonists not only produce muscle tone suppression but also block spontaneous myoclonic jerks and locomotion. Furthermore, locomotion and myoclonus could be blocked by NMDA antagonists, which do not suppress muscle tone. We hypothesize that locomotion and myoclonic jerks in the decerebrate cat are mediated by NMDA receptors in NMC.

BLOCKADE BY STRYCHNINE OF THE INHIBITION OF MASTICATORY MOTONEURONS INDUCED BY MEDULLARY STIMULATION. Pablo Castillo,* Cristina Pedraza,* Francisco R. Morales, and Michael H. Chase. Dept. de Fisiología, Facultad de Medicina, Montevideo (Uruguay), the Brain Research Institute, Dept. of Physiology, University of California, Los Angeles, CA 90024.

Stimulation of the parvocellular reticular formation (PcRF) results in the induction of short latency IPSPs in trigeminal (jaw-closer and jaw-opener) motoneurons (Brain Research 535 [1990] 339-342). The present study was performed to determine whether glycine is the neurotransmitter that mediates these IPSPs. Experiments were conducted on 3 anesthetized cats (Nembutal 40 mg/kg, i.p.). Seventeen motoneurons were recorded before and ten following the intravenous injection of strychnine nitrate (0.2 mg/kg). IPSPs in trigeminal motoneurons were first evoked by stimulation of the PcRF (80 μ A, 0.2 ms; P13-14, L2.0-2.5, H -6.0 to -8.0). Following the application of strychnine, these IPSPs were no longer present. Strychnine also suppressed the short lasting glycinergic component of the inferior alveolar nerve-induced IPSP, whereas the longer lasting GABA-mediated IPSP of inferior alveolar nerve origin was resilient to the effects of this drug. We conclude that glycine, or a structurally-similar inhibitory amino acid, is the neurotransmitter released by the PcRF pathway whose activation results in the non-reciprocal inhibition of trigeminal motoneurons. NEURAL MECHANISMS OF ACOUSTIC STARTLE REFLEX: ANATOMICAL ANALYSIS USING C-FOS. M.-F. Wu, H. M. Fahringer*, T. S. Kilduff, & J. M. Siegel. Neurobiol. Res., VA Med. Ctr., Sepulveda, CA 91343, Dept. Psychiatry, UCLA, Los Angeles, CA 90024, & Dept. Psychiatry, Stanford Univ., Stanford, CA 94305

The neural structures mediating the primarily acoustic startle reflex have been investigated previously using lesioning, electrical stimulation, and anatomical tracing techniques (cf. Davis et al., 1982; Pellet, 1990). Anatomical analysis of the startle circuit at the cellular level, however, has not been done. These kind of analyses are crucial for a better understanding of the elicitation and modulation of startle (Wu et al., 1988).

The fos proto-oncogene (c-fos) has been proposed to function as the third messenger in a stimulus-transcription coupling cascade that converts external stimuli into intracellular long-term genetic action (Curran, 1988). Fos expression in the cell nuclei can be induced by many external stimuli. The present study employed Fos immunohistochemistry to determine the structures activated during startle elicitation.

Cats were given *p*-chlorophenoalanine (PCPA) for 4 days (125 mg/kg/day, IP). This procedure has been shown to enhance startle and reduce habituation (Wu et al., 1990). They were presented with 115 dB, 20 msec noise bursts once every 5 sec for 2-2.5 hr. Cats given no stimulation served as the controls. Cats were sacrificed at the end of the stimulation followed by immunohistochemical procedures for Fos.

Within the primary startle circuit identified previously, Fos-immunoreactive nuclei were found in the cochlear nucleus, nucleus of the lateral lemniscus, and less heavily, ventral pontine reticular formation. In addition, consistent Fos expression was found in structures that have been shown to modulate startle, e.g., inferior colliculus, nucleus cuneiformis, raphe, and central gray. By combining retrograde tracing techniques, this procedure can provide detailed analysis of the neural mechanisms of startle modulation. SPONTANEOUS MOTOR RHYTHM AND GLYCINE EFFECTS ON RHYTHM GENERATION IN MOUSE SPINAL CORD, IN VITRO. Y. Tao* and M.H. Droge. Dept. of Biol., Texas Woman's Univ., Denton TX 76204.

EMG patterns in the gastrocnemius (G) and tibialis anterior (TA) muscles of spinal cord-hindlimb explants from neonatal mice were investigated. Compared to non-hemisectioned explants, neither hemisection of the spinal cord nor hemisection plus transection at L1 significantly altered the incidence of spontaneous motor rhythm. Therefore, not only does each half of the neonatal spinal cord contain sufficient circuitry to generate motor rhythm but the more reduced preparations were just as likely to produce such activity. Hemisectioned preparations, however, exhibited slower spontaneous rhythm. In all explants tested, sequences of spontaneous rhythm occurred in either the G or TA muscle, but not in both muscles simultaneously.

Bath applications of 1-3mM glycine had excitatory as well as inhibitory effects on EMG activity. Glycine as well as its antagonists not only failed to block ongoing rhythmic activity, but could evoke rhythm in previously nonrhythmic explants. The observed excitatory effects from glycine perfusions may reflect: 1) disinhibition; 2) functional immaturity of glycine₁ receptors; and/or 3) NMDA-associated depolarizations via glycine₂ receptors. Since strychnine (a glycine₁ receptor antagonist) and cycloleucine (a glycine₂ receptor antagonist) could evoke motor rhythm when given separately or in combination, glycine transmission appears not to be required for motor pattern generation in mice. The fact that synchronized bursting in G and TA muscles occurred only in the presence of either or both glycine antagonists, suggests that glycine does provide some reciprocal inhibition between their motor nuclei.

THE EFFECTS OF EXCITATORY AMINO ACID RECEPTOR ANTAGONISTS, CNQX AND CPP, ON TRANSMISSION OF RHYTHMICAL MASTICATORY DRIVE TO BRAINSTEM INTERNEURONS DURING FICTIVE MASTICATION. T. Inoue*, N. Hashimoto*, D. Junge and S.H. Chandler. Dept. of Kinesiology and the Brain Research Institute, UCLA, Los Angeles, CA 90024

Previous pharmacological experiments from our lab suggest that transmission of rhythmic masticatory drive from premotoneurons to jaw-opener motoneurons during rhythmic masticatory activity in paralyzed guinea pigs (RMA) is mediated, in part, by excitatory amino acid (EAA) receptor activation. During RMA, many brainstem trigeminal premotoneurons and interneurons are rhythmically active, yet there is no information regarding the contribution of EAA subtypes in transmission of the masticatory drive signal to these brainstem neurons. Therefore, the present study was performed using classical extracellular single unit recording and microiontophoretic techniques. In ketamine/urethane anesthetized, and paralyzed guinea pigs, repetitive stimulation (30-40Hz) of the masticatory area of the cortex was used to evoke fictive mastication (RMA). Extracellular recordings of rhythmically active brainstem neurons were made through a glass pipette attached to a five-barreled microelectrode. Responses of neurons during RMA were challenged with either kainate, quisqualate, N-methyl-D-aspartate (NMDA), 6-cyano-7-nitroquinoxaline-2,3-dione (CNQX) or 3-(2-carboxypiperazine-4-yl)-propyl-1-phosphonic acid (CPP). The results are summarized as follows: 1) Application of EAA agonists induced rhythmic spike discharge in previously silent neurons during RMA, 2) application of the specific non-NMDA antagonist CNQX reduced rhythmic spike activity by greater than 50% whereas CPP, a specific NMDA antagonist, reduced activity less than 50% of control. Simultaneous application of both antagonists at individual doses 1/2 that were shown previously to reduce rhythmic spike discharge produced greater reductions than individual application of either antagonist at 2 times the combined dose. The results suggest that excitatory amino acids may be involved in activation and/or modulation of rhythmic discharge of brainstem interneurons involved in RMA. Supported by NIH grant DE 06193.

ADRENERGIC AGENTS INFUSED INTO THE MEDIAL PONTINE RETICULAR FORMATION (mPRF) MODULATE REM SLEEP AND UNIT ACTIVITY IN BEHAVING CATS.

M. Bier and R.W. McCarley. Lab. Neuroscience, Harvard Medical School/VAMC, Brockton, MA 02401

Adrenergic input to the mPRF has been postulated to play a role in the control of REM sleep. In vitro studies from our lab indicate that a majority of mPRF neurons have α_1 -mediated depolarizing responses and a minority have α_2 -mediated hyperpolarizing responses to norepinephrine (NE), with almost no neurons displaying both responses. We postulated that clonidine (CL, an α_2 agonist) microinjected in vivo would suppress REM sleep and associated unit activity while phenylephrine (PE, an α_1 agonist) might enhance REM sleep, since cholinergic agonists such as carbachol (CARB) which depolarize mPRF neurons induce a REM sleep-like state. A series of microinjections into the mPRF of NE, CL and PE (each 55 nmol, 0.5 μ L) were performed at sites effective in producing at least a 3-fold increase in REM sleep in response to CARB (all sites histologically localized to mPRF). REM sleep was significantly decreased in the first hour and over the entire 4 hr recording following both CL (-96% hr 1, -89%, all 4 hr) and NE (-88.0%, -50%). PE significantly increased REM (+395%) in the fourth hour only. Paralleling REM state changes, NE and CL produced a significant reduction in unit activity during REM but not the other states. PE altered unit activity only in the last hour, increasing the firing frequency during REM. These data indicate a REM-suppressive effect of CL, presumably by action at an α_2 receptor. NE had effects on REM which paralleled CL, suggesting α_2 receptors in the mPRF play an important role in REM sleep, and may be preferentially localized to neurons important in regulation of this state.

EFFECTS OF CLONIDINE, CYPROHEPTADINE AND BACLOFEN ON KNEE SWING IN SPINAL CORD INJURED (SCI) HUMANS. P.W. NANCE, F. HU*. Dept. of Medicine, U. Manitoba, Winnipeg, Man., CANADA

In ten SCI subjects, the ability of the lower leg to swing about the knee in response to passive knee extension and flexion was tested before, during and after treatment with putative antispasticity agents: clonidine (an α_2 noradrenergic agonist), cyproheptadine (a 5-HT₂ antagonist) and baclofen (a GABA-b agonist). Also, the subjects' leg tone was graded using the Ashworth scale (AS). The pendulum score (PS) was recorded using an electrogoniometer attached via velcro straps about the knee (subject sitting and supine), the number of swings greater than 40 degrees over three seconds after the foot was released was summed. In the drug free period, the PS of the subjects sitting correlated with the AS, $r=.94$. Both scores were reduced similarly by clonidine and cyproheptadine; whereas, the AS was most reduced and the PS was least reduced by oral baclofen. The PS of the subjects in a supine position was minimally changed by these treatments. Intrathecal baclofen in four of these subjects produced the greatest change in all measurements. Supported by the Rick Hansen Man-in-Motion Legacy Fund.

SPINAL CORD AND BRAINSTEM: ANATOMY

ABSENCE OF CGRP mRNA EXPRESSION IN PHRENIC MOTONEURONS. G.C. Sieck, P. Popper, W.Z. Zhan and P.E. Micevych. Mayo Clinic and Foundation, Rochester MN 55905 and UCLA School of Med., Los Angeles, CA 90024.

Calcitonin gene-related peptide (CGRP) mRNA expression in alpha motoneurons is altered by axotomy, spinal cord transection and androgens, all of which influence muscle activity. Because the diaphragm muscle is stereotypically activated with breathing, its activation history is unique compared to limb muscles. Therefore, we examined CGRP mRNA expression in labelled phrenic motoneurons in adult rats. In addition, we examined the influence of 14 days of TTX-induced inactivation of the diaphragm muscle. Phrenic motoneurons were labelled by intramuscular injection of fluorogold and identified in 20 μ m transverse sections. Alternate sections were processed for CGRP immunohistochemistry and in situ hybridization with a probe complementary to the 3'-end of α CGRP mRNA. Eight controls and 7 TTX-inactivated spinal cords were studied, with 20-30 phrenic motoneurons per animal identified. The expression of CGRP mRNA was not detected in either control or TTX-inactivated phrenic motoneurons. This contrasted to the clear expression of CGRP mRNA in other cervical cord alpha motoneurons. We conclude that CGRP is either not expressed in phrenic motoneurons or expressed at such a low level that it is not involved in neuromuscular plasticity of the diaphragm muscle.

PSUEDORABIES VIRUS (PRV) DEFINES EFFERENT PROJECTIONS TO PHRENIC MOTONEURONS IN THE RAT. E.G. Finlon & J.L. Feldman. Systems Neurobiology Lab. Department of Kinesiology, UCLA, Los Angeles, CA 90024-1527.

Phrenic motoneurons receive diverse projections from brainstem and spinal cord. Conventional labelling studies, which require extracellular deposition of tracers, have serious limitations due to unavoidable contamination by nonspecific transport. Developments in transneuronal tracing techniques (G. Ugolini et al., *Science*, 243('88): 89) allow exclusive labeling of specific projections to a motoneuron pool. PRV is such a transneuronal tracer (J.P. Card et al., *J. Neurosci.*, 10('90):1974). Following dorsal rhizotomies, 1-2 μ L injections of 10⁸ PFU of PRV (Becker Strain) were made into the right phrenic nerve of Wistar rats. After processing, PRV positive cells were visualized by a polyclonal antibody and subsequent amplification. Following first order labelling in the phrenic motoneuron pool, numerous cell bodies were labelled in the thoracic spinal cord in inspiratory motoneuron pools, and in the ventral respiratory group (VRG) in the medulla. In addition, cells were labelled in ventrolateral nucleus of the solitary tract, raphe nuclei, parapyramidal region, B3 serotonergic region, and A5 noradrenergic region. Spinal cord segmental interneurons, predominantly ventromedial and ventrolateral to the phrenic motoneurons, appeared with the same time course as the VRG label. No cells were labelled in the upper cervical spinal cord. We are grateful to J.P. Card, Ph.D., E.I. Dupont de Nemours & Co., for his generous gift of PRV and antibody. Supported by NIH Grants NS24742.

188.3

RETROGRADE LABELLING OF RESPIRATORY NEURONS IN LAMPREYS. D.F. Russell. Dept. of Anesthesiology, Washington Univ. Med. School, St. Louis, MO 63110.

The aim was to retrogradely label premotor respiratory interneurons in adult lampreys, either *Petromyzon marinus* or *Ichthyomyzon unicuspis*, from *in vivo* injections. The tracers used were HRP, WGA-HRP, or colloidal gold-apoHRP; as reporters, either DAB, TMB, or silver intensification were used. Survival times were 3 weeks to several months. Tracer was injected unilaterally into one of the respiratory motor nuclei, including cranial nuclei IX or X_r, usually sub-ependymally among the somata of respiratory motoneurons. Vibratome sections were cut.

This approach consistently labelled a compact bilateral nucleus rostral to nuc.V, situated dorsally, just under the cerebellum, near the ventricular surface. A unilateral injection into nuc.X gave bilateral labelling of this rostral nucleus. In TMB material, labelled somata had average diameters ~8 μ . This cell group will be called the "subcerebellar respiratory nucleus".

More caudally, there was consistent labelling of a low-density group of medium-size neurons along the rostral and lateral edges of nuc.V. Injection of HRP into nuc.X_r gave solid diffusion labelling of several large crossing fibers in the midline commissure near nuc.V, and also labelled numerous small fibers that decussated more rostrally. Injections of colloidal gold-apoHRP, which appeared to not diffuse, helped define the labelling of neurons near to the injection sites in nuc.IX or X_r; small labelled neurons were observed near the midline in the reticular formation. Caudal to the injection sites, there was consistent labelling of contralateral neurons near obex, situated dorsal to the reticular formation near the ventricular surface.

Supported by NIH grant NS23028.

ANALYSIS OF THE MOTOR NUCLEUS OF THE EXTENSOR DIGITORUM LONGUS IN THE C57Bl/KsJ-dbm DIABETIC MOUSE. Kathleen M. Klueber and Sue Stansel, Department of Anatomical Sciences and Neurobiology, University of Louisville, School of Medicine, Louisville, KY 40292

Ultrastructural evidence revealed a degeneration of neuromuscular junctions in diabetic muscle resulting in denervation (Feczko and Klueber, *Am.J.Anat* 182: 224, 1988). However, analysis of the central connections of these denervated myofibers has not been reported. The objective of this study was to determine the size and location of the motor neuron pool to a diabetic muscle. The extensor digitorum longus muscle (EDL) from diabetic (db/db) and control (db/+) mice (n=5/age; 6 and 12 wks) were injected with HRP. After 24 hours, the animals were perfused, the spinal cords removed and processed. HRP reaction products were formed using TMB as the chromogen. Morphometric analysis of the size of the motor neurons revealed a significant change ($p < .05$) in the size of the neurons with the pathogenesis of the disease. The size of the motor neuron pool was not effected. Funded by: NIDDK 1R29DK41553.

MOTOR INNERVATION OF THE PHARYNX AND LARYNX: AN ELECTRON MICROSCOPIC AND HRP STUDY OF THE NUCLEUS AMBIGUUS IN THE RAT. D.A. Hopkins and D.W. Saxon.

Department of Anatomy, Dalhousie University, Halifax, NS B3H 4H7.

Motoneurons innervating the striated musculature of the pharynx and larynx are located in the nucleus ambiguus (NA) but little is known regarding their ultrastructure. Injections (2-6 μ l) of WGA-HRP (5%) or CT-HRP (0.25%) into the musculature of the pharynx or larynx resulted in retrogradely labeled neurons in the semicompact (NA_{sc}) and loose (NA_l) formations of the NA, respectively. Pharyngeal and laryngeal motoneurons (25-40 μ m diameter) shared similar morphological features: i.e., multipolar, large round nucleus, eccentric nucleolus, large quantities of short stacks of rough endoplasmic reticulum. Neurons in both subdivisions received many synaptic contacts on the somata and dendrites. Axon terminals with round vesicles and asymmetric synaptic contacts (RA) were more numerous on NA_{sc} somata and dendrites while terminals with pleomorphic vesicles and symmetric synapses were more numerous on NA_l somata and dendrites. A few atypical labeled motoneurons (12-20 μ m diameter) with an invaginated nucleus, eccentric nucleolus and sparse Nissl substance were also identified in the pharyngeal division of the NA. Pharyngeal and laryngeal motoneurons differ from each other with respect to proportions of types of synapses and from esophageal motoneurons which have very few synapses on their somata and predominantly RA synapses on their dendrites. These differences in afferent inputs may be related to functional differences in each of the subdivisions of the NA. Supported by MRC of Canada Grant MT-7369.

CO-LOCALIZATION OF GAMMA-AMINOBUTYRIC ACID (GABA) AND PARVALBUMIN IN CHICK SPINAL MOTONEURONS. E. Philippe, F. Gaulin*, G. Audet* and C. Zhou*. Centre de recherche en neurobiologie, Université Laval et Hôp. de l'Enfant-Jésus, 1401, 18e rue, Québec, Canada, G1J 1Z4.

Chick spinal motoneurons have been shown to express a clear GABA-immunoreactivity (Philippe *et al.*, Neurosci. Lett., 116: 12-16, 1990). However, since GABA is co-localized with acetylcholine, the classical excitatory neurotransmitter of vertebrates neuromuscular system, it seems unlikely that GABA plays the role of an inhibitory neurotransmitter in this system. Moreover, since it has previously been suggested that a dysfunction between amino acids as well as an uncontrolled modulation of intracellular calcium could contribute to neuronal death in a wide variety of neurological diseases, GABA might have a function in the maintenance of cellular interactions in the neuromuscular system. Hence, the aim of this study was to determine whether a co-localization between GABA and calcium binding proteins might be detected within spinal motoneurons.

Immunocytochemistry performed with parvalbumin antiserum, according to the peroxidase anti-peroxidase (PAP) technique, showed a clear and strong immunoreactivity in some chick spinal motoneurons. Such is not the case for calbindin, another calcium binding protein (Philippe and Droz, J. Comp. Neurol., 283: 153-160, 1989). Moreover, combination of pre- and post-embedding immunocytochemical procedures showed that parvalbumin and GABA are co-localized in the majority of motoneurons.

It is interesting to note that the sensory innervation of chick skeletal muscles is assumed, at least in part, by primary sensory neurons of dorsal root ganglia and their related neuromuscular spindles, which are immunoreactive to both GABA and calbindin antisera. Hence, it appears that innervation of skeletal muscles is, at least in part, under a GABAergic control. However, the co-localization of GABA with parvalbumin was restricted to the motor innervation, whereas the co-localization of GABA with calbindin was restricted to the sensory innervation of the skeletal muscles.

C-FOS-LIKE EXPRESSION IN THE BRAINSTEM OF THE CAT DURING CARBACHOL-INDUCED ATONIA. J. Yamuy*, J.R. Mancillas, F.R. Morales and M.H. Chase. Brain Research Institute, Dept. of Physiology and Dept. of Anatomy and Cell Biology, UCLA School of Medicine, Los Angeles, CA, 90024.

The expression of the early proto-oncogene c-fos has been related to neuronal activity. In the present study we were interested in determining whether neurons in areas of the reticular formation that have been implicated in the production of atonia during active sleep became active, as determined by their c-fos expression, when atonia is induced by the pontine injection of carbachol.

Under nembutal anesthesia, 5 chronic cats were prepared for microinjection and the recording of the EEG, EOG, EMG and PGO waves. After recovery, 3 cats were injected with a carbachol solution (4 μ g in 25 μ l) and 2 cats with saline (25 μ l). Injections were directed to the rostro-medial pontine tegmentum. The cats injected with carbachol entered into a state similar to active sleep, which consisted of atonia, desynchronized EEG and PGO waves, whereas the control cats remained awake. After approximately 2 hours the animals were sacrificed with an overdose of nembutal. Following perfusion and fixation, the brainstem was submerged in Bouin's solution. Brainstem frontal sections 7 μ m thick were immunostained with a Fos polyclonal antiserum and developed using the alkaline phosphatase and the ABC methods.

Sections at the level of cranial motor nuclei nV, nVI, nVII and nXII were selected for analysis because they sampled the reticular formation at different brainstem levels below the site of injection. Carbachol-injected cats exhibited c-fos-like immunoreactivity in neurons within the paramedian reticular nucleus, magnocellular tegmental field and gigantocellular tegmental field, whereas the control cats displayed low counts of immunostained cells in these areas. C-fos-like expression was also found in other areas which were not the focus of this report.

These results indicate that different patterns of c-fos expression are present during wakefulness and carbachol-induced atonia and that the medial and ventral areas of the reticular formation, which have been implicated in the promotion of atonia during active sleep, exhibit increased neuronal activity during carbachol-induced atonia. DIFFERENTIAL LABELING OF ORAL MOTOR SYSTEMS USING PSEUDORABIES VIRUS. R. A. Fay and R. Norgren.

Neuroscience Program and the Department of Behavioral Science, Col. of Medicine, Penn. State Univ., Hershey, PA 17033.

Pseudorabies virus was injected into the masticatory and intrinsic tongue muscles of the rat. Injections of 12 μ l of viral suspension (1x10⁷ pfu/ml) resulted in retrograde, transsynaptic labeling of neurons in the brainstem and forebrain. Viral injections into the masseter, digastric, and temporalis muscles produced specific myotopic labeling within the trigeminal motor nucleus. Transsynaptically labeled neurons occurred in a variety of brainstem structures, but secondary infection from all 3 muscles was restricted to the principal trigeminal nucleus, the Kolliker-Fuse nucleus, and the subcoeruleus area in the pons and the area postrema, the nucleus of the solitary tract, some raphe nuclei, and the paraventricular and rostroventrolateral areas in the medulla. Viral injections into the intrinsic tongue muscles resulted in myotopic labeling in the hypoglossal nucleus. In the brainstem, transsynaptic labeling overlapped extensively with that following injections into masticatory muscles. In the forebrain, more differences were observed. Infections of the muscles of mastication resulted in weak, but widespread labeling in the cortex and extensive labeling in the hypothalamus. After tongue injections, cortical label was restricted to the frontal and piriform zones, but extensive labeling occurred in both the hypothalamus and the amygdala. Supported by PHS grants DC 00240 and MH 00653.

MOLECULAR SPECIFICATION OF LARGE NEURONS IN THE RAT SPINAL CORD REVEALED BY MONOCLONAL ANTIBODY 8B3. A. R. Tate*, M. F. Barbe, A. F. Pimenta, T. J. Cunningham, P. Levitt. Dept. of Physical Therapy, Temple University, Philadelphia, PA, 19140 and Dept of Anatomy and Neurobiology, Med. Coll. of Pa, Philadelphia, Pa, 19129.

A monoclonal antibody, 8B3, was generated by immunizing Balb/C mice with homogenized motor cortex (Guimaraes, et al., Neuroscience Abst 16: 240, 1990), and was found to crossreact with spinal cord. The distribution of immunohistochemically stained neurons was investigated in the rat throughout the rostrocaudal extent of the spinal cord in both longitudinal and coronal sections. Immunoperoxidase labeling revealed that 8B3 stained a small subpopulation of neurons in the spinal cord. In all instances, immunoreactivity was associated with the surface of somata and dendrites of these neurons. The most prominent group of stained neurons were large diameter cells found in medial and lateral subdivisions of the ventral horn, corresponding primarily to lamina IX. The number of these ventral horn 8B3 immunoreactive cells was the greatest in the lumbar enlargement. In addition, at thoracic and sacral levels, preganglionic motor neurons were stained with 8B3. There were small numbers of the scattered immunoreactive neurons in intermediate laminae V and VI. A third region containing immunoreactive neurons surrounding the central canal, including cells in the dorsally situated Clarke's nucleus. Very few immunoreactive neurons were seen in any of the sections examined in laminae I-III of the dorsal horn. Double-labeling studies are currently being performed to determine whether the phenotype of the 8B3-immunoreactive neurons is motor, ascending projection or interneuronal. The present data suggest that one of these groups may be specified at the molecular level by selective expression of the 8B3 antigen. Supported by NIH grant NS24707.

GIANT NEURONS IN THE CAUDAL PONTINE RETICULAR FORMATION RELAY THE ACOUSTIC STARTLE RESPONSE IN THE RAT. K. Lingenhöhl, E. Friauf and M. Koch. Dept. Animal Physiology, Univ. of Tübingen, D-7400 Tübingen, Fed. Rep. Germany.

The caudal pontine reticular formation (PnC) was proposed as a relay station in the acoustic startle pathway (Davis et al., J Neurosci 2:791, 1982). We investigated PnC neurons using electrophysiology and anatomy to test this idea. Intracellular recordings showed that PnC neurons receive excitatory input from both ears with a mean latency of 4.2 ms. The retrograde tracer Fluoro-Gold was injected into the PnC and labeled auditory neurons bilaterally in the dorsal cochlear nucleus, the lateral superior olive and the ventral periolivary nuclei, indicating multiple direct inputs from 1st and 2nd order auditory nuclei to the PnC. Intracellular iontophoresis of HRP into PnC neurons (N=25) identified giant neurons with large dendritic arborization mainly within the PnC. Two types of axonal trajectories were seen: one type (N=23) had a caudal course on the ipsilateral side and could be traced into the upper ventral spinal white matter before fading; the second type (N=2) projected bilaterally with thick axonal branches in caudal and rostral directions. Both axon types showed numerous collateral endings within the reticular formation. PHA-L injections into the PnC substantiated the projections to the spinal cord. Electrical stimulation of the thoracic spinal cord elicited antidromic action potentials in acoustically driven giant PnC neurons with a mean latency of 1.5 ms. Our data show that acoustic information is relayed via giant PnC neurons within 5.7 ms to the thoracic spinal cord, a timespan which matches the latency of the acoustic startle response. Quinolinic acid lesions of PnC neurons greatly impaired or even abolished the acoustic startle response, depending on the number of giant PnC neurons that were eliminated. We conclude therefore that giant PnC neurons are required in the acoustic startle pathway. Supp. by DFG SFB 307.

CORTICAL AND CEREBELLAR CONVERGENCE UPON SINGLE NEURONS IN THE PRIMATE RED NUCLEUS: AN ELECTRON MICROSCOPIC ANALYSIS. D.D. Ralston. Department of Anatomy, University of California, San Francisco, California, 94143.

The red nucleus of the primate receives major input from the motor cortex and from the deep cerebellar nuclei. Rubral neurons, both in parvocellular and magnocellularis must then integrate this afferent information. This study in the primate demonstrates convergence of these inputs to the red nucleus from cortical and cerebellar sources. Spatial segregation of cortical and cerebellar inputs exist in each of the divisions of the nucleus: those of cortical origin synapse upon distal dendrites and those of cerebellar origin synapse upon proximal dendrites and somata. Tsukahara, et al, 1975, in the cat, reported sprouting of cortical input to rubral neurons in cerebellar afferent territory after deafferentation from cerebellum, inferring convergence of these two inputs onto the same rubral neuron. In this study convergence of inputs can be demonstrated in parvocellularis in the range of medium sized dendrites of the neuronal dendritic arbor due to the overlap of the two sources of input. However, the magnocellularis division, where spatial segregation is more marked, requires single neuronal identification for confirmation. Results demonstrate anatomical evidence for the presence of degenerating boutons of cortical origin and WGA-HRP labeled cerebellar terminals onto the same rubral neuron to carry out the task of integration of motor information. The red nucleus therefore is involved in the continuous integration and monitoring of cortical and cerebellar input and, given the possible climbing fiber training of the mossy fibers in cerebellum, may in fact modulate the pontine input to cerebellum in processing motor information. Supported by NS23347 from N.I.H..

ULTRASTRUCTURAL ANALYSIS OF TH AND 5-HT INPUTS TO THE SNB OF THE MALE RAT. M.G. Leedy, J.C. Bresnahan, and M.S. Beattie, Dept. Cell Biology, Neurobiology and Anatomy, Ohio State Univ., Columbus, OH 43210

While the existence of supraspinal inputs to the spinal nucleus of the bulbocavernosus (SNB) has been proposed, there is presently only limited ultrastructural description of identified inputs to this nucleus. The present study reports quantification of tyrosine-hydroxylase (TH) and 5-HT inputs to somata and dendrites in the SNB. L5/L6 spinal cord segments from adult male rats were sectioned and processed using ABC immunohistochemistry for TH and 5-HT. The sections were then flat embedded for sequential light and EM analysis. At the light level, both TH and 5-HT staining were seen in the SNB. 5-HT fibers had an almost exclusive association with the somata, often encircling the perimeter. TH fibers were also seen in proximity to cell bodies, but in addition were scattered throughout the nucleus, often following the motoneuron dendritic arbors. EM analysis supported the light level findings. Sampled 5-HT terminals were frequently in direct contact with somata (45% of terminals were axo-somatic; 27% axo-dendritic). In contrast, the majority of the sampled TH terminals contacted dendrites (17% axo-somatic; 66% axo-dendritic). The quantification of these inputs to the SNB provides the basis for comparisons between spinally intact and transected animals. (NIH grant NS10165)

AFFERENT AND EFFERENT CONNECTIONS OF THE MESENCEPHALIC LOCOMOTOR REGION WITH THE PONTOMEDULLARY RETICULAR FORMATION IN THE RAT. C.A. Livingston, S. Pylvas, L.M. Jordan & D.M. Nance. Departments of Physiology and Pathology, University of Manitoba, Winnipeg, MB R3E 0W3 Canada

Previous studies indicate that the midbrain locomotor region (MLR) projects monosynaptically onto reticulospinal (RS) neurons located in those regions of the reticular formation (RF) from which the descending locomotor pathways originate. Our goal was to identify the specific population of RS cells in the medial pontomedullary RF that receive direct input from the MLR. We injected 5-20 nl of fluorogold (0.5%, retrograde label), mixed with tetramethylrhodamine dextran (5.0%, anterograde label) into the MLR. In the same animals, we injected 3.0 ul of Fast Blue (2.0%; retrogradely transported) into the thoracolumbar spinal cord. Seven days later the animals were perfused with 4.0% paraformaldehyde. The brains were transversely sectioned (40-100 um, thickness) and the tissue was viewed using either transmitted or epifluorescent optics. The distribution of retrogradely labeled neurons in the pontomedullary RF was compared with that of fibers and terminals anterogradely labeled from the MLR. In the caudal brainstem, numerous cells were retrogradely labeled from the MLR in the gigantocellular, parvocellular, intermediate and pontine reticular nuclei. Fibers anterogradely labeled from the MLR coursed caudally and ventrally from the MLR and into the lateral pontomedullary RF, or medially and caudally into the medial pontomedullary RF. Fibers and terminals were distributed bilaterally in the pontine reticular nucleus, the dorsomedial tegmental area, the parvocellular, intermediate and gigantocellular reticular nuclei, and the caudal raphe nuclei. Neurons retrogradely labeled from both the spinal cord and the MLR were distributed and closely intermingled within these same nuclei. Despite the coincident distribution of the RS cells and terminals from the MLR, we found few terminal-like structures in close proximity to the somas of labeled RS cells. This suggests that direct input from the MLR onto these cells occurs at synapses located on their dendrites. The close intermingling of RS cells and reticular neurons that project to the MLR suggests that these cells could be synaptically connected. Our results indicate that the MLR and the reticular formation are reciprocally connected.

REDEFINING RAT RED NUCLEUS: MULTIPLE LABELLING OF INDIVIDUAL NEURONS FROM SPINAL CORD, INFERIOR OLIVARY NUCLEUS AND CEREBELLAR NUCLEI. D.Y. Yu, S. Na*, J. Wilson* and P.R. Kennedy. Neurosci. Lab, Georgia Tech, Atlanta, GA 30332.

Previous studies (Tucker and Kennedy, Soc. Neurosci. Abstr. 1990, 16(1):729) showed that Red Nucleus (RN) neurons were doubly labelled from the spinal cord and inferior olivary nucleus (ION). About two thirds of RN neurons that projected to the spinal cord also projected to the ION. Huisman et al. (Brain Res., 1983, 264:181-196) showed that RN neurons also projected to both the spinal cord and the cerebellar nuclei (CbN). The possibility that individual RN neurons might project to all three targets was examined using Fluorogold, Diamidino Yellow and WGA-HRP.

Each neuron was examined under brightfield and fluorescent light. The previous findings of double labelling between spinal cord and ION, and spinal cord and CbN were confirmed. A new finding of neurons doubly labelled from ION and CbN was made. More importantly, some RN neurons were triply labelled. We are analyzing labelled neuron classes, their numbers and distributions. In sum, individual RN neurons project to spinal cord, ION and CbN. Grant: NS 24602-03.

Brainstem projections to the upper cervical spinal cord in the macaque. J.O. Phillips, E.R. Robinson, and A.F. Fuchs, Western Regional Primate Research Center, Department of Psychology, and Department of Physiology and Biophysics, University of Washington, Seattle, WA 98195

We identified the areas of primate brainstem that project to the level of the neck motoneuron pools by injecting 3 monkeys with a 1% solution of the tracer WGA-HRP. We injected the upper cervical spinal cord (C1 to C3) in 1 rhesus and 1 cynomolgus monkey and the lower cervical and upper thoracic spinal cord (C6 to T1) in 1 cynomolgus monkey. After 24 hours (upper cervical) or 48 hours (lower cervical), we perfused the monkeys with 3% paraformaldehyde and cut frozen sections of the brainstem and spinal cord. We reacted the sections with TMB using a modified Mesulam technique. We plotted the location of labeled cells with an electronic pantograph under polarized light.

A unilateral 60nl injection into C2 labeled neurons bilaterally in the lateral part of the medial vestibular nucleus and the medullary and pontine reticular formation. The lateral vestibular nucleus also contained labeled cells bilaterally. There were also labeled cells in the contralateral superior colliculus and the contralateral fastigial and interpositus nuclei of the cerebellum. Other areas containing labeled cells included the red nucleus, interstitial nucleus of Cajal, and the mesencephalic area just lateral to the central grey. A 140nl unilateral injection into the lower cervical cord filled cells in many of the same areas but labeled very few cells in the medial vestibular nucleus and more cells in the lateral vestibular nucleus, but only ipsilaterally. There were no labeled cells in the superior colliculus or cerebellum.

A comparison of these results with the data obtained in previous HRP injections of the abducens nucleus suggests that brainstem regions providing pre-abducens and pre-neck motoneuron afferents are largely separate in the monkey. Those regions that do project to both areas (eg., lateral portions of the medial vestibular nucleus) often constitute the overlapping borders of two largely separate populations projecting to each motoneuron pool.

PROJECTIONS OF MOTOR CORTEX TO THE PRETECTUM OF THE CAT. B. Hutchins¹, S.L. Liles², and B.V. Updyke³ Department of Anatomy¹, Baylor College of Dentistry, Dallas, Tx. 75246 and Departments of Anatomy³ and Physiology², Louisiana State University Medical Center, New Orleans, La. 70112.

The association of the pretectal complex with the visual system has been well established. There have also been a few studies reporting motor projections to the pretectum, yet there are few studies which have analyzed these projections in detail. Therefore, as part of an integrated study of the cat motor system, the pretectum was analyzed for afferents from specific somatotopic areas of motor cortex. Briefly, the methods were to electrophysiologically stimulate motor cortex in adult animals anesthetized with ketamin and xylazine to define muscular responses and inject ³H-proline into these same cortical areas. Animals were sacrificed 48 hrs. later with an overdose of Nembutol and the tissue was transcardially perfused with 4% paraformaldehyde. After the brains were removed and saturated in a 0.1 M phosphate buffer with 30% sucrose for cryoprotection, 50 µm frozen sections were cut in the coronal plane. Every fifth section was processed for routine autoradiography and counterstained with cresyl violet. Analysis of five cases, reveal afferent projections to only the anterior pretectal nucleus (NPA). Silver grains were typically located over the ventral border of the nucleus without regard for the two subnuclei, compacta or reticularis. These terminal fields often appeared in the shape of a "U" as they closely followed the ventral border. When cases were analyzed with respect to their muscle representations, there appeared to be a crude somatotopy present, with some overlap of terminal fields. Of the three somatotopic regions tested, hindlimb muscles were represented rostrally, the forelimb muscles were represented posteriorly, and the shoulder muscles represented in an intermediate position. Because portions of NPA have been shown to receive both retinal and somatosensory projections, these motor projections may be involved with corollary discharges used in sensorimotor transformations. RETROGRADE LABELLING OF SPINAL EFFERENTS IN AN ANIMAL MODEL OF SPASMODIC TORTICOLLIS. P.M. Young¹, F. Mullin² & J. Robertson-Rintoul³. Dept. of Psychology, Lancashire Polytechnic and ⁴Dept. of Biol. & Preclin. Med., University of St. Andrews, U.K. (Spon: European Neuroscience Association.)

The motor efferents to the sternomastoid (SM) and cleidomastoid (CM) were investigated using cholera toxin side chain B conjugated to horseradish peroxidase (CTB-HRP), and a wheatgerm agglutinin-HRP conjugate (WGA-HRP) as retrograde tracers. Under tribromoethanol anaesthesia 10 rats, six guinea pigs and six rabbits received an injection of tracer to the SM or CM. In control animals, injection to the muscles was preceded by section of the spinal accessory nerve (SAN). Twenty four to seventy two hours after injection animals were sacrificed and 80 µm frozen sections through the brain stem and cervical cord were processed by the TMB technique. SM and CM receive a motor innervation through both the upper cervical spinal nerves and the SAN. The spinal accessory nucleus and the nucleus of cervical efferents, supplying both the SM and CM, extended from C3 caudally, to a continuity with the caudal component of the hypoglossal nucleus for the SAN efferents. The spinal accessory nucleus supplying SM and CM occupied the medial layer 8 and the lateral layer 9 of Rexed. With CTB-HRP, axons from both subnuclei were seen to join to form the SAN. There was no evidence in this study of retrograde transport of tracer to either the dorsal motor nucleus of the vagus or the nucleus ambiguus. There was however evidence of transneuronal transport of CTB-HRP to the contralateral spinal accessory nucleus and the significance of this finding is under investigation.

THE TERMINATION PATTERN AND POSTSYNAPTIC TARGETS OF RUBRO-SPINAL FIBERS IN THE RAT SPINAL CORD. M. Antal^{1,2}, G.N. Sholomenko¹, A.K. Moschovakis¹, J. Storm-Mathisen³, C.W. Heizmann⁴ and W. Hunziker⁵ ¹Lab. Neur. Cont., NINDS, NIH, Bethesda, USA; ²Dept. Anat., Univ. Med. School, Debrecen, Hungary; ³Anat. Inst., Univ. Oslo, Norway; ⁴Dept. Pediat., Univ. Zurich, Switzerland; ⁵Cent. Pharm. Res. Dept., F.Hoffmann-La Roche Co., Basle, Switzerland

The spinal projections of the red nucleus were studied in the rat using the anterograde tracer Phaseolus vulgaris leucoagglutinin (PHA-L). After injecting PHA-L unilaterally into the red nucleus, labelled fibers and terminals were detected at cervical, thoracic as well as lumbar segments of the spinal cord. Descending fibers were located in the dorso-lateral funiculus, most of them contralateral to the injection site. Terminals were found predominantly in laminae V-VI and in the dorsal part of lamina VII at all levels and on both sides of the spinal cord. The proportion of terminals revealed on the ipsilateral side varied at different segments and represented 10-30% of the total number of boutons. Terminals were also found in the ventro-lateral aspect of Clark's column on both sides.

Synaptic contacts of rubro-spinal terminals and GABA as well as glycine immunoreactivity of their postsynaptic targets were investigated in a correlative electron microscopic study.

To obtain a more global view of the relationship between rubro-spinal fibers and spinal interneurons sections from the cervical and lumbar cord were stained for both PHA-L and calbindin-D28k (CaBP), a calcium-binding protein which has been reported to be a marker of certain subsets of spinal interneurons. CaBP-immunoreactive neurons in laminae V-VI were found to receive contacts from rubro-spinal axons. Labelled boutons impinged mainly upon dendrites, but somatic contacts were also revealed.

GOLGI STUDY OF THE MEDIODORSAL THALAMIC NUCLEUS IN THE RAT. M. Kuroda and J.L. Price, Dept. Anat. & Neurobiol., Washington Univ. Sch. of Med., St Louis, MO 63110

The Golgi technique was used to investigate the distribution and domain of neurons in each segment of the mediodorsal thalamic nucleus (MD) in the rat.

All impregnated neurons exhibited small sessile and thorn-like appendages on higher order dendrites, but these appendages were either absent or sparse on the soma and proximal dendrites. The configuration of the dendritic tree varied with the location of neurons. Cells in the central segment of MD had a stellate shape with dendrites radiating in all directions. These dendritic arbors formed a restricted spheroidal dendritic field within the central segment. Within the medial and lateral segments, stellate-shaped neurons were also present, although they were often distorted, such that their major dendrites tended to avoid the boundaries around MD, or between different segments. Cells just lateral to the border between the central and lateral segments were semicircular in shape, with dendrites only in the lateral segment. Impregnated neurons located close to the medial or lateral boundary of MD were fusiform in shape, with their dendrites aligned parallel to the boundary of the nucleus. These findings indicate that major dendrites of neurons do not extend across subdivisional boundaries. Therefore, cells and their dendrites are relatively confined to a single segment of MD.

Supported by NIH research grant DC 00093.

TOPOGRAPHICAL ORGANIZATION OF THE MEDIAL ORBITOFRONTAL-STRIATAL PROJECTION AND ITS RELATIONSHIP TO STRIOSOMES AND ENKEPHALIN PATCHES IN THE MONKEY. M. Mizobuchi and S.N. Haber, Dept. of Neurobiology and Anatomy, Univ. of Rochester, Rochester, NY 14642

The ventromedial portion of the striatum receives input from structures related to the limbic lobe. As part of a larger study to understand the organization of limbic striatal input, we injected ³H-AA into discrete areas of the medial orbitofrontal cortex (area 13A). Routine autoradiography was carried out on 50 µm sections throughout the striatum. To compare acetylcholinesterase (AChE)-poor "striosomes" and enkephalin (ENK) immunoreactive patches to the cortical terminal fields, adjacent compartments on either side were processed for AChE and ENK immunocytochemistry (ICC). In addition, sections were processed for both autoradiography and ENK ICC.

A dense patchy distribution of labelled fibers was observed in a narrow strip along the ventromedial aspect of the head of the caudate continuing ventrally into the medial nucleus accumbens. Caudally, label continued in the medial edge in the body of the caudate. No terminal fields were observed in the putamen. All injections produced a similar pattern of terminal labeling, however, medial injections terminated in the medial most edge of the striatum, while more lateral injections terminated just lateral to this. Thus the medial-lateral organization of area 13A was topographically preserved in its projection to the striatum. Comparison between terminal fields and striosomes revealed inconsistent matches. In some areas, striosomes and terminals clearly demarcated each other, and while in other regions, they either avoided each other or were partially overlapped. A similar relationship was observed with the ENK staining. Supported by NIMH MH45573.

189.3

PREFRONTAL CORTICAL PROJECTIONS TO THE AMYGDALOID COMPLEX: A PHA-L STUDY IN THE RAT. F. Mascagni and A.J. McDonald. Dept. of Anatomy, Cell Biology, and Neurosciences, Univ. of South Carolina School of Medicine, Columbia, SC 29208.

The cortico-amygdaloid projections of different areas in the prefrontal cortex (PFC) were investigated using the PHA-L anterograde tract tracing technique. The distribution of fibers in the amygdala seen with injections into different PFC areas appears to be topographically organized. Fibers from the ventromedial frontal cortex (i.e., the infralimbic cortex) terminate mainly in rostral parts of the olfactory amygdala and, to a lesser extent, in discrete portions of the central and basolateral amygdaloid nuclei. In contrast, more dorsal portions of the medial PFC (i.e., the prelimbic area and medial agranular cortex) have strong projections to rostromedial portions of the basolateral amygdala and light projections to the lateral capsular portion of the central nucleus. The lateral PFC (ventral and dorsal agranular insular areas; AIV and AID) sends fibers to the central nucleus and rostral portions of the basolateral amygdala. In addition, AIV projects to rostral portions of the olfactory amygdala. In general, the topographical organization of the projections of different prefrontal fields to the amygdala suggests that these cortical areas are involved in discrete behavioral functions. (Supported by NIH Grant NS19733)

COLOCALIZATION OF CALCIUM-BINDING PROTEINS, VC1.1-IR MEMBRANE PROTEIN, AND NEUROFILAMENT PROTEIN (SMI-32) IN NEURONS OF THE BASOLATERAL AMYGDALA. A.J. McDonald. Dept. of Anatomy, Cell Biology, and Neurosciences, Univ. of South Carolina School of Medicine, Columbia, SC 29208.

This study utilized two-color immunoperoxidase techniques to characterize neurons in the rat basal amygdaloid nucleus (ABN) that exhibited immunoreactivity to calbindin (CB+), parvalbumin (PV+), VC1.1-IR membrane protein (VC+), and nonphosphorylated neurofilament protein (SMI32+) antibodies. Previous studies in this laboratory have indicated that CB and PV are extensively colocalized in ABN and constitute a subpopulation of nonpyramidal GABAergic interneurons. The present study demonstrated that virtually all VC+ neurons were PV+, and about 90% of VC+ neurons were CB+. These VC+ neurons, which comprised almost the entire population of large CB+ and PV+ cells, constituted about 1/3 of all PV+ and CB+ neurons. Virtually all somata with moderate to intense SMI32 immunoreactivity were also PV+ or CB+. In addition, there was almost 100% colocalization of VC and SMI32 immunoreactivity. These studies indicate that there is a unique subpopulation of large PV+/CB+ GABAergic interneurons in ABN that constitute virtually the entire population of VC+ and SMI32+ neurons. The functional significance of this colocalization pattern, as well as the role of these neurons in the microcircuitry of ABN, remains to be determined. Supported by NIH Grant NS19733.

γ -AMINOBUTYRIC ACID(GABA) SYSTEMS IN THE RAT CENTRAL AMYGDALOID NUCLEUS N. Sun and M. D. Cassell. Department of Anatomy, University of Iowa, Iowa City, IA 52242.

The GABAergic structures of the rat central amygdaloid nucleus(Ce), their co-existence with met-enkephalin, and the possible source of the GABAergic terminals and fibers in Ce have been investigated using immunocytochemical detection of GABA, GAD and enkephalin. Antisera to GABA and GAD revealed a differential distribution pattern of GABAergic immunoreactivity in Ce. Most GABA- and GAD-positive perikarya in Ce were located in the lateral(CeL) subdivision, with some cells in the lateral capsular(CeLC), intermediate(CeI) and caudal part of medial(CeM) subdivisions. Only a few labeled perikarya were observed in rostral CeM. Morphologically these GABAergic neurons resemble the medium-sized neurons of Ce. The distribution pattern of GABAergic neurons in Ce overlaps with enkephalin-positive neurons. Double-labeling indicated that 70-80% of GABA-positive perikarya in Ce are also immunoreactive to met-enkephalin. The staining pattern of GABA- and GAD-positive neuropil did not match the distribution of GABA- and GAD-positive perikarya, as the intensity of GABAergic terminals and fibers was highest in caudal CeM, moderate in rostral CeM, CeLC and CeI, and lowest in CeL. Lesioning the stria terminalis resulted in a small decrease in GABAergic immunoreactivity in Ce but a large decrease in the lateral bed nucleus of the stria terminalis(BNST). The result suggests that a complex GABAergic system exists in the Ce, with GABAergic neurons in Ce providing major projections to both the BNST and Ce. The co-existence of GABA with enkephalin in these neurons suggests that both transmitters may be involved in this intrinsic circuit. Supported by NS25139.

HIPPOCAMPAL CONNECTIONS OF THE AMYGDALA AND CLAUSTRUM IN THE CAT. A. Llamas, A. Román-Guindo and F. Clascá. Dept. Morfología, Fac. Medicina, Univ. Autónoma, 28029 Madrid, SPAIN.

The connections of the various sectors of the cat's hippocampal formation with the amygdala and endopyriform claustrum (ECI) were studied by using WGA-HRP injected in discrete portions of Fascia Dentata (FD), Cornu Ammonis (CA), Subicular Complex (S) or in the amygdala in 19 adult cats. Hippocampal parcellation was based on the staining patterns present in adjacent serial sections processed for Nissl, Myelin, AChE and Timm's stain.

The rostral two thirds of S receive projections from the ventral part of ECI, but do not project back to it. CA and FD are not connected with the claustrum. The amygdala is only connected with the rostral two-thirds of the temporal stem of the hippocampus, particularly with the rostral third. Projections from amygdala reach the superficial part of the molecular layer of CA1 and prosubiculum. They arise mainly from the superficial division of the accessory basal and the cortical nuclei, and more scarcely from the parvocellular division of the accessory basal and the lateral nuclei. In addition, the lateral nucleus projects to the parasubiculum. Hippocampo-amygdaloid projections arising from the subiculum, prosubiculum and CA1 reach the posterior cortical nucleus, parvocellular and superficial subdivisions of the accessory basal nucleus, and the medial division of the central nucleus.

Present data, together with other reports in the literature show that hippocampo-amygdalar and hippocampo-claustral connections are organized in comparable anatomical patterns in cats and primates. CICYT PB 86-0558 and 88-0170

DISTRIBUTION OF NADPH-DIAPHORASE POSITIVE CELLS AND FIBERS IN THE MONKEY AMYGDALA. A. Pitkänen and D.G. Amaral. Salk Institute, La Jolla, CA 92037.

The NADPH-diaphorase (NADPH-d) enzyme histochemical method stains a selective population of neurons in the central nervous system. Although the functional significance of these cells is unknown, they are of interest because they are selectively spared in Huntington's disease and they also seem to be resistant to NMDA mediated neurotoxicity. In the present study we describe the distribution of NADPH-d positive cells and fibers in the monkey amygdaloid complex. Based on the intensity of somal staining, three classes of NADPH-d positive cell types were described. *Type 1 cells*, which were the most intensely stained NADPH-d positive cells in the monkey amygdala, were of different morphological types: pyramidal, modified pyramidal, fusiform or stellate. They were most commonly found in the accessory basal nucleus, basal nucleus, lateral nucleus and in the nucleus of the lateral olfactory tract. The intermediately stained *Type 2 cells*, that were mostly stellate in shape, were the most common. NADPH-d positive cells in the monkey amygdala. They were found in the lateral, basal and accessory basal nuclei. The oval or round, lightly stained *Type 3 cells* were mainly found in the medial, anterior cortical and paralaminar nuclei. The highest densities of NADPH-d positive fibers were found in the lateral nucleus, parvicellular portion of the accessory basal nucleus and in the anterior amygdaloid area. The lowest densities of NADPH-d positive fibers were found in the amygdalohippocampal area, in the lateral part of the central nucleus and in the intercalated nuclei. In some regions, such as the amygdalohippocampal area, the NADPH-d staining was helpful in establishing nuclear boundaries.

AMYGDALOID CRF NEURONS ARE INNERVATED BY CGRP TERMINALS. E. Harrigan*, D.J. Magnuson and T.S. Gray. Dept. Cell Biology, Neurobiology and Anatomy, Loyola Stritch Sch. of Med, Maywood, IL 60153

The central amygdala contains a high density and number of CRF neurons and calcitonin gene-related peptide (CGRP) containing terminals. The possibility that CGRP terminals innervate CRF cell bodies in this region was investigated using a double-labeling immunohistochemical technique. The subjects of the study were Long-Evans, black-hooded male rats. Animals were overdosed with sodium pentobarbital and their brains were fixed using 4% paraformaldehyde. The procedure involved application of the nickel intensified DAB staining of CGRP followed by normal brown DAB immunostaining of CRF. This resulted in distinct black punctuate reaction product associated with CGRP terminals and brown reaction product associated with CRF cell bodies.

CRF labeling was primarily localized in the lateral part of the central nucleus. CGRP terminals were densely distributed in the lateral and lateral capsular subdivisions. More than 50% of the CRF cell bodies were innervated by CGRP terminals as judged by the imperceptible distances between CGRP terminals and CRF cell bodies. Thus, there is a significant innervation of CRF neurons in the central amygdala by CGRP terminals. Previous studies have demonstrated the parabrachial nucleus is the source of these terminals and that CRF neurons are projecting to brainstem autonomic neurons. CGRP injected into the central amygdala produces increases in heart rate, blood pressure and plasma catecholamines. Since the effects of central administration of CRF is similar CGRP in the amygdala, the effects of CGRP could be mediated by activation of CRF neurons in the amygdala. The anatomical pathways would likely involve an interaction between the parabrachial nucleus neurons and amygdaloid CRF brainstem projection neurons. Supported by NIH NS 20041.

AMYGDALA DIRECTLY INNERVATES CRF NEURONS IN THE LATERAL HYPOTHALAMUS. D.I. Magnuson and T.S. Gray, Dept. of Cell Biology, Neurobiology and Anatomy, Loyola University Stritch Sch. of Med, Maywood, IL 60153

The central amygdala (Ce) projects heavily into the lateral hypothalamus. Numerous CRF immunoreactive neurons are located in this region. The present study investigated the possibility that amygdaloid terminals innervate CRF expressing neurons of the lateral hypothalamus.

Long-Evans, black-hooded male rats were the subjects of the study. The animals were injected with *Phaseolus vulgaris* leucoagglutinin lectin (PHA-L) tracer and allowed to survive for 10 to 16 days. Animals were overdosed with sodium pentobarbital and their brains were fixed using 4% paraformaldehyde. Tissue was processed using brown DAB staining of PHA-L followed by glucose-oxidase blue immunostaining of CRF. This resulted in distinct brown punctate reaction product associated with amygdaloid terminals and blue reaction product associated with CRF cell bodies.

Numerous amygdaloid terminals were found in the lateral hypothalamus including regions that contained CRF immunoreactive neurons. Approximately 70% of CRF neurons in the lateral hypothalamus were innervated after injections of PHA-L in the medial Ce. Fewer CRF neurons were innervated after PHA-L injections in the lateral Ce. Amygdaloid terminals were especially apparent surrounding the soma of CRF neurons.

Thus, the amygdala directly innervates CRF neurons in the lateral hypothalamus. Previous studies of have demonstrated that CRF lateral hypothalamic neurons innervate the central grey, parabrachial nucleus and dorsal vagal complex. The amygdala could influence autonomic and behavioral adaptations to threat or stressor through this pathway. Supported by NIH NS 20041.

A COMPARISON OF THE EFFERENTS OF THE BED NUCLEUS OF THE STRIA TERMINALIS AND MEDIAL AMYGDALOID NUCLEUS. H.A. Al-Shamma, S. Numan*, N.A. Bullock*, and G.J. De Vries. Prog. in Neurosci. and Behav., Univ. of Mass., Amherst.

The bed nucleus of the stria terminalis (BST) and medial amygdaloid nucleus (MA) supposedly evolved from one continuous area, which was separated during evolution by the emergence of the internal capsule (Alheid GF, Heimer L, *Neurosci.* 27:1 '88). The BST and MA still share many characteristics such as neurotransmitter content, cell morphology, and steroid sensitivity. Presumably differences in the connections of these nuclei underlie differences in their functions. We compared the efferents of these two nuclei focussing on the areas that contain steroid-sensitive vasopressin neurons, using the anterograde tracer *Phaseolus vulgaris* leucoagglutinin. In general, we confirmed earlier studies showing that the efferents of the MA were concentrated in the preoptic and premammillary areas, while those of the BST were more widely distributed. MA and BST efferents overlapped in some of the areas that contain steroid-sensitive vasopressin innervation such as the perimeter of the diagonal band of Broca. In other areas these efferents did not overlap. For example, the caudal part of the lateral septum receives a dense input from the BST but not from the MA. These differences suggest that the MA and BST contribute differently to the steroid-sensitive vasopressin innervation of the brain.

A SEROTONIN PROJECTION TO THE LATERAL AMYGDALOID NUCLEUS FROM THE DORSAL RAPHE NUCLEUS. N.M. Kheck, C. Farb, and J.E. LeDoux, Dept. of Biology and Center for Neural Science, New York University, New York, NY 10003.

The lateral nucleus of the amygdala is a critical link in the circuitry through which sensory information is endowed with emotional significance. The purpose of this study was to determine the neurochemical identity of brainstem afferent projections to the lateral amygdala. WGA-HRP was injected unilaterally into the lateral amygdala and histochemically visualized with tetramethylbenzidine (TMB) for single label studies; for double label studies the TMB reaction product was stabilized with diaminobenzidine (DAB) and cobalt acetate. Retrograde transport was seen in the thalamus, as previously reported (LeDoux et al, 1990), and in the dorsal raphe nucleus. Other brainstem areas were seldom labeled. An antibody specific to serotonin (Inctar) was used to establish whether the projection neurons in the dorsal raphe contain serotonin. Serotonin was visualized immunocytochemically with DAB, which is distinguishable from the TMB reacted WGA-HRP retrograde label, under light microscopy. Many of the cells containing the retrograde marker were also serotonin-immunoreactive. These findings demonstrate that the dorsal raphe is one of few brainstem areas that projects to the lateral amygdala and that many of the projection neurons contain serotonin. Thus, the serotonin innervation of the lateral amygdaloid nucleus arises at least in part from the dorsal raphe. Through these projections, serotonin may modulate the activity of the amygdala and thereby contribute to its emotional and memory functions. Supported by MH 38774.

PATTERNS OF INNERVATION OF THE CENTRAL NUCLEUS OF THE AMYGDALA AND THE BED NUCLEUS OF THE STRIA TERMINALIS IN RAT. E.L. Gustafson, G.M. Zhang* and P. Greengard, Lab. of Molecular and Cellular Neuroscience, The Rockefeller Univ., New York, NY 10021.

First messenger regulation of protein phosphorylation by cAMP-dependent mechanisms is an important component of neuronal function in the mammalian CNS. Dopamine, acting via cAMP, causes an increase in the phosphorylation of the phosphoprotein DARPP-32. While the striatum is the most prominent brain structure containing dopamine and DARPP-32, the bed nucleus of the stria terminalis (BST) and the central nucleus of the amygdala (CeA) also contain both substances. The BST and CeA are closely related structures which share many hodological and neurochemical characteristics. The purpose of the present study was to determine if the BST and CeA are innervated by common dopaminergic axons which bifurcate, or if the cells of origin comprise separate populations. This was accomplished by combining the retrograde transport of two tracers, gold-labeled WGA-apoHRP and fluorogold or rhodamine beads, with tyrosine hydroxylase immunocytochemistry. Preliminary observations indicate that there are three projection patterns of dopaminergic neurons which innervate the BST and CeA. One population innervates only the BST, another only the CeA, and a third, much smaller population innervates both areas. The majority of the retrogradely labeled dopaminergic neurons are found in the lateral substantia nigra, and in the ventral tegmental area. While further studies are clearly needed, these results indicate that the BST and CeA share some common dopaminergic inputs, which may result in common phosphorylation events if dopamine is released simultaneously in both brain areas.

189.12

INTRINSIC AMYGDALOID PROJECTIONS OF THE LATERAL AMYGDALOID NUCLEUS. C.R. Farb, G. Go*, and J.E. LeDoux, Center for Neural Science, New York University, New York, NY 10003.

The lateral nucleus of the amygdala (AL) receives efferent projections from sensory processing areas in the thalamus and neocortex and is the main channel through which sensory information accesses the emotional and mnemonic functions of the amygdala. While these extrinsic inputs to AL are well-characterized, the intrinsic amygdaloid connections of AL are poorly understood. The purpose of the present study was to examine projections from AL to other amygdaloid areas using modern tracing techniques that allow the production of injection sites restricted to small brain areas. Of particular interest were pathways by which inputs might be relayed from AL to the central amygdaloid nucleus. PHA-L or biocytin was iontophoretically ejected into AL and anterograde transport was examined. In several cases injections were confined within the cytoarchitectural boundaries of AL. Collectively, these produced anterograde terminal labeling in the central (ACE), basolateral, basomedial, intercalated, and cortical nuclei of the amygdala, as well as in the amygdalo-striatal transition area and the piriform cortex. The direct projection to ACE is strongest caudally, where most of ACE is filled with labeled processes. More rostrally, the projection is greatest in the ventral and lateral aspects of ACE. The basolateral and intercalated nuclei are known to project to ACE and thus constitute multisynaptic intra-amygdala links between AL and ACE. Supported by MH 38774.

SINGLE MEDIAL AMYGDALA NEURONS ARE MODULATED BY SYNAPTIC CONNECTIONS WITH BOTH THE OLFACTORY BULB AND THE VENTROMEDIAL HYPOTHALAMUS. M. Wong & R.L. Moss, Dept. of Physiology, Univ. Texas Southwestern Medical Center, Dallas, TX 75235

The medial amygdala (m-AMG) has direct reciprocal connections with both the accessory olfactory bulb (AOB) and the ventromedial hypothalamus (VMH). As the accessory olfactory system can modulate reproductive physiology, such as gonadotropin release and lordosis in the rat, the m-AMG may mediate the regulation of hypothalamic function by olfactory inputs. This study investigated the influence of stimulation of the olfactory bulb and VMH on electrical activity in the m-AMG, as well as the effect of iontophoretically-applied drugs. Extracellular single-unit recordings were obtained from urethane-anesthetized ovariectomized female rats (200-300g) with seven-barreled glass microelectrodes. Stimulating electrodes were placed in the VMH and either the AOB or the main olfactory bulb (MOB). AOB stimulation induced orthodromic excitatory (n=61, 21%) or inhibitory (n=194, 67%) responses in 255 (88%) of 288 m-AMG cells. The majority of m-AMG neurons responsive to AOB stimulation also showed orthodromic responses (n=228) to VMH stimulation. Furthermore, 14 other of these AOB-responsive cells were antidromically-activated by the VMH, showing that the AOB can influence m-AMG neurons which project directly to the VMH. While iontophoretic application of GABA inhibited 98% of m-AMG neurons, bicuculline could block some of the orthodromic inhibitory responses from AOB and VMH stimulation. In separate experiments, MOB stimulation also induced orthodromic excitation (39%) and inhibition (50%) in m-AMG neurons, but this orthodromic distribution was significantly different than that due to AOB stimulation. Our results indicate that individual m-AMG neurons can integrate and relay excitatory and inhibitory information directly between the AOB and VMH. Supported by NIH Grant MH47418.

189.15

SINGLE MEDIAL AMYGDALA NEURONS ARE MODULATED BY SYNAPTIC CONNECTIONS WITH THE VENTROMEDIAL HYPOTHALAMUS AND MIDBRAIN, ESTROGEN-PRIMING, AND LOCALLY-APPLIED NEUROTRANSMITTERS. R.L. Moss & M. Wong, Dept. of Physiology, Univ. Texas Southwestern Medical Center, Dallas, TX 75235

The medial amygdala (m-AMG) is an estrogen-receptor-containing region, which can modulate hypothalamic-controlled reproductive function, such as gonadotropin release and lordosis in the rat. This study investigated the influence of stimulation of two structures implicated in sexual behavior, the ventromedial hypothalamus (VMH) and midbrain central gray (MCG), on electrical activity in the m-AMG, as well as the effect of iontophoretically-applied drugs and estrogen-priming. Extracellular single-unit recordings were obtained from urethane-anesthetized ovariectomized female rats (200-300g) with seven-barreled glass microelectrodes. Stimulating electrodes were placed in the VMH and MCG. VMH stimulation elicited excitatory (27%) or inhibitory (45%) orthodromic responses in 72% and antidromic responses in 7% of a total of 221 m-AMG neurons, whereas MCG stimulation induced only orthodromic responses in 43% (19% excitatory, 24% inhibitory). Most cells that were responsive to MCG stimulation also showed orthodromic responses to VMH stimulation in the same direction. Lesioning of the VMH in 4 out of 7 cases eliminated the orthodromic response from the MCG, indicating that the MCG influences the m-AMG at least partially via the VMH. m-AMG neurons were largely excited by iontophoretically-applied glutamate and ACh and inhibited by GABA. Estrogen-priming increased the spontaneous firing rate and the responsiveness to ACh of m-AMG cells. The results of this study suggest that the m-AMG may mediate synaptic and hormonal signals relating to hypothalamic and brainstem control of reproductive behavior. Supported by NIH Grant MH47418.

NEURONAL RESPONSES OF THE MONKEY AMYGDALOID COMPLEX TO DYNAMIC VISUAL STIMULI. F.K.Nahm, T.D.Albright and D.G. Amaral UCSD Group in Neurosciences, La Jolla, CA 92093; The Salk Institute, La Jolla, CA 92037.

The amygdaloid complex has been implicated in the processing of affective information which is an important attribute of complex visual stimuli such as faces. For non-human primates in particular, accurate assessment of facial gestures is critical for normal social interaction. Lesions of the amygdala are known to severely disrupt social behavioral patterns. Developing theories concerning the role of the amygdala necessitates determining which characteristics of complex stimuli are particularly salient for altering amygdaloid neuronal activity. To this end, we have developed a strategy whereby neuronal responses of the monkey amygdala to realistic, dynamic visual stimuli can be studied.

In these studies, single units were recorded in the amygdala of the awake, behaving monkey (*Macaca mulatta*). Two main classes of stimuli were presented: 1) static and dynamic complex images; 2) real-time video footage of conspecific facial expressions. All stimuli were stored on optical laser discs and presented over a computer controlled high-resolution video monitor.

Presentation of the stimuli described above revealed substantial variability in visual responsiveness. Baseline firing rate varied considerably across cells, and both excitatory and inhibitory responses were observed. The majority of neurons exhibited differential responses to both static and dynamic stimuli. In several cases, responses to monkey facial expressions were significantly above that of non-monkey images; at times exhibiting selectivity for monkey identity and/or expression. Taken together, these data confirm earlier findings that amygdaloid neurons are highly sensitive to visual stimuli. As more data are accumulated, we hope to determine whether the affective quality of visual stimuli is also relevant to visually responsive neurons in the amygdala. ACOUSTIC RESPONSES OF SINGLE NEURONS IN THE LATERAL NUCLEUS OF THE AMYGDALA IN BEHAVING AND ANESTHETIZED RATS. F. Bordi, C. Pavlides, C. Clugnet, and J.E. LeDoux, Center for Neural Sci., New York Univ., New York, NY 10003.

The lateral nucleus of the amygdala (AL) receives inputs from sensory processing areas in the neocortex and thalamus. In order to understand the contribution of these sensory inputs to emotional and memory functions of the amygdala, we have studied the activity of single neurons in AL in freely behaving and anesthetized animals in response to acoustic stimuli. Responses elicited by broad spectrum auditory stimuli (white noise, clicks) were recorded from AL and, for comparison, from the ventral division of the medial geniculate body (MGV) of anesthetized rats. AL units responded with short latencies (15-20 ms) as well as longer latencies (100-150 ms). The threshold for activating these neurons was in the 60-80 dB SPL range. Some of the short-latency response units showed frequency preferences. MGV neurons also responded with short (9-12 ms) and long (100-150 ms) latencies but to much lower intensities and with much stronger frequency preferences than AL neurons. In freely moving animals neurons recorded in AL from implanted microwires responded to broadband acoustic stimuli with short (20-25 ms) and long (100-150 ms) latencies. Spontaneous firing was higher and a greater number of neurons responded to acoustic stimuli in the awake than in the acute AL recordings. In conclusion, acoustic response properties (latencies, breadth of tuning) of AL neurons suggest that they are outputs of auditory processing areas. It remains to be determined exactly how the amygdala converts these auditory signals into emotional and mnemonic representations. Supported by MH38774.

EFFECTS OF LESIONS IN AND AROUND THE ROSTRAL CENTRAL AMYGDALOID NUCLEUS OF THE RAT ON DRINKING PASSIVE AVOIDANCE. G.D. Coover, Department of Psychology, Northern Illinois University, DeKalb, IL 60115.

Electrolytic lesions of the rostral half of the central amygdaloid nucleus (ACE) produce a marked deficit in drinking passive avoidance (dPA) that appears to be due to a reduction in fear and conflict, an "anxiolytic" effect (Coover, Murison and Jellestad, *Soc. Neurosci. Abstr.*, 15:1251, 1989). Small electrolytic lesions were placed in 11 locations in and around ACE to better localize the neurons whose damage produces this deficit.

Lesions of the rostral third of ACE produced a marked deficit in dPA whether they extended dorsally into globus pallidus (rACE+gp) or ventrally into the basomedial nucleus of the amygdala (rACE+bm). These groups required 4.3 ± 2 (±SE) or 4.5 ± 2 footshocks of increasing intensity to avoid the water spout for 5 min, compared to 2.0 ± 1 for the control group. In contrast, intermediate deficits were produced by lesions placed .7 mm away from rACE+gp rostrally (3.2 ± 4), laterally (3.3 ± 2), caudally (3.2 ± 3) or medially (3.6 ± 5), and also by lesions placed 1.0 mm dorsal to rACE+gp (3.4 ± 3). Lesions did not produce a deficit in dPA when in the caudal third of ACE (2.4 ± 4), .7 mm dorsal to the middle third of ACE (2.4 ± 3) or .7 mm ventral to either the middle third (2.6 ± 5) or caudal third (2.3 ± 2) of ACE.

The rostral third of ACE continues to stand out as the most dramatic site for lesion-induced anxiety.

BRAIN METABOLISM AND BLOOD FLOW II

190.1

RESIDUAL EFFECTS OF TRACER IN SEQUENTIAL DOUBLE LABEL DEOXYGLUCOSE (DG) STUDIES. M.J. Lyon, C.B. Smith, B.W. Agranoff and L. Sokoloff, Laboratory of Cerebral Metabolism, NIMH, Bethesda, MD 20892.

In DG studies in which there is a high level of variability among experimental animals, it would be advantageous to be able to measure local metabolic rates (LCMR_{plc}) twice in the same animal, i.e. during control and stimulated periods or during two periods with different stimuli. Studies employing sequential double label approaches have been qualitative and/or have not adequately accounted for incorporation of the first label during the second experimental period. The purpose of this study was to quantify in rats the degree of incorporation of residual first label during the second experimental period while holding the total duration of the experiment close to the establish optimum of 45 min. In ten barbiturate-anesthetized rats, the proximal portion of the transected right sciatic nerve was placed on a bipolar electrode and stimulated with 2 msec, 15 Hz, 200-400 μ A pulses. The stimulus was continuously monitored and maintained for 25 min beginning either at the time of ¹⁴C-DG injection or 25 min later. Each rat was killed 50 min after tracer injection. LCMR_{plc} was determined in the medial regions of laminae 2-6 in the dorsal horns of the lumbar spinal cord. When the stimulus is applied during the first or second 25 min after tracer injection, LCMR_{plc} in the dorsal horn ipsilateral to the stimulus was 190% and 150% of the contralateral side, respectively. In an attempt to decrease the body burden of free ¹⁴C-DG, an exchange transfusion with fresh blood was carried out at a rate of 4 ml/min starting 10 min after isotope injection and lasting 10 min. In these experiments, the effect of stimulation during the second 25 min was to increase LCMR_{plc} in the ipsilateral dorsal horn to 140% of the contralateral side. These results show that stimulation during the second experimental period from 25-50 min still produces a significant effect on LCMR_{plc}, even following transfusion. Sequential double label methods must take into consideration this residual effect which tends to obscure possible differences in LCMR_{plc} between two states.

190.2

ELEVATION OF LOCAL CEREBRAL GLUCOSE UTILIZATION IN SPONTANEOUSLY HYPERTENSIVE RATS BY UNILATERAL SUPERIOR CERVICAL GANGLIONECTOMY. L. Wei*, S.-Z. Lin, V. Acuff*, T. Otsuka*, C. Patlak* and J. Fenstermacher, Department of Neurological Surgery, SUNY at Stony Brook, NY 11794

Hyperactivity, cerebral atrophy, and lowered local cerebral glucose utilization (LCGU) have been reported in adult spontaneously hypertensive rats (SHR). The hypertension of SHR has been postulated to rise in part from increased sympathetic nervous system activity. To test this hypothesis, we measured LCGU six months after unilateral removal of the superior cervical ganglion (uGX) from infant SHR and Wistar-Kyoto (WKY) rats (the normotensive control for SHR). Age-matched intact (control) SHR and WKY were also studied. LCGU was measured by the 2-deoxyglucose technique; tissue radioactivity was measured by quantitative autoradiography. Blood pressure was unaffected by uGX. In 7-month-old rats, LCGU in most gray matter areas was lower in control SHR than WKY; the differences were significant ($p < 0.05$) in 16 of 28 gray matter areas. Six months after ganglionectomy, LCGU was slightly higher in some areas of WKY and significantly higher ($p < 0.05$) in most areas of SHR relative to their respective controls. Rates of LCGU were similar in uGX-WKY and uGX-SHR. The wide-spread effects of uGX on adult SHR suggest that neural activity was increased throughout the brain of SHR by unilateral ganglionectomy during infancy.

190.3

PARALLEL REDUCED CEREBRAL GLUCOSE UTILIZATION IN GABAERGIC NIGRAL EFFERENT TARGET REGIONS IN 2 RAT MODELS FOR TARDIVE DYSKINESIA. F.I. Tarazi, S.E. Bachus, O. Shirakawa, M. Gottschalk, C.A. Tamminga. Maryland Psychiatric Research Center, University of Maryland at Baltimore, Baltimore, MD 21228.

Vacuous chewing movements, proposed as an animal model of tardive dyskinesia, can be induced in rats either by chronic neuroleptic treatment, or by bilateral intranigral microinfusion of isoniazid¹. Reduced outflow in GABAergic nigral efferents has been hypothesized in dyskinesias². Thus, we have examined here whether an alteration in regional cerebral glucose utilization (rCMRglu) is produced in the nigroreticular and nigrostriatal target regions in rats treated with either 6-12 months of haloperidol (1.5 mg/kg/day po; n=17) or water (n=11); or with bilateral intranigral microinfusion of isoniazid (1.02 micromoles/1 microliter/8 min; n=6) or saline (2.04 osmol n=6) 20 min. prior to [¹⁴C]-2-deoxyglucose administration³. rCMRglu was significantly reduced (p<.001) in both the nigroreticular and nigrostriatal target regions in isoniazid-treated rats relative to saline controls (to 72% and 77%, respectively), but did not differ in control regions. Similarly, in chronic haloperidol-treated rats, local cerebral glucose utilization was decreased in the nigroreticular target region (p, .025), to 81% of control values. These results both strengthen the rationale for using acute intranigral isoniazid treatment as an animal model for tardive dyskinesia, and further implicate alterations in GABAergic nigral efferent projections in vacuous chewing movements in rats, and by analogy, in tardive dyskinesia.

REGIONAL CEREBRAL BLOOD FLOW RESPONSES TO ELECTRICAL STIMULATION OF THE DORSAL RAPHE NUCLEUS IN THE RAT.

M.J. Bakalian, M.D. Underwood, V. Arango, and J.J. Mann. Laboratories of Neuropharmacology, University of Pittsburgh, Pittsburgh 15213.

We have previously demonstrated both an increase and decrease in cortical blood flow (CrBF) in response to electrical stimulation of the dorsal raphe nucleus (DRN) using laser doppler flowmetry (LDF) (*Neurosci. Abstr.* 16:290, 1990). We sought to determine whether the changes in blood flow are restricted to cerebral cortex or widespread throughout the brain.

Rats were anaesthetized (α -chloralose), paralyzed and artificially ventilated. Arterial pressure, heart rate and blood gases were continuously monitored and regulated. The DRN was stimulated electrically (1 s on/1 s off, 200 Hz, 100 μ A) and the resulting increase in arterial pressure was controlled by exsanguination. Regional cerebral blood flow (rCBF) was measured in 13 dissected brain regions using ¹⁴C-iodoantipyrine (IAP) as tracer. Local CrBF was monitored using LDF with the probe placed extracranially over the parietal cortex. The stimulation sites were verified histologically.

In unstimulated controls (n = 6), rCBF varied significantly across brain regions (p < 0.05) and ranged from 86 \pm 11 ml/min/100g in parietal cortex to 51 \pm 3 ml/min/100g in corpus callosum. Based on CrBF responses to DRN stimulation, animals were divided into 2 groups: increased (n = 6) and unchanged or decreased (n = 7) CrBF. Changes observed in rCBF were in the same direction as the change in CrBF in 12 of 13 brain regions with the exception of medulla. Increases in rCBF ranged from 49% in parietal cortex to 11% in cerebellum. Decreased rCBF ranged from 25% in hippocampus to 9% in pons. The magnitude of the increase in rCBF did not correlate with that of the decrease in rCBF across brain regions (r = 0.14, p > 0.05).

We conclude that stimulation of functionally distinct regions of DRN results in either increased or decreased cerebral blood flow across multiple brain regions. The different degree of rCBF changes in the two responses across brain regions suggest the involvement of different effector mechanisms. (Supported by MH46745.)

190.7

EFFECTS OF SUMATRIPTAN ON AFFERENT AND EFFERENT MECHANISMS OF TRIGEMINAL SENSATION. G.A. Lambert*, J. Michalick*, D. Tan*, H. Angus-Leppan and P. Boers*. Institute of Neurological Sciences, Prince Henry Hospital and University of New South Wales, Little Bay 2036 Australia.

The antimigraine drug sumatriptan was tested for its effects on trigeminal sensation and craniovascular control. In cats anaesthetized with chloralose, carotid blood flows were measured with electromagnetic flow probes and cortical microcirculation with laser Doppler flow probes. Each trigeminal ganglion was stimulated electrically. One trigeminal root was sectioned through a craniotomy made through the petrous temporal bone. Cortical circulatory mechanisms were left intact by inserting electrodes under additional halothane anesthesia. Cortical circulatory integrity was tested by subjecting animals to 5% inhaled CO₂. Single unit responses of cervical spinal cord units receiving input from the superior sagittal sinus were studied before and after intravenous injection or iontophoretic application of sumatriptan. Stimulation of the intact trigeminal pathway produced falls in blood pressure and increases in ipsilateral carotid blood flow (+60% at 2 sec⁻¹) as previously reported ("reflex response") but only small and variable effects (-7% at 2 sec⁻¹) on cortical blood flow. Stimulation of the trigeminal ganglion on the lesioned side did not produce changes in blood pressure or carotid flows and only small changes in cortical flows ("antidromic response"). Sumatriptan (100 μ g/kg iv) produced a transient biphasic change in blood pressure (+16/-14 mmHg), a prolonged decrease in carotid blood flow (-20%) and a transient increase in cortical flow (+10%). Sumatriptan had no significant effect on responses to trigeminal stimulation except for a slight potentiation of the antidromic dilator response in the cortical circulation. Iontophoretic application of sumatriptan (40 nA) reduced or abolished the response of approximately one third of all units responding to electrical stimulation of the superior sagittal sinus, an effect comparable to the ergot antimigraine drugs. We conclude that pain in the trigeminal system produces changes in cranial blood flow largely through reflex mechanisms and that sumatriptan reduces cranial blood flow without affecting cortical microcirculation.

190.4

NEOCORTICAL METABOLIC RESPONSES TO CHOLINERGIC AND NON-CHOLINERGIC DRUGS ARE NOT MODIFIED BY PRIOR UNILATERAL ABLATION OF THE NUCLEUS BASALIS MAGNOCELLULARIS IN RAT. E. De Micheli, D.M. Larson*, H.W. Holloway*, V. Lamour, T.T. Soncrant. Unit on Pharmacology and Pharmacokinetics, Lab. Neurosci., NIA, NIH, Bethesda, MD 20892.

Unilateral ablation of the nucleus basalis magnocellularis (NBM), which reduces cholinergic inputs to the ipsilateral frontoparietal neocortex, transiently depresses regional cerebral metabolic rates for glucose (rCMRglc) in denervated cortical areas, but rCMRglc recovers within 2 wk. To determine the possible effect of cholinergic deafferentation on the responsiveness of other transmitter systems, we studied rCMRglc responses to cholinergic, serotonergic and dopaminergic drugs in rats after unilateral NBM ablation. NBM lesions were made in young rats by stereotaxic ibotenate injection. Two wk later, arecoline, physostigmine, nicotine, DOI, m-chlorophenylpiperazine, haloperidol or apomorphine was administered, and rCMRglc was measured with the autoradiographic [¹⁴C]deoxyglucose method. No significant left-right rCMRglc asymmetries were found in any drug-treated group as compared to saline controls. rCMRglc effects of all drugs were similar to those found in unlesioned rats. Hence, a reduction in cortical cholinergic inputs (as occurs early in Alzheimer's disease) does not by itself alter the responsiveness of cholinergic, dopaminergic or serotonergic neocortical mechanisms.

190.6

THE REGIONAL DISTRIBUTION OF CEREBRAL GLUCOSE UTILIZATION DURING THE "RUSH" PERIOD FOLLOWING COCAINE ADMINISTRATION. A.E. Carmazola*, M.B. DeJoseph*, D.W. McCandless* and R.A. Hawkins. UHS/The Chicago Medical School, North Chicago, IL, 60064.

The most prominent clinical effect of cocaine on mood is that of euphoria, resulting from the prolonged stimulating action of the neurotransmitter dopamine. The action of dopamine is enhanced by cocaine's ability to block the reuptake of the neurotransmitter. This augmented dopaminergic activity has been seen most prominently in the nucleus accumbens. In the present study we also noted a significant increase in the energy metabolism of the nucleus accumbens. Since energy metabolism of the brain is tightly coupled to its function, we used radiolabeled glucose as a means of identifying neuroanatomical sites that were stimulated or depressed by the administration of cocaine. Comparisons were then made between cerebral glucose utilization (CMR_{Gluc}) in the "rush" phase and controls, and also between the "rush" phase and the steady "high" state. We used three groups (Control, 2.5 and 10 mg/kg cocaine) of male, Long Evans rats which ranged between 270-320 grams. Cocaine was administered by intravenous injection, as this is a common route of administration among cocaine-abusing humans. We observed that the CMR_{Gluc} of the "rush" period differs from that of the steady "high" state. Whole brain glucose utilization in rats given 2.5 and 10 mg/kg cocaine was shown to increase by 53% and 47%, respectively, above control levels. This increase also represented a rise in CMR_{Gluc} above the corresponding steady state levels of 11% and 17%, respectively. All brain regions examined demonstrated an increase in the CMR_{Gluc}, with the greatest increases occurring in certain components of the olfactory, extrapyramidal motor and cholinergic pathways.

190.8

WISCONSIN CARD SORT rCBF ACTIVATION IN NORMAL SUBJECTS: DISTRIBUTION IMAGES VS COMPUTED rCBF VALUES. S. Marengo, R. Coppola, D.W. Jones, D.R. Weinberger. Clinical Brain Disorders Branch, NIMH Neuroscience Center at St. Elizabeth's Hospital, Washington DC 20032, USA.

The use of radioactivity distribution images for the analysis of regional cerebral blood flow (rCBF) studies has been advocated for PET studies to avoid arterial sampling. We applied the same concept to Xe-133 inhalation rCBF studies using dynamic single photon emission tomography. 10 normal subjects were studied in two conditions: during execution of the Wisconsin card sort (WCS) and of a sensorimotor control task. 3 slices (2 cm thick) 4, 6 and 8 cm. above and parallel to the CM line were acquired using a 16 mm (FWHM) collimator. rCBF values were computed (Kanno Lassen method) for ROIs defined with the aid of a template adaptable to the individual head size. Count rates for each ROI were obtained for each acquisition interval (first 1.5 minutes of examination [wash in] and one collection for each of the following 3 minutes of examination [wash out]) and for the sum of the four collections (SUM). The ROI count values were normalized to the total count rate in the slice.

Analysis of absolute rCBF values by multiple t-tests showed significant differences between WCS and BAR in two ROIs. 9 ROIs were significant when rCBF values were normalized by the global CBF of the slice. Count rates for the first collection period differed in 10 areas and among them the left dorsolateral prefrontal cortex, where activation was expected to occur, as demonstrated by several previous reports. The analysis of the SUM images yielded 12 areas of statistical significance, including the left dorsolateral prefrontal activation. It is therefore possible that count rate distribution analysis, based on more reliable information than rCBF values computed from only 4 time points, may be more accurate in detecting regional activation. Though the variance due to arterial input is ignored with this method, the assumption that this and other interfering factors (e.g. recirculation) should not differ between two back to back examinations is reasonable.

190.9

REGIONAL CEREBRAL BLOOD FLOW PRIOR TO, DURING, AND FOLLOWING RECOVERY SLEEP. A.R. Braun, T.J. Balkin*, N.J. Wesensten*, K. Berman, P. Baldwin*, S. Stein*, R.E. Carson*, G. Belenky and P. Herscovitch. NIDCD, NIMH and Dept. of Nuclear Medicine, NIH, Bethesda, MD 20892, and Dept. of Behavioral Biology, WRAIR, Washington, D.C. 20307.

Regional cerebral blood flow (rCBF) was measured with $H_2^{15}O$ positron emission tomography (PET) in 8 healthy male subjects (ages 21-32) after 24-48 hours of sleep deprivation (pre-sleep), during slow wave sleep (SWS), and following recovery (post-sleep). During each of these states, 30 mCi of $H_2^{15}O$ was administered i.v. by bolus infusion and PET scans were performed on a Scanditronix PC2048-15B tomograph (axial and in-plane resolution of 6.5 mm FWHM). Sleep stages were monitored by an experienced polysomnographer. Irregular regions of interest were placed on the reconstructed images, and data were normalized by dividing each pixel value by the mean global flow rate calculated for each scan. Normalized blood flow values were analyzed by repeated measures ANOVA. F-tests for the individual components of variation were used to determine differences between means, when appropriate, and are reported below ($p < .05$, each case).

Normalized rCBF rates were lower in SWS than in both sleep-deprived and post-sleep states in subcortical structures including cerebellum, pons and thalamus. In caudate and putamen, blood flow values did not differ significantly between SWS and sleep-deprived states, but were significantly increased following recovery sleep. On the other hand, in post-rolandic sensory (temporal and occipital) cortices, normalized blood flow rates in SWS exceeded those measured in either pre- or post-sleep states.

Previous PET studies of regional cerebral metabolism in sleep have utilized the fluorodeoxyglucose method which does not afford the temporal resolution possible with $H_2^{15}O$ or permit direct comparison with temporally associated pre- and post-sleep states. Although these results may be affected by the normalization process, SWS appears to be associated with differential, regionally specific changes in cerebral blood flow which differentiate it from both sleep-deprived and post-recovery states.

190.11

CEREBRAL HEMODYNAMICS IN THE CHRONIC HYDROCEPHALIC RAT. S.C. Kim, P. Tompkins*, P.A. Roberts*, D. Horton*, E. Bates* & M. Pollay. Division of Neurosurgery, University of Oklahoma and Veterans Administration Medical Center, Oklahoma City, OK 73190.

Because of an interest in changes in cerebral hemodynamics with pathologic conditions, a kaolin induced chronic hydrocephalus rat model was used to evaluate cerebral perfusion flow and cerebral blood volume. Hydrocephalus was induced by injection of kaolin into the cisterna magna of rats. Enlargement of the ventricles occurred in 8-10 weeks. In one set of experiments hydrocephalic animals were shown to have significantly reduced cerebral perfusion flow (1.77 ml/min/gm control, 1.53 ml/min/gm hydrocephalic, $p < 0.05$). In separate experiments, cerebral blood volume tended to be increased in chronic hydrocephalus (11.8 ul/gm) as compared to controls (10.1 ul/gm), although this increase was not significant ($p = 0.08$). Since flow is equal to volume divided by transit time, it would appear that transit time through the cerebral circulation is increased in chronic hydrocephalus. Experiments in progress will simultaneously determine brain and choroid plexus blood flow, blood volume, and CSF production rates in a rabbit model of chronic hydrocephalus.

CARDIOVASCULAR CHANGES AFTER MIDDLE CEREBRAL ARTERY OCCLUSION (MCAO) IN RATS. A. D. Perez-Trepichio, J. L. Williams, and S. C. Jones. Department of Brain and Vascular Research, Cleveland Clinic Foundation, Cleveland, OH 44195.

MCAO changes autonomic function by affecting central neural mechanisms. Stroke patients exhibit increases in plasma catecholamines, cardiac arrhythmias, and myocardial cell damage (*Stroke* 13: 838, 1982). In animals, MCAO causes autonomic changes acutely, but chronic autonomic changes have not been examined. In this study, we measured mean arterial pressure (MAP) and heart rate (HR) immediately and 24 hr after MCAO.

Sprague-Dawley rats were anesthetized (halothane in 70% N_2O -30% O_2) and ventilated mechanically. The left pterygopalatine artery was cauterized, and saline vehicle (Sham) or a silicone cylinder in saline (MCAO) was injected into the left external carotid artery retrogradely. After initial measurements of MAP and HR, we discontinued anesthesia. 24 hr after MCAO or sham treatment, the rat was reanesthetized. Measurements (means \pm SE) before (Control) and after treatment were:

	Control	10 min	90 min	24 hr
MAP, Sham	114 \pm 4 (8)	106 \pm 5 (8)	109 \pm 6 (8)	116 \pm 6 (8)
MAP, MCAO	112 \pm 2 (9)	127 \pm 4 (9)*	125 \pm 3 (9)*	116 \pm 7 (6)
HR, Sham	352 \pm 17 (8)	331 \pm 11 (8)	353 \pm 29 (5)	334 \pm 39 (8)
HR, MCAO	343 \pm 7 (9)	386 \pm 21 (7)*	412 \pm 31 (6)	365 \pm 11 (6)

* Different from Sham group, $P < 0.05$. Number in parenthesis = n.

MCAO produced immediate increases in MAP and HR. 24 hours after MCAO, however, MAP and HR decreased to preocclusion levels and were not different from sham rats. Our findings suggest that by 24 hr after MCAO, changes in MAP and HR are compensated either centrally or peripherally to maintain MAP and HR at normal levels. (Supported by NIH NS24343)

190.10

EFFECT OF NITRIC OXIDE SYNTHETASE INHIBITION ON CEREBRAL BLOOD FLOW (CBF) IN THE CONSCIOUS RAT. I.M. MACRAE, D.A. DAWSON*, J.L. REID*, J. McCULLOCH. Dept. of Medicine, University of Glasgow, G12 8QQ, U.K.

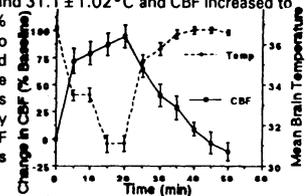

Nitric oxide is the major endothelium-derived relaxing factor of vascular smooth muscle. Inhibitors of the enzyme, nitric oxide synthetase (e.g. N^G -nitro-L-arginine methyl ester (L-NAME)) give rise to marked hypertension and bradycardia with differential effects on flow in peripheral vascular beds in the conscious rat. We have studied the effect of inhibition of nitric oxide synthesis on CBF.

L-NAME (30 mg/kg i.v.) elicited a significant hypertension ($+34 \pm 2$ mmHg) and bradycardia (-134 ± 6 beats/min) in conscious lightly restrained, male, Sprague Dawley rats. The maximum response was reached within 3 min of administration and hypertension was maintained for the duration of the experiment. Regional CBF 15 mins post-drug was analysed in microdissected areas of brain following a ramped, 30 sec infusion of ^{14}C -iodoantipyrine. CBF was significantly reduced throughout the brain. Control flows in cerebellum, hippocampus, cortex and thalamus were 85 ± 4 , 71 ± 3 , 102 ± 4 and 91 ± 4 mls/100g/min, resp. This compares with flows following L-NAME of $56 \pm 2^*$, $44 \pm 2^*$, $63 \pm 4^*$ and $65 \pm 3^*$ mls/100g/min, resp. ($*p < 0.001$, Dunnett's test). These results are consistent with a tonic involvement for nitric oxide in the control of CBF.

190.12

SELECTIVE BRAIN COOLING INCREASES CBF IN RATS. J. Kuluz*, D. Smith*, R. Busto, MD Ginsberg, WD Dietrich, MYT Globus. Cerebral Vascular Disease Research Ctr, Univ of Miami, Miami, FL 33136.

Previous measurements of CBF during hypothermia have been done with total body cooling. Since body cooling decreases cardiac output and thus CBF, we measured CBF using laser doppler (LD) flowmetry during selective brain cooling while rectal temp was maintained at 37°C. Five adult male Wistar rats underwent eight 20-min periods of brain cooling. For the 1st ten min room temp air was blown across the head followed by liquid N_2 vapor for the next 10 min. CBF was measured by LD in the lateral parietal cortex. CBF was recorded continuously and the mean value for each 5-min period was compared to baseline. Brain temp was measured in the outer parietal cortex contralateral to the LD probe. Halothane was discontinued 45 min prior to brain cooling and rats received 2:1 N_2O_2 and pancuronium for paralysis. $PaCO_2$ was 35-40 torr. Results: Air cooling caused a rapid decrease of brain temp to 33.5 ± 0.26 and 33.5 ± 0.34 (mean \pm SEM), and an increase in CBF to 72.1 ± 11.8 and $79.5 \pm 10.8\%$ above baseline during the 1st two 5-min periods. With liquid N_2 brain temp fell to 31.1 ± 1.19 and 31.1 ± 1.02 °C and CBF increased to 87.3 ± 10.4 and $94.9 \pm 10.5\%$ above baseline during the 2nd two 5-min periods. MAP and ICP did not change. Conclusion: Selective brain cooling acutely increases CBF in normal rats as measured by LD. If brain cooling increases CBF after ischemia this may explain its protective effects.

IR THERMAL IMAGING OF A MONKEY'S HEAD: LOCAL TEMPERATURE CHANGES IN RESPONSE TO SOMATOSENSORY STIMULATION.

J.S. George, J.D. Lewine, S.W. Moore* & E.R. Flynn. Los Alamos National Laboratory, M-715, Los Alamos, NM 87545

Physiological activation of small populations of cortical neurons is accompanied by changes in regional blood flow and metabolic activity that might produce measurable local temperature changes. Motivated by reports from a Soviet group (Gorbach *et al. Thermology*, 3:108-111, '89), we have begun to investigate the use of thermal imaging for mapping neural activity. An Inframetrics model 600 IR thermal video imager was positioned above the shaved head of an anesthetized macaque monkey. In the first experiment, we attempted to resolve the early timecourse of transient thermal responses to brief electrical depolarization of either the left median or tibial nerve. Stimuli were delivered at 30 second intervals. A sequence of 64 video frames (at 30 Hz) spanning each stimulus (16 pre- and 48 poststimulus) was collected in frame memory of an Imaging Technology video digitizer. Image sequences from 16 trials were summed in main memory. Groups of 16 sequential frames (~.5 sec) were summed, and the prestimulus composite image was subtracted from 3 poststimulus composite images. In a second experiment we attempted to image steady-state changes in temperature distribution associated with repetitive stimulation. A sequence of 64 prestimulus frames was collected to construct a baseline image. Electrical stimuli were then delivered at 5 second intervals for 2 minutes; two sequences of 64 frames were collected and stored. Stimulation was discontinued for 3 minutes, and a poststimulus baseline image was collected. Images in each sequence were averaged, and differences between control and stimulated average images were examined. Difference images for both steady-state and transient conditions demonstrated stimulus-induced warming at locations consistent with *a priori* knowledge of the topographic organization of somatosensory cortex. Although these experiments clearly established the necessity (and difficulty) of adequate thermal control, they also demonstrate the potential utility of thermal imaging techniques for noninvasive characterization of patterns of neural activity.

AGE AFFECTS EYEBLINK CONDITIONING AND RESPONSE DISCRIMINATION IN HUMANS. J.F. Disterhoft, S.W. Conroy*, L.T. Thompson, B.J. Naughton* & L.D.E. Gabrieli. Departments of CMS Biology, Medicine and Psychology, Northwestern University Medical School, Chicago, IL 60611.

Eyeblink conditioning was originally used by experimental psychologists as an objective paradigm to investigate laws of learning in humans. This simple learning task has been used extensively to investigate the neural substrates of eyeblink conditioning in animal models. We recently showed that trace blink conditioning is impaired in aging rabbits, and that the learning deficit is reversed with i.v. nimodipine (Deyo, et al., 1989). Since trace conditioning is hippocampally-dependent (Moyer et al., 1989), we hypothesize that nimodipine enhances hippocampal function in aging. CA1 pyramidal cell excitability is increased by nimodipine in a dose- and age-dependent fashion both *in vivo* (Thompson et al., 1990) and *in vitro* (Moyer et al., 1991). We are now beginning studies to determine if our behavioral data in the rabbit model can be generalized to the human.

Younger (N=5, mean age=24.6) and older (N=6, mean age=66) humans were trace eyeblink conditioned, with a differential reaction time task to one of two lights as a distractor. All Ss had normal hearing at 3 kHz; were within normal ranges on Benton Visual Retention Test, WMS-R Logical Memory & Paired Associates subtests, WAIS-R Vocabulary subtest, Mini-Mental Status Exam and Geriatric Depression Scale; were in good health on physical exams; and were nonsmokers. Older Ss showed significantly fewer eyeblink CRs in 50 training trials; no difference in UR amplitude was noted. Older Ss blinked more to both lights on the reaction time task. These blinks were apparently generalized CRs as they had similar latency, form, and amplitude as the blinks on tone-puff trials. These data suggest that older humans show reduced acquisition of this hippocampally-dependent learning task. Older Ss also exhibit less response discrimination between stimuli. (Supported by Miles Inc., Pharmaceutical Division).

RESPONSE BIAS IN GERIATRIC DEPRESSION WITH AND WITHOUT COGNITIVE IMPAIRMENT. R.C. Young, S. Mattis*, B. Kalayam*, B.S. Meyers*, and G.S. Alexopoulos*.

New York Hospital-Cornell Medical Center, Westchester Division, White Plains, NY 10605.

State-dependent abnormalities in response bias reported in mixed-age depressives (Corwin et al, 1990) have not been investigated in the elderly. Patients (n=35) with major depression by DSM-III criteria treated in a geriatric psychiatry service were given a verbal learning task. Signal detection measures of immediate and delayed recognition memory (d') and response bias (beta and C) were obtained. Testing was performed before, and at two week intervals during, six weeks of pharmacotherapy with nortriptyline. Patients were retrospectively categorized as persistently impaired (n=11) or unimpaired (n=24) based on Dementia Rating Scale scores after optimal treatment. Hamilton Depression Rating Scale scores improved in both groups. Overall there was persistently poorer immediate and delayed recognition memory ($p < .001$ and $p < .03$), more liberal delayed beta ($p < .04$), and more liberal immediate and delayed C ($p < .001$ and $p < .05$) in the impaired group. With treatment, immediate beta and immediate C became more conservative in the impaired group ($p < .07$ and $p < .01$) but not in the unimpaired group. Treatment did not significantly change recognition memory in either group. MH40726-01A2

FUNCTIONAL CORRELATES OF ERP CHANGES OBSERVED DURING RECOGNITION MEMORY TESTING IN HUMANS. Michael E. Smith, Dept. of Psychology, Texas A&M University, College Station, TX 77843.

The scalp-recorded ERP discriminates between items (words) that are, and those that are not, recognized as episodically familiar. This discrimination is correlated with similar changes in hippocampal ERPs (Smith et al, '86, ECN) as well as in changes in the firing of hippocampal neurons (Heit et al, 88, Nature), and it is eliminated following lesions to the temporal lobe (Smith & Halgren, '89, JEP:LMC). However, its' functional interpretation remains unclear. Recognizing that an item has recently occurred can either be based on specific recollection of a study episode, or on some non-specific feeling of familiarity (e.g. Tulving, '89, EJCP). We performed an experiment designed to assess whether the memory-related ERP changes described above are more closely related to one or the other of these forms of recognition. Preliminary results suggest that the ERP discrimination is most closely related to specific memory for the study episode. Supported by NIH and the McDonnell-Pew Program in Cognitive Neuroscience.

191.2

EFFECTS OF AGING ON COGNITIVE, VISUOPERCEPTUAL, AND VISUOMOTOR SKILL LEARNING. J. Doyon^{1,2}, B. Laforte¹, E. Léger¹, D. Lacerte¹, J. Roy¹, L. Rousseau¹, P.J. Bédard². ¹ Ecole de Psychologie, ² Centre de recherche en neurobiologie, Univ. Laval, Québec, Canada, G1J 1Z4.

There is now a well-developed body of empirical data in humans showing that normal aging affects secondary memory, leaving sensory, primary, and tertiary types of memory relatively intact (for reviews, see Craik, 1977; Poon, 1985). However, age-related effects on skill learning are still poorly documented. The main goal of the present study was thus to investigate the effects of aging by comparing the performance of young (Mean = 22 yrs.; SD = 2.7) and older healthy adults (Mean = 60 yrs.; SD = 6.3) on cognitive, visuo-perceptual, and visuomotor skill learning tasks. A second objective was to explore the possibility of a dissociation between incremental learning capacities and declarative memory for the same stimuli in these two groups. Cognitive, visuo-perceptual, and visuomotor skill learning was measured using versions of the Digital Logic Gates Test (Carlson et al., 1989), the Repeated Sequence Test (Nissen & Bullemer, 1987), and the Mirror reading Test (Cohen & Squire, 1980), respectively. These tasks were administered to all subjects on six occasions, once a week over a period of 6 weeks. Measures of declarative knowledge for the material presented during the skill learning tasks were also given either before and after (for the cognitive task) or only after completion of the learning tests. The results for the three tasks showed an equivalent improvement in performance over practice in the two groups, even though the younger subjects were significantly better than the older ones on the measures of declarative memory. These findings suggest that aging does not impair incremental skill learning.

191.4

AN AUTOMATED DELAYED NONMATCHING-TO-SAMPLE TASK TO ASSESS VISUAL RECOGNITION MEMORY IN HUMANS. C. Chavoix, C. Hagger, A. Sirigu*, M. Gravelle*, and T. Algnar*. Laboratory of Neuropsychology, NIMH, Bethesda, MD 20892; Clinical Brain Disorder Branch, NIMH, St. Elizabeth's Hospital, Washington, DC 20032; Cognitive Neuroscience Section, NINDS, Bethesda, MD 20892.

Delayed nonmatching-to-sample (DNMS) with trial-unique 3-dimensional objects is a task of choice to assess visual recognition memory in normal and brain-damaged monkeys. As a step toward validating tasks that measure memory abilities in both humans and monkeys, we developed a computer-automated version (aDNMS) of the classic DNMS (cDNMS) task and compared performance of normal humans on the aDNMS with that of normal rhesus monkeys on the cDNMS. Performance of patients with Alzheimer's disease or schizophrenia was also evaluated on the aDNMS. Two-dimensional nonverbal symbols, and nonverbal visual feedback, projected onto a color computer monitor fitted with a touch-sensitive screen were used in the aDNMS task. Memory performance was assessed in a session of 96 trials of randomized delays (3, 6, 9, 12, 18, and 60 sec) between sample and choice presentations, followed the next day by a session of progressively increasing list lengths (10 lists of 3 stimuli, 5 lists of 6, 3 of 10, and 2 of 15).

Performance of normal humans (n=10) on the aDNMS task did not differ significantly from that of normal monkeys (n=3) on the cDNMS task, in either delay or list length conditions. In addition, patients with Alzheimer's disease (n=3) or schizophrenia (n=5) were significantly poorer than the normal humans. A significant correlation was also found between average performance across all conditions on the aDNMS task and performance on the Wechsler memory test in humans. These results indicate that this automated DNMS is an appropriate test to compare mnemonic abilities in humans and monkeys, and may be useful in the investigation of the neuroanatomical and neurochemical substrates involved in amnesic disorders.

191.6

NEURONAL ACTIVITY IN NONDOMINANT HUMAN LATERAL TEMPORAL CORTEX RELATED TO SHORT TERM SPATIAL MEMORY AND VISUOSPATIAL RECOGNITION. M.D. Holmes*, G.A. Ojemann, D.F. Cawthon, and E. Lettich*, Department of Neurological Surgery, University of Washington, Seattle, WA 98195

Extracellular microelectrode recordings from subsequently resected nondominant lateral temporal cortex, in patients undergoing craniotomies under local anesthesia for treatment of medically intractable epilepsy were obtained during performance of visually presented tasks of short term spatial memory and visuospatial recognition. Recordings from 5 populations, each reflecting activity predominantly in 1 neuron, in 2 patients, exhibited statistically significant relation to short term spatial memory or visuospatial recognition: 2 altered activity during spatial memory alone and 3 altered activity during both memory and some measures of recognition. Decreased neuronal activity was observed during the information input phase of spatial memory, and during face, line and complex figure matching tasks. Increased neuronal activity was observed during information retrieval phase of memory and during complex figure matching and recognition of facial expression. Thus, at least some areas of nondominant temporal cortex have a participatory role in spatial memory and visuospatial recognition. 191.7

IMPAIRED WORKING MEMORY IN UNMEDICATED PARKINSON'S PATIENTS. J. Singh, I.D.E. Gabrieli and C.G. Goetz. Department of Neurological Sciences, Rush-Presbyterian-St. Luke's Medical Center, Chicago, IL 60612 and Department of Psychology, Northwestern University, Evanston, IL 60208.

Working memory (WM), defined as the storage of information while simultaneously processing the same or other information, has not been studied in patients with Parkinson's disease (PD). We hypothesized that WM is abnormal in PD because some aspects of WM have been linked to frontal-lobe functions and studies have found PD patients to be selectively impaired on measures of memory sensitive to frontal-lobe lesions. We administered two tests of WM to 5 medication-free, nondemented PD patient and 10 normal control (NC) subjects matched for mean age and education. The WM tests (Salthouse & Babcock, 1990) demanded that the subjects answer verbal and arithmetic questions while simultaneously trying to remember the final word or number of a given question. Subjects also took tests of Vocabulary (WAIS-R), verbal Recognition, verbal Recall, Self-ordered Pointing, and Temporal Ordering (the last three are known to be impaired in patients with frontal-lobe lesions). The PD patients obtained significantly lower WM scores by all measures (span, number of trials, and number of items) than the NC group ($p < .01$). The same patients were unimpaired on the Vocabulary and verbal Recognition tests, but performed significantly worse than the NC group on the three tests of frontal-lobe memory capacities (verbal Recall, Self-ordered Pointing and Temporal Ordering tasks). These results suggest that WM involves an integrative frontal-subcortical system and raise the possibility that poor memory performance in PD may relate selectively to deficits in WM capacities. Supported by McDonnell-Pew Grant.

191.9

AUTOBIOGRAPHICAL MEMORY IN NORMALS AND BRAIN-DAMAGED SUBJECTS. A. Sirigu,¹ J. Grafman,¹ I. Litvan,² and J. Tothman¹ (Spons. J. Grafman). Cognitive Neuroscience Section,¹ Experimental Therapeutics Branch,² NINDS, NIH, Bethesda, MD 20892.

We investigated Autobiographical Memory (ABM) in 52 normal subjects (40 to 80 y.o.), 10 patients with dementia of Alzheimer type (DAT, mean age= 74 y.o.) and one patient with amnesia due to cerebral anoxia. In a complementary experiment we studied the effects of scopolamine on ABM in 6 healthy normal subjects. Each decade of the subjects' biography was assessed using a questionnaire that distinguished among four kinds of information: facts ("what"), people ("who"), places ("where") and dates ("when"). Results showed that (1) normal subjects in their eighties obtained lower overall scores than the other age groups. (2) Recall was best for facts and worst for dates. This effect was robust and was present in all age groups. (3) There was no consistent pattern of recall across decades in normals. (4) DAT patients were impaired relative to all normal groups and for all classes of information. Recall of ABMs in DAT patients was most affected for the middle decades, and least affected for the most remote and most recent ones ("primacy-recency" effect). (5) The amnesic patient showed an information-specific temporal gradient in ABM: recall of people's names and of dates was impaired for just the two decades preceding the onset of his illness, while recall of facts and their spatial context was preserved for all decades. (6) Scopolamine at dosage levels that impaired recall of recent information, did not affect ABM in any way. We conclude that: (1) ABM is not organized around a single unitary memory system but may depend on several distinct systems of representation. (2) ABM performances in DAT indicate an increased susceptibility to interference effects analogous to those found in normal memory (e.g. proactive and retroactive). (3) Cholinergic blockade alone cannot account for the changes in ABM recall found in DAT patients.

191.11

EFFECTS OF SEVERE BRAIN INJURY IN CHILDREN ON EXPERIMENTAL COGNITIVE TASKS. H.S. LEVIN, K. Culhane, D. Mendelsohn, H. Harward, J.M. Fletcher, L. Ewing-Cobbs. Division of Neurosurgery, Univ. Texas Medical Branch, Galveston, TX 77550.

To investigate the long-term neurobehavioral effects of closed head injury (CHI) in children, we administered experimental tasks of cognition to 25 children who had sustained severe injuries and to 14 children who had mild/moderate injuries. Severity of CHI was defined according to the lowest post-resuscitation GCS score; severe CHI was defined as a GCS score of less than or equal to 8; mild/moderate injuries had GCS scores of greater than 8. Age at the time of study and age at injury were comparable in the severe (mean age at study=9.8 yrs, mean age at injury=7.7 yrs) and mild/moderate (means=8.7 and 7.3, respectively) groups. A comparison group of 38 uninjured controls was also tested (mean age=9.3 yrs). The tasks involved problem solving, planning, and concept formation. These tasks included the Tower of London, 20 Questions, verbal fluency, and the Go-No go test. General linear model analysis revealed a significant injury severity effect on several of these measures, including the Tower of London (number of trials, $p=.01$), 20 Questions (% questions which constrained alternatives by referring to semantic categories, $p=.02$), verbal fluency (total number of words produced, $p=.005$), and Go-No go (trials to criterion, $p=.001$). Reclassification of the CHI groups by localization of lesion (via magnetic resonance imaging) revealed differences between children with frontal vs nonfrontal lesions on several measures. We conclude that (1) the late effects of severe injury of the young brain can be elucidated by experimental cognitive tasks; and (2) that prefrontal lesions may result in a distinctive pattern of cognitive deficits.

PRIMARY MEMORY AS STUDIED WITH FDG-PET IN NORMAL CONTROLS AND PATIENTS WITH FRONTAL LOBE EPILEPSY. B.E. Swartz^{1,2,3}, M. Gee^{*1,2}, M. Mandelkern^{*2,4}, J. Fuster³. 1. Cal-CEP 2. VAMC Wadsworth 3. UCLA Dept Neurology 4. UCI Dept Physics 5. UCLA Dept Psychiatry. Los Angeles, Cal 90073.

Primary memory has been linked to the prefrontal region in primates. To test whether this was also the case in humans a delayed sample matching task was administered to a group of 8 normal adults. A task of immediate sample matching was also administered as a control for attention, and the FDG uptake in each was compared to a resting control scan in the same subject. We then analyzed 6 subjects with frontal lobe epilepsy in the same way to see if the activations induced by the protocol would differ in these two groups. 80 regions of interest were drawn on each scan and each regional value normalized to the mean of the whole brain glucose uptake prior to statistical analyses in an ANOVA framework.

The controls showed task induced increases in 6 frontal, 1 parietal and 2 temporal regions, with decreases seen in two subcortical regions ($p < .05$). The patients showed increases in only 1 frontal, 1 temporal, and 1 visual region. Differences between the controls and patients occurred under all three scan conditions. A difference with respect to orbital frontal cortex was noted between immediate and delayed sample matching tasks. 6 additional subjects are currently being analyzed. The data will be interpreted with respect to known neuronal circuits and theories of frontal lobe function.

INTACT PRIMING FOR PICTURE NAMING IN GLOBAL AMNESIA. C.J. Kreiser, S.L. Reminger*, M. Verfaellie*, and I.D.E. Gabrieli. Boston University Memory Disorders Research Center, Boston, MA 02130 and Department of Psychology, Northwestern University, Evanston, IL 60208.

Despite recall and recognition deficits, patients with global amnesia (GA) have shown preserved priming (facilitation in processing a repeated stimulus) with a variety of stimuli. To date, however, amnesics have not shown fully intact priming with pictures of common objects and animals. The subjects were 12 patients with GA (7 with Korsakoff's Syndrome and 5 with amnesia of other etiologies, including patient H.M.) and 14 controls. Subjects named 45 pictures. Then they named 90 pictures (45 repeated and 45 new); naming latencies were recorded. Finally, subjects performed a yes/no recognition test for the pictures seen for the first time in the second phase plus 45 foils. Patients with GA were impaired significantly on the recognition test; however, both groups showed equivalent priming by naming previously seen pictures significantly faster than new pictures. In a second study, normal subjects named pictures and then did either a naming or a yes/no recognition test. Within each test, half of the previously seen pictures were rotated 180° about the vertical axis and half appeared exactly as before. Latencies to identify previously seen pictures in the recognition test were slower for rotated pictures than for those not rotated. The effect of rotation upon picture-naming priming was minimal. The dissociation between intact picture-naming priming and impaired recognition memory in GA may reflect separable memory systems with distinct functions. One system records rotation-invariant properties of percepts useful for visual reidentification and another system records variant properties useful for recognizing specific encounters with percepts. Supported by NINDS grant #IP50NS26985.

MEDIAL TEMPORAL LOBE VS DIENCEPHALIC AMNESIA IN CHILDHOOD. F. Vargha-Khadem, E. Isaacs and K. Watkins, (SPON: European Brain and Behaviour Society), Department of Psychological Medicine, Hospital for Sick Children, Great Ormond Street, London WC1, England.

Chronic anterograde amnesia resulting from either medial temporal lobe or diencephalic damage in childhood is a rare occurrence. Two boys with amnesia of differing aetiology and age of onset showed impairment in the acquisition and retention of declarative knowledge.

Case JF had normal development except for a memory and learning deficit developing from age 4. Case JL became amnesic at age 12 following diagnosis and excision of a craniopharyngioma of the pituitary. MRI scans showed bilateral medial temporal sclerosis and hippocampal atrophy in the case of JF and midline pathology involving the thalamus, mammillary bodies and other diencephalic regions in JL's case. At 13, both patients were impaired in tests of declarative memory whereas performance on tasks of procedural memory was normal.

It is concluded that the evidence from childhood amnesia is consistent with the distinction in adulthood between declarative and procedural memory systems.

191.13

EFFECTS OF THE BENZODIAZEPINE TRIAZOLAM ON MEMORY AND METAMEMORY. R.G. Lister, E.M. Joyce, H.J. Weingartner* and M.J. Eckardt. Lab. of Clin. Studies, NIAAA, DICBR, Bethesda, MD 20892.

To examine the nature of triazolam-induced amnesia, student volunteers received on four separate occasions in a randomized order triazolam (0, 0.25 mg, 0.375 mg, 0.50 mg). On each test day subjects were shown a list of words just prior to drug administration, and a second list 90 min after drug administration. When each word was presented subjects were asked to rate the probability of their remembering the word later. Triazolam caused a marked, dose-related impairment in the free recall of words presented after its administration, but enhanced the recall of words presented before its administration. Although triazolam impaired acquisition processes, at the time of acquisition triazolam-treated subjects rated the likelihood of later remembering words no differently from placebo-treated subjects. In a test of metamemory, triazolam impaired free recall, recognition and feeling of knowing judgments. The cognitive deficits observed with triazolam resemble those seen in some organic amnesias. Triazolam, however, fails to impair retrieval mechanisms.

SIMULATING HEBB CELL ASSEMBLIES. P.A. Hertherington and M.L. Shapiro. Department of Psychology, McGill University, Montreal, Quebec, Canada H3A 1B1.

Cell assemblies (Hebb, 1949) are self-activating groups of interconnected neurons with connections that grow and persist within a larger neural matrix. Here, computer simulations of Hebb's theoretical cell assemblies produced patterns of activation across a partially interconnected population of simple, simulated neurons. The network was presented with several patterns of input that were stored using variations of Hebb's unsupervised learning rule. During learning, patterns of activation arose which, after learning, persisted in a sparse and distributed fashion. Units within an assembly excited one another and inhibited units in other assemblies. As a result of this learned excitatory interconnectedness, the cell assemblies became active with a given stimulus pattern and persisted in the absence of that stimulus. If the stimulus pattern was degraded, part of the cell assembly was active, and the rest of assembly became active over successive time steps. In addition, injecting low level random noise diffusely and nonselectively across the entire matrix (of 360 units) caused select cell assemblies to arise one, and only one, at a time.

Various implementations of the Hebb rule, Stent (1973) rule, and correlation rule were evaluated in this network to the extent to which they produced and supported cell assemblies. These simulations showed that: (1) the simple Hebb rule did not allow stable patterns to be stored in the network, but led to sporadic activation; (2) the Stent rule generated stable, but not persistent assemblies; and (3) the correlation rule did not work in this simulated neural matrix. The computational effects of additional neurobiological properties is now being explored.

191.14

INTRA-NEURONAL INFORMATION PROCESSING IN CYTOSKELETAL NETWORKS: THEORETICAL ASPECTS. R. Lahoz-Beltra¹, A. Samsonovich², S. Rasmussen³, A. Scott², S. Hameroff¹. ¹ABL-Anesthesiology, ²Applied Math, University Arizona, Tucson, AZ, 85724; ³CNLS, Los Alamos National Labs, Los Alamos, NM, 87545.

Brain models and artificial neural networks (ANNs) generally consider neurons and synapses as simple switches with weighted connections. However, neurons are complex processing devices supported by cytoskeletal networks including microtubules (MT) and MT associated proteins (MAPs) such as dendrite-specific MAP₂. These intra-neuronal networks are suitable for molecular level information processing which could subserve neural level functions and provide a substrate for cognition. Cytoskeletal links to neural level events include MAP₂ phosphorylation via protein kinase C, G protein and structural links, Ca⁺⁺ influx and others. We consider theoretical aspects: 1) Energy pumping via phosphorylation and hydrolysis drives coherent nanosecond conformational excitations in cytoskeletal networks. In MT, these coherent "phonons" can localize and give rise to conformational patterns of excited subunits such as MAP attachment sites. 2) Cooperativity among MT subunits and MAPs enables molecular automata behavior suitable for computation and memory. 3) MAP₂ connections among dendritic MT can behave as "molecular synapses" regulating information flow among MT within neurons. 4) Signalling in MT retrograde to membrane depolarization can provide a synaptic regulation function analogous to "back-propagation" in ANNs. We present computer simulation which demonstrate and explore these theoretical aspects.

LEARNING AND MEMORY—ANATOMY III

192.1

DEVELOPMENTAL CHOLINERGIC REGULATION OF ADULT BEHAVIORAL FUNCTIONS. J.E. Sweeney, M. Smith*, E. Bachman*, J.T. Coyle and C.F. Hohmann. INSERM, Unité 161, Paris, France 75014 and Dept. of Child Psychiatry Johns Hopkins University, Baltimore, MD 21205.

We have shown previously that neonatal basal forebrain (BF) lesions in mice produce transient morphological changes in cortex that correlate with the degree of cholinergic deafferentation. We have now examined the behavioral performance of neonatally BF-lesioned mice that were allowed to reach adulthood (when recovery of cortical cholinergic parameters has taken place). Eight Balb/cByJ mice received bilateral electrolytic lesions to the BF. Mice were housed until 6-8 weeks of age and were then tested along with 20 control mice in an activity chamber and then on a passive avoidance task. During the dark cycle, BF-lesioned group exhibited significant increases in motor activity as compared to controls including increased speed (41.1 ± 5.7 m/hr vs 17.6 ± 1.5 m/hr) and increased movement time (38.9 ± 9.1 min/hr vs 26.9 ± 7.4 min/hr). On the 20 min. retention of passive avoidance, BF-lesioned mice exhibited a significantly shorter latency to enter the dark (14.8 ± 8 sec vs 65.6 ± 11 sec). On the 24-hour retention, the BF-lesioned mice exhibited a shorter latency to enter the dark (115 ± 30 sec vs 146.1 ± 15.5 sec). This difference, however, did not reach statistical significance and more mice are being tested. Additionally, all mice are being evaluated on a spatial navigation task. These results suggest that early BF projections to the cerebral cortex play a role in adult behavioral performance. While cortical cholinergic parameters have recovered in adulthood following a neonatal BF lesion, the behavioral deficits remaining are profound.

192.2

EFFECTS OF AGE AND NBM LESION ON MAZE LEARNING AND CORTICAL NEUROCHEMISTRY. D.J. Connor, P.J. Langlais, R.J. Mandel and L.J. Thal. Neurology Research, VAMC, San Diego, CA 92161.

The effects of age and cortical cholinergic depletion (NBM lesion) were examined using 2 water maze tasks and HPLC analysis. Male F-344 rats (300 gm) were lesioned by bilateral infusion of ibotenic acid (ag/NBm) or underwent sham surgery (ag/con). One year later, a second set of young adults underwent the same procedure (yg/NBm and yg/con). Significant and independent main effects of age and lesion were observed in the impairment of acquisition on the Morris water maze task. None of the groups showed a further decline on this task after a 10-day retention interval. In a water motivated T-maze, only the ag/NBm group showed a consistent impairment in performance. Biochemical analysis revealed a significant decrease in ChAT activity by the NBM lesion but no effect of age. In the anterior cortex, HVA levels were decreased in the aged groups but were not affected by lesion. No other differences in monoamines or their metabolites were noted for cortical or hippocampal areas.

192.3

COMPARATIVE EFFECTS OF NUCLEUS BASALIS OR HIPPOCAMPAL LESIONS AND NORMAL AGING ON RECOGNITION MEMORY IN THE RHESUS MONKEY. L.L. Beason-Held, M.B. Moss and D.L. Rosene. Boston Univ. Sch. Med., Boston, MA 02118.

A decline in memory function has been associated with normal aging in humans and non-human primates. Two structures implicated in both memory function and age-related neuropathology are the hippocampus and nucleus basalis. To assess their role in age-related memory decline, young adult monkeys (5-8 years of age [yoa]) with lesions of either nucleus basalis (sparing the septum and diagonal band, n=4) or the hippocampus (n=3) or control operations (n=3) were compared with normal aged monkeys (n=5; 26-27 yoa) on the Delayed Recognition Span Task (DRST). The DRST requires the animal to identify the novel stimulus added to an increasing array of stimuli. The number of correct responses made before an error constitutes a "recognition span score". The DRST was administered to all groups in spatial and color conditions. Consistent with earlier findings in our laboratory, the results showed that the recognition span of animals with nucleus basalis lesions did not differ from controls on either the spatial or color conditions. In contrast, animals with hippocampal lesions as well as aged monkeys had significantly lower recognition spans on both conditions of the task (spatial 1.9 and 1.9, color 2.2 and 2.5, respectively) relative to controls (4.0 and 3.5) but there was no significant difference in degree of impairment between the aged and hippocampal groups. These findings raise the possibility that age-related changes in the hippocampal formation and not the nucleus basalis may underlie the decline in memory that occurs in normal aging. The findings also suggest that the anterograde memory deficits in Alzheimer's disease may be due to pathology in the hippocampal formation or associated structures of the temporal lobe limbic system and not a consequence of damage to the nucleus basalis. "Supported by NIH grants AG-04321 and AG-00001".

192.5

IMPAIRMENT OF VISUAL ATTENTIONAL PERFORMANCE FOLLOWING CHOLINERGIC NUCLEUS BASALIS LESIONS IN RATS. J.L. Muir, T.W. Robbins and B.J. Everitt Departments of Experimental Psychology and Anatomy+ University of Cambridge, CB2 3EB, U.K.

Recent studies suggest that cognitive functions other than learning and memory may be significantly affected by loss of cortical acetylcholine. In order to investigate further the role of forebrain cholinergic projections in attentional function and to clarify cholinergic specificity, the effects of infusions of the excitotoxin AMPA, which effectively and with considerable selectivity destroys cholinergic cells of the nucleus basalis magnocellularis (nbM) (70% reduction in cortical ChAT activity), while producing little damage to pallidum and other basal forebrain neurons, were investigated.

These lesions impaired the rats' accuracy in localising brief visual targets in a 5-choice serial reaction time task and lengthened the latency to respond correctly several months following surgery. The behavioral deficits observed using this excitotoxin were in many cases even more profound than those following quisqualic acid-induced lesions of the basal forebrain (50% reduction in cortical ChAT activity). Furthermore, the AMPA-induced deficits could be exacerbated or ameliorated by certain behavioral challenges: thus, reducing the stimulus duration significantly impaired, while increasing this duration significantly improved performance of the task. The results provide further support for a role for the basal forebrain-neocortical cholinergic projection in attentional function.

192.7

EVIDENCE FOR SPECIFIC RELATIONSHIP BETWEEN DISCRIMINATION PERFORMANCE AND CHOLINE ACETYLTRANSFERASE IN THE POSTERIOR CINGULATE CORTEX OF THE RAT. H.M. Marston, B.J. Everitt and T.W. Robbins. Dept. of Expt. Psychology, Univ. of Cambridge, Cambridge, CB2 3EB, UK.

Differential reductions in the level of posterior cingulate (Pcg) and hippocampal (Hip) choline acetyltransferase activity (ChAT) were achieved by a series of quisqualate lesions to the septum and the diagonal band. The behavioural consequence of these, and ibotenate hippocampal lesions were compared in the acquisition and performance of a conditional visual discrimination. The task required the rat to respond either to the left or the right dependent upon a preceding visual cue that either flashed slow or fast.

A strong correlation ($r=0.82$) was found between post mortem Pcg ChAT activity and errors made in performance. There was little correlation with Hip ChAT ($r=0.40$), nor were hippocampal lesioned animals severely debilitated. These animals were however more susceptible to the interpolation of a response delay. Finally it was found that animals with large Pcg ChAT reductions were less susceptible to the deleterious effects of physostigmine and scopolamine compared with Sham controls on the task.

The results suggest a significant role for Pcg cholinergic function in the mediation of conditional behaviour independent of the mnemonic role of the hippocampus.

192.4

PERFORMANCE ON DELAYED NON-MATCHING TO SAMPLE IS NOT IMPAIRED IN RATS BY AGING UP TO 30 MONTHS. Susan M. Koger, Robert G. Mair, & Russell L. Knott. Psychol. Dept., Univ. of New Hampshire, Durham, NH 03824.

In a longitudinal study, rats were trained on spatial delayed non-matching to sample (DNMTS) prior to 6 months of age and then re-tested at 12 (n=7), 24 (n=5), and 30 (n=3) months of age. At each age, animals were first retrained at a 3 s interval and then tested for 150 trials at each of 4 retention intervals (0.1, 3, 9, 15 s) presented in a counter-balanced order (600 trials total). Accuracy decayed as a function of both retention interval and response latency at all ages. There was no evidence that DNMTS performance decreased for individual animals as they aged. These results suggest that with extensive training at an early age, there are no consistent age-related effects on this measure of working memory in rats within the life-span tested.

192.6

NUCLEUS BASALIS STIMULATION ALTERS SPONTANEOUS AND STIMULUS-EVOKED RESPONSES OF SOMATOSENSORY CORTICAL NEURONS. M.A. Howard and D.J. Simons. Dept. Neurosurg., U.Wash., Seattle, WA 98195 and Dept. Physiol., U.Pitt., Pittsburgh, PA, 15261

Responses of SmI barrel cortex neurons to controlled whisker stimulation were examined in urethane anesthetized rats before and after electrical stimulation of the Nucleus Basalis Magnocellularis (NBM). Twenty-six of 60 cells showed statistically significant alterations in spontaneous activity (SA). Short-term effects of <5 min consisted of abrupt decreases (n=6) or increases (n=2) in SA. Eighteen cells showed long-term effects that could last > 60 min. Most (n=14) showed abrupt or gradually developing decreases in SA. In cells with diminished SA, stimulus-evoked activity either decreased slightly, remained unchanged or increased, sometimes substantially; on average, responses to whisker movement increased 50% despite an average decrease in SA of >50%. Both acute and long-term effects of NBM stimulation could be prevented by systemic injection of atropine. NBM activation can thus alter cortical excitability for long periods and in some cases selectively enhance the net response to a tactile stimulus. Supported by NS08438 and NS19950.

192.8

IMPAIRED REVERSAL LEARNING BUT PRESERVED LATENT INHIBITION FOLLOWING EXCITOTOXIC LESIONS OF THE BASAL FOREBRAIN IN THE RAT. T.W. Robbins, A.C. Roberts, J.L. Muir, A.S. Killcross* and B.J. Everitt (SPON: European Brain and Behaviour Society). Departments of Experimental Psychology and Anatomy+, University of Cambridge, CB2 3EB, U.K.

Injection of the excitotoxin ibotenic acid into the region of the cholinergic cell bodies of the nucleus basalis magnocellularis (nbM) produces a wide range of behavioral deficits. However, interpretation of these data is confounded, both by the non-cholinergic damage produced by this neurotoxin and the lack of behavioral specificity. The present study therefore uses the more selective excitotoxins quisqualic acid and AMPA to destroy cholinergic cells in the nbM and investigates the effect of this lesion on tests specific for associative learning and selective attention.

In Experiment 1 lesioned rats were impaired on reversal of a visual discrimination task which required them to switch their responding either towards or away from the lever paired with the cue light. Experiment 2 showed that the performance of lesioned rats during extinction of a conditioned response was insensitive to the presence of stimuli previously associated with reward. In contrast, there was no effect of the lesion on latent inhibition, a test of selective attention. The results will be discussed in relation to the intimate direct connections that exist between the orbitofrontal cortex, the amygdala and the nbM.

192.9

DIFFERENT PASSIVE AVOIDANCE AND MILK MAZE DEFICITS WITH DIFFERENT SUBSTANTIA INNOMINATA LESIONS. R.C. Meyer and G.D. Coover. Department of Psychology, Northern Illinois University, DeKalb, IL 60115.

Basal forebrain lesions affecting passive avoidance (PA) and milk maze (MM) performance have involved damage to portions of the substantia innominata (SI). We examined the effects on drinking PA (dPA), step-through PA (sPA) and MM performance of three electrolytic lesions in the rat all at V -8.2 mm relative to bregma: caudolateral SI (cSI, L ± 4.2 , A -1.9), middle SI (mSI, L ± 3.5 , A -1.2) and rostromedial SI (rSI, L ± 2.8 , A -0.5). Our cSI lesions damaged the rostral third of the central amygdaloid nucleus, where lesions produce a deficit in dPA that appears to be "anxiolytic" in character.

Large deficits in dPA were produced by cSI and also mSI lesions, but not rSI lesions. The control group (CON) took a mean \pm SE of only 21 \pm 2 footshocks of increasing intensity to avoid drinking for 5 min, while cSI and mSI took 42 \pm 4 and 37 \pm 3, and rSI took 27 \pm 3. In sPA, only cSI showed a significant deficit, mSI was intermediate, and rSI was indistinguishable from CON. In the MM, rSI was very slow over test sessions to reach the hidden platform (60 \pm 16 sec) compared to mSI (26 \pm 12), cSI (14 \pm 4) and CON (11 \pm 2).

Lesions in SI produce different deficits in PA and spatial tasks depending on lesion location. PA deficits from cSI and mSI lesions appear to stem from an anxiolytic effect rather than a learning deficit.

192.11

EFFECTS OF MEDIAL SEPTAL LESIONS ON AN OPERANT DELAYED GO/NO-GO DISCRIMINATION IN RATS. R. Numan. Psychology Department, Santa Clara University, Santa Clara, CA 95053.

Male hooded rats received either a medial septal lesion (N=11) or a control operation (N=10). The rats were then tested on an operant go/no-go discrimination task (30 min sessions, 5 days/wk, 45 mg food reward) first without a delay contingency (20 days), followed by 25 days under an 8-sec delay. A discrete trial procedure with symmetrical reinforcement was used. When the rat was placed in the operant chamber it was dark, except for back-illumination of a centrally located press panel. Depression of this panel extinguished the back-light and initiated a random presentation of either the "go" stimulus (2800 Hz tone) or the "no-go" stimulus (10 Hz pulsing light) for 3-sec. When this stimulus terminated the chamber was darkened for 0.1 sec (0-sec delay) or 8.0 sec (8-sec delay). The delay was followed by the availability of a lever for 2-sec. If the rat pressed the lever on "go" trials, or refrained from pressing the lever on "no-go" trials a food pellet was delivered. At the end of the 2-sec lever availability period, or following a lever press, the central press panel was again back-illuminated to begin the next trial. The data (% correct responses) were averaged over 5-day blocks. Overall, the septal lesioned rats performed significantly better than the control rats under both 0-sec delay ($p < 0.025$) and 8-sec delay ($p < 0.001$) contingencies. While there was not a significant difference between the groups during the last block of the 0-sec delay (septals 93% correct, controls 89% correct, $p > 0.05$) or the first block of the 8-sec delay (septals 54% correct, controls 53% correct, $p > 0.05$), the septal lesioned animals performed significantly better than the controls during all the remaining phases of the experiment. For example, during the final 5-day block of the 8-sec delay, the septal rats averaged 71% correct and the control rats averaged 61% correct ($p < 0.001$). The results will be discussed in terms of various theories of septo-hippocampal function.

192.13

ATTENTION DEFICITS PRODUCED BY UNILATERAL OR BILATERAL MEDIODORSAL THALAMIC LESIONS IN THE RAT. J.M. Vargo and P.J. Best. Department of Psychology, Miami Univ., Oxford, OH 45056.

Bilateral lesions of the mediodorsal thalamic nucleus (MD) produce deficits in spatial context recognition (K.A. Stokes & P.J. Best, *Neurosci. Abs.*, 13: 1067, 1987) similar to those seen following bilateral medial precentral prefrontal cortex (Agm) lesions (J.M. Vargo et al., *Neurosci. Abs.*, 16: 1095, 1990). These animals fail to react to a familiar environmental cue when it is out of place. Unilateral but not bilateral Agm lesions produce neglect (deficits in orientation to unilaterally presented stimuli) (J.M. Vargo et al., *Neurosci. Abs.*, 16: 1095, 1990).

Long-Evans hooded rats with unilateral or bilateral MD lesions were tested for neglect (degree of head turning toward unilaterally presented stimuli was recorded). Unilaterally lesioned animals demonstrated unilateral orientation deficits. Bilaterally lesioned animals did not demonstrate bilateral neglect. In the same animals, bilateral but not unilateral lesions led to deficits in spatial context recognition.

192.10

MAP-2 EXPRESSION IN CHOLINOCEPTIVE PYRAMIDAL CELLS OF RODENT CORTEX AND HIPPOCAMPUS IS ALTERED BY PAVLOVIAN CONDITIONING. Nancy J. Woolf, Stacey L. Young, Michael S. Fanselow, and Larry L. Butcher. Dept. of Psychology, UCLA, Los Angeles, CA 90024-1563, U.S.A.

Immunohistochemical studies have revealed that only a subpopulation of pyramidal cells in the cerebral cortex and hippocampus are cholinergic. These cells additionally contain high levels of certain cytoskeletal proteins, including MAP-2. Recently, we found that cholinergic deafferentation decreases MAP-2 in cholinergic pyramidal cells, indicating that levels of this protein are subject to modulation. The present study was done in order to determine whether or not a learning paradigm would have any modulatory effect on the expression of MAP-2 in these cholinergic pyramidal cells. Hooded rats were randomly assigned to one of three groups: tone paired with shock, tone unpaired with shock, and tone only. After 5 days of training the paired group evidenced conditioning to the tone relative to controls. The rats were immediately sacrificed after the last session. MAP-2 staining density was assessed in the pyramidal cell layer of the cortex and hippocampus. The density of MAP-2 staining in various cortical regions varied as a function of experimental group ($p < .05$, ANOVA, repeated measures). In contrast to the other groups, tone-conditioned animals exhibited significantly higher MAP-2 staining in auditory regions of the cerebral cortex compared with the hippocampus ($p < .005$) and visual and limbic cortices ($p < .05$). [Support: USPHS grant NS 10928 to L.L.B.]

192.12

INTERACTION OF OPERANT HISTORY AND SEPTAL LESIONS IN THE RAT ON VARIABLE-RATIO RESPONDING. Alex Poplawsky. Dept. of Psychology, Bloomsburg Univ. of Penna. Bloomsburg, PA 17815.

The over responding of rats with septal lesions on a variety of schedules of reinforcement can be altered by training procedures. Since few studies have investigated the effects of septal damage on Variable Ratio (VR) behavior, rats with septal lesions or control operations were trained to leverpress for food on a VR 20 schedule of reinforcement for five sessions. This was followed by 44 sessions of VR schedules that ranged between VR 60 to 100 before the rats were returned to the VR 20. Rats with septal lesions responded at higher rates than control rats during the early VR-20 sessions; however, both groups had equivalent response rates after the higher VR-requirement sessions. These findings suggest that the operant history of the rat is an important factor when interpreting the effects of brain damage on food-reinforced lever-pressing.

192.14

IN THE RAT, BOTH ANTERIOR AND POSTERIOR PORTIONS OF MEDIAL THALAMUS MUST BE LESIONED TO IMPAIR DNMTS PERFORMANCE. R.G. Mair, G.D. Fox*, Y.-P. Zhang*, J.K. Robinson. Dept. Psychol. University of New Hampshire, Durham, NH 03824.

Impairments in DNMTS performance have been associated with lesions involving lateral portions of the internal medullary lamina (L-IML) produced by either: pyridoxamine-induced thiamine deficiency (Robinson & Mair, this meeting); or radiofrequency (RF) methods. We pretrained 32 rats on DNMTS and assigned 8 to each of four treatments: RF lesions of the complete L-IML site, anterior portions of the L-IML site, posterior portions of the L-IML site, and sham surgery. Animals with complete IML lesions showed DNMTS deficits comparable to previous studies, performing significantly worse than either sham operated controls or animals with partial IML lesions. The animals with partial IML lesions did not differ significantly from sham operated controls.

192.15

MK-801 PROTECTS RATS FROM BRAIN LESIONS AND BEHAVIORAL IMPAIRMENTS FOLLOWING PYRITHIAMINE-INDUCED THIAMINE DEFICIENCY (PTD). John K. Robinson & Robert G. Mair. Psychol. Dept., Univ. of New Hampshire, Durham, NH 03824.

Rats were pre-trained on spatial delayed non-match to sample (DNMTS) and given one of four treatments: PTD, PTD + MK-801 (3 mg/kg, followed by 1.5 mg/kg t.i.d. for the last three days of PTD treatment), pair-fed control, and pair-fed + MK-801 control. Following recovery, the PTD group was impaired compared to all other groups on several measures of DNMTS performance; including: reacquisition at a 3s delay; performance at delays from 0 to 15s; and delay producing 75% accurate performance with a staircase procedure. The PTD group retained the capacity to perform DNMTS accurately (mean = 92.8% correct) following extensive training at short delays. The PTD group made more errors learning a radial arm maze task, although they reached criteria for both discrimination and working memory problems. These impairments are consistent with the effects of RF lesions centered on the internal medullary lamina (IML) and involving the mediodorsal nucleus (MDn) of thalamus.

Histological analyses showed: thalamic lesions involving IML & MDn in 17/17 PTD rats; 1/12 PTD + MK-801 rats; and none of the two control groups. These results demonstrate that MK-801 treatment prior to the onset of seizures protects from PTD-induced lesions.

192.17

CEREBRAL DEOXYGLUCOSE METABOLISM FOLLOWING CHRONIC ETHANOL CONSUMPTION IN MICE: A SELECTIVE EFFECT ON DIENCEPHALIC STRUCTURES. B. Bontempi*, D.J. Beracochea, C. Desfrade, R. Jaffard. Lab. Neurosciences Comportementales & Cognitives, Univ. Bordeaux 1, URA CNRS 339, 33405 Talence-cedex, France.

Ten week-old male mice were submitted to a 12% v/v alcohol consumption during 17 months and then withdrawn at least 8 months before the experiment began. Controls were either pair-fed or had received ad lib. water and dry food. The (¹⁴C)-deoxyglucose (2-DG) was injected in the jugular vein 10 min before the animals were placed in a T-maze. They were allowed to freely visit the apparatus during 20 min. Then, the animals were removed from the maze and sacrificed 5 min later; the brains were processed for autoradiography. The regional uptake of 2-DG was analysed using the relative 2-DG method. A significant decrease of labelling was found in diencephalic areas, mainly in the mammillary bodies and thalamic nuclei. A slight but not significant decrease was found in the hippocampal formation, whereas no decrease was observed in other cortical and subcortical structures. These results are consistent with the hypothesis that the memory disorders observed following chronic alcohol administration in mice may be related to diencephalic rather than hippocampal or cortical damages.

INCREASE IN IPSILATERAL LH SELF-STIMULATION AND BEHAVIORAL ASYMMETRIES INDUCED BY UNILATERAL LESION OF THE TUBEROMAMMILLARY NUCLEUS. U. Wagner*, H.-T. Weiler* and J.P. Huston, Institute of Physiological Psychology, University of Düsseldorf, D-4000 Düsseldorf, Germany

The subnuclei of the tuberomammillary nucleus (TM) are located in the posterior part of the hypothalamus. The neurons of this nucleus innervate extensive parts of the brain with several transmitters; they represent the only source of histaminergic projections in the brain. This is the first study dealing with the effects of a lesion in this region on sensorimotor behavior and self-stimulation. Unilateral electrolytic lesions of the TM had the following effects: 1. An asymmetry in thigmotactic scanning behavior; at 11 days but not 1 day post-lesion, the rats scanned the walls of an open field more with the vibrissae contralateral to the lesion side. 2. More ipsiversive than contraversive turning. 3. Application of the histamine precursor histidine led to a compensation of these asymmetries. 4. Beginning with the first post-lesion day an increase in lateral hypothalamic self-stimulation rate ipsilateral to the lesion was found. Response rates continued to rise for two weeks post-lesion. Recently we found evidence for an involvement of the TM in asymmetries, and recovery therefrom, induced by unilateral removal of the vibrissae (Weiler et al., *Neurosci.*, 1990, 37, 463-469). Thus, the TM may function in reinforcement, sensorimotor asymmetry and behavioral neuroplasticity.

192.16

Mammillary bodies or medio-dorsal thalamic lesions differentially modify anxiety in mice.

D.J. Béracochea, A. Krazem* and R. Jaffard. Lab. Neurosci. Comport. & Cognitive, Uni. Bordeaux 1, URA CNRS 339, 33405 Talence-cédex, France.

Several studies have shown that damage to the mammillary bodies (MB) and the medio-dorsal thalamus produced emotional disturbances. Thus, the MB are an important site of anti-anxiety action of benzodiazepines, and lesions of this area and/or the mammillothalamic tract induced deficits in various tasks involving negative reinforcers (Kataoka et al., *Brain Res.*, 1982, 241, 374-377). The MD receives afferents coming from the amygdala which has anxiogenic functions. In this study, we have decided to determine whether emotional disturbances might be found following lesions of these structures in mice. Anxiety was measured in an elevated plus maze, a motivation artifact free test measuring strength of antagonism between exploratory tendency and avoidance of open novel spaces. Results showed that MB-lesioned subjects spent significantly more times in the open alleys than both control and MD subjects, whereas the opposite effect was observed for MD animals. Thus, MB-lesioned subjects were "hypo-anxious" whereas MD-lesioned ones were "hyper-anxious". The relationships between the emotional and memory disorders resulting from diencephalic lesions will be discussed.

192.18

PERFORMANCE ON A NON-SPATIAL MEMORY TASK FOLLOWING LESIONS TO THE REGION OF THE MAMMILLARY BODIES. V. Sziklas and M. Petrides. Dept. of Psychology, McGill University, Montreal, Quebec, Canada H3A 1B1.

In the present study, rats with extensive lesions to the mammillary region (MB-R), the amygdala (A), or a control operation (OC) were trained postoperatively on a high interference non-spatial delayed nonmatching-to-sample task (DNMS) and on a spatial DNMS task. On the non-spatial task, only two stimuli, a black and a white arm, were used repeatedly throughout testing. A greater proportion (90%) of animals with MB-R lesions were able to acquire the non-spatial task, within the limits of testing, as compared with the OC (38%) and A (50%) groups. In sharp contrast, the performance of the MB-R group was significantly impaired on the spatial task in comparison with both the OC and the A groups. These findings suggest that lesions to the MB-R may not result in a global memory impairment and that this region may be selectively involved in spatial learning and memory.

192.20

GENETIC INFLUENCE ON RADIAL MAZE PERFORMANCE IN MICE. Dudley Peeler. Department of Neurosurgery, University of Mississippi Medical Center, Jackson, MS 39211.

Recombinant inbred (RI) mouse strains have been used to investigate possible major gene determinants of behaviors reflecting learning, memory and emotion. Major single gene influences have been described for various measures of activity and shuttle box performance of shock avoidance. In this study, the CXB set of 7 RI strains and their BALB/cBY and C57BL/6By progenitors were tested for working memory (number of re-entries) on an 8-arm radial maze. A 2-hr deprivation schedule and food incentive provided motivation to explore the maze. Male and Female adult mice were allowed two, 5-min familiarization sessions followed by 5 test sessions, one session per day. All strains showed a decrease over the 5 test sessions in the number of re-entries before 8 arms were entered. However, there was a significant strain effect and significant interaction between strain and session. There were differences in terms of mean number of re-entries for all test sessions (BALB/c = CXBE > all other strains), and in terms of mean number of re-entries in the final session (BALB/c > CXBI = CXBK). The pattern of decline of number of re-entries over test sessions also differed among strains. Failure of some mice to enter all 8 arms during the familiarization sessions indicated a different strain distribution pattern which was essentially like that found in one study of shuttle box performance. Genetic effects upon working memory (number of re-entries) differ from those reported for various measures of activity and for shock avoidance learning. There is apparent similarity between genetic effects upon initial exploration of the maze (emotionality) and shuttle box performance.

193.1

ENHANCED LEARNING OF A SEXUALLY DIMORPHIC SPATIAL TASK IN MEADOW VOLES FOLLOWING BRIEF EXPOSURE TO 60HZ MAGNETIC FIELDS. M. Kavaliers, L. Eckel, K.-P. Ossenkopp and N. Yu., Univ. Western Ontario, London, Ontario, Canada.

Meadow voles, *Microtus pennsylvanicus*, are polygamous microtine rodents that display marked sex differences in activity and spatial performance. Adult male voles have been shown to range more widely in the wild and to perform better on laboratory measures (radial and symmetrical mazes) of spatial ability than adult female voles. Meadow voles are also excellent swimmers and have been shown to make extensive aquatic excursions in the wild. In this study we examined the spatial abilities of adult male and female meadow voles in the Morris water maze task. The males showed significantly faster acquisition and better retention of this spatial task than did females.

A variety of factors have been shown to affect spatial learning in rodents. In the present study we also examined the effects of exposure to weak (1 gauss) 60 Hz magnetic fields on performance of the spatial task. Exposure of the voles to the magnetic fields during the daily testing procedures (maximum daily exposure 6 minutes) significantly enhanced the acquisition of the learning task in both males and females. The magnetic stimuli may be providing directional information and/or affecting a number of modulatory systems (endogenous opioid systems, protein kinase C activity and calcium ion levels) which have been previously implicated in learning.

193.3

MNEMONIC PROPERTIES OF VISUAL-SENSITIVE HEAD DIRECTION CELLS IN LATERAL DORSAL THALAMUS. S. J. Y. Mizumori and J. D. Williams. Department of Psychology, Univ. Utah, Salt Lake City, UT 84112

While more is becoming known about the behavioral correlates of cells recorded in different subfields of the hippocampal formation, the functional contribution of its many afferents is not clear. The present study addresses this issue by investigating the nature of information provided by afferents arising from the lateral dorsal nucleus (LDN) of the thalamus.

Single unit activity of LDN neurons was recorded while rats (n=4) performed 15 working memory trials daily on an 8-arm radial maze. Of 26 LDN units, 8 exhibited head direction firing patterns that were similar to those observed for postsubicular cells (Taube et al. *J. Neurosci.*, 1990). These head direction cells were found in the dorsolateral aspect of the LDN, which projects directly to postsubiculum. The directional preference (DP) of the LDN cells was disrupted if rats were placed on the maze in darkness. If the room light was then turned on, the reliability of the DP was restored. When rats began maze trials in darkness 30 sec after being allowed to view the room, DPs were maintained. Delays of more than 1 min resulted in altered DPs. Thus, directional specificity was initialized by visual input, and maintained briefly when visual cues were absent. Many cells had DPs which varied depending on the arrangement of visual cues in a lit room. When tested in subsequent dark trials, the DPs of these cells corresponded to the most recent visual input. DPs during passive movement through space were not different from DPs during active translational movements by the rat, suggesting a limited contribution by motor systems. These data suggest that the LDN may provide the hippocampal formation with a visual reference framework for use in computations concerning visuospatial learning. LIMBIC SEIZURES, BUT NOT KINDLING, IMPAIR PLACE LEARNING IN THE MORRIS WATER MAZE: RETROGRADE AND ANTEROGRADE DEFICITS. R.D. Kirkby, R.K. McNamara, R.W. Skelton & M.E. Corcoran. Dept. Psychology, Univ. Victoria, P.O. BOX 3050, Victoria, British Columbia, Canada, V8W 3P5.

Kindling or seizure induction in the hippocampus produces retrograde, but not anterograde, amnesia on the radial arm maze (e.g., Olton & Wolf, *Behav. Neural Biol.*, 33: 437, 1981). The present study examined the effects of kindling and pretraining stimulation-induced seizures (SIS) in the medial perforant path (MPP), septum or amygdala, and posttraining SIS in the MPP on place learning in the Morris water maze.

Bipolar electrodes were implanted in the MPP, septum or amygdala and rats were kindled to three stage 5 seizures. Control rats were handled in a similar manner without receiving stimulation. Rats were trained (8 days, 4 trials/d) to locate a submerged platform maintained in a constant position in a pool of cool (22±1°C), opaque water. SIS were triggered in half the rats 25-45 min. prior to training, and a group of MPP rats received SIS immediately posttraining. Kindling *per se* did not produce place learning deficits, regardless of the site of stimulation. Pretraining SIS in the MPP or septum produced severe place learning deficits, with rats taking longer to locate the escape platform and failing to show a quadrant preference during the probe trial. Pretraining SIS in the amygdala produced a small but significant impairment of place learning. Pretraining SIS in all locations failed to impair the rats' ability to swim to a single visible platform. Posttraining SIS of the MPP also impaired place learning. These results demonstrate that both pre- and posttraining SIS in the limbic system, but not kindling, impair place learning in the Morris water maze.

193.2

EFFECTS OF ISCHEMIA ON HIPPOCAMPAL SINGLE-UNIT ACTIVITY IN FREELY BEHAVING RATS. P.A. Garcia, S.J.Y. Mizumori, and B.T. Volpe. Dept. Psychol., Univ. Utah, S.L.C., UT 84112 and Dept. Neuro. & Neurosci., Burke Inst. Med. Res., Cornell Univ. Med. Ctr., White Plains, NY 10605.

In hippocampus, transient forebrain ischemia primarily causes a severe loss of CA1 pyramidal cells. Using the stereotrode recording method, the electrophysiological properties of hippocampal cells were recorded from 4 ischemic (4 vessel occlusion method) and 4 sham operated Wistar rats while they performed a radial maze task. Consistent with previous results, ischemic animals showed impaired acquisition, but asymptote performance was equal to that of controls. A total of 161 units were recorded following acquisition of the task. Preliminary unit analysis revealed the following pattern of results. Place specificity of CA1 complex spike (CS) cells was not different for ischemic (n=2) and control animals (n=14). This was also the case for CA3 CS cells. However, place cells recorded in the hilar region were significantly less specific for ischemic animals (n=11) compared to controls (n=5). For all populations tested, theta cells showed no difference between groups in terms of place specificity. Other analyses revealed that CA1 CS cells had a significantly higher mean firing rate in ischemic animals, and ischemic CA3 CS cells showed a significantly higher spike amplitude.

CA1 (n=6 ischemic, 4 sham), CA3 (n=5, 4), hilar (n=8, 3), subiculum (n=11 ischemic only), and stratum granulosum (n=10, 4) theta cells showed statistically significant movement sensitivity. Also, ischemic theta cells were rhythmically modulated in a manner similar to that observed for controls. Thus, CA1 retains functionally active theta cells despite a significant reduction in pyramidal cells. Also, these data provide evidence for the hypothesis that CA3 place fields are maintained by direct entorhinal input. [Supported by URC Grant 15155 and MH40090]

DIFFERENTIAL FUNCTIONS OF SUBCLASSES OF HIPPOCAMPAL THETA CELLS. A. M. Lavoie, S. J. Y. Mizumori and K. E. Ward. Department of Psychology, University of Utah, Salt Lake City, UT 84112

Hippocampal theta cells (presumed interneurons) may be classified according to immunohistochemical characteristics. The present study was conducted to compare the functional properties of oriens, pyramidal, lacunosum-moleculare/ radiatum and stratum granulosum (SG) interneurons recorded in dorsal and ventral hippocampus. Stereotrode recording was used to monitor single unit activity of hippocampal theta cells (N=271) while rats (N=16) completed 15 trials daily on an 8 arm radial maze. Upon initial analysis it was clear that theta cells recorded in dorsal hippocampus exhibited different firing patterns than those in ventral hippocampus. There were no significant regional differences between CA1, CA3 and SG interneurons, so the cell classes were collapsed for subsequent analysis.

The predominant finding to emerge thus far involves differential firing rates as a function of various behavioral conditions. Dorsal pyramidal theta cells (n=29; which may correspond to parvalbumin interneurons) showed a significant increase in firing as a function of translational movement. This result is consistent with the finding that place cells, usually recorded in the dorsal hippocampus pyramidal cell layer, require movement input (Foster et al., 1989). Dorsal oriens theta cells (n=25; possibly corresponding to somatostatin or parvalbumin interneurons), on the other hand, demonstrated no significant movement sensitivity. As found previously, dorsal SG interneurons (n=34) showed significant movement sensitivity. Examination of different classes of ventral hippocampal theta cells revealed no significant effect of movement (N=106). The differential sensitivity of dorsal and ventral hippocampus to movement may reflect distinct patterns of innervation. [Supported by BRSG Grant S07 RR07092]

193.6

STRENGTH AND DIRECTION OF LATERALITY: EFFECTS ON SPATIAL LEARNING. N.S. Waters, L.M. Schrott, G.W. Boehm*, G.D. Rosen, G.F. Sherman, A.M. Galaburda, and V.H. Denenberg Biobeh. Sci. Grad. Deg. Prog., U. Conn., Storrs, CT 06269, and Dept. Neurol., Harvard Med. School and Beth Israel Hosp., Boston, MA 02215.

177 mice of 15 NXSM recombinant inbred lines (Eicher & Lee, *Gen.* 125:431-446) and the two parental lines were tested on a battery of behavioral tests, including the lateral paw preference (LPP) test (Waters & Denenberg, *Phys. Beh.* submitted), the Collins paw preference test (Collins, *J. Hered.* 59:9-12), and the Morris water escape test. The latter consisted of 5 days of standard testing followed by one day in which the escape platform was moved to a new location. The animals were sacrificed and examined for the presence of cortical ectopias (Sherman et al., *Acta Neuropathol.* 74:239-242). Performance on the Morris maze was analyzed in terms of strength or direction of paw laterality, and the presence of cortical anomalies. The Collins paw measure was not associated with spatial learning, but LPP was. Right pawed ectopics were significantly impaired in acquisition of the task. This finding coincides with the finding of Denenberg et al. (*Neurosc. Abs.* 16:450; *Br. Res.* submitted) that ectopic animals who are left pawed on the Collins paw preference test performed better on a simple water escape task. Strength of LPP lateralization did not affect Morris maze acquisition, but strongly lateralized animals showed significant improvement in learning the new location over initial learning, while weakly lateralized subjects did not. This improvement indicates acquisition of a learning set (Whishaw, *Phys. Beh.* 35:139-143), and that highly lateralized individuals acquire this set more easily than less lateralized subjects. Supported, in part, by NIH grant HD20806. We wish to thank Dr. E. Eicher, who supplied the RI mice.

CAUDATE NUCLEUS AND HIPPOCAMPAL UNIT RECORDINGS IN RATS PERFORMING A SPATIAL NAVIGATION TASK. S.L. Wiener, B. Delord and A. Berthoz. CNRS Laboratoire de Physiologie Neurosensorielle URP2, Paris, FRANCE.

The caudate nucleus and the hippocampus have been implicated in cognitive processing of spatial information in egocentric and allocentric reference frames, respectively. To better understand how these complementary processes may be performed in parallel, simultaneous recordings were made from fine wire multiple electrodes in these two structures in freely behaving rats.

In an uncovered 50 cm cubic box with water reservoirs in the corners and in the center of the floor, Long-Evans rats (under 23.5 hr/day water deprivation) were rewarded at the corners on a win/shift basis with interleaved rewards at the center reservoir through automated control. Head position, heading angle and visits to the reservoirs were monitored with a video system detecting two light bulbs on the headstage as well as with photodetectors positioned over the reservoirs.

Neurons in the rostradorsal portion of the caudate nucleus (AP 4.2, ML 2.2 relative to bregma) had reductions in their tonic level of activity synchronous with the departure from the water cups. The caudate neuron activity was spatially selective. In contrast, the hippocampal neurons (AP 2.0, ML 2.0), as previously reported, had spatially selective increases in activity during goal approach movements.

193.9

SPATIAL NAVIGATION IN THE SPLIT-BRAIN RAT. M.E. Novotny and D.P. Crowne. Dept. of Psychology, Univ. of Waterloo, Waterloo, Ont. N2L 3G1, CANADA.

Hemispheric specialization and interocular transfer of spatial learning in the Morris water maze was examined. Rats underwent split-brain (optic chiasm and corpus callosum), chiasm (optic chiasm), callosum or chiasm-sham surgeries. They were tested monocularly on the distal cue version of the water maze. Performance of the hemispheres did not differ significantly. The lack of hemispheric differences may have been due to the subcortical involvement in spatial navigation. Overall, the split-brain rats were significantly slower and entered more non-target quadrants than the other 3 groups, ($p < .01$). All groups displayed a decrement in performance when the platform location was reversed, which demonstrated the animals had learned the task. The results suggested the isolation of the hemispheres produced a visuospatial deficit. A lack of transfer for latency, but not quadrant entries was found when the 2nd eye was tested, and did not differ as a function of group.

193.11

IS LTE IN THE HIPPOCAMPUS NECESSARY FOR PLACE LEARNING? R. J. Sutherland, H. C. Dringenberg, J. M. Hoelsing and R. W. Skelton. Depts. of Psychol., Univ. of Lethbridge, Lethbridge, AB, T1K 3M4 and Univ. of Victoria, Victoria, BC, V8W 3P5, Canada.

Recent evidence suggests that activity in hippocampal circuitry provides animals with a representation of information that is essential for recent place learning. Long-lasting changes at synapses (LTE) in the hippocampus may be the basis for the initial storage of place memories. To examine this idea we interfered with these processes by means of bilateral LTE "saturation" of the perforant path-dentate connection with repeated, tetanic perforant path stimulation and by means of injections of the NMDA receptor antagonist MK-801.

At least 2 wk prior to tetanic stimulation or drug treatment rats were trained to swim to a hidden platform in the Morris water task. Each day the goal was placed in a new location. Neither saturation (as measured by induction to maximal population spike area and field EPSP slope) nor MK-801 treatment (0.05, 0.08, or 0.1 mg/kg, ip) affected learning to locate the platform position each day. The rats were then tested in a pool in a new room. Despite saturation or MK-801 treatment, they showed normal acquisition of navigation to the hidden platform in one trial. The rats displayed normal retention of this information for 24 hr. In rats that are naive to the task, LTE saturation or MK-801 treatment impairs initial performance.

These results suggest that place learning can proceed normally despite interference with perforant path-dentate LTE provided the animals have acquired the procedural requirements or behavioural supports for the task.

193.8

THE RELATION OF ROTATION TO EGOCENTRIC AND ALLOCENTRIC SPATIAL LEARNING IN THE RAT. D.P. Crowne, P.A. Tokrud* and P. Brown*. Dept. of Psychology, Univ. of Waterloo, Waterloo, Ontario, CANADA N2L 3G1.

There is a well-grounded relation between amphetamine-induced rotation and the learning and retention of left-right discrimination. In this experiment, we asked whether that relation is a more general one, extending to allocentric spatial learning or is limited to tasks requiring egocentric spatial orientation. Rats were successively trained on 2 spatial tasks: navigation in the Morris water maze, requiring place localization by means of distal (allocentric) cues, and delayed spatial alternation in a water T maze, an egocentric task considerably more difficult than left-right discrimination. Rotational behavior was established following injections of *D*-Amphetamine sulfate, and rats were classified in 3 groups: nonrotators, mid-rotators, and strong rotators. Rotational behavior was not related to latency, quadrant entries, or heading error in water maze learning but was significantly related to delayed spatial alternation learning but not retention. Nonrotators made nearly 40% more errors in reaching criterion than rotators. Our results extend the generality of the earlier left-right discrimination findings in showing that rotation is also related to difficult egocentric spatial learning. But they emphasize that if a rose is a rose, spatial is not spatial is not spatial (necessarily).

193.10

DOES LEARNING PRODUCE LONG-LASTING CHANGES IN PERFORANT PATH-DENTATE EVOKED POTENTIALS? J.M. Hoelsing, R.W. Skelton, J. Evanson & R.J. Sutherland. Depts. of Psychol., Univ. of Lethbridge, Lethbridge, AB, T1K 3M4 and Univ. of Victoria, Victoria, BC, V8W 3P5, Canada.

The hypothesis that long-lasting changes in synapse strength (LTE) in the hippocampal formation represent the neural bases of place learning was examined. Perforant path-evoked potentials in the dentate gyrus of rats were examined during exposure to a novel, complex environment. A robust, long-lasting increase in the size of the population spike and a less consistent increase in the field EPSP was observed. Further investigation demonstrated that the increases in evoked potentials were not due to changes in the behaviour of the rat at the time the stimulus pulses were delivered. In a second experiment rats with electrolytic lesions in the perforant path were unable to acquire place navigation in the Morris water task. Rats with ibotenic acid lesions in the vicinity of the perforant path were not impaired in the Morris water task. In a third experiment, perforant path-dentate evoked potentials were examined during place learning in the Morris water task. A small, but statistically reliable, increase in the field EPSP was observed, but the size of the population spike was unchanged.

These results provide some support for the notion that LTE-like changes in the perforant path-dentate synapses underlie certain forms of learning in the rat.

193.12

PLASTICITY OF RAT HIPPOCAMPAL PLACE CELL RESPONSIVENESS RELATIVE TO LOCATION OF REWARDING ICSS DELIVERY. T. Kobayashi*, M. Fukuda, T. Ono and S. Eifuku*. Department of Physiology, Faculty of Medicine, Toyama Medical and Pharmaceutical University, Toyama 930-01, Japan.

Electrophysiological studies show that hippocampal pyramidal cells fire when the animal is in a particular region of the environment. It has been demonstrated that spatial firing patterns of hippocampal cells are not fixed, but can be changed readily. The plasticity of the hippocampal cells might be a factor in spatial learning. Using a spatial navigation task which can be easily acquired within several trials, we tested several types of plastic responsiveness of place cells.

In a circular open field, rats were trained in a spatial navigation task that required them to visit two invisible reward areas, alternately, to get electrical stimulation of the lateral hypothalamus as reward. During the task, unit activity from the dorsal hippocampus was recorded. Some hippocampal cells of naive rats gradually developed location specific firing as the task was acquired. After learning the task, the location of a reward area was moved into a place field, after which the hippocampal cells tended to fire within and immediately before entering the new reward area. The results suggest plasticity of the place cells in the hippocampus, and an important role in learning and memory of place, and that some of the plastic neurons might not be place neurons per se, but their activity might reflect integrated inputs.

193.13

PLACE FIELDS OF SINGLE HIPPOCAMPAL CELLS ARE SMALLER AND MORE SPATIALLY LOCALISED THAN YOU THOUGHT. M. Recce*, A. Speakman and J. O'Keefe*. Department of Anatomy and Developmental Biology, University College, London, WC1E 6BT U.K.

Hippocampal complex spike cells in freely moving rats have spatially specific firing properties or place fields which represent the animals spatial memory of an environment. Many methods have been used to analyse the correlates and plasticity of place fields. Previously published descriptions of place fields have reported a range of sizes, activity in more than one contiguous region (double fields), and the absence of topography. It is clear that all of these descriptions rely on the assumption that single cells have been successfully isolated.

Using the newly developed, high resolution, tetrode recording technique (Recce and O'Keefe, 1989, Soc. Neurosci. Abstr. p1250) we find several differences from previous reports. In particular fields are smaller, restricted to one contiguous region of the environment and in some cases show a degree of topography. Our data include 48 place cells recorded from 11 rats in one of three different environments.

By resampling our tetrode data under the lower resolution conditions corresponding to earlier methods, the previously reported field properties emerged. For example, there are several cases in which neuronal waveforms separable by the tetrode method were confounded when examining only one or two electrodes (stereotrode). In these cases the confounded waveform was associated either with a double field or with a larger place field. In light of these results, we strongly advise the use of the tetrode method in all experiments where isolation of hippocampal single units is necessary.

LAYERED NETWORK MODELING OF CROSS-MODAL TRANSFER EFFECTS ON RELEARNING AFTER VISUAL CORTEX LESIONS IN RATS. E.R. Delay, N.J. Matsushima*, and D.Q. Nguyen*. Dept. Psychology., Regis College, Denver, CO 80221.

Kehoe's layered network model of associative learning (*Psychol. Rev.*, 95:411-433, 1988) combines a threshold concept for adaptive units with the Rescorla-Wagner delta rule. This model was applied to data from visual decorticate rats given postoperative training to relearn a brightness discrimination using procedures previously described (Delay & Rudolph, *Neurosci. Abs.*, 15:762, 1988). The raw data indicated that postoperative training with an auditory intensity S+ reduced the visual relearning deficit more than additional training with the preoperative brightness S+. Model simulations suggested that visual cortex lesions did not alter thresholds of adaptive units nor total connective weight of the US. However, the rate of change parameters, $\alpha(j)$, were reduced by the cortical lesions. Post-operative training with auditory intensity cues before retraining on the brightness discrimination increased the rate parameter to a greater extent than comparable training with the original visual cue. The model suggests that cross-modal transfer effects on recovery may reduce lesion deficits through processes using convergent input to common adaptive units.

A MODEL OF CONDITIONING BASED ON CS FACILITATION OF US-ELICITED NEURONAL ACTIVITY. D.J. Weisz. Departments of Neurological Surgery and Behavioral Neuroscience, Univ. of Pittsburgh, Pittsburgh, PA 15260.

A major goal of the model systems approach to learning and memory is the identification of critical site(s) at which repeated pairings of conditioned (CS) and unconditioned stimuli (US) result in an alteration of neuronal activity such that the CS eventually comes to elicit overt conditioned responses (CRs). The most likely candidates for these critical sites are those that are necessary for normal conditioning and, in addition, receive information about both the CS and US. This research has focused on CR development as the primary goal, and much progress has been made in many model systems in identifying structures that are critical for CR development. Furthermore, electrophysiological studies have identified neuronal populations that exhibit activity that correlates with the appearance of CRs.

In these studies, however, little attention has been given to the effects that the CS can exert on behavioral and neuronal events elicited by US presentation at the very beginning of training and long before the development of overt behavioral CRs. In contrast to the research that has focused on the appearance of overt CRs, the present hypothetical model is based on the effects the CS exerts on US-elicited activity from the very first pairing. Specifically, this model argues that the neuronal plasticity that underlies behavioral conditioning develops out of CS alterations of US-elicited neuronal responses. Not only must a CS and US converge on a neuron, but they must do so in a way such that the CS can alter the neuron's response to the US. Furthermore, the magnitude of the influence predicts the potential for plasticity at that site. For example, improper timing or weak stimulus intensity could reduce the CS's influence on US-elicited activity and therefore slow or prevent neuronal plasticity. Although the model has been formally developed using data from studies of the conditioned nictitating membrane response, it is easily applied to other model systems. (Supported by MH 42800)

A NEURAL NETWORK MODEL OF HIPPOCAMPAL PLACE CELLS THAT DEMONSTRATES PLASTICITY OF PLACE FIELDS. Robert E. Hampson, Don W. Drawbaugh*, and Sam A. Deadwyler. Dept. of Physiology & Pharmacology, Bowman Gray School of Medicine, Winston-Salem, NC 27157-1083.

Hippocampal place cells demonstrate place-specific firing in a variety of experimental tasks. Whether these "place fields" are static maps of spatial locations or representations which can be shifted to new positions by varying behavioral stimuli has been discussed previously (Deadwyler *et al.*, *Psychobiology* 17:221-227, 1989). We have developed a neural network based on hippocampal neuroanatomy to simulate place fields and study theories of place cell functions.

The neural network model is organized in a layered design with input, output and hidden layers (Drawbaugh, '91 Intl. Joint Conf. on Neural Networks II:717, 1990). Inputs consist of encoded positions in a simulated environment, and outputs that correspond to hippocampal place cells. Once the model is "taught" all of the possible navigational paths through the environment, the output demonstrates emergence of place-correlated firing as the model encounters all possible positions. Once the initial set of "place fields" are expressed in this manner, they remain unchanged until the model is reset (*i.e.* to a new environment). An optional input consists of a bias which denotes significance of a location or the "satisfaction value" associated with occupying specific locations (such as obtaining food or water). When the significance cue is used, only the locations labelled with the highest significance values will demonstrate place fields. Furthermore, when one location is significantly higher in significance, than all others, only that location produces place fields.

Thus, the model demonstrates both the static and plastic features of place fields and suggests a mechanism whereby the hippocampal spatial map can be adjusted to encode location relative to its significance for the subject. Comparison with animal derived experimental results will be presented.

NEURAL NETWORK ERROR SURFACES: LIMITATION OF NETWORK SIZE, INPUT SIGNAL DYNAMICS, AND METAKNOWLEDGE IN MEMORY STORAGE. G. J. Mpiticos. Hatfield Marine Science Center, Newport, OR 97365.

Simple neural networks may provide access to questions that would be impossible to address presently in biological systems. For example, using error backpropagation, we found that: (1) The ability of networks to learn increases as the size of the network increases, but only with marginally larger networks; network size eventually prevents learning, even for simple tasks. (2) These networks learn nothing about the dynamics of their input signals, but the dynamics nonetheless has a decisive role in the learning process. (3) Learning in the presence of noise enhances later learning when no noise is present.

The present work analyzed error surfaces, arising from the responses of the network to systematic changes in the strength of its synapses, to account for the above findings: (1) As network size increases, high error volumes in multidimensional space increase exponentially by comparison to low error regions. Error gradients become increasingly flatter, the length of the synaptic weight-error trajectory increases, and low-error regions become increasingly difficult to find. (2) Chaotic point processes (as might occur in spike trains) and random noise are statistically identical, but the short-term determinism of chaos provides for efficient searches of error space. Limit cycles and continuous signals pose certain problems. (3) Noise-exposed and noise-unexposed networks reach equally low errors during learning. But networks exposed to noise learn more of the teacher error-surface than do networks not exposed to noise. Such noise-exposed networks are able to learn future tasks rapidly when the tasks involve error surfaces having some similarity to the surface in the first task. Thus, synaptic weights not only encode information about a given task, but also a form of metaknowledge relating to how they reached their settings. Biological analogies are presented. HEBB RULE IS NECESSARY BUT NOT SUFFICIENT FOR PLASTICITY OF FUNCTIONAL CONNECTIONS IN THE ADULT MONKEY - BEHAVIORAL RELEVANCE IS REQUIRED. E. Ahissar, M. Ahissar, E. Vaadia and M. Abeles. Dept. of physiology, The Hebrew University - Hadassah Medical school, Jerusalem 91010, Israel.

Multiple single units were extracellularly recorded in the auditory cortex of adult monkeys. The aim of the study was to find the crucial conditions for plasticity of functional connections (F.C.N.) as revealed by cross-correlation histograms. The monkey was trained to touch a switch for the trial to start. Then a train of short duration (30ms) auditory stimuli (US) were delivered. After a few seconds (0.8 to 2.2) the characteristic of the US was changed and the monkey had to remove his hand quickly to gain a drop of juice. 77 pairs of neurons were studied under three conditioning paradigms: Full-, Hebbian- and Pseudo-conditioning. In each pair, one of the neurons was defined as the "CS" neuron (CSN) and the other as the "CR" neuron (CRN). The F.C.N. between the CSN to the CRN was studied. An auditory stimulus which was most effective in activating the CRN was used as the "US". Contiguity between the firings of the two neurons was caused by delivering the US every time and immediately after the CSN fired a spike, causing the CRN to fire a spike at high probability. Behavioral relevance of the US was achieved during the performance of the task. During Hebbian-cond no task was performed and during Pseudo-cond no contiguity was present (table). Strengthening of F.C.N.s, as expressed by Gain (= strength after / strength before), was evident only in Full-conditioning (table). We believe that changes in F.C.N.s represent changes in the relevant neural network configuration. These results, thus, suggest that both contiguity and behavioral relevance are necessary for learning at the network level.

	Full	Hebbian	Pseudo
Contiguity	+	+	-
Behav. rel.	+	-	+
Gain (S.D)	2.8(1.5)	1.3(5)	0.9(2)

A NEURAL NETWORK MODEL OF ADAPTIVELY TIMED REINFORCEMENT LEARNING AND HIPPOCAMPAL DYNAMICS. Grossberg, S. and Merrill, J. W. L.* Center for Adaptive Systems, Boston University, Boston, MA 02215.

A neural model is described of how reinforcement learning is adaptively timed and modulates the course of recognition learning, attention switching, memory search, selective forgetting, and the timing of goal-oriented actions. The model suggests how NMDA receptors in the dentate-CA3 region of the hippocampus may participate in adaptively timed reinforcement learning, and helps to explain the changes in trace conditioning, delay conditioning, and reversal conditioning that are caused by hippocampal ablations. The model distinguishes between cerebellar influences on motor learning and hippocampal influences on adaptive timing of reinforcement learning. The model clarifies how hippocampal damage eliminates attentional blocking and causes symptoms of medial temporal amnesia. It suggests how normal acquisition of subcortical emotional conditioning can occur after cortical ablation, even though extinction of emotional conditioning is retarded. The model also distinguishes emotional conditioning from conditioning of adaptive timing. The model suggests how an increase in US duration increases amplitude but not timing of emotional conditioning, and how an increase in CS intensity but not US intensity "speeds up the clock". Computer simulations fit parametric conditioning data from the rabbit NMR paradigm, including primary and secondary adaptively timed conditioning, and conditioning using multiple ISIs, gradually or abruptly changing ISIs, and partial reinforcement.

CONJECTURE UNIFYING THREE "CONSTANTS": SHORT TERM MEMORY CAPACITY, NUMBER OF PYRAMIDAL CELL INPUT SOURCES, AND ALPHA RHYTHM PERIOD.

R. B. Glassman, Dept. of Psychology, Lake Forest Col., Lake Forest, IL 60045.

The fact that immense long term memory evolved suggests that short term memory holds only 7 ± 2 chunks for some important reason. If every combination of n chunks in STM is tested for meaning, this requires

$$T = \sum_{r=0}^n \binom{n}{r} = 2^n \text{ tests. If } n=7, \text{ then } T=128.$$

Pyramidal neurons have about 7 ± 2 segregated input sources in hippocampus and cortex (i.e. cortical layers). If each meaning-test involved briefly activating a combination of inputs (differently in each member of a momentary complement of many neurons), sufficient recovery from graded potentials might allow about one test every 0.6-1.0 msec, thus 128 tests in $1/13 - 1/8$ sec, the period of the alpha rhythm. This entails a conception in which underlying alpha paces desynchronized cortical areas lit by attention. During every cycle, a complement of pyramidal neurons awaits a match between exogenous inputs, due to a set of 7 ± 2 chunks, and myriad memory-fragments in endogenous inputs to the same cells.

NMDA RECEPTOR ANTAGONIST MK-801 INHIBITS ACQUISITION OF CLASSICAL FEAR CONDITIONING IN GOLDFISH. R.E. Davis, X. Xu, P.D. Klinger, Mental Health Research Institute, University of Michigan, Ann Arbor, Michigan, 48104-1687.

Investigations in mammals indicate that selective antagonists of NMDA (N-methyl-D-aspartate) receptors inhibit acquisition and/or retention of learning but not the expression of learning. The results are consistent with the thesis that NMDA receptor functions mediate activity-driven synaptic plasticity which may be the neuronal basis of some forms of learning. The present experiments examined the effects of the NMDA antagonist MK-801 on learning and memory in the goldfish. Classical conditioning of fear evoked by an electrical bodyshock US to a neutral light CS was employed as it is a rapidly acquired form of associative learning. The branchial suppression response (BSR), a defensive fixed action pattern, was measured as the response index of conditioning. Intracranial injection of .1 μ g (ca. .01 mg/kg) or higher of MK-801 30 min prior to the training session impaired retention in a subsequent test session increasingly with the dose. Fish given 2 μ g MK-801 immediately following the training session showed normal retention. Thus, the deficit produced by pretrial MK-801 was not a result of lasting behavioral toxicity - nor of a disruption memory consolidation. Giving .5 μ g MK-801 during training and during testing did not improve retention, revealing no evidence of state-dependent learning. Giving .5 μ g MK-801 only during testing did not impair expression of the conditioned BSR in the retention trials. The results suggest that pretrial MK-801 impaired retention by inhibiting acquisition and, moreover, that it inhibited acquisition by impairing learning processes as opposed to perception of the CS or US or performance of the BSR.

194.2

NMDA ANTAGONIST MK-801 BLOCKS ASSOCIATIVE FEAR CONDITIONING BUT NOT NONASSOCIATIVE SENSITIZATION OF CONDITIONAL FEAR.

J. P. DeCola, J. J. Kim & M. S. Fanselow. Psychology Dept., UCLA, Los Angeles, CA 90024.

Previously we demonstrated that administration of the NMDA antagonist APV, blocks associative fear conditioning. The present experiments assess the role of NMDA dependent processes in the sensitization of conditional fear. Sensitization can be demonstrated behaviorally as an enhanced response to a Conditional Stimulus (CS) when conditioning is preceded by a series of Unconditional stimuli (US) alone preexposure trials. In our paradigm the sensitization pretreatment is done by exposing rats to a series of 15 (1s, 1 mA) footshocks in a distinct context the day prior to a single pairing of a novel CS, a unique context, and a shock US (1s, 1mA). The sensitized animals exhibit enhanced fear in the novel context as compared to a nonsensitized group. Control groups show that this effect is not due to generalization of fear between the two contexts. Administration of the NMDA antagonist MK-801 (.2 mg/kg, i.p.) during the sensitization treatment in the first context did not block the sensitization of conditional fear to the second novel context. However, it did block the acquisition of conditional fear to the context where the pretreatment shocks were delivered. These data indicate that similar to the NMDA antagonist APV, MK-801 blocks associative fear conditioning. Furthermore, this associative failure is not caused by an inability to process the US. Also, a nonassociative sensitization of fear exists that is mediated by an NMDA-independent process.

INFUSION OF AN N-METHYL-D-ASPARTATE ANTAGONIST INTO THE AMYGDALA BLOCKS EXTINCTION OF FEAR-POTENTIATED STARTLE. W.A. Falls, M.J.D. Miserendino & M. Davis, Depts. of Psychology & Psychiatry, Yale Univ. Med Sch., 34 Park St., New Haven, Ct. 06508.

Paired presentation of a neutral stimulus, such as a light, with an aversive stimulus, such as shock, leads to the acquisition of a variety of behavioral effects that are used to define a state of conditioned fear. If the same light is then presented in the absence of shock, it loses its ability to produce these behavioral effects. The reduction in conditioned fear is called experimental extinction and is thought to involve the formation of a new memory rather than a decay or erasure of the original memory. We have previously shown that intra-amygdala infusion of N-methyl-D-aspartate (NMDA) antagonists blocks the acquisition of conditioned fear-potentiated startle (Miserendino et al., *Nature*, 345, 716, 1990). Moreover, the amygdala is also important for extinction because intra-amygdala infusion of the non-selective excitatory amino acid (EAA) antagonist γ -D-glutamyl-glycine blocked extinction of fear-potentiated startle (Falls et al., *Neurosci. Abs.*, 1990, 316.6). The present study employed more selective EAA antagonists to further examine the role of amygdala EAA receptors in extinction of fear-potentiated startle.

Rats were implanted with bilateral cannulae aimed at the basolateral nucleus of the amygdala and one week later underwent training in which a light was paired with footshock. Five days after training, fear-potentiated startle was assessed by measuring the amplitude of noise-elicited startle in the presence or absence of the light. On the next two days, the rats were infused with either DL-2-amino-5-phosphonovaleric acid (AP5; 1.5, 6.25, 12.5, 25 nmol), 6-cyano-7-nitroquinoxaline-2,3-dione (CNQX; 12.5 nmol) or vehicle immediately before receiving 30 light-alone extinction trials. One day later, fear potentiated startle was again assessed without drug infusion.

AP5 dose dependently blocked extinction of fear-potentiated startle whereas CNQX did not. This effect showed anatomical specificity because AP5 infused into the interpositus nucleus of the cerebellum did not block extinction. Moreover, these results could not be explained by reduced salience of the light or by cytotoxic effects of the compounds tested. Therefore, these data implicate and NMDA-dependent process within the amygdala in the extinction of conditioned fear and may provide the basis with which to begin studying the mechanisms of extinction.

194.4

INFUSION OF AN N-METHYL-D-ASPARTATE ANTAGONIST INTO THE AMYGDALA BLOCKS ACQUISITION OF FEAR-POTENTIATED STARTLE TO AN AUDITORY CONDITIONED STIMULUS. M.J.D. Miserendino, S. Campeau & M. Davis, Psychiatry Dept., Yale University, New Haven, CT. 06508

The amygdala appears to be critically involved in a variety of aversive conditioned responses. NMDA receptors, which are implicated in neural plasticity underlying learning, occur densely in the lateral and basolateral nuclei of the amygdala. We previously showed that intra-amygdala infusion of NMDA-selective antagonists blocked acquisition of fear conditioning to a visual stimulus as measured by fear-potentiation of the acoustic startle reflex (Miserendino et al., *Nature*, 345 716-718, 1990). We now examine the generality of this finding by testing whether an NMDA receptor-mediated process in the amygdala might similarly be involved in the acquisition of fear-conditioning to an auditory conditioned stimulus. Rats were implanted with bilateral cannulae aimed at the basolateral nucleus of the amygdala. Following recovery, rats received two training sessions on consecutive days, each session consisting of 5 noise-footshock pairings (noise=2 KHz bandwidth noise, 70 dB; footshock=0.6 mA; ISI=2 min). Immediately prior to training, rats were infused with the competitive NMDA antagonist DL-2-amino-5-phosphonovaleric acid (AP5; 3.125, 12.5, 50.0 nmol) or ACSF vehicle. One day later, rats were tested for conditioned fear by comparing the magnitude of the startle reflex to a noise burst presented either alone or in the presence of the previously fear-conditioned 2 KHz noise. Local infusion of AP5 blocked acquisition of conditioned fear to this auditory stimulus, an effect that was linearly related to dose ($F(1,20)=11.03$, $p<0.005$), without altering reactivity to the footshock unconditioned stimulus or baseline startle amplitude in the absence of the conditioned stimulus. These data extend our previous findings and support the idea that across different sensory modalities, the amygdala may be a common locus of neural plasticity for associative fear conditioning.

TIME-DEPENDENT IMPAIRMENT AND ENHANCEMENT OF INHIBITORY AVOIDANCE LEARNING BY INTRA-AMYGDALA 2-AMINO-5-PHOSPHONOPENTANOIC ACID (AP5) INFUSION. D.L. WALKER and P.E. GOLD. Neuroscience Graduate Program & Department of Psychology, University of Virginia, Charlottesville, VA 22903.

Peripheral and central injections of *N*-methyl-D-aspartate (NMDA) receptor antagonists disrupt performance on a variety of learning and memory tasks. The present experiment examined the effects on memory of direct intra-amygdala injections of AP5. Rats received bilateral intra-amygdala injections of AP5 (1, 10, 25, or 50 nmol) 15 min before or immediately after inhibitory avoidance training, or 15 min prior to test (48 h later). Pre-training (25 and 50 nmol) but not pre-testing (50 nmol) injections of AP5 significantly impaired retention. The amnesia was not secondary to seizures (though AP5 increased the occurrence of low-frequency, high-amplitude EEG) or to drug-induced analgesia. Injections dorsal to the amygdala were ineffective. Surprisingly, post-training injections of AP5 enhanced performance on the retention test -- i.e., AP5 impaired (pre-training) or enhanced (post-training) retention depending on a 15-min difference in time of drug administration. One interpretation is that the impairment reflects a requirement for NMDA receptor activation during acquisition, while the enhancement reflects post-training regulation by NMDA receptors of other neurotransmitters (e.g., noradrenaline) which retroactively modulate memory storage. Or, post-training AP5 may prevent subsequent learning that would normally produce retrograde interference for the learned avoidance response. These results indicate that antagonism of NMDA receptors in the amygdala influences acquisition and storage of a learned avoidance response. [Supported by ONR (N0001489-J-1216), NIA (AG 07648), and NSF (BNS-9012239); DLW is an NIMH predoctoral trainee (5-T32-MH18411)].

POSTTRAINING GLUTAMATE RECEPTOR BLOCKADE IMPAIRS OLFACTORY LEARNING IN NEONATAL RAT PUPS. D. A. Weldon and C. M. Lorusso. Dept. of Psychology, Hamilton College, Clinton, NY 13323.

Norepinephrine, dopamine, and glutamate receptors appear to play an important role in early olfactory conditioning in neonatal rats. Administration of receptor antagonists for these neurotransmitters before training can prevent learning. The critical time for the effect dopamine receptor antagonists, however, is during a posttraining period (Weldon, et al., *Behav. Neurosci.* 1991). The present experiment was designed to investigate whether posttraining administration of an *N*-methyl-D-aspartate (NMDA) receptor antagonist would impair olfactory conditioning.

Six day old Sprague-Dawley rat pups were exposed to anise odor paired with tactile stimulation (stroking the skin with a paint brush) for a 10 minute conditioning session. Pups received either vehicle (saline) or the noncompetitive NMDA antagonist MK-801 (0.3 mg/kg, i.p.) either 30 minutes before or immediately after the conditioning period. The next day, the pups were placed in a testing chamber for a total of 6 minutes, and the amount of time that they spent over the conditioned odor was recorded. Treatment with MK-801 produced a statistically significant reduction in the conditioned preference for the anise odor, regardless of whether the drug was administered before or after the training period. The data indicate that posttraining activation of NMDA receptors is required for normal olfactory learning to occur in neonatal rats.

EFFECTS OF A GLUTAMATE AGONIST AND ANTAGONIST ON WEAK MEMORY FORMATION IN CHICKS. D.W. Lee, A. Hittelman, S. Shrawder, E.L. Bennett, & M.R. Rosenzweig. Department of Psychology, University of California, Berkeley, CA, 94720.

In rodents, glutamate (GLUT) enhances memory, whereas GLUT antagonists (such as AP5) impair memory. In 2-day-old chicks, memory for a 1-trial peck avoidance task using 100% methyl anthranilate (MeA, a liquid aversant) is impaired by both GLUT and AP5. The lack of evidence for enhancing effects of GLUT in chicks may be due to a ceiling effect obtained with very strong training. To allow for memory enhancement as well as impairment, we investigated the effects of GLUT and AP5 using weak training (10% MeA).

Bilateral i.c. injections (10 μ l/hemisphere) were made into the region of the IMHV 5 min pretraining using either saline (SAL): .001, .01, .1, 1, 10, 25, or 50 mM GLUT; or 250 pg or 250 ng AP5 per chick. When tested at 24 hr, memory for weak training is impaired by both GLUT (50 mM) and AP5 (250 pg and 250 ng) at the same doses that impair memory for strong training. Results with the lowest doses of GLUT indicated a trend towards memory enhancement. This was further tested by injecting either SAL or .001, .005, .01, or .05 mM GLUT. From these two experiments we conclude that, in the chick, GLUT does not produce significant memory enhancement.

PRETEST INTRA-AMYGDALA INJECTION OF LIDOCAINE OR GLUTAMATE ANTAGONISTS IMPAIRS RETENTION PERFORMANCE IN AN INHIBITORY AVOIDANCE TASK. K.C. Liang. Dept. Psychology, Natl' Taiwan Univ., Taipei, Taiwan 10764, R.O.C

The amygdala is implicated in memory processing of emotional experience. However, whether the amygdala may be a neural substrate underlying long-term storage of affective memory remains controversial. Such a view implies that memory retrieval after different retention intervals would be equally affected by altering amygdala functioning prior to retention tests. In view of the evidence that local anesthetic infusion produces reversible neural inactivation and that memory processing in the amygdala involves glutamate transmission, the present study examined the effects of pretest intra-amygdala injections of lidocaine or various glutamate antagonists on retention of an inhibitory avoidance response tested at different times after training.

Male Sprague-Dawley rats were implanted with cannulae aiming at the basolateral amygdala. They were trained on a one-trial step-through inhibitory avoidance task with a 1.25 mA/1 s footshock and tested for retention 1, 2 or 21 days after training. Drugs (1 μ l) were infused into the amygdala 5 min prior to the retention test. In Exp. I, rats received vehicle (Veh) or 2% lidocaine. Results indicated that lidocaine significantly impaired retention when given before a 2-day retention test, but had no significant effect when given before a 21-day retention test. In Exp. II, rats received Veh, an *N*-methyl-D-aspartate antagonist--dl-2-amino-5-phosphonovaleric acid (APV, 1.25 μ g), or a kainate/quisqualate antagonist--6-cyano-7-nitroquinoxaline-2,3-dione (CNQX, 1.0 μ g dissolved in DMSO). Results indicated that in a 1-day retention test, pretest CNQX impaired retention performance significantly, but pretest APV failed to produce a significant deficit. In contrast, neither CNQX nor APV affected retention performance when given prior to a 21-day retention test. These findings suggest that successful retrieval of an emotion-related memory requires the integrity of amygdala functioning for a limited period of time after its formation and eventually becomes independent of the amygdala. Such findings are inconsistent with a notion that the amygdala is the permanent storage site of memory. THE NMDA RECEPTOR/CHANNEL COMPLEX AND ASSOCIATIVE LEARNING: OPPOSITE EFFECTS OF PCP AND D-CYCLOSERINE. L.T. Thompson & J.F. Disterhoft. Department of CMS Biology, Northwestern University Medical School, Chicago, IL 60611.

Activation of the neuronal NMDA receptor may play a critical role in many forms of associative learning, via receptor-mediated changes in intracellular calcium levels. We evaluate here the effects both of non-competitive blockade of the receptor-associated cation channel and of allosteric agonism of the glycine coagonist binding site on the receptor on long-interval trace eyeblink conditioning in rabbits. Previous work from our laboratory has shown that this task is hippocampally-dependent (Moyer et al., *Behav. Neurosci.*, 1990, 104: 241-250). Recently, we demonstrated that a monoclonal antibody (B6B21) binding to the NMDA receptor's glycine coagonist site in hippocampus facilitates acquisition of this task (Disterhoft et al., *Soc. Neurosci. Abstr.*, 1990, 16, 264) and that acquisition alters the number of binding sites for the NMDA antagonist MK-801 in rabbit hippocampus (Thompson et al., *Soc. Neurosci. Abstr.*, 1990, 16, 263).

Groups of 6 rabbits per dose and treatment were trained to a behavioral criterion of 80% conditioned responses (CRs) using 500 msec trace eyeblink conditioning, with pseudoconditioned animals as controls. Phencyclidine (PCP, a common drug of abuse), which non-competitively blocks the NMDA receptor's cation channel, blocked acquisition of the task in a dose-dependent fashion. Doses as low as 1 mg/kg completely blocked conditioning, while unconditioned eyeblink responses were unaffected. D-cycloserine, a partial agonist at the strychnine-insensitive glycine binding site, facilitated acquisition of the task without altering unconditioned responses. Doses of 6 mg/kg of D-cycloserine improved acquisition rates by more than 50%, similar to the behavioral improvement observed after intraventricular treatment with B6B21. Both PCP and D-cycloserine cross the blood-brain barrier readily after systemic administration.

MEMORY FACILITATION BY NMDA RECEPTOR BLOCKADE

C. Mondadori. Ciba-Geigy Pharma Research Division, Basle Switzerland and L. Weiskrantz, Dept. of Experimental Psychology, University of Oxford, Oxford, England. (SPON: European Brain Behaviour Society)

A single administration of MK 801 (0.003 - 0.1 mg/kg i.p.) or CGP 37849 (0.01 - 3 mg/kg i.p.) 30 or 60 minutes before the training trial of a passive avoidance task reliably improved subsequent retention performance of mice after a retention interval of 3 days. Since similar memory facilitating effects were observed when the compounds were administered after the learning trial ("posttrial"), the effects on retention were not likely to have been due to indirect influences via modulation of perception, motivation, emotion etc. The posttrial facilitation effects were found to be time-dependent: they were still detectable even when an interval of 8, but not 16 hours was allowed between the learning trial and the treatment. The similarity of the results after competitive (CGP 37849) or noncompetitive (MK 801) NMDA-receptor blockade indicated that the observed memory effects were most likely mediated via NMDA-mechanisms.

194.11

WHAT ASPECTS OF A PASSIVE AVOIDANCE TASK ARE RESPONSIBLE FOR MEMORY FACILITATION BY NMDA BLOCKADE? L. Weiskrantz*, Dept. of Experimental Psychology, University of Oxford, Oxford, England, and C. Mondadori*, Ciba-Geigy Pharma Division, Basle, Switzerland. (SPON: European Brain and Behaviour Society)

When NMDA blockers are administered post-trial to mice, thereby avoiding possible interfering effects of the drugs at the acquisition stage, memory in a one-trial mild passive avoidance task is reliably enhanced (Mondadori et al., *Exp. Br. Res.*, 1989, 75: 449). The present study analyses which features of the task govern the animal's behaviour, and which are important for the facilitating effect of MK-801 on retention. The results of behavioral manipulation of task components demonstrate that the memory of undrugged control animals is strongly based on perception of the floor of the apparatus, and is only weakly controlled by an instrumental response contingency, or by the spatial locus of the reinforcer. But the drug does not enhance this perceptual control. Instead, it facilitates memory for the spatial locus, and raises the influence of this factor from a sub-threshold to supra-threshold level. It follows from the results that whatever is important for control animals may be different from the factor on which this drug treatment operates.

194.13

NMDA ANTAGONIST AP5 IMPAIRS SPATIAL WORKING MEMORY PERFORMANCE IN TRAINED RATS. Z. Caramanos and M.L. Shapiro. Dept. of Psychology, McGill University, Montreal, Quebec, H3A 1B1.

NMDA receptor activity is necessary for inducing glutamate-dependent LTP. Non-competitive NMDA antagonist MK801 (0.06 mg/kg i.p.) blocks acquisition of spatial working memory (WM) in a radial arm maze (RAM) task. However, MK-801 did not impair WM performance in rats pre-trained for 34 days (Shapiro & Caramanos, 1990). Thus, NMDA-dependent synaptic plasticity may be required for establishing the neural representation of a spatial environment, but not for WM operations upon such a representation. We now report that the competitive NMDA antagonist AP5 does impair spatial WM performance in trained rats. Rats were trained on a standard, 8 arm RAM task for 20 days. WM errors (returning to an arm visited during the first 8 choices of a trial) decreased from a mean of 1.9 during the first four days of training to 0.4 during the last 12 days. After training, rats were implanted with osmotic minipumps that infused either artificial CSF (ACSF) or a 33 Mm AP5 solution (0.5 μ l/hr) into the left lateral ventricle, a regimen known to block LTP induction and spatial reference memory acquisition (Morris, 1989). Two days after surgery, the rats were tested for another 12 days. Rats given ACSF (n=8) continued performing the WM task well. However, the rats given AP5 (n=7) were impaired for the full 12 days of post-op testing, making a mean of 1.7 WM errors—performance similar to that shown at the start of training. The AP5 group also had mild motor deficits, but these disappeared after the first few days of testing. Thus, spatial WM can be impaired by competitive NMDA antagonists in trained rats. These results suggest that: (1) >20 days of training is necessary to establish spatial representations of the environment sufficient for WM performance given NMDA receptor blockade; or (2), spatial WM memory depends upon NMDA receptor mechanisms that are unaffected by the doses of MK801 that block spatial learning.

194.15

MK-801, AN NMDA RECEPTOR ANTAGONIST, IMPAIRS LEARNING OF A SPATIAL AND A NONSPATIAL DELAYED-NONMATCHING-TO-SAMPLE TASK. S. Das and R.M. Douglas, Departments of Psychology and Ophthalmology, University of British Columbia, Vancouver, B.C. V6T 1Y7

The effects of a noncompetitive NMDA receptor antagonist, MK-801, were assessed on a spatial and a nonspatial delayed-nonmatching-to-sample task. Saline controls reached criterion on both tasks after 400 trials, whereas rats treated with .1 mg/kg MK-801 (i.p.) 30 min. prior to testing were unable to reach criterion on either task at a minimal delay (testing was discontinued after 900 trials). A lower dose (.06 mg/kg) did not impair acquisition of either task as compared to controls. In contrast to rats which received MK-801 prior to training, those rats given the higher dose of MK-801 (.1 mg/kg) after reaching criterion were not impaired and could remember the sample following a 30 sec. delay. These results suggest that NMDA receptor dependent processes might be necessary for learning the nonmatching-to-sample rule but are not involved in working memory.

194.12

DIFFICULTY DETERMINES THE REFERENCE OR WORKING MEMORY IMPAIRING EFFECTS OF EXCITATORY AMINO ACID ANTAGONISTS IN GERBILS. Maurer, S.A.*, Storch, F.E.*, Morris, H. and Boast, C.A. Wyeth-Ayerst Research, Princeton, NJ 08543.

Working memory (WM) and reference memory (RM) impairments have been reported following treatment with excitatory amino acid antagonists (EAAA) (Shapiro & Caramanos, *Psychobiol.*, 1990, 18:231). We assessed the effects of a noncompetitive EAAA, MK801, a competitive EAAA, CPP, and the muscarinic antagonist, scopolamine, in two cognitive tasks with WM and RM components that vary in the relative degree of difficulty of the two components. Specifically, gerbils were trained on a split stem T-maze (Olton, *Neurobehav. Tox. & Teratol.*, 1983, 5:635) in which WM is more difficult than RM and other gerbils were trained on a radial maze (Olton & Samuelson, *J. Exp. Psychol.*, 1976, 2:97) in which RM is more difficult than WM. In the T-maze, MK801 (0.1 mg/kg i.p., 30 min prior) selectively impaired WM. CPP (30 mg/kg i.p., 2 hr prior) and scopolamine (0.3 mg/kg i.p., 30 min prior) impaired both components of the T-maze, but the magnitude of the effect was greater on WM than on RM. In the radial maze all three drugs impaired both components, but the magnitude of the RM impairment was greater than that of the WM impairment. These data indicate 1) that both RM and WM can be impaired by EAAA and 2) that apparent selective effects on either WM or RM can be due to the degree of difficulty of each component of a given task.

194.14

NMDA ANTAGONIST MK-801 IMPAIRS SPATIAL WORKING MEMORY PERFORMANCE IN A NEW, BUT NOT IN A FAMILIAR, PLACE. M.L. Shapiro & C. O'Connor* McGill Univ., Montreal, Quebec H3A 1B1.

NMDA receptor blockade impairs glutamate-dependent LTP induction and spatial learning in rats. MK-801 (MK), a non-competitive NMDA antagonist, impairs acquisition, but not performance, of spatial working memory (WM) in the radial maze (Shapiro & Caramanos 1990, *Psychobio.*, 18(2):231). Does MK produce spatial learning deficits by impairing the rule learning needed for spatial tasks, or by blocking the acquisition of spatial representations? If impaired rule learning underlies WM acquisition deficits, then rats pre-trained and then given MK should have good WM in both familiar and new places. If, however, impaired representational learning underlies WM acquisition deficits, then pre-trained rats given MK should have impaired WM only in new places. To distinguish between these possibilities, rats were trained in a spatial WM task in a familiar room, tested with MK after criterion performance was achieved, and tested in an unfamiliar spatial environment with MK. Thirty two female SD rats were trained to perform a spatial WM task in an 8 arm radial maze. After reaching criterion performance, the rats were injected with either MK-801 (0.06 mg/kg) or saline (i.p., 30 min. before testing), and tested in the same maze for 5 days. WM performance was unimpaired by MK, as shown previously. The rats were then tested in the same task, but in a different room. Rats given MK performed the WM task poorly when tested in the new room, and did not improve in 15 days of testing. In contrast, control rats performed the WM task well, and consistently outperformed rats given MK ($F(1,29) = 22, p < .05$). Thus, MK-801 blocks storage of spatial representations, which are required for spatial WM performance, and the learning deficit produced by the drug is not an impairment in rule learning.

EFFECTS OF THE NON-COMPETITIVE NMDA-RECEPTOR ANTAGONIST MK-801 ON SPATIAL MEMORY, MOTIVATION, AND MOTOR PERFORMANCE OF RATS IN A T-MAZE. P. Bialobok*, J.M. Ordry, T.M. Wengenack, W.P. Dunlap* (SPON: G.J. Thomas). Fisons Pharmaceuticals, Rochester, NY 14623, Univ. of Rochester, Rochester, NY 14642, and Tulane University, New Orleans, LA 70118.

The NMDA receptor complex for excitatory amino acid neurotransmitters may play a critical role in "long term potentiation" (LTP) and hippocampal neural mechanisms of learning and memory. The non-competitive NMDA receptor antagonist MK-801 has been reported to block the induction of NMDA-dependent hippocampal LTP and also inhibit learning and memory without effects on performance. One controversy in the NMDA receptor blockade strategy of correlating LTP and memory is the equivocal evidence for the selective effects of MK-801 on LTP, learning, and/or memory independent of general or non-associative effects on performance. The aims of this study were to evaluate the effects of MK-801 at low doses on spatial memory of rats in a T-maze in which drug effects on spatial memory can be dissociated from effects on motivation and motor performance. In a within-subject design, male, Sprague-Dawley rats were injected with either saline, 0.025, 0.05, 0.1, or 0.2 mg/kg, i.p. of MK-801 and tested 30 min post-injection in the T-maze for effects on spatial memory, at 10, 90, and 180 sec delays, and on start, choice, and goal speeds. According to analyses of variance followed by Newman-Keuls tests of significance, there was a significant and dose-dependent impairment of spatial memory, with increased start speed, or motivation, choice speed, and goal speed, or motor performance. In view of the significant dose-dependent effects on spatial memory impairment and the significant increases in hyperactivity and motor speed, it may be concluded that MK-801 effects on memory may not be selective or be dissociated from non-associative effects on other sources of performance even at very low dose levels.

DRUG EFFECTS ON REPEATED ACQUISITIONS IN THE MORRIS SWIM TASK. Julian Keith, Carmen McLamb, Erin Yard, Carl Schmidt, and Mark Galizio. Dept. of Psychology, UNC-Wilmington, Wilmington, NC 28403.

The Morris swim task (MST) is widely used to evaluate drug effects on the navigation abilities of rats. Performance on the place version (where the platform is hidden) of the MST is impaired by some drugs at doses that do not impair performance on the cued task (where the platform is visible). Taken at face value this pattern of results suggests that these drugs can selectively disrupt spatial learning while not affecting other (i.e. sensorimotor, motivational, and procedural) factors critical for successful performance. We describe a repeated acquisitions procedure that permits evaluation of acquisition of a new place navigation task and performance of a previously learned task within a session. Subjects were tested (5 days/week for approximately 3 mths) in two pools, alternating pools on each trial (6 trials/pool/day). In one pool (the performance pool) the platform was in the same location each day. In the other pool (the acquisition pool) the platform location changed each day. Results of studies evaluating alcohol, Chlordiazepoxide (CDZ) and MK-801 will be presented. Inconsistencies between our results and those of several previous studies will be discussed. Supported by NC ARA # 9101.

A COMBINATION OF 0.0125 mg/kg DIZOCLIPINE (MK801) AND 0.125 mg/kg SCOPOLAMINE (SCOP) IMPAIRS DETOUR MAZE PERFORMANCE IN ADULT AND AGED RATS. E. Brasnahan, N. Muth*, E. Spangler, and D. Ingram. Essex Community College, Baltimore, MD 21237; Gerontology Research Center, NIA, Baltimore, MD 21224

Male Fischer-344 rats (N=15) received extensive training with all possible problems (P) and 3-P sequences in a detour (D) maze. Rats had to run to a goal through a path containing pairs of U-shaped D's deviating bilaterally at 3 locations. Each P required: 2 forced runs with the entrance to 1 side of a D-pair blocked at 1 or more locations (sample); and 2 errorless choice runs with both entrances of a D-pair opened (delayed choice trials). To avoid 0.4 mA footshock, the rat must proceed to the goal without stopping. Errors during choice runs were punished by a shock pulse. At age 11 mo, 7 of the 15 rats were tested on a new 4-P sequence (Exp 1). On wk-1, more errors occurred on a 0.05 mg/kg MK801 session than on 0.025 mg/kg or saline (SAL) sessions (Spangler, et al., Soc. Neurosci. Abstr., 16:316.1, 1990). On wk-2, compared to SAL and non-SAL sessions, a combined (COMB) drug session (MK801-0.025 mg/kg s.c. & SCOP-0.3 mg/kg i.p.) increased errors ($p < 0.001$). For the next 11 mo all 15 rats were tested extensively on this 4-P sequence. At 23 mo, 10 surviving aged rats were tested on SAL and drug sessions (Exp 2). On wk-1, both 0.025 mg/kg and 0.05 mg/kg MK801 doses increased errors ($p < 0.05$). On wk-2, the 3 drug sessions were: (a) COMB - MK801-0.0125 mg/kg s.c. and SCOP-0.125 mg/kg i.p.; (b) MK801 only; and (c) SCOP only. More errors occurred on COMB than on all remaining sessions except that of MK801 ($p < 0.05$); errors during MK801 were no greater than those on other sessions; and no differences existed among control sessions. Thus, with this well-learned 4-P sequence, MK801-0.05 mg/kg continued to disrupt choice performance at 23 mo; this small dose of 0.025 mg/kg was disruptive at 23 mo; whereas it was not at 11 mo; and at 23 mo, COMB in smaller doses increased errors; whereas neither MK801 nor SCOP alone at these smaller doses was disruptive. Within subjects evaluation of DMTS performance in this D-maze is both efficient and meaningful for drug evaluation studies.

194.21

COMPARISONS OF THE ANTI-ISCHEMIC DRUGS REMACEMIDE AND MK-801 ON CNS SAFETY PROFILES IN NON-ISCHEMIC RATS. T.M. Wengenack, J.M. Ordy, and P. Bialobok*. Fisons Pharmaceuticals, Rochester, NY 14623.

Remacemide, (\pm) 2-amino-N-(1-methyl-1,2-diphenylethyl)-acetamide, is an anticonvulsant currently in Phase II clinical trials. The desglycinated metabolite of remacemide is a non-competitive NMDA antagonist. Studies with remacemide in the rat four-vessel occlusion (4-VO) model of global ischemia have indicated significant improvement of 4-VO memory impairment and reduction of hippocampal CA1 neuronal damage. Studies with the non-competitive NMDA receptor antagonist, MK-801, in global and focal models of ischemia have also reported neuroprotective efficacy in some rodent models. Because there is no currently approved neuroprotective reference drug for cerebral ischemia, comparisons were made of remacemide and MK-801 on CNS safety profiles in non-ischemic rats. Efficacy-safety studies of neuroprotective candidates are considered critical for establishing therapeutic safety margins in drug treatment of cerebral ischemia. Specifically, adverse drug treatment effects on memory, body temperature, glucose levels, and glucocorticoid concentrations may interact with ischemia effects on these variables and thus exacerbate neuronal damage. Remacemide, at 10 and 20 mg/kg, i.p., had no adverse effects on memory, psychotomimetic signs, body temperature, blood glucose, and corticosterone levels. MK-801, at 0.1, 0.2, and 1.0 mg/kg, i.p., produced significant, dose-dependent impairment of memory, psychotomimetic signs, biphasic hypo-hyperthermia, increased blood glucose, and corticosterone concentrations. Compared to the adverse CNS profile of MK-801, remacemide had no demonstrable effects on CNS and physiological variables that could exacerbate the effects of cerebral ischemia.

MK-801 REDUCES BEHAVIORAL DEFICITS ASSOCIATED WITH X-RAY-INDUCED HIPPOCAMPAL GRANULE CELL HYPOPLASIA. G.A. Mickley*, J.L. Ferguson and T.A. Nemeth*+. Armed Forces Radiobiology Research Institute, Bethesda, MD 20814-5145 and * USAF School of Aerospace Medicine, Brooks AFB, TX 78235-5301

MK-801 (NMDA antagonist) has been shown to protect newborns from hypoxia-induced brain damage. Here, we tested if MK-801 could attenuate behavioral deficits associated with radiation-induced hypoplasia of fascia dentata granule cells. We pretreated neonatal rats (N=20) with MK-801 (0, 0.1 or 0.2 mg/kg, i.p.) before each of 6 fractionated, head-only doses of X-rays (12 Gy total) administered during the first 16 days *post partum*. Other rats (N=18) received the same drug treatments but were sham irradiated. At age 16 months, water-escape latencies to a submerged platform were measured in a water maze. Irradiated rats with hippocampal damage exhibited impaired learning (longer latencies to find the platform) than did sham-irradiated subjects. Moderate doses of MK-801 (0.1 mg/kg) facilitated the learning of the water maze by irradiated subjects, whereas higher doses (0.2 mg/kg) provided no such benefits. In fact, this high dose significantly impaired the learning of the water maze by sham-irradiated rats. Thus, early MK-801 treatment produces dose-dependant behavioral protection for adult rats exposed (as neonates) to a procedure that causes selective hypoplasia of hippocampal granule cells.

REPEATED ACQUISITION OF FOUR-LEVER SEQUENCES: DIFFERENTIAL EFFECTS OF SCOPOLAMINE, MK-801, AND NMDA. J. Cohn and D.A. Cory-Slechta. Environmental Health Sciences Center, Univ. Rochester School of Medicine & Dentistry, Rochester, NY 14642.

The cholinergic and glutamnergic (NMDA) neurotransmitter systems are known to serve as biological substrates for learning. Analyses of the behavioral mechanisms by which drugs influence learning processes may yield a more complete understanding of the relative role different neurotransmitter systems play. Prior studies from this laboratory have shown a differential role for the cholinergic antagonist scopolamine and the NMDA antagonist MK-801 in learning, as indicated by different patterns of errors in a 3-member response sequence paradigm (3M; Soc. Neurosci. Abstr. 16:766, 1991). In this study, the effects of those same compounds as well as NMDA itself, were examined on the acquisition of 4-lever (4M) response sequences (e.g. Left (L), Right (R), Left (L), Center (C), excluding perseverative sequences such as LLLR) to determine the extent to which task complexity modified drug effects. Baseline accuracy was approximately 55%, substantially lower than that obtained on the 3M. Each drug produced different patterns of errors across the sequences, some of which differed from previously observed 3M effects. As on the 3M, MK-801 produced strong decreases in overall accuracy primarily due to an increase in perseverative errors early in the sequence. Skipping errors were more prevalent on the 4M than on the 3M paradigm with MK-801, particularly later in the sequence. Early and mid-sequence errors were predominantly perseverative with scopolamine, followed by a rise in skipping errors later in the sequence, in contrast to a predominance of skipping errors on the 3M. NMDA increased the likelihood of a correct response (returning to the start of the sequence) following an error. These studies indicated that different neurotransmitter systems can impact learning through different underlying behavioral processes. The pattern of skipping and perseverative errors induced in the 4M relative to the 3M sequences by MK-801 and scopolamine administration suggests that these drugs may have multiple behavioral mechanisms of action. MICROSTRUCTURAL ANALYSIS OF LICKING BEHAVIORS IN ZUCKER FATTIES AND LEANS, AND IN RATS GIVEN NEUROPEPTIDE-Y ICV. K.E. Asin and L. Bednarz, Neuroscience Research Div., Pharmaceutical Discovery, Abbott Labs, D-47H, Bldg-AP10, Abbott Park, IL 60064.

Recent reports have provided considerable information regarding the licking behaviors of rats. These studies have indicated that these behaviors can be assessed quantitatively and that particular feeding-related variables change in a predictable manner depending on the palatability of the fluid being consumed.

The analysis of licking behaviors has also been useful for characterizing how various pharmacologic treatments, particularly anorectics, act to suppress feeding. In the present study, we examined how different patterns of licking might promote increased food intake and obesity. We therefore chose to study the licking behaviors of obese (Ob) and lean (Ln) Zucker rats, and we also examined feeding in albino rats following ICV administration of NPY.

Female Zucker rats were trained to consume various concentrations of sucrose (0 - 0.8 M) and Ensure™ (0-100%). Overall, there were considerable differences between groups. Obs failed to increase their burst size (BS) as much as Lns in response to increasing palatability, showed shorter interlick intervals (ILI) and made fewer licks/ml (L/ml), suggesting greater licking efficacy. Although sucrose intakes were similar between groups, there were concentration-dependent differences in their drinking patterns. Ensure™ intakes were higher in Obs; this was accompanied by a reduction in burst number (BNo) and the ILI.

In another study, NPY (10 µg/rat) was infused into the lateral ventricle of rats trained to drink 0.05M sucrose. NPY increased intakes 25%, primarily by producing a 2-fold increase in burst number, which was accompanied by a shift of the ILI distribution from longer (>0.50 sec) to shorter (<0.23 sec) intervals. BS and lick rate were reduced by NPY; L/ml was unchanged. Thus, the enhanced intakes of Ob and NPY-treated rats reflect different alterations in licking patterns.

195.3

FEEDING RESPONSES TO PERIFORNICAL HYPOTHALAMIC INJECTION OF NEUROPEPTIDE Y IN RELATION TO DAILY RHYTHMS OF EATING BEHAVIOR. B.V. Aramakis, W.J. Thomas* & B.G. Stanley, Dept. of Psychology, Univ. of California, Riverside, CA 92521.

To determine whether the perifornical hypothalamus (PFH) might exhibit a daily rhythm of sensitivity to the eating stimulatory effect of neuropeptide Y (NPY), rats were given PFH injections of NPY (78 pM/10 nl) or artificial CSF vehicle at 6 different times of the 12/12 hr light/dark cycle. The injections were given in the first, middle, and last hour of the light phase, as well as in the first, middle, and last hour of the dark phase (n = 10 rats/time). Food intake was measured 1, 2 & 4 hours postinjection. Analysis of the results revealed that there was a marked effect of injection time on food intake following injection of either NPY or CSF. Food intake measures following both types of injection showed that the largest intakes occurred at the end of the light phase and the early to middle portion of the dark phase. Subtracting the CSF scores from the NPY scores at each time to reveal the increases produced by just the peptide, established that NPY elicited significant eating throughout the light/dark cycle. There was a tendency for the NPY to be most effective at the end of the light and throughout the dark phase, as compared to the early to mid-light phase. These findings suggest that in the PFH there is, at best, a modest daily variation in the sensitivity to the eating stimulatory effects of NPY.

CHARACTERISTICS OF AND MECHANISM UNDERLYING CHOLECYSTOKININ (CCK) CLASSICAL CONDITIONING IN NEONATAL RATS. A. Weller¹, E.M. Blass², G.P. Smith³, & J. Gibbs³. ¹Dept. of Psychology, Bar Ilan Univ., Ramat Gan, Israel; ²Depts. of Psychology & Nutrition, Cornell Univ., Ithaca, NY 14853; ³Bourne Behavioral Lab., New York Hospital-Cornell Medical Center, White Plains, NY 10605.

When an odor that had previously predicted and been paired with i.p. injections of CCK (0.25-2.0 µg/kg) was presented to 11-day-old rats, the following ensued: 1. Behaviors affected by injections of CCK were similarly affected by the conditioned odor. Specifically, ultrasonic vocalizations (UV) in isolated rats were reduced (230 vs 100 UV) as was independent feeding (4.7 vs 3.5 ml milk) during exposure to the conditioned odor. Yet more time (45 vs 27%) was spent over the normally aversive orange odor by rats conditioned with CCK. 2. Behaviors not affected by CCK injections such as activity and heat escape were likewise not affected by the conditioned stimulus. 3. Pretreatment with the Type A CCK receptor antagonist MK329 prevented conditioning formation. 4. Treatment with MK329 prior to testing prevented the expression of conditioning.

These data imply, in neonatal rats, that a stimulus associated with administration of exogenous CCK gains control over behavior by sensitizing Type A afferents. A model of a specific mechanism will be proposed and alternative models considered.

195.2

NEUROPEPTIDE Y PRODUCES CONDITIONED TASTE AVERSIONS (CTAs) TO LIQUID DIETS IN LEAN BUT NOT OBESE ZUCKER RATS.

A. J. Siplos, F. Kessler*, M. Shimogi* and S. C. Woods, Department of Psychology, University of Washington NI-25, Seattle, WA 98195

Neuropeptide Y (NPY) elicits hyperphagia when administered intraventricularly (IVT). This phenomenon is more robust in lean (Fa/Fa) and heterozygous (Fa/fa) Zucker rats than in their obese (fa/fa) siblings, and this genotype-dependent effect has been seen with solid food, wet mash, calorically dense liquids, and non-caloric liquids. Lean and heterozygous Zucker rats also develop more robust CTAs in response to IVT NPY than do obese animals. We now report that Zucker genotype is also associated with susceptibility to NPY-induced CTAs to calorically-dense liquids. Male Zucker rats (N=20) with 13VT cannulas were adapted to solid food (18 hr/day), with vanilla Ensure available for 30 min after 4-hr deprivation. After adaptation to the schedule, subjects in each genotype received IVT saline (1 µl) or NPY (9.5 µg) before access to 5 ml of novel flavored Ensure (chocolate or strawberry). On the following day, subjects were presented with both chocolate and strawberry Ensure. Homozygous (Fa/Fa) (48 ± 31 vs. 85 ± 20%, p<0.05) and heterozygous lean (Fa/fa) (52 ± 17 vs. 113 ± 31%, p<0.05) rats developed significant CTAs following NPY whereas obese (fa/fa) (65 ± 22 vs. 77 ± 19%) subjects did not. The lack of CTA formation in obese Zucker rats is independent of the caloric density of the novel liquids.

195.4

NEUROPEPTIDE Y (NPY) INCREASES RESPONDING OF RATS UNDER PROGRESSIVE RATIO SCHEDULES OF FOOD REINFORCEMENT. D.C. Jewett, D.W. Schaal, J. Cleary, T. Thompson & A.S. Levine, University of Minnesota and VA Medical Center Minneapolis, MN 55455 and 55417.

In the present study, progressive ratio (PR) schedules (i.e., schedules in which the number of responses required for food increases with each reinforcer) were used to assess the effects of NPY on the reinforcing efficacy, or value, of food. The number of responses rats emitted in the last completed ratio before stopping (i.e., the break point) was taken as the index of reinforcer value. The effects of NPY were also compared to those of food deprivation. Five rats were initially maintained at 80% of their free feeding weights and trained to press for food under a PR 1 schedule. When responding showed no increasing or decreasing trends, rats were given free access to food which decreased break points. After responding stabilized again, rats were injected icv with 0.3, 1.0, 3.0, 5.0 and 10.0 µg of NPY 30 minutes before the session. The effects of 12, 24, 36 and 48 hours acute food deprivation were also tested. Effects of NPY and food deprivation were expressed as a percentage of the break points obtained when rats were maintained at 80% of their free-feeding weights. NPY increased mean break points in a dose-dependent manner (0µg= 7.3%; 0.3=30.3; 1.0=41.1; 3.0=39.82; 5.0=51.0; 10.0=50.1). All levels of acute food deprivation also increased break points. Break points obtained after each dose of NPY were higher than those obtained after 12 (22.2%) and 24 hours (25.4%) food deprivation; break points after 5.0 and 10.0 µg of NPY were comparable to those obtained after 48 hours (70.4%) food deprivation.

195.6

DEVAZEPIDE COMPLETELY REVERSES CCK-INDUCED SATIETY IN SHAM FEEDING RATS. L. D. Melville*, G. P. Smith, J. Gibbs & J. Sechzer, Bourne Laboratory, NY Hospital-Cornell Medical Center, White Plains, NY 10605.

The selective, potent CCK₁ antagonist devazepide (DV) blocks the satiating effect of exogenous, peripherally administered CCK-8 in a variety of test conditions in which rats eat normally and all of the endogenous postingestive satiating mechanisms are stimulated. We wished to investigate the effect of DV when CCK-8 was given (ip) prior to sham feeding, which minimizes or eliminates those postingestive satiety mechanisms. Male Sprague-Dawley rats (n=8) were prepared with chronic gastric cannulas for sham feeding. Rats were deprived of food, but not water, for 17 hours. DV (0.025-1.0 mg/kg) or vehicle was given ip at -30 minutes; CCK-8 (8 or 16 µg/kg) or vehicle was given at -5 minutes. Sham fed intakes of a sweet milk diet were measured for 30 minutes. All doses of DV significantly blocked the satiating effect of CCK-8; complete reversal occurred with 0.05, 0.1, and 1.0 mg/kg DV.

DV (mg/kg)	SHAM INTAKES (ml/30 min)		DV + CCK-8
	Vehicle + Vehicle	Vehicle + CCK-8	
0.025	61.0 ± 2.8	30.1 ± 4.3	54.3 ± 3.6**
0.05	58.7 ± 2.7	34.5 ± 4.9	59.6 ± 3.5***
0.1	50.9 ± 4.1	33.4 ± 4.2	52.0 ± 3.8***
1.0	53.3 ± 2.6	34.6 ± 3.8	59.3 ± 4.1**

Note: Data are mean ± SE. **p<.01, ***p<.001, DV + CCK-8 significantly larger than vehicle + CCK-8.

These results demonstrate for the first time that DV is a very potent antagonist of the satiating effect of exogenous CCK-8 during sham feeding. Since sham feeding minimizes or eliminates all other endogenous satiating mechanisms and thus removes potential interactions between CCK-8 and other mechanisms, the sham feeding rat provides a sensitive and simple assay system for studying the interaction between CCK-8 and CCK antagonists.

A-71623, A NOVEL CCK-A TETRAPEPTIDE AGONIST: COMPARATIVE ANORECTIC EFFECTS IN RAT, MOUSE, DOG AND MONKEY. A.M. Nadzan, K.E. Asin, L. Bednarz, P. Gore*, A. Nikkel, W. Montana*, K. Shiosaki* and R. Craig, Neuroscience Research Division, Pharmaceutical Discovery, D-47H, AP-10-3, Abbott Laboratories, Abbott Park, IL 60064.

We have reported recently on a nonsulfated CCK-A tetrapeptide agonist A-71623, Boc-Trp-Lys(e-N-2-methylphenylaminocarbonyl)-Asp-(NMe)Phe-NH₂, which exhibits high affinity (IC₅₀ = 4 nM) and selectivity (1200-fold) for CCK-A receptors (Shiosaki, et. al., *J. Med. Chem.*, 33, 2950, 1990) and potentially suppresses food intake in several species. In the present study, the anorectic efficacy of A-71623 is compared in rat, mouse, dog and monkey.

Male mice and rats (deprived) were maintained exclusively on a liquid diet of ENSURE™ presented twice daily. A group of sated rats, maintained on rat chow, was allowed daily access (60 min.) to the liquid diet. Male cynomolgus monkeys (N=5) were trained to drink a liquid diet of ENRICH™ available twice daily. Female beagles were maintained on dog chow, with normal chow being removed in the AM prior to access to a gravy + chow mixture for 3 hours. Dogs, monkeys and sated rats were injected i.m. with either vehicle or A-71623 at 15-30 min. prior to the feeding period. Deprived rats and mice were injected i.p. approximately 10 min. prior to the AM feeding session.

A-71623 suppressed food intake in all species studied. Monkeys were the most sensitive to A-71623 (ED₅₀ = 3 nm/kg @60 min., i.m.). In dogs and rats, A-71623 was equipotent at the 60 min. time point, but dog intakes were reduced less than rats at later times. A-71623 was more potent in rats than in mice when administered via the i.p. route. These results demonstrate that A-71623 is a highly selective CCK-A agonist with potent anorectic actions in several mammalian species. The relatively small size of this peptide offers the potential for development of orally-effective CCK-based anorectic agents.

195.9

EXOGENOUS ADMINISTRATION OF CCK-8 INHIBITS GASTRIC EMPTYING THROUGH A-TYPE NOT B-TYPE RECEPTORS. D. Greenberg, A.J. Strohmayer, D.R. Lewis, G.P. Smith and J. Gibbs. Dept. of Psychiatry, Cornell University Medical College: The New York Hospital, White Plains, NY 10605 and North Shore Univ. Hospital, Manhasset, NY 11030.

Injections of CCK are known to slow gastric emptying (GE) in rats, dogs, monkeys, mice and humans. Green et al. (*Am. J. Physiol.*, 1988) showed this effect was partially mediated by CCK A-type receptors in rats. In the present study the specific CCK receptor subtype (A or B) involved in GE was identified.

Male Sprague-Dawley rats (n=9 per group; body weight = 250g) were maintained on a liquid diet (Research Diets Inc.) for at least 10 days prior to testing to insure that stomachs were free of solids. For testing, rats were 17h food deprived. Fifty minutes prior to a gastric gavage, rats were injected (sc) with either Devazepide (A-type CCK antagonist; 0.01, 0.1, 0.5, or 1 mg/kg), L-365,260 (B-type CCK antagonist; 1 mg/kg) or vehicle. Rats were then gavaged with 5ml 0.15M NaCl, and were injected (ip) with 8 µg/kg CCK-8, 8 µg/kg desulfated CCK-8, or 0.15M NaCl. Ten minutes later, rats were sacrificed, their stomachs were removed and weighed to determine GE.

With CCK alone GE was 16%. When desulfated CCK was given at the same dose 60% of the load emptied. When saline was given, 64% of the load emptied. Pretreatment with the B-antagonist plus CCK resulted in only 13% GE. Pretreatment with the A-antagonist resulted in a dose related attenuation of the slowing of GE by CCK, with 1 mg/kg being the most effective.

Since desulfated CCK was ineffective at slowing GE and L-365-260 was not able to reverse the effects of sulfated CCK, we conclude that the B-type receptor is not involved in the CCK effect on GE. The A-type receptor is involved in this effect but may not completely account for it.

195.11

CCK-A RECEPTOR ANTAGONIST IS MORE EFFECTIVE PERIPHERALLY THAN CENTRALLY FOR ATTENUATION OF SUPPRESSION OF SHAM FEEDING BY INTESTINAL OLEATE. L.A. Brenner and R.C. Ritter. Dept. of VCAPP, Washington State University, Pullman, WA 99164.

Previously, we reported that peripheral administration of a CCK type A (CCK-A) receptor antagonist, MK-329, but not a CCK type B (CCK-B) receptor antagonist, L-365,260, attenuates the suppression of sham feeding by systemic injection of exogenous CCK-8 or by intraintestinal oleate. These results suggest that suppression by oleate is mediated by endogenous CCK acting at CCK-A receptors. Though generally considered a "peripheral" type, the CCK-A receptor is also present in the brain. To determine whether CCK mediating the suppression of sham feeding by intraintestinal oleate acts at a central nervous or peripheral site we injected MK-329 into the lateral ventricles of intraintestinally infused, sham feeding rats. MK-329 at doses of 0.18, 0.37 or 0.74 µmol/rat icv failed to attenuate suppression of sham feeding by oleate. These doses were sufficient, however, to attenuate or abolish suppression of sham feeding by oleate when administered peripherally. Suppression of sham feeding by intraperitoneal CCK-8 (2µg/kg), previously shown to be more sensitive than oleate to attenuation by ip MK-329, was abolished by icv injection of 0.18 µmol/rat. This icv dose of MK329, however, was higher than ip doses that abolished CCK-induced suppression of sham feeding. Assuming that icv injection produces brain antagonist concentrations at least as high as those achieved by peripheral injection, then these results argue against participation of central CCK type A receptors in suppression of food intake by intraintestinal oleate and suggest mediation by endogenous CCK acting at peripherally located CCK-A receptors. Supported by NINDS Grant NS20561.

ENDOGENOUSLY RELEASED CCK INHIBITS GASTRIC EMPTYING THROUGH A-TYPE NOT B-TYPE RECEPTORS. A.J. Strohmayer, D. Greenberg, D.R. Lewis, G.P. Smith and J. Gibbs. Dept. of Psychiatry, Cornell University Medical College: North Shore Univ. Hospital, Manhasset, NY 11030 and The New York Hospital, White Plains, NY 10605.

Intragastric infusions of Soybean Trypsin Inhibitor (STI) slow gastric emptying (GE) and release endogenous CCK (Strohmayer et al. 1990, Liddle et al. 1984). The present study was designed to identify the CCK receptor subtype(s) (A and/or B) which mediate the GE effect of STI.

Male Sprague-Dawley rats (n=9 per group; body weight = 250g) were maintained on a liquid diet (BioServ) for at least 10 days prior to testing to insure that stomachs were free of solids. For testing, rats were 17h food deprived. Fifty minutes prior to a gastric gavage, rats were injected (sc) with either Devazepide (A-type CCK antagonist; 0.5 mg/kg), L-365,260 (B-type CCK antagonist; 1 mg/kg) or vehicle. Rats were then gavaged with STI (230 mg/rat) in 5ml 0.15M NaCl, or 5 ml 0.15M NaCl alone. Ten minutes later, rats were sacrificed, their stomachs were removed and weighed to determine GE.

As in previous studies, intragastric STI significantly slowed GE to 43% compared to 61% by saline alone. Pretreatment with the A-antagonist completely reversed the STI effect (GE=62%). The A-antagonist alone had no effect on GE (GE=64%). Pretreatment with the B-antagonist did not reverse the slowing of GE by STI, in fact it augmented this effect (GE=10%). The B-antagonist alone had an agonistic effect on GE (GE=22%).

The slowing of GE by STI was totally reversed only by Devazepide. We therefore conclude that the effect on GE by endogenous CCK acts through A-type CCK receptors.

ATTENUATION OF CCK SATIETY BY JMV-180, AN ANTAGONIST OF LOW AFFINITY PANCREATIC CCK A RECEPTORS. L.A. Neterville*, S. Weatherford, G.J. Schwartz, W. Danho*, J.W. Tilley* and T.H. Moran. Department of Psychiatry, Johns Hopkins University School of Medicine, Baltimore, MD. 21205, Roche Research Center, Hoffmann-LaRoche Inc., Nutley, N.J. 07110.

The synthetic cholecystokinin (CCK) analog, Boc-Tyr(SO₃)-Nle-Gly-Trp-Nle-Asp-2-phenylethyl ester (JMV-180) has been demonstrated to differentially interact with high and low affinity pancreatic CCK A receptors in that it is an agonist at the pancreatic high affinity site but an antagonist at the low affinity site. The present study utilized this compound to address whether the receptor site mediating CCK's effects on food intake was pharmacologically similar to either the high or low affinity pancreatic CCK receptor. Male Sprague-Dawley rats were adapted to 1 hr daily access to a 0.5 kcal/ml glucose solution following a 6 hr daytime deprivation. Seven min prior to glucose access, rats received IP injections of various dosages (vehicle or 0.1, 0.32 or 1.0 µmol/kg) JMV-180, and, 5 min prior to glucose access, received 3.2 nmol/kg CCK-8 IP. Intake was monitored at 15 min intervals for the 60 min test. CCK alone resulted in a 70 % suppression of intake at the 15 min time point and maintained a 55 % suppression through the other time points. JMV-180 significantly attenuated this suppression at all dosages such that by the 1.0 µmol/kg dose, intake was no longer significantly suppressed by CCK. These results suggest that exogenous CCK inhibits intake through an interaction with CCK A receptors which are functionally similar to the pancreatic low affinity binding site.

195.12

INDIVIDUAL, BUT NOT COMBINED, INFUSIONS OF PANCREATIC GLUCAGON AND CHOLECYSTOKININ REDUCE MEAL SIZE IN MEN. N. Geary, V. Hinton*, H.R. Kissileff & F.X. Pi-Sunyer* Obesity Research Core Center, St. Luke's/Roosevelt Hospital, NY NY 10025.

Exogenous pancreatic glucagon (PG) and cholecystokinin octapeptide (CCK-8) produce functionally synergistic satiety signals in rats. To determine whether these peptides interact similarly in men, 8 normal weight men received 3 ng/kg-min PG, 2 ng/kg-min CCK-8, PG plus CCK-8, or saline. IV infusions began 15 min after a 500 ml soup preload and 5 min before a lunch of macaroni and beef with tomato sauce. Meal size (MS) was less after either PG (708 g, p<.05) or CCK-8 (587 g, p<.01) than after saline (856 g, SED=43 g). Simultaneous infusion of PG and CCK-8 did not reliably reduce MS (742 g, p>.05). Indeed, the decrease in MS after simultaneous infusion (113 g) was less than predicted by the sum of the two individual effects (417 g, p<.05). Psychophysical ratings failed to detect non-specific side effects after any of the infusions. In further tests, 1.5 ng/kg-min PG and 1 ng/kg-min CCK-8 had neither individual nor interactive effects on MS.

That PG and CCK-8 each reduced MS in a subjectively specific way suggests they participate in the physiological control of human appetite. Because their simultaneous infusion resulted in an infra-additive MS effect, PG and CCK-8 may interact antagonistically in humans.

195.13

POTENT ANTAGONISM OF THE FEEDING INHIBITORY ACTIONS OF EXOGENOUS CCK-8 BY A SELECTIVE PYRAZOLIDINONE TYPE A CCK RECEPTOR ANTAGONIST (LY219057). J.J. Howbert¹, N.B. Mason¹, B.E. Bruns¹, L.A. Netterville², G.J. Schwartz², and T.H. Moran². ¹Lilly Research Labs., Eli Lilly & Co., Indianapolis, IN 46285 and ²Dept. of Psychiatry, Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205.

Recent studies have demonstrated that feeding inhibitory actions of exogenous and endogenous cholecystokinin (CCK) are mediated by type A CCK (CCK-A) receptors. The present experiments evaluated the ability of a novel pyrazolidinone CCK antagonist (LY219057) to block the feeding inhibitory actions of exogenous CCK. *In vitro* binding, LY219057 showed good affinity for the pancreatic CCK-A receptor (IC₅₀ = 50 nM in rat pancreatic membranes) and moderate selectivity relative to the brain CCK (CCK-B) receptor (IC₅₀ = 1300 nM in guinea pig brain membranes). For the feeding experiments, male Sprague Dawley rats were adapted to 1 hr access to a 0.5 kcal/mL glucose solution following a 6 hr daytime deprivation. Thirty minutes prior to glucose access, rats received IP injections of various doses (vehicle or 0.1 to 100 µg/kg in half log steps) of LY219057 and, 5 min prior to glucose access, received 4 µg/kg CCK-8. Intake was recorded at 15 min intervals for the 60 min test period. CCK alone resulted in a 60% suppression of intake at 15 min and a 50% suppression of intake at the other time points. Beginning at a dose of 0.32 µg/kg, LY219057 attenuated CCK's inhibition of glucose intake in a dose-dependent fashion. This attenuation was maximal at a dose of 10 µg/kg. The potency of LY219057 in blocking CCK-induced suppression of intake appears significantly greater than would be predicted from its relative affinity for pancreatic CCK-A receptors.

195.15

METHADONE AND FEEDING: DIFFERENT EFFECTS IN THE HOME CAGE AND THE OPERANT CHAMBER. J.M. Rudski, T. Thompson*, D.W. Schaal*, J.P. Cleary*, C.J. Billington*, and A.S. Levine. Univ of MN, Mpls, MN 55455 and VA Medical Center, Mpls, MN 55417.

Levine et al. have shown that mu-opiate agonists increase food intake in free-feeding rats at times when feeding is a low probability behavior. Thompson et al. have shown that methadone, a predominantly mu-opiate agonist, decreases food reinforced operant behavior in food-deprived animals. To examine this apparent paradox of opiates' effects on feeding, food-reinforced operant behavior at a time when feeding is usually not observed was measured for 4 hours in satiated rats living in an operant chamber. One group of rats received methadone 5.0 mg/kg and the other received vehicle for 10 days. Pellets were delivered under an FR 1 reinforcement schedule. Differences for each rat between mean intake of the last 5 baseline days and last 5 drug days were compared. Results were not statistically significant; the methadone group increased their food intake a mean of 0.68 g and the saline group increased their intake a mean of 0.13 g. Thus, methadone does not result in decreases in food-reinforced operant behavior observed in food-deprived animals. Furthermore, increases similar to those reported in free-feeding following mu agonists are not seen when food was contingent on an operant response. This suggests that the increases observed in free-feeding do not reflect a significant increase in food motivation similar to that induced by food deprivation, since an additional response requirement to procure food resulted in methadone failing to increase food-maintained behavior.

INVOLVEMENT OF KAPPA AND MU OPIOID RECEPTORS IN SUCROSE INTAKE IN RATS. I.W. Beczkowska and R.J. Bodnar. Dept. of Psych., Queens College, CUNY, Flushing, NY 11367

General opioid antagonists like naloxone and naltrexone (NTX) reduce intake of palatable liquid diets, including sucrose and saccharin solutions. Studies using selective mu and kappa agonists and antagonists have implicated these receptor subtypes in general palatable effects. The present study evaluated whether ingestion of a palatable (10%) sucrose solution was differentially altered in 5-min blocks over a 1 h period by central pretreatment with a general (NTX), mu-selective (beta-funaltrexamine; BFNA) or kappa-selective (nor-binaltorphamine; nor-BNI) antagonist in rats. Central NTX reduced sucrose intake over the 1 h time course with inhibition ranging from 30% (5 µg) to 47% (50 µg). Central norBNI significantly reduced sucrose intake over the 1 h time course with 5 and 20 µg doses producing inhibition of 47%. In contrast, the reduction in sucrose intake by central BFNA (20 µg) did not begin until 10 min of ingestion and the magnitude of inhibition did not exceed 30%. These data support the previously-stated role for kappa receptors as integral modulators of palatability, but indicate that the mu receptor also participates to a lesser degree in these effects (Supported by NIDA Grant 04194).

195.14

MICROINJECTION OF NALOXONE INTO THE SUBSTANTIA NIGRA OF RATS BLOCKS EATING INDUCED BY STRESS. M.F. Hawkins, B. Cubic*, A.A. Baumeister, and J.C. Barton*. Dept. of Psychology, Louisiana State Univ., Baton Rouge, LA 70803

Stress produced by pinching the tail elicits eating in rats which is reversible by naloxone. Little is known about what sites in the CNS may mediate these effects. Male Sprague-Dawley rats were maintained on free access to food and water. Five minutes after naloxone (3, 10, 20, or 30 nmol) or water was injected into the substantia nigra (0.5 µl/side) food intake was recorded for four minutes during continuous tail pinch. Immediately afterward, nociceptive threshold was assessed with tail-flick and hotplate tests. Naloxone produced a significant [$F(4,34) = 11.41$; $p < .0000$] and dose related [$r(37) = -.71$, $p < .0000$] reduction in the feeding elicited by tail pinch. Naloxone had no effect on gnawing (spillage) or nociceptive threshold. These results suggest that the SN may be an important site for the regulation of stress induced feeding. Additional studies in our lab are attempting to determine the degree of neuroanatomical specificity of this effect.

195.16

EVALUATION OF AGING AND GENDER EFFECTS UPON NALOXONE HYPOPHAGIA FOLLOWING REGULATORY CHALLENGE OR PALATABLE SITUATIONS IN RATS. A.K. Islam, I.W. Beczkowska, R. Basile*, M.L. Cooper* and R.J. Bodnar. Dept. of Psychology, Queens College, CUNY, Flushing, NY 11367.

Aging reduces the sensitivity of rats to hypophagia induced by the opiate receptor antagonist naloxone during spontaneous feeding. Naloxone reduces food intake under other circumstances including the regulatory challenge of food deprivation for 24 h and the palatable situation of intake of a high-fat diet. Different opiate receptor subtypes are responsible for different forms of ingestive behavior. To determine whether aging and gender differentially influence different forms of naloxone hypophagia, intake of male and female rats at different ages (4, 8, 14, 20 and 26 mo) was examined following systemic naloxone (0, 0.25, 1, 2.5 and 5 mg/kg) in two paradigms: a) reintroduction of food after 24 h of deprivation and b) intake of a high-fat diet. Both aging and gender affected basal intake following deprivation with reduced intake observed in older and female rats respectively. Neither variable consistently altered high-fat intake. Aging but not gender increased the sensitivity to naloxone hypophagia following deprivation. Neither gender nor aging altered the dose-response function of naloxone hypophagia following intake of a high-fat diet. Overall, rats were more sensitive to naloxone hypophagia in the palatable relative to the deprivation situation.

WITHDRAWAL FROM DAILY NALTREXONE STIMULATES EXCESS SUCROSE INGESTION IN NAIVE RATS. W.C. Lynch and L. Moe. Dept. of Psychology, Montana State Univ., Bozeman, MT 59717.

In previous work we reported that daily naloxone treatment blocks ingestion of preferred sucrose solutions and stimulates sucrose intake following NAL withdrawal (Lynch, W.C. and Burns, G., *Appet.* 15: 23-32, 1990). The withdrawal effect may be due to modification of opioid receptor function resulting in supersensitivity to sucrose taste. In order to rule out possible effects due to taste experience, the present experiment measured intake following withdrawal from repeated naltrexone (NALT) in animals with no prior sucrose experience. Twenty Sprague-Dawley albino rats (200gm male) were randomly assigned to two groups. One group was injected with NALT (2mg/kg, sc) and the other with saline (1ml/kg, sc) for 13 days (10am daily). Animals had free access to lab chow and water and body weights were recorded daily throughout testing. At 24, 48 and 72h following the last injection, all animals were given 2h access to a 20% (w/v) sucrose solution and intake was recorded hourly. NALT had no effect on normal body weight gain. Following withdrawal, however, sucrose intake in the NALT group was significantly elevated at 24h and 48h, returning to control levels by 72h. Thus NALT withdrawal transiently increases sucrose ingestion in naive animals and this effect has a time course similar to the upregulation of opioid receptors following withdrawal from chronic NALT.

195.19

EFFECTS OF CENTRALLY ADMINISTERED NALOXONE ON THE INTAKE OF CARBOHYDRATE AND FAT. B.A. Gosnell and D.D. Krahn, Dept. of Psychiatry, University of Michigan, Ann Arbor, MI 48109-0656.

We have reported recently that baseline preference for carbohydrate vs. fat is an important determinant of the effect of morphine on diet selection (Gosnell et al., *Pharmacol. Biochem. Behav.* 37:207, 1990). In this experiment, we examined the effects of centrally administered naloxone on diet selection in rats selected for different baseline preferences for fat and carbohydrate. Male Sprague-Dawley rats ($n=32$) were given *ad lib* access to 2 diets: a fat/protein diet and a carbohydrate/protein diet. Both diets contained equal amounts of protein (20% of total energy). After adaptation to these diets, groups of fat-preferring and carbohydrate-preferring rats were formed ($n=7$). All rats were then placed on a food restriction schedule (diets available 5 hrs/day). Cannulas for icv injections were implanted after adaptation to this schedule. Fat-preferring rats consumed $86 \pm 1\%$ of total daily calories from the fat diet prior to food restriction; the restriction schedule did not change this preference ($89 \pm 3\%$ of daily calories). Carbohydrate-preferring rats consumed $38 \pm 2\%$ of total calories from the fat diet. After adaptation to food restriction, preference for the fat diet increased significantly ($55 \pm 5\%$ of daily calories). Rats were given icv injections of naloxone (0, 20 or 50 μ g) 10 min before diets were presented; intake was measured at 1, 2, and 5 hrs. Each rat was tested with all doses. In fat-preferring rats, both doses of naloxone reduced 1 hr intake of the fat diet; intake of the carbohydrate diet was low and was unaffected by naloxone. In carbohydrate-preferring rats, naloxone (50 μ g) reduced the intake of both diets by an approximately equal amount (in calories). These results, together with our previous findings, indicate that the effects of opioid manipulations on diet selection must be interpreted in light of baseline diet preferences. 195.21

MU OPIOID ACTIVITY IN ANTERIOR CINGULATE CORTEX MAY MEDIATE STIMULATION-INDUCED FEEDING. T. Wolinsky, D. Gilady* and K.D. Carr. Millhauser Labs, NYU Medical Center, NY, NY 10016.

In a recent *in vivo* autoradiographic study, we demonstrated that feeding elicited by lateral hypothalamic electrical stimulation reduces 3 H-diprenorphine binding in supragenual cingulate cortex (Stein, Carr & Simon, 1990). This suggests competitive displacement by an endogenous opioid peptide that is released during feeding. In an effort to verify the involvement of supragenual cingulate opioid activity in stimulation-induced feeding, a follow-up microinjection experiment was conducted. Since supragenual cingulate contains mu and delta receptors but seems devoid of kappa receptors (Mansour et al., 1988), effects of mu- and delta-selective compounds on stimulation frequency threshold for eliciting feeding were determined. Bilateral microinjection of the mu-preferring antagonist, naloxone (20.0 μ g), produced a significant (34 ± 5.8) increase in feeding threshold ($F_{4,16} = 14.4$, $p < .001$; Dunnett t , $p < .01$) while the delta-selective antagonist, naltrindole (5.0 μ g) did not (Dunnett t , $p > .05$). Bilateral microinjection of the mu-selective agonist, DAMGO (1.0 μ g) produced a significant reduction (25.8 ± 2.6) in feeding threshold (Dunnett t , $p < .01$) while the delta-selective agonist, DPDPE (10.0 μ g) did not. These findings support our interpretation of the autoradiographic results and suggest that mu opioid activity in supragenual cingulate cortex plays a significant role in stimulation-induced feeding. Supported by DA 03956.

195.23

SPINAL VISCERAL AFFERENTS CAUDAL TO T₁₃ ARE SUFFICIENT TO MEDIATE THE SATIETY ACTION OF BOMBESIN. C. Walsh*, S. Mindell*, T.C. Kirkham, D. Greenberg, J. Gibbs & G.P. Smith, Bourne Laboratory, The NY Hospital-Cornell Medical Center, White Plains, NY 10605.

The combination of total abdominal vagotomy (vgx) and disconnection of spinal visceral afferents caudal to T₂ abolishes the inhibitory action of peripherally-administered bombesin on food intake at a test meal in rats (Stuckey et al., 1985). Since vgx alone does not alter this satiety effect of bombesin, spinal visceral afferents entering the cord caudal to T₂ are sufficient to mediate the effect. To delineate further the extent of the visceral afferents involved, we tested the satiety effect of bombesin in groups of rats with the following surgical lesions in addition to vgx: bilateral greater splanchnic nerve section ($n=5$); bilateral central dorsal rhizotomy (dr) T₃-T₁₃ ($n=4$); dr T₃-T₁₀ ($n=18$); dr T₃-T₁₀ + cord section at T₁₀ ($n=6$); and appropriate sham lesions. After overnight (17h) food deprivation, one dose of tetradecapeptide bombesin (Bachem; 2.4, or 8 μ g/kg) or vehicle control was injected intraperitoneally immediately prior to 30 min access to liquid food (BioServ, 0.37 kcal·ml⁻¹). When vgx was combined with dr T₃-T₁₀ + cord section at T₁₀, the satiating effect of the largest dose of bombesin was abolished. No other lesion significantly changed the satiating potency of bombesin. The differential results between rats with vgx + dr T₃-T₁₃ (full satiety effect of bombesin) and with vgx + dr T₃-T₁₀ + cord section at T₁₀ (no satiety effect of bombesin) demonstrate that spinal visceral afferents entering the cord caudal to T₁₃ are sufficient to mediate the satiety action of bombesin.

DIFFERENTIAL EFFECTS ON FEEDING BEHAVIOR AND LOCOMOTOR ACTIVITY OF MU, DELTA AND KAPPA AGONISTS INFUSED INTO THE NUCLEUS ACCUMBENS AND VENTROLATERAL STRIATUM. V.P. Bakshi* and A.E. Kelley, Dept. of Psychology, Northeastern University, Boston, MA. 02115.

Previous evidence has indicated that systemic administration of opiates can affect both locomotor activity and feeding behavior. In this study, we investigated the role of specific receptor subtypes as well as different striatal regions in the regulation of these behaviors in satiated animals. In 6 separate experiments, 8 rats were implanted with cannulae aimed at either the nucleus accumbens (N.Acc.) or the ventrolateral striatum (VLS). Equimolar doses of either a mu (DAGO), delta (DPEN) or kappa (U50,488H) agonist were bilaterally infused into these sites. The doses were: DAGO (0, .025, .25 and 2.5 μ g/.5 μ l); DPEN (0, .031, .31 and 3.1 μ g/.5 μ l); U50,488H (0, .019, .19 and 1.9 μ g/.5 μ l). Behavior was rated every 10 min. over a 4 hr. session. Total food intake and spillage were calculated at the end of the testing period. When injected into the N.Acc., DAGO elicited delayed yet robust locomotor and feeding responses. The .25- μ g dose produced a biphasic effect on general activity; an initial suppression was followed by a significant enhancement over the saline baseline. Feeding was markedly potentiated by the highest dose. In contrast, administration of the highest dose of DPEN produced an immediate and significant increase in locomotor activity, but only a mild enhancement of feeding. U50,488H treatment did not significantly alter either behavior. Administration of DAGO into the VLS augmented both feeding and locomotor activity, whereas infusion of DPEN into this region only elicited locomotor activity. An experiment to determine the effects of U50,488H infused into the VLS is in progress. The results in general indicate that different opioid receptor subtypes may play different roles in the regulation of ingestive and locomotor behaviors. In addition, the relative involvement of different striatal subregions is discussed.

195.22

EFFECTS OF CHRONIC NALTREXONE INFUSIONS ON THE ACQUISITION AND MAINTENANCE OF DIET PREFERENCES. D.D. Krahn, B.A. Gosnell and D.H. Averbach*. Dept. of Psychiatry, Univ. of Michigan, Ann Arbor, MI 48109.

Opioids may play a role in the acquisition of taste preferences. Opioid agonists increase preference for sweet tastes while opioid antagonists or opioid receptor deficiency decrease preference for sweet tastes. We hypothesized that opioids might be important in diet preferences also and performed an experiment to determine whether chronic infusion of the opioid antagonist naltrexone causes changes in the acquisition of diet preferences or changes already established diet preferences. Two groups of 10 male, Sprague-Dawley rats were implanted with minipumps which delivered naltrexone (200 μ g/kg/hr) or saline for the first 7 days of self-selection from high CHO (80% CHO, 20% protein) and high fat (80% fat, 20% protein) diets. After 7 days, the minipumps of the naltrexone-treated group (Group I) were replaced with saline-containing minipumps while the minipumps of the saline-treated group (Group II) were replaced with naltrexone-containing pumps and 7 more days of food intake were measured. Intakes of each diet were measured daily. Group I displayed an unexpected response to naltrexone as 6 of 10 rats ate more than 80% of calories from the high CHO diet while 3 of 10 ate more than 90% of calories from the high fat diet. After the switch to saline, Group I showed a gradual moderation of these extreme preferences such that, under saline treatment, most rats ate a higher percentage of calories from the diet which was least preferred with naltrexone. Under initial saline treatment in Group II, no rats ate more than 80% of either diet. After switching to naltrexone, only one rat (which ate 95% high CHO) in Group II developed the extreme preference for one diet seen during naltrexone treatment in Group I. Overall, naltrexone-treated rats in each group ate significantly less total calories than under saline conditions. Thus, the effects of opioid antagonists on diet preferences are modified dramatically by previous experience with the diets available for selection. (Supported by NIDA grant 05471).

195.24

POTENTIATION OF BOMBESIN-INDUCED SUPPRESSION OF FOOD INTAKE AFTER COMBINED VAGOTOMY AND CELIAC GANGLIONECTOMY. S.C. Weatherford, J. McQuade, L.D. Melville*, G.P. Smith and J. Gibbs, Department of Psychology, University of Washington, Seattle, WA 98195 and Department of Psychiatry, New York Hospital-Cornell Medical Center, White Plains, NY 10605.

Gibbs and Smith (1988) have shown that combined high thoracic spinal-visceral disconnection and total subdiaphragmatic vagotomy (TSV) block the satiety effect of bombesin (BBS) in rats, while neither lesion alone is effective. Similarly, we have observed (unpublished observations) that celiac ganglionectomy (CGX) alone does not affect BBS-induced suppression of food intake. In this study we examined the effect of BBS on 18-min intake of 20% sucrose in rats that had received both TSV and CGX and in sham-operated controls.

RESULTS: Values are mean \pm SEM \pm suppression

	Dose (μ g·kg ⁻¹)		
	2	4	16
Sham	9 \pm 5	9 \pm 13	38 \pm 12*
TSV/CGX	36 \pm 8*	37 \pm 13*	59 \pm 4*
			56 \pm 12*

Tests were conducted at 2 p.m. after a 6 hr fast. * $p < 0.05$, * BBS vs. vehicle, # sham vs. TSV/CGX.

CONCLUSIONS: Inasmuch as the minimal effective dose and the magnitude of the response to BBS were enhanced in the TSV/CGX rats, these results suggest that not only do these neural substrates not mediate the satiety effect of BBS, but that their integrity may function to attenuate BBS-induced satiety. [supported by NIH DK33248 (JG).]

GRF EFFECTS ON MACRONUTRIENT SELECTION. P.R. Dickson and F.J. Vaccaro, Dept Psychology, University of Toronto, Toronto, Canada, M5S 1A1.

Growth hormone releasing factor (GRF) is a peptide which releases growth hormone from the anterior pituitary and stimulates food intake centrally. Microinjection of GRF into the suprachiasmatic nucleus/medial preoptic area (SCN/MPOA) stimulates intake of chow by non-deprived male rats. The present study extends these findings to examine how GRF affects intake of macronutrients (fat, protein and carbohydrates). Male Wistar rats with SCN/MPOA cannulae were habituated to macronutrient-specific diets for 2 weeks and then tested with GRF (1 pmol) and vehicle (.01% ascorbic acid). Intake (controlled for spillage) was recorded at 1, 2, and 4 hours post-injection. Diets were isocaloric, visually and texturally similar, and nutritionally complete. Results suggest that GRF specifically stimulates protein intake, and that there is a reliable time course to this effect. These results are in keeping with evidence implicating opiates in the expression of GRF-induced feeding, and further support the hypothesis of a central-peripheral integration of function for GRF.

CHRONIC INTRAHYPOTHALAMIC INSULIN INFUSIONS DIFFERENTIALLY AFFECT DIURNAL RHYTHMS OF FOOD INTAKE AND BODY TEMPERATURE IN THE RAT. K.M. Andrews*, M.K. McGowan†, & S.P. Grossman, Committee on Biopsychology & †Department of Anesthesia & Critical Care, University of Chicago, Chicago, IL 60637.

Insulin infused intrahypothalamically significantly decreases body weight and alters daily food intake patterns; day-time intake increases while night-time intake falls. To test whether insulin non-specifically influences other diurnal rhythms, rats were implanted with a thermosensor i.p. in order to measure daily pattern of body temperature. Body temperature was recorded hourly. Following baseline temperature readings, rats received chronic infusions of 1.5µU/hr of insulin into the ventromedial nucleus of the hypothalamus. In this experiment, insulin infusion shifted food intake patterns in a manner consistent with previous reports but differentially altered the diurnal pattern of body temperature. Insulin shifted the peak of the temperature cycle away from the light period; body temperature reached its zenith at a later point of the dark period, reaching significance only after the infusion terminated. Also, unlike the dampening effect of insulin on the food intake cycle, insulin significantly increased the core temperature range over a 24h period. Mean daily core temperature rose significantly under insulin infusion relative to both saline infusion and pre-op levels and remained significantly elevated during the post-infusion period. This mirrors insulin's effects on body weight, which was significantly depressed during infusion and post-infusion. These data suggest that insulin's effects on food intake patterns are not the result of a non-specific alteration of circadian rhythms. However, they imply that intrahypothalamic insulin may exert its effects on body weight by altering both food intake and metabolic processes.

196.1

AN EXAMINATION OF POSTINGESTIVE MECHANISMS THAT SUPPRESS MEALS INITIATED IN RESPONSE TO CONDITIONED CUES. L. Whitten, S. Callaghan* and H.P. Weingarten, Dept. of Psychology, McMaster University, Hamilton, Ontario, Canada, L8S 4K1.

Cues conditioned to food reliably elicit meal initiation and large meals. We examined postingestive factors that suppress intake in response to the presentation of food-associated conditioned cues.

We trained male Long Evans hooded rats (approx 280 gm) to associate a tone-light conditioned stimulus (CS) with food by presenting the CS for 4 min prior to each of six daily meals for 12 days. The meal consisted of 7 ml of a nutritionally-adequate liquid diet. On test days, maintenance food was removed and rats were provided with a 7 mls liquid diet premeal. One hour later, the CS was presented followed by a test meal of 15 mls liquid diet. Meal sizes induced by presentation of the CS were determined by measuring the amount remaining in the food cup 15 minutes after meal delivery.

First, we compared the ability of intraperitoneal (ip) and subcutaneous (sc) glucose to suppress eating. Glucose, at doses of .5, 1.0 and 1.5 g/kg, was injected 30 min prior to CS onset. Equivolumes of ip or sc .15M saline was the control. With ip injections, intake suppression was directly related to dose; overall, ip injections were more effective than sc in suppressing meals. Second, we tested the synergy between ip glucose and gastric distension. Treatments were .5 g/kg ip glucose and 10 mls intragastric .15M saline administered either alone or in combination 30 min prior to CS onset. Control condition was .15M ip saline and sham gavage. Neither glucose nor distension alone suppressed meal size. However, the combined treatment resulted in a 28% suppression of eating. These studies provide results encouraging future searches for postingestive mechanisms capable of suppressing conditioned eating.

MEAL SIZE IS DETERMINED BY STOMACH VOLUME. V.E. MENDEL AND M. PALIESCHESKY, DEPT. AN. PHYSIOLOGY, UNIV OF CALIF., DAVIS, CA 95616

Voluntary consumption of food in mammals in all species is an episodic process. This suggests that either the brain monitors energy levels in tissues, including blood, or that the amount of food eaten in any feeding episode may be determined by volume and rate limiters in the gastrointestinal tract. Daily food intake can be determined by changing either meal size or meal frequency or both. This study was designed to determine whether size of the first meal following periods of fast is limited. Twelve Sprague-Dawley, male rats, averaging 389gm were placed in individual Meal Pattern Analysis modules. Six of the animals received a 15% casein basal diet (BD), the remaining six rats were offered a BD+30% corn oil diet (BD+30). Baseline food intake data were collected for 10 days and the first meal consumed following lights out during the last 3 days of baseline period was averaged and used as the zero meal size. Rats were randomly fasted 12, 24, 36, 48 hr. and size of the first meal was measured. Food was introduced 10 min. before lights out. First meal size (1st MS) at zero hr. averaged 2.7 ± 0.30 gm BD and 2.6 ± 0.30 gm BD+30. The 1st MS increased to 4.9 ± 0.46 (P<0.02) gm on average after 12 hr. fast and did not significantly increase with fasts of greater duration. These results suggest that meal size is limited by stomach volume.

196.3

THE ROLE OF DELAYED GASTRIC EMPTYING IN ANOREXIA INDUCED BY INTESTINAL INFLAMMATION IN THE RAT. K.J. McHugh, H.P. Weingarten and S.M. Collins*, Intestinal Disease Research Unit and Department of Psychology, McMaster Univ. Hamilton Ont. Canada L8S4K1.

We have recently characterized a dramatic suppression of feeding that occurs in a rat model of intestinal inflammation induced by intra-rectal (i.r.) administration of trinitrobenzene sulfonic acid (TNB) and ethanol. We investigated the role of gastric emptying in the reduction of food intake in this model. Intestinal inflammation was induced by infusing 30mg TNB in 0.25ml of 50% ethanol in male Sprague Dawley rats. Control rats were infused with the 50% ethanol vehicle only. The rate of gastric emptying was measured by infusing a test meal of 15ml liquid diet (evaporated milk, sucrose, water and vitamins) by gavage directly into the stomach. Either 60 min or 90 min post- gavage rats were sacrificed, their stomachs removed and stomach contents emptied and dried. The percent of the original test load remaining in the stomach was determined by comparing the dry weight of remaining stomach contents with the dry weight of 15ml of liquid diet. Results were as follows:

Group	% remaining at 60 min	% remaining at 90 min
TNB + EtOH	55.9 ± 4.2	55.6 ± 6.9
EtOH	44.1 ± 5	37.4 ± 3.7
	p<.05	p<.001

This inflammation of the colon leads to a delay of gastric emptying. Although the mechanism mediating this effect is unclear, cytokines (eg. IL-1, TNF) released by the inflamed bowel segment may be relevant. Our results leave open the possibility that delayed gastric emptying may contribute to the decreased food intake that accompanies intestinal inflammation.

A ROLE FOR HIPPOCAMPUS IN THE CONTROL OF INGESTIVE BEHAVIOR. T.L. Davidson* and L.E. Jarrard, Dept. Psychol. Sci., Purdue Univ., West Lafayette, IN 47907, and Dept. Psychol., Washington & Lee Univ., Lexington, VA 24450.

Rats with ibotenate (IBO) lesions of the hippocampus were compared to controls with respect to (1) feeding behavior; (2) the ability to use food deprivation and exteroceptive stimuli as discriminative cues. For 12 days postsurgery, feeding, drinking, and activity of the rats was monitored by an automated system. The rats were then given Pavlovian discrimination training. For half of the rats in each group, 24-hr food deprivation plus tone signaled shock and 0-hr food deprivation plus clicker signaled no shock. The remaining rats had the reversed contingency. Both groups were then tested in extinction (i.e., without shock) with deprivation cues alone, then with auditory cues alone. Discrimination was indicated to the extent that more freezing (i.e., skeletal muscle immobility) was elicited by the previously shocked cue (deprivation or auditory) than by the nonshocked cue.

Relative to controls, IBO lesioned rats were markedly impaired in their ability to use food deprivation cues, but not auditory cues, as predictors of shock. In addition, the feeding behavior of the IBO lesioned rats indicated that they were also unable to use their deprivation cues to predict when feeding was followed by rewarding consequences. The results suggest that the hippocampus may be involved in the utilization of information provided by food deprivation states.

HORMONAL AND SOMATIC CHANGES IN RATS PAIR FED BY COMPUTER OPERATED FEEDERS TO GROWTH RETARDED DORSOMEDIAL HYPOTHALAMIC NUCLEI LESIONED (DMNL) ANIMALS. L.L. Bellinger, T.W. Castonguay and L.L. Bernardis. Dept. Physiol., Baylor Coll. Dent., Dallas, TX 75246; Univ. Maryland, College Park, MD 20742; V.A. Med. Ctr., Buffalo, NY 14215.

Rats with DMNL are hypophagic and show reduced linear and ponderal growth, but have normal body composition and anabolic hormone concentrations. In the present study weanling Sprague Dawley rats were either bilaterally DMNL and ad lib fed (body weight, [BW], $93 \pm 3.5g$, $n=7$); sham operated (BW, $90 \pm 3.4g$, $n=7$) and pair fed to the DMNL group (SPF); or sham operated (BW, $92 \pm 2.7g$, $n=17$) and ad lib fed (SAD). Pair feeding (Bioserve, 45 mg Rodent Grain Pellet) was accomplished using 14 photobeam-computer-activated pellet feeders in which the food availability of an individual SPF rat was "yoked" to the ad lib intake of a DMNL rat. Food intake, BW, nasoanal length (NAL), Lee Obesity Index, body composition using Model SA-2 EM-SCAN were calculated over the 3 week experiment. At experiment's end, blood was collected in the middle of the light phase after a 4 hr fast and assayed for insulin, corticosterone and T_3 ; correct lesion placement was determined histologically. DMNL rats were hypophagic ($P < 0.01$) and gained less BW ($P < 0.01$) than SAD. The Δ BW gains were similar in DMNL and SPF. The SPF showed the most ($P < 0.01$) NAL growth retardation. Fat percentages calculated by EM-SCAN Model SA-2 were unreliable and Lee Obesity Indices were all in normal range at experiment's end. Plasma T_3 were similar in DMNL and SPF, but slightly lower than SAD. Corticosterone concentrations were similar in the three groups, whereas insulin was reduced ($P < 0.05$) in SPF compared to SAD, while DMNL was not. The data indicate that the hypophagia of the DMNL rats may be producing some, but not all, of the physiological manifestations following lesioning. EFFECTS OF AREA POSTREMA LESIONS ON TASTE REACTIVITY IN RATS. L.A. Eckel and K.-P. Ossenkopp. Dept. Psychology, Univ. of Western Ontario, London, Ontario, CANADA N6A 5C2.

The present study examined the effects of intra-oral infusions of varying concentrations of sucrose solutions on taste reactivity in rats with area postrema lesions (APX) or sham lesions (APS). The taste reactivity test involves videotaping the activity of lingual, masticatory, and facial muscles during direct oral contact with specific taste stimuli. In the first phase of the experiment, rats were habituated to the test chamber while distilled water was infused via a chronically implanted intra-oral cannula. The second phase of the experiment involved the infusion of four concentrations of glucose (.01 M, .03 M, .30 M, and 1.0 M), each for a period of 3 minutes at a rate of .78 ml/min. During all infusions, the resulting oral and somatic responses to the taste stimuli (taste reactivity test), were videotaped and analysed at one-fifth the normal tape speed. The results revealed comparable enhanced ingestive responses by both groups to the sucrose solutions in comparison to the distilled water. Furthermore, these responses were concentration dependent such that both groups showed successively stronger ingestive sequences in response to the increasing concentrations of sucrose ($p < .05$). This finding indicates that lesioning the area postrema is not disrupting the rat's ability to discriminate between the varying concentrations of sucrose, relative to the APS group.

CENTRAL BLOCKADE OF GLUCOCORTICOID RECEPTORS IN THE ZUCKER RAT. V.B. Burden*, B.D. White and R.J. Martin. Dept. of Foods and Nutrition, University of Georgia, Athens, GA 30602.

In the Zucker obese rat, it appears that glucocorticoids are necessary for hyperphagia and the development of obesity. While peripheral delivery of the glucocorticoid antagonist, RU 486, has resulted in food intake and body weight gain parallel to lean Zuckers, it is not known whether this occurs through a peripheral or central site of action. This study was designed to investigate the effect of centrally administered glucocorticoid antagonists. Lean (fa/?) and obese (fa/fa) male Zucker rats (8-9 weeks) were implanted with cannula directed toward the lateral ventricle of the brain. Rats received glucocorticoid antagonists (RU 318, RU 486) or vehicle at a rate of 20 ng/hr through mini-osmotic pumps attached to the cannula. After 18 days of infusion there were no statistical differences in body weight or food intake among rats receiving the different compounds within each phenotype. At this time, the osmotic pumps were replaced with new pumps containing the glucocorticoid antagonists that delivered at a higher rate of 1 ug/hr. After 13 days body weight gain was significantly decreased ($p < .05$) in obese rats receiving RU 486 compared to rats receiving vehicle. Total food intake was also reduced in the RU 486 treated obese rats ($p < .05$). The antagonists had no significant effects on body weight or food intake of lean rats. These results show that obese Zuckers are more susceptible to blockade of central glucocorticoid action than lean Zuckers.

196.6

Decreased Intestinal Transit following Area Postrema Ablation (APX). M. Kathleen Gruver*, Tom H. Burchard*, Nancy J. Kenney, Dept. Psychology, University of Washington, Seattle, WA 98195.

Gastrointestinal (GI) transit is reduced following APX. These studies examine the longevity of this effect and the possibility that APX-induced hypophagia may underlie the change of GI transit.

In the first study, conditioned taste aversion (CTA) development and GI transit of APX and control (CONT) rats were monitored 4 months after surgery. After an 8-day exposure to a novel AIN diet, APX rats demonstrated an aversion to AIN compared to CONT rats. GI transit was measured 2 hr after injection of 200 ul of a 20% charcoal suspension into the stomachs of urethane anesthetized (1.25 g/kg) rats. The charcoal traversed 9.1% of the total intestinal length of APX rats as compared with 23% of controls. Thus, decreased GI transit is a chronic effect of APX and may underlie the CTA induced by APX.

In the second study, GI transit of APX, ad-lib-fed CONT rats and intact rats whose daily food intake was restricted to the amount eaten by the APX rats (DEP rats) was studied. GI transit of APX rats (7.0%) was suppressed compared to that of CONT (30.0%) or DEP rats (27.5%). GI transit of CONT and DEP rats did not differ. Thus, hypophagia alone does not account for decreased GI transit of APX rats.

INTRAVENTRICULAR INJECTIONS OF GLUCOCORTICOID IN ADRENALECTOMIZED AND SHAM OPERATED SPRAGUE-DAWLEY RATS: EFFECTS ON DIETARY SELF-SELECTION. T.W. Castonguay, M.E. Bligh*, and K. Kamara*. Department of Human Nutrition and Food Systems, University of Maryland, College Park, MD 20742.

Adrenalectomy (ADX) promotes a change in the dietary selection patterns of adult male rats. ADX rats typically reduce protein and fat intake when compared to sham operated controls. Systemic corticosterone therapy restores dietary selection patterns so that the proportion of calories taken from protein, fat and carbohydrate in the diet of ADX rats does not differ from that of sham operated controls. The present study was conducted to test the relationship between glucocorticoid replacement of ADX rats that was limited to the brain and dietary self-selection patterns. Sixty-four male Sprague-Dawley rats were surgically fitted with intraventricular (ICV) cannulae and either bilaterally adrenalectomized or given sham operations. Patency of the ICV cannula was verified by ICV injection of 150 ng Angiotensin II followed by at least 5 ml of water consumed within 1 h of injection. Adx rats were then assigned to one of four dose groups (0, 5, 50 or 500 ug glucocorticoid [either corticosterone or corticosterone acetate] in volumes ranging from .2 - 10 ul).

Sham operated rats were given vehicular injections only. Vehicles used included ETOH, 50% ETOH in isotonic saline, or Tween 80 + carboxymethylcellulose + ETOH. Each rat was injected and weighed daily, and its daily intake of separate protein, fat and carbohydrate determined. Results from these procedures failed to demonstrate any specific effect of ICV glucocorticoid replacement. Of particular note was that all rats with the exception of those given very low volume vehicle injections (0.2 ul/d) failed to gain weight during the injection period. (Sponsored by a grant from the Maryland Agricultural Experiment Station Competitive Grants Program.)

EFFECTS OF CENTRAL TYPE I AND TYPE II GLUCOCORTICOID RECEPTOR STIMULATION ON FOOD INTAKE, BODY WEIGHT GAIN, AND FOOD EFFICIENCY. B.D. White, R.G. Dean* and R.J. Martin. Dept. of Foods and Nutrition, University of Georgia, Athens, GA 30602.

In this study, we further examined the role of Type I and Type II glucocorticoid receptor stimulation on food intake and body weight gain, by the central administration of specific agonists and antagonists. Forty-eight male Sprague-Dawley rats (approx. 175 g) were divided into five groups. Each was implanted with an ICV cannula connected subcutaneously to an osmotic pump containing vehicle. After one week, four of the groups were ADX and the pumps were replaced with pumps containing either ALDO and RU486, RU362 and RU318, RU362 and ALDO, or vehicle (propylene glycol). Each was delivered at a rate of 20 ng/hr. The remaining group was sham-operated and received vehicle. After two weeks, food intake or body weights of the treatment groups were not different from the ADX-vehicle treated group. Replacement pumps, delivering at a rate of 1 ug/hr, were then administered. From the point of the second pump replacement, Type II receptor stimulation, alone or in combination with Type I receptor stimulation, resulted in lower weight gains as compared to the other groups. Food intake was not different between the groups. Differences in food efficiency mirrored differences in body weight gain. Type I receptor stimulation resulted in a restoration of body weight in ADX rats.

GLUCOC- AND MINERALOCORTICOID RECEPTOR MODULATION OF FOOD INTAKE. D.L. Tempel, T. Kim*, S.F. Leibowitz. Rockefeller Univ., N.Y. N.Y. 10021.

Glucocorticoids, which bind to both type I and type II steroid receptors, are involved in the control of food intake. Mineralocorticoids, which only bind to type I receptors, may also play a role in feeding behavior. These experiments studied the impact of adrenalectomy (ADX) and subsequent corticosterone (CORT) and aldosterone (ALDO) administration on food intake in male Sprague-Dawley rats maintained on pure diets of protein (P), carbohydrate (C) and fat (F). Feeding was monitored over the 24 hr period, and during the first 2h of the dark feeding cycle. Results indicate that, in animals eating 20% of each diet over 24hr, ADX decreases total intake by 30-40%, due to a decline in both C (~30%) and F intake (~40%). At dark onset, a strong suppression of C is observed (~93%), accounting for most of the decrease in 24h C intake, whereas, only a small decline (~15%) in F intake, accounting for ~15% of the decrease in daily F intake is evident. C feeding (2h and 24hr) is restored by CORT at doses of 0.25-2.0 mg/kg (s.c.), while F intake (2h and 24h) is stimulated only by higher doses (~2.0mg/kg s.c.). ALDO (0.1mg/kg s.c.), strongly enhances F intake, both in the early dark and also throughout the 24 hr feeding period. ALDO also potentiates C intake at dark onset, but this effect is small relative to ALDO's effects on fat intake. These results are consistent with those found after hypothalamic (PVN) implant of CORT and ALDO, and may indicate a central site of action for these hormones. These data indicate that there may be diurnal variations in CORT's effects on food intake and further suggest that F may be modulated by the type I mineralocorticoid receptor, whereas, C intake, specifically at dark onset, may be dependent upon the type II glucocorticoid receptor or a combination of both type I and type II activity.

196.13

ACTIVATION OF CENTRAL TYPE II ADRENAL STEROID RECEPTORS ENHANCES RATE OF WEIGHT GAIN IN UNDERWEIGHT ADRENALECTOMIZED RATS.

P.K. Green, C.W. Wilkinson, S.C. Woods. Depts. Psych. and Psychiat. and Behav. Sci. Univ. of Washington, Seattle, WA 98195 and VA Med. Ctr., Tacoma, WA 98493

We have previously reported that corticosterone (CORT) acts directly on the central nervous system to modify central regulators of adiposity. Intraventricular (IVT) administration of CORT enhances rate of weight gain in underweight adrenalectomized (ADX) lean rats, and slightly decreases rate of weight gain in sham-ADX rats, and in ADX rats at control body weight. Since it has been reported that there are two types of corticoid receptors with differing affinities for CORT located in the rat CNS, we investigated the receptor type through which CORT acts to increase weight gain. Male Long-Evans rats weighing 280-320g were restricted to half baseline food intake (pelleted chow, 13g/day) for 10 days, and then given ADX or sham-ADX. The next day, animals received a single IVT injection of 100 ng aldosterone (ALDO), dexamethasone (DEX), RU-28362, or synthetic CSF vehicle. Animals were then restored to ad lib chow, and body weight was monitored for six days. IVT-ALDO, a specific type I receptor agonist, slightly suppressed weight gain in underweight ADX rats over the 6 days following treatment (VEH: 28.6 g, ALDO: 23.1 g, n.s.). IVT-DEX, a mixed type I and II receptor agonist, and RU-28362, a specific type II receptor agonist, significantly increased weight gain (VEH: 27.2 g, DEX: 43.7 g, RU: 46.6 g, p < .05). We therefore conclude that CORT acts centrally via type II corticoid receptors to enhance weight gain in underweight lean rats.

196.15

BLOOD GLUCOSE LEVEL AFFECTS INGESTION IN THE GASTROPOD, LIMAX FLAVUS. C.B. Phifer and F.H. Perkins. Louisiana Scholars' College, Northwestern State University, Natchitoches, LA 71497.

Blood nutrient levels affect feeding behavior in mammals and some other vertebrates but the relationship between fluctuations in nutrient levels, particularly glucose, and feeding has proven to be quite complex and resistant to interpretation. Results from a few previous studies have indicated that invertebrate animals, particularly molluscs, might regulate blood glucose levels, but the possible role of blood glucose in ingestive-behavior control has not been investigated. In this study on the terrestrial slug Limax flavus, food deprivation was shown to be associated with decreased blood glucose levels (32.4 ± 2.8 mg/100ml for fed, 7.3 ± 1.3 for 14-day fasted). A probable role for glucose level in ingestion was demonstrated when glucose injections that raised the blood glucose level of fasted slugs to that of free-feeding slugs also inhibited food intake. Control injections of mannitol, a non-metabolizable alcohol sugar, had no effect on intake. Continuing studies may reveal the physiological significance of these results. The accessibility of the gastropod CNS and relative ease of neurophysiological study may make this simple invertebrate preparation a valuable model for experiments on blood glucose regulation and nutritive control of feeding.

196.12

EFFECTS OF TYPE I AND II CORTICOSTERONE RECEPTOR AGONISTS ON VENTROMEDIAL HYPOTHALAMIC LESION-INDUCED OBESITY. T.L. Thomas and L.D. Devenport. Dept. of Psychology, University of Oklahoma, Norman, OK 73019.

Ventromedial hypothalamic (VMH) lesions result in rapid weight gain and obesity. While this syndrome is known to be dependent on corticosterone (Cort) for its full expression, it is not known whether Cort acts via stimulation of type I or II Cort receptors. To test this, female S-D rats received bilateral VMH lesions, followed 2 weeks later by adrenalectomy (ADX), and 1 week later by mini-pump implantation for delivery of various doses of Aldosterone (type I agonist), RU 28362 (type II agonist), or combinations. Weight gains and food intakes were measured throughout. Results replicated previous findings that VMH lesion causes animals to eat more and gain more weight, and that ADX reverses this effect. VMH lesion was found to invert the normal response to both receptor agonists. Therefore, it is type II receptor stimulation that supports the enhanced weight gain following VMH lesion. It does this by a combination of altered metabolic efficiency and increased food intakes.

196.14

"SELF-IMPOSED" INGESTIVE BEHAVIOR STRATEGIES IN RATS: EFFECTS OF CHRONIC CALORIC RESTRICTION ON HORMONES, GROWTH, AND BODY TEMPERATURE. J.K. Nishita, C.E. Serface*, and P.D. Martorano*. Dept. of Psychology, San Jose State Univ., San Jose, CA 95192-0120.

Our previous research has attempted to describe and analyze the "self-imposed" ingestive behavior strategies of female rats during long-term caloric restriction in our novel apparatus. In these studies, we have described changes in ingestion, body weight, hoarding behavior, and stress-related hormones (Nishita et al., 1989, 1990a,b). When housed in our novel apparatus, rats must crawl through a Plexiglass cylinder to obtain daily food and water. We hypothesized that these rats will manifest neuroendocrine changes similar to those produced by other stress-related paradigms. In the present study, the stress effects of the physical restriction produced by two different cylinder sizes (Small (SM) = 3.3 cm, Large (LG) = 4.2 cm, i.d.) were compared in male and female rats.

Both SM and LG rats showed weight loss and decreased linear growth compared to controls housed with No Cylinder (NC). SM male rats showed significantly lower rectal temperatures (36.0°C) than LG (36.4°C) and NC (36.7°C) rats following six weeks of housing in our apparatus. SM female rats (n = 11) showed elevated plasma vasopressin (21.5 pg/ml) compared to LG (7.1 pg/ml) and NC (6.1 pg/ml) littermates. However, plasma osmolality, sodium, and potassium were not significantly different among these groups. Furthermore, adrenal weights and plasma corticosterone levels did not differ among the SM, LG, and NC female rats following 100-120 days of continuous housing.

196.16

SUMMATION OF REWARDING EFFECTS PRODUCED BY HYPOTHALAMIC STIMULATION AND INTRAORAL SUCROSE INFUSION. K.L. Conover & P. Shizgal. Concordia Univ., Montreal, Quebec H3G 1M8.

Competition and summation between the rewarding effects produced by tastants and by electrical stimulation of the lateral hypothalamus (LH) were measured in a preference paradigm. In the competition test, rats with open gastric cannulae were offered a forced, two-alternative choice between a 0.055 ml infusion of 1M sucrose and a train of LH stimulation; the parameters of the sucrose infusion (the "standard") were fixed whereas the frequency of the LH stimulation (the "alternative") was varied across trials. In the summation test, LH stimulation again served as the alternative but the standard was the combination of a sucrose infusion and the equi-preferred frequency of LH stimulation as determined in the competition test. The combination of the LH stimulation and the sucrose infusion acted as a more potent reward than either of its individual components; the frequency of the alternative had to be increased by 26-58% in order to match its value to that of the compound standard. These findings indicate that the rewarding effects of hypothalamic stimulation and sucrose can be evaluated in a common system of units and combined.

196.17

COMPARISONS AMONG THE CALMING AND ANTINOCICEPTIVE EFFECTS OF SUCROSE, GLUCOSE, FRUCTOSE, AND LACTOSE IN INFANT RATS. D.J. Shide¹ and E. M. Blass². ¹Dept. of Psychiatry, Johns Hopkins Univ., Baltimore, MD 21205; ²Depts. of Psychology & Nutrition, Cornell Univ., Ithaca, NY 14853.

These experiments compared the quieting and antinociceptive effects of different sugars. In Exp. 1, individually housed 10-day-old Sprague-Dawley rat pups received 18 BW intraoral infusions of either 0.22, 0.44, or 0.66 M concentrations of sucrose, glucose, fructose, lactose, distilled water, or no infusion. Ultrasonic vocalizations were recorded. In Exp. 2, Day 10 pups received an infusion of 0.22 M sucrose or glucose solution, or 0.44 M fructose or lactose solution, while separated from the mother but group-housed as a litter; paw-lift latencies from a 48° C hot-plate were determined immediately after infusion termination. In both experiments pups were injected with either naltrexone (1.0 mg/kg) or saline 30 min prior to testing to evaluate the contribution of endogenous opioids.

Sucrose and glucose were equally effective calming agents, at all concentrations tested, fructose at the higher concentrations (0.44 & 0.66 M); naltrexone reversed taste-mediated calming at the lowest (0.22M), but not the higher, sugar concentrations. Sucrose, glucose, and fructose elevated pain threshold in a naltrexone-reversible fashion. Lactose, the milk sugar, was ineffective at calming or elevating pain threshold.

196.19

STIMULUS EFFECTS OF OREXIGENIC OPERATIONS: INSULIN, 2-DEOXY-GLUCOSE (2-DG), AND FOOD DEPRIVATION. K.J. Schuh*, D.W. Schaal*, J. Cleary*, T. Thompson* & A.S. Levine. Univ. of MN and VA Med. Ctr., Minneapolis, MN 55455 and 55417.

Three groups of rats (4 rats per group) were trained to discriminate the stimulus effects of insulin (1.0 U/kg) or 2-DG (125.0 mg/kg) from saline, or 2 hrs since feeding from 23 hrs since feeding (i.e., relative food deprivation and food satiation). 15 presses on one lever were reinforced with sweet water following administration of insulin or 2-DG or when relatively food deprived, and 15 presses on the other lever were reinforced after saline or when relatively food satiated. 15 presses on the condition-inappropriate lever resulted in an 8-s period of darkness (time-out). After training, other doses of 2-DG (25.0, 75.0, 175.0 mg/kg) were tested under conditions in which the lever first chosen produced a reinforcer. Rats chose the saline-appropriate lever after saline or 25.0 mg/kg, the 2-DG-appropriate lever after 125.0 and 175.0 mg/kg, and both levers equally after 75.0 mg/kg. Rats trained to discriminate food deprivation were tested after being fed 6 and 14 hrs prior to testing. Rats chose the lever associated with food satiation after 2 and 6 hrs, but chose the opposite lever after 14 and 23 hrs since being fed. Insulin (0.25, 0.5, 1.0 and 1.5 U/kg) was tested in rats trained to discriminate 2-DG. 1.0 and 1.5 U/kg resulted in 2-DG-appropriate responding, although in some rats response rates were greatly suppressed by these doses, making firm conclusions difficult. Lower doses of insulin resulted in saline-appropriate responding. These results indicate that 2-DG, insulin, and food deprivation are discriminable and that their stimulus effects may substitute for one another.

196.21

ATTENUATED BODY WEIGHT RECOVERY IN AGED MALE BUT NOT FEMALE LONG-EVANS RATS Collin R. Park*, Sabine M. von Preyss-Friedman*, Robert S. Schwartz & Stephen C. Woods Program in Physiology/Psychology, and Departments of Medicine and of Psychology, University of Washington, Seattle WA 98195

We have previously found that aged male Long-Evans rats have a decreased rate of weight loss and attenuated weight regain compared to young rats. We now extend this model to aged female rats. Food intake and body weight were determined daily on 18 mo. old female Long-Evans rats. Other measures taken include plasma insulin and glucose, body temperature and general activity.

After a 2-week Baseline period, food was restricted to 70 % of baseline intake given as two meals separated by 6 h. until animals had lost 25 % of their baseline weight. Animals were then allowed ad lib access to food. Control animals had 100% of their baseline food intake available throughout.

Restricted animals averaged 55 days to reach criterion, and 2 weeks to recover, although hyperphagia continued for over 7 weeks (18.9 g vs 25.7 g, p=0.02, within-subjects).

In contrast, aged male Long-Evans rats require over 5 weeks to regain body weight. Our results suggest that abnormalities of body weight regulation are more pronounced in aged male than female Long-Evans rats.

196.18

DUODENAL LIPID INFUSIONS SUPPRESS SHAM INTAKE OF SUCROSE, POLYCOSE, AND A LIQUID DIET. L.A. Foster, K. Nakamura, R. Norgren, D. Greenberg, and G.P. Smith. Dept. Beh. Sci., Col. Med., Penn State Univ., Hershey, PA 17033 and Dept. Psychiatry, New York Hosp.-Cornell Med. Center, White Plains, NY 10065.

A lipid infusion into the duodenum will suppress sham-fed intake of liquid food in rats before significant absorption of the lipid occurs. In this study, a duodenal infusion of lipid decreased intake of a liquid diet, a solution of glucose polymers (Polycose), and a sucrose solution. Rats were fitted with a chronic gastric fistula and a duodenal catheter (n=4 for each diet). After an overnight fast, the rats sham fed either a nutritionally complete liquid diet, a 10% Polycose solution, or a 0.3M sucrose solution for 90 min. Twelve min after the start of the sham feeding session, a duodenal infusion of Intralipid (from a concentration series) or saline was given over a 20 min period. Fluid intake was measured every 5 min throughout the 90 min test period. Although the efficacy varied depending upon the oral stimulus, a duodenal infusion of lipid did suppress sham intake of all 3 solutions during at least 30 min of the test period (p<0.02). These results support earlier observations that food deprived rats treat a sucrose solution in a manner similar to more complex liquid foods. In addition, the data demonstrate that intraduodenal lipids will suppress sham intake of diets that do not contain any fat. HEPATIC ENERGY METABOLISM CORRELATES WITH FEEDING IN RABBITS. L. O'Farrell and D. Novin. Neuroscience Program and Dept. of Psychology, UCLA, Los Angeles, CA 90024.

Slow hepatic portal glucose or fructose infusion (1 ml/min) has previously been shown to decrease subsequent chow intake in rabbits, while fast infusion (3 ml/min) increases it. A possible mechanism for these effects was investigated in the present research by testing whether liver metabolism correlated with feeding.

Rabbits were infused with either fast glucose, slow glucose, fast fructose or slow fructose, which included tracer amounts of U-¹⁴C-glucose or U-¹⁴C fructose, and tritiated water.

Hunger-stimulating infusions caused more uptake of tritium into hepatic lipid than satiety-inducing infusions. Satiety-inducing infusions caused more uptake of monosaccharide into hepatic glycogen and hepatic mitochondria than hunger-stimulating infusions.

The results suggest hunger may be induced by diversion of incoming carbon skeletons away from oxidation and toward lipid synthesis in the liver of rabbits. Satiety may be related to increased hepatic glycogen synthesis.

GALANIN IMMUNOREACTIVE (GAL-I) CELLS WITHIN THE MEDIAL PREOPTIC AREA (MPOA) OF THE RAT: SEX DIFFERENCES AND RESPONSE TO GONADAL STEROIDS. C.B. Eckerseil, R. Mills, B. Padgett and G.J. Bloch. Dep't of Psych., Brigham Young U., Provo, UT, 84602. GAL-I cell bodies and fibers are found in the rat brain, including the MPOA (Melander et al., Eur. J. Pharm. 124, '86; Levin et al., J.C.N. 261, '87). Estrogen (E) concentrating cells contain GAL, E affects GAL-immunoreactivity, and increases GAL mRNA levels (Bloch et al., Neurosci. Abst. 15, '90; Kaplan et al., P. Nat. Acad. Sci. 85, '88; Gabriel et al. Neuro-end. 51, '90). The number and density of GAL-I cells was determined within the sexually dimorphic anteroventral periventricular nucleus and central part of the medial preoptic nucleus (AVPV, MPNc; Simerly et al.; Bloch et al.; J.C.N. 225, 275, '84, '88) in 18-day gonadectomized (Gxd) rats. There were significantly greater numbers of GAL-I cells within the MPNc, and fewer within the AVPV, of the Gxd male than the Gxd female. Estrogen increased GAL-I cell numbers and densities within the AVPV of the male, and the MPNc of rats of both sexes. These findings support data suggesting that GAL within the MPN affects gonadal steroid-sensitive functions (Neurosci. Abst. 16, 17, '90, '91).

ONSET OF THE HORMONE-SENSITIVE PERIOD FOR SEXUAL DIFFERENTIATION IN FEMALE RATS. R.W. Rhees, S. Sephton*, G.J. Bloch, and D.E. Fleming. Depts. of Zoology and Psychology, Brigham Young University, Provo, UT 84602.

Sexual differentiation of many brain structures and functions is dependent on levels of testosterone during the last few days of gestation and the first few days postpartum. If testosterone is present during this perinatal period, masculinization and defeminization of sexual behavior, reproductive physiology, and central nervous system morphology occur. The purpose of the present study was to determine the precise onset of the prenatal component of the period. To avoid complications induced by endogenous testicular activity, only females were used. Free testosterone was used because of its short half-life, so that the effects induced by its administration on a specific day of gestation could be evaluated. Pregnant rats were injected SC with sesame oil or 5 mg testosterone (T) on day 16, 17, 18, 19, 20, 21, or 22 of gestation. Female offspring exposed to T displayed an increase in anogenital distance (16-18), delayed vaginal opening (16-19), abnormal vaginal morphology (16-20), and lower levels of lordotic behavior (18-22). Exposure to T, on any of the prenatal days, however, did not alter their ability to exhibit an LH surge. We conclude that the onset for altered reproductive morphology occurs at least as early as day 16 whereas the onset of sexual behavior sensitivity occurs precisely on day 18 and that the normal pattern of adult LH release is not altered by prenatal androgen treatment using this specific paradigm.

INTRACEREBRAL ADMINISTRATION OF GLUTAMIC ACID DECARBOXYLASE (GAD) ANTISENSE OLIGODEOXYNUCLEOTIDE REDUCES LORDOSIS BEHAVIOR IN THE RAT. M.M. McCarthy, S. Schwartz-Giblin and D.W. Pfaff. Rockefeller University, NY, NY. 10021

Antisense oligodeoxynucleotides to mRNA hybridize and specifically block protein translation in a variety of cell culture systems. GABA in the ventromedial hypothalamus (VMH) and midbrain central gray (MCG) facilitates lordosis, but in the preoptic area (POA) GABA is inhibitory (McCarthy et al., 1990, 1991). We administered a 15-mer antisense oligonucleotide spanning the start codon for the GABA synthetic enzyme, GAD, into the brain of hormonally-induced sexually receptive females. The antisense oligo was either unmodified (ODN) or contained a methyl-phosphonate group (MP-ODN). Controls consisted of oligos containing the same bases in a scrambled order. Female rats were implanted with 23g guide cannulae directed at the POA, VMH or MCG. Injection cannulae (28g) were loaded with crystalline ODN or MP-ODN mixed with cholesterol (1:1 for ODN; 1:10 for MP-ODN) and placed in the brain for 3 days after which they were removed and examined, indicating some inconsistencies in rates of oligo delivery. Nonetheless, either ODN or MP-ODN in the VMH or MCG caused a significant decrease in lordosis at 1, 2 and 3 days post implantation compared to pretest levels. In the VMH, there was also a smaller nonsignificant reduction in lordosis in animals receiving scrambled ODN and MP-ODN. There was no effect on lordosis of ODN or MP-ODN in the POA. In a separate experiment, females were bilaterally infused into the VMH with ODN (500ng) dissolved in oil (0.5µl/side; n=11). There was a significant 50% reduction of lordosis compared to scrambled controls at 1, 2 and 3 days post-infusion with full recovery by 6 days. The precise mechanism of GAD antisense ODN and MP-ODN reduction of lordosis remains unclear but may involve hybridization arrest of GAD mRNA as well as some non-specific disruption of protein synthesis, and is likely to depend on the hormonal milieu.

GALANIN (GAL) MICROINJECTED INTO THE MEDIAL PREOPTIC AREA (MPOA) FACILITATES MALE-TYPICAL COPULATORY BEHAVIOR IN THE FEMALE. J.G. Kohlert, P. Butler, C. Lowry, R. Hammond, D. Schwitters, J. Peterson, S. Kurth, S. Shillingford and G.J. Bloch. Dep't of Psychology, Brigham Young Univ., Provo, UT, 84602.

Since steroid concentrating cells that contain GAL-immunoreactive material have been found in sexually dimorphic regions of the male and female rat MPOA (Bloch et al., Neurosci. 15, '89), and microinjections of GAL into the MPOA of male rats significantly increased measures of male sexual behavior (Butler et al., Neurosci. 16, '90), female and male sexual behaviors were assessed in gonadectomized adult females. There were no significant differences in lordosis and proceptive behaviors in females given 0.3ul microinjections of 0 (vehicle), 10, 50, 100, or 500 ng GAL into the MPOA. However, when given testosterone at a level comparable to that of intact males, 50 and 500 ng GAL microinjections caused an increase in mount frequencies and a significant reduction in mount latencies. General arousal was unaffected by GAL. Coupled with previous findings, these data suggest that GAL affects male-typical copulatory behavior in both males and females. Supported by BYU research funds.

CHRONIC TESTOSTERONE (T) IN FEMINIZED MALE RATS DURING 15-30 DAYS OF AGE: SEX REVERSAL OF BEHAVIORAL FUNCTION IN ADULTHOOD. S.D. GALE, G.J. BLOCH, R.W. RHEES, AND D.E. FLEMING, Psychology and Zoology, Brigham Young U., Provo, UT, 84602.

Lordosis behavior in male rats can be markedly stimulated in adulthood under special circumstances such as after microinjection of CCK into the medial preoptic area [Bloch et al, Physiol. Behav. 46, '89], or after pulse administration of estrogen [Sodersten et al, Endoc. 112, '83; Olster et al, Horm. Behav. 6, '88]. Last year we reported that chronic free T during 15-30 days of age can permanently defeminize endocrine and behavioral function in females [Gale et al, Neurosci. 16, '90]. To extend this finding to the male, 7 mm T capsules or nothing (blank) were implanted into 15-day-old males that had been castrated neonatally, and the capsules were removed 15 days later (30 days of age). T-implanted males showed significantly lower levels of lordosis behavior and proceptive behaviors when compared to blank-implanted males (neonataly castrated controls). Thus, as in the female, chronic androgen during a period well beyond the perinatal time can also permanently defeminize reproductive function in the male.

EFFECTS OF ALPHA-ADRENERGIC AGONISTS AND ANTAGONISTS INFUSED INTO THE MEDIAL PREOPTIC AREA (MPOA) AND MEDIAL BASAL HYPOTHALAMUS (MBH) ON LORDOSIS IN THE GUINEA PIG. K.F. MALIK, J.I. MORRELL, and H.H. FEDER. INST. OF ANIM. BEHAV., RUTGERS UNIVERSITY, NEWARK, NJ 07102.

We sought to characterize central targets mediating alpha-adrenergic modulation of lordosis.

Exp. 1. Ovariectomized (OVX) females were given 10ug estradiol benzoate (EB) subcutaneously and 40hrs later infused via bilateral cannulae with 2ug/0.5ul of the alpha-adrenergic agonist clonidine (CLON) or saline (SAL). CLON infused in the MBH (N=10) transiently (15min to 2.0hr) increased, up to 92%, the time (secs) animals held lordosis (p<.01) compared to SAL (N=8). CLON infused in the MPOA had no effect on lordosis.

Exp. 2. OVX females received 10ug EB, then 40hrs later 500ug progesterone (subcutaneously); 4hrs later the alpha-adrenergic antagonist phentolamine (PHEN; 5ug/0.5ul) or SAL was infused. PHEN in the MBH (N=8) transiently reduced the time that animals held lordosis posture by as much as 64% (1.0 hr) after infusion (p<.01) compared to SAL (N=8). Conversely, PHEN (N=8) in the MPOA increased time in lordotic posture by 74% (1.0hr) after infusion (N=9 SAL; p<.01).

These results suggest that alpha-adrenergic neurotransmission accounts in part for opposing actions of the MPOA and MBH in the regulation of lordosis. (Supported by HD 04467 to HHF and JIM)

α_1 -ADRENERGIC AGONISTS ACT ON VENTROMEDIAL HYPOTHALAMUS TO CAUSE NEURONAL EXCITATION AND LORDOSIS FACILITATION. L.M. Kow, G.D. Weesner, D.W. Pfaff. The Rockefeller University, New York, NY, 10021

To investigate the suggestion that norepinephrine (NE) acts through α_1 -adrenergic receptors (α_1 -) in the brain to facilitate lordosis, we first infused α_1 -agonists, phenylephrine (PhE) or methoxamine (MA) into the lateral ventricle of estrogen-primed female rats. Both PhE (0.2 and 1.0 μ mol/rat) and MA (0.2, 0.5, and 1.0 μ mol/rat) facilitated lordosis in a dose-dependent fashion, while MA at 0.1 μ mol/rat had no effect. Infusion of a β -agonist, isoproterenol (Isop, 0.2 μ mol/rat), was not effective, either. Neural mechanisms potentially underlying the facilitatory effect were then studied. Since the ventromedial hypothalamic nucleus (VMN) is a likely site of action, the effects of PhE and MA, both at 10 μ M, on the electrical activity of single VMN neurons *in vitro* were recorded. MA excited 78% of 65 neurons tested, and never caused inhibition. PhE excited 61% of 64 neurons, but also caused inhibition (9%) and biphasic responses (3%). Although excitations by PhE and MA differed in time courses, both were blocked by α_1 -antagonist, prazosine (PZ, 0.5 μ M), and also by chloroethylclonidine (CEC, 100 μ M), an α_1 -antagonist.

To see if the excitatory action on VMN neurons was responsible for the facilitation of lordosis, PhE or MA was infused bilaterally into the VMN of ovariectomized rats. At 2 or 4 nmol/site, both PhE and MA facilitated lordosis in estrogen-treated, but not in untreated rats. Infusion of MA outside the VMN, or infusion of Isop or an α_2 -AR agonist, clonidine, at doses similar to or higher than those of MA had no effect. The facilitatory effect of MA was abolished or attenuated by a preceding infusion of PZ or CEC (both 2 nmol/site), respectively. Thus, our combined electrophysiological and behavioral investigations indicate that, NE can facilitate lordosis by increasing the activity of VMN neurons, and that the effect is mediated largely through α_1 -receptors, known to be coupled to the hydrolysis of phosphoinositides.

SERUM 1,25 DIHYDROXYVITAMIN D₃ (SOLTRIOI) LEVELS INFLUENCE SEROTONIN LEVELS IN THE HYPOTHALAMUS OF THE RAT T.H. Privette, W.E. Stumpf¹, R.A. Mueller^{2*} and B.W. Hollis^{3*} Dept Anatomy and Cell Biology, East Carolina University School of Medicine, Greenville, NC, ¹Dept of Cell Biology and Anatomy, ²Dept of Anesthesiology, UNC School of Medicine, Chapel Hill, NC, ³Dept of Pediatrics, USC School of Medicine, Charleston, SC.

Vitamin D precursor is synthesized in the skin, dependent on ultraviolet wavelengths of electromagnetic radiation from the sun. Due to the dependence of vitamin D synthesis on sunlight and to the strategic localization of its receptors, vitamin D has been suggested as a transducer of the seasons. Receptors for the steroid hormone 1,25 dihydroxyvitamin D₃ have been demonstrated in various brain nuclei including the midbrain raphe nucleus suggesting a potential influence on synthesis of serotonin. Serotonin levels in post mortem human hypothalamus are higher in the fall and lower in the spring (Acta Psychiatr Scand 61: [supp 280] 75-85, 1980) which is also reflective of the serum levels of vitamin D during these seasons. We studied rat hypothalamus following treatment with high, normal or low calcium diet which is known to produce low, normal or high serum levels of vitamin D, respectively (Endocrinology 121:278-283, 1987). Neurochemical analysis revealed enhanced levels of serotonin in the group with high serum vitamin D levels and attenuated levels of serotonin in the group with low serum vitamin D levels compared to the control group. A metabolic by-product of serotonin (5-HIAA) did not vary among groups suggesting an influence by vitamin D on synthesis but not release of serotonin. These findings suggest Vitamin D may influence serotonin synthesis in neurons of the raphe nucleus, which results in an enhanced storage of the transmitter in raphe nucleus terminal fields in the hypothalamus, and provides further support for vitamin D as a seasonal neuroendocrine regulator.

197.11

EFFECTS OF ANTERIOR ROOF DEAFFERENTATION ON ULTRASOUND PRODUCTION AND LORDOSIS IN FEMALE HAMSTERS. Q.R. Floody. Dept. of Psychology, Bucknell Univ., Lewisburg, PA 17837.

Studies of the mechanisms controlling female-typical mating behavior have focused on the ventromedial hypothalamus (VMN), reflecting, in part, the extent and reliability of the decrements in lordosis caused by VMN lesions (Pfaff & Sakuma, *J. Physiol.*, 288, 203, 1979). However, opposed changes of comparable size are produced by horizontal cuts projecting forward from the anterior commissure (anterior roof deafferentation, or ARD; Yamanouchi, *Physiol. Behav.*, 25, 721, 1980). These data suggest the existence, at least in the female rat, of a lordosis-inhibiting system of forebrain structures, possibly including the preoptic area and lateral septum.

To assess the generality of this system, each of 17 ovariectomized hamsters was subjected to either control surgery or ARD. Both before and after this treatment, females were primed with estradiol benzoate (1.0-10.0 μ g/100g) and progesterone (500 μ g) prior to tests of ultrasound production and lordosis. Specifically, ultrasound rates were observed before and after exposure to stimulus males. Tests of lordosis also included measures of responsiveness to males, but focused on the extent to which females already emerging from lordosis could be returned to this posture (lordosis reinstatement) by light manual stimulation along the dorsal midline.

Consistent with previous observations (Kim & Floody, *Behav. Neurosci.*, 99, 1142, 1985), the results documented a clear facilitation of ultrasound rates by ARD. In contrast, the same treatment had no consistent impact on the duration of male-elicited lordosis. In part, this probably reflects contamination by variability across males, since ARD did facilitate lordosis reinstatement responses to manual stimuli. Nevertheless, these changes in lordosis seem less dramatic than those produced by ARD in female rats. Accordingly, these data suggest species differences in the dependence of lordosis on forebrain lordosis-inhibitory mechanisms.

197.8

GABAERGIC-SEROTONERGIC INTERACTIONS IN REGULATING LORDOSIS. Victoria Luine and Maya Frankfurt. Hunter College and Rockefeller University, New York, N.Y. 10021.

We investigated interactions between hypothalamic GABA and 5HT in regulating lordosis. OVX rats, primed with 5 μ g of EB and 500 μ g of progesterone (P), were given Baclofen, a GABA B agonist, and lordosis was tested 3 h. later. Baclofen inhibited lordosis quotients (LQ) and quality scores in a dose-dependent manner (2.5 to 10 mg/kg). To assess possible GABA-5HT interactions, intra-hypothalamic 5,7-DHT was given to deplete 5HT. In these rats, Baclofen, 7.5 or 10 mg/kg, significantly reduced LQs to approximately 60. In unlesioned rats, Baclofen reduced LQs to 26 (7.5 mg/kg) and 0 (10 mg/kg), suggesting that part of Baclofen's inhibitory effect may be mediated through interactions with 5HT terminals in the preoptic-hypothalamic area. Baclofen effects on activity of 5HT and NE containing terminals in the medial preoptic nucleus (mPOA), ventromedial nucleus (VMN) and midbrain central gray (MCG) were evaluated with Pargyline using HPLC with EC detection for measurements. 3 h. post Baclofen administration to EB + P primed rats, 5HT levels increased 54% in the mPOA; 5HT turnover decreased 3-fold in the mPOA, was totally inhibited in the VMN, and increased sixfold in the MCG. NE turnover was unaffected in the VMN but increased tenfold in the mPOA. These results indicate that effects of GABA on lordotic behavior may involve an interaction of this transmitter with 5HT. (Grant HD12011).

197.10

EFFECTS OF NONCOMPETITIVE NMDA RECEPTOR ANTAGONISTS ON LORDOSIS AND MOTOR BEHAVIORS IN FEMALE RATS. A.Fleischmann, P.A.Vincent and A.M.Etgen. Depts. Psychiatry & Neuroscience, Albert Einstein Coll. Med., Bronx, NY 10461.

MK-801 and dextrorphan, selective noncompetitive antagonists at NMDA receptors, were used to evaluate the effect of NMDA receptor blockade on sexual and motor behaviors in female rats. Ovariectomized rats were treated with estradiol benzoate (EB) plus progesterone (P) and were tested for sexual and motor behaviors 4 hr after P. Sexual behavior was inhibited in animals that received 0.5 mg/kg MK-801 30 min before EB, but not if the MK-801 injection was delayed until 24 hr after EB. Moderate doses of MK-801 (≥ 0.05 mg/kg) and 30 mg/kg dextrorphan also inhibited lordosis when injected 30 min before behavior testing. However, when 30 mg/kg dextrorphan was administered 30 min before P, sexual behavior was not affected. Thus NMDA receptor blockade can interfere both with the estrogen priming process and with the performance of lordosis behavior.

The effect of MK-801 administered after EB+P on motor behaviors was also assessed. Drug doses that inhibited sexual behavior also antagonized "vertical" motor behaviors such as rearing and jumping. In contrast, low doses of the drug increased general locomotion and circling behaviors. Only very high doses (0.4 mg/kg) inhibited lateral movement and righting reflexes. These data indicate that different features of movement are affected differentially by NMDA receptor antagonism. Supported by MH41414 and RSDA MH00636 to AME.

197.12

SELECTIVE MU OPIOID RECEPTOR AGONISTS INHIBIT WHEREAS DELTA AND KAPPA RECEPTOR AGONISTS FACILITATE LORDOSIS BEHAVIOR IN THE FEMALE RAT: DIFFERENTIAL MODULATION BY PROGESTERONE. J.G. Pfau and D.W. Pfaff. The Rockefeller University, New York, NY, 10021.

Previous studies indicate that selective opioid receptor agonists infused into the lateral ventricles can inhibit (μ) or facilitate (δ) lordosis behavior in ovariectomized (OVX) rats treated with estrogen and a low dose of progesterone. Both effects are reversible with naloxone. The present study investigated whether these effects depend upon the presence of progesterone. Sexually experienced OVX rats were implanted stereotaxically with guide cannulae aimed at the right lateral ventricle. One group of rats was treated with estradiol benzoate (EB; 10 μ g) 48 h and progesterone (P; 250 μ g) 4 h before testing, whereas the other was treated with EB alone. Rats were infused with different doses of the selective μ receptor agonist D-Ala²,MePhe⁴,Gly⁵-enkephalin (DAMGO), the selective δ agonist D-Pen²,D-Pen⁵-enkephalin (DPDPE), or the selective κ receptor agonist U50-488H. The females were placed with a sexually vigorous male in a bilveel chamber for three tests of sexual behavior, beginning 15, 30, and 60 min after infusion. DAMGO reduced lordosis quotients and magnitudes significantly in rats treated with EB and P, but not in rats treated with EB alone. In contrast, DPDPE and U50-488H increased lordosis quotients and magnitudes significantly in both steroid-treatment groups. Measures of proceptivity, rejection responses, and locomotor activity were not affected significantly by any drug treatment. These results suggest that the facilitation of lordosis behavior by δ and κ receptor agonists is independent of progesterone treatment, whereas the inhibitory effect of the μ receptor agonist requires the presence of progesterone. The site(s) of action of these drugs are currently being investigated.

197.13

BEHAVIORAL RESPONSES AS A FUNCTION OF ESTRUS CYCLE IN WKY RATS. W.P. Paré and E. Redei, VA Medical Center, Perry Point, MD 21902 and U. Pennsylvania, Philadelphia, PA 19104

Previous animal studies attempting to demonstrate gender differences in response to stress have been equivocal. The inability to demonstrate an effect may be attributable to the fact that these studies did not control for genetic and estrus cycle differences. The Wistar Kyoto (WKY) normotensive rat strain is hyperresponsive to stressor stimulation (Physiol. Behav., 46, 993, 1989). WKY, as well as Wistar and Fischer-344 female rats were exposed to the ulcerogenic procedure of water plus restraint. WKY rats revealed significantly more stomach ulcers as compared to Wistar and Fischer-344 rats. In addition stress ulcer incidence was significantly greater in WKY rats during proestrus as compared to anestrus and diestrus. Thus ulcer severity was a function of the strain and estrus cycle factors. In a subsequent study, proestrus female WKY rats were judged as more emotional in the open field test of emotionality as compared to anestrus and diestrus rats. The same animals were also observed in the Porsolt forced-swimming test of depression where WKY proestrus females were judged as more behaviorally depressed. These studies suggest that the steroid hormone milieu may be responsible for these behavioral changes and that these effects can be demonstrated in a stress-susceptible strain.

197.15

EFFECTS OF SCOPOLAMINE ON SEXUAL BEHAVIORS OF FEMALE RATS. S. M. Ross*, C. S. Menard, M. M. Brazier*, and G. P. Dohanich, Dept. of Psychology and Neuroscience Program, Tulane University, and Dept. of Psychology, Loyola University, New Orleans, LA 70118.

The muscarinic antagonist, scopolamine, reliably inhibits lordosis in female rats under a variety of conditions. However, the effects of scopolamine, as well as other cholinergic agents, on other components of sexual behavior exhibited by female rats have not been reported. In the present experiments, the effects of scopolamine on lordosis, solicitation, pacing, and locomotion were evaluated in female rats. To activate sexual receptivity, ovariectomized Long-Evans rats were injected with estradiol benzoate (EB, 1 µg/kg, i. m.) at 72, 48, and 24 hours before behavioral testing. Progesterone (500 µg, i. m.) was injected at 5 hours before testing. Behaviors were tested in a partitioned arena that allowed females to escape the stimulus male by exiting into a neutral compartment. Under this condition, females were able to determine or pace their contacts with the male. Females injected with scopolamine (1 mg) displayed a reduced incidence of lordosis (LQ = 28) and solicitation (SQ = 6) compared to females treated with saline vehicle (LQ = 94, SQ = 43, $p < .01$). Although females treated with saline spent significantly more time in the neutral compartment than in the male compartment ($p < .01$), females treated with scopolamine divided time equally between the compartments. While females treated with scopolamine did not display typical pacing behavior they did not avoid contact with the male. In addition, locomotor activity generally was reduced following treatment with scopolamine. Females treated with saline or scopolamine received equal numbers of sexual contacts, although females treated with scopolamine received significantly fewer intromissions and ejaculations and significantly more mounts without intromissions ($p < .01$). On almost all measures, the behaviors of females treated with scopolamine were similar to behaviors exhibited by nonreceptive ovariectomized rats that had received no hormone treatment. The results indicate that the muscarinic antagonist, scopolamine, disrupted various components of sexual receptivity including lordosis, solicitation, and pacing. However, scopolamine did not appear to reduce female attractiveness nor cause females to avoid a stimulus male.

197.17

EFFECTS OF DIABETES MELLITUS ON ESTROUS CYCLICITY AND COPULATORY BEHAVIOR IN FEMALE SYRIAN HAMSTERS. H. Y. Li and G. N. Wade, Neuroscience and Behavior Program and Psychology Department, University of Massachusetts, Amherst, MA, 01003

Food deprivation inhibits ovulation and estrous behavior in Syrian hamsters (*Mesocricetus auratus*). In diabetic hamsters, utilization of metabolic fuels, particularly carbohydrates, is greatly impaired. Diabetes mellitus was induced in female hamsters by intraperitoneal injections of 60 mg/kg streptozotocin for 3 successive days which led to decreases in body weight, glycosuria, and irregular estrous cycles. Furthermore, diabetic hamsters which stopped estrous cycles showed decreased response of lordosis behavior to exogenous estradiol benzoate (5 µg) and progesterone (200 µg) when tested with male hamsters. It was also demonstrated that daily injections of 10 U of U-100 Lente insulin were sufficient to restore estrous cycles, increase body weight, and prevent glycosuria. Withdrawal insulin treatment on specific days of the estrous cycle reduced the number of corpora lutea compared with hamsters that were given continuous insulin treatment.

197.14

EFFECTS OF SYSTEMIC AND CENTRAL PROLACTIN INJECTION ON FOOD INTAKE, WEIGHT GAIN AND ESTROUS CYCLICITY IN FEMALE RATS. Miriam Beth Noel and Barbara Woodside*, Department of Psychology, Concordia University, Montreal, Quebec, Canada.

Previous research has suggested that prolactin may contribute to the hyperphagia of lactation (Gerardo-Gettens, Moore, Stern and Horwitz, 1989). In the current study the effects of peripheral and central prolactin administration on food intake, weight gain and estrous cyclicity in female rats were compared. Prolactin was administered twice daily at 0800hr and at 1900hr either subcutaneously at 3mg/kg or 1mg/kg body weight or by intracerebral ventricular (icv) infusion (2µg/0.5µl) for 10 days to female wistar rats. Control animals received similar injections of vehicle. Food intake, body weight and vaginal smears were taken daily. Results showed that peripheral administration of prolactin increased food intake and weight gain and disrupted vaginal cyclicity. In contrast, icv administration of prolactin increased food intake but had no effect on weight gain or cyclicity. These data suggest that prolactin acts both peripherally and centrally to regulate energy balance in the female rat.

197.16

SIGNALS GENERATED IN CNS GLUCOSE METABOLISM AFFECT ESTROUS CYCLES IN SYRIAN HAMSTERS. J. E. Schneider*, A. J. Hall*, D. G. Friedenson*, M. H. Brown and G. N. Wade, Neuroscience and Behavior Program, Department of Psychology, University of Massachusetts, Amherst, MA 01003.

Estrous cycles are inhibited by signals generated when there is a decrease in oxidation of metabolic fuels. We examined the relative importance of peripheral versus central metabolic signals. Food deprivation-induced anestrus was prevented by feeding hamsters either of the peripherally oxidized substrates, shortening or fructose, or by prefattening hamsters prior to food deprivation. These results might suggest a role for peripheral metabolic signals. However, food deprivation-induced anestrus was not prevented by any of these manipulations when the hamsters were treated with 2-deoxy-d-glucose (2DG), a general inhibitor of glucose utilization. Thus, fuels oxidized peripherally may prevent anestrus by sparing glucose for the central nervous system. Estrous cycles were interrupted in *ad libitum*-fed hamsters treated with inhibitors of glucose metabolism (2DG) and fatty acid oxidation (methyl palmitate) when the drugs were given concurrently, but not separately. The results of the food and drug manipulations were the same whether the hamsters had received bilateral sub-diaphragmatic vagotomies or sham surgeries. Thus, vagally-mediated information about peripheral fuel availability is not critical for the effects of decreased metabolic fuels on estrous cycles. (Supported by NS10873, AM32976 from NIH, and BNS8719361 from NSF.)

CENTRAL AND PERIPHERAL EFFECTS OF RU486 ON AGONISTIC RESPONDING AND PLASMA HORMONE LEVELS IN HAMSTERS. D.M. Hayden-Hixson¹ and C.F. Ferris², ¹Dept. of Psychiat., Duke Univ. Med. Ctr., Durham, NC 27710; ²Dept. of Physiol., Univ. Mass. Med. Ctr., Worcester, MA 01655.

The agonistic behaviors of male golden hamsters (N=48 dyads) treated with the glucocorticoid antagonist, RU486, were examined 5min after acute microinjection (100nl) in the anterior hypothalamic area (AHA) and paraventricular nucleus (PVN), or 15, 30, and 45min after subcutaneous (sc) injections (210µg). RU486-treated animals were tested for aggressive/submissive responding in a neutral arena pairings with vehicle-treated (AHA or PVN) or cholesterol-treated (sc) opponents. Two hours after treatment, trunk bloods were collected and assayed for cortisol, ACTH, and testosterone.

Agonistic responding was not affected by any of the RU486 treatments. Males receiving PVN injections of RU486 had significantly elevated circulating ACTH levels compared to sc or AHA injections. ACTH levels were also significantly higher in males receiving 10⁻⁶M RU486 injections than 10⁻⁴M or 10⁻²M injections in AHA. These results suggest RU486 has pronounced, differential effects on adenyhypophysal function when administered in AHA, PVN or sc, but no effect on aggressive/submissive behavior. (Work supported by NIH grant #NS23557).

SCOPOLAMINE INHIBITION OF LORDOSIS: EFFECTS OF VARIABLE DOSES AND REPEATED ADMINISTRATIONS OF ESTROGEN. C. S. Menard, T. J. Hebert, and G. P. Dohanich, Dept. of Psychology and Neuroscience Program, Tulane University, New Orleans, LA 70118.

Previous evidence indicates that the muscarinic antagonist, scopolamine, inhibits lordosis in female rats. In the first experiment, the effects of various doses and repeated administrations of estrogen on the scopolamine inhibition of lordosis were examined. Ovariectomized rats were injected for 3 days with estradiol benzoate (EB, i.m., .25, .5, or 25 µg) followed by progesterone (500 µg, i.m.) 5 hrs before behavior testing on day 4. Lordosis was inhibited 15 min after scopolamine injection (1 mg, i.p.) in females primed with all doses of EB ($p < .01$). However, scopolamine inhibition after priming with .25 or .5 µg EB was greater than inhibition after priming with 25 µg EB ($p < .01$). When hormone priming was repeated on a second week, scopolamine continued to inhibit lordosis in females that received .25 µg EB but was less effective in females primed with .5 µg EB. Scopolamine failed to inhibit lordosis in females treated with 25 µg EB ($p < .01$). Consequently, the inhibitory effect of scopolamine on lordosis was dependent both on the dose and number of EB treatments. To examine if this estrogen-dependent reduction in scopolamine inhibition could be counteracted, various doses of scopolamine (1, 2, 4 mg, i.p.) were administered to females primed with the highest dose of EB (25 µg) and progesterone (500 µg). Lordosis was inhibited equally 15 min after all scopolamine doses during the first week. As in the first experiment, scopolamine failed to inhibit lordosis at all doses during the second week of testing in females primed with 25 µg EB. In addition, lordosis was not inhibited in females that received saline on the first week and the highest dose of scopolamine (4 mg) on the second week. Therefore, the failure to inhibit lordosis on the second week was not due to repeated exposure to scopolamine, but rather to repeated exposure to a high dose of EB. Data indicate that the ability of scopolamine to inhibit lordosis can be reduced by increasing the dose or the number of estrogen exposures. Because higher doses of scopolamine failed to restore its inhibitory effect on lordosis it is unlikely that repeated exposure to estrogen induces an upregulation of muscarinic receptors.

FOOD DEPRIVATION SUPPRESSES STEROID-INDUCED ESTROUS BEHAVIOR IN OVARIECTOMIZED SYRIAN HAMSTERS.

R. W. Dickerman, H. Y. Li, and G. N. Wade, Neuroscience and Behavior Prog. and Dept. of Psychology, University of Massachusetts, Amherst, MA 01003.

Hamsters fail to ovulate or show estrous behavior when access to metabolic fuels is limited by food deprivation (FD). Plasma estradiol (E_2) concentrations are depressed by FD, but lack of estrous behavior may also be due to decreased neural responsiveness to E_2 . The hypothesis that FD decreases neural responsiveness was tested by measuring lordosis duration in steroid-primed ovariectomized hamsters following FD. FD or fed hamsters were injected with E_2 -benzoate (5µg) at -48 hours and progesterone (200µg) at -4 hours. At time=0, time spent in lordosis out of 5 min. in the presence of a male was recorded. There were two FD regimens with food withdrawn for 48 hours starting at either -96 hours or -48 hours. Both treatments reduced lordosis time. When FD and E_2 were coincidental lordosis was shown for 70 ± 24 sec. vs. 202 ± 30 sec. in fed controls. When FD preceded E_2 treatment lordosis was shown for 159 ± 21 sec. vs. 212 ± 14 sec. in fed controls. Reduction in lordosis time was greater when FD and E_2 treatment were coincidental compared to when FD preceded E_2 treatment. FD animals lost 19.6 ± 1.0 grams which was 18.6% of pretreatment body weight. Previous work has suggested that FD affects metabolism of exogenous E_2 . However, plasma E_2 concentrations were not different between FD and fed animals in either treatment regimen at time=0. These data show that FD decreases induction of estrous behavior by exogenous steroids in hamsters. Supported by NS10873, DK32976 and MH00321.

P-3-BSA IMPLANTS IN THE VTA RAPIDLY FACILITATE RECEPTIVITY IN HAMSTERS AFTER PROGESTERONE PRIMING TO THE VMH. C. A. Frye and J. F. DeBold, Psychology Dept., Tufts Univ., Medford, MA 02155.

Recent evidence suggests progesterone (P) may have behaviorally relevant actions on neuronal membranes in the ventral tegmental area (VTA). When progesterone conjugated to BSA (P-3-BSA), which cannot permeate the cell membrane, is applied to the VTA concurrent with normal P to the VMH, estrogen-primed hamsters are maximally receptive after 2 1/2 hours. As the reverse treatment is ineffective, this suggests non-genomic effects in the VTA may require concurrent genomic activation by P in the hypothalamus.

In the present experiment we exploited the different time courses necessary for genomic and non-genomic actions of steroid hormones. We assessed whether estrogen-primed hamsters would be immediately receptive after P-3-BSA applied to the VTA, when P had been aimed at the VMH 2 hours earlier. Ovariectomized hamsters were implanted with chronic cannulae, one aimed above the VMH and the other over the contralateral VTA. These animals were later estrogen-primed and tested for sexual receptivity two hours after P or P-3-BSA containing tubes were applied above the MBH. Immediately after this pretest, the opposite hormone containing insert was applied over the VTA. The following week the contents of the tubes were reversed. Facilitation of receptivity only occurred when P was applied to the VMH and 2 hours later P-3-BSA was inserted into the VTA. The reverse treatment was not effective. These data demonstrate that the action of progesterone in the VMH takes 1-2 hours but in the VTA the effect of a progestin occur in 5 minutes. These time courses are consistent with a genomic action in the VMH and a non-genomic action in the VTA.

ACTIVATION OF THE ACCESSORY OLFACTORY SYSTEM IN THE FEMALE RAT BY EXPOSURE TO MALE-SOILED BEDDING AND REPEATED MATINGS. C. A. Dudley, G. Rajendren*, and R. L. Moss, Dept. of Physiology, Univ. of Texas Southwestern Med. Ctr., Dallas, TX 752355

The activity of the accessory olfactory system in ovariectomized female rats was examined by c-fos immunohistochemistry after estrogen administration (EB; 5µg), EB administration followed 48 h later by exposure to male-soiled bedding, and EB administration followed 48 h later by several copulatory episodes with male rats. Animals were sacrificed and perfused immediately after treatment was complete. Vibratome sections (40µ) through the accessory olfactory bulb (AOB), medial amygdala (mAMYG) and ventromedial hypothalamus (VMH) were processed immunohistochemically using the ABC technique with DAB as the chromagen. EB administration alone was not sufficient to induce appreciable amounts of c-fos activity in any area examined. EB administration combined with exposure for 1 or 2 hr, but not 10 or 30 min, to bedding soaked with male urine was effective in inducing intense c-fos activation in the mitral and granular cell layers of the AOB. Staining in the mAMYG was less intense and was scattered in the baso and medial portions of the nucleus. A circular pattern of c-fos activity was noted in the VMH. When EB-primed females were mated four times for 15 min each with 15 min intervals separating the tests, very intense c-fos activity was observed in the granular cell layer of the AOB, in the mAMYG close to the optic tract, and in a circular area in the lateral portion of the VMH. The results indicate discrete activation of the accessory olfactory system by sexually relevant stimuli. Supported by MH41784.

EFFECTS OF 6-OHDA LESIONS AND DRUG CHALLENGE ON EXTRAPYRAMIDAL- VERSUS TARDIVE DYSKINESIA-LIKE EFFECTS IN RATS. S. K. Johnson, H. Fisher* and G. C. Wagner, Depts. of Psychology and Nutritional Sciences, Rutgers University, New Brunswick, N.J. 08903

Age is a strong predictor of both extrapyramidal side-effects and tardive dyskinesia associated with neuroleptic administration. This susceptibility in the aged may be due to the loss of dopaminergic cells. The present study used 6-OHDA to create 35% lesions of striatal dopamine and then assessed rats for haloperidol-induced catalepsy and chewing behavior. Lesioned animals were significantly more sensitive to haloperidol-induced catalepsy than sham-lesioned animals, but chewing behavior was not significantly different between the two groups. Rats were also administered drug challenges of D1 and D2 agonists, serotonergic and cholinergic agonists and antagonists at the beginning and end of chronic haloperidol (2 mg/kg) treatment as well as after withdrawal from haloperidol. It was observed that serotonergic agents had opposing effects on catalepsy versus chewing, while cholinergic agents acted in the same manner on both catalepsy and chewing bouts.

198.2

URIDINE AND STIMULANT-INDUCED ACTIVITY. C. S. Myers*, M. Napolitano*, H. Fisher*, and G. C. Wagner, Depts. of Psychology and Nutritional Sciences, Rutgers University New Brunswick, NJ 08903

Chronic administration of uridine has been shown to alter both dopaminergic activity and dopaminergic-mediated behavior. The present studies further investigated this effect using amphetamine (AMPH) and cocaine (COC)-induced activity and rotation in rats with unilateral dopaminergic lesions.

10 adult, female, individually housed Sprague-Dawley rats with free access to food and water received daily IP uridine (16 mg/kg) and 10 received an equal volume of saline. Activity was assessed for 10 min in a photocell chamber 30-min after IP AMPH or COC (0.5 - 4.0 mg/kg). 20 otherwise comparably treated rats had unilateral dopaminergic lesions and were assessed for stimulant-induced rotation.

Uridine exerted no effect on body weight, activity, or rotation under baseline conditions. AMPH and COC increased activity at low doses and decreased activity at higher doses and caused a dose-dependent increase in the number of rotations. For both tests, uridine-treated rats exhibited a significant increase in their sensitivity to AMPH but not COC indicating that uridine may differentially affect cytoplasmic versus vesicular release of dopamine.

QUANTIFYING OPERANT BEHAVIOR DEFICITS IN RATS WITH MODEST BILATERAL 6-HYDROXYDOPAMINE LESIONS OF THE VENTROLATERAL STRIATUM. R.-M. Liao, S.C. Fowler, & M.J. Kallman; Dept. of Psychology, Ntal. Cheng-Chi Univ., Taiwan, ROC., & Dept. of Psychology and Pharmacology, Univ. of Mississippi, MS., USA.

Rats (N=6) with bilateral 6-OHDA lesions (6 ug/1 ul/site) to the ventrolateral striatum (AP=0.9mm, L=+3.7mm, D=-5.7mm; referred to bregma) were compared to a vehicle-treated group (N=6) using specially modified operant chambers, which allowed measurement of successive behaviors occurring within a cycle of the operant/licking complex. Determined by HPLC analyses, the lesioned group exhibited dopamine levels that were 35 % of the control group. During the first postoperative week, the lesioned rats exhibited increased forelimb response duration (p=0.06). The frequencies of head-entry into the reward well and licking of the reward significantly dropped in the lesioned rats (p<0.05). Furthermore, the lesioned rats significantly increased the latencies required to switch from one motor response to another (p<0.05). These results suggest the important role of the ventrolateral striatum in the control of behavioral sequences.

198.5

THE EFFECTS OF SELECTIVE PREFRONTAL DOPAMINE (DA) LESIONS ON COGNITIVE TESTS OF FRONTAL FUNCTION IN PRIMATES. A.C. Roberts, M.A. de Salvia*, J.L. Muir, L.S. Wilkinson*, B.J. Everitt, and T.W. Robbins. Departments of Experimental Psychology and Anatomy*, University of Cambridge, Cambridge, CB2 3EB, U.K.

Degeneration of the mesocortical DA pathway which occurs in Parkinson's disease (PD) may contribute to the frontal-like cognitive impairments associated with this disorder. The present study therefore examined in marmosets the effects of selective prefrontal DA lesions on a series of behavioral tests sensitive to frontal lobe damage. These included attentional set-shifting, serial discrimination reversal learning and object retrieval (a detour problem using a transparent barrier), tests all requiring behavioral inhibition but at different levels of psychological control of responding. Injection of 6-hydroxydopamine into the prefrontal cortex of monkeys, pretreated with specific noradrenaline (NA) and serotonin (5-HT) uptake blockers, resulted in selective DA depletion (90% loss of DA, < 50% loss of NA, < 10% loss of 5-HT). The lesion impaired both serial reversal learning and object retrieval but improved performance of individual animals on the attentional set-shifting task. These results will be compared to the behavioral pattern of changes on the same series of tests seen following lesions of the frontal cholinergic system and in patients suffering from PD.

ELECTRICAL SELF-STIMULATION OF RAT MEDIAL FOREBRAIN BUNDLE INCREASES BOTH ENDOGENOUS DOPAMINE AND PULSE LABELED [³H]-DOPA STRIATAL METABOLISM

W.P. Melega, J.R. Barrio*, M.F. Phelps, R.F. Ackermann Division of Nuclear Medicine and Biophysics, UCLA School of Medicine, Los Angeles, CA 90024

Changes in homovanillic acid (HVA) and 3,4-dihydroxyphenylacetic acid (DOPAC) / dopamine (DA) concentration ratios subsequent to electrical stimulation are generally accepted as evidence for increases in dopamine turnover. Our rat self-stimulation/reinforcement model effected parallel changes in [³H]-DA and endogenous DA metabolism, indicative of increased turnover of both amines. The combination of procedures comprised: a) an awake, freely moving animal b) active driving of an operant/reward pathway via electrical stimulation of the substantia nigra and ventral tegmental area and c) labeled and endogenous DA metabolite analyses. Increases in DA and [³H]DA turnover were observed (n=6), primarily in either caudate-putamen (CP) or nucleus accumbens (NA)/olfactory tubercle (OT). Ipsilateral increases (40-60%) in both labeled and endogenous DOPAC/DA and HVA/DA ratios and stimulated/non-stimulated regional DOPAC and HVA ratios were detected.

These experiments demonstrate for the first time that, in vivo, [³H]-DOPA probes the functional state of an activated dopaminergic system. Such changes in DA metabolism suggest fundamental alterations in DA metabolism regulation consequent to increased availability of amino acid precursors, and/or to activation of aromatic amino acid decarboxylase, rather than mere increases in steady state DA function.

SHOCK-ELICITED BEHAVIORAL DIFFERENCES IN RAT MODELS OF RISK FACTORS CONTRIBUTING TO CHRONIC ABERRANT BEHAVIOR. C.J. Stodgall, S.R. Schroeder* and B.E. Tessel Dept. of Pharmacol. and Toxicol., Univ. of Kansas, Lawrence, KS 66045.

Spontaneously Hypertensive rat pups (SHR), and 3 groups of Sprague-Dawley (SD) rat pups [controls, microcephalic rat offspring generated by IP injection of methylazoxymethanol (MAM) to pregnant dams, and rat pups neonatally depleted of brain dopamine by intracranial injection of 6-hydroxydopamine (6HD)] remained with their mothers until weaning. Animals of each group were then housed 3/cage (Group Housed; GH) or 1/cage (Socially Isolated; SI) for at least 30 days until exposed to a scrambled electric foot shock (six 1.6 mA, 150 msec shocks/2 sec every 10 sec) for 1 hr, and the behaviors occurring during the hr period were recorded on video tape. The frequencies with which various behaviors occurred during selected 1-min observation periods were then scored. The behaviors and group differences observed were as follows (">" = p<0.05; "<" and "=" = p>0.05; lack of housing designation indicates absence of difference based on housing condition): Locomotor activity (MAM>SD>SHR=6HD); Maintained Rearing (a stereotypy; MAM>SD>6HD>SHR); Cage Biting (aggression; SHR>SI>SHR>GH>SD>SI>SD>GH>MAM=6HD). No self-injurious behavior was observed. Surprisingly, the 6HD groups but no other groups rapidly learned to avoid the scrambled shocks. These data suggest that genetic, organic and environmental risk factors alone and in combination can markedly and predictably determine the types of behavior elicited by stress in rats, and suggest that respondent mechanisms may importantly contribute to the chronic incidence of some aberrant behaviors in man. (Supported by NICHHD grant 1 PO1 HD28927)

BEHAVIORAL DEFICITS CAUSED BY STRESSORS AND LATERALIZED CHANGES IN THE MESOCORTICAL DOPAMINE SYSTEM. J.N. Carlson, K.L. Rossman*, R.W. Keller, and S.D. Glick Dept. of Pharmacology & Toxicology, Albany Medical College, Albany, NY 12208

Rats exposed to stressors that cannot be controlled exhibit profound behavioral and physiological disturbances that have been used as an animal model of human depression. We have previously shown that uncontrollable stress has differential effects on shock escape learning in rats having left- and right-sided turning preferences and causes lateralized changes in the mesocortical (PFC) dopamine (DA) neurochemistry. In the present study we have attempted to relate the behavioral effects of such treatment to specific alterations in PFC DA function by measuring both indices in the same subjects. Left and right sided male Long-Evans rats were exposed to controllable (CS) or identical uncontrollable (UCS) footshock and were tested for footshock escape behavior on the next day. Following testing, bilateral samples of the PFC were removed and analyzed for DA and metabolites. As seen in previous studies, right sided rats were more susceptible to the behavioral effects of UCS as evidenced by more escape failures and longer escape latency. A lower concentration of DA and its metabolite homovanillic acid (HVA) was measured in the right side than in the left side of the PFC in these animals. Across groups a significant inverse correlation was seen between mean shock escape latency and the DA concentration in the right side of the PFC. This relationship was strongest in animals with the most successful escapes (CS). These findings suggest that the behavioral disruption observed following UCS may depend upon an alteration of DA function in the right PFC.

EFFICACY OF ANTIPARKINSONIAN DRUGS ON THE SPONTANEOUS PAW REACHING AND SENSORIMOTOR DEFICITS CAUSED BY COMPLETE UNILATERAL DOPAMINE DEPLETION OF THE RAT FOREBRAIN. B.C. Gray*, C.S. McNeish*, R.J. Mandel¹, and R.E. Strecker, Dept. of Psychiatry, SUNY @ Stony Brook, NY, 11794, ¹ Dept. of Psychol., Univ. IL, Champaign, IL.

Rats bearing unilateral dopamine (DA) depletions of the striatum and subsequent DA-rich neural grafts show a complete recovery of drug-induced asymmetric behavior, but exhibit no improvement on some behaviors such as spontaneous paw reaching. One hypothesis holds that the grafts do not contain enough DA neurons and/or their outgrowth has not reached enough different target sites to produce complete recovery. This hypothesis would be supported if peripherally injected antiparkinsonian drugs reversed the deficits previously shown to be resistant to graft-induced recovery. Rats received complete unilateral DA denervation via the injection of 6-OHDA into two midbrain sites (N=7). Rotation was measured following several doses of amphetamine, apomorphine, and a carbidopa/levodopa combination to determine sub-rotational doses. Also, these rats exhibited marked contralateral sensorimotor neglect, and had an impaired ability to use their left forelimb to grasp and consume 45mg food pellets in the staircase test (Montoya et al.1990). Surprisingly, pretreatment with various sub-rotational doses of carbidopa/levodopa (i.p.), or apomorphine (s.c.) did not produce a performance improvement in either behavioral tests. Thus, merely providing the denervated receptors with DA agonists via drug treatments, or by analogy, with multiple graft placements appears inadequate to reverse all behavioral deficits. Instead, the complete normalization of the spontaneous behavioral deficits may require a more complex reconstruction of the damaged circuitry than is provided by either drug injection or the standard DA graft paradigm (e.g., greater re-afferentation of the graft by the host may be required). Alternatively, the severe (>95%) DA depletion in this rat model may be similar to end stage Parkinson's patients who also may no longer respond well to medication. Hence, some surviving DA terminals may be needed to provide effective functional regulation of the DA produced from levodopa. Supported by P. D. Fdn fellowships to CSM & BCG.

CELLULAR EFFECTS OF L-DOPA AND SELECTIVE DOPAMINE COMPOUNDS IN RAT NEOSTRIATUM. Nantwi, K.D. and Schoener, E. P., Dept. of Pharmacology, Wayne State Univ., Detroit, MI 48201.

The effects of specific dopamine receptor agonists and antagonists on spontaneously active neostriatal neurons were examined in urethane-anesthetized rats. Adult male Sprague-Dawley rats (200-250gm) were mounted in a cranial stereotaxic apparatus after surgical preparation for intravenous drug administration, recording systemic arterial blood pressure, and providing ventilatory assistance as needed. Extracellular single-unit activity was detected with glass-coated, platinum-iridium microelectrodes, stereotaxically guided into the striatum, and recorded continuously throughout the experiment.

L-DOPA was administered following pretreatment with the peripheral aromatic amino acid decarboxylase inhibitor carbidopa (1.0mg/kg). Neuronal depression and excitation were observed after a low dose of L-DOPA was given (0.25mg/kg), while depression predominated at higher doses (0.50 and 1.0mg/kg). These changes in activity were reflected in the average firing rate and duration of action, and were antagonized with haloperidol. The D-1 agonist SKF38393 also induced depression (62%) and excitation (38%), both of which were sensitive to SCH23390. Quinpirole, the D-2 agonist, primarily depressed activity (86%) in a dose-dependent, eticlopride reversible manner.

These experiments reveal that selective activation of dopamine receptors in the striatum can evoke changes in spontaneous neuronal behavior. Responsiveness of D-1 and D-2 receptors appears to be more balanced in the striatum than reported for the nucleus accumbens. This distinction may have potential therapeutic value in developing selective dopamine compounds for psycho/motor deficits.

198.11

THE EFFECTS OF INTRASTRIATAL DOPAMINE DEPLETIONS ON INSTRUMENTAL RESPONSES IN A NOVEL COST/BENEFIT PARADIGM. C. V. Alma and J. D. Salamone. Dept. of Psychology, Univ. of Connecticut, Storrs, CT 06269-1020.

A novel food-choice paradigm was utilized to determine if rats would lever press on an FR5 schedule to obtain a more-preferred food (BioServe Pellets) or consume less-preferred food (Lab Chow) that was freely available in the operant chamber. Prior to intrastriatal dopamine depletion, rats exhibited high frequencies of bar pressing per 30-min experimental period, and concomitant low consumption of the freely available, less-preferred lab chow. Bilateral 6-hydroxydopamine (6-OHDA) injections into either anteroventromedial (AVMS) or dorsolateral (DLS) striatum shifted instrumental response choice, such that level pressing frequency decreased and lab chow consumption increased. These changes in lever pressing frequency and chow consumption occurred for both 6-OHDA placement groups. Rats with AVMS and DLS dopamine depletions showed recovery of function in the post-surgical period and complete recovery was evident by day 21 after surgery. These results indicate that intrastriatal dopamine depletion suppressed a complex instrumental response for food. Nevertheless, the behavior of the rat remained directed toward the acquisition and consumption of food.

EFFECTS OF REPEATED STRESS ON MESOLIMBIC, MESOCORTICAL AND NIGROSTRIATAL DOPAMINE RELEASE: AN ELECTROCHEMICAL STUDY IN FREELY-BEHAVING RATS. M.D. Doherty & A. Gratton. Douglas Hosp. Res. Ctr., McGill Univ., Montréal, CANADA.

The present study was designed to characterize the effects of repeated, once daily exposure to either tail pinch (TP) or restraint (RES) stress on dopamine (DA) release in nucleus accumbens (NAcc), prefrontal cortex (PFC) and striatum (CPU). Male rats each implanted with a voltammetric probe in one of these three DA terminal fields were subjected to either 10 min of TP or 15 min of RES every day for 5 consecutive days. Acutely, TP produced reliable increases in DA levels in all three regions. While there was some indication, especially in NAcc and PFC, of enhanced DA release with repeated exposure to TP, this effect was highly variable both between animals and between test days. In contrast, the magnitude and the rate of DA release in NAcc and to a lesser extent in CPU increased with each daily exposure to RES. This effect was particularly noticeable in NAcc. Compared to the first exposure which caused a weak and transient (5-6 min) increase in NAcc DA levels, the fifth exposure to RES produced a sustained, 5-6 fold greater increase in DA levels. Such day to day changes in RES effects were not observed in PFC. In fact, compared to TP the effects of RES on PFC DA release were highly variable. Of the PFC 9 animals tested, RES either had no effect on any test day (n=3), increased DA levels on only the first two test days (n=3) or increased DA levels on only some of the 5 test days. Surprisingly, subsequent tests revealed that TP could stimulate PFC DA release in three animals that were unresponsive to RES. The present data indicate that a relatively mild stressor such as TP can stimulate DA release in limbic, cortical and striatal terminal fields. Furthermore the data show that mesolimbic but not mesocortical DA release is potentially enhanced, or sensitized when the animal is repeatedly exposed to a more intense stressor such as RES. *Supported by MRC.*

CONDITIONING-RELATED SINGLE-UNIT ACTIVITY IN THE NEOSTRIATUM DURING CLASSICAL EYELID CONDITIONING IN RABBITS: EFFECTS OF HALOPERIDOL. I.M. White, G.V. Rebec & J.E. Steinmetz. Prog. in Neural Sci., Dept. of Psych., Indiana Univ., Bloomington, IN, 47405.

Multi-unit recording from the cerebellar interpositus nucleus (INP) during classical eyelid conditioning indicates that haloperidol disrupts conditioning-related activity in the INP and reduces the percent conditioned response (CR) (Sears & Steinmetz, Pharm. Biochem. Beh., 1990). To determine if haloperidol disrupts CRs by altering modulatory forebrain regions, the present study examined neuronal activity in the neostriatum during eyelid conditioning and assessed the effects of haloperidol in this task. During the acquisition period (0-50% CR) animals received a 90 dB auditory CS. During the training period (51-100% CR) they received an 80 dB CS. A total of 192 single-units were recorded over the course of conditioning. During the acquisition phase, 55 units were conditioning related (18 CR-, 14 CS-, 13 US-, 10 CS+US-units) and 20 units were non-specific. During the training phase, 90 units were conditioning related (37 US-, 36 CR-, 8 CS-, 9 CS+US-units) and 27 units were non-specific. Units that were responsive to CRs increased activity as percent CRs increased. Haloperidol (0.5 and 1.0 mg/kg, s.c.) was administered when percent CR at 80 dB CS was 51% or greater for at least two consecutive sessions. At both doses of haloperidol, a variety of unit patterns was observed. Some CR-related units showed either an increase or a slight decrease in activity after the low dose, whereas some CR units decreased activity after the high dose. Most US units and CS+US units were inhibited at a both doses. In most cases, however, such inhibition by haloperidol was greater to the lower CS-intensity (80- dB). Disruption of percent CRs was greater with the higher dose and to the lower intensity CS. These findings indicate that haloperidol disrupts CRs and also affects neostriatal activity. Although the neostriatum is not essential for eyelid conditioning, such disruption may produce a failure to modulate processing of sensory information and alter information to areas that project to the cerebellum. HALOPERIDOL EXAGGERATES PROPRIOCEPTIVE-TACTILE SUPPORT REFLEXES AND DIMINISHES VESTIBULAR DOMINANCE OVER THEM. A. J. Cordover,* S. M. Pellis and P. Teitelbaum. Dept. Psychol., Univ. Florida, Gainesville, FL 32611.

Rats made immobile and cataleptic by the dopamine receptor blocker, haloperidol, maintain their stable static equilibrium by employing a variety of allied postural support reflexes. Under some test conditions competition between such reflexes occurs, and in haloperidol-treated rats, unlike undrugged controls, proprioceptive-tactile stimuli appear to be dominant over vestibular stimuli. We investigated this relationship in rats by testing their air-righting with and without simultaneous contact of the tail on a wooden platform. The rats were inverted and held upside down by the shoulders and pelvis 40 cm above the ground, with either none, or varying degrees of tail contact on a small wooden platform. Undrugged rats showed the normal pattern of righting, involving cephalocaudal recruitment of axial rotation, whether contacting the platform or not. The haloperidol-treated rats (2.5 mg/kg) gripped the platform with their tail upon release, which interfered with the righting reflex. Furthermore, some undrugged labyrinthectomized rats also gripped with their tail when released, and this appeared to be exaggerated under haloperidol. This suggested that a tactile signal from the tail is present in all rats, but in normal rats receiving simultaneous tactile and vestibular stimulation this is ignored, and the vestibular signal is dominant which triggers air-righting. Therefore, it appears that proprioceptive-tactile triggered postural support reflexes are dominant over vestibular ones in haloperidol-treated rats, reversing the normal relationship.

PARTIAL 6-OHDA LESIONS POTENTIATE THE EFFECTS OF RESTRAINT STRESS ON AMPHETAMINE-ELICITED LOCOMOTION AND DOPAMINE RELEASE. K.E. Banks, J. B. Mitchell & A. Gratton. Douglas Hosp. Res. Ctr., McGill Univ., & Ctr. Studies Behav. Neurobiol., Concordia Univ., Montréal, CANADA.

Recently, we have shown that partial (60-80%) depletion of DA levels potentiates the reward attenuating effects of neuroleptics (Doherty & Gratton, 1990). In the present study, we examined how partial DA depletion modifies the sensitizing effects of repeated exposure to stress on locomotion and on mesolimbic DA release elicited by d-amphetamine (d-A). The locomotor activity of 4 groups of male rats-lesion-stress, intact-stress, lesion-control, intact-control-was monitored during 150 min sessions in computer-monitored activity chambers. Following 5 days of habituation to the test chambers, the activity elicited by d-A was monitored in all animals. On each of the following 5 days animals in the stress groups were restrained for 30 min in the chambers 30 mins after the beginning of session; control animals were left undisturbed in the test chambers. Five and 13 days following the last stress session, the activity of all animals in response to a d-A challenge was examined. The data show that, compared to the control groups, locomotor activity elicited by d-A on the two challenge days was significantly higher in the two stress groups. Furthermore, d-A-elicited locomotion following repeated restraint was significantly higher in the lesioned animals than in the intact animals. High-speed chronamperometry was then used to monitor DA release in nucleus accumbens of intact and lesioned rats subjected to the same treatment. The preliminary results of this study indicate that, following repeated stress, mesolimbic DA release induced by d-A is enhanced in lesioned animals when compared to intact animals. Taken together, these data indicate that repeated exposure to a relatively painless stress potentiates the facilitatory effects of d-A on DA neurotransmission. The enhanced effects of restraint stress in partially depleted animals suggest that the surviving A10 DA neurons are hypersensitive to the sensitizing effects of stress or that the lesion eliminated an opponent (possibly mesocortical) DA system that inhibits the development of sensitization (see Mitchell & Gratton, this meeting). *Supported by FCAR.*

ELECTROCHEMICAL MONITORING OF MESOLIMBIC DOPAMINE RELEASE ASSOCIATED WITH DAILY COCAINE ADMINISTRATION IN FREELY-BEHAVING RATS. *E.A. Kiyatkin, R.A. Wise and A. Gratton**, Ctr for Studies in Behav. Neurobiol., Concordia Univ. and *Douglas Hosp. Res. Ctr, McGill Univ., Montréal, CANADA.

Following repeated daily cocaine (COC) administration rats exhibit an enhanced locomotor response to this and other psychostimulant drugs. Enhanced mesolimbic and nigrostriatal dopamine (DA) release has been reported to be associated with the sensitized behavioral response to COC. However, the daily changes in the pattern of DA release during the development of behavioral sensitization to COC have yet to be characterized. The present study used high-speed chronoamperometry to obtain this information in freely-behaving rats. Male rats each implanted with a voltammetric electrode in the nuc. accumbens (NAcc) received COC (15 mg/kg/day i.p.) on 5 consecutive days and also 3-4 days later (challenge). Changes in extracellular DA concentration were monitored for 2 hours prior to and 4 hours following COC. On day 1, COC caused a transient, 30-40 min decrease in DA levels followed by a longer lasting (approx. 100 min) increase. However, the initial decrease in DA after the first COC injection was no longer evident on subsequent days (2-5). Instead, DA levels began to rise 5-10 mins after injection, peaking in the 150-200 nM range 50-60 mins later and returning to baseline levels approximately 2 hours after injection. Changes in the amplitude and duration of DA increases in response to COC were highly variable both between animals and between days. However the greatest daily change in peak DA levels occurred between days 1 and 2; more progressive increases were recorded on subsequent days. The amplitude and latency measures of DA release in response to the COC challenge were similar to those obtained on days 2-5. The present data suggest that mesolimbic DA release is significantly enhanced after only 1 injection of COC. A suppression of the transient inhibition of DA release following the first injection of COC was found to be the most reliable and enduring change associated with subsequent COC administration. This effect may reflect a decreased effectiveness of negative feedback mechanisms that regulate A10 DA cell activity. *Supported by NIDA and FCAR.*

INCREASED SENSITIZATION OF MESOLIMBIC DOPAMINE RESPONSES TO PRIMARY INCENTIVE STIMULI IN RATS WITH 6-OHDA LESIONS OF THE PREFRONTAL CORTEX. *J.B. Mitchell and A. Gratton*, Douglas Hosp. Res. Ctr., Dept. of Psychiatry, McGill Univ., Montreal, CANADA H4H 1R3.

Repeated, intermittent presentation of stimuli, such as stress or psychomotor stimulants, that activate the mesolimbic dopamine (DA) system leads to an enhanced, or sensitized, response upon subsequent activation of this system (see Banks et al., this meeting). Several recent reports suggest that the mesocortical DA system may function, in part, to inhibit mesolimbic DA release. Thus, animals were given 6-OHDA lesions of the medial prefrontal cortex or left intact, and were then given repeated daily presentation of one of two primary incentive stimuli, a highly palatable food or sex-related olfactory cues, bedding from cages that housed estrus female rats. During presentation of these stimuli, extracellular DA concentrations were measured within the nucleus accumbens using high speed chronoamperometry. The electrochemical signal was obtained by applying a +0.55 V pulse, relative to a Ag/AgCl reference electrode, to a carbon fiber electrode, at a rate of 5 Hz. Among intact animals, presentation of both food and bedding reliably elicited an increase in the electrochemical signal. The response to bedding, but not food, increased across days. Depletion of prefrontal cortex DA, resulted in an enhanced response to both food and bedding, and the response to both stimuli increased across days. Furthermore, the basal oxidation current, obtained during the first 20 min in the testing apparatus, was relatively constant across days for the intact animals receiving repeated presentation of food, but increased across days for the intact animals exposed to the bedding, and especially for the lesioned animals receiving either stimulus. These results indicate that naturally rewarding stimuli increase activity within the mesolimbic DA system, and that the response to sex-related cues, but not food, sensitizes with repeated, intermittent presentation. Furthermore, the augmented response and facilitated sensitization found in animals with DA depletion of the medial prefrontal cortex suggests that the mesocortical DA system functions, in part, to dampen the reactivity of the mesolimbic DA system. *Supported by a grant from NSERC of Canada to AG.*

EFFECTS OF NOCICEPTIVE AND "PSYCHOSOCIAL" STRESSORS ON REGIONAL DOPAMINE UTILIZATION. *S. Uysal, K.D. Carr, J.W. Schweitzer* and A.J. Friedhoff*, Millhauser Labs, NYU Med. Ctr., NY, 10016.

It is well established that mild inescapable footshock selectively activates mesoprefrontal dopamine (DA) neurons (e.g. Thierry et al., 1976; Reinhard et al., 1982). The anatomical specificity of the DA response to stressful stimulation may, however, depend upon the nature and intensity of the stressor employed (e.g. Dunn, 1988). In the present study, rats were exposed to one of three stressors on an acute basis and effects on DA utilization in caudate, accumbens, and medial prefrontal cortex (mpfc) were determined. Rats in the first group received a nociceptive stressor consisting of 0.3 sec tailshocks delivered every 30 sec for 20 min. Rats in the second group "witnessed" the tailshock treatment through a wire mesh partition. Rats in the third group were placed in the treatment chamber following removal of each tailshock/witness pair to be stimulated by residual olfactory cues. A control group remained in home cages. Following treatment, rats were sacrificed by decapitation and DA terminal regions were microprobed from frozen brain sections. Tissues were assayed for DA, HVA, and DOPAC by HPLC. Ratios of DOPAC: and HVA: to DA were calculated as indices of DA utilization. None of the treatments altered DA utilization in the caudate. Tailshock increased HVA:DA ($F_{3,24}=7.03$, $p<.01$; Dunnett t, $P<.01$) and DOPAC:DA ($F_{3,24}=9.71$, $p<.01$; Dunnett t, $p<.01$) in mpfc and HVA:DA in accumbens ($F_{3,24}=3.58$, $p<.05$; Dunnett t, $p<.05$). "Witness" stress increased HVA:DA in the mpfc only (Dunnett t, $p<.05$). "Olfactory" stress increased both ratios in the mpfc, but not significantly. These results are compatible with proposals that mesocortical DA neurons are activated by diverse stressors and also support proposals that anatomical specificity of the DA stress response may vary according to nature of the stressor. *Supported by MH 08618.*

ACCESSORY OLFACTORY SYSTEM STIMULATION ELICITS DOPAMINE RELEASE WITHIN THE NUCLEUS ACCUMBENS. *A. Gratton and J.B. Mitchell*, Douglas Hosp. Res. Ctr., Dept. of Psychiatry, McGill Univ., Montreal, CANADA H4H 1R3.

Previous studies from our laboratory have found that the presentation of sex-related olfactory cues increase extracellular dopamine (DA) concentrations within the nucleus accumbens (nAcc) of freely-behaving male rats. In the present study, male rats were anesthetized with chloral hydrate, and extracellular DA concentrations in the nAcc were measured using high speed chronoamperometry. The electrochemical signal was obtained by applying a +0.55 V pulse to a carbon fiber electrode, relative to a Ag/AgCl reference electrode, at a rate of 5 Hz. Air was passed through bedding obtained from cages that housed estrus female rats, and directed into the nasal cavity of anesthetized male rats. Application of olfactory stimuli resulted in an increase in the electrochemical signal recorded within the nAcc. The peak amplitude and the duration of bedding-elicited increases in the electrochemical signal were increased by pretreatment with the specific DA reuptake inhibitor GBR-12909 (10 mg/kg, s.c., 30-60 min prior to testing). Using pulled-glass capillary micropipettes, depolarizing concentrations of potassium (120 mM KCl, 2.5 mM CaCl₂) were applied, using pneumatic pressure, directly to the accessory olfactory system. The application of potassium to the vomeronasal nerve layer of the anterior accessory olfactory bulb, and to the accessory olfactory bulb, itself, elicited reproducible increases in the electrochemical signal recorded within the nAcc. The reversibility of the oxidation reaction and the amplifying effects of GBR-12909 suggest that DA was the primary contributor to the electrochemical signal. The results of these experiments suggest that the accessory olfactory system, which is thought to be activated by molecules of low volatility, such as pheromones, is able to activate mesolimbic DA system.

IN-VIVO MICRODIALYSIS MEASURES OF DOPAMINE AND HOMOVANILIC ACID OVERFLOW IN THE NUCLEUS ACCUMBENS AFTER REPEATED MORPHINE INJECTIONS: TESTS WITH REPEATED PROBE IMPLANTATIONS. *J.P. Druhan, D. Funk, H. Rajabi and J. Stewart*, Center for Studies in Behavioral Neurobiology, Concordia University, Montreal, Quebec, Canada, H3G 1M8.

This study examined whether enhanced release of nucleus accumbens (NAS) dopamine (DA) after repeated morphine injections could be detected using in-vivo microdialysis with repeated probe implantations. Levels of DA and homovanillic acid (HVA) were measured in rats on two occasions (6 days apart) 18-24 h after implantation of removable microdialysis probes into the NAS. After collecting at least 6 baseline samples (20 min/sample), the rats were injected with morphine (5 mg/kg IP or 8 nmol/0.5 ul into the VTA) and samples collected for 3 h. The same doses of morphine were injected twice in the period between each test at two day intervals. On the first test, both systemic and intra-VTA morphine injections increased DA levels by about 50% of the baseline values and they increased HVA levels by 100-150%. Behavioral sensitization was observed on the second test after both IP and intra-VTA morphine injections, however DA levels were increased only to the same extent as on the first test by each of these treatments. Similarly, HVA levels were increased to the same extent on the each test with intra-VTA injections, although there was a slightly greater increase in HVA levels during the second test with systemic morphine. This lack of evidence for neurochemical sensitization with repeated microdialysis tests contrasts with previous ex-vivo results, and further raises questions about the feasibility of using repeated probe implantations to assess the development of sensitization within animals.

GLUTAMATE-DOPAMINE FUNCTIONAL INTERACTION WITHIN THE STRIATUM AND THE NUCLEUS ACCUMBENS.

M. Amalric, A. Ouagazzal, and A. Nieoullon*, Neurochemistry unit, Functional Neurosc. Lab, CNRS, 13402 Marseille cx 9 (France).

Antagonists of glutamatergic transmission at the N-methyl-D-aspartate (NMDA) receptor, like MK-801, have been shown to induce a locomotor hyperactivity in rats. This study was conducted to see whether this enhanced motor activity could be mediated by the D1 or D2 dopamine (DA) receptor subtypes and if this was dependent on DA neuronal activity in the two main DAergic pathways. MK 801 (0.05 - 0.3 mg/kg s.c.) induced a robust and dose-dependent increase in locomotor activity. MK 801 (0.3 mg/kg) was then challenged to different doses of a D1 receptor antagonist (SCH 23390, 10, 20 and 40 µg/kg s.c.) or a D2 receptor antagonist (raclopride, 100, 200 and 300 µg/kg s.c.). At doses known to potentially antagonize amphetamine induced locomotor activity, SCH 23390 only slightly antagonized MK 801 effect. This effect was not affected by raclopride, except at the highest dose known to produce a cataleptic effect. Furthermore, a 6-OHDA induced destruction of DA nerve terminals within the nucleus accumbens (N. Acc.) would not prevent MK 801 stimulant effect. In contrast, the 6-OHDA lesion of nigrostriatal nerve terminals resulted in an enhanced activation following MK 801 injection. In another experiment, microinjection of the NMDA receptor antagonist AP5 (5, 10 µg) in the N. Acc. induced a dose-dependent increase in locomotor activity and in the striatum induced a stereotyped behavior. These results suggest that the modulatory action of NMDA receptors on locomotor activity is not closely linked to the dopaminergic transmission in the mesolimbic system, while striatal NMDA receptor blockade antagonizes behavioral impairments due to DA nigrostriatal dysfunction.

DECREASED PROSTAGLANDIN D2 SYNTHESIS IN THE CNS OF TRISOMY 16 EMBRYOS: A MODEL OF DOWN'S SYNDROME. D. Minc-Golomb* and S.L. Rapoport, Lab. of Neurosciences, NIA, NIH, Bethesda, MD 20892.

Fibroblasts of Down's Syndrome (DS) embryos have been found to exhibit a reduced ability to release prostaglandins (PGs) (Minc-Golomb et al. Mouse Molecular Genetics Meeting - CSH, N.Y. Abstr 143, 1990). In order to examine whether similar alterations in PG synthesis occur in CNS, the release of PGD2 from different brain areas was compared between normal and trisomy 16 mice (Ts16), an animal model of DS based on the homology between human chromosome 21 and mouse chromosome 16. Hemispheres and cerebelli of 8 Ts16 and 8 normal mice were removed and placed in DMEM. The amount of PGD2 released to the medium in 60min was determined by RIA. PGD2 release from the cerebelli of Ts16 fetuses was significantly less by 22% than that in littermate control embryos (3.84 ± 0.34 and 4.94 ± 0.27 pg/mg respectively, $\text{mean} \pm \text{SEM}$ $n=8$, $p<0.05$). A similar difference was found in the hippocampus. However, no difference was found in the release of PGD2 from the whole hemisphere (Ts16: 4.18 ± 0.67 ; control: 4.14 ± 0.45 pg/mg tissue). These findings suggest that there are regional disturbances in arachidonic acid metabolism in the CNS in Ts16 fetuses. As PGD2 is an important neuromodulator in the CNS, the alteration described may contribute to CNS disturbances which characterize DS.

SPROUTING OF SEROTONERGIC FIBERS IN THE FOREBRAIN AND CORTEX OF NEONATAL MALE BRINDLED MICE. P.M. Martin, M. Ohno, and K. Suzuki, Brain and Development Research Center, and Dept. of Pathology, Univ. of North Carolina, Chapel Hill, N.C. 27599.

Mottled brindled (MO^{Br}) is an X-linked mutation in the mouse, maintained in hybrids of the C3H and C57BL strains. Hemizygous males ($\text{MO}^{\text{Br}}/\text{y}$), who usually do not live beyond postnatal (P) day 15, have low copper concentrations in the brain, an almost total lack of fur pigmentation, and neuronal degeneration of the cerebrum. Since copper is a cofactor for dopamine- β -hydroxylase, hemizygous males have decreased concentrations of norepinephrine in the cortex and other regions of the cerebrum, along with high concentrations of 5-HT in the brainstem, and high concentrations of 5-hydroxyindoleacetic acid, the metabolite of 5-HT, in the hindbrain and all areas of the cortex and forebrain (Satoh et al., J. Neuropathol Exp Neurol, in press). In the present experiment, 5-HT immunoreactive cell bodies in the dorsal raphe nucleus, and 5-HT immunoreactive fibers in cortex and forebrain have been compared in hemizygous males and control littermates at P10 and P12 ($n = 2$ pairs at each time point). Immunohistochemical staining was carried out with free-floating, 40 micrometer, Vibratome sections, using 3,3'-diaminobenzidine-HCl (DAB) or DAB-nickel staining. No differences were observed between the 5-HT immunoreactive cell bodies in brainstem nuclei of the hemizygous males and their littermate controls. However, 5-HT immunoreactive fibers were more dense throughout the cortex and forebrain areas of the hemizygous males in comparison to the same areas of normal male littermates. This increase in density of 5-HT immunoreactive fibers was apparent at both ages. Additional pairs of animals at ages P7 and P14 currently are being tested. This increase in density possibly reflects sprouting of collateral serotonergic fibers, and may be similar to the sprouting which has been observed following neonatal 6-OHDA lesioning of dopaminergic or noradrenergic pathways in rat pups. HIGH DOSE ASPARTAME HAS NO EFFECT ON EEG SPECTRAL PARAMETERS IN PHENYLKETONURIC HETEROZYGOTES (PKUH). Ch. Benninger, P. Matthis*, L.M.J. de Sonnevile, B. Lanz-Engler*, F.K. Trefz*, and H. Bickel*, University of Heidelberg, Heidelberg, Germany.

The effects of aspartame (APM) on EEG, cognition, and biochemical parameters were evaluated in 48 adult (21 male, 27 female) PKUH whose carrier status had been proven by DNA analysis. Subjects received APM (either 15 or 45 mg/kg/day) and placebo in capsules in a randomized, double-blind, placebo-controlled, crossover study for twelve weeks on each treatment. EEG's were recorded at baseline and at the end of each treatment (weeks 12 & 24). The relative powers (%) in the delta, theta, alpha, and beta bands between 1.0 - 25 Hz were computed from six leads using the fast Fourier transform. The mean power frequencies across all bands, across the major alpha-theta bands, and the half-power frequency were also computed. There were no significant differences in the clinical EEG evaluation, or in any of the EEG spectral parameters, when APM was compared to placebo. There were no significant effects of treatment on urinary organic acids, or adverse experiences. In addition, the results of a computerized battery of neuropsychological tests (the de Sonnevile visual attention tasks) demonstrate that APM has no effect on cognitive function. These results reaffirm the safety of APM in PKUH and refute the speculation that APM causes changes in neurological function.

199.2

SOMATOSTATIN EXPRESSION IN TS16 CULTURES INFLUENCED BY THE PRESENCE OF NON NEURONAL CELLS.

P.Corsi, C.DiBenedetta, M.L.Oster-Granite, J.T.Coyle,

Istituto di Fisiologia Umana, Univ. di Bari, Italy and Depts. of Neuroscience and Pharmacology, Johns Hopkins Univ., Baltimore, MD 21205.

Since the gene encoding pre pro-somatostatin (ppSS) is located on mouse chromosome 16 (MMU16) we have studied the effects of Trisomy (Ts) of MMU16 on SS immunoreactivity (IR) in primary disaggregated cultures of neocortex prepared from gestation day 15 Trisomy 16 mice and their littermate euploid controls. Primary cultures of papain dissociated cells were plated at different plating density ranging from 2.5×10^5 to 1×10^6 in poly-D-lysine coated dishes to examine the effect of different plating density on Somatostatin expression in both type of cultures. Two culture models were used: 1) neuron enriched cultures obtained by exposing to 5uM cytosine arabinoside (AraC) for 48h between day 3 and 5 after plating and whole cell cultures obtained by using the same protocol but untreated with AraC to investigate the effect of non neuronal cells on Somatostatin content in both group of cultured cortical cells. Immunocytochemical analysis indicated an increase in the relative density of SS-IR neurons ranging from 1-3 fold above euploids in Ts16 whole cultures at 2 and 3 weeks in vitro, although differences in SS expression disappear in cultures treated with AraC. The morphology of SS-IR neurons studied in Ts16 cultures and euploid sister cultures revealed a more complex pattern of staining for the Ts16 SS-IR neurons compared to euploids. Our data suggest that even though an extra copy of ppSS gene in Ts16 results in SS expression in an increased number of cortical neurons in whole cell cultures also a functional interaction between glial cells and neuron secreting Somatostatin occurs.

INCREASED EXPRESSION OF NEUROPEPTIDE Y-IMMUNOREACTIVE NEURONS IN MURINE TRISOMY 16 CORTICAL CULTURES. Maria T. Caserta Depts. of Psychiatry and Neurobiology and Physiology, Northwestern University Medical School and Evanston Hospital, Evanston, IL 60201.

Murine trisomy 16 has been used as a model of human trisomy 21 and may be useful in elucidating the neurobiological mechanisms that are involved in mental retardation and the predisposition to Alzheimer's disease in individuals with trisomy 21. Trisomy 16 fetuses, however, die *in vitro* and therefore, studies of neuronal development and differentiation must be done *in vitro*. We have previously shown that somatostatin (SMST) - immunoreactive neurons were overexpressed in cortical cultures derived from 15 day *in utero* trisomy 16 mouse fetuses when compared to their euploid littermate controls (Caserta et al., 1990, *Mol.Br.Res.* 7:269-272). The gene for pre-pro-SMST has been mapped to chromosome 16 in the mouse. Since SMST and neuropeptide Y (NPY) are frequently co-localized in mammalian brain and both of these neuropeptides are depleted in Alzheimer's disease, the expression of NPY-immunoreactive neurons in cortical cultures derived from trisomy 16 mouse fetuses and their euploid littermates was investigated. Neuronal plating density and dissociation protocols were varied to maximize neuronal survival in trisomic cultures and identical conditions were employed for the euploid control cultures. The NPY peptide was visualized by immunocytochemistry and the cultures were examined at varying ages *in vitro*. All cultures were counterstained for the expression of neuron-specific enolase to identify neurons. There was an increased expression of NPY-immunoreactive neurons in trisomy 16 cortical cultures when compared to control cultures (4% vs. 7%). These studies suggest that NPY and SMST expression may be regulated by similar genetic and/or developmental mechanisms in trisomy 16 cortex.

AGE-RELATED MOLECULAR AND MORPHOLOGICAL CHANGES IN THE CEREBELLUM AND HIPPOCAMPUS OF SPASTIC HAN-WISTAR RATS. R.W. Cohen, T.P. Duong, R.S. Fisher, J.B. Watson, A.T. Campagnoni, N.A. Buchwald, and M.S. Levine, Mental Retardation Research Center, UCLA School of Medicine, Los Angeles, CA 90024.

A genetic mutation of a strain of Han-Wistar rat is characterized by the postnatal development of ataxia, tremor and limb rigidity. Our previous findings suggested that a dysfunction in glutamate neurotransmission occurred in the cerebellum of these rats which led to losses in Purkinje cells and a reorganization of the granule cell layer (Cohen, et al., *Mole. Brain Res.* in press, 1991). To investigate the role of glutamate receptors in this disorder, we obtained clones of GluR1, GluR2 and GluR3 mRNA (Boutter, et al., *Science* 249:1033-1037, 1990; gift from S. Heinemann and M. Hollmann). Northern blot analysis revealed decreased expression of each glutamate receptor mRNA in mutant cerebellum (ages 45-50 days). The results suggest that cerebellar cell death may reduce overall receptor mRNA levels and changes in glutamate conductance may be due to elevated expression of a different receptor or preferential assembly of a multimeric, cerebellar glutamate receptor with potent kainate binding affinity. Parallel morphological studies assessed the time course of the defect. Mutant and normal rats were examined histologically at 30, 40, 56 and 60 days postnatally. Coronal sections from cerebellum and hippocampus were stained with Cresyl violet or processed immunochemically for neurofilament proteins. Mutant cerebella showed losses of Purkinje cells starting at 40 days. Labeling mutant cerebella with a neurofilament antibody also revealed cell loss and Purkinje cell axonal swellings that extended into the granule cell layer. Loss of pyramidal cells in the CA3 region was observed after 50 days in the mutants, corroborating the results of Wagemann et al. (*Neurosci. Letts.* 121:102-106, 1991). Axonal swellings were not observed in the hippocampal neurons. Based on the evidence, we propose that the spastic Han-Wistar rat disorder represents a disturbance in cerebellar glutamate transmission. The hippocampus may also be involved. Supported by NICHD HD05958 AND HD25831.

Manganese and Epilepsy: Mn^{2+}/Mg^{2+} Effects on Rat Brain Glutamine Synthetase Activity. G.F. Carl, J. Williams*, V. Livingston* and B.B. Gallagher. Med. Coll. Ga. and VAMC, Augusta, GA 30912

It has been repeatedly demonstrated that blood Mn concentrations are lower in epileptics than in a control population. Lower blood and brain Mn concentrations have also been demonstrated in genetically epilepsy prone rats (GEPR) when compared to their non-epileptic progenitors. GEPRs also exhibit lower brain glutamine synthetase activity. Since both the Mn concentration and the glutamine synthetase activity in GEPR brain were lower, we examined the effect of variations in Mn^{2+} concentration on the activity of the enzyme purified from both GEPRs and their progenitor strain, genetically epilepsy resistant rats (GERRs), to determine if the decreased brain Mn concentration might account for the decreased brain glutamine synthetase activity observed in the epileptic animals.

By varying the Mg^{2+} concentrations from 0 to 25 mM and the Mn^{2+} concentration from 0 to 5 mM, we observed that Mn^{2+} inhibits the Mg^{2+} -stimulated activity of brain glutamine synthetase in a concentration dependant manner at physiological pH, 7.2. We conclude that the decreased Mn^{2+} concentration observed in GEPR brain is not contributing to the decreased activity of glutamine synthetase in the brains of these animals. The relationship between decreased glutamine synthetase activity, decreased Mn^{2+} concentration and seizure susceptibility remains undefined.

ENHANCED STIMULATION OF DOPAMINE RELEASE BY SEROTONIN IN WEAVER MICE. J.A. Richter, H. Yu, B. Ghetti and J.R. Simon. Indiana Univ. Sch. Med., Indianapolis, IN 46202.

The weaver mutant mouse has about a 70% loss of nigro-striatal dopamine (DA) neurons. Previously we found that there was a compensatory increase in the basal release of DA (expressed as a fraction of the tissue content) from weaver striatal slices, and the amphetamine-evoked fractional DA release was also higher. In the present study we examined the effect of serotonin (5-HT) on weaver striatal DA release since 5-HT is known to increase DA release from normal striatum.

Striatal slices were superfused in vitro and release of endogenous DA was assayed by HPLC-EC. A concentration-related increase in fractional DA release was induced by 5-HT perfusion of +/- striatal slices and the effect increased over 40 min of 5-HT exposure. When a 20 min perfusion with 10 μ M 5-HT was followed by perfusion with normal medium, the evoked DA release peaked in the fraction following the end of the 5-HT exposure. In contrast to these results in +/-, the evoked DA release from weaver striatal slices occurred with less delay. Basal fractional release was once again higher for weaver than +/-, and the 5-HT-evoked fractional DA release was greater in the weaver than in the +/- . These results suggest that weaver striatum is more sensitive to the stimulatory effect of 5-HT on DA release. The mechanism for the greater and more rapid effect is under investigation. Supported by R01 NS14426 & P01 NS27613.

CHANGES IN STRIATAL GLUTAMIC ACID DECARBOXYLASE ACTIVITY IN WEAVER MUTANT MICE. H. Yu, B. Ghetti and J.R. Simon. Indiana Univ. Sch. of Medicine, Indianapolis, IN. 46202

The weaver mutant mouse (*wv/wv*) has a defect in the nigrostriatal dopaminergic pathway. Morphological and neurochemical evidence indicates that these dopaminergic neurons play a role in regulating the activity of GABAergic neurons in the striatum. The objective of the present study was to determine if the loss of tonic DA inhibition in weaver mice results in alterations in striatal GABA neurons. We assessed GABA uptake and glutamic acid decarboxylase (GAD) activity in striatal homogenates from age matched +/- and *wv/wv* mice. In 9 and 12 month old mice, GABA uptake was unaffected in *wv/wv* mice compared to +/- mice (N=6). Striatal GAD activity, determined at a sub-saturating substrate concentration of 25 mM Glu, was significantly increased in 10 month old *wv/wv* mice (75 ± 6.6 vs 100 ± 5 nmol/mg prot. N=4), and in 45 day old *wv/wv* mice (73 ± 4.5 vs 102 ± 8.5 nmol/mg prot. N=4). When saturating concentrations of Glu were employed, no differences in GAD activity were observed between the 2 genotypes at either 45 days or 10 months of age. GAD activity in the substantia nigra determined using 25 mM Glu, did not differ between +/- and *wv/wv* mice. The alterations in GAD suggest that a population of striatal GABA neurons is affected by the dopamine depletion in the weaver mutant mouse, and that GAD from *wv/wv* striatum may itself be altered. 199.8

REDUCED ACTIVITY OF A NAAG-HYDROLYZING ENZYME IN BRAIN REGIONS OF 21 DAY-OLD SEIZURE-SUSCEPTIBLE DBA/2 MICE. J.L. Meyerhoff¹, R.E. Carter², D.L. Yourick¹ and J.T. Coyle¹. ¹Dept. Med. Neurosci., Walter Reed Army Inst. Res., Wash., DC 20307. ²Div. Child Psychiatry, Johns Hopkins Univ. School of Med., Balt., MD 21205.

N-Acetyl-aspartyl-glutamate (NAAG) is a dipeptide in brain, which is localized to neurons, releasable by depolarization from brain tissue, increased by kindling, and excitatory when applied to neurons. NAAG is hydrolyzed into glutamate (GLU) and N-acetyl-aspartate (NAA) by N-acetylated- α -linked acidic dipeptidase (NAALADase). Thus, NAALADase could affect the availability of GLU at certain synapses. NAAG might be an excitatory neurotransmitter, but it could also function as a precursor/storage form of GLU. We recently found increased NAALADase activity in adult genetically epilepsy-prone rats (GEPRs). In contrast, DBA/2 mice, at the time of maximal seizure susceptibility (21 days), had NAALADase activity about 50% lower in several brain regions as compared with C57BL/6 seizure resistant mice. Separate genes reportedly regulate seizure spread vs susceptibility in DBA/2s, and different genes control juvenile vs adult-onset audiogenic seizures. Therefore, it is important to determine whether NAALADase activity is related to seizure susceptibility or seizure spread, and to compare the ontogeny of regional brain NAALADase in GEPRs, DBA/2s, and mouse strains susceptible to seizures as adults.

DOPAMINE UPTAKE IN THE SUBSTANTIA NIGRA: EFFECT OF THE WEAVER GENE. J.R. Simon, A.D. Miller* and B. Ghetti. Indiana Univ. Sch. of Medicine, Indianapolis, IN 46202.

The aim of the present study was to establish conditions for assessing dopamine (DA) uptake into DAergic elements in the substantia nigra (SN) of the mouse and then determine the effect of the weaver gene (*wv*) on this transport process. The SN, including the pars compacta and pars reticulata, was dissected from a 0.7 mm coronal section and chopped into 0.1 mm x 0.1 mm slices. Uptake of [³H]-DA was determined by incubating the slices at 37°C for 15 min. Approximately 60-70 % of the estimated DA uptake was inhibited by 1 μ M fluoxetine, indicating a significant contribution from serotonergic terminals. DA uptake measured in the presence of 1 μ M fluoxetine was temperature sensitive and inhibited by GBR12909 and nomifensine, suggesting the presence of a classical DA uptake carrier in the SN. Heterozygotes (*wv/+*) have a severe reduction in the number of TH-immunopositive dendrites in the pars reticulata of the SN (Triarhou and Ghetti, 1989). However, as measured by the method described above, DA uptake into SN slices from *wv/+* mice did not differ significantly from that observed in +/- mice. It is possible that the uptake is occurring into soma as opposed to dendrites or that homozygosity is required for an effect on the transport system in the SN. Uptake studies in the SN from *wv/wv* mice are currently in progress. (Supported by P01 NS27613)

HYPEREXCITABLE GRANULE CELL RESPONSES EVOKED *IN VITRO* AFTER PROLONGED *IN VIVO* STIMULATION. B.W. Strowbridge¹, P.S. Buckmaster¹ and P.A. Schwartzkroin^{1,2}. Depts. of ¹Physiology & Biophysics, and ²Neurological Surgery, Univ. of Washington, Seattle, WA 98195.

Mossy cells and somatostatin-immunoreactive neurons appear to be especially vulnerable in the dentate gyri in temporal lobe epileptic patients with presumed hippocampal foci (de Lanerolle, N., et al., 1989, *Brain Res.* 495: 387-395). A similar pattern of hilar cell loss can be produced in rats with prolonged perforant pathway stimulation (Sloviter, R., 1987, *Science* 235: 73-76). In order to study further the role of hilar neurons in regulating dentate gyrus excitability, we have examined synaptic responses of granule cells of stimulated and control animals *in vitro*. The normal synaptic response of granule cells to perforant path stimulation (an EPSP which may elicit a single action potential, followed by an IPSP) was observed in all granule cells in control animals (n=21) and some cells in stimulated animals (n=11 of 22). In those slices in which granule cells responded normally, we also obtained normal intracellular recordings from hilar mossy cells (n=8), suggesting that hilar cell loss was not pervasive. Other granule cells (n=11 of 22) from stimulated animals responded to stimulation with a prolonged depolarization that could trigger a burst of action potentials. In these cells, the short latency (Cl⁻-mediated) IPSP was diminished or absent, but the late, K⁺-mediated IPSP component was present. In the presence of glutamate-receptor antagonists, CNQX (10-40 μM) and APV (20-30 μM), stimulation near the granule cell recording electrode elicited inhibitory synaptic responses with both early and late components (n=2). These results support the hypothesis that prolonged *in vivo* stimulation affects the local circuitry that activates the inhibitory neurons that mediate the early IPSP recorded in granule cells.

Supported by NIH grants NS20482 and NS07097.

EVIDENCE FOR HYPEREXCITABILITY IN THE ISOLATED HIPPOCAMPAL CA1 AREA OF LONG-TERM KAINATE-LESIONED RATS. C.L. Meier, A. Obenaus and F.E. Dudek. Mental Retardation Research Center, UCLA School of Medicine, Los Angeles, CA 90024

Loss of Schaffer collateral input to CA1 pyramidal cells due to kainate-induced lesions may lead to synaptic reorganization in the CA1.

Simultaneous intra- and extracellular recordings were obtained in CA1 minislices prepared from 5 control rats and 5 animals 41 to 363 days after subcutaneous injection of kainate (18 mg/kg). Stimulation of the stratum radiatum close (less than 500 μm) to the recording site evoked an EPSP-IPSP sequence in all 9 CA1 neurons in control slices but only in 4 out of 9 neurons recorded in slices from kainate-treated animals. In the other 5 neurons, stimulation of the stratum radiatum evoked an EPSP only. The mean duration (measured at baseline) of the EPSP in slices from kainate-treated animals was significantly longer than the stimulation-evoked EPSP in slices from controls (44 ± 7 ms vs 14 ± 3 ms; mean ± SEM, t-test, p<0.02). In 8 out of 10 slices from kainate-injected rats, the extracellular response consisted of 2-3 population spikes. Two slices showed only a single population spike similar to the response seen in all 7 control slices. In slices from both groups, bath application of 30 μM bicuculline for 20-100 min led to stimulation-evoked bursts of 4-8 population spikes and prolonged EPSPs with 2-6 action potentials. Therefore, in bicuculline, there were no apparent differences in stimulation-evoked responses between control and kainate-treated rats. Spontaneous bursts were never observed in the isolated CA1.

Our preliminary results confirm the results of Nakajima et al. (1991) (*Hippocampus*, 1, 67-78) and are consistent with the hypothesis that kainate treatment leads to loss of inhibition within the CA1 area, which can persist for more than a month.

USE-DEPENDENT CHANGES IN DENTATE GRANULE CELL FIELD RESPONSES RECORDED FROM NAIVE AND KINDLED RATS. L.J. Burdette, G.J. Hart*, & L.M. Masukawa. Depts of Neurology & Research, Graduate Hospital, Philadelphia, PA

Low frequency (1 Hz) stimulation of the perforant path results in a decrease in the population spike (PS) amplitude of dentate granule cell field responses. To determine if this decrease reflects the long-lasting time course of late inhibition, we compared waveform changes in naive and kindled rats during trains of single pulses (30 pulses, 0.1 ms, 60% maximum PS amplitude) to the strength of paired pulse inhibition (interstimulus intervals: 20, 50, 100, 200 ms) delivered at 0.05, 1 and 5 Hz. No significant waveform changes were evident in either group during trains of 0.05 Hz stimulation. Both groups exhibited a similar decrease in PS amplitude to single pulse trains of 1 Hz stimulation, despite the presence of significantly enhanced paired pulse inhibition recorded at 0.05 Hz from kindled rats. A similar, but more pronounced, decrease in PS amplitude preceded afterdischarge initiation elicited by 5 Hz stimulation (single or paired pulses) in both groups. When the amplitude of the first PS was matched during 1 Hz paired pulse stimulation to that recorded during 0.05 Hz, kindled rats exhibited a greater decrease in late inhibition to 1 Hz paired pulses than that observed in naive rats. These results suggest that the decrease in PS amplitude observed with repetitive low frequency stimulation is not due to late inhibition, but instead may reflect some mechanism involved in seizure initiation.

IN VITRO VISUALIZATION OF HIPPOCAMPAL MOSSY FIBER SPROUTING AFTER STATUS EPILEPTICUS IN RATS. M.M. Okazaki and J.V. Nadler. Depts. Pharmacology and Neurobiology, Duke Univ. Med. Ctr., Durham, NC 27710.

We have developed a method for visualizing dentate granule cells and their mossy fibers in the rat hippocampal slice after extracellular iontophoresis of biocytin (Okazaki and Nadler, *Soc. Neurosci. Abstr.* 16:123, 1990). The present study applied this methodology to visualize mossy fiber sprouting into the inner portion of the dentate molecular layer after status epilepticus (SE). SE was induced in adult male Sprague-Dawley rats by one of two methods: 325 mg/kg (i.p.) of pilocarpine preceded by 1 mg/kg (i.p.) of methylscopolamine or 18 mg/kg (s.c.) of kainic acid. Pilocarpine-induced SE was terminated after 3 h with 50 mg/kg (i.p.) of phenobarbital. At least 4 weeks later, horizontal 400 μm-thick slices of the caudal half of the forebrain were prepared and incubated in a static interface chamber. Alternate slices were set aside for Timm's staining. Biocytin was iontophoretically applied to stratum lucidum of area CA3b. This procedure labeled the dentate granule cells and their mossy fibers by retrograde transport of the tracer. Biocytin was visualized with the NBT/BCIP chromogen reaction in sections prepared from these slices.

Whenever Timm's staining indicated the growth of mossy fibers into the dentate molecular layer, many small diameter biocytin-labeled fibers were observed to penetrate the dentate granule cell layer from the hilus and then to course parallel to the layer. These fibers were studded with relatively large varicosities. Their abundance correlated with the intensity of the Timm's reaction in the same region; they were rarely observed in sections from control animals. This is the first demonstration of mossy fiber sprouting that does not depend on a histochemical marker. (Supported by NIH grant NS 17771.)

EVIDENCE FOR G PROTEIN MODULATION OF GENERALIZED ABSENCE SEIZURES. O. Carter Snead III. Dept Neurology, Univ. Southern Calif; Div Neurology, Childrens Hospital Los Angeles, Los Angeles, CA 90027

γ-Hydroxybutyric acid (GHB) is a naturally occurring compound which has the ability to produce absence-like seizures in rats (Snead, *Epilepsia* 1988;29:361). It is known that GABA_A agonists exacerbate experimental absence, but we have recently demonstrated that the GABA_B agonist baclofen also prolongs spike wave discharge (SWD) duration in the GHB model of absence. Since the GABA_B receptor is coupled to a G protein, we sought to determine G protein involvement in the GHB model of absence. G protein inactivation (Andrade et al, *Science* 1986;234:1261) by pertussis toxin administered icv 3 days prior to GHB induction of absence seizures in rats resulted in a significant (p<0.05, n=6, nonparametric ANOVA) decrease in SWD duration in this model of absence. In view of these results, the effect of GTP on both [³H]GHB and [³H]GABA (GABA_B) binding in synaptosomal membranes was determined. GTP resulted in a 40-60% inhibition of binding of both ligands to their respective receptor sites. These data raise the possibility that GHB-induced absence seizures are mediated through a G-protein which is coupled to both the GABA_B and GHB receptor.

THE NMDA-ANTAGONIST, MK-801, DIFFERENTIALLY AFFECTS AFTERDISCHARGE DURATION AND SEIZURE DEVELOPMENT IN PERFORANT PATH KINDLING. ME Gilbert. ManTech Environmental Technology Inc., RTP, NC, 27709.

In amygdala kindling, NMDA antagonists have been reported to possess strong antileptogenic, but only mild anticonvulsant properties. MK-801 retards the development of amygdala and perforant path (PP) kindling and reduces afterdischarge (AD) durations induced by amygdala stimulation. However, AD's evoked by PP stimulation appear to be prolonged by MK-801 (Gilbert and Mack, 1990). The following study was designed to evaluate further the effects of MK-801 on AD and seizure development in response to PP stimulation. A crossover design was utilized in which male Long Evans rats were stimulated once daily for 10 sessions in the PP (60 Hz, 2 s, 800 μA), 30 m following MK-801 (1mg/kg, ip) or saline. Following a 1 wk rest period, stimulation resumed with the drug conditions reversed. MK-801 suppressed kindling development, but 3/12 animals had displayed generalized seizures (GS, stages 3-5) by the 10th session. When stimulation was resumed under saline conditions following the rest period, 8/10 animals displayed GS by the 4th stimulation session. Naive, saline-treated control animals required a mean of 7.8 sessions to evoke GS. MK-801 also resulted in longer ADs. Mean AD durations dropped after the rest period when animals were stimulated under saline conditions. These data suggest that the conditions that modulate focal AD duration in the PP may be distinct from those in the amygdala. Savings in kindling development following high dosages of MK-801 indicates that a significant progression of kindling has occurred under this drug regimen.

HIPPOCAMPAL MOSSY FIBER ZINC AND KINDLING SUSCEPTIBILITY IN INBRED MICE. HD Rees, RC Green and DD Savage. Dept. of Neurol., Emory Univ. School of Med., Atlanta, GA 30322; Dept. of Pharmacol., Univ. of New Mexico School of Med., Albuquerque, NM 87131.

The relationship between mossy fiber zinc and genetic differences in olfactory bulb kindling rates was studied in 5 strains of mice. Six to ten male mice of each strain were killed at age 5-7 weeks, before onset of movement-induced seizures in El mice, and without elicitation of audiogenic seizures in DBA mice. The brains were frozen and a quantitative histofluorescence procedure utilizing the chelation of zinc and TS-Q was employed to measure zinc density in stratum lucidum of CA3 in sections of dorsal and ventral hippocampus. Results (mean \pm SD) are as follows:

	DBA/2	C57Bl/6J	El	ddY	C3H/He
Mossy Fiber Zinc Density in Dorsal/Ventral Hippocampus (femtograms/100 μ m ²)					
Kindling Rate (Number of Stimulations to First Stage 5 Seizure)					
Ventral Hipp	3.29 \pm 0.43	3.12 \pm 0.19	2.37 \pm 0.13	2.27 \pm 0.21	2.06 \pm 0.16
Dorsal Hipp	3.44 \pm 0.61	3.63 \pm 0.45	2.59 \pm 0.13	2.82 \pm 0.13	2.70 \pm 0.08
Kindling Rate	4.0 \pm 1.4	9.6 \pm 2.2	14.8 \pm 3.0	18.5 \pm 2.5	22.6 \pm 3.8

At both dorsal and ventral levels of the hippocampal formation, one-way ANOVA followed by Scheffé post-hoc test indicated that DBA/2 and C57Bl/6J strains had significantly higher mossy fiber zinc levels than the other 3 strains. Comparison by two-tailed *t*-test of mossy fiber zinc levels in the epileptic El mice to those in the genetically similar but non-epileptic ddY mice revealed no significant differences in either the ventral ($p=0.73$) or dorsal ($p=0.24$) hippocampus. Mossy fiber zinc density values were correlated by linear regression with olfactory bulb kindling rates for these strains derived from earlier experiments in animals of similar age (Green & Seyfried, *Epilepsia* 32:22, 1991). The coefficients of determination (r^2) were 0.93 in the ventral hippocampus and 0.63 in the dorsal hippocampus. These findings suggest that strains with higher levels of hippocampal mossy fiber zinc kindle more rapidly.

200.9

RECOVERY FROM UNILATERAL CORTEX DAMAGE IN KINDLED RATS: EFFECT OF SEIZURE STAGE ON SOMATOSENSORY DEFICITS. T.D. Hernandez, J.C. Green*, L.C. Russell* and J.M. Droogan*. Department of Psychology, University of Colorado, Boulder, CO 80309

It has been reported that generalized seizures induced by chemoconvulsants or electroconvulsive shock facilitate recovery from behavioral deficits (i.e. sensorimotor asymmetries) produced by cortical damage. In contrast, anti-convulsant administration following cortex damage interferes with behavioral recovery and can reinstate behavioral deficits in fully recovered animals. The present studies were undertaken to assess the effect of focal epileptogenesis (using amygdala kindling) on behavioral recovery following unilateral frontal cortex damage in rats.

Animals were chronically implanted with a stimulating electrode in the amygdala during the same surgery in which they sustained a unilateral electrolytic lesion of the frontal cortex. Daily electrical stimulation of the amygdala began 48 hours after surgery. Recovery from somatosensory asymmetry (as measured by the bilateral tactile stimulation test) was facilitated during the early stages of kindling when compared to implanted/unstimulated controls. In addition, when multiple Stage 5 seizures were administered to fully kindled animals that had completely recovered from somatosensory asymmetry, the asymmetry was reinstated. Thus, seizures administered during the development of kindling had very different effects on behavioral recovery than did seizures administered within the kindled state itself. The degree to which these results may be a function of post-lesion plasticity and/or seizure severity will be discussed.

ANALYSIS OF EXCITATORY AMINO ACID RECEPTORS IN THE DISCRETE BRAIN AREAS OF KINDLED RATS. K. Akiyama¹, Y. Yoneda^{2*}, K. Ogita^{2*}, T. Itoh^{1*}, A. Daigen^{1*}, I. Sora¹, I. Kohira¹, H. Ujike¹ and S. Otsuki¹. ¹Department of Neuropsychiatry, Okayama University Medical School, Okayama 700, JAPAN, and ²Department of Pharmacology, Setsunan University, Hirakata 573-01, JAPAN.

The present study examined the binding of excitatory amino acid receptor subtypes in the five brain areas (amygdala, hippocampus, striatum, frontal cortex and cerebellum) of the kindled rats, by using extensively washed and Triton X-100-treated membranes. 7 days after the last amygdala kindled seizure, specific [³H]MK-801 binding decreased significantly only in the amygdala of the kindled rats as compared to the control in the equilibrium assay conditions. There was no significant change in the [³H]MK-801 binding in the amygdala or hippocampus 7 days after the last hippocampal kindled seizure, or 28 days after the last amygdala kindled seizure. Nor was there significant change in NMDA-sensitive [³H]glutamate, [³H]glycine, [³H]spermidine, [³H]kainate or [³H]AMPA binding in any brain area 7 days after the last amygdala kindled seizure, or in the hippocampus 28 days after the last amygdala kindled seizure. These results indicate that NMDA receptor channel in the amygdala undergoes down-regulation only transiently, but that none of the excitatory amino acid receptor subtypes exhibit long-lasting change at steady state following the completion of amygdala kindling.

200.8

AMYGDALA KINDLING, ANXIETY AND CORTICOTROPHIN RELEASING FACTOR (CRF). R.E. Adamec. Depts. of Psychology/Basic Medical Science, Memorial University, St. John's, NF, Canada

Male Wistar rats were kindled in the right medial amygdala until four stage 5 seizures were evoked. One week later anxiety was assessed in the elevated plus maze. One kindled group was simply tested. Additional kindled groups were tested in the plus maze one hour after an icv injection of either saline, CRF or the CRF antagonist, α -helical CRF. Parallel groups of implanted control animals were tested in the plus maze in the same manner as kindled rats. Controls were handled like kindled rats, but not kindled. Kindling alone increased anxiety in the plus maze relative to controls. CRF did not alter anxiety in handled control animals. In contrast, icv injections of saline or CRF were equally anxiolytic in kindled animals. Kindled rats injected icv were less anxious than uninjected kindled rats, and did not differ from controls. α -helical CRF reversed the anxiolytic effect of icv injection in kindled rats, but had no effect on anxiety in handled rats. Kindled rats given α -helical CRF were as anxious as uninjected kindled rats, and more anxious than controls given α -helical CRF. These findings suggest that amygdala kindling increases anxiety for some time after kindling has ceased. Moreover, kindling seems to alter the behavioral effects of injection stress mediated by endogenous CRF. Normally, stress induced increases in endogenous CRF are anxiogenic. Kindling seems to change this effect of CRF to an anxiolytic action.

EFFECTS OF GLUCOCORTICOIDS ON COCAINE-INDUCED KINDLING AND BEHAVIORAL SENSITIZATION. M.A. Kling, D. Pluznik*, M.D. DeBellis*, J. Demas*, J.R. Glowa and M.A. Smith. Clinical Neuroendocrinology Branch, NIMH/DIRP, Bethesda MD 20892.

Repeated administration of cocaine to rats produces both kindled seizures and behavioral sensitization (e.g., stereotypic behavior). Previous studies have shown that glucocorticoids and their antagonists can influence the development of local anesthetic-induced kindling. We report here a study of the effects of the glucocorticoids dexamethasone (DEX) and corticosterone (B) on cocaine-induced kindling and sensitization. Male Sprague-Dawley rats, 250-300g, were pretreated with DEX (250 μ g/rat/d), B (10 mg/rat/d), or vehicle i.p. at 1600 h X 3 d prior to initiating daily i.p. injections of cocaine (40mg/kg/d) at 0900 h. Rats were observed for 30 min. in an open field for seizure activity and stereotypy, rated on a 0-7 scale. DEX-treated animals kindled significantly more rapidly than B-treated rats or controls, with 90% of DEX-treated rats developing seizures by day 5, compared with 40% of B-treated rats; 50% of controls kindled, all between days 8 and 17 ($X^2=11.8$, $p<0.02$). A second experiment showed that DEX given at 25, but not 2.5 μ g/rat/d, significantly increased kindling frequency compared with controls ($X^2=9.2$, $p<0.01$). Neither steroid significantly affected the development of cocaine-induced sensitization of stereotypy. These results suggest that glucocorticoids (DEX>B) enhance the development of cocaine kindling but not sensitization, compatible with the idea that these phenomena are mediated by different neural substrates.

DIFFERENTIAL EFFECTS OF CONDITIONING STIMULATION IN THE STRIATUM ON KINDLED SEIZURE DEVELOPMENT. M.J. Berg*, C.D. Applegate, J.L. Burchfiel. Comprehensive Epilepsy Program, University of Rochester Medical Center, Rochester, NY 14642.

Activation of the striatum has been reported to have an anti-convulsant effect in a variety of rodent seizure models. In this study we evaluated the influence of striatal activation on kindled seizure development. Male, Sprague-Dawley rats were implanted with bipolar stimulating electrodes into either the ventral (N=8) or dorsal (N=4) striatum and the ipsilateral basolateral nucleus of the amygdala. Conditioning stimulation (5s train of 1ms pulses, 3Hz, 1.5mA) was delivered to the striatum 1 minute prior to each amygdala kindling stimulation trial. Results demonstrated an effect of striatal stimulation on kindling rates which differed based on the site of the conditioning stimulation. Activation of the ventral striatum significantly increased kindling rates, while activation of the dorsal striatum was ineffective in altering the rate of amygdala kindling in comparison with controls. The mean number of trials to the first stage 5 seizure was 15.3 \pm 0.8 ($p<.01$) for the ventral striatal group, 6.5 \pm 0.3 ($p>.1$) for the dorsal striatal group and 8.5 \pm 1.0 for control animals (N=6). The increased number of trials in the ventral striatal group was totally accounted for by an increased number of stage 1-2 trials. No differences in afterdischarge duration or thresholds were observed among groups. These observations support a role of the striatum in the development of amygdala kindling and suggest a striatal influence on afterdischarge propagation. This effect may be mediated by topographically organized striatal output to the substantia nigra.

200.13

THE PIRIFORM CORTEX AND KINDLING: BEHAVIORAL AND PHYSIOLOGICAL EVIDENCE FOR A COMMON SUBSTRATE. J.L. Burchfiel and C.D. Applegate. Dept. of Neurology, University of Rochester School of Medicine, Rochester, NY 14642.

A growing body of evidence suggests that the piriform cortex (PC) is uniquely sensitive to the effects of limbic kindling. Male, Sprague-Dawley were implanted with bipolar electrodes into either the olfactory bulb (OB) or septal nucleus (S) and the ipsilateral PC, and kindled using standard protocols from either the OB or S. Following primary kindling, transfer kindling of the PC was assessed. Afterdischarge (AD) characteristics were recorded on each trial during primary and transfer kindling.

Each OB AD during primary kindling elicited a PC AD with identical characteristics to that elicited by direct stimulation of the PC. During primary S kindling, the emergence of an "endogenous" PC AD was delayed and was directly related to the development and expression of the initial stage 3 seizure. The PC was virtually fully kindled following primary kindling of either OB or S, requiring only 1-2 stimulations to exhibit a stage 5 seizure. Data indicate that the PC is a highly involved structure in both OB and S kindling. Experiments to test whether the PC also is involved in the kindling of dorsal hippocampus and other structures are currently being conducted.

200.15

C-FOS EXPRESSION IN PILOCARPINE-INDUCED STATUS EPILEPTICUS. L.E.A.M. Mello, A.M. Tan* and D.M. Finch. Department of Neurology and Brain Research Institute, University of California, Los Angeles, CA 90024.

Injection of a single dose of pilocarpine (320 mg/kg, i.p.) was used to induce status epilepticus (SE) in Sprague-Dawley rats (male, 200-300 g). At various times after the induction of SE, animals were sacrificed and processed immunocytochemically for c-fos expression. Analysis with light microscopy was performed to determine which areas showed c-fos expression. After 15 min of SE, c-fos expression could already be seen in neocortex (layer IV) as well as in the subicular complex, entorhinal cortex and striatum, but not in the hippocampus or any thalamic nuclei. After 1 or 2 h of SE, c-fos could be seen in the olfactory tubercle, diagonal band, supraoptic nucleus, amygdala, hippocampus, subicular complex, entorhinal cortex, piriform cortex, neocortex, striatum, medial geniculate and thalamus (paraventricularis, intermediodorsal, reticular, laterodorsal and rhomboid nuclei). Several areas showed remarkably preferential staining: layer II of entorhinal and piriform cortices; dentate gyrus and CA1; amygdaloid laterodorsal, central and basolateral anterior nuclei; and the marginal zone of medial geniculate. This selective pattern of c-fos expression in SE presumably indicates which brain areas are involved in seizure genesis and propagation, but c-fos expression may also reflect an adaptive process. Further studies can contribute to a more complete understanding of the mechanisms leading to a state of chronic epilepsy after pilocarpine-induced SE. Supported by NIH Grants NS 23074 and NS 16721, and FAPESP (Brazil).

EFFECT OF PRECOLLICULAR TRANSECTION ON AUDIOGENIC SEIZURES IN GENETICALLY EPILEPSY-PRONE RATS (GEPRs). R. A. Browning, C. Wang, and P.C. Jobe. Southern Illinois Univ. Sch. of Med., Carbondale, IL, 62901 and Univ. of Illinois Coll. of Med., Peoria, IL, 61656.

Previous studies have demonstrated that electroshock or pentylenetetrazol (PTZ)-induced seizures characterized by running-bouncing (R/B) clonus or tonic extensor convulsions occur as a result of seizure discharge in the brainstem (Browning & Nelson, Exp. Neurol. 93: 546, 1986). In order to test the hypothesis that audiogenic seizures (AGS) also emanate from the brainstem and do not require forebrain circuitry, we have examined the response of two strains of GEPR (GEPR-3s and GEPR-9s) to seizure-evoking auditory stimuli 3 hours after a precollicular transection or sham surgery performed under ether anesthesia. Following the transection, 50% of the GEPR-9s (N=8) displayed their typical tonic seizure in response to the usual auditory stimulus, and 50% showed the tonic seizure in response to sound after receiving a subconvulsant dose of PTZ (25 mg/kg.i.p.). In contrast only 20% of the GEPR-3s (N=5) displayed their usual R/B clonic seizure in response to auditory stimulation after the transection, but the remaining 80% became audiogenic seizure-sensitive after pretreatment with PTZ. All sham-operated rats exhibited their usual seizure in response to sound stimulation 3 hours after sham surgery. The effect of precollicular transection was also assessed in normal rats rendered sensitive to AGS by the infusion of NMDA into the inferior colliculus (IC, 10 nMoles, bilaterally). Three hours after transection all (N=5) the normal rats displayed audiogenic or audiogenic-like seizures after receiving an IC infusion of NMDA. These findings support the hypothesis that the anatomical substrate necessary for AGS resides within the brainstem. However, the present study also suggests that the threshold for sound-induced seizures is elevated 3 hours after a precollicular transection. Whether the latter is due to surgical trauma or the removal of a seizure-facilitating system in the forebrain is not known. The greater resistance of GEPR-3s to AGS after transection is consistent with known threshold differences between GEPR-3s and GEPR-9s (Browning et al., Epilepsy Res. 6: 1,1990).

FAST AND SLOW KINDLING RAT STRAINS: *IN VITRO* RESPONSE OF PYRIFORM AND PERIRHINAL CORTEX TO MAGNESIUM-FREE PERFUSATE. Heather J. Lennox* and Dan C. McIntyre. Dept. of Psychology, Carleton Univ., Ottawa, ONT Canada K1S5B6.

Prolonged exposure of a coronal slice including the amygdala, perirhinal cortex and pyriform cortex to magnesium-free (0-Mg) perfusate produces spontaneous epileptiform activity, and continued hyperexcitability in a reduced form after re-exposure to normal-Mg perfusate. Thus, this treatment might be an *in vitro* analog of *in vivo* kindling (Hoffman & Haberly (1989) J. Neurosci. 9:206-215). In the present study, electrophysiological properties of such slices from two rat strains previously bred as prone (fast) and resistant (slow) to amygdala kindling were observed under normal and 0-Mg perfusates. First, the identifying interstrain difference *in vivo*, the kindling rates, emerged *in vitro* when slices from slow rats, compared to fast rats, were slower to exhibit regular epileptiform burst discharge activity. Second, frequent independent pyriform discharges in slow slices seem to be an *in vitro* analog of the *in vivo* interictal spikes prevalent in the slow strain. Third, the pyriform cortex of slices from the slow strain were surprisingly excitable in 0-Mg. And finally, kindling-like effects were produced in both strains by prolonged 0-Mg-induced hyperexcitability: increased excitability was seen in measures of both evoked and spontaneous population discharges during normal reperfusion after 0-Mg.

200.16

CONSTANT HIGH DOSE PYRIDOXINE TREATMENT STARTED PRENATALLY INCREASES REGIONAL SEROTONIN LEVELS IN EPILEPSY-PRONE BALB/C MICE.

J. Vriend, A. H. Greenberg*, N. A. Alexiuk* and S. Dolina*, Dept. of Anatomy, Univ. of Manitoba and Manitoba Inst. of Cell Biology, Winnipeg, MB, Canada R3E 0W3

Regional concentrations of serotonin (5HT) and 5HIAA were determined in extracts of brain tissue of selectively bred epilepsy-prone (EP) and epilepsy-resistant (ER) substrains of Balb/c mice. Significantly decreased levels of 5HT were found in cortex, but slightly increased levels of 5HT and 5HIAA were observed in brainstem of EP mice compared to ER, at 6 weeks of age. Constant pyridoxine treatment started prenatally (100 mg/L in the drinking water) increased significantly 5HT concentrations in hypothalamus and hippocampus compared to non-treated EP animals. The level of 5HT in their cortex was restored to 92% of the level observed in normal ER mice. In contrast similarly treated ER mice had decreased 5HT concentration in their cortex, without significant changes in 5HT levels in other brain structures. These data show that ER and EP mice are differentially sensitive to pyridoxine treatment. A disorder of pyridoxine dependent L-amino acid decarboxylase, susceptible to early correction by pyridoxine is considered as a possible mechanism for the genetically enhanced convulsibility in EP Balb/c mice.

Genetical analysis of neocortical-spike-and-wave patterns in inbred rat strains. R. Urioste, Z. Horváth, X. G. Li*, E. Pierre*, D. Vadi*, M. Hsu and C. Vadász¹, G. Buzsáki. Center for Neuroscience, Rutgers University, Newark, NJ 07102 and Nathan S. Kline Institute for Psychiatric Research, Orangeburg, NY 10962¹

Spontaneously occurring high voltage spike-and-wave spindle patterns (HVS) were examined in 6-month-old rats of the Fischer 344 (F344) and Brown Norway (BN) strains and their F1 hybrids. Neocortical activity and movement were monitored for 12 night hours in each rat and the analog data were digitized (100 Hz) and recorded on laser disks. HVS episodes, occurrence of movement and slow-wave periods (sleep, drowsiness) were detected by a software program. The intra-HVS frequency was significantly slower in F344 rats (7.4 Hz) than in the BN strain (8.1 Hz) and the F1 cross. HVS-associated tremor was very rare in F344 but frequent in BN and F1 rats. A significant sexual dimorphism in BN and F1 rats but not in F344 animals and marked strain differences in males were observed in the total duration of HVS during awake immobility. The incidence, average duration and total duration of HVS were significantly higher in F1 hybrids than in the parental strains. The results suggest that control of HVS involves genotype-dependent sex effects and genetic additive and dominance effects. Heterosis in F1 hybrids can be attributed to overdominance or dispersion of genes.

AUDIOGENIC SEIZURE SUSCEPTIBILITY IN WSP AND WSR MICE. **D.J. Feller and C.A. Le Fevre***, VA Medical Center and Oregon Health Sciences University, Portland, OR 97201.

Mice have been genetically selected for susceptibility (WSP) and resistance (WSR) to handling-induced convulsions during withdrawal from chronic ethanol treatment. The neurochemical basis for this difference is unknown. We have shown that hippocampal mossy fiber zinc is decreased in WSP compared to WSR mice. Reduced hippocampal mossy fiber zinc has also been found in rats predisposed to audiogenic seizures. These observations led us to test naive WSP and WSR mice for audiogenic seizures. Mice were tested using a 121 dB sound source at ages 17, 22, 28 and >70 days. Mice were exposed to the bell for 60 sec or until a response was observed. WSR mice did not respond at any age to audiogenic stimulation, while WSP mice displayed peak susceptibility at age 22 (58%). Percentages for each seizure category were: wild running, 18%; spasms, 8%; clonic, 3%; tonic, 3%; lethal, 26%. WSP mice did not have audiogenic seizures if tested at >70 days. However, exposure to 121 dB stimulation increased handling-induced convulsion scores above baseline levels (4.2 compared to 1.0). Differences between WSR and WSP mice in susceptibility to audiogenic seizures and increased handling-induced convulsions after a 121dB stimulus are correlated responses to selection. Therefore, these traits may share some common genetic basis with ethanol withdrawal seizures, and may thus be regulated to some extent by a similar neurochemical mechanism which may involve hippocampal mossy fiber zinc.

These studies were supported by a grant from the VA Medical Center.

EPILEPSY: BASIC MECHANISMS II

201.1

LIMBIC STATUS EPILEPTICUS IN THE RAT REQUIRES ACTIVATION OF THE BASOLATERAL AMYGDALA. **L.E. White and J.L. Price**. Dept. Anat. & Neurobiol., Washington Univ., St. Louis, MO 63110.

Limbic status epilepticus was induced in adult albino rats by 40 min of continuous electrical stimulation of either the basolateral amygdala, the anterior olfactory nucleus, or the anterior piriform cortex (White and Price, 1990, Proc. Soc. Neurosci. 16:281). In each experiment, one of four types of limbic status was induced; of these, Types II and III were encountered most frequently (25% and 60%, respectively). Type II status is characterized by discontinuous locomotor activity and low frequency (1-2 Hz) sharp waves observed in depth electroencephalographic recordings. Type III status includes all of these features, with recurrent episodes of facial and forelimb clonus during discrete segments of high frequency (10-20 Hz) activity. [¹⁴C]2-deoxyglucose autoradiography and Fos immunocytochemistry revealed that the anatomical substrates of both types of status include the basolateral amygdala, and its efferent targets. Type II status also involved restricted parts of the olfactory cortex, but not the piriform cortex. Type III status involved the entire amygdala and olfactory cortex, the insular cortex, the ventral striatum, the ventral hippocampus, and the substantia nigra.

The possibility that activation of the basolateral amygdala is required for the expression of limbic status was investigated by acutely injecting muscimol or lidocaine into this region during Type II or Type III status. Deactivation of the basolateral amygdala resulted in the complete cessation of Type II or Type III status. For each type of status, [¹⁴C]2-deoxyglucose autoradiography revealed that the entire anatomical substrate was deactivated, except for the amygdalohippocampal area. These findings implicate the basolateral amygdala as a primary generator of limbic status epilepticus activity. Supported by NIH DC00093.

GLUTAMATE RECEPTORS IN PIRIFORM CORTEX REGULATE SUSCEPTIBILITY TO SEIZURES EVOKED FROM PREPIRIFORM CORTEX. **T. Halonen, H. Zrebet, K. Gale**. Department of Pharmacology, Georgetown University Medical Center, Washington, D.C., 20007.

The area tempestas (AT) is an epileptogenic site within the prepiriform cortex from which bilateral limbic motor seizures can be evoked with unilateral application of GABA antagonists or glutamate agonists. In the present study, we evaluated the functional relationship between the AT and a region of the posterior piriform cortex (PC) (6-7mm caudal to the level of AT) in which strong increases in immediate early gene expression and glucose metabolism occur in response to seizures evoked from AT.

Seizures were evoked by the unilateral application of bicuculline methiodide (BIC) (118 pmol in 120 nl) into AT. Glutamate antagonists were applied unilaterally to the caudal PC (lateral to amygdala) of the same hemisphere as the AT injection, 5 min prior to BIC in AT. Antagonists selective for NMDA-sensitive receptors only partially attenuated the AT-evoked seizures, with relatively high doses of CPP (10 nmol or more) or AP7 (20 nmol or more) required for obtaining a significant protective effect. Kynurenic acid, a relatively low potency antagonist of both NMDA and non-NMDA receptor subtypes, was effective in completely blocking AT-evoked seizures when applied into PC at a dose of 100 nmol. These observations suggest that the homolateral posterior PC may be a critical initial target for the relay of propagated seizures triggered from AT and that non-NMDA receptors, in addition to NMDA receptors, are important mediators of this activity. Studies with focal application of selective antagonists of non-NMDA receptors will allow us to determine the relative contribution of the various glutamate receptor subtypes in PC for propagation of the AT-evoked seizures.

Supported by HHS grant #NS28130 and fellowship #NS08750.

ANATOMICAL CONNECTIONS OF THE AREA TEMPESTAS IN THE RAT. **N. Sahibzada¹, W. Chen¹, T. Halonen² and K. Gale¹**. ¹Dept. of Psychology, Univ. District of Columbia and ²Dept. of Pharmacology, Georgetown Univ. Medical Center, Washington, DC.

The area tempestas (AT), a deep prepiriform cortical site, has been demonstrated to be involved in the generation of limbic seizures in the rat. Microinjection of GABA antagonists or glutamate agonists into the AT elicit seizures that are characterized by facial and forelimb clonus accompanied by rearing and falling. The AT, as functionally defined, is highly discrete, with a radius of approximately 1mm. In order to characterize afferent and efferent projections of the region containing the AT, we applied fluorescent tracers Fluoro-Gold and Fluoro-Ruby (a few animals received WGA-HRP) into this site. Bicuculline methiodide (60ng) was included in the tracer infusions in order to functionally verify the accuracy of the infusion site. Animals exhibiting convulsive seizures within 3 min of the the infusion were considered to have correctly placed cannulae.

After a period of 2-14 days the animals were perfused, their brains removed and sectioned. Brains injected with WGA-HRP were processed according to the TMB protocol of Mesulam (1978). Our results show that the AT receives afferent projections from a number of structures which include: dorsal tegmental nucleus, piriform cortex, entorhinal cortex, olfactory bulb, midline thalamic nuclei, pedunculoportine tegmental nucleus, locus coeruleus and amygdaloid nuclear complex. Several of these structures also appear to be reciprocally innervated by AT. Based on these initial findings, we are verifying efferent targets of AT by placing retrograde tracers in those targets in order to identify cells of origin in AT.

Supported by HHS grant #NS28130.

201.4

EFFECT OF LIDOCAINE HYDROCHLORIDE MICROINFUSED INTO THE PONTINE RETICULAR FORMATION ON MAXIMAL ELECTROSHOCK SEIZURES IN THE RAT. **M.L. Maring, D.C. Smith¹, and R.A. Browning**. Depts. of Physiology and ¹Psychology, School of Medicine, Southern Illinois University, Carbondale, IL 62901.

The pontine reticular formation (PRF) has been implicated in the expression of generalized tonic seizures. Specifically, bilateral lesions of the pontine tegmentum involving the superior cerebellar peduncles and the nucleus reticularis pontis oralis (RPO) have been shown to attenuate the tonic components of generalized seizures induced by maximal electroshock (MES), pentylenetetrazol and sound stimulation (audiogenic) (Browning et al., *Epilepsia* 22:583, 1981). While attenuation of tonic seizures following lesions of the RPO indicates a critical role of this structure in the expression of such seizures, it is possible that neurophysiological changes may have occurred during the post-surgical recuperative period, prior to seizure testing. In order to confirm the observed effects of RPO lesions on tonic seizures, we have investigated the effects of reversible inactivation of the RPO on MES. Reversible inactivation of the RPO was accomplished through the use of microinfusions of lidocaine HCl, a local anesthetic which produces reversible neuronal inactivation via a voltage-dependent blockade of sodium channels. Sprague-Dawley rats were pretested to ensure the presence of full hindlimb extension (HLE) in response to MES. The rats were bilaterally implanted with epidural 23 gauge guide cannulae directed at the RPO. One week after implantation the rats were infused with lidocaine HCl (1 µl of 2%, 0.5 µl of 5% or 1 µl of 5%) or saline bilaterally, and ten minutes later subjected to transcranial MES (0.2 sec, 150 mA). While lidocaine HCl, in the doses employed, failed to alter the latency to or duration of HLE (in those displaying HLE) compared to vehicle-infused controls, a reduction in the incidence of HLE was observed. Bilateral infusions of 1 µl of 2%, 0.5 µl of 5%, or 1 µl of 5% lidocaine HCl reduced the incidence of full HLE in 22% (N=9, p=.13), 38% (N=8, p=.05) and 75% (N=4, p=.03) of the rats tested, respectively. These findings support the proposed critical role of the RPO nucleus in the expression of tonic seizures.

AUDIOGENIC SEIZURE SENSITIZATION BY UNILATERAL SUBSTANTIA NIGRA LESIONS IN RESISTANT WISTAR RATS. N. Garcia-Cairasco and M.C. Doretto. Department of Physiology, School of Medicine of Ribeirão Preto, University of São Paulo, 14049, Ribeirão Preto - SP - Brazil.

Lesions or neurochemical manipulations of substantia nigra reticulata (SNR) have shown that this structure is differentially involved in control of threshold and seizure spreading in several epilepsy models. Muscimol and excitatory amino acid antagonists block audiogenic seizures (AS) in innately susceptible (S) rats and unilateral SNR lesions can sensitize resistant (R) rats to AS. In order to evaluate the participation of different nigral sites in these effects, we made a series of small (5 mCoulombs; n=28), medium (10mC; n=57) and large (15mC; 3 points of 5 mC each; n=19) unilateral electrolytic SNR lesions in R rats. Animals were evaluated at 5, 10 and 15 days post-surgery. Bilateral SNR lesions (15 mC type) were made in S animals and evaluated at 1, 3, 10 and 15 days post-surgery. The behavior was evaluated using a neuroethological method (Garcia Cairasco and Sabbatini, Braz. Med. Biol. Res. 16:171-181, 1983). Small unilateral lesions induced AS susceptibility in 17% of R animals with 5% of them displaying tonic-clonic AS. Medium size lesions induced AS susceptibility in 50% of the animals with 18% of these exhibiting tonic-clonic seizures similar to those displayed by naturally S animals but with predominance of wild running (gyri) contralateral to the lesioned SNR. The AS severity was higher at day 5 post-surgery, decreasing at days 10 and 15. Large SNR unilateral lesions destroying the whole SNR failed to cause tonic/clonic seizures, although procursive behaviors (giry, jumping and atonic falling) occur in 10% of the animals. Bilateral large SNR lesions did not modify AS in S animals, only inducing a statistically significant increase in the AS latency. The present data suggest: 1) The AS severity after SNR lesions is not a linear function of the lesion size; 2) Functionally different and antagonistic AS related substrates may exist in the SNR; 3) Neurochemical and hodological characterization of these areas should be important for a better understanding of their role in AS. Financial support: Capes (PICD), Brazil.

ANALYSIS OF NEUROPEPTIDE mRNA EXPRESSION AT DIFFERENT STAGES OF AMYGDALA KINDLING. J.B. Rosen, C.J. Cain*, S.R.B. Weiss, R.M. Post. Biological Psychiatry Branch, NIMH, Bethesda, MD 20982.

In situ hybridization was used to assess the spatiotemporal changes in neuropeptide mRNA during the evolution of amygdala kindling. Twenty-four hrs following a stage 1 or stage 5 amygdala kindled seizure or 2 weeks following a stage 5 seizure, autoradiograms with ³⁵S labeled oligonucleotide probes to mRNA of somatostatin (SOM), enkephalin (ENK), dynorphin (DYN) and thyrotropin releasing hormone (TRH) were analyzed by computer-assisted image analysis.

Consistent increases in SOM mRNA in the retrosplenial and fronto-parietal cortices were seen only after stage 1 seizures. ENK mRNA was increased in the pyriform cortex ipsilateral to the stimulation and bilaterally in the entorhinal cortex 24 hr after both stage 1 and 5 seizures. There was no change in DYN mRNA at stage 1. However, DYN mRNA in the dentate gyrus showed a decrease 24 hr (3 of 4 rats) and two weeks after a stage 5 seizure (3 of 5 rats). TRH mRNA was expressed ipsilateral to the stimulation in the pyriform and entorhinal cortices after stage 1, and ipsilateral or bilateral after 24 hr after stage 5. Dentate gyrus TRH mRNA levels were inconsistently increased after stage 1 but were increased bilaterally 24 hr after stage 5. Our results demonstrate both transient and more persistent alterations in regional expression of neuropeptide mRNAs which progressively evolve during the process of kindling.

INDUCTION OF VIMENTIN IMMUNOREACTIVITY IN THE BRAINS OF AMYGDALA KINDLED RATS. G.O. Ivy, M. Khurgel and R.J. Racine. Division of Life Sciences, Univ. of Toronto at Scarborough, Ont., M1C 1A4 and Department of Psychology, McMaster Univ., Hamilton, Ont. L8S 1B9.

Increased GFA content in astrocytes has been shown to accompany the establishment of the kindled state. We now report that vimentin (VIM), a functionally different cytoskeletal protein, accumulates in certain astrocytes following the development of kindling. The brains of amygdala kindled rats and electrode implanted control rats were processed for immunoreactivity (IR) to anti-VIM, anti-GFA and anti-BrdU (a marker of cell proliferation). While no VIM-IR was present in astrocytes of control animals, anomalous VIM-IR was detected in astrocytes in the amygdala-pyriform area as well as in hippocampus of kindled animals. Also, the extent of VIM-IR appeared to correlate well with both levels of afterdischarges and behavioral measures of seizures. There was a parallel, though much more extensive, increase in GFA-IR in these brain regions. No astrocyte proliferation was seen one week following the development of kindling. These results demonstrate that astrocytes differentially modify the composition of their cytoskeleton in response to abnormal levels of neuronal activity.

DESTRUCTION OF DENTATE GRANULE CELLS PROLONGS HIPPOCAMPAL ELECTRICAL AFTER-DISCHARGE BUT NOT THE RATE OF KINDLING ELICITED BY STIMULATION OF THE PERFORANT PATH. C. L. Mitchell and M. I. Barnes*. LMN/NIEHS/NIH, Research Triangle Park, NC 27709.

Colchicine (C) induced destruction of dentate granule cells (DGC) lowers the threshold for behavioral seizures elicited by stimulation of the perforant path (PPS) (Barnes and Mitchell, FASEB J. 5:A211, 1991). In contrast, kindling induced by stimulation of the entorhinal cortex is delayed by destruction of DGC (Frush et al. Exp. Neurol. 92:92, 1986). We were interested, therefore, in determining the effect of destruction of DGC on kindling induced by PPS. Rats were implanted with stimulating electrodes in the perforant path and recording electrodes in the dorsal hippocampal formation (HF). Kindling commenced 8 weeks after bilateral destruction of DGC in the dorsal and ventral HF. Destruction of DGC had no effect on the threshold for after-discharge (AD) before or after kindling. Neither did it affect the number of stimulations required to attain kindling. However, the duration of AD was significantly longer (2-3x) in C lesioned animals compared to those receiving artificial cerebrospinal fluid. This was true for the threshold for AD, the AD at the first kindling trial and the last kindling trial. These data suggest that DGC may inhibit the duration of AD induced by PPS or that other post lesion changes occur which result in a prolongation of the AD.

DECREASED INHIBITORY NEUROTRANSMISSION IN THE AMYGDALA-KINDLED RAT: A POTENTIAL MECHANISM OF EPILEPTOGENESIS.

K.M. Ryder*, W.F. Collins Jr., D.D. Spencer, and M.J. Doring. Dept. of Surgery, Yale Sch. of Med., New Haven, CT 06510.

An imbalance of excitatory and inhibitory influences, favoring excitation, may underly the initiation and spread of epileptiform discharge. Potassium stimulated release of GABA from slices in animal models of epilepsy has not conclusively demonstrated a depressed GABA response, and GABA release in response to glutamate (GLU) stimulation has not been studied. In normal brain tissue, GLU-induced GABA release is not calcium-dependent and is thought to involve reversal of the GABA transporter. We used microdialysis to investigate GABA release in response to potassium and GLU perfusion in both hippocampi of freely-moving amygdala-kindled rats. One week after the last seizure, dialysis probes were implanted; the probes were perfused with artificial extracellular fluid the following day. The perfusate was analyzed for GABA concentration by HPLC. After baseline collections, either 56mM potassium or 5mM GLU (pH 7.4) was perfused through the probe. GABA release in response to potassium perfusion was not attenuated in kindled rats, while GLU-induced release was significantly lower. GLU-induced GABA release is not blocked by the absence of calcium, while it is attenuated after 1 hour preincubation with nipecotic acid, a GABA transporter inhibitor. These *in vivo* studies demonstrate that GLU-induced GABA release is not calcium-dependent in the rat hippocampus, and that there is a depressed GABA response to GLU perfusion in kindled rats.

201.10

MODULATION OF POSTSEIZURE REFRACTORY PERIOD BY THE ADENOSINE SYSTEM IN AMYGDALA KINDLED RATS.

R. J. Kleinsorge¹, M. F. Jarvis², and B. E. Berman¹. ¹Dept. of Psychology, Wayne State Univ., Detroit, MI. 48202, ²Rhone-Poulenc Rorer Central Research, Horsham, PA 19044.

"Kindled" seizures can be produced in rats by giving low-intensity electrical stimulation to the amygdala. Kindled animals are typically refractory to further seizures for a short time following the initial seizure. The hypothesis that the refractory period is due, in part, to the activation of the brain adenosine system following a seizure was tested. Rats were electrically stimulated for 1 sec, once per day, through an electrode stereotactically implanted into the amygdala until fully generalized kindled seizures were produced. Trials of paired stimulations, separated by increasing time intervals out to 25 min, were then given to determine the refractory period. Adenosine receptors were then up-regulated by injecting animals for 14 days with theophylline (75 mg/kg/day). Seizure severity at the end of the previously determined refractory period was then tested. Chronic theophylline treatment significantly increased [³H]-cyclohexyladenosine binding in thalamus, hippocampus and cerebellum. In addition, the seizure refractory period was significantly shortened, although the response to the initial stimulation was unchanged. The effect of receptor modification lasted about nine days after the last theophylline injection. These results support a role for adenosine in the kindled-seizure refractory period. (Supported by NIH Grant GM 08167).

RELATIONSHIP BETWEEN MAXIMAL DENTATE ACTIVATION AND AFTERDISCHARGE PRODUCTION IN THE ANESTHETIZED RAT. J.L. Stringer and E.W. Lothman, Dept. Neurology, Univ. Va. Med. Ctr., Charlottesville, Va. 22908.

Recently, a phenomenon has been described in the dentate gyrus, termed maximal dentate activation, which is defined by the appearance of bursts of large amplitude population spikes associated with a negative shift of the DC potential and a secondary rise of the extracellular potassium level. Previous work has linked maximal dentate activation to kindling of afterdischarges, either when they are elicited in the hippocampus or outside of the hippocampus in the amygdala. Recording bilaterally in the dentate gyrus, it was found that maximal dentate activation occurred on both sides, with the side ipsilateral to the stimulus (either CA3 or angular bundle) being activated first. An afterdischarge did not appear unless bilateral maximal dentate activation had occurred. With repeated stimulation, the time to onset of maximal dentate activation on the two sides of the brain became nearly equal. This was associated with the appearance of afterdischarges. However, complete synchronization of the onset of maximal dentate activation was not necessary for afterdischarge production. Maximal dentate activation and afterdischarges could be readily elicited in rats in whom the hippocampal commissures had been cut. It appears that, in the intact brain, the lack of maximal dentate activation on one side of the brain can function as a "brake" for epileptic activity, preventing afterdischarges. Once this brake is removed, by cutting the hippocampal commissures or by initiating maximal dentate activation, the dentate gyrus readily expresses afterdischarges.

ELECTROPHYSIOLOGY OF PAIR-PULSE RESPONSES IN HIPPOCAMPAL CA1 IN VITRO. Xiao-Wen Fu, L. Stan Leung and D. Zhao*, Depts. Clin. Neurol. Sci. and Physiology, Univ. Western Ontario, London, Ontario N6A 5A5 Canada.

Previous studies in our laboratory indicate that the pair-pulse response in the hippocampal CA1 is facilitated by kindling and modulated by behavior. The electrophysiology of the pair-pulse response evoked by str. radiatum stimulation in hippocampal CA1 in vitro was studied here. Both field and intracellular data indicated that the excitatory postsynaptic potentials (EPSPs) in pyramidal cells were facilitated by about 20-30% at an interpulse interval (IPI) of 30-100 ms. Pair-pulse facilitation of the population spike varied from >200% at low stimulus intensity to about 20% at high intensity, the maximal facilitation also occurred at 30-100 ms IPI. Bath perfusion of bicuculline methiodide (25-50 μ M) significantly increased the pair-pulse index of the intracellular EPSPs (EPI = slope of 2nd EPSP/ slope of 1st EPSP) to > 1.5 at 40-90 ms IPI, as did perfusion of 8mM $[K^+]_o$. Perfusion of 10mM $[Mg^{2+}]_o$ reduced the EPI to near unity at all IPIs, with or without bicuculline. High Mg^{2+} may suppress pair-pulse facilitation by suppressing a presynaptic Ca^{2+} current; thus, the effect of bicuculline on the EPI may be presynaptic, though postsynaptic effects have not been totally excluded. The contribution of the spike afterhyperpolarization (AHP) was studied by stimulation at intensities that sometimes evoked a first spike and sometimes not. The effect of the AHP on the EPSP and the latency and amplitude of the spike evoked by the 2nd pulse at 30-200 ms IPI was small. Putative glial cell recordings indicated that even at submaximal stimulus intensities, a single afferent pulse evoked depolarization of 2-5 mV suggesting that $[K^+]_o$ increased by 0.5-1 mM, which may facilitate the spike response to the 2nd pulse. In summary, bicuculline or high $[K^+]_o$ (or kindling) enhances the pair-pulse facilitation of the EPSP, possibly through suppression of presynaptic GABA-A inhibition. (Supported by NSERC and NS25383).

KINDLING IN THE PERIRHINAL CORTEX. I. KINDLING RATE AND SEIZURE CHARACTERISTICS. M. E. Kelly, J. N. Armstrong and D. C. McIntyre, Department of Psychology, Carleton University, Ottawa, Ontario K1S 5B6.

Evidence suggests that the pyriform cortex (PC) plays an important role in the genesis and/or maintenance of secondarily generalized limbic-kindled seizures. In *in vitro* experiments, we have shown that the PC and overlying perirhinal cortex possess a strong disposition for developing spontaneous rhythmic burst discharges, and that the relationship between these two areas changes as a result of previous *in vivo* amygdala kindling.

Since the PC manifests rates of kindling faster than any other structure in the limbic system, we compared the PC, amygdala and perirhinal cortex for their respective rates of kindling. The perirhinal cortex kindles faster than the PC and amygdala. Further, the latency to onset of forelimb clonus was much shorter in the perirhinal subjects. These findings suggest that the perirhinal cortex may be more intimate with the mechanisms of secondary generalization than the PC or amygdala.

201.12

EPILEPTIFORM POTENTIALS IN SLICES OF PIRIFORM CORTEX FROM KINDLED RATS ORIGINATE IN DEEP STRUCTURES. W.H.Hoffman* and L.B.Haberly, Neuroscience Training Program and Dept. of Anatomy, Univ. of Wisconsin, Madison WI 53706

In previous studies from this laboratory it has been shown that bursting activity evoked by a variety of manipulations in slices of piriform cortex induces persistent epileptiform EPSPs by an NMDA dependent process. These epileptiform responses have recently been shown to be driven by deep cells concentrated in the endopiriform nucleus and adjacent structures that underlie the piriform cortex (Hoffman & Haberly, J. Neurosci., in press). Since similar epileptiform responses occur in the piriform cortex of kindled rats *in vivo* (Racine et al., Br. Res. 322:101; Russell & Stripling, Br. Res. 361:61), the present experiments were undertaken to determine if kindled epileptiform activity in slices of piriform cortex also originates in deep cells. Rats were kindled by standard methods through bipolar electrodes chronically implanted in the olfactory bulb. Experiments were performed on 7 rats that had undergone 30 to 82 class 5 seizures and 3 littermate controls that had received low rate stimulation. Slices were prepared 1 to 50 days after the last seizure. Long latency epileptiform (all-or-none) components were observed in intracellular and extracellular responses to stimulation of excitatory fiber systems in standard bathing medium in 6/7 kindled rats. These epileptiform components closely resembled those induced in slices from normal rats by bursting activity. No epileptiform activity was observed in implanted or normal controls. Three observations suggest that these responses originated in deep cells: (a) they were typically high in amplitude and suprathreshold in cells in the endopiriform nucleus vs small and subthreshold in superficial pyramidal cells, (b) local injection of glutamate and KCl through micropipettes evoked epileptiform potentials only in the endopiriform nucleus and adjacent claustrum, and (c) local injection of Ca^{2+} blocked epileptiform EPSPs only from the endopiriform nucleus and adjacent portion of the claustrum. These results provide further evidence that cells at the deep boundary of piriform cortex play an important role in epileptogenesis and suggest that studies of epileptiform activity induced by bursting *in vitro* may have implications for kindled epileptogenesis. Supported by grant NS19865 from NINDS.

201.14

EFFECTS OF ANTICONVULSANTS AND NMDA ANTAGONISTS ON HIPPOCAMPAL LTP AND KINDLING-INDUCED PLASTICITY. L. Stan Leung and B. Shen*, Depts. Clin. Neurol. Sci. and Physiology, Univ. Western Ontario, London, Ontario N6A 5A5 Canada.

Recently, we found a robust long-term potentiation (LTP) of the commissurally activated basal-dendritic synapse on CA1 pyramidal cells in freely moving rats (Leung, Neurosci Abstr 16:652). Here, we studied the effects of 2 NMDA antagonists APV and MK-801 and 2 anticonvulsants (phenytoin, U54494A) on the LTP induced by 2 types of tetanic stimulations in chronically implanted rats: (1) Primed bursts (PB: 8 bursts, each of 1 pulse followed 190ms later by 10 pulses at 100 Hz); no afterdischarges (ADs) were evoked. (2) 1-s, 200 Hz high-frequency tetanus followed by an AD (HF). Counter-balanced, repeated tetani were given. In un-drugged rats, LTP was evoked by the PB; a smaller LTP was evoked after an AD (of > 15s duration) by HF, preceded by 5-30 min depression. Intraventricular (icv) 20 μ g D,L-APV blocked the LTP induced by PB or HF ($P < 0.0001$; ANOVA), but had no effect on the AD duration or the early depression following an AD. At 30 min post-PB, LTP after APV was 1.26 ± 0.22 times the baseline population EPSP slope values, vs 2.09 ± 0.36 after icv saline injections. MK-801 (0.5mg/kg ip) had a weaker (but significant) effect on blocking LTP. U54494A (50mg/kg ip) and phenytoin (40mg/kg ip) had no effect on the PB-induced LTP. However, U54494A and phenytoin attenuated the AD duration and depression induced by HF, thus apparently enhancing the HF-induced LTP. In conclusion, (1) LTP following a PB or HF (with AD) in behaving rats was blocked by NMDA antagonists. (2) A long-term depression and an even more persistent LTP followed an AD (evoked by HF). (3) U54494A and phenytoin had no effect on the LTP induced by PB, but they enhanced the LTP following a HF perhaps by partially blocking the AD and the AD-induced depression. Supported by UpJohn, NS-25383 and NSERC.

Regulation of α -CaM Kinase II Gene Expression in Kindling. J.B. Perlin, E.R. Jakoi*, C.M. Gerwin*, and R.J. DeLorenzo, Depts of Neurology and Pharmacology, Medical College of Virginia, Richmond VA 23298-0599.

The Rapidly Recurring Hippocampal Seizure (RRHS) or 'rapid kindling' model was used to explore regulation of the activity of type II calcium/calmodulin-dependent protein kinase (CKII). In crude synaptic plasma membrane, CKII activity was found to be 56% inhibited 6 weeks following administration of the kindling paradigm. Limited inhibition of CKII was also found in this same fraction immediately after kindling. Diminished activity could not be accounted for by loss of the enzyme itself as CKII was present on polyacrylamide gels in equal proportion to kinase from naive and surgical control rats. In addition, biotinylated calmodulin binding to CKII was not reduced compared to either control group suggesting that neither proteolysis nor loss of calmodulin-binding capacity had occurred.

To assess pretranslational regulation of CKII expression, steady state levels of mRNA encoding CKII were measured by slot hybridization assays. Blots were probed with an oligonucleotide complementary to the 3' noncoding tail of the α -subunit of CKII (c.f. Burgin et al, J. Neurosci. 10:6(1990):1788-98). An increase in mRNA for the α -subunit of CKII was observed following electrically-induced hippocampal seizures in both non-kindled and kindled animals, suggesting that a transient increase in CKII transcription occurs following limbic seizure. However, long-term expression of α -CKII message (6 weeks) after kindling was not different from either control group. Thus, sustained alterations in CKII activity following kindling arise at the level of post-translational modification.

201.17

TIME COURSE OF SELECTIVE NEURONAL DAMAGE AFTER STATUS EPILEPTICUS (SE) TRIGGERED FROM A KINDLED AMYGDALA FOCUS: A SILVER IMPREGNATION STUDY. L.E. Markert, D. C. McIntyre, M. E. Kelly and D. C. S. Roberts. Department of Psychology, Carleton University, Ottawa, Ontario K1S 5B6.

After development of 6 generalized kindled seizures, rats were exposed to amygdala stimulation triggering either partial or generalized SE. The time course of brain damage was studied using Nadler and Evenson's silver staining method after 2, 6, 24, or 72 hrs of partial SE, or 2 hrs of generalized SE.

Six hrs of partial SE produced argyrophilic cells in dorsomedial thalamus, endopyriform n., pyriform and perirhinal cortex ipsilateral, but not contralateral, to the kindled amygdala. Bilateral damage appeared in reuniens n. and, unexpectedly, bed n. of stria terminalis. No hippocampal damage was observed after 24 hrs, when ipsilateral CA1 showed darkened nucleoli and, within 3 days, argyrophilia. Novel fibers were seen in thalamus and cerebral peduncles, but not substantia nigra reticulata (SNR). On the other hand, generalized SE caused extensive argyrophilia bilaterally in neocortex, and massive silver granules in SNR.

201.19

PENTYLENETETRAZOLE (PTZ) KINDLING IN DIAZEPAM-SENSITIVE AND -RESISTANT MICE, M.C. Anderson and E.J. Gallaher. Depts. of Medical Psychology & Pharmacology, Oregon Health Sciences University and Portland Veteran's Administration Medical Center, Portland, OR. 97201

In this study we induced chemical kindling in diazepam-sensitive and -resistant (DS & DR) lines of mice by daily administration of pentylenetetrazole (PTZ). These mice were derived from heterogeneous stock (HS/lbg) mice in our laboratory, and were initially selected for differential sensitivity to sedative effects of diazepam. They have subsequently been tested for a number of behavioral and neuro-chemical parameters. DS mice are 15 fold more sensitive to motor impairment produced by diazepam as compared to DR mice, but show no differences to anti-convulsant properties of diazepam or in acute response to chemical convulsants acting at the GABA-benzodiazepine binding site (Gionet & Gallaher, 1989, Soc. Neurosci. Abst. 15:668). In the current study, DS and DR mice were treated daily with 35 mg/kg PTZ to induce sensitivity to the convulsant activity of PTZ (PTZ-kindling). Mice were monitored daily following PTZ treatment for the presence of myoclonic jerks, mild clonic seizures characterized by facial clonus and rearing, tonic-clonic hindlimb extensor seizures and death due to *status epilepticus*. At the end of 1 week, DR mice were fully kindled and showed a decreased threshold to tonic-clonic hindlimb extensor seizures induced by intravenous PTZ, in addition, 64% died in *status epilepticus*. DS mice failed to show a kindled response. Pilot EEG studies showed that kindled DR mice displayed intermittent spiking 24 hours following treatment with PTZ. These data suggest differences in the underlying functional mechanisms, possibly GABAergic, governing convulsive behavior between DS and DR lines of mice. Research supported by NIAAA Grant # 5T32 AA07468-04, NINCDS Grant # 23927 and VA Medical Research Service.

201.18

EFFECT OF CHRONIC NALOXONE TREATMENT ON BENZODIAZEPINE RECEPTOR LEVELS IN NORMAL AND KINDLED RATS. L. Rocha, J. Engel Jr., H.T. Chugani, K. Tatsukawa * and R.F. Ackermann. UCLA School of Medicine, Los Angeles, CA 90024.

We found that chronic naloxone pretreatment facilitates amygdaloid kindling and enhances postictal depression. Benzodiazepine (BZ) receptors were studied in naloxone pretreated rats (NA) (n=3), kindled rats with naloxone (N+K) (n=3) or saline (S+K) (n=3) pretreatment and control saline pretreated rats (S) (n=3). Stimulation electrodes were implanted in anterior amygdala. Animals received chronic treatment (14 d) with osmotic minipumps s.c. containing either saline or naloxone solution (the delivery rate was 75 µg/h). S and NA rats were sacrificed 48 h after completion of treatment. After the minipumps were withdrawn, S+K and N+K received daily amygdaloid kindling trials until they experienced 5 stage V seizures or 30 kindling trials. They were sacrificed 24 h after the last stimulation. BZ binding sites were labeled with 3H-flunitrazepam (2 nM) and their levels were determined by quantitative autoradiography. Compared to S group, NA group presented 90% increase of BZ receptors in substantia nigra; S+K animals showed an enhancement of 78% in dentate gyrus (78%), whereas N+K rats presented 81% and 130% increase in dentate gyrus and substantia nigra respectively. These data show that chronic naloxone treatment alters BZ receptor binding in substantia nigra, an effect that persists during the kindling process possibly contributing to the seizure suppressive effect.

TEACHING OF NEUROSCIENCE: COURSES AND PROGRAMS

202.1

ORGANIZATION OF AN INTERDISCIPLINARY INSTITUTE FOR NEUROSCIENCE AT NORTHWESTERN UNIVERSITY. P.E. Meyers. Institute for Neuroscience and Department of Neurobiology and Physiology, Northwestern University, Evanston, IL 60208.

During the planning phases of a graduate program for a large interdisciplinary institute for neuroscience at Northwestern University we sought to satisfy a number of objectives; 1) identify and present a common core of information to all students, 2) provide the benefits of both interdisciplinary and departmental programs, 3) provide a broad exposure to research in neuroscience, and 4) promote a sense of community among the members of the institute and rapidly incorporate new students into the community. The institute is dispersed over two totally separate campuses and includes 88 faculty in several schools and departments.

The salient features of this program include: all students take a series of common core courses, students become affiliated with individual departments and satisfy modest course requirements for that department, students are exposed to the research of institute members through seminars and special events, students conduct at least brief research projects on both campuses of the University, and the institute promotes a number of special events that combine social and scientific opportunities for all of its members.

After two years of experience with this program, we are reviewing our success, and invite discussion.

202.2

THE NEUROBIOLOGY OF DISEASE: A GRADUATE COURSE FOCUSING ON HUMAN NERVOUS SYSTEM DISEASES AND DISORDERS. E.A. Kravitz and W.J. Korshetz. Depts. of Neurobiology and Neurology, Harvard Medical School and MGH, Boston, MA 02115. Aimed at graduate students, MD/PhD, MD students and advanced undergraduates, this course is designed to introduce students to the diseases and disorders of the nervous system. The course involves patient presentations, clinical and basic science core lectures, literature readings, student seminar presentations and general discussion of each topic. The course meets two evenings a week and a major disease or disorder is covered each week. Topics covered in a typical year include Muscular Dystrophy, Myasthenia Gravis and Myasthenic Syndrome, Multiple Sclerosis, Huntington's, Parkinson's and Alzheimer's Diseases, Amyotrophic Lateral Sclerosis, Epilepsy, Chronic Pain, Viral Attack on the Nervous System, Stroke and Affective Disorders. Approximately 20 students register for the course and between 20 and 30 regularly attend. Each week the first session begins with a patient presentation by a clinician, who is told to address his/her remarks to non-specialists. Clinical and basic science core lectures finish these sessions. The second session each week is reserved for student presentations of assigned readings and general discussion. The goal of the course is to educate students about the diseases and disorders of man, to show them in a clear and direct way that the fundamental research they are performing is relevant to the problems of mankind, and to leave them prepared to make extrapolations between what they are doing and the important unsolved diseases of man.

202.3

USE OF CLINICAL CORRELATIONS IN THE TEACHING OF NEUROSCIENCE. M.E. Melnick. Dept of Physical Therapy. Wayne State Univ., Detroit, MI 48202.

Students in a professional program consistently desire clinical information while learning basic science courses. Case histories can be used in many ways to enhance learning of neuroanatomy. Traditionally, lesion questions have been used in which the student must detail the specific signs and symptoms expected with a variety of lesions or a detailed evaluation of a patient is presented and the student must then decide upon the probable localization of the lesion. Use of CT and PET scans as well as MRIs are often more effective than diagrammatic pictures. These applications can be taken a step further and incorporate clinical decision making and evaluation techniques with the basic science. The student is given a detailed description of the patient as they are sitting in the waiting room and as they move to the treatment room. From this description the student must begin a problem solving approach that requires a listing of the problem(s), the possible tracts or area(s) of the nervous system that could be involved and the methods they would use to determine which of their possibilities is most correct. Students have found this last approach challenging, helpful in integrating the material.

202.5

USE OF EASY-SHAPING MATERIAL TO FOSTER THE TEACHING-LEARNING PROCESS OF NEUROEMBRYOLOGY. M.C. Márquez-Orozco, A. Márquez-Orozco and A. Lastiri*. Embriol. Dept. Sch. of Med. and Center Inv. Educ. Serv. UNAM. P.O.B. 70-553 México 04510 D.F. MEXICO.

Psychometric tests were applied to 180 freshman students of the School of Medicine (UNAM) to analyze their IQ, their abstraction capacity and spatial perception, as well as their analysis and synthesis of thought. We found that 85% of the students had difficulties to establish space relations and make abstractions. Half of this population randomly selected, was submitted to a teaching-learning strategy which included the use of easy-shaping material made of wheat flour, aimed at testing whether this didactic resource fosters acquisition of the knowledge of CNS development. The other half of the students underwent traditional teaching, lacking this resource. Models that change shape according to the different stages of the CNS development were made, using colored material for each of the different structures of the CNS developing sequence. Results were evaluated through the institutional test of achievements and a year after applying this strategy, the same psychometric tests were given to the same students. Achievement, measured in terms of their capacity for spatial abstraction and perception, and abstraction and synthesis of thought, were significantly higher ($p < 0.01$).

202.7

EXPERIENCES IN TEACHING HUMAN PHYSIOLOGY TO MEDICAL STUDENTS. E. Gijón and X. García. Dept. of Physiol. Sch. of Med. Universidad Nacional Autónoma de México. Ap. P. 70-250, México, D.F. 04510. MEXICO.

Due to changes in the medical curriculum and a decrease in the number of students for each group, our groups instead of being formed by 80 or more students are actually formed by an average of 30 students. The change in the curriculum started in 1985, so it is known as Plan 1985. The time of one semester with 200 hours was changed to one year with 320 hours for Human Physiology. The time for theory and the reduction in the number of students led to a change in the traditional lecture for student oral presentation tutored by their professor. The traditional exercises of laboratory have been extended to an innovative program called Directed Projects. The first change allowed us to know what the student understood of every topic with his own words, and the second change to introduce the student to the scientific method. The effectiveness of both changes have positive results, as it can be judged by the improved grades obtained by the students, and the increase in the % of accreditation of the course.

202.4

•WHY EXCELLENT STUDENTS MISS EASY QUESTIONS: THE PROBLEM OF SYNONYMS AND MULTIPLE MEANINGS IN FUNCTIONAL NEUROANATOMY. • T. R. Anthony. Behav. & Soc. Sci., Sch. of Med., South. Ill. Univ., Carbondale, IL 62901.

•A student knows a term but not its synonyms. S/he learns an accepted meaning of a term but is unaware of alternative accepted meanings. An instructor asks questions using a synonym or an alternative meaning. Result?—wrong answers and confusion.

A rare occurrence? Probably not. Review of 26 recent textbooks of functional neuroanatomy, including those used most at schools of medicine or osteopathy in the USA and Canada in 1985, revealed 2-12 synonyms for each of 474 terms and multiple meanings for 368 terms. Many terms with multiple meanings are basic—e.g., aphasia, ataxia, basal ganglia, bradykinesia, brainstem, bulbar, cerebral and cerebellum, cerebral peduncle, hemiplegia, interneuron, involuntary movement, medial lemniscus, nerve and nerve root, neuroglia, nystagmus, peripheral nerve, recent memory, rigidity, scotoma, somatosensory, spinthalamic tract, tegmentum, tic, tremor, and visual field(s).

Though continued work toward a standardized set of terms and meanings is desirable, the Nomina Anatomica experience suggests that the problem will remain substantial. A reference text, indexed by term for rapid access to synonyms and multiple meanings, seemed desirable and was written. Details of its preparation and contents are described. Also, sample questions with multiple incompatible correct answers are given, as are questions involving synonyms.

202.6

A CHANGE IN THE TEACHING LABORATORY OF HUMAN PHYSIOLOGY. M. Najjar-Joa*, B. Barrera-Mera, and P. Vergara*. Depto de Fisiologia Fac. Medicina UNAM Mexico 04510 D.F.

When in 1985 a curricular change in the medicine studies at our faculty was announced, it looked as a nice opportunity to make also a change in the practicing activities at the laboratory, thus achieving a more scientific approach in the teaching of Human Physiology. The academic activities were divided in two phases. In the first one the old model was used, with the teachers directing the activities and the students learning the techniques and being progressively prepared to handle the concepts of hypothesis, variables and analysis. The second phase was named "Free Projects Phase" and was aimed to prepare students to develop a research project based on their own ideas. The change of model was not easy one. Teachers' response was divided among positive and negative opinions: fortunately there were more positive responses. The students were more receptive although some of them were afraid of this new approach. The most frequent complaint of the students was the lack of freedom to develop their original ideas. A very difficult aspect was on the teachers' side, their different approaches. Due to the lack of resources to handle all the projects, it was necessary to direct the work to those projects for which the required material was available. The students response, however was amazing. Some students bought their own material or equipment, or went to other institutions to ask for information and support. More than 60 per cent of the projects were on Neuroscience Research.

202.8

NEUROSCIENCE IN AN EXPANDING OPTOMETRIC CURRICULUM. P. Simmons and W.H. Ridder*III, Southern California College of Optometry, 2575 Yorba Linda Blvd., Fullerton, CA 92631.

In a growing national trend, optometrists are becoming increasingly responsible for the diagnosis and/or treatment of both ocular and systemic disease. Thus neuroscience, along with other biomedical sciences, is becoming a more important component of optometric training. The challenge in the optometric curriculum is to provide additional material in biomedical sciences without sacrificing traditional optometric training in optics and visual science. At the Southern California College of Optometry, neuroscience is taught in a lecture/laboratory combination in which lectures focus on clinically relevant neurophysiology, and laboratories provide intensive training in the clinical correlates of neuroanatomy, with emphasis throughout on the sensory and motor aspects of the visual system as well as the cranial nerves. In later portions of the course, students are asked to determine the anatomical correlates of clinical symptoms or signs, including those functions evaluated in a complete optometric examination, such as visual fields and oculomotor functions. The aim of this course design is to provide a broad background in basic neuroscience while keeping the number of class hours relatively low, currently approximately 30 hours each for lecture and laboratory. Thus, students are able to integrate an increased amount of neuroanatomical knowledge into their 4-year professional program.

202.9

SHOULD A SCIENCE ORIENTED TEACHING BE DIRECTED TOWARDS MEDICAL STUDENTS? EXPERIENCES IN THE TEACHING LABORATORY THROUGH DIRECTED PROJECTS. L.P. Solano-Flores, R. Guevara-Guzmán, G. Reyes-Guerrero*, and M.P. Rosas-Arellano*. Fisiología, Medicina-U.N.A.M. A.P. 70250, 04510 México, DF.

WHAT?, HOW?, and WHY? These are the questions to be kept in mind whenever trying to understand nature by means of a scientific pathway. A laboratory is a place where nature variability can be restricted in order to OBSERVE -to answer the "WHAT"-, to DESCRIBE -to answer the "HOW"-, and to INTERPRET -to answer the "WHY"-.

The Teaching Laboratory is the optimal tool to awake, to develop, and to mature the inquiring, critical, analytical and integrative attitudes needed to understand nature. One question: Should a science oriented teaching be directed towards medical students? The answer: Since a great similitude essentially exists among the physiological, pathological and the therapeutical phenomena, then "every physician should be an experimenter" (Claude Bernard). Thus, since the utmost way to understand science is precisely making science following the complete path, the above ideas have been limited in the Directed Projects Phase of the Teaching Laboratory in the Human Physiology Course for medical students. In order to achieve this, a deep and huge effort is required from both students and academic staff to change the established conceptions and methods to acquire knowledge. This experience, however, is worthwhile to live. The purpose of this work will be to present our experiences on this teaching modality.

202.11

A NEUROSCIENCE PROGRAM AT A LIBERAL ARTS COLLEGE. J. J. Ramirez. Dept. of Psychology, Davidson College, Davidson, NC 28036.

The objective of our educational program is to enhance the training and enrich the experience of students interested in CNS. To this end, we are developing a curriculum in Neuroscience. This program consists of three levels of training: 1) an introductory and advanced course in neuroscience, 2) advanced seminars, labs, and independent studies, and 3) a research project in which original research is conducted by students. An integral component of each level involves training in laboratory methods, with the aim to guide students from the structured lab exercises of the introductory course to a level of competence at which the students may productively pursue independent research. Behavioral, neuroanatomical, and neurophysiological components of the program are presently in place. The students emerge from our program with an understanding of the theoretical and empirical literature in neuroscience, a sophisticated appreciation of scientific methods and analysis, and extensive laboratory skills. As a result, these students are well prepared to pursue careers in science, medicine, or public policy. Supported by The Pew Charitable Trusts.

202.13

TEAM-TAUGHT INTRODUCTION TO NEUROSCIENCE COURSE. L. J. Achor, L. M. Barker*, J. R. Flynn, J. H. Patton, and C. A. Weaver III*. Dept. of Psychology, Baylor Univ., Waco, TX 76798-97334.

We offer an entry-level team-taught course on introductory neuroscience, which is used by 250 students per year to partially satisfy the university requirement for three laboratory science courses for the bachelor's degree. It is taken by both science majors and non-science majors.

The goals for this course include (1) the presentation of a balance of classic and current information on theory, methods, and findings in neuroscience; (2) the enhancement of scientific literacy; (3) increased understanding of scientific methodology; (4) encouragement of intellectual skepticism and critical thinking; and (5) the development of greater understanding of those individuals whose thinking and behavior are different from the norm.

Our primary purpose in team teaching *Introduction to Neuroscience* has been to enable a group of professors to bring to the course their individual expertise in major areas of the rapidly expanding field of neuroscience. Each of the five members of our team teaches a three-week unit. To enhance the flow of information and smooth the transition from one professor to another, lecture outlines and abbreviated notes are provided to the students at the beginning of the semester.

Computer exercises simulating scientific procedures and phenomena in neuroscience are used to facilitate learning of the neuroscience curriculum.

202.10

TEACHING NEUROSCIENCE IN AN UNDERGRADUATE INSTITUTION: A GRADUATE MODEL IN AN UNDERGRADUATE INSTITUTION. M. J. SAARI. Neuroscience Research Unit, Nipissing University College, North Bay, Ontario, Canada P1B 8L7.

An undergraduate neuroscience teaching model based on undergraduate research participation is described. The model involves extensive "hands-on" laboratory experience with an emphasis on research productivity and dissemination of results through conference papers and manuscripts. The model attempts to create a typical graduate neuroscience laboratory experience using the student/advisor apprenticeship relationship commonly found in graduate schools. The students involved are undergraduates. The model was developed in order to allow undergraduates the opportunity to gain research skills and to demonstrate their potential for research productivity thereby allowing an early start to their careers as research neuroscientists. Student case studies are presented to demonstrate the effectiveness of the model.

202.12

TEACHING NEUROSCIENCE: PUT PRINCIPLES BEFORE DETAIL. F. Delcomyn. Department of Entomology and Neuroscience Program, University of Illinois, Urbana, IL 61801.

Beginning students studying neuroscience are often so overwhelmed by the presentation of the minute facts and detailed experimental results of the subject that they lose any sense of their meaning. When teaching beginning students it is imperative to provide a context within which specific facts or experimental results can be understood. The principle will be illustrated with examples from two different neuroscience areas. The first example, from the area of membrane channel diversity, will describe a sample of the enormous variety of channel types present in nerve membranes. The second, from the area of sensory-motor integration, will describe results of several experiments in which sensory feedback has been manipulated during a motor performance. Each set of material will be described as it might be in typical textbooks. However, further explanatory, context-setting material will be provided and highlighted, so that in each case viewers of the poster will be able to examine the factual material with or without specific consideration of the context of the information. In this way, viewers will be able to judge the added effectiveness of an attention to context and underlying scientific principles.

202.14

AN UNDERGRADUATE COURSE IN BEHAVIORAL NEUROSCIENCE. C.H. Vanderwolf. Dept. of Psychology, Univ. Western Ontario, London, Ontario, Canada, N6A 5C2.

Undergraduates who have completed introductory biology, psychology, and a brain-behavior lecture course may enroll in a laboratory course (13 weeks) comprising 3 hrs laboratory and 1 hr lecture/week. Laboratory exercises include: (A) neuroanatomy and neurohistology, 7 weeks; (B) brain lesions and behavior, 1 week; (C) recording brain electrical activity and behavior, 1 week; (D) drugs and behavior, 1 week; and (E) electrical stimulation of the brain, 1 week. Demonstrations are also given. Evaluation is based on written and practical examinations on A plus written reports on B-E. A laboratory manual for topic A (Vanderwolf, C.H., & Cooley, R.K. *The sheep brain: a photographic series*, London, Ontario: A.J. Kirby, 1990, 105 pp.) and instructions for topics B-E have been prepared. The course has been refined over a period of over 20 years.

202.15

AN INTEGRATED APPROACH TO TEACHING NEUROSCIENCE. C.A. Paul and B.S. Beliz. Dept. Biol. Sci., Wellesley College, Wellesley, MA 02181

A multi-disciplinary approach is used to examine aspects of structure, function and biochemistry in the adult leech nervous system. Students are expected to relate their findings to developmental mechanisms illustrated in the lecture.

1. Immunocytochemical localization of transmitters: Amine and peptide antibodies are utilized to ask: "Are labelling patterns for particular transmitters distinctive or similar?" These studies illustrate how determinate developmental mechanisms result in stereotyped patterns of organization.

2. Anatomical characterization of identified neurons: Neurons identified immunocytochemically are injected with lucifer yellow by iontophoresis to answer: "What is the anatomical profile of a particular neuron?"; "Is this profile the same between segmental ganglia and between animals?" Students learn that there is tight developmental control over primary branching patterns but less regulation of the secondary pattern.

3. Physiological characterization of the identified cells: Thresholds, action potential shapes and response properties of the identified neurons are determined. Extracellular stimulation of peripheral nerve roots and connectives, while recording intracellularly, can verify whether projections identified by dye injection can be demonstrated physiologically.

4. Independent projects: Students formulate new questions, utilize the above methods to generate and analyze novel data, and compose a research report.

This sequence fulfills four goals in addition to teaching the scientific method: (1) to "demystify" science by using state of the art technologies; (2) to provide an opportunity for discovery by exploring current problems; (3) to illustrate the interdisciplinary nature of science by using several methods to address related questions; and (4) to learn to communicate ideas and think critically. (Supported by NSF - ILI grants #USE- 8851888 and #USE-9152022)

202.17

A SUCCESSFUL FORMAT FOR COVERING TWELVE NEUROPHYSIOLOGY LABORATORIES IN FIVE LABORATORY SESSIONS. J. Hore, J. Van Dijk-Smith* and M. Robinson. Dept. of Physiology, University of Western Ontario, London, Ont. Canada N6A 5C1.

Objective: To expose 48 third year science students to a large number of neurophysiological concepts and phenomena in an active learning laboratory situation. **Constraints:** 5 three hour sessions, minimum budget, but 12 teaching assistants. **Method:** Students sign up for one of 12 experiments that illustrate important concepts presented in concurrent lectures. They include: Rat motor cortex, Rat evoked potentials, Human eye movements, Frog and human vestibular function, Rat Parkinson's disease, Frog spinal reflexes, Rat VMH lesion, Human EEG, Rat dorsal column recording, Rat limbic lesion, Human evoked potentials. Over the first 3 laboratory periods students develop expertise in their chosen experiment. On week 4, half of the students present their experiment in a 10 min demonstration to their classmates in a "bell ringer" format, i.e. 2 members of the group present 11 times to rotating groups of two. On week 5 roles are reversed. Emphasis is placed on the 2 visitors having a hands-on experience and being able to ask questions. Objectives and answers to objectives are provided for all experiments. This format in which any one student sees the 11 other experiments in a student-teaching-student situation has proven to be highly successful.

202.19

AN OPTIMAL SEQUENCE IN NEUROSCIENCE FOR PHYSICAL AND OCCUPATIONAL THERAPY STUDENTS. S.S. Palmer. Dept. of Physical Therapy, Texas Tech Univ. Sch. of Allied Health, Lubbock, TX 79430.

The optimal time for learning neuroscience in therapy programs is between gross anatomy and clinical courses. An optimal sequence of topics was hypothesized to start from spinal cord and work rostrally. Labs would start with meninges, blood vessels and peripheral nerves, and work inward to CNS at each caudal-to-rostral level. Two other sequences would be imposed, one moving from structure to normal and pathological function, the other moving from disease to research methodologies and potential clinical therapies. This plan resulted in the following sequence: neurons/glia & meninges/ventricles; arteries/veins; spinal cord development, investments, vessels & dermatomes; spinal cord reflexes, disorders & nerve plexuses; brain stem & cerebellum; cranial nerves & brain stem sections; development of brain, diencephalon & pituitary; autonomic & limbic systems, hemisected brain, basal ganglia, cortical areas & lobes; motor & sensory systems; aphasia, EEG, epilepsy, evoked potentials & white fasciculi; aging/dementias, motor disorders, alcoholism, parasagittal, coronal & horizontal sections; regeneration/plasticity, immunocytochemistry & imaging; EMG, neurologic exam & cases. The course that sequentially dismantles the human brain and builds upon a structural foundation with clinical and research directions was judged superior to other sequences by students, and it produced a better knowledge of neuroscience as determined by testing.

202.16

UNDERGRADUATE PARTICIPATION IN THE DEVELOPMENT OF A SCIENCE COMPETITION: AN INTEGRATIVE METHOD TO PROMOTE SCIENTIFIC AWARENESS. A. Bettica, M.A. Behr, and A.C. Santucci. Depts. of Biology and Psychology, Manhattanville College, Purchase, NY 10577.

Recent trends of undergraduate majors indicate a decreasing interest in the sciences and allied fields. These trends parallel discouraging reports demonstrating a decline of scientific and technological aptitudes within the general population of the United States. Several recent programs developed to enhance scientific literacy have been suggested such as large-scale endeavors aimed at changing curricula at all educational levels (e.g., Project 2061). Moreover, individual faculty have implemented innovative teaching techniques as a way to enhance scientific literacy and student participation. With these goals in mind, a collaborative effort of the science departments of a small liberal arts college has been initiated. This effort focused on the development of an integrative annual science competition drawing on available community and educational resources. High school students from 200 area schools were invited to submit proposals of their current research projects. The undergraduate science majors played a significant role in determining the applied categories for entrants, judging the scientific merit of the presentations for a special honor society award, and coordinating the integrative aspects of the program. In addition, the students were exposed to various presentations of faculty research and attended an awards luncheon highlighted by a keynote lecture on recombinant DNA applications. Although the focus of this year's events was not specifically neuroscience in nature, this integrative program is a potential mechanism to promote education in neuroscience and other contemporary fields.

202.18

"THE BRAIN IS WIDER THAN THE SKY": AN HISTORICAL SURVEY OF BRAIN IMAGERY IN THE POETRY OF EMILY DICKINSON. R.A. Johnson and L.L. Butcher. Behavioral Neuroscience Program, Department of Psychology, UCLA, Los Angeles, CA 90024-1563.

The word *brain* appears 26 times in the poems of Emily Dickinson (1830-1886) of Amherst, Massachusetts. That is the same word frequency as *cold*, *secret*, *sunset*, and *winter*. Though far less than *I* (1682 times) or *you* (378 times), it is more than *moon* (25), *june* (21), *music* (22), *circumference* (17), *notwithstanding* (7), *amen* (1), and *scientist* (1). One piece, written in 1862 (published 1892), begins:

The Brain is wider than the sky—
For— put them side by side—
The one the other will contain—
With ease— and You— beside—

For over 15 years, undergraduate Psychology majors in L.L. Butcher's classes at UCLA have been asked to consider the above stanza and respond to the question, "In 25 words or less, what did she mean?" Excerpts and an informal cluster analysis of hundreds of responses will be presented, alongside a collection of commentary on the poems. While raised in a latter-day New England Trinitarian (Puritan) community, Emily Dickinson developed a profound self-consciousness and facility with both humanistic and scientific knowledge. Of particular interest is a consideration of her exposure to the science of the day, started while studying under Edward Hitchcock, president of Amherst College and professor of both geology and moral theology, and continued at Mount Holyoke Seminary. Attendees of the meeting will be invited to comment on the efficacy and merits of citing historical and literary sources in a neuroscience survey course.

202.20

USE OF MINITHEMES TO ENCOURAGE CONCEPTUAL UNDERSTANDING OF NEUROPHYSIOLOGY. J.A. McMillan. Biology Dept. and WAMI Regional Medical Education Program, Montana State Univ., Bozeman, MT 59717

The greatest challenge in teaching neurophysiology is facilitating development of a strong conceptual framework of basic principles as early as possible. One strategy is the use of take-home minithemes, limited to one side of an 8.5 X 11" paper.

Two formats for the minithemes, in which students assume different roles, are especially successful. In the first (expert medical witness), they must determine if a given set of data do or do not support a stated hypothesis. Often one piece of information is designed to make the data inconclusive; this helps students become comfortable with inconsistencies. In the second (basic scientist), a set of data consistent with two hypotheses are given and students must design an experiment which would enable them to determine which hypothesis is correct.

Minithemes are evaluated for accuracy, originality, logic and grammar. A satisfactory performance (S) gets full credit and a non-satisfactory performance (NS) gets no credit. An "NS" can be changed to an "S" by submitting a satisfactory revision of the minitheme. This enables faculty to be very critical, both of content and style, without jeopardizing the student's grade.

Students consistently consider the minithemes to be a valuable learning experience. They typically report that the exercise helps them understand the material better and that they enjoy the opportunity apply their knowledge to a practical situation. Furthermore, most of them appreciate the fact that all aspects of their efforts, including writing skills, are evaluated critically but constructively by faculty in the course.

202.21

YAWNING AS CLASS DEMONSTRATION OF FIXED ACTION PATTERN, RELEASING STIMULUS, CONTAGION, AND FACE PERCEPTION. R. R. Provine, Dept. of Psychology, Univ. of Maryland Baltimore County, Baltimore, MD 21228.

Yawns are easy to produce for study in the classroom because most stimuli associated with yawning trigger yawns - even reading or talking about yawns. The students are part of this demonstration! Yawning is an ethological "fixed action pattern" (FAP) that is the likely product of a central motor pattern generator. Yawns meet the classical criteria of FAP's: they are more complex and long lasting than reflexes, they occur at "typical intensity," and once initiated, they go to completion (try to stifle a yawn). Research by the author shows yawns to be most frequent in subjects who are sleepy, bored, or stretching. Yawning is not influenced by blood levels of CO₂, O₂, or by exercise.

Observed yawns are ethological "releasing stimuli" for the FAP of yawning. The resulting "contagious" yawning response is a primitive, neurologically programmed social coupling process that synchronizes the behavioral and physiological state of a group. The search for the elements of the yawning face that trigger yawns is a non-invasive approach to the neuropsychological problem of face recognition, a problem traditionally approached using brain damaged humans (prosopagnosics) and face-specific neurons in the brains of non-human species. Research shows our neurological yawn detector to be independent of axial orientation and seems tuned to the overall configuration of the yawning face - specific features such as the yawning mouth are not necessary to evoke yawns.

202.23

CURRENT EVENTS: A STUDENT LABORATORY EXERCISE FOR EXAMINING IONIC CURRENTS UNDER VOLTAGE CLAMP IN SNAIL NEURONS. B.R. Johnson, M.L. May* and P.D. Brodfuehrer, Neurobiology and Behavior, Cornell University, Ithaca, NY 14853 and Dept. of Biology, Bryn Mawr College, Bryn Mawr, PA 19010.

We use the circumesophageal ganglia preparation from the land snail, *Helix aspera*, to teach electrical properties of neurons in the undergraduate laboratory. Snails are inexpensive, easy to maintain, the neurons are large (up to 200 µm in diameter), and remain viable for at least several hours in chilled saline. Here we describe an exercise that is designed to teach intracellular voltage clamp techniques and examine the ionic basis of neuronal activity. First, students simulate the procedures for the voltage clamp experiments using commercially available software for the Macintosh. This ensures their familiarity with the experimental paradigm before using the voltage clamp amplifiers. Second, they describe the time and voltage dependency of the total ionic current in identified neurons using different voltage steps from a holding potential. Third, each student group describes the same parameters of an isolated ionic current using pharmacological and stimulation techniques to separate it from the total membrane current. For example, a group may describe the early potassium current by pharmacologically blocking other currents and then comparing the currents obtained with depolarizing steps to 0 mV from holding potentials of -50 mV and -80 mV. Results from all student groups are pooled during a general discussion of the contribution of each individual current to neuronal activity. Supported by grants from the NSF (DIR9051880), the Howard Hughes Medical Institute and Apple Computer, Inc.

202.25

A LABORATORY EXERCISE IN SOMATOSENSORY PSYCHOPHYSICS THAT IS EXPEDITIOUS, INEXPENSIVE, AND SUITABLE FOR LARGE CLASSES. J.D. Greenspan, Depts. of Neurosurgery and Physiology, SUNY Health Science Center, Syracuse, NY 13210

A procedure is described which allows a large class (>100) to determine tactile acuity in the form of two-point discrimination. The key to this laboratory is having a large number of stimulating apparatus that are reasonably accurate. Such a device can be made with a six-inch plastic ruler and paper clips in less than five minutes for less than \$1.00 each.

This laboratory was conducted by a first year medical school class (N=160). One stimulating device was given to every three students. Each of the three students in a group took turns as the subject, experimenter, and record keeper. They were instructed to use a method of limits to determine two-point thresholds on four locations of their right hand: the fingertip of digit 2, the proximal part of the distal phalanx of digit 2, the middle of the proximal phalanx of digit 2, and the thenar eminence. The students could see for themselves the dramatic regional differences in tactile acuity, as well as the practical problems associated with an "objective" assessment of perception. Furthermore, class means could be determined and presented to the students at a later date. These results can be compared to published data on mechanoreceptor density in the human hand (Johansson and Vallbo, 1979). Also, these results can be discussed with respect to the size of cortical representation of different body regions (Kandel and Schwartz, 1985, Chap. 25).

202.22

SENSORY ADAPTATION: EXTRACELLULAR RECORDING FROM THE LOCUST FOREWING HINGE STRETCH RECEPTOR. R.M. Robertson, Department of Biology, Queen's University, Kingston, Ontario, K7L 3N6, Canada.

Elevation of each of a locust's wings is monitored by a wing hinge stretch receptor. The stretch receptor comprises a single multipolar sensory neuron innervating a connective tissue strand spanning skeletal elements at the base of the wing. The adequate stimulus for the sensory neuron is stretch of the strand caused by elevation of the wing. This provides a simple preparation for demonstrating and investigating the process of sensory adaptation. Experiments using it can be performed by students who have limited manual dexterity and/or little experience with recording techniques.

The legs and head of a locust are cut off and the gut is removed by pulling it through the neck. The animal is mounted on a support which allows free movement of the forewings. One of the forewings is extended laterally and fixed to a simple device which will hold the forewing at desired wing elevations. A monopolar silver wire hook electrode is inserted through the neck into the thorax and is positioned near the base of the forewing under investigation. The electrode must be moved in search of activity of the stretch receptor which is easily recognized as it fires at around 10 Hz when the wing is extended laterally from the thorax. Once the electrode is in position the opening at the neck can be sealed with a mixture of petroleum jelly and mineral oil to prevent desiccation. Preparations like this will remain viable for more than 24 hours. Measurements are made of the frequency of discharge of the sensory neuron at different times after different elevation/depression movements of the wing.

202.24

AN INTEGRATED LABORATORY PROGRAM FOR PHYSIOLOGICAL AND MORPHOLOGICAL EXAMINATION OF MOTOR CONTROL. R. R. Hoy, B.R. Johnson, and S.J. Zottoli, Neurobiology and Behavior, Cornell Univ., Ithaca, NY 14853 and Dept. of Biology, Williams College, Williamstown, MA 01267.

Crayfish are widely used for undergraduate laboratory exercises because they are inexpensive, easy to maintain, and there is a large background of research literature for reference. In addition, they are cultured, thus their use causes little environmental impact, and they can easily substitute for vertebrate preparations in the student neurobiology laboratory. We have organized an integrated series of laboratory modules for the neurosciences using this animal. These emphasize scientific methodology, principles of nervous system function, and physiological and morphological techniques of experimental neurobiology. Here we present two integrated modules and provide handouts. The first is an exercise using extracellular recordings to monitor spontaneous activity in a purely motor nerve (6 axons) that innervates only the superficial flexor muscle (contributes to posture) in the crayfish abdomen. Students describe patterns of neural activity, and from the amplitude distribution of the action potentials, they predict the number and relative sizes of motor neurons innervating the muscle. In the second module, students are taught cobalt backfilling techniques to visualize the motor neurons within the central nervous system, and thus directly test their predictions. Their results lead to discussions of motor control and functional morphology of neurons. Subsequent modules will focus on basic synaptic mechanisms and their plasticity. Supported by NSF grants BNS8809445 and DIR9051880, the Howard Hughes Medical Institute, the Grass Foundation and Apple Computer, Inc.

TO STUDY THE EFFECT OF SENSORY DEFICITS ON FOOD SEARCHING BEHAVIORS AND RECOVERY OF FUNCTIONS WITH PLANARIANS. S. HSIAO AND J. MASSENGALE*, Dept. of Psychology, Univ. of Arizona, Tucson, AZ 85721

Students can easily measure various behaviors of planarians. This inexpensive animal regenerates missing parts readily and is unique as the most primitive species to possess organ systems, with bilateral symmetry, and cephalo-caudal/dorso-ventral axes. Planarian food searching behavior was studied as a function of unilateral lesioning and regeneration of chemosensory auricles. 20 planarians, 1.5 cm long, housed in petri dishes (7.5 cm dia.) with 200 ml tap water and food-deprived for 11 days, were randomly divided into 4 groups of n=5: Intact Control, Left Auricle Excised, Right Auricle Excised, Surgery Control (tail tissue excised). In PRE-SURGERY test, a live tubifex was placed into the dish 4.2 cm away from the head. The head location was recorded every 10 sec for a 10 min period. Surgery consisted of removal of an auricle with about 1 mm of indentation toward the eye, or of about the same amount of tail tissue. The test was repeated the next day (POST-SURGERY), and upon complete auricle regeneration in about a week (POST-RECOVERY). We measured the time to capture the prey (600 sec assigned to that failed to capture), the distance to prey when a straight move to the prey was commenced, and the number of times animals circled within 24 mm of prey. Results: The auricle-lesioned animals (a) approached very near to the prey before commencing a direct move toward it (3.5 vs 13 mm) (b) circled around the prey with the lesioned side toward it, but (c) the time to capture prey was not altered. No deficit was detected in the tail-excised and recovered groups. (UofA SBS Small Research Grant.)

OIL RED O: A SIMPLE PATHWAY STAIN FOR USE IN THE NEUROSCIENCE TEACHING LABORATORY. M. LeGare and B. Winegar. Dept. of Psychology, California State Univ., Sacramento, 95819-6007; Dept. of Pharmacology, Sch. of Med., U.C. California, San Francisco, 94143-0450.

One solution to the time-money problem in the undergraduate neuroscience teaching lab is our development of Oil Red O (ORO), a lipid stain (Humason, 1967), for staining mounted rat brain sections. Rats are sacrificed with nembutal and perfused through the heart with 10% formalin. Extracted brains are placed in 10% formalin for >24 hours. Frozen sections (25-35 microns) are made on a clinical freezing microtome, mounted in a water bath on slides which have a thin coating of 50% glycerol-50% fresh egg albumin, and placed on a slide warmer at 40° C until dry (30-40 min.). The ORO (Sigma) stock solution is 250-500 mg ORO in 100 ml of 99% EtOH (saturated). The staining solution is 120 ml stock solution and 80 ml water which is allowed to stand for 10-15 minutes and then filtered. The slides are rinsed twice in water, stained for 20 minutes followed by a final rinse. Slides are removed one at a time, enclosed with glycerol gelatin (Sigma), covered with a #1 cover slip and ringed with Preserv-a-slide. Pathways are red-orange to dark red. Cellular areas are pink. Our students do all work except for the animal sacrifice and brain extraction. The slides are examined and pathways drawn using low power (x25) light microscopy and projecting microscopy. Students use Paxinos and Watson (1986) for pathway identification.

THE STAR PROGRAM: A COOPERATIVE VENTURE IN SCIENCE EDUCATION BETWEEN THE UNIVERSITY OF SOUTHERN CALIFORNIA HEALTH SCIENCES CAMPUS AND FRANCISCO BRAVO MEDICAL MAGNET HIGHSCHOOL IN EAST LOS ANGELES. R.E. Brinton, D.C. Moot and M. Mayo. ♦ Dept of Molecular Pharmacology and Toxicology, School of Pharmacy University of Southern California, Los Angeles, CA 90033 and * Francisco Bravo Medical Magnet High School, Los Angeles, CA 90033.

The STAR Program for Science, Technology And Research provides junior and senior high school students interested in learning about scientific exploration the opportunity to participate in research projects. The goals of the STAR Program are to: 1. Expose Students to The World of Science 2. Teach Students the Discipline of The Discovery Process. 3. Create an Environment That Nurtures Curiosity. 4. Provide Role Models of The Investigative Explorer. STAR students participate in research projects as an integral part of their curriculum and work in the laboratory 3 afternoons or more a week. A total of 30 research laboratories at the USC Health Science Campus participate in the STAR Program. Bravo Medical Magnet High School, a public high school located in East Los Angeles, has an enrollment of 60% Latino-Am, 18% African-Am, 16 %Asian-Am, 5 % Anglo-Am and 1% Native Am. Of the 12 STAR students of 1990, **92%** went onto college, **25%** of STAR Students were Latino-Am and **100%** of the Latino-Am students went on to colleges such as Penn State and Berkeley. Two of the 12 were early acceptance students, one to Cal Tech and the other to Penn State. Of the 30 participating laboratories 50% are conducting research related to neuroscience. Of the 1990 STAR students **30%** are continuing to do research as part of their undergraduate curricula. The class of 1991 has tripled in size relative to the 1990 STAR class with **30%** of the current students presenting their research at the Los Angeles County Science Fair. Last year's winner was a STAR student whose research project was "The Effect of Stress Hormones on Hippocampal Nerve Cell Growth in Culture."

202.31

THE PITTSBURGH NEUROSCIENCE EDUCATION PROGRAM FOR JUNIOR HIGH SCHOOL STUDENTS. Weisz, D.J.*, Bradler, J.E.*, Hurrianko, A.E.*, Pandalai, S.P.*, and Smith, I.D.* Departments of Neurological Surgery* and Behavioral Neuroscience*, University of Pittsburgh, Pittsburgh, PA 15260.

Over the past two years faculty members from the Departments of Behavioral Neuroscience and Neurological Surgery and several graduate students from the Department of Behavioral Neuroscience at the University of Pittsburgh have gone into the junior high school classrooms in the Pittsburgh City School System to talk to approximately 1500 seventh grade students about neuroscience. The goals of this expanding project are to introduce students to research in neuroscience, to illustrate how neuroscientific research can help people with nervous system disorders, and to generate a high level of awareness concerning the necessity of both animal and human research. Individual presentations are given to approximately 20-75 students and are focused on two or three demonstrations depending on the length of classroom sessions. Demonstrations include recording of EEG, EMG, and EKG, comparison of diseased and normal human brains, activation of motor responses by electrical stimulation, and recording of sensory evoked potentials. Benefits of neuroscientific research to paralyzed individuals, Parkinson's patients, and people with sensory deficits are demonstrated with the use of slides or videotape. Student participation in the discussion and demonstrations is actively encouraged.

202.28

UNIVERSITY RESEARCH EXPERIENCE FOR HIGH SCHOOL SCIENCE TEACHERS AS A MEANS TO INTRODUCE NEUROSCIENCE INTO THE SECONDARY CURRICULUM. Joseph, G.* & DeRiemer, S.A.† W. Taft H.S., Bronx, NY 10457, & † Dept. of Biological Sciences, Columbia Univ. NY NY 10027.

Columbia University has introduced a program to expose New York high school science teachers to the experience of conducting basic research. The program currently involves 20 teachers who spend 8 weeks each summer for two years in Columbia laboratories. They are given weekly seminars by prominent scientists on topics of contemporary interest and have year round use of Columbia facilities including libraries, stockrooms, and computers. At the end of each summer, teachers present their scientific work and develop a plan for the incorporation of this experience into their teaching. Following is one example of how such programs can lead to innovative teaching of neuroscience at the secondary level.

W. Taft H.S. in the Bronx serves a low-income, minority population of students coming from primarily single parent homes. Eighty-five of the 2500 students are currently enrolled in Regent's (Upper level) Biology. The changes introduced into the teaching of these students following a summer of laboratory research include the following: 1) Substituting an emphasis on the use of scientific reasoning (generation and evaluation of hypotheses) for answering questions instead of a reliance on "right" answers from the teacher or text; 2) The relating of first hand experiences and information collected during the summer to capture the interest and excite students; 3) Reconstruction in the classroom of the preparation and experiments done in the Columbia laboratory. For example, peristalsis in an isolated intestinal section was used to demonstrate the presence of nerves outside the brain, the autonomy of isolated organs, the complex, coordinated control of contractions produced by the myenteric system, and the effects of neurotransmitters. Program supported by a grant from the Howard Hughes Foundation.

202.30

PRINCIPLES OF NEUROSCIENCE AS AN ELECTIVE COURSE IN HIGH SCHOOL. J. Hart Romeo*, C. Poole*, I.G. McQuarrie. Department of Science, Lakewood High School, Lakewood, Ohio 44107.

An educational initiative designed to increase awareness and understanding of neuroscience has been developed at Lakewood High School in Ohio. Principles of Neuroscience is offered as an elective course, and, to capture the widest possible audience at the school, requires only a general biology course as a prerequisite. The course also functions as a feeder for the advanced physiology and anatomy course offered to junior and senior students.

Written to provide intellectual stimulation and challenge, the course utilizes input from neuroscientists, neurosurgeons, and educators. The format includes lecture, discussion, presentation by members of the scientific community, development of a familiarity with the neuroscience literature, essay examination, and an individual investigative or research project. Students are encouraged to develop links with the neuroscience community, visit laboratories, and assist in on-going research where possible. Course topics include neural physiology, cell biology of neurons, the chemical basis of synaptic transmission, reactions of neurons to injury, and axon regeneration. Special integrated topics include the physiology of sleep and dreaming, neurochemistry of seizure activity, sexual differentiation of the nervous system, the development and aging of the brain, biochemistry of mental disorders; biochemical approaches to learning and memory.

202.32

LABORATORY EXERCISE IN COMPARATIVE NEUROANATOMY: BREAKING DOWN BARRIERS TO ANIMAL DISSECTION IN THE CLASSROOM. M.C. Fields and R.D. Fields. Sidwell Friends School, Washington D.C. 20016.

Many classroom teachers face the dilemma of whether or not to use organisms, yet feel a need to expose precollege students to animal dissection. In an effort to overcome student objections, minimize the number of organisms used and avoid wasting any part of an animal, I use common "seafood items" to illustrate features of the nervous system. Squid, octopus, lobster, fish and shark can give students hands-on knowledge about giant axons, nerve cords, brain structure, visual, auditory and electrosensory systems. Knowledge of comparative anatomy can be gained from "cleaning" these organisms and ending the session with a seafood feast. In the context of food preparation, students lose the inhibition of cutting into animals, and the use of lower organisms is acceptable to more students, including some vegetarians. Through this practical exercise, individuals address the important "animal rights" issues involving the justification of using animals for food, clothing, and scientific research. Student response is outstanding: they enjoy the experience, learn the material better, and relate the lab exercise positively to other students and parents. This activity tends to break down many biases that students (and teachers) have about classroom dissections, and it can be used to lead into the standard dissection of the earthworm, frog, and pig.

202.33

PROJECT SEED: A COLLABORATIVE UNIVERSITY / PUBLIC SCHOOL DISTRICT EFFORT TO REVITALIZE EARLY SCIENCE EDUCATION. L. Gonzalez, J.M. Bower and J. Pine. Divs. of Physics and Biology, California Institute of Technology, Pasadena, CA. 91125

Caltech in association with the local Pasadena Unified School District has been involved for the last six years in a program to develop an exemplary K-5 public science education program. The program is strongly based on "hands-on" science activities used by regular classroom teachers. The activities themselves are in the form of experimental "kits" used in the classroom for five to six weeks. The kits are derived from existing materials invented in the 1960's and concern a broad range of scientific subjects including biological and, even, neurobiologically related topics. These include, for example, a fourth grade kit called "Action Reaction" in which students perform reaction time experiments on themselves, and a fifth grade kit that involves children exploring the physiology and behavior of crayfish.

Project SEED also has a strong teacher training component based on interactions between Caltech and community science professionals and classroom teachers. The training program is somewhat unusual in that it is organized around the use of the science materials themselves. The principle training emphasis is, accordingly, on the process of doing science rather than the factual base for the experiments being performed. With this approach discussions about science content arise naturally from actually doing science.

Following a successful three year pilot in one test school, the local school board has recently adopted Project SEED as the science curriculum for the entire district (22 schools). As a result, Caltech is now in the midst of training 430 classroom teachers in the use of hands-on science materials. Within two years, experimental science will constitute a significant component of the elementary educational experience of every one of the 10,000 young children in the Pasadena public schools. Planning is currently underway to extend this approach through all grade levels.

Project SEED is supported by the NSF grant TPE-9050276, the Pasadena Community Bank, Rockwell International, Apple Computer Inc., and the Caltech Presidents Fund.

202.34

TEACHING NEUROSCIENCE TO ELEMENTARY STUDENTS. V.J. Sanders*, C. Mathes, M. Derosa, P. Dasonville, and A.B. Scheibel. Brain Res. Inst., UCLA, Los Angeles, CA. 90024

Students in the Interdisciplinary Neuroscience Ph.D. Program at UCLA have started a community outreach program teaching the fundamentals of neuroscience to elementary school children (ages 7-12). The program is aimed at exposing students to elements of the sciences that would otherwise not be accessible and at promoting scientific research as a career.

Sessions consist of one hour long presentations given on consecutive weeks; usually two sessions are given per visit (for example: 2nd grade: 10:00-11:00, 3rd grade: 11:00-12:00.) The first visit teaches the anatomy and function of the human brain. Students are asked about the location and the appearance of the brain, connections with the rest of the body, and activities and substances that are "good" or "bad" for the brain. Visuals include one whole human brain, two hemispheres, coronal sections, and a spinal cord. Sheep, cat, and mice brains are used for comparison. The second visit teaches electrical and chemical communication between cells. Analogies are made to multi-party telephones (action potentials traveling along axons and dendrites) and bursting water balloons (synaptic release). Visuals include a patellar reflex hammer as an example of speed and efficiency of communication between cells and a tuning fork as an example of transduction of sound waves into electrical signals within the auditory cortex. The students are asked questions as often as possible in order to maintain attention; similarly, questions from the students are answered immediately to promote interaction.

Since April, 1990, 25 classes (8 schools) have been visited, including a school for the blind. The program has received great enthusiasm from both students and teachers. [Sponsored by the Brain Research Institute at UCLA, the LA chapter of ARCS (Achievement Rewards for College Scientists), and the W.F. Muller Foundation.]

202.35

TEACHING NEUROSCIENCE THROUGH A LABORATORY EXPERIENCE: YOU CAN'T START TOO YOUNG. L.L. Stark and T.J. Carraw. Interdepartmental Program in Neuroscience and Depts. of Psychology & Biology, Yale University, New Haven, CT 06520.

In an effort to expose children to science at an early age, our laboratory has annually opened our doors to a second-grade class (7-8 yrs. old). For three hours, we attempt to provide students a perspective on science, emphasizing neuroscience, which they can't get in the classroom. In our laboratory we investigate behavioral plasticity and its underlying cellular mechanisms in the marine mollusc *Aplysia*. Because our research spans many levels, the children can participate in behavioral, anatomical, developmental, and physiological experiments and demonstrations. In groups of 4-5 the children rotate through 5 stations. STATION 1 emphasizes OBSERVATION. The children examine the body plan of a dissected *Aplysia* and learn to look through a stereomicroscope to observe and draw neurons in an *Aplysia* central ganglion. STATIONS 2 & 3 emphasize EXPERIMENTATION, one examining feeding behavior and the other learning (habituation of siphon withdrawal). We pose questions, ask the children to generate and discuss hypotheses, and conduct experiments to test ideas. Finally, we introduce them to statistical analysis, using a computer to analyze and graph results. STATION 4 allows an INTEGRATION of science with the children's experience of growing: they examine stages of the *Aplysia* life cycle from egg, through metamorphosis, to adulthood. STATION 5, the "Electricity Room," is a DEMONSTRATION. Emphasizing the role neurons play in the children's own brains, we explain how neurons communicate through action potentials and show them different patterns of neuronal firing.

Our goal is to demystify the process of science and the people who do it, encouraging the children to view science as an exciting process of discovery. Then we all get ice cream.

TEACHING OF NEUROSCIENCE: COMPUTER-BASED EDUCATION

203.1

Computer-assisted education (CAE): a new approach and a module for teaching neuroanatomy. Louis Cornacchia*1, Ellen Mower*2, and James Hatton1, 1 Div. of Neurosurgery and 2 Office of Learning Resources, UCSD, La Jolla CA.

Education in the neurosciences maximally taxes the teaching process because it involves the communication and synthesis of a voluminous, diverse and conceptually challenging data set. We have developed software to simplify the construction of educational modules and we have used this system to develop CAE software for teaching neuroanatomy.

To harness more of the potential benefits of CAE beyond "automatic page turning," the one-on-one tutoring session can be referenced as the archetype of the information transfer scenario. The tutor provides more than a source of information. For instance, the tutor provides a history of the interaction which is used to plan future studies and to guide the student on how to best learn the material considering his or her learning style and cognitive assets. Secondly, the tutor is capable of "natural language" and free-form querying of the database which allows the student to test formulations and hypotheses. Also, the tutor provides a mechanism by which a student can assess his progress.

We have implemented a system that provides a close facsimile of the one-on-one session and a platform for further research in this area. This system provides for both hierarchical and direct-access organization of neuroanatomic information. It provides for detailed record-keeping regarding the interaction of the user with the subject matter. Furthermore, the journaled information contains sufficient detail that, when evaluated by the author, can be used to optimize the lesson for more efficient learning. We provide facilities for instructor-, author-, or student-directed questioning to help the system assess progress. The system provides a flexible interface to the database, allowing the student to adjust the system to his personal learning style. Finally, we have implemented a lesson construction system that provides for rapid, simple construction of CAE software without prior programming experience. Future implementation of natural language and artificial intelligence algorithms will provide for context-sensitive remediation and automatic adaptation of the environment to the user's learning style. A neurophysiology module is currently under development.

203.2

NEURODATABASE: A MULTIMEDIA NEUROSCIENCE DATABASE FOR RESEARCH AND TEACHING S.L. Wertheim and R.L. Sidman. New England Regional Primate Research Center, Harvard Medical School, Southborough, MA 01772-9102

NeuroDatabase is an information tool for neuroscience that is being developed to aid research and teaching. It focuses on the acquisition, analysis and presentation of two and three-dimensional data sets. It is distinguished from most other computer-based neuroscience tools by the presence of a flexible underlying database. This design enables a neuroscientist to handle the data of current and future experiments and teaching exercises as well as to engage in collaborative efforts. Each laboratory can have its own, private copy of the database to which local data can be added. The vocabulary, data storage structures and tools for creation of teaching materials are shared.

NeuroDatabase has four major functional modules: Microscopy, Laboratory Notebook, Database and Education. The Education module allows the student to browse freely through the visual database, or to obtain guided instruction by using the Guided Tours, glossary, programmed instruction or testing functions.

The software requires a Macintosh II with 8 MB RAM, hard disk and 19" color display. Sony rewritable optical disks (650 MB) are used for archival storage and data exchange. The software was created using SuperCard (Silicon Beach) and Oracle (Oracle Corp.). 3D reconstruction will be done using the Silicon Graphics Iris.

203.3

THE GRAPHIC BRAIN. T.J.Vonida, T.J.Taylor & P.J.Vertucci. *Neurobiology Dept., NEOUCOM, Rootstown, OH 44272.*

Two areas of neuroscience that are difficult to teach using traditional means (textbooks, lectures and slides) are the three-dimensional anatomy of the brain and the physiological changes that occur in neurons as a function of time. Conventional neuroanatomy teaching involves extensive reiteration of two-dimensional material to (hopefully) develop a three-dimensional representation of brain structures in the student's mind. We are using a graphics computer to develop neuroanatomical teaching materials to better illustrate the three-dimensional anatomy of the brain.

The second area is cellular neurophysiology, including the binding of receptors by ligands, opening of channels, movement of ions across membranes, and generation of electrical potentials. These dynamic events vary in time and space, and are difficult to convey via books or slides. We believe that the computer animation of physiological events at the cellular, membrane, and molecular levels will make the teaching of neurophysiology not only more effective, but more interesting. We have created computer models of neural membranes, receptors, ion channels, ions, and neurotransmitters, and show these elements interacting in normal and abnormal states.

These computer-generated instructional segments will be initially videotaped and used in the classroom to illustrate certain key points. Ultimately, we hope to create an interactive electronic textbook of neuroscience. We foresee that individual student interaction with graphic images on a computer will provide an opportune medium for neuroscience instruction. In addition, the flexibility of the computer will allow us to tailor the content from professional levels (medical & graduate) to high school.

203.5

NEUROQUIZ: A MODULAR PROGRAM FOR REVIEWING NEUROANATOMY ON COLOR MACINTOSH COMPUTERS. T. Gibbs, G. Conyers* and J.L. Kubie, Department of Anatomy and Cell Biology, S.U.N.Y. Health Science Center at Brooklyn, Brooklyn, NY 11203 and Department of Pharmacology, Boston University School of Medicine, Boston, MA 02118

The Neuroquiz programs for Macintosh computers provide an interactive review of neuroanatomy. Each module is a series of 2 to 25 photographic images of brain specimens arranged around a theme, such as coronal sections or external views of the human brain. The image quality is dramatic with high resolution and photographic quality color. Student reaction has been highly favorable.

Each module can be run in one of three modes. In Review mode a list of identified structures accompanies each picture. The student can click on an item in the list and the appropriate structure will highlight, or click on a structure in the photo and its name will highlight. Drill mode is a self test in which a series of brain images is presented. The student is asked to click at the location of a named structure on the current image. The program responds with immediate visual and audible feedback, and the correct structure is highlighted. A running score is maintained. All structures on a photo are presented in random sequence; incorrectly identified structures repeat. When all structures are correctly identified, the next photo is presented. In Quiz mode, the student is asked to identify a series of randomly selected structures and the student's name and score may be saved to disk.

Neuroquiz is programmed in Supercard and runs off a file server that currently serves 6 computers. The programs are intuitive -- students learn to use them in under 5 minutes. The programs are also robust and need little supervision. The skeleton of each module is identical. It is an easy job, requiring no programming, to add new modules or to edit old ones. Conversely, the skeleton of an existing module can be modified or replaced while retaining existing photos and structural information. We currently have modules that cover external morphology, coronal sections, horizontal sections, floor of the fourth ventricle, dissection of the lateral ventricle, gyri and sulci, and a Pal-Weiger atlas. Several enhancements, such as the addition of voice, are in late stages of development and will be presented.

203.7

INTEGRATING INTERACTIVE COMPUTER MODULES INTO THE NEUROSCIENCE CURRICULUM. Kerry D. Walton, Dept. of Physiology & Biophysics, NYU Medical Center, 550 First Ave., New York, NY 10016.

While the content of science courses given in colleges and medical schools has increased tremendously in recent years, many new graphic techniques are now available that make the teaching of difficult concepts more achievable. Such an approach is significant in a wider sense as today's student must be able to integrate the material within each course and among related curricula. This issue is especially critical in Neuroscience courses as they are rich in concepts which are supported by a multitude of facts that must be known and understood. With this in mind and to return laboratory exercises to the classroom, over the last three years the Neuroscience Course faculty at NYU School of Medicine has developed, with student help, a set of interactive computer programs that allow self-paced, random access to information and the blending of conceptual and quantitative elements. These modules have been incorporated into four main areas of the course: (1) providing computer modeling capable of displaying real-time numerical solutions to sets of equations (synaptic transmission) or animation during lectures (sensory processing); (2) allowing students to perform computer based experiments (single cell and single channel properties); (3) acting as interactive neuroanatomical atlases (brain surface structures, brain sections, histology, MRI, spinal cord); (4) student self tests and review. Ours is a Macintosh-based system with digitized images and 19" color monitors. Some modules were developed as part of the Hippocrates Project.

203.4

SuperBrain: A MULTIMEDIA COMPUTER APPLICATION FOR INTERDISCIPLINARY NEUROSCIENCE EDUCATION. R. P. Hammer, Jr. and S.A. Jacobson, Dept. Anatomy & Reprod. Biol., Univ. Hawaii Sch. Med., Honolulu, HI 96822, and Dept. Psychiatry & Biobehav. Sci., UCLA Sch. Med., Los Angeles, CA 90024.

The field of neuroscience lends itself well to an interdisciplinary educational approach in both medical and graduate education. The introduction of problem-based medical curricula provides the opportunity to construct a learning tool which presents current information in both basic and clinical neuroscience. **SuperBrain** is a Macintosh-based computer application which incorporates graphics, videodisc displays, on-screen animation and sound together with textual descriptions. The application is oriented toward clinical problems, whereby one utilizes navigational menus containing diagnostic categories and differential diagnoses to explore the structural, functional, chemical, pathological, diagnostic and therapeutic bases of brain disease. The user may change topics as desired using "buttons" and/or textual "links." An additional menu allows direct access to basic neurobiological information on brain structure and chemistry. User evaluations reveal that the most valuable features of the application are graphic animations of processes such as synaptic function, NBME-type questions with direct user feedback, graphical interfaces and linkage of clinical disorders with underlying basic mechanisms. This application facilitates exploration of the biological substrates of brain function and dysfunction, illustrating the relevance of current neuroscience research findings. This concept should be useful for neuroscience instruction in graduate, medical, postgraduate and continuing medical education.

203.6

A COMPUTER IMAGE ACCESS DATABASE FOR TEACHING NEUROSCIENCE. D.E. Hillman, M.S. Nachbar*, X. Hom*, and A. W. Hunger*. Depts. of Physiol. & Biophys. and Microbiol., NYU Med. Ctr., New York, NY 10016.

Three neuroscience teaching modules have been generated for image and graphic illustration of the brain surface and the brain in sections. A program was written on a Macintosh IITM system with a high resolution color display (SuperMac Technology, Sunnyvale, CA 94086) using a software authoring environment, SuperCardTM (Silicon Beach Software, San Diego, CA 92126), to control image access, graphics and text manipulation. Two modules define various surface views of the human telencephalon, diencephalon (midsagittal), cerebellum and brainstem while a third displays sections through the brainstem and diencephalon. The images are displayed as cursor selectable frames in SuperCard windows on a high resolution color monitor. Cursor interrogation of objects in images highlights a graphic overlay of the specific region while a scrollable list highlights the object name. Alternatively, the object name is interrogated while the corresponding image region is highlighted. Object descriptions are requested by another information button. Access of overlapping objects is afforded through a hierarchic modality scheme which switches modes for gross, detailed or functional regions. Self-testing of objects by name or location is afforded by a routine of the software. The acquisition of digitized color images was through a 35 mm slide scanner (Bameyscan Corp., Alameda, CA 94501) for sections and a bed scanner (Truvel Corp., Chatsworth, CA 91311) for surface structures. Images were manipulated for size, orientation, and color using PhotoshopTM (Adobe System Inc., Mountain View, CA 94039). The approach provides student's 24 hour access to a tutorial of self-help teaching-aids.

203.8

BRAINSTORM, AN INTERACTIVE COMPUTER ATLAS FOR STUDYING HUMAN NEUROANATOMY. G. P. Coppa,*E. J. Tancred and P. Dev. SUMMIT, Stanford Medical School, Stanford, CA. 94305 and *School of Anatomy, UNSW, Sydney, Australia.

Using Macintosh computers and SuperCard software, we have developed a highly interactive program to enhance the study of human neuroanatomy. It includes a series of digitized color images (cards) of myelin-stained cross-sections and gross sections of the human brain and spinal cord, as well as diagrams and information (text) cards. When a structure or system is selected by clicking on it in the image or structure list, the corresponding shape is outlined and information on its connectivity and function can be presented from an underlying database. The database also provides extensive cross-references, allowing the user to follow a structure through consecutive cross-sections or to move to other representations such as diagrams, text or gross dissections. A Quiz button on each card presents randomly selected structures from the card and uses the database to generate questions and multiple-choice answers on identification and theory. The program also features several animations, including a clinical examination of cranial nerves, which illustrates the effect of lesions and tests the user's ability to recognize randomly selected lesions.

The effectiveness of BrainStorm as a teaching tool will be assessed in a controlled study at UNSW in August-September 1991, but preliminary results obtained at Stanford in early 1991 showed that 78% of students who used BrainStorm found it more effective for studying the internal anatomy of the brainstem than either practical classes or textbooks. The cross-sections and the quiz mode were the most popular aspects of the program.

203.9

NeuroImage: A CBL Program To Study Correlated Brain Images and Blood Supply. R.M. Kriebel and M.J. Patney. Dept. of Anatomy, Philadelphia College Osteopathic Medicine, Philadelphia PA 19131.

This Computer Based Learning (CBL) program is designed to provide a concise instructional program which correlates cerebrovascular distribution with images obtained with modern MRI/CAT scan technologies. Most medical neuroscience courses emphasize these two important aspects of the central nervous system (CNS) because of the prevalence of cerebrovascular disorders. Regardless of the individual's final specialty choice, all physicians in training will encounter patients with insufficient cerebrovascular supply and resultant neurological deficits. Non-invasive brain imaging techniques have dramatically assisted the physician in prognostication and management of individuals with cerebrovascular problems. By progression through a layer upon layer window format, the user can review basic brain structure, brain image anatomy, correlated regional blood supply, and exercise this knowledge with a case study problem solving segment. This CBL program is intended to provide opportunity for review for national boards and may have usefulness to those allied health students preparing for careers in neurologically related nursing, therapy, counseling, and rehabilitation. The program was developed for use on an IBM or compatible platform by using a hypermedia authoring program, The Knowledge Engine™, a product of Software Artistics Inc. This project was supported by a Pew Foundation grant to RMK.

203.11

IMPLEMENTATION OF A HIGH-RESOLUTION, DIGITAL COLOR IMAGE AUTHORING SYSTEM FOR THE TEACHING OF HUMAN NEUROANATOMY. U. J. Balis* and S. Saporta. Department of Anatomy, Univ. S. Florida College of Med., Tampa, FL 33612.

Current trends in neuroanatomy education clearly highlight the importance of audio-visual materials as a teaching adjunct. Typically, such materials are prepared and distributed by commercial educational publishers. As a result, the educator is constrained to presentation of materials found within the selected product.

Authoring systems, conversely, are computer programs which allow for an educator to directly assemble textual and graphic teaching materials, which may later be replayed on student computer workstations, as an adjunct in the teaching of a given course. These systems have become increasingly widespread in their use for medical education but remain limited in their application to image-intensive topics, due to the high expense of equipment needed to realize high quality digital color images.

We have developed an authoring system which has the capability of rendering digital, high-resolution color images, with minimal additional expense, thus making it ideal in educational settings where multiple student workstations are needed. The system is made possible by the availability of a new series of recently designed semiconductors, originally used in the imaging aspects of the defense industry. With these devices, it has become possible to fabricate hardware that is essential to the digitization process and rendering of color images. This hardware allows for a personal computer to render digital images in true, high-resolution color (1000x800 pixels @ 18 bits/pixel). Previously, this degree of resolution and colorspace was available only in digital video processors with prohibitively expensive image storage buffers. Using the above technology, the authors have successfully designed a neuroanatomy authoring system as a prototype teaching adjunct.

203.13

CATECHOLLISION: A GAME OF CATECHOLAMINE SYNTHESIS FOR IBM-PCs AND COMPATIBLES. W. Jeffrey Wilson* & Jennifer A. Cook*, Dept. of Psychological Sciences, Indiana University - Purdue University at Fort Wayne, & *Dept. of Anatomy, Indiana University School of Medicine, Fort Wayne, IN 46805

CATECHOLLISION is an arcade-style game based on catecholamine synthesis. Tyrosine and the enzymes involved in the synthesis fall from the top of the screen. The player must combine them to produce DOPA and the catecholamines (dopamine, norepinephrine, and epinephrine). For example, dropping tyrosine on tyrosine hydroxylase produces DOPA, and dropping dopamine on dopamine beta-hydroxylase on dopamine produces norepinephrine. As play progresses, the screen fills with unused chemicals until too much has accumulated and the game ends. Late in the game monoamine oxidase falls, destroying the catecholamines and helping to clear the screen. Successful synthesis of catecholamines causes higher scores, increases the level of difficulty of the game, and allows the game to last longer as the screen does not fill as quickly. Users quickly become familiar with the synthetic pathway.

CATECHOLLISION has a musical score and sound effects (which can be disabled), saves high scores to disk, offers four levels of difficulty plus hints for the novice, and runs on any IBM-PC or compatible with graphics capabilities (CGA, EGA, VGA, or Hercules). CATECHOLLISION is distributed as shareware; a copy is free upon receipt of a disk and self-addressed, postage-paid mailer. A registration fee of \$20 is requested if you like the program.

203.10

INTERACTIVE USE OF VIDEO DISC ANIMATIONS OF COMPUTER-RECONSTRUCTED HUMAN BRAIN. J.W. Sundsten*, J.F. Brinkley*, K. Eno*, R.M. Harris, K. G. Kastella*. Dept. of Biological Structure, University of Washington School of Medicine, Seattle, WA 98185.

We are using 3-D computer graphic animations of brain components in neuroanatomy tutorials. Brain serial sections are digitized and the x-, y-, z-coordinates transferred to a computer graphic work station. The data are reconstructed and the images recorded on videodisc. (Sundsten, J.W. et al., J. Biocommun., 18:45-49, 1991). Objects include: amygdala, anterior commissure, brainstem, caudate, cerebellum, cerebral cortex, choroid plexus, claustrum, corpus callosum, fornix, globus pallidus, hypothalamus, hippocampal formation, internal capsule, olfactory tract, optic nerve and tract, putamen, thalamus, ventricles, and white matter.

The disc is divided into chapters. Useful animations include: structures seen through translucent cerebral cortex; slicing the forebrain with or without objects protruding; removal or addition of structures to show relationships to the cerebral ventricles; and selected functional pathway presentations. Each object can be viewed alone or in combinations with other objects in different structural contexts.

The disc is controlled by a Macintosh computer that runs our Anatomy Browser software. The system contains serial sections of brainstem and forebrain that provide a base for quizzing, browsing and accessing videodisc 3-D animations of objects seen in the cross section. The Browser has authoring tools that readily enable expansion and updating of material. Its neuroanatomical "knowledge base" adds textual information including structural definitions and neuroanatomical subdivisions. The Browser is currently in use for courses in neuroanatomy. We will present examples of the material seen on the videodisc and on the Browser.

Supported in part by a grant from the National Library of Medicine, LM04925.

203.12

A COMPUTER MODEL OF THE CEREBELLUM. K. R. Dunleavy* and S. J. Velez. Department of Biological Sciences, Dartmouth College, Hanover, New Hampshire 03755.

A computer model of the cerebellum was developed for the Macintosh II using Object-Oriented Pascal and tested with undergraduate neurobiology students. The program allows the user to assess four different areas: Anatomy, Physiology, Pathology and Experimental. The Anatomy area allows the user to view in detail particular anatomical structures. In the Physiology area, the user is provided with a model which maintains cell geometry, the number and ratios of cells in cerebellar microzones, and the number and strength of contacts per cell in order to calculate cell locations and innervations. By clicking on selected cells, the user can then mimic the progress of climbing or mossy fiber activation in a microzone array of Purkinje cells. Snapshots of cell activity at different time intervals may be taken for later analysis. The Pathology area makes available different libraries of known conditions that alter the microzones, allowing the user to study the physiological manifestations generated by the pathological changes. In the Experimental area, changes in all of the aforementioned characteristics can be made in order to study their effects on the processing of information in cerebellar microzones. Help windows throughout the program provide information about the cells and the processes being observed. The level of difficulty of the program can be tailored to the user's knowledge of cerebellar function.

203.14

COMPUTER PROGRAM TO ILLUSTRATE PROPERTIES OF SEMIPERMEABLE MEMBRANES. P. J. Best and R. Fessler. Department of Psychology and Systems Analysis, Miami University, Oxford, OH 45056.

A computer program was developed to illustrate the interaction between membrane potential and ion concentration across a semipermeable membrane. The program displays a two-chambered bath with a semipermeable membrane stretched vertically across it. Individual ions move with constant velocity in the bath and cross the membrane with a specific probability determined by the membrane's permeability to that ion species. Below the pictorial representation of the bath, a number of values are displayed; ion concentrations, resulting equilibrium potential, membrane potential. The concentration of the ions and membrane permeability can be altered. A pump can be inserted in the membrane, and a voltage clamp can be imposed across it. By varying the basic parameters of the membrane, students master the relationship of ion concentration gradient to equilibrium potential. Thereafter, additional ions can be added to the bath with varying valences, permeabilities, and pump properties. Thus the program can be used to help students understand basic membrane biophysics including the Nernst Equation and the Goldman Equation at a conceptual level.

203.15

BRINGING MOLECULES TO LIFE: AN ANIMATED HYPERCARD TOUR OF NEURONS AND MUSCLES. W.H. Watson III and J.J. Sasner*. Dept. of Zoology, University of New Hampshire, Durham, N.H. 03824

During the last decade there has been a revolution in our understanding of biological phenomena so that it is now possible to explain events such as action potentials and muscle contraction at the molecular level. One of the most difficult challenges biology professors face is communicating our understanding of these molecular events to our students. In particular, we must devise ways to help them: (1) understand the relationships between molecular processes and overt behavior and; (2) visualize the dynamic interactions between molecules which are too small to capture on film.

We have developed a series of animations, using the program Macromind Director, which depict processes such as transmitter release and muscle contraction. These animations are integrated into a Hypercard Stack so students can take a tour of different physiological systems. Thus, simply by clicking on different images, students can work their way into an organism and see, for instance, how interactions between actin and myosin give rise to muscle contractions. The processes that are difficult to conceptualize are illustrated in a dynamic way through animations. This work was funded, in part, by grants from the U.N.H. Discovery Program and Apple Computer Corp.

203.17

A GENERAL SIMULATION PROGRAM FOR DESCRIBING NEURONAL IONIC SIGNALS. K. Miller and P. Pennefather. Faculty of Pharmacy and MRC Nerve Cell and Synapse Group, University of Toronto, M5S 2S2.

In recent years there has been an explosion of quantitative information concerning the influence of independent variables on the processes that govern ionic signal formation in neurons. Such processes include: gating of ion channels mediated by membrane potential, ions, and chemicals; diffusion and buffering of ions inside neurons; and transport of ions across cell membranes. Computer simulations are extremely useful in helping the student appreciate how these disparate processes and influences interact to generate ionic signals. We have developed a general and open ended simulation program that allows the student to define or consider as many steps as are thought to be needed to describe the system under consideration. A system of ordinary differential equations (ODE's) describing trans membrane ion fluxes and the dynamics of gating and transport mechanisms is solved explicitly with systems of partial differential equations describing buffered diffusion of ions and diffusion of buffers defined to be diffusible. These systems are defined from an intuitive user interface that facilitates definition of the number of states of the channel and transport mechanisms and the influence of ions, chemicals and voltage on the transition rates between states. A numerical integrator for stiff systems of ODE's (Gear method) is included to allow rates to span many orders of magnitude. The program allows voltage clamp and current clamp experiments to be simulated and I/V and gating/V relations to be calculated. A multitude of variables can be plotted or stored in a file. The program runs on the IBM PC platform and is written in the C programming language. On an 80386 machine equipped with a math coprocessor even very complicated systems are simulated at 50-1000x real time. Results of the simulation compare well with other less versatile simulation programs and match the results of analytical solutions for systems where such solutions are possible.

203.19

COMPUTER SIMULATIONS AS A TEACHING AID IN NEUROSCIENCES. Enrique Soto. Departamento de Ciencias Fisiológicas, Universidad Autónoma de Puebla, P.O. Box 406, Puebla 72000, México

Computer simulations seem particularly suited as an aid for teaching some elementary physiological phenomena. A set of programs for this purpose has been developed; membrane potential experiments, Lorente de Nó's classical demonstration of nerve field potential and osmotic phenomena.

Programs are written in Turbo Pascaltm to operate in IBM-PC or compatibles. Continuous interactive display of results, and freedom to select display characteristics maintains the user's interest. An introductory tutorial and a users guide, allows usage of the programs without the mediation of a teacher. Programs are fully debugged and protected, and no computer expertise seems necessary to use them.

The programs have been used in several graduate general physiology courses taught at our University. Students acquainted with the required experimental setup, and the type of results that should be expected from an experiment. These turn into a significant increase in their experimental success.

Students were encouraged to understand who the simulation programs are constructed introducing this as a new teaching element. This provides students with a deeper comprehension of the parameters which determine the dynamics of physiological processes.

Supported by SEP DGICSA C90-01-0472 México.

203.16

THE SECOND MESSENGER SYSTEM. S.S. Ball* and V.H. Mah. Dept. of Pathology, Univ. of Mississippi, Jackson MS 39216 & Div. of Neuropathology, Thomas Jefferson Univ., Philadelphia, PA 19107.

The long range objective of this project is to provide an interactive computer workstation for students, educators, and research investigators in the molecular neurosciences. The workstation will allow an individual to ask a sequence of questions in a single interactive session, thereby facilitating the development and testing of several hypotheses in a short period of time. Graphical representations of molecular events will enable investigators to grasp the spatial, temporal and functional relationships among molecules, cellular compartments, and cell regions. Limited reasoning capabilities will allow an individual to ask sophisticated questions and to predict novel molecular events or pathways. A prototype system, the SECOND MESSENGER SYSTEM (SMS), is under development. SMS contains information about: 1) the molecules of signal transduction processes and the motifs that impart function to these molecules; 2) the molecular events of signal transduction processes; 3) cell-specific expression of genes critical to signal transduction processes. Signal transduction is a particularly appealing area to develop a prototype neurosciences information system for two reasons: 1) the complexity of regulatory cascades that result from numerous but relatively simple interactions provides a system relatively straightforward to represent, and at the same time, exploits something computers do well, keep track of details; 2) the central role that aberrations in signal transduction play in disorders of development, aging, and mental health. SMS is being developed through object-oriented programming in COMMON LISP for remote access on any computer terminal that can run X windows.

203.18

COMPUTER SIMULATION IN NEUROPHYSIOLOGY INSTRUCTION FOR UNDERGRADUATES. J.G. New and R.R. Fay*. Depts. of Biology and Psychology and Parmlly Hearing Inst., Loyola University of Chicago, Chicago, IL 60626.

Teaching neurophysiological principles in a laboratory setting to undergraduate students is often difficult due to limited and expensive equipment, large numbers of students, and the relative difficulty of neurophysiological manipulations. As an alternative to traditional labs, we have been using interactive software as an instructional tool to introduce neurophysiological principles to our undergraduate classes.

We have been using the *Loligo electronicus*TM (EDUCE) and Sensory Neurons (Hill-Fay Assoc, Inc) software in our Neurobiology and Psychobiology courses taught primarily to undergraduates. The *Loligo* program is a "laboratory environment" program that introduces students to both the tools of neurophysiological investigation, as well as principles of cellular physiology. The Sensory Neurons program models the responses of peripheral and central sensory neurons to applied stimuli and teaches principles of sensory coding and processing with an emphasis on the auditory system.

Experiments are performed individually and independently by students with periodic meetings with faculty. The principle advantage of using computers in this type of instruction is that they make each student an "independent investigator", extracting relevant principles of neurophysiology in a "failsafe" laboratory setting in which they become familiar with the tools, strategies and principles of experimental design employed by researchers. Additional advantages include the reduction of costs for acquisition and maintenance of equipment and specimens, avoidance of issues associated with the ethical use of living animals in teaching laboratories, and minimizing student frustration in attempting complex experiments that sometimes fail after considerable effort. Although by no means a total substitute for traditional "wet" labs, computer simulation is a valuable alternative in providing undergraduate students with an investigative experience in neurophysiology.

203.20

TRION MODEL OF CORTEX AND MUSIC COMPOSITION: AN INTERACTIVE EXHIBIT FOR SCIENCE MUSEUMS Xiaodan Leng* and Gordon L. Shaw. Center for the Neurobiology of Learning and Memory, Univ. of California, Irvine, CA, 92717.

The trion model [Shaw et al. (1985) PNAS, 82, 2364] is based on the Mountcastle columnar organizational principle of cortex. This model of memory and information processing is highly structured in time and spatial connections. "Translating" the probabilistic spatial-temporal firing pattern evolutions of the model onto music [Leng et al. (1990) Music Perception, 8, 49] gave results having the "flavor of a minuet, a waltz, or styles of specific periods of Western art music. A theme can be learned. Further, such musical styles are controllable and are done in real time. Such special features of the model integrate brain theory, music and science into an unique system that can be accessed and learned through hands on experience by people from various background and ages. An interactive trion music exhibit is now being setup at the Science Museum in the Stanford University Physics Department. Supported in part by the National Association of Music Merchants.

203.21

GENESIS: USE OF A COMPUTER SIMULATION ENVIRONMENT FOR UNDERGRADUATE AND GRADUATE INSTRUCTION IN NEUROBIOLOGY. D. Beeman and J.M. Bower, Division of Biology, California Institute of Technology, Pasadena, CA. 91125

Over the last six years we have developed a computer simulation platform for the construction of realistic numerical simulations of different nervous system components. This simulation system, called GENESIS (General Neural Simulation System), is designed to support a wide range of neural models from parts of single cells to large scale network reconstructions. While developed as a research tool, from the beginning we have been interested in the instructional use of the GENESIS system. Accordingly, GENESIS has been used at Caltech and in the course on "Methods in Computational Neurobiology" co-directed by J.M. Bower and C. Koch each summer at the Marine Biological Laboratory in Woods Hole, MA.

Recently, we have begun to make GENESIS available to other universities for both research and educational purposes. Associated with this activity, we have been developing tutorials within the system based on different neurobiological subjects. Currently, for example, tutorials exist for neuronal cable theory and for the dynamics underlying the Central Pattern Generator found in Tritonia. These and other existing tutorials are already being used in several locations around the country. Tutorials provide on screen support for student use and include a series of exercises performed by the student using the simulation. Because GENESIS is in addition a research tool, these tutorials also serve as a mechanism to start the process of building new research related simulations. Supported by NSF grant DIR-9017153.

203.23

APPLICATION OF COMPUTER-GENERATED GRAPHICS AND ANIMATION TO TEACHING NEUROPHYSIOLOGY. G.E. Lucier and R. Egizii, Dept. of Med. Physiol., Univ. of Calgary, Calgary, AB. T2N 4N1.

With the advent of low-cost computer and video systems, the ability to produce sophisticated low-budget audiovisual material is becoming a realistic tool for the teacher. This presentation will highlight the production of a fully animated 5-minute teaching video reviewing the neurophysiological control of orthostatic hypotension. Techniques employed in the production involved photographing cut-out paper characters moved under a single-frame 35mm film camera, as well as computer-generated graphics filmed directly from a CRT screen. All computer graphics were generated on a personal computer and were created by tracing outline material with a stylus on a digitizing pad and then utilizing a drawing and paint program to add color, shading, etc. Each graphic component was stored as a separate file and was recalled and manipulated for assembly of a final screen, which could consist of several files. This provided a stored data base of figures and shapes which could be used for several different composites. The files can be manipulated by use of available word-processing packages such as WordPerfect. Although specific equipment used in this particular production may not be available to every teacher, similar equipment could be easily assembled. The technique of creating a data base of physiological pictographs can not only be used to generate videos, but also for the production of 35mm slides, overheads and other visual material. Once assembled and stored, the data becomes a library of visual information with a variety of uses and applications.

203.25

HYPERBRAIN, AN INTERACTIVE, MULTIMEDIA SOFTWARE PROGRAM. Suzanne S. Stensaas, Department of Pathology, Cornell University Medical College, 1300 York Ave., New York, NY 10021

HyperBrain was designed to supplement or substitute for neuroanatomy labs (25 hrs). The decreased number of TAs and faculty, scarcity of brains from autopsies, and drop in price of videodisc players and computers prompted a search for alternatives. The program uses an authoring environment, HyperCard, and is based on a syllabus by O. E. Millhouse and a videodisc, *Slice of Life*. The hypertext feature links diagrams, text, glossary, and atlases with images, animations, pathway quizzes as well as graphics from Haines' *Neuroanatomy: an Atlas of Structures, Sections and Systems*.

Traditional wet labs and 14 VHS videotapes provide other alternatives for students to learn the same material. The 80 hr course (32, lectures; 25, labs, video or computer; 6, small group case studies; 12, neurology correlations; 3, exam) is integrated in time with neurophysiology and psychiatry. Course examinations include neurology cases with multiple short answers, and a traditional practical using kodachromes, radiographs, gross specimens, models, and diagrams. The results of student surveys at the University of Utah during its three years of development will be presented as well as a demonstration of the program. The software is available through the Univ. Utah Medical Library; it can be modified to link or launch other programs. Modules for neurology, head and neck anatomy, ear, eye, neurosurgery, neuropathology, neuroradiology developed at the University of Utah or elsewhere have been linked to the program providing a software shell for medical and graduate students using Apple Macintosh Hardware (Stensaas, S. S. and D. K. Sorenson, 1988. *12th Symposium Computer Applications in Medical Care*:p415-420).

203.22

MACINTOSH PLATFORMS FOR TEACHING LABORATORY COMPUTING, BIOMECHANICS AND NEUROETHOLOGY. J. Avers, G. Fletcher and K. Hoff, Marine Science Center, Northeastern Univ., East Point, Nahant, MA 01908

We have developed a set of programs which are used in undergraduate and graduate instruction in neuroscience classes. (1) The *Laboratory Toolbox HyperCard*™ stack implements an object-oriented "Laboratory Notebook" structure for the acquisition and management of sensor acquired data with NUBus, SCSI and serial line peripherals. It supports interactive control of consumer-grade VCRs, as well as acquisition and display from frame grabbers and a variety of GPIB™ analog interfaces. It provides XCMDs and XFCNs for an interactive instrument programming environment which students can adapt to different experimental paradigms while maintaining records of their activities and acquired data. (2) *Color Image* is an extension of *NIH Image* which supports color acquisition and segmentation of video images as well as interactive control of VCRs. *ColorImage* generates spreadsheet tables of numerical parameters of segmented objects as well as time-series data sets of the motion of objects from digital "movies" acquired from videotape sources. In addition *ColorImage* supports the correlated acquisition of kinematic and electrophysiological data by synchronizing the acquisition of digital "movies" with analog acquisition using A/D converters. (3) *MacGraph* generates parametric graphs from data generated by *ColorImage* including histograms, scattergrams and time-series graphs. (4) *Spike Train* processes analog files generated by the *Laboratory Toolbox*, *ColorImage* or the *MacRecorder*™ to segment multi-unit neuronal recordings into the activity patterns of individual units using a clustering algorithm. It generates raster diagrams of the activity patterns of individual units as well as graphical representations of the cluster distributions. The programs generate MacPaint™ files for report generation. Supported by NSF Grant DIR-8917532

203.24

NEURODYNAMIX: A GRAPHICAL SYSTEM FOR SIMULATING NEURONAL ELECTROPHYSIOLOGY. W.O. Friesen and J.A. Friesen*, Dept. of Biology, Univ. of Virginia, Charlottesville, VA 22901.

We have developed a computer-based neuronal modeling system as an aid for teaching electrophysiological concepts to advanced undergraduate and graduate students. This hierarchical system incorporates an integrated set of models that simulates neuronal function at four levels of analysis: the ionic channels observed in membrane patches; the macroscopic membrane currents in nerve-cell compartments (voltage, but not time-dependent currents in passive membrane, and time- and voltage-dependent currents that underlie impulse generation in axons); longitudinal currents in spatially distributed neurons; and synaptic currents that generate excitatory and inhibitory synaptic potentials in neuronal networks.

NeuroDynamix employs a custom-designed graphical user interface that underlies all aspects of the modeling system. This interface generates multiple time-series and phase-plane graphs of model variables. In addition, windows are used to set parameter values, to control a stimulator and to activate the measurement cursor. These windows are available at any time, allowing for instant visualization of the effects of experimental perturbations. The models that comprise *NeuroDynamix* include configuration files with which the user can select (and save) specific experiments for simulation. A set of modeling exercises developed for *NeuroDynamix* are an integral component of our 'Cellular and Molecular Neurobiology' course at the University of Virginia. Students spend class and individual time performing model exercises that are described in a workbook that accompanies the *NeuroDynamix* software.

203.26

PATHMAC: USING DIGITAL IMAGING AND HYPERTEXT FOR MEDICAL EDUCATION.

Dana Brooks* and Steven M. Erde, Depts. of Cell Biology and Anatomy, and Pathology, Cornell Univ. Medical College, New York, NY 10021.

The computer based teaching lab at Cornell University Medical College originally grew out of a need to help medical students review for the second year pathology course. The first pass, developed 5 years ago, was based on a "user-friendly" computer interface (using Apple Macintosh) and recordable videodisks (Panasonic OMDR). This technology was immediately adapted for the teaching of neuroscience, initially with the creation of a self-paced neuroanatomy tutorial called "MacBrains".

Three years ago, digital imaging and hypertext systems became available on the Macintosh platform. This enhancement in imaging technology allowed an instructor, working at the desktop, to retouch, crop, color correct, and add overlays to neuroscience images. The hypertext system permitted migration away from the linear "frame-oriented" system (too constraining for purposes beyond review of images) to a far more versatile "electronic textbook".

We will demonstrate this improved technology, as currently utilized by medical students at Cornell University Medical College for part of the first-year Neuroscience course. Additional materials, including computer-based simulations developed at our institution (Gardner and Abato 1991, this volume) as well as those produced at other medical schools, are being used to enhance the neurophysiology component of the Neuroscience course.

Supported by Cornell's PATHMAC Project.

203.27

STOCHASTIC REAL-TIME SIMULATION REPRODUCES BIOLOGICAL VARIABILITY AND TIME COURSE.

Daniel Gardner and Michael Abato, Dept. of Physiology and Project PATHMAC, Cornell Univ. Medical College, New York, NY 10021.

VIRTUAL CAT: In an early attempt to simulate a first-year Neuroscience laboratory in plasticity and pharmacology of neuromuscular transmission in the cat, the VIRTUAL CAT was developed in 1986 for the PC/AT. Four classes of students utilized the program in standard teaching labs, often alongside the experiment being modeled. On-screen and hardcopy chart records plot muscle twitch and tetanic tension to nerve stimulation, as modified by each of four neuromuscular drugs. Two design features distinguish this program from other educational software: 1) To accommodate biological variability, the non-deterministic simulation, based on arrays of real data, uses more than 60 pseudo-random parameters to calculate simulated responses within appropriate limits. 2) Delays based on physiological timings stress the time course of drug and posttetanic effects. A goal was for the simulation to be able to pass a modified Turing test: students should not be able to tell from the responses whether they resulted from a live preparation or a simulation.

ALARUM: The main-event-loop based structure of VIRTUAL CAT facilitated implementation of a modified version of the simulation on the Apple Macintosh II, as ALARUM: A LABORATORY ANIMAL REPLACEMENT USING MACINTOSH. Additional advantages include a user interface uniform for Mac applications, a scrollable virtual 'chart record' of the complete experiment, the ability to instantiate multiple virtual cats simultaneously, and integration with other Neuroscience teaching software. This version, which has been in use for two years, will be demonstrated.

Supported by an AEP grant from IBM and by Cornell's PATHMAC Project.

INSIGHT 2 - A SERIES OF FULL-COLOR, INTERACTIVE DEMONSTRATIONS IN VISION SCIENCE FOR THE MACINTOSH COMPUTER. J.A. Baro* & S. Lehmkuhle. School of Optometry, University of Missouri-St. Louis, St. Louis, MO 63121.

InSight 2 is designed for use in educational laboratories to supplement classes in experimental psychology, experimental methods, sensation and perception, or vision science. InSight 2 provides an interactive, dynamic environment in which students actively participate and can fully appreciate visual phenomena that are not well conveyed in a static medium (e.g., textbooks or slides). As such, InSight 2 is an alternative to traditional educational software, much of which is based on the database/flashcard concept.

All programs have a consistent, easy-to-use HyperCard interface, and also make use of external commands to take full advantage of the Macintosh's graphics capabilities for presenting gray scale/color images and animation. The programs can be divided into two general categories: experiments, which present stimuli, record responses, and graph/analyze data; and interactive demonstrations, which present visual phenomena and permit a variety of student interactions. Each program includes an introduction to the topic, instructions, references, and editable questions. Experiments include Spatial Contrast Sensitivity, Stereopsis and Depth, and Color Vision Test. Demonstrations include Random-Element Stereograms, Additive Color Mixing, Brightness Effects/Lateral Inhibition, Spatial Filtering/Subsampling, and Illusions and Aftereffects.

SYMPOSIA

205

SYMPOSIUM. MOLECULAR MECHANISMS OF NEUROTRANSMITTER SECRETION. G. Augustine, Duke Univ. (Chair); P. De Camilli, Yale Univ.; R. Llinás, NYU; T. Südhof, HHMI, Univ. Texas; W. Almers, Univ. Washington; H. Betz, Max Planck Institute.

The objective of the symposium is to bring together recent information on the properties of molecules found in presynaptic terminals and the possible functions of these molecules in the secretion of neurotransmitters. To achieve this objective, the symposium will present pairs of speakers who will address putative molecular mechanisms from either a molecular biological or physiological standpoint. Three molecular mechanisms will be considered: (1) *Synapsin I*, which may serve as a phosphorylation-sensitive link between synaptic vesicles and the cytoskeleton (De Camilli, Llinás). (2) *GTP-binding proteins*, which may be involved in vesicle trafficking within the presynaptic terminal (Südhof, Augustine). (3) *Fusion pores*, which may serve as the site of exit of materials from within vesicles and may be produced by synaptophysin, an integral protein of the vesicle membrane (Almers, Betz).

203.28

MacRETINA: SIMULATED MAPPING OF RETINAL GANGLION CELLS.

Richard F. Olivo, Dept. Biol. Sci., Smith College, Northampton, MA 01063.

MacRetina is a Macintosh simulation of an experiment to map the receptive fields of ganglion cells in the cat retina. MacRetina was designed with two principal goals: to provide rapid responses that mimic the "look and feel" of a real experiment, and to represent accurately the dynamic on- and off-responses of ganglion cells and the center-surround characteristics of their receptive fields. Many neuroscience textbooks describe the receptive fields of retinal ganglion cells, but students find the concept difficult to grasp because static illustrations do not readily convey dynamic properties. MacRetina simulates the ganglion cells' dynamic properties, and allows students to conduct experiments that would not otherwise be feasible.

MacRetina's screen has three areas: an oscilloscope trace that displays spikes (which also are heard as clicks), a projection screen where a spot of light is moved and flashed by moving the mouse, and a control zone with buttons to select drawing tools and single or repeated sweeps. Additional controls are available in dialog boxes. By "positioning" an extracellular electrode near different cells, a student can map sustained (X) or transient (Y) cells with on- or off-centers and antagonistic surrounds. The simulated spike trains are remarkably realistic in their appearance and sound, and the receptive field sizes and positions are based on published accounts of retinal anatomy. Help screens provide guidance and background information. The help files are written in MacWrite's simple text format, and can be customized or replaced by instructors who wish to do so.

Supported by a grant from NECUSE, the New England Consortium for Undergraduate Science Education.

206

SYMPOSIUM: THERAPEUTIC POTENTIAL OF NEUROTROPHIC FACTORS K. NIKOLIC, Genentech, Inc.

(Chairperson); R. M. LINDSAY, Regeneron Pharmaceuticals; I. A. KESSLER, Albert Einstein College of Medicine; F. HEFTI, Univ. Southern California; D. F. PRICE, Johns Hopkins Univ. Sch. Med.

Molecular and biological properties of neurotrophic factors and their receptors will be discussed. Neurotrophins and other trophic factors have differential effects on specific neuronal subpopulations *in vitro* and *in vivo* that provides the basis of their potential therapeutic applications. Neurotrophic factors stimulate regeneration of mechanically or toxically lesioned peripheral nerves. They also stimulate the survival of central neurons following mechanical lesions and they may prevent toxin-induced neurodegeneration of specific subpopulations of central nerve cells. Rodent and primate animal models of neurodegenerative diseases and attempts of rescuing specific nerve cells by neurotrophic factors will be discussed. Morphological and functional aspects of recovery from lesions as a result of neurotrophic factor treatment will be discussed.

208.1

OSCILLATORY NEURONAL ACTIVITY IN THE SUPERIOR TEMPORAL SULCUS OF MACAQUE MONKEYS. Andreas K. Kreiter and Wolf Singer, Max-Planck-Institut für Hirnforschung, Deutscherordenstr. 46, 6000 Frankfurt 71, F.R.G.

It has been proposed that synchronization of temporally structured neuronal responses in the cat visual cortex could serve as a mechanism to bind spatially segregated features of visual objects. To further explore this possibility we performed single and multiple electrode recordings in STS of one awake behaving monkey. The animal was trained to fixate a dimming light spot while moving stimuli were passed over the receptive fields of the recorded units. At many recording sites, neurons tended to discharge rhythmically with frequencies between 30 and 60 Hz, epochs with regular rhythmicity lasting about 100 to 300 ms. During these epochs the different neurons recorded from the same electrode discharged in synchrony but these coherent patterns were not phase locked to the stimulus. Response synchronization occurred also between groups of cells recorded from different electrodes separated by 0.3 to 1.3 mm, and again, the synchronous events were not locked to the stimulus. In comparison to the anesthetized cat epochs of patterned and correlated activity were shorter and frequency variations larger. These results suggest that the basic requirements for temporal coding, the quasi periodic time structure of responses and the synchronization of responses of spatially distributed neurons are met in the STS of behaving monkeys.

208.3

TRANSPARENCY AND MOTION INTEGRATION: RESPONSES OF AREA MT NEURONS. G.R. Stoner and T.D. Albright, The Salk Institute, La Jolla, CA 92037

Mounting evidence indicates that there are at least two stages of cortical motion processing. Local motion signals detected by the first stage are integrated by the second to yield a representation of 2D object motion. Since local motion signals in close proximity may or may not arise from a common object, factors affecting image segmentation should contribute to the integration process. Using "plaid patterns", we showed previously that perceptual transparency, a reliable image segmentation cue, exerts strong influence over perceptual integration of motion signals.

The two stages of motion processing are manifest by two types of directionally selective neurons in macaque visual cortex. Cells have been classified as component (stage 1) or pattern (stage 2) type based on responses to perceptually coherent plaid patterns. A thorough understanding of the integration process, however, requires knowledge about the behavior of both classes of cells under non-coherent conditions.

We have compared responses of MT neurons to coherent and non-coherent plaids, using transparency to manipulate coherence. Seventy neurons have been studied in two alert fixating macaques. Approximately 50% of the cells in this sample responded differentially to coherent and non-coherent plaids. When compared to coherent plaids, non-coherent plaids typically yielded enhanced responses to motion of the component gratings and decreased responses to pattern motion. This increase in "component-like" activity was observed for neurons of component, pattern and "unclassifiable" types, although the most striking changes were observed for pattern neurons. As a result, a net increase in component vs. pattern responses was observed for "transparent" plaids.

Thus motion signal integration by MT neurons is "gated" by stimulus factors that affect perceptual integration. As a consequence, the population ratio of component/pattern responses is a good predictor of perceptual coherence. This finding strengthens links between perceptual motion integration and neural processing in area MT, providing further evidence that transparency is used in the coherence "decision".

CHROMATIC PROPERTIES OF NEURONS IN MACAQUE MT.

J. Anthony Movshon, Daniel Kiper, Jack Beusmans, Karl Gegenfurtner, Qasim Zaidi and Matteo Carandini, Howard Hughes Medical Institute, Center for Neural Science, New York University, New York 10003, and *Department of Psychology, Columbia University, New York 10027.

The role of chromatic signals in visual motion processing is much debated. Some aspects of motion perception are altered or impaired when isoluminant colored targets are used, but it is clear that chromatic signals can support both motion perception and pursuit eye movements. In macaques, extrastriate visual area MT is thought to be of unique importance in visual motion processing. We have therefore studied the responses of MT neurons to moving grating targets modulated in luminance and chromaticity. We describe our stimuli using the color space of Derrington *et al.* (1984), in which the three cardinal axes correspond to luminance, red-green, and blue-yellow modulations.

Most MT neurons responded briskly and with high contrast sensitivity to targets whose luminance was modulated, with or without added chromatic contrast. When modulation was confined to the isoluminant plane, the responses of all MT neurons were attenuated. Most could in fact be completely silenced by stimulation with targets whose modulation lay within a "null" plane in color space; these null planes varied from neuron to neuron, but all lay within 5° of the canonical isoluminant plane. For a minority of neurons, we could find no color direction at which responses are abolished; these neurons had a definite minimum response for modulation near the isoluminant plane. Responses to isoluminant targets were generally inconsistent, and only intensely modulated targets were effective. The best sensitivity of MT neurons to luminance targets was close to behavioral contrast threshold, but the best sensitivity to chromatic modulation was many times worse.

We conclude that MT neurons can carry weak chromatic signals. But because they respond only at the highest chromatic contrasts, they do not seem to be the source of the chromatic motion signals revealed behaviorally.

208.2

ARCHITECTURE OF PRIMATE AREA MT, R. B. H. Tootell and R. T. Born, Dept. Neurobio., Harvard Med. Sch., Boston, Mass. 02115.

To investigate how motion information is extracted and organized, we studied the functional and anatomical organization of area MT. It has an elaborate and interesting architecture with at least three columnar systems.

Studies were done in both Aotus (owl) and Macaque monkeys, using deoxyglucose (both single- and double-labelled: DG and 2LDG) and single unit mapping, microstimulation, histological staining and tracer injections. Among our findings are the following: 1) In 2LDG tests, random-dot arrays drifting in opposed (180°) directions produced interdigitated bands of columns [spacing = 800-600 um (macaque); 400-600 um (Aotus)]. This is evidence for a 360° map of direction in area MT. 2) We see no 2LDG evidence of an organization for velocity nor binocular disparity. 3) The 2LDG-labelled retinotopy in macaque MT is patchy and asymmetric, but not diffuse. 4) Microstimulation at parameters used by Newsome and colleagues (Salzman *et al.*, 1990) produced very discrete regions of high DG uptake at the electrode tip (half-width at half-height = 120 um), with minimal activation away from the tip. This supports the idea that microstimulation can preferentially activate cells within a "single" direction column in MT. 5) Extensive DG and single unit mapping indicate a prominent columnar grouping of cells into "bands" and "interbands". Band cells respond well to large-field stimuli such as random dot arrays, and interband cells show surround inhibition. 6) Cytochrome oxidase patchiness is present in MT layers 1-4 in both the New World Aotus monkey (Tootell *et al.*, 1985) and the Old World green monkey (*Cercopithecus aethiops*). However, the topography and laminar profile of the cytochrome oxidase "patch/interpatch" architecture are different from that of the DG-labelled "band/interband" architecture. In addition, the specific inputs to the patches appear different from those to the bands. This work was supported by EY07980 and T32NS07112.

208.4

THE USE OF COLOR- AND LUMINANCE-DEFINED EDGES FOR MOTION CORRESPONDENCE. KR Dobkins and TD Albright, Salk Institute, La Jolla, CA

Previous studies from our laboratory have shown that neurons in macaque area MT detect motion of drifting chromatic edges that undergo repetitive contrast reversal (Dobkins and Albright, 1991). This property is predicted by the presence earlier in the magno pathway of neurons that detect chromatic contrast but are unselective for sign. To further explore mechanisms underlying this phenomenon, we have studied motion detection for achromatic gratings that undergo repetitive contrast reversal.

In human psychophysical experiments we used chromatic (red/green) and achromatic sine-wave gratings moved by repetitive phase shifts of < 30°. With each displacement, gratings underwent contrast reversal. When presented with isoluminant chromatic gratings, Ss reported motion in the direction of contrast-reversing edges. Away from isoluminance, perceived direction reversed; Ss reported motion in the direction that preserved luminance and color correspondence. When presented with achromatic gratings, Ss reported motion in the direction that preserved luminance correspondence, regardless of luminance contrast.

We used identical stimuli to study MT neurons in fixating macaques. Results were congruent with the psychophysics. For chromatic stimuli, cells selected the direction of contrast-reversing edges at isoluminance but reversed selectivity at non-isoluminance to follow the direction of luminance and color correspondence. When presented with achromatic gratings, however, cells responded in the direction of luminance correspondence. We observed a similar phenomenon using aperiodic contrast-reversing patterns (random textures). This result reveals a neural correlate of the "reversed phi" motion percept (Anstis, 1970).

These data demonstrate that under certain conditions the motion system uses information about edges defined by color at the expense of disregarding information about the colors that make up those edges. By contrast, for achromatic stimuli, luminance polarity dictates direction of motion.

MT NEURONS ENCODE THE SIGNAL-TO-NOISE RATIO OF SIGNALS IN A STOCHASTIC MOTION DISPLAY. Kenneth H. Britten*, William T. Newsome, and J. Anthony Movshon, Dept. of Neurobiology, Stanford University, Stanford, CA 94305 and §Howard Hughes Medical Institute, Center for Neural Science, NYU, NY 10003.

We have previously shown that dynamic random dot stimuli can be used to explore the sensitivity of directional signals in monkey extrastriate area MT. These stimuli, in which a portion of dots carry a correlated motion signal while the remaining dots move randomly, are also well suited for studying the input-output characteristics of these neurons. Increasing the proportion of dots in correlated motion produces a proportional increase in the signal-to-noise ratio of the motion signal across a wide range of correlations. We have explored the effect of this signal-to-noise ratio on the responses of 217 MT neurons by presenting motion in the neurons' preferred and null directions over a range of correlations.

The majority of MT response functions were linear with stimulus correlation; a minority showed nonlinearities, with roughly equal numbers showing positively and negatively accelerating responses. Analysis of the quadratic term of polynomial fits to the data showed that the distribution of this acceleration was unimodal and centered about zero for both preferred and null direction stimuli. Thus most MT cells are dominantly linear in their responses to stimuli of increasing signal-to-noise ratio; this is quite different from their responses to increasing stimulus contrast, which generally show strong saturation (negative acceleration). We are presently exploring the relationship between these data and the predictions of motion energy models of the sort proposed by Adelson and Bergen (1985).

DO CELLS IN AREA MT CODE THE ORIENTATION OF A KINETIC BOUNDARY? V.L. Marcar*, S.E. Raiguel, D. Xiao*, H. Maes* & G.A. Orban. Laboratorium voor Neuro- en Psychofysiologie, K.U.Leuven, GHB, B-3000 Leuven, Belgium.

The cells in the area MT of the owl monkey appear to be suited for detecting kinetic boundaries (Allman *et al.*, Perception, 1985). Lagae *et al.* (Brain Research, 1989) reported that the different layers within area MT of the macaque monkey process motion stimuli of increasing complexity. Does this hierarchical processing within MT include cells that code the orientation of a kinetic boundary? We investigated this question using the macaque monkey prepared for acute electrophysiological recording.

Our stimuli consisted of 16 random dot fields moving coherently in directions differing by 23° and 8 kinetic boundaries, differing in orientations by 23°, generated by combining two random dot fields moving in opposite directions. Two types of motion attributes were used to define a kinetic boundary; motion parallel and motion orthogonal to the orientation of the boundary. We also used two types of kinetic boundary stimuli, kinetic edges and kinetic gratings.

None of the cells located within area MT showed such selectivity for the orientation of kinetic boundaries. Cells shifted their apparent 'orientation preference' by 90° when the motion attributes changed from parallel to orthogonal to the orientation of the kinetic boundary. The response level of cells to their preferred kinetic edge was 30%-50% of their response level to a random dot field moving in their preferred direction and response levels to a kinetic grating was lower still. The consecutive reversal between 'Preferred' and 'Null' direction of motion of a kinetic grating was therefore much more effective in inhibiting the cell than the single reversal of a kinetic edge stimulus, confirming that cells in MT respond to the local motion only. MICROSTIMULATION OF VISUAL AREA MT: EFFECTS ON CHOICE BEHAVIOR IN THE ABSENCE OF MOVING VISUAL STIMULI. Chieko M. Murasugi, C. Daniel Salzman and William T. Newsome. Dept. of Neurobiology, Stanford Univ. Sch. of Med., Stanford, CA 94305.

We previously reported that electrical microstimulation of MT during a two-alternative, forced choice direction discrimination biases a monkey's perceptual judgments in favor of the preferred direction of neurons at the stimulation site (*Nature* 346, 174-177). In those experiments, microstimulation was applied during the presentation of a dynamic random dot motion stimulus within the receptive field of the stimulated neurons. In a continuing attempt to describe the necessary and sufficient conditions for eliciting the effect, we examined the influence of microstimulation on choice behavior in the absence of moving visual stimuli.

Our methods were the same as in the original experiments except that a small number of "no motion" test trials were randomly interleaved among the usual range of dynamic random dot stimuli. The test trials were of two types: 1) static random dot patterns, and 2) no visual stimulus at all. Microstimulation occurred on half of the test trials. Since there was no "correct" answer on these test trials, the monkey was randomly rewarded with a probability of 0.5. Across 48 experiments, microstimulation in both "no motion" conditions induced a mean increase (*t*-test, *p* < .01) in the number of choices favoring the preferred direction of the neurons at the stimulation site. On average, the size of the effect on the "no motion" trials was 1/3 - 1/2 of that observed on the randomly interleaved dynamic random dot trials. Thus, microstimulation has its largest influence on the monkey's choice behavior in the context of the normal motion discrimination task on which the monkey was trained. Microstimulation can, however, elicit smaller choice biases in the absence of moving visual stimuli.

MAGNOCELLULAR AND PARVOCELLULAR CONTRIBUTIONS TO THE VENTRAL EXTRASTRIATE CORTICAL PROCESSING STREAM. J.A. Nealey, V.P. Ferrera and J.H.R. Maunsell. Department of Physiology and Center for Visual Science, University of Rochester, Rochester, NY 14642.

The magnocellular and parvocellular subdivisions of the lateral geniculate nucleus (LGN) relay different types of visual information and terminate in different sublaminae in striate cortex (V1). Several lines of evidence support the idea that these channels remain separate in cortex and contribute differentially to the dorsal and ventral extrastriate streams of processing. We have previously used reversible inactivation of LGN laminae to show that area MT in the dorsal cortical pathway is dominated by magnocellular input. We now report the results of similar experiments examining magnocellular and parvocellular contributions to elements in the ventral cortical pathway. We reversibly blocked individual LGN layers with small injections (75-150 nl) of either lidocaine (2%) or GABA (25 mM) while recording from area V4 or the superficial layers of V1. We tested 90 single or multiunit sites in V4 during either magnocellular or parvocellular blockade. As expected, parvocellular blockade reduced V4 responses (mean reduction of 28%). However, magnocellular blockade unexpectedly produced comparably strong effects on the V4 responses (mean reduction of 38%). In V1, 19 sites in the superficial layers of V1 were recorded during magnocellular blockade. Many showed reduced responses, with a mean reduction of 42%. Responses of V1 sites in the interblob regions of V1 showed somewhat stronger effects of magnocellular block than those in the blobs. Thus it appears that elements in the ventral extrastriate cortical processing stream receive substantial excitatory drive from both magnocellular and parvocellular LGN.

MICROSTIMULATION OF MT DURING AN EIGHT-ALTERNATIVE MOTION DISCRIMINATION: DIRECTIONAL TUNING OF THE BEHAVIORAL EFFECT. C. Daniel Salzman and William T. Newsome. Department of Neurobiology, Stanford University, Stanford, CA 94305.

Previously, we reported that microstimulation in visual area MT can bias a monkey's perceptual judgements of motion direction towards the preferred direction of neurons at the stimulation site (*Nature* 346: 174-177). Since in those experiments we required the monkey to discriminate between two directions of motion 180° apart, we did not measure the directional tuning of the microstimulation effect. MT neurons, though direction selective, generally respond to motion over a broad range of directions near the preferred (mean bandwidth at half-height = 83°, Albright, 1984). We therefore sought to determine whether activation of such neurons would bias a monkey's judgements towards all directions within the tuning bandwidth of neurons at the stimulation site, or only towards the neurons' preferred direction.

To measure the directional tuning of the microstimulation effect, we trained a monkey on an eight-alternative, forced choice motion discrimination in which each of the eight possible directions of motion was separated by 45°. Thus the monkey's choices spanned 360°. We then applied microstimulation (10 μ A, 200 Hz, biphasic pulses) to selected sites in MT while the monkey performed the eight choice discrimination. In 25 experiments, microstimulation induced a choice bias towards a direction within the tuning bandwidth of neurons at the stimulation site. Moreover, the bandwidth of the behavioral effect was typically much narrower than that of the neurons, frequently being restricted to a single direction. This narrow bandwidth suggests that the cortex computes a single, most likely direction of motion consistent with the activity in a population of broadly tuned neurons.

Supported by the National Eye Institute (EY-05603) and by the McKnight Endowment Fund for Neuroscience. CDS supported by a Medical Student Fellowship from the Howard Hughes Medical Institute.

LIMITATIONS OF THE OPTIC FLOW SELECTIVITY IN MST NEURONS. G.A. Orban, L. Lagae*, D. Xiao*, S. Raiguel and H. Maes*. Laboratorium voor Neuro- en Psychofysiologie, K.U.Leuven, B-3000 Leuven, Belgium.

We previously reported on the selectivity of MST cells for optic flow components (rotation, expansion, deformation). We showed that position invariance of the directional responses for the optic flow components indicates genuine optic flow selectivity (Lagae *et al.*, *Inv.Opt.Vis.Sc.*, 1991). We now report on the limitations of this selectivity.

If these units encode optic flow components, then it is expected that they can extract the optic flow component for which they are selective from a more complex motion stimulus. Therefore, we tested the selectivity of these units for combinations of the selective component which remained constant and another optic flow component or translation which changed. It was found that the majority of the cells tested (*n*=14) remained direction selective only for combinations in which the fixed component was stronger than the variable component. These are combinations in which the direction offset of the local vectors is less than 45 degrees on either side. These units are thus extracting the optic flow component only over a limited range of combinations.

To test the receptive field organization, we compared a normal area summation test with an inverse summation test for a number of speeds. In the former, stimuli of increasing area were presented while in the latter one, masks of increasing size covered the centre of the receptive field. While the responses increased with increasing stimulus size, masking the centre of the receptive field did not change the response for the optic flow component. This indicates a silent inhibitory discharge region under the excitatory discharge region and correlates with the fact that the centre of an optic flow component is not necessary for the detection of that component.

RESPONSES OF CELLS IN AREA V4 OF MACAQUE VISUAL CORTEX TO SIMULATED 3D SURFACES. Jack L. Gallant, Jochen Braun, and David C. Van Essen. Div. Biology, Caltech, Pasadena, CA.

We have examined neural responses to texture patterns that simulate flat surfaces oriented in 3-dimensional space, in order to ascertain how 3D objects are represented in primate visual cortex. The surfaces were computer-graphic representations composed of circular texture elements, transformed so as to appear to be oriented in 3D space. The flat surfaces we simulated can be parameterized by the slant of the surface normal away from the image plane, and the tilt of the surface normal around the line of sight. Changes in slant and tilt produce changes in the distribution of their 2D Fourier energy, so we also collected data on 2D spatial frequency and orientation tuning.

We studied 106 cells in detail in area V4 of anesthetized, paralyzed macaque monkeys. In 72 cells quantitative analyses were obtained for both 2D grating and 3D texture patterns. About one-third of the cells were tuned for 3D slant and/or tilt, and about half were tuned for 2D orientation and/or spatial frequency. Only a minority of cells responded well to both gratings and textures, but for this subset the optimal 3D and 2D parameters were correlated: the best slant contained textures with high Fourier energy near the optimal spatial frequency, and the best tilt corresponded to the optimal grating orientation. Many cells responded well to gratings but poorly to all textures tried, and some cells responded well to textures but poorly to all gratings, suggesting that these cells are spatially nonlinear. Altogether, we find that many cells in V4 appear to be tuned for the 3D orientation of surfaces, but that for most (but perhaps not all) cells this tuning is a result of the correspondence between their 2D spatial and orientation tuning and the 2D distribution of energy in images of surfaces differing in their 3D orientation.

209.1

GABA RECEPTOR FUNCTION IS ALTERED IN THE *C. ELEGANS* MUTANT UNC-49. J. R. Mancillas^{1,3}, A. Ruiz-Morales¹ and R. Olsen².
¹Depts. of Anatomy and Cell Biology and ²Pharmacology, UCLA School of Medicine and ³Molecular Biology Institute UCLA, Los Angeles, CA 90024.

Unc-49 is a genetic locus identified by mutation which causes a "shrinker" phenotype. Worms attempting to move backward shrink by simultaneous contraction of dorsal and ventral muscles suggesting a defect in the system of cross-inhibitor GABAergic motoneurons, the DDs and VD. While DD and VD morphology and axonal trajectories are normal, GABA receptor activity is impaired. Binding studies reveal a 3 fold reduction in receptor-specific GABA binding in unc-49 as compared to wild type. Unc-49 displays a 10 fold increased delay in responses to muscimol [8mM], which inhibits motility measured either as rate of locomotion on an agar plate or as frequency of swimming motions. Analysis of muscle responses to GABA and muscimol in cut worm assays also reveals altered responses in unc-49.

Unc-49 has been cloned by transposon tagging. 2.9 kb of genomic sequences flanking a TC1 insertion were cloned and used to isolate 3 cDNAs (1.5, 2.8 and 3.5 kb) and to identify two genomic YAC clones, Y40C2 and Y52C5, as containing the unc-49 coding region. These YACs overlap and are located in a region of the *C. elegans* physical map predicted to include the unc-49 genetic locus. We are currently sequencing unc-49, and performing Northern blots of staged mRNA and in situ hybridization to establish its temporal and spatial patterns of expression. Preliminary results using in situ hybridization show the presence of a putative unc-49 message in the body wall musculature.

209.3

ACTIVATION OF GABA_A RECEPTORS BY ENDOGENOUS GABA RELEASE IN DEVELOPING RAT OPTIC NERVE. K. Sakatani, J.A. Black, and J.D. Kocsis. Dept. of Neurosurgery, NYU Medical Center New York, NY 10016, and Dept. of Neurology, Yale University, New Haven, CT 06510

A number of reports indicate that GABA can modulate the excitability of some CNS white matter tracts where synapses and neuronal cell bodies are not present. We studied immunolocalization of GABA and sensitivity of GABA receptors in the rat optic nerve during development by immunohistochemical and electrophysiological techniques.

We report that transient endogenous GABA is present *in situ* in rat optic nerve and localized to astrocytes and premyelinated axons during the first few weeks of postnatal development; GABA immunoreactivity of the optic nerve is markedly reduced in the adult. Electrophysiological results, obtained by a modified sucrose gap technique, demonstrate that the optic nerve axons are depolarized by the activation of GABA_A receptors and the inhibition of GABA-uptake with nipecotic acid, indicating that functional endogenous GABA and the GABA-uptake mechanism are present in the neonatal optic nerve. Baclofen, a GABA_B receptor agonist, did not result in membrane potential change. Furthermore, the GABA-induced depolarization is extremely attenuated in the adult.

Although the biological role of GABA and GABA_A receptors in the optic nerve is not certain, it is clear that GABA and GABA_A receptor interactions can occur at a nonsynaptic region in CNS white matter in an age dependent manner. The transient nature of the GABA and GABA_A receptor expression is in agreement with other developmental studies suggesting a trophic role of GABA. Alternatively, this interaction may provide for a nonsynaptic signal pathway between glia and neurons. Supported by the NIH, the NMSS, and the VA.

209.5

DIFFERENTIAL MODULATION OF STIMULUS-EVOKED AND SPONTANEOUS GABA RELEASE BY PRESYNAPTIC GABA_B AUTORECEPTORS. T.S. Otis and I. Mody, Dept. of Neurology & Neurological Sciences, Stanford Univ. Sch. of Med., Stanford, CA.

Spontaneous miniature inhibitory postsynaptic currents (sIPSCs) and monosynaptically evoked inhibitory postsynaptic currents (evIPSCs) were recorded in the whole-cell mode in dentate gyrus granule cells of 400 μ m thick hippocampal slices maintained at 34 \pm 1°C in the presence of CNQX (5-10 μ M) and APV (20-40 μ M). The evIPSCs, elicited by stimulating in the molecular layer, showed marked paired-pulse depression (30-60%), which peaked at approximately 200 ms inter-stimulus interval, and lasted over 3 s. This depression was sensitive to the GABA_B antagonist CGP 35348 (1 mM). The evIPSCs were also depressed (86 \pm 5%) by 1 μ M (-)baclofen. To determine the effect of evoked GABA release on sIPSCs, we performed a peri-stimulus analysis, comparing sIPSCs occurring in a 500 ms epoch beginning 100 ms after a stimulus to an identical epoch preceding the stimulus. Post-stimulus, despite the marked depression of evIPSCs, the amplitudes and inter-event intervals (IEIs) of the sIPSCs were statistically indistinguishable from those in the pre-stimulus category. Consistent with this effect, 1 μ M (-)baclofen had minimal effects on the average sIPSC amplitude (18 \pm 6% depression) and IEI (17 \pm 23% increase).

These results strongly suggest that the stimulus-evoked release of GABA causes a presynaptic autoinhibition of subsequent evoked release but it has little effect on the spontaneous GABA release. We conclude that spontaneously active presynaptic GABAergic terminals do not contribute substantially to the evIPSC, and that these terminals have few, if any, functional GABA_B autoreceptors. CLONING AND SEQUENCING OF GENOMIC DNA FOR THE HUMAN β 1 SUBUNIT OF THE GABA_A/BENZODIAZEPINE RECEPTOR S.J. Russek* and D.H. Farb. Department of Pharmacology and Experimental Therapeutics, Boston University School of Medicine, Boston, MA, 02118.

The GABA_A receptor is the major inhibitory neurotransmitter receptor in the CNS. Molecular biological studies demonstrate that the pharmacology of the GABA_A receptor is critically dependent on its subunit composition. *In situ* hybridization reveals a differential distribution of subunit specific mRNAs in different brain regions. To study regulation of GABA_A receptor expression in the nervous system we are identifying the regulatory elements of this gene family. Polymerase chain reaction (PCR) with human genomic DNA was carried out using primers made to the human β 1 cDNA. A probe was prepared from the first 133 bp of the β 1 cDNA and was used to identify, by Southern hybridization, the relevant PCR products. Subcloning and sequencing of a 1 kb PCR product revealed sequence identity with the 5' end of the human β 1 cDNA, and several intron/exon boundaries have been mapped. Using inverse PCR and ligation mediated PCR, we have identified the 5' flanking region of the human β 1 gene. To study the cellular regulation of the β 1 gene, conditions have been established for the optimal transfection of embryonic chick neurons in primary cell culture. Our previous studies have demonstrated that GABA downregulates receptor number and α subunit specific mRNA levels (Roca et al. Mol. Pharmacol. (1990) 37:37; Montpied et al. J. Biol. Chem. (1991) 266: 6011). Studies suggest that, as for the muscle nACh receptor, the 5' flanking region of the β 1 gene may contain the regulatory elements necessary for the control of this gene's expression in the nervous system.

THE POSTSYNAPTIC ACTIONS OF SPONTANEOUSLY RELEASED GABA. I. Mody and T.S. Otis, Dept. of Neurology & Neurological Sciences, Stanford Univ. Sch. of Med., Stanford, CA.

Spontaneous miniature postsynaptic currents (sIPSCs) were recorded in dentate gyrus granule cells of 400 μ m thick hippocampal slices maintained at 34 \pm 1°C in the presence or absence of 1-5 μ M tetrodotoxin (TTX). These inhibitory currents generate an average conductance ranging between 200-600 pS (in TTX) which may effectively control the excitability of CNS neurons by providing a filtering mechanism for various inputs reaching the cells.

The sIPSCs were solely mediated by GABA_A receptor activation, since they reversed at the Cl⁻ equilibrium potential, were blocked by bicuculline methiodide but were unaffected by the GABA_B receptor antagonists 2-OH-saclofen (200 μ M) or CGP 35348 (1 mM) while the stimulus-evoked IPSCs (in the presence of CNQX and APV) displayed a prominent GABA_B receptor mediated component. The decay time constant (τ_D , range: 4.2 to 7.2 ms) of the sIPSCs was mostly monoexponential and was dependent on the membrane potential and temperature. A 133 mV change in membrane potential produced an e -fold change in τ_D while the Q_{10} (measured between 22-37°C) was 2.0. As expected, the τ_D of sIPSCs were prolonged in a dose-dependent manner by pentobarbital and the benzodiazepine (BZ) midazolam. The midazolam effect was antagonized by the BZ receptor antagonist flumazenil (RO 15-1788), which by itself had no effect on the τ_D of sIPSCs indicating no endogenous BZ receptor activation. The τ_D of sIPSCs was also modulated by loading the neurons with various concentrations of Ca²⁺ through the patch pipette. Elevating intracellular Ca²⁺ concentration produced a gradual prolongation of the τ_D without a significant change in the rise-time or amplitude of the events. SINGLE CHANNEL KINETIC PROPERTIES OF NEUROSTEROID REGULATION OF GABA_A RECEPTORS.

R.E. Twyman+ and R.L. Macdonald+#. Depts. of Neurology+ and Physiology#, Univ. of Michigan, Ann Arbor, MI.

Neurosteroids have been shown to be potent regulators of GABA_A receptors. The mechanism of enhancement of GABA-evoked current remains unclear, but has been suggested to be "barbiturate-like". However, steroids and barbiturates appear to bind to separate sites on the GABA receptor. To determine the mechanism of action on GABA receptor currents, the gating (opening and closing) kinetics of single channel GABA receptors regulated by androstosterone (10 nM - 10 μ M) and pregnanolone (100 nM - 10 μ M) were analyzed.

Excised outside-out patches were obtained from mouse spinal cord neurons in culture and voltage clamped at -75 mV in symmetric chloride solutions. Average GABA- (2 μ M) evoked current was increased by the steroids, but single channel conductance was unchanged. There were concentration-dependent increases in average channel open and burst durations and channel opening frequencies. Three open and burst duration and two brief intraburst closed duration time constants were unchanged by the steroids. There was a concentration-dependent increase in the relative fraction of the longest open and burst duration time constants which accounted for the increased average open and burst durations. This mechanism of potentiation of single GABA-receptor currents was similar to that previously described for barbiturates and suggested that although their binding sites may be different, both had a common effector mechanism for enhancement GABA receptor current. The increased opening frequency observed with these steroids, however, has not been described as a consistent finding for barbiturates.

ACTIONS OF AN ENDOGENOUS STEROID ON CHINESE HAMSTER OVARY CELLS TRANSFECTED WITH THE $\alpha 1\beta 1$ GABA SUBUNIT COMBINATION. C. Hill-Venning, J.A. Pinewells* and J.J. Lambert, Department of Pharmacology, Ninewells Hospital, Dundee, DD1 9SY, Scotland, U.K.

Some endogenous steroids e.g. 5β -pregnan- 3α -ol-20-one ($5\beta 3\alpha$) are potent positive allosteric modulators of the GABA_A receptor. In an attempt to better understand the molecular basis of this interaction, we have used the whole-cell mode of the patch-clamp technique to examine the actions of $5\beta 3\alpha$ on GABA-evoked responses in a stable Chinese hamster ovary cell line. These cells have been initially transfected with an expression vector for the $\alpha 1$ and $\beta 1$ subunits cDNAs of the bovine GABA_A receptor, and transcription was achieved using a dexamethasone-inducible promoter (Eur. J. Pharmac. 189, 77-88, 1990). GABA ($50\mu\text{M}$) induced an inward current on 44% of cells tested ($n = 169$) (i.e. successfully transfected cells), while voltage clamped at -55mV . The GABA-evoked current varied considerably from approximately 50pA to 3nA . $5\beta 3\alpha$ (30nM - 300nM) enhanced such currents in a dose-dependent manner. Additionally, application of the steroid alone induced a dose-dependent inward current which was antagonized by bicuculline ($10\mu\text{M}$), and potentiated by pentobarbitone ($10\mu\text{M}$). Collectively, these observations demonstrate that the $\alpha 1\beta 1$ GABA_A receptor subunit combination is sensitive to both steroids and barbiturates, and additionally supports the proposal that these agents bind to different sites. We thank E.A. Barnard for the cells and T.G. Smart for technical advice.

MODULATION OF GABA_A RECEPTOR BINDING BY PREGNANE STEROIDS IN RAT BRAIN. E.H.F. Wong, H.L. Wu*, P. Nelson* and R.M. Eglén*. Institute of Pharmacology and Chemistry, Syntex Research, Palo Alto, CA 94303.

Radiolabel binding studies were done to characterize steroid modulation of binding at the picrotoxin site and the benzodiazepine site of the GABA_A receptor complex. Crude P₂ fractions of rat brain tissue were incubated with selected steroids and either [³⁵S]TBPS or [³H]flunitrazepam for 90 min at 25°C. In rat cortical membranes, the following compounds were shown to inhibit [³⁵S]TBPS binding: 5β -pregnan- 3α -ol-20-one ($\text{pIC}_{50} = 7.01$), 5α -pregnan- 3α -ol-20-one (6.66), 5α -pregnan- $3\alpha 21$ -diol-20-one (6.50), 5β -pregnan- $3\alpha 20\alpha$ -diol (6.33), 5β -pregnan- $3\alpha 20\beta$ -diol (6.26), 5β -pregnan- 3α -ol-11,20-dione (6.05), 5α -androstan- 3α -ol-17-one (5.79), 5β -pregnan- 3β -ol-20-one (4.95), 5α -pregnan- 3β -ol-20-one (<4), 5β -pregnan- $3,20$ -dione (<4), 5α -pregnan- $3,20$ -dione (<4), and 5β -pregnan- $3\alpha,17\alpha,21$ -triol-11,20-dione (<4). Enhancement of [³H]flunitrazepam binding was demonstrated by these compounds with similar potencies and rank order. Two stereoisomer pairs were chosen to evaluate modulation of binding in the following additional rat brain regions: cerebellum, hippocampus, striatum, midbrain, and brain stem. For both [³⁵S]TBPS and [³H]flunitrazepam binding, the 3α -OH analogs of 5α or 5β pregnan-20-one were approximately 30-fold greater in potency than the corresponding 3β -OH pair. The same results were obtained for all brain regions. While different steroid compounds demonstrated a dose-dependent and stereoselective modulation of binding at the picrotoxin and the benzodiazepine sites of the GABA_A receptor complex in rat brain, no differences among brain regions have been observed so far.

209.11

BENZODIAZEPINES ACTING AS FULL AND PARTIAL MODULATORS ON NATIVE AND RECOMBINANT GABA_A RECEPTORS

G. Puia, G. Mereu, S. Vicini, and E. Costa. FIDIA-Georgetown Institute for the Neuroscience, Washington DC.

Pharmacological studies (Haefely, W., 1990 TIPS, 11:452) indicated that *in vivo* the positive allosteric modulator of GABA_A receptor, Bretazenil, is endowed of an intrinsic activity much lower than that of other structurally related positive modulators such as diazepam, clonazepam etc. This action could be due to a selective intrinsic activity on a small number of GABA_A receptor subtypes or to a reduced intrinsic activity on every GABA_A receptor subtypes. To investigate which of the two alternative hypothesis was valid, we employed whole-cell recordings of GABA-activated Cl⁻ currents in human kidney tumoral cells transiently transfected with cDNAs encoding different molecular forms of α , β , and γ subunits of the GABA_A receptor. Bretazenil is a positive allosteric modulator with partial intrinsic activity in each receptor assembly we tested that contains a γ subunit. Dose-response study indicates that bretazenil has lower efficacy but a potency similar to that of diazepam. When we applied Bretazenil together with a high intrinsic activity full positive allosteric modulator that acts on GABA-gated Cl⁻ currents such as diazepam, the efficacy of the latter was considerably curtailed. The clinical use of a low intrinsic activity allosteric modulator of GABA action may be of interest because its regulated efficacy appears to reduce unwanted collateral effects such as sedation and tolerance that are typical of high intrinsic activity.

GABA_A RECEPTOR-ACTIVE NEUROSTEROIDS IN THE RAT BRAIN. R.H. Purdy¹, P.H. Moore, Jr.¹, N. Hagino^{2*}, A.L. Morrow³, and S.M. Paul⁴. ¹S.W. Found., San Antonio, TX 78228, ²Univ. Tex. Hlth. Sci. Cr., San Antonio, TX 78284, ³Univ. N.C. Sch. of Med., Chapel Hill, NC 27599, ⁴NIMH, Bethesda, MD 20892.

Electrophysiological and biochemical studies have shown that the neuroactive steroids 3α -hydroxy- 5α -pregnan-20-one (allopregnanolone, AP) and $3\alpha,21$ -dihydroxy- 5α -pregnan-20-one (allotetrahydrodeoxycorticosterone, alloTHDOC) are the most potent known ligands of the GABA_A-receptor complex in the CNS. These endogenous steroids allosterically augment GABA_A receptor-mediated Cl⁻ ion conductance in a manner similar to that of the anesthetic barbiturates. Using specific radioimmunoassays to measure these steroids in extracts of brain tissue after purification of the steroids by HPLC, we have recently demonstrated that AP is low and alloTHDOC undetectable in the cerebral cortex of male rats, but increased after acute swim stress to about 5-6 ng/g and 1-2 ng/g, respectively. Because of the cyclic nature of progesterone in female rats, we have examined the role of age, the estrus cycle and pregnancy on AP levels in the brain of females. In juvenile and diestrus rats, low but detectable levels of AP (2 ng/g) were found in cortex. A relatively uniform regional distribution was found throughout the female rat brain in proestrus and estrus, ranging from 4-7 ng/g. Aged female rats had cerebral cortex levels of about 3 ng/g. The level of AP reached 12 ± 1.0 ng/g in cerebral cortex of pregnant rats (gestational day 15), where plasma levels were also elevated to 17 ± 2.0 ng/ml. These findings suggest that GABA_A receptor-active steroids may modulate CNS excitability in various physiological states.

209.10

ENDOZEPINE-2: IDENTIFICATION AND PURIFICATION OF AN ENDOGENOUS LIGAND FOR THE BENZODIAZEPINE RECEPTOR.

J.D. Rothstein, W. Garland¹, G. Puia², A. Guidotti², E. Costa², Johns Hopkins Univ, Dept. Neurology, Baltimore, MD, 21205; ¹Hoffman-La Roche, Nutley NJ, 07110; ²FGIN-Georgetown Univ, Washington D.C., 20007.

Recently, we demonstrated the existence of multiple benzodiazepine-like substances (endozepines) in human and animal brains. We have now purified one of these chemicals to homogeneity. Endozepine-2 was purified from rat (1 kg) or bovine (~20 kg) brain using tissue acidification, chloroform/acid extraction, and tandem reverse-phase - silica/organic HPLC. This material appears to be identical to "peak 2" from our previous HPLC purification (J Neurochem 55:2015). Using this protocol, microgram quantities have been purified. The final purified chemical is a non-peptide, weak base with a molecular weight of less than 700. Although the chemical structure is not yet known, gas chromatography/negative chemical ionization mass spectroscopy revealed that endozepine-2 is not halogenated, in contrast to reports by others of halogenated 1,4 benzodiazepines in brain (PNAS 87:5263). Endozepine-2 specifically binds to the benzodiazepine receptor with an apparent nM affinity and a unitary Hill coefficient. Its physiological properties were studied on patch clamped human embryonic kidney cells transfected with cloned GABA receptor subunits α, β, γ , and in whole cultured rat cortical neurons. Endozepine-2 potentiated GABA mediated chloride currents in a dose response manner ranging from 10^8 to 10^5 M (diazepam equivalents). Its actions were readily blocked by flumazenil. Endozepine-2 has also been found in microdialysis dialyzates from rat brain. Furthermore endozepine-2 and another endozepine, yet to be characterized, are released by potassium depolarization in microdialysis preparations. The exact molecular weight and chemical structure of endozepine-2 is under investigation.

LONG-TERM INFLUENCE OF TETRODOTOXIN AND HISTAMINE ON GABA_B RESPONSES IN THE CNS OF NEWBORN OPOSSUM IN CULTURE. J.M. Treherne, D.-J. Zou¹, R.R. Stewart, J.G. Nicholls and N.R. Saunders* Pharmacology Dept., Biocenter Basel, Switzerland and Clinical Neurological Sciences, Southampton University, UK.

The CNS of the newborn opossum, *Monodelphis domestica*, has been isolated and maintained in culture to study neurotransmitter action. Immediately after isolation and after 7 days culture GABA reversibly inhibited synaptic transmission in the spinal cord. Inhibition involved both GABA_A and GABA_B receptors as determined by selective agonists (muscimol and baclofen) and antagonists (bicuculline and CGP 35348). Dose-response curves for both GABA_A- and GABA_B-mediated responses remained virtually unchanged over 7 days in culture. GABA_B-mediated responses to baclofen, however, were virtually abolished by chronic exposure to L-histidine ($150\mu\text{M}$). Modulation of GABA_B receptors was dependent on electrical activity, since TTX (which reversibly blocked all action potentials) protected preparations from the actions of L-histidine. Further experiments suggested that L-histidine acted indirectly and was converted to histamine. These results demonstrate the potential of this preparation for the study of receptor regulation and synaptic plasticity during development.

210.1

EVIDENCE THAT PNMT-CONTAINING NERVE TERMINALS IN RAT SPINAL CORD ARE NORADRENERGIC. A.F. Sved, C.T. Hasselman, M.G. Backes, J.N. Salter. Department of Behavioral Neurosciences, University of Pittsburgh, Pittsburgh, PA 15260.

We have previously reported that, although the intermediolateral cell column (IML) of the rat spinal cord is densely innervated by the C1 PNMT-containing catecholamine cell group in the ventrolateral medulla, the IML does not contain epinephrine. In the present study, two approaches were used to address the hypothesis that the terminals in the IML arising from the C1 neurons are instead noradrenergic. First, the effect of destruction of the A5 cell group on norepinephrine (NE) level in the IML was determined, since the A5 cell group in the caudal pons is the only classical noradrenergic cell group to innervate the IML. Two weeks following complete bilateral lesions of the A5 cell group (less than 5% of the A5 cells remaining) by local administration of 6-hydroxydopamine, NE levels in the IML were reduced but not eliminated (2.17 ± 22 pg/mg protein compared to 5.30 ± 49 in control rats; $n=6$; $p<0.01$). Next, the effect of electrical stimulation of the region containing the C1 cell group on NE levels in the IML was determined in anesthetized rats (urethane, 1.5g/kg i.p.). Stimulation of the C1 region (0.2 msec. pulses at 100 Hz, 100uA, 1 sec. trains at 0.5 Hz for 45 min.) in rats treated with a tyrosine hydroxylase inhibitor (alpha-methyltyrosine methyl ester, 400 mg/kg i.p.) produced a significant decrease in NE level in the IML (6.40 ± 35 compared to 7.96 ± 33 in non-stimulated controls; $n=6-8$; $p<0.01$). These results support the hypothesis that terminals in IML arising from the C1 neurons are noradrenergic.

210.3

GLUCOCORTICOID-MEDIATED TRANSCRIPTIONAL AND TRANSLATIONAL REGULATION OF PHENYLETHANOLAMINE N-METHYLTRANSFERASE. A. Lesage, S. Levine and D.L. Wong. Dept. of Psychiatry & Beh. Sci., Nancy Pritzker Laboratory, Stanford Univ. Sch. Med., Stanford, CA 94305.

To examine the role of corticosteroids in the *in vivo* regulation of phenylethanolamine N-methyltransferase (PNMT) transcription and translation, steady-state levels of PNMT activity and mRNA were analyzed in the adrenal glands of intact and hypophysectomized rats, following administration of ACTH (4 I.U. s.c.) or dexamethasone (DEX, 1 mg i.p.) for 7 days. In intact animals, PNMT activity is depressed to 85% and 78% of control values by ACTH and DEX respectively, while PNMT mRNA is not significantly altered. Hypophysectomy also reduces PNMT activity, but more markedly, to 13% of control levels. ACTH and DEX administration reverses this depression and restores activity to 32% and 27% of normal values. However, changes in PNMT mRNA are not coincident; while hypophysectomy decreases PNMT mRNA to 15% of control, ACTH only restores message to 22% while DEX increases message to 48% or twice the restoration observed for PNMT enzymatic activity. Effects of dexamethasone were further investigated in hypophysectomized rats by administering a range of doses (0.2-3.0 mg daily i.p.). As previously, hypophysectomy reduced PNMT activity and DEX reversed this effect; maximum restoration was comparable to the 1 mg daily dose, and doses ≥ 1 mg daily showed no significant differences in their restorative capacity. PNMT mRNA was again elevated to a greater degree than PNMT activity. These results are consistent with independent regulatory mechanisms for PNMT transcription and translation. Transcriptional control may be mediated via the glucocorticoid responsive element (GRE) identified in the 5' regulatory region of the rat gene, which has been demonstrated *in vitro* functionality. In addition, however, glucocorticoids or other factors appear to regulate PNMT translation and hence, are enzyme limiting.

210.5

COMPARISON OF THE D1 DOPAMINE AGONISTS SKF-38393 AND A-68930 ON BEHAVIORAL RESPONSES AND C-FOS PROTEIN INDUCTION IN 6-OHDA-LESIONED RATS.

K.B. Johnson, K.F. Jensen, H.E. Criswell, R.A. Mueller, and G.R. Breese. Neurobiology Curriculum, and Brain and Development Research Center, UNC School of Medicine, Chapel Hill, NC 27599.

In order to examine the specificity of c-fos induction as an indicator of D1-dopamine receptor supersensitivity, SKF-38393-induced behavior and c-fos responses were compared with changes induced by A-68930, a new D1 dopamine agonist, in 6-OHDA-lesioned rats. The two agonists produced similar behavioral responses, but the behavioral activity induced by SKF-38393 was greater than that for A-68930. The time courses for FLI by both agonists were found to peak at 2 hrs. after drug administration, decreasing to baseline levels after 8 hrs. Dose-response relationships for both agonists were observed on FLI. Even though activity with quipirole, a D2 agonist, was greater than that for D1 agonists, quipirole produced no increase in FLI, eliminating activity as a factor in the FLI increase seen with D1 agonists. Further, the FLI induction by both D1 agonists could be effectively blocked with SCH-23390, a D1 dopamine antagonist. The NMDA antagonist MK-801, at a dose of 1 mg/kg, failed to block D1 agonist-induced FLI, indicating that an NMDA link is not involved in this response, as it is in the development of D1-dopamine receptor sensitivity (i.e. priming). These results indicate that c-fos induction may be a specific and sensitive indicator of D1-dopamine receptor supersensitivity. (Supported by HD23042).

210.2

GLUCOCORTICOID CONTROL OF ADRENERGIC FUNCTION IN VIVO. D.L. Wong, A. Lesage, B. Siddall & J.W. Funder. Dept. Psychiatry & Beh. Sci., Nancy Pritzker Laboratory, Stanford Univ. Sch. Med., Stanford, CA 94305

A glucocorticoid responsive element (GRE), present in the 5' regulatory region of the rat PNMT gene, acts classically as a transcriptional enhancer *in vitro*. However, in mature rats, glucocorticoids (GC) control adrenal medullary PNMT by regulating its degradation through the cosubstrate, S-adenosyl-methionine. To examine the *in vivo* role of the GRE, the effects of RU28362, a type II GC agonist, and dexamethasone (DEX), a mixed type I and type II GC agonist, on PNMT activity and mRNA were compared. Drugs were administered over 3 log doses (1-1000 μ g daily i.p.). RU28362 reduced PNMT activity in a dose dependent fashion, with a plateau at 68% of control (≥ 100 μ g). While low doses of DEX (≤ 30 μ g) similarly decreased enzyme activity, high doses reversed this suppression, so that activity was again normal. For both drugs, PNMT mRNA is not significantly different from normal at low doses, but increases 6-10 fold at high doses, with DEX again showing greater potency. Thymus weight, an indirect measure of plasma corticosterone (CORT), and adrenal weight reached a plateau of 9% and 50-60% of normal weight respectively after steroid treatment. When the two steroids were administered to hypophysectomized animals, both replenished PNMT activity, but to no greater than 30% of normal values, despite the fact that PNMT mRNA was substantially elevated. Again, DEX was more effective, but less effective than ACTH at reversing PNMT depletion. To examine the involvement of a GC type I receptor (classical mineralocorticoid receptor), aldosterone was elevated by feeding rats a diet of rice and administering the diuretic lasix (4 mg/day i.p.). Neither PNMT activity or mRNA were significantly altered. Thus, while corticosteroids may control PNMT transcriptional activity *in vivo*, they or unidentified factors also exert posttranscriptional controls on PNMT expression. Moreover, these translational/posttranslational regulatory mechanisms seem to determine the limits of adrenergic function.

210.4

COOPERATIVE INTERACTION BETWEEN TRANSMITTER RECEPTOR FUNCTION AND STEROID HORMONES ON NUR/77 (NGF1-B) GENE EXPRESSION IN ASTROCYTOMA CELLS. A.M. Szekely, D.R. Grayson and E. Costa. FGIN, Georgetown University, Washington D.C. 20007.

In glial cells transmitters, hormones and other extracellular signals change the expression of specific genes encoding for growth factors or cytokines. These changes presumably are mediated by cooperative interactions among various classes of specifically targeted transcription factors (nuclear "third messengers"). In the C6-2B rat astrocytoma cell line, β -adrenergic receptor stimulation by isoproterenol (1 μ M), in a manner sensitive to propranolol (10 μ M), causes a transient induction of *c-fos* and of *nur/77* mRNAs by 5-6 and 7-9 fold, respectively. *Nur/77* mRNA encodes a protein highly homologous to members of the ligand-dependent transcription factor steroid/thyroid receptor superfamily. Dexamethasone (100 nM) also increases *nur/77* mRNA content by 3 fold, which increase is sensitive to RU-486 (5 μ M), an antagonist of the glucocorticoid/progesterone receptor. Co-treatment of the cells with dexamethasone and isoproterenol leads to a synergistic increase of *nur/77* mRNA content, but to an antagonism of *c-fos* mRNA induction, suggesting a differential regulation of these genes. Progesterone, testosterone, 17- β -estradiol (100 nM), as well the peptide hormone ACTH (10 nM) fail to change *c-fos* or *nur/77* mRNA expression. However, when progesterone receptor expression is amplified by estrogen pretreatment, progesterone (100 nM) results in a 2.5 fold increase of *nur/77* mRNA content. This astrocytoma cell line, similarly to certain glia cells, synthesizes steroid hormones in a manner facilitated also by "mitochondrial" benzodiazepine receptors (MBR) agonists. Therefore it is of significance to further elucidate the mechanisms, whereby steroid hormones modulate the pattern of gene expression elicited by transmitter receptor-mediated changes of nuclear third messengers.

NEW CATECHOLAMINERGIC BRAIN AND ADRENAL CELL LINES FROM TRANSGENIC MICE. C. Suri, B. Fung and D. M. Chikaraishi. Neurosci. Prog., Tufts Univ. Sch. of Med., Boston, MA 02111.

New catecholaminergic cell lines were derived from adrenal and brain tumors in which SV40 T antigen (Tag) was under the control of 773 bp of the rat tyrosine hydroxylase (TH) 5' flanking sequences. CNS tumors spanned the midbrain and anterior brain stem regions on the ventral surface of the brain, whereas a single massive adrenal tumor in a separate founder occupied almost half of the upper abdominal cavity. Immunohistochemistry revealed the presence of both TH and Tag within the tumors.

Cell cultures were derived using standard techniques. Various subclones differing in morphology and TH expression have been selected from the adrenal culture. Their TH specific activities range from .05-2.02 nmoles DOPA/mg protein/min. The parent culture produces dopamine (DA, .28 nmoles/mg protein) and norepinephrine (NE, .35 nmoles/mg protein). Earlier passages also produced epinephrine (E). Subclones are also being isolated from two brain cell cultures which express both TH and Tag. These cells extend varying lengths of processes without treatment. Their TH specific activities are .11 and .21 nmoles DOPA/mg protein/min. and both synthesize DA and NE. Adrenal and brain cell cultures stain positively for NF and are negative for GFAP. Further characterization of individual subclones with respect to catecholamine uptake, regulated secretion and expression of receptors for NGF, ACh, GABA is underway.

210.7

UNBIASED ESTIMATION OF TOTAL NUMBER AND MEAN CELL VOLUME OF PIGMENTED NUCLEUS LOCUS COERULEUS NEURONS IN THE HUMAN AND MONKEY BRAINSTEM: P.R. Mouton*, B. Pakkenberg, R.S. Burns, and H.J.G. Gundersen. Neurological Research Lab., Bartholin Institute, Kommune Hospital, 1399 Copenhagen K; Stereological Research Lab., Dept. Anatomy, Århus Univ., 8000 Århus, Denmark.

Nucleus locus coeruleus (LC) is a compact group of densely pigmented neuron cell bodies in the dorsal mammalian brainstem. Projections from LC provide the primary noradrenergic innervation to the entire neural axis. Functionally, LC appears to regulate attentional and motivational states, and may exert an inhibitory influence on impulse flow in the neocortex. The importance of quantitating LC parameters is underlined by a general age-related disruption in noradrenaline levels, in addition to reports of severe changes in LC neuron number and noradrenaline transmission in dementia conditions, including Alzheimer and Parkinson diseases. Innovative and unbiased neurostereological methods developed within the last decade, the optical disector/Cavalieri combination for total number and the rotator method for mean cell volume, were used to estimate total number and volume of LC pigmented neurons in aged, Alzheimer, and Parkinson diseased brains, and total LC number in aged and young monkey brains. In addition to the methods for these highly efficient, precise, and inexpensive estimations, results will be presented which are available as far as codes have been broken in these continuing studies.

210.9

ARE DOPAMINE SYNTHESIS-MODULATING AUTORECEPTORS PRESENT IN PRIMATE BRAIN? J.D. Elsworth, D.E. Redmond Jr. and R.H. Roth. Depts. Pharmacology and Psychiatry, Yale University Sch. Medicine, New Haven, CT 06510.

In the rodent brain, many dopamine (DA) neurons are equipped with synthesis- and impulse-modulating autoreceptors which regulate their biochemical and physiological activity. However, it is not known whether autoreceptors are present in primate brain, which hinders the logical development of pharmacological treatments for conditions or diseases that involve central DA dysfunction. Thus, in the monkey we have applied an *in vivo* paradigm, which was developed in the rat, to identify those DA neuronal systems in the primate that possess synthesis-modulating autoreceptors. This method is based on the observation that DA neurons with autoreceptors respond to cessation of impulse flow by increasing tyrosine hydroxylase activity, measured by the short-term accumulation of DOPA after inhibition of DOPA decarboxylase activity.

Under light pentobarbital anesthesia, vervet monkeys were treated with gamma-butyrolactone (GBL; 400 mg/kg i.v.) to interrupt impulse flow in DA neurons, or saline 20 min before sacrifice. Five min later all animals received NSD-1015 (100 mg/kg i.v.), a DOPA decarboxylase inhibitor. Under deep anesthesia, the monkeys were killed. Brain regions were removed and later analyzed for DOPA concentration by HPLC. In several subcortical brain regions (eg. putamen, caudate, accumbens) DOPA levels were increased by GBL treatment. However, preliminary data suggest that in other regions (eg. cingulate cortex) this does not occur. Thus, this model provides evidence for the presence of autoreceptors in some regions of primate brain.

EXTRACELLULAR INOSITOL HEXAKISPHOSPHATE (InsP₆, PHYTIC ACID) AND ADRENAL CHROMAFFIN CELLS: BINDING AND EFFECT ON Ca²⁺ FLUXES AND CATECHOLAMINE SECRETION. D.J. Reis, S. Regunathan and C. Wahlestedt. Div. of Neurobiol., Dept. of Neurol. & Neurosci., Cornell Univ. Med. Coll., New York, NY 10021.

In brain InsP₆ possesses extracellular binding sites (Hawkins et al., *BBRC* 167:819, 1990). To establish whether such InsP₆ is biologically active, we have investigated the possibility that InsP₆, which is contained in adrenal chromaffin cells (Sasakawa et al., *JBC* 265:17700, 1990), (a) binds to specific membrane sites; (b) elicits Ca²⁺ influx; and (c) modulates catecholamine secretion in primary culture of bovine adrenal chromaffin cells. ³H-InsP₆ bound specifically to a standard membrane preparation with a K_d of 90 nM and a B_{max} of 700 fmol/mg protein. The Hill coefficient was not significantly different to unity. Association of ³H-InsP₆ was relatively slow, with equilibrium binding being reached within 10 min. Dissociation of ³H-InsP₆ showed monophasic kinetics. In intact cells, InsP₆ elicited a concentration-dependent facilitation of ⁴⁵Ca²⁺ influx and release of epinephrine and norepinephrine, the responses being slower and longer-lasting than those elicited by depolarization by nicotine and K⁺. Catecholamine release by InsP₆ required extracellular Ca²⁺. Reduction in number of phosphorylated sites on inositol resulted in gradual loss of binding and secretagogue potency. In conclusion, adrenal chromaffin cells contain specific InsP₆ binding sites functionally coupled to the regulation of Ca²⁺ influx and catecholamine secretion. Conceivably, IP₆ may act as a neurotransmitter/hormone in adrenals and possibly brain.

210.8

CHOLINOLYTIC SEIZURES: POSSIBLE ROLE OF NUCLEUS LOCUS COERULEUS (LC). M. El-Etri, M. Ennis, M.T. Shipley, and W.T. Nickell. Dept. Anat., Univ. Cinti. Coll. Med., Cinti, OH, 45267.

We are determining the earliest genetic, cellular and neurochemical changes during organophosphate-induced seizures. We have reported that systemic soman injection in rats produces rapid (1-2 hr), profound depletion of forebrain norepinephrine (NE) and induces a wave of early (30-45 min) c-fos expression in only two areas: piriform cortex and LC. Soman microinjection into LC rapidly and tonically increases LC discharge by 3-7 fold (blocked by iv scopolamine, and induces c-fos in LC cells. Thus, soman inhibition of AChE appears to cause tonic hypercholinergic stimulation of LC, leading to depletion of forebrain NE. It is possible, however, that seizures, and not cholinergic hyperstimulation, causes LC activation during soman-induced convulsions.

New results suggest that seizures are not necessary for LC activation. Systemic soman injection increased the discharge rate of LC neurons in anesthetized rats by 3-7 fold and caused desynchronization of cortical EEG, but not seizures. Systemic pilocarpine (380 mg/kg, im) also activated LC neurons in the absence of seizures. By contrast, the GABA antagonist picrotoxin caused only a transient (30-60 sec), 0.5 - 1.0 Hz increase in LC activity, however, LC neurons discharged in their characteristic regular pattern during prolonged seizures.

These findings indicate that cholinolytic agents potentially activate LC neurons in the absence of cortical seizures. Moreover, LC neurons can discharge in a normal manner during intense seizures. Thus, depletion of forebrain NE induced by soman may be due to cholinergic hyperstimulation of LC rather than to seizures. (US Army DAMD17-86-C-6005 and PHS Grant NS24698).

EFFECT OF NEUROPEPTIDE Y ON THE RELEASE OF DOPAMINE IN FREELY MOVING CONSCIOUS RATS USING MICRODIALYSIS. T.C. Westfall, V. Tseng* and L.E. Vickery*. Dept. Pharmacol. & Physiol. Science, Saint Louis Univ. Sch. of Med., St. Louis, MO 63104

We have previously observed that neuropeptide Y (NPY) decreased the nerve stimulation induced release of NE from peripheral sympathetic neurons and the K⁺-evoked release of NE from hypothalamic slices (*Synapse* 2:299, 1988). NPY neurons are also known to be present in the striatum in close juxtaposition to dopamine (DA) neurons. The present studies were designed to examine the effects of NPY on the evoked release of dopamine using *in vivo* microdialysis. Rats were anesthetized with ketamine/acepromazine and a guide cannula stereotaxically implanted into the striatum. The microdialysis probe was introduced into the guide cannula after 5-7 days and the experiment carried out in conscious freely moving rats. The microdialysis probe was perfused with Ringer's solution (2 µl/min). Fractions were collected at 20 min intervals for analysis of DA and metabolites by HPLC-EC detection. K⁺ (30 mM) was administered twice 120 (S₁) and 250 (S₂) min after the start of perfusion. In other experiments NPY (10⁻⁷M) was introduced 20 min before the second stimulation with K⁺. Basal DA levels could be readily measured in the dialysate from microdialysis probes placed in the striatum. Removal of extracellular Ca²⁺ resulted in a marked lowering of basal DA levels. Introduction of K⁺ produced a marked increase in the overflow of DA. With S₁ resulting in a 861 ± 230 and S₂ 639 ± 232 % increase over basal. The presence of NPY during S₂ resulted in a significant attenuation of the K⁺-evoked increase in overflow with a 212 ± 39 % increase over basal (p < .01). These results are consistent with NPY exerting an inhibitory effect on DA transmission in the striatum (Supported by HL26319, 35202 and DA02688).

210.12

HETEROGENEITY OF THE PREFRONTAL CORTICAL DOPAMINE SYSTEM IN RESPONSIVENESS TO STRESS. Ariel Y. Deutch. Yale University School of Medicine, New Haven, CT 06510.

We have recently demonstrated that stress evokes Fos protein expression in a distinct subpopulation of midbrain dopamine (DA) neurons which project to the medial prefrontal cortex (PFC). This observation suggests that the dopamine innervation of the PFC may be biochemically heterogeneous in response to stress. In order to determine if there are differences in the magnitude of stress-elicited changes in DA utilization in various PFC regions, animals were subjected to mild stress and different regions of the PFC dissected for biochemical analyses. Low intensity footshock stress or alternatively short duration immobilization stress resulted in differences in the degree to which DA utilization was augmented in the PFC. The magnitude of stress-induced increases in utilization was prominent rostrally within the medial cortical region. We also demonstrated differences in the susceptibility of the DA innervations of different nucleus accumbens compartments (core and shell) to stress. Ongoing analyses will determine the relationship between the precise PFC sites responsive to stress and the subcortical targets of these areas. These data further illustrate the functional heterogeneity of the PFC DA innervation, and suggest that specific DA innervations of the cortex may be in register with specific corticofugal pathways to form a stress circuit. Supported by MH-45124 and the National Parkinson Foundation Center at Yale University.

BOVINE TYROSINE HYDROXYLASE GENE - REGIONS MEDIATING ACTIVATION BY PMA AND C-FOS/C-JUN. M.K. Stachowiak, A. Goc, E. Puchacz*, E.K. Stachowiak*, Barrow Neurol. Inst., Phoenix AZ 85013

Previous studies in our laboratory demonstrated regulation of tyrosine hydroxylase (TH) gene expression by protein kinase C (J. Biol. Chem. 1990, 265, 4694). In this study we examined whether the 5'flanking region of the TH gene contains elements that mediate this regulation. SH-SY5Y human neuroblastoma cells were lipofectin-transfected with plasmids containing upstream sequences of the bovine TH gene fused to CAT reporter gene. Subsequently, cells were treated with 0.1 μ M PMA or incubated in drug-free control medium. PMA treatment induced a 6.3 fold increase in CAT expression directed by the -245/+21 fragment of the TH promoter. CAT expression controlled by longer -1523/+21 fragment was less affected by PMA (1.6 fold increase). Deletion of sequences between -265 and -52 nt abolished PMA stimulation. These observations indicate that main PMA regulatory element is located in the -245/-52 region and that additional negative modulatory element(s) exist in more distal regions of the TH promoter.

Our previous experiments demonstrated binding of AP1/c-Fos-like factors to multiple sites in the TH promoter and its stimulation by protein kinase C-activating agents (Mol. Cell. Neurosci. 1990, 1, 202). In the present study the -245/-52 region of the TH promoter conferred activation of TH-CAT gene by c-Fos and c-Jun expressed from cotransfected plasmids. In contrast to PMA effects, this activation was enhanced by sequences upstream from -245. In conclusion, PMA activation of the TH gene could be mediated by c-Fos and c-Jun, however additional inhibitory factor(s) appear to participate in the regulation by PMA.

211.3

BOVINE TYROSINE HYDROXYLASE GENE - REGIONS CONTROLLING EXPRESSION IN NEURAL CELLS. A. Goc, E. Puchacz*, E.K. Stachowiak*, M.K. Stachowiak, Barrow Neurol. Inst., Phoenix AZ 85013.

In this study we examined whether the 5'flanking region of the bovine tyrosine hydroxylase (TH) gene contains genetic elements that determine its cell specific expression in the nervous system. Chimeric TH-CAT genes were prepared by ligating a -1523/+21 nt fragment of the TH gene to the coding region of the CAT reporter gene. TH promoter mutants were derived by deleting sequences upstream from -245 nt [pTH(dP)CAT] or between -265 and -52 nt [pTH(dA)CAT]. As a control, promoterless pCATbasic plasmid and pCATcontrol containing the SV40 promoter were used. Plasmids were lipofectin-transfected into neuron-like neural crest-derived cell lines, human SH-SY5Y and rat PC12, and into glia-like SF-763 glioma cells. In PC12 and SH-SY5Y cells CAT expression from the wild type TH promoter occurred at the level 12-15 times higher than from the SV40 promoter and 2-3 higher than from mutant pTH(dP)CAT and pTH(dA)CAT plasmids. No expression from promoterless pCATbasic was detected. In glioma cells the levels of CAT expression from wild-type pTHCAT did not differ from the levels expressed from promoterless pCATbasic and were 100 times lower than expression from the SV40 promoter. In contrast to SH-SY5Y, SF-763 cells transfected with pTH(dP)CAT or pTH(dA)CAT expressed CAT activity at the levels 11-14 times higher than from the wild type TH promoter. In conclusion the 5'flanking region of the TH gene contains elements that control its cell specific expression. Regions that support TH promoter function in neural crest-derived cells also contain elements that repress expression in the glia-derived cells. Supported partially by APDA and Women's Board of BNI.

TRANSLATIONAL CONTROL OF POMC GENE EXPRESSION. CM Spencer & JH Eberwine, Dept. of Pharmacology, University of Pennsylvania School of Medicine, Philadelphia, PA 19104

In the rat anterior pituitary, proopiomelanocortin (POMC) gene expression is stimulated by corticotropin releasing hormone and inhibited by glucocorticoids. The time course of these responses is such that changes in peptide levels are apparent within minutes of treatment and hours before changes in POMC mRNA levels are detected. Translational control is therefore a potentially important aspect of POMC gene expression that may play an especially critical role in the acute responsiveness of the cell.

In order to evaluate the translational status of POMC in rat pituitary and AIT-20 cells, we have utilized *in situ* transcription followed by electrophoresis of the labeled newly-synthesized cDNAs. The banding pattern that is generated correlates to the sequence of the mRNA and reflects the progression of reverse transcriptase as it travels along the mRNA. The observed changes in the IST-generated banding patterns can be correlated to changes in translational status as assessed by polysome profiles. Furthermore, the banding pattern can be altered by pharmacological manipulations expected to influence translational status.

POMC mRNA is predicted to contain a stable (-45 kcal) stem-loop structure. We have observed this structure *in situ* using a 5'end-labeled oligonucleotide primer complementary to a region 35 bases 3' to the proposed stem-loop structure. This banding pattern can also be altered by pharmacological treatment. We observed in RNA gel shift assays the binding of at least four proteins from AIT-20 cytoplasmic extracts to a 60-nt riboprobe corresponding to the stem-loop structure. We are currently in the process of characterizing these RNA-binding proteins.

FUNCTIONAL DISSECTION AND MOLECULAR ANALYSIS OF THE UPSTREAM SEQUENCE OF TYROSINE HYDROXYLASE (TH) GENE. K.S. Kim, J.M. Carroll, M.K. Lee*, D.H. Park and T.H. Joh, Cornell Univ. Med. Coll., Burke Med. Res. Inst., White Plains, NY 10605.

TH, the first and rate-limiting enzyme in catecholamine biosynthesis, is expressed in neurons which synthesize and release catecholamines. Sequencing of the 5' flanking region of the rat TH gene revealed some putative regulatory sites (AP1, AP2, POU/Oct, Sp1 and CRE) within 250 base pairs (bp) as well as a 35 GT pair repeat at around 2.5 kb from the transcriptional start site.

To investigate the underlying molecular mechanisms of TH gene regulation, the model systems used were two human neuroblastoma cell lines which are either adrenergic (SK-N-BE; TH-expressing) or cholinergic (SK-N-MC; TH-nonexpressing). Different lengths of upstream sequence of the rat TH gene were fused to the bacterial CAT gene. Transient transfection analysis of these constructs showed that the 150 bp flanking region retains sufficient information for full transcriptional activity in the SK-N-BE cell line. In contrast, none of these constructs derived any significant level of expression in the SK-N-MC cell line. Furthermore, site-directed mutagenesis of the putative regulatory motifs demonstrated their functional importance in TH expression. These data suggest that the utmost 5'flanking sequences play a critical role in TH gene regulation. Supported by MH24285.

211.4

TISSUE SPECIFIC EXPRESSION DIRECTED BY UPSTREAM SEQUENCES FROM THE RAT TYROSINE HYDROXYLASE GENE IN TRANSGENIC MICE. S.A. Banerjee and D.M. Chikaraishi, Dept. of Microbiology and Molecular Biology and Neuroscience Program, Tufts Univ. Schl. of Med., Boston, MA 02111.

To identify sequences that direct tissue-specific expression of tyrosine hydroxylase (TH) *in vivo*, we generated 4 lines of transgenic mice with 4.8 kb of 5' flanking TH sequences linked to a chloramphenicol acetyl transferase (CAT) reporter. Only one line expressed the reporter and it did so in a tissue-specific manner. CAT activity was detected in lysates from the olfactory bulb, brain, superior cervical ganglia (scg), and adrenal, tissues containing TH expressing cells. However, CAT was expressed to higher levels in the bulb and brain than the adrenal or scg, suggesting preferential expression in the CNS. In contrast, all non-TH expressing organs (liver, kidney, spleen, heart) lacked CAT activity.

We also studied the regulation of CAT in the olfactory bulb where others have shown that TH is transsynaptically regulated; deafferentation induces loss of TH. Denervation of the bulb by ZnSO₄ lavage induced a parallel loss of CAT and TH activity in transgenic mice. During development, CAT expression increased linearly after birth in the bulb, similar to the postnatal rise in TH levels, but dropped slightly in the adult. We have thus obtained transgenic mice in which TH regulatory sequences direct correct tissue-specific, developmental and transsynaptic expression.

211.6

CHARACTERIZATION OF THE RAT PROOPOMELANOCORTIN GENE SEQUENCES RESPONSIBLE FOR PITUITARY SPECIFIC EXPRESSION.

B. Liu, G. Hammer* and M. J. Low, Vollum Institute for Advanced Biomedical Research, Oregon Health Sciences University, Portland, OR 97201.

The POMC gene is expressed at high levels in the anterior and intermediate lobes of the pituitary gland. Earlier data from our laboratory demonstrated that the 5' flanking region of the rat POMC gene (-706 to +64) targeted reporter gene expression specifically to pituitary corticotropes and melanotropes of transgenic mice. To define the minimal sequences required for pituitary specific expression, we produced new lines of transgenic mice with a series of fusion genes containing different lengths of 5' rPOMC gene sequences between -480 and -33, linked to the enhancerless viral thymidine kinase promoter (-109 to +51) and the KI mutant SV40 T antigen. 80% of the mice carrying the transgene with 5' rPOMC sequences from -480 to -33 expressed T antigen specifically in the corticotropes and melanotropes. 50% of the mice carrying the fusion gene with 5' rPOMC sequences from -323 to -33 had similar expression. Shorter promoter constructs, including -323 to -166 and -166 to -33, failed to express in the pituitary gland. To correlate potential DNA binding sites for transcription factors with our functional mapping of the rPOMC 5' flanking sequences, we performed gel-retardation and DNase I footprinting assays with AIT20 cell nuclear protein extracts. We observed at least 4 specific mobility shifted bands using the radiolabeled -323 to -33 DNA as the probe. Only minor differences were observed in the gel-shift pattern using nuclear protein extracts from GH4C1 cells and HeLa cells. Footprinting assays with the same DNA (-323 to -33) labeled at the 5' end revealed 2 sites obviously protected from DNase I, ranging from -98 to -168 and -183 to -218. With the 3' end labeled probe we detected the site of -98 to -168. These data indicate that DNA elements essential for pituitary-specific rat POMC gene expression are within the region from -323 to -33. The importance of the individual protected sites within this region is being investigated currently by further transgenic experiments.

211.7

MULTIPLE SIGNALS ACTIVATE A PURKINJE CELL-SPECIFIC PROMOTER. J. Oberdick*, K. Schilling, R.J. Smeyne, J. Corbin*, T.N. Sato, and J.I. Morgan, Dept. of Neuroscience, Roche Institute of Molecular Biology, Nutley, NJ 07110.

To identify mechanisms that orchestrate neurodevelopment we have investigated the expression of a Purkinje cell-specific transgene (L7βGal) in developing cerebellum and in dissociated cerebellar cultures. L7βGal *in vivo* is expressed in a dynamic parasagittal banding pattern during development. During late embryogenesis, when expression is first detected, this pattern correlates with birth date, a cell-intrinsic property. In Purkinje cell primary cultures, L7βGal is expressed roughly on schedule despite an absence of extracerebellar signals, also suggesting intrinsic regulation. However, depolarization with high extracellular K⁺ in these cultures leads to an upregulation of both L7βGal and the cognate gene, indicating additional extrinsic mechanisms. Thus neuronal activity may be an underlying component of the banding pattern seen during development, a pattern which is reminiscent of parasagittally organized olivocerebellar projection zones. In addition, reduced activity could account for the gradual decline in L7βGal expression observed with age after 25 days postpartum. Successive 5' truncations of the promoter (from 4kb down to 0.25kb) retain Purkinje cell specificity but show subtle alterations in banding patterns; in all cases, however, bands give way to uniform distribution as animals age. The truncations also result in systematic reductions in the overall level of expression of L7βGal. This shows that multiple enhancer elements control the level of L7 expression. Since a TRE is bounded by one pair of truncations, and since its deletion results in a decrease in L7βGal, thyroid hormone may be one component of extrinsic regulation of this gene.

ALTERNATIVE SPLICING GENERATES A VARIANT SNAP-25 PROTEIN DURING DEVELOPMENT. Christina Bark & Michael C. Wilson, Dept. of Neuropharmacology, Research Institute of Scripps Clinic, La Jolla, CA 92037.

SNAP-25 (synaptosomal associated protein of 25 kD) is a neuron-specific protein enriched in presynaptic terminals. Its expression is widely distributed but discriminates between subpopulations of neurons. The 206 amino acid sequence of SNAP-25 is remarkably conserved throughout evolution (Risinger et al., 1990 Neurosci Abst. 154.14), and contains two domains that may play important roles for biological function and targeting of the mature protein. The amino terminus of SNAP-25 can form an amphipathic helix and a cluster of cysteine-residues is substrate for palmitoylation.

SNAP-25 is a component of fast axonal transport. However, in rat it has been shown that the sub-localization of SNAP-25 protein changes from axons to presynaptic terminals during development and translocation of SNAP-25 immunoreactivity to distal ends of neurites in induced PC12 cells appears to be coupled to new RNA and protein synthesis. Taken together, this might imply the presence of alternative SNAP-25 proteins during development and/or differentiation, or that auxiliary protein(s) are synthesized to target SNAP-25 to the presynaptic membrane.

In order to investigate the first possibility, SNAP-25 cDNA-clones from a human fetal 17-18 week brain library were isolated and analyzed by DNA-sequencing. The majority of clones correspond to a SNAP-25 variant, with an alternative exon 5, as inferred from the exon organization of the chicken gene. Although the alternative splicing of exon 5 only changes 8 out of 39 amino acids, the biological significance might be dramatic since the evolutionary conserved domain spanning the cysteine-residues is replaced.

EXPRESSION OF MURINE NCAM IN CELLS AND TRANSGENIC MICE. W. Wille, E. Heider*U. Hartmann*H. Cremer*R. Kehlenbach* & D. Barthels Inst. f. Genetik, Univ. Köln (Cologne), Zùlpicher Str. 47, D-5 Köln 1, FRG

The neural cell adhesion molecules are a class of cell surface glycoproteins which mediate autoadhesive cell-cell interactions. In addition, the molecules carry a functional heparin-binding site and a fibronectin-like domain in the extracellular portion of the protein. Besides the three major isoforms, NCAM-120, -140 & -180, alternative splicing generates almost 200 diversity forms. These types are due to small extra-sequences, which can be introduced into the Ig-like domain IV and into a site between exons 12 and 13. An alternative acceptor site at the 5'-end of exon 14 contributes to the high number of diverse NCAMs in brain and muscle. In order to study the function of NCAMs *in vivo* and to analyze the biological relevance of various diversity forms, we established different *in vitro* and *in vivo* systems.

On the one hand, we obtained transgenic founder mice carrying 2 to 10 copies of a pUC derivative with NCAM-120 cDNA-clone N1 cloned into the 3'-end of exon 1b of the Thy-1 gene. This construct is transcribed in the CNS under the control of the Thy-1.2 promoter causing levels of vector-derived NCAM messengers 30-95 fold higher than in control tissues. Transgenic mice with this construct carrying *lac Z* instead served as controls.

On the other hand, fibroblast cell lines have been transformed with pMV7-NCAM-constructs with various iso- and diversity forms. These NCAM-synthesizing fibroblasts have been applied to four adhesion assays: i) cell adhesion in suspension, ii) adhesion of single cells to monolayers, iii) gap junction formation, and iv) out-growth of chicken retina neurons on alternating stripes containing different NCAM-forms ("stripe assay" after Bonhoeffer et al.). Data on *in vitro* and *in vivo* systems and the impact of ectopic NCAM-expression on brain development will be presented.

211.8

MULTIPLE HOMOLOGS OF E12/E47 HELIX-LOOP-HELIX TRANSCRIPTIONAL FACTORS IN DEVELOPING MOUSE NERVOUS SYSTEM. T. Neuman, H.O. Nornes, M.X. Zuber*, Dept. of Anatomy & Neurobiology, *Dept. of Biochemistry, Colorado State University, Fort Collins, CO 80523.

Transcriptional factors that belong to the family of helix-loop-helix (HLH) proteins have been implicated in the regulation of differentiation of several tissues in several species of vertebrates and invertebrates. In order to study neuronal differentiation, cDNA libraries were prepared from different postnatal stages of development of the mouse cerebellum. Using PCR, several cDNAs with high homology to the HLH region of E12/E47 protein were isolated. RNase protection analysis shows tissue and organ specific expression of these cloned genes during development. Furthermore, electrophoretic mobility shift analysis with different E motif containing oligonucleotides (binding site for E12/E47) gives a changing pattern of binding proteins in the developing nervous system. Two of these proteins, BrE2 and BrE3, are highly enriched in differentiating granular neurons. These data suggest that the E12/E47 family of transcriptional factors contains several members which may be important in regulating differentiation in a variety of organs.

211.10

DEVELOPMENTALLY REGULATED ASTROCYTIC EXPRESSION OF A THY-1.2/lacZ FUSION GENE IN THE CNS OF TRANSGENIC MICE. K.A. Kelley, V.L. Friedrich Jr. and K. Herrup, The Fishberg Research Center for Neurobiology, The Mount Sinai School of Medicine, New York, NY 10029 and The E.K. Shriver Center, Waltham, MA 02254.

A transgenic mouse strain has been prepared from a Thy-1.2/lacZ hybrid gene. As previously reported (Soc. Neuro. Abst., 14: 622; Soc. Neuro. Abst., 15: 957), the transgene is expressed in CNS neurons of adults, and in neuroblasts and neuroepithelial cells during embryogenesis. Subsequent studies have revealed that expression also occurs in neuroglial cells during early postnatal life. Double immunofluorescence with bacterial β-galactosidase and glial fibrillary acidic protein (GFAP) antibodies revealed substantial transgene expression in astrocytes from birth through postnatal day 20 (P20). In cerebellum, the double labeled cells included radially oriented Bergmann glia as well as astrocytes in granular layer and subcortical white matter. By P25, astrocyte expression was significantly reduced, and at later stages was barely detectable. The same developmental pattern prevailed in many other CNS areas. An exception was the olfactory bulb where astrocytic expression persisted throughout adulthood. These results suggest that the Thy-1 promoter can be expressed and developmentally regulated in non-neuronal as well as neuronal CNS cell types, which may reflect factors associated with the structure of the transgene or its site of integration. Alternatively, the endogenous Thy-1 gene may be transcribed in young astrocytes at previously undetected levels.

VIDEO MICROSCOPY OF GROWTH CONES EXTENDING IN THE CORPUS CALLOSUM OF A HAMSTER CORTICAL BRAIN SLICE. **M.C. Halloran and K. Kalil.** Neuroscience Training Program and Dept. of Anatomy, University of Wisconsin, Madison, WI 53706.

Previous observations in fixed tissue (Norris and Kalil, 1990, J. Comp. Neurol. 293:268-281) showed that populations of axonal growth cones in the developing hamster corpus callosum assumed a variety of complex lamellar and filopodial morphologies within the callosum. We wished to determine whether shape changes of individual growth cones are associated with specific behaviors, such as rapid extension or changes in direction. We therefore developed a callosal slice preparation through the newborn hamster sensorimotor cortex, in which growing callosal axons and their growth cones were labeled with Dil injected *in vivo*. Using a SIT camera under low light level conditions, and an image processing and storage system, we were able to make real time video observations of callosal growth cone behaviors within the living brain slice. Preliminary results from video recording sessions lasting up to 10 hours showed that rates of outgrowth for populations of callosal axons were consistent with those estimated in fixed tissue (i.e. about 50 $\mu\text{m}/\text{hour}$). However, rates of extension of individual growth cones were highly variable, and low power observations suggested an overall saltatory motion of developing callosal axons. Individual growth cones continually changed shape during bouts of rapid extension, and often changed direction along their callosal trajectory, observations consistent with those made in fixed tissue. Preliminary analysis of video images suggests a correlation between growth cone expansion and rapid axon outgrowth. These results *in vitro* suggest that the living slice preparation will be useful in understanding how changes in growth cone shape relate to guidance decisions by callosal growth cones *in vivo*. Supported by NIH Grant NS14428 (K.K.) and Training Grant T32 GM 07048 (M.H.).

212.3

REGULATION OF AFFERENT GROWTH BY TARGET NEURONS *IN VITRO* IS AFFECTED BY TTX, HIGH MAGNESIUM OR A GLUTAMATE ANTAGONIST. **D.H. Baird** Dept. of Pathology, College of Physicians and Surgeons of Columbia University, New York, N.Y. 10032.

The outgrowth of axons from pontine nuclei explants, a source of cerebellar mossy fibers, is arrested upon contact with their target neuron, the cerebellar granule cell (Baird *et al. Soc. Neurosci. Abstr.* 16: 1127). After three days *in vitro*, explants grown on laminin, poly-L-lysine or cerebellar astroglia extend axons greater than 300 μm in length. When explants are added to granule cells plated at high density on any of these substrates, explants produce a short fringe of axons, less than 200 μm in length. This "stop-growing" signal is afferent specific, as climbing fibers (Purkinje afferent) grow to comparable lengths on granule cells or laminin. To investigate if perturbing electrical and synaptic activity affects the stop-growing signal, murine pontine nuclei explants were co-cultured with granule cells in the presence of 1 μM TTX, 4 mM magnesium (5X normal), or an antagonist of glutamate receptors (on granule cells), kynurenic acid (1 mM). All of these agents interfered with the ability of granule cells to arrest mossy fiber outgrowth. In treated co-cultures, axons extended over 300 μm from explants on granule cell monolayers. The agents have little or no effect on outgrowth from explants cultured in the absence of granule cells, the survival of granule cells, or their morphology during the three day culture period.

During development, the stop-growing signal may help determine the target neuron specificity of axons or regulate the size of afferent arbors. These experiments suggest that electrical and synaptic activity play a role in the regulation of axonal growth by target cells. The cerebellar afferent-target co-cultures provide an accessible system to further investigate the activity dependence of axon-target interactions. Supported by NS 08761 to D.B and NS16951 to C.A. Mason.

STROBOSCOPIC ILLUMINATION ALLOWS TIME-LAPSE OBSERVATION OF GROWING AXONS IN LIVING MOUSE MUSCLE. **P. van Mier, S.G. Turney, and J.W. Lichtman.** Department of Anatomy & Neurobiology, Washington University School of Medicine, St. Louis, MO 63110.

To better understand the behavior of growing axons in living animals, we studied the re-growth of crushed motor axons and the formation of terminal sprouts in the mouse sternomastoid muscle *in situ*. In order to do this, many views of single vitally stained axons were obtained over intervals of minutes. It was necessary to drastically shorten the time that each growing axon was exposed to light. For this purpose we used intermittent illumination during imaging from a Xenon-arc stroboscope coupled by fiber optics to a standard epifluorescence microscope. Typically, 4-7 days after nerve crush, an anesthetized mouse was placed on the microscope stage, mechanically ventilated and its left sternomastoid muscle exposed. A vitally stained axon was chosen, and with 5-15 stroboscopic light flashes (16 μsec each) and the use of a SIT camera connected to an imaging system, a digitized image was obtained. During averaging, the flashing of the stroboscope was triggered by the stroke of the ventilator to eliminate respiratory movements. At short intervals repeated images were taken of the same axon.

Preliminary results show that sprouting axons no longer stop growing or retract as was seen in experiments using either continuous or prolonged intermittent illumination (1-15 sec). Sprouts were observed to grow tens of microns over periods of several hours, and in some cases we observed branch formation near the growing tip. Movement of organelles along the length of the sprouts was also observed. Thus stroboscopic illumination offers the possibility of following dynamic events in real time in living animals.

A STEP GRADIENT OF CHONDROITIN SULFATE PROTEOGLYCAN CAN MODULATE THE TIMING OF NEURITE ELONGATION. **D.M. Snow and P.C. Letourneau.** The University of Minnesota, Minneapolis Minnesota, 55455.

Although chondroitin-sulfate proteoglycan (CS-PG) has been shown to repel elongating neurites *in vitro*, there exist regions of the developing nervous system where CS-PG expression coincides with growing axons, e.g. rodent forebrain. Relevant to this observation is our previous finding that CS-PG can be modified to become growth-permissive if present in conjunction with an appropriate concentration of laminin. We hypothesized that the function of CS-PG in regions of the developing brain where axons grow may be not to prevent their forward progress, but rather to slow their rate of elongation, thereby regulating the timing of axonal outgrowth.

We have developed a technique to produce an overlapping step gradient of CS-PG and laminin in a culture dish. Within the step gradient, concentration changes occur over a distance of 20-30 μm . Quantitative fluorescence of immunocytochemically-labeled CS-PG and laminin was used to determine the concentration of each molecule at positions along the gradient. Neuronal explants from a variety of sources were placed on a laminin-coated substratum facing the CS-PG gradient. As neurites grew along the gradient, they traversed an increasing concentration of CS-PG. Analysis with time-lapse video microscopy showed that growth cones were not repelled by concentrations of CS-PG that were repellent in previous paradigms where growth cones were confronted by sharp concentration changes (Snow *et al.*, J. Exp. Neurol. 109, 1990). Importantly, as the growth cones grew along increasing concentrations of CS-PG in the gradient, the rate of outgrowth decreased.

These data combined with previous results indicate that CS-PG may be a multifunctional molecule *in vivo*. When present in high concentrations and lacking significant contributions from growth-promoting molecules, CS-PG may prevent neurites from entering forbidden territories. Alternatively, when present in a gradient and modified by growth-promoting molecules such as laminin, CS-PG may merely reduce the rate of neurite outgrowth to precisely regulate the timing of axonal elongation.

212.4

CONTACT-DEPENDENT MECHANISMS OF MOTOR AXON SEGMENTATION **R.A. Oakley and K.W. Tosney.** Neuroscience Program & Biology Dept., Univ. of Michigan, Ann Arbor 48109.

Motor axons become segmented in the chick by preferentially invading the anterior half of each somite and interacting with sclerotome. Since motoneurons grown on explanted somites exhibit contact-mediated avoidance of posterior sclerotome, contact-mediated interactions contribute to segmentation. To elucidate mechanisms at the cellular level, we used videomicroscopy to compare the interactions of identified motoneurons with identified somite cells in culture.

Motor growth cones do not cross posterior sclerotome cells but will cross cells from the anterior somite. Preliminary analysis suggests that such differential behavior results from very local differences in growth cone activity that can be initiated when a single filopodium contacts either cell type. Filopodia form persistent contacts with *posterior* sclerotome cells and exert obvious tension, but only poorly support the distal progression of veils. Since this inhibition of veil activity is local, it is not sufficient to fully impede the forward advance of the growth cone until the entire leading edge makes contact. Veils at the leading edge that contact the cell ultimately retract while veils at the lateral edges remain active. In contrast, filopodia that initially contact *anterior* somite cells are less persistent, appear to generate less tension, and support veil activity. These filopodia gradually thicken and consolidate to form a nascent neurite. We suggest that a local inhibition of veil formation by posterior cells in combination with an enhancement of neurite formation by anterior cells contributes significantly to the preferential advance of motor axons into the anterior somite. Supported by NS-21308.

DEVELOPMENT OF MOSSY FIBER AXONS AND SYNAPSES IN RAT HIPPOCAMPAL SLICES EXAMINED WITH A SCANNING LASER CONFOCAL MICROSCOPE. **M.E. Dailey & S.J. Smith**, Dept. of Molecular & Cellular Physiology, Stanford University School of Medicine, Stanford, CA 94305.

Little is known about the initial interactions of afferent axons and target cells leading to synapse formation in developing mammalian CNS tissue. We are examining the growth and cellular interactions of dentate granule cell mossy fibers (MF) that extend into hippocampal area CA3 and form giant *en passant* synapses on apical dendrites of pyramidal cells. To examine growing MF directly, we made focal injections of a lipophilic fluorescent dye (DiO or Dil) into the dentate hilus of live hippocampal slices from early post-natal (P3-P5) rats, when many MF are first contacting their targets. MF were labeled to their tips within 4-6 hr. A scanning laser confocal microscope was used to follow labeled fibers over time. When images were acquired at 30-120 sec intervals, extended (>6 hr) time-lapse observations could be made with no evidence of tissue rundown. We were able to observe highly motile growth cones with distinct filopodia and lamellipodia at the tips of growing axons 20-80 μm below the slice surface. Some of these axons extended at rates of up to 30 $\mu\text{m}/\text{hr}$, and occasionally individual growth cones would abruptly stop and remain relatively quiescent for extended periods of time while adjacent fibers continued to extend. Active filopodia-like structures were also found along the length of many axons. Some slices were counter-stained with DiO or Fluo-3, a fluorescent Ca-sensitive dye, permitting simultaneous imaging of afferent growth cones and candidate target cells. In conjunction with post-fixation immunostaining with Synapsin I antibodies (gift of P. DeCamilli, Yale), which has provided a suitable method for morphological detection of developing synapses, these methods hold promise for direct observation of synaptogenic interactions *in situ*. Supported by NIH grants NS09027 & NS25857.

IN VIVO TIME-LAPSE VIDEO MICROSCOPY OF COMMISSURAL GROWTH CONES IN THE GRASSHOPPER CNS. Paul Z. Myers and Michael J. Bastiani. Dept. of Biology, University of Utah, Salt Lake City, UT.

We have used time-lapse video microscopy to observe the behavior of a neuron, Q1, that pioneers the posterior commissure of the grasshopper. Our goal is to discover the significant interactions that play a role in Q1's pathfinding by identifying the dynamic and transient associations that the Q1 growth cone makes during its outgrowth.

We labeled individual cells by iontophoresing a 0.5% solution of the lipophilic dye Di-I in DMSO onto the surface of the soma. The labeled neurons were then imaged at regular intervals (typically every 3 minutes) at low levels of illumination using a video intensifier and image processing software to enhance the signal, and computer-driven shutters to minimize exposure to light. Our system has sufficient spatial resolution to detect individual filopodia. The temporal resolution is more than adequate to follow the migration of growth cones, which move at 4-5 $\mu\text{m/hr}$, and has also allowed us to observe the behavior of single filopodia, which extend and retract at rates of up to 250 $\mu\text{m/hr}$.

We have found that the Q1 growth cone often (50% of the time) retracts or halts in its growth at the time its filopodia first touch the midline. In cases in which we have labeled both Q1 and its contralateral homolog, we have seen that this cessation of growth does not occur when filopodia from both growth cones meet at the midline; instead, growth is accelerated and the growth cones rapidly translocate by expanding into the contacting filopodium, a behavior previously described in the grasshopper limb by O'Connor *et al.* (J. Neurosci. 10:3935, '90). Our results suggest that the Q1 growth cone may be inhibited by contact with unidentified and possibly non-neuronal elements at the midline, but that this inhibition can be overcome by a strong preferential interaction with filopodia of the growth cone of the contralateral Q1.

THE WEAVER GENE ACTS NON-AUTONOMOUSLY IN GRANULE NEURON DIFFERENTIATION IN VITRO. W.-Q. Gao, X.-L. Liu* and M.E. Hatten. Department of Pathology and Center for Neurobiology and Behavior, College of Physicians and Surgeons, Columbia University, New York, NY 10032

In the neurological mutant mouse *weaver*, although generation of the cerebellar external granule cell layer occurs normally, differentiation of granule cell precursors via the extension of parallel fiber axons and migration along the Bergmann glia fails. In a reaggregate culture system (Gao *et al.*, 1991, *Neuron* 6, 1-11), the proliferation of P5-P7 B6CBA-Aw-J-wv (wv/wv) granule cell precursors, as measured by ^3H -thymidine incorporation and BrdU labelling assays, was comparable to that of wild-type cells. By contrast, several aspects of neural differentiation were impaired in *weaver* cells. Whereas wild-type cells extended neurites 300 μm in length in the reaggregate culture system, *weaver* neurite extension was limited to 5-25 μm . Moreover, expression of the axonal glycoprotein TAG-1 and the neuron-glia ligand astrotactin was reduced in *weaver* cells compared to wild-type cells.

To determine whether the *weaver* gene acts autonomously or non-autonomously in neural differentiation, we labeled *weaver* precursor cells with a fluorescent dye (PKH2), intermixed them with wild-type cells in reaggregate cultures, and measured neurite extension of labeled *weaver* cells. In co-culture with wild-type cells, *weaver* granule cells extended neurites 200-400 μm in length, a value that was indistinguishable from wild-type cells. These results suggest that the *weaver* gene acts non-autonomously and that granule cell precursors produce a ligand which induces CNS neural differentiation.

212.11

RAPID DISAPPEARANCE AND GRADUAL REAPPEARANCE OF ACETYLATED MICROTUBULES FOLLOWING AXOTOMY AND REGROWTH OF HELISOMA NEURONS. R. D. Hadley and J. D. Miller. Dept. Anat. & Cell Biol., Med. Univ. of SC, Charleston, SC 29425.

When a neuron is axotomized and induced to regrow its axon, its cytoskeleton must undergo rapid and dramatic changes. One obstacle that the neuron must overcome is that the cytoskeleton is stabilized by a variety of factors. One stabilizing factor that contributes to the maintenance of cellular form is the acetylation of microtubules on the α -tubulin subunit, conferring a resistance to the depolymerizing actions of antimicrotubule drugs. We used a monoclonal antibody against the acetylated epitope of α -tubulin (kindly provided by G. Piperno, Rockefeller Univ) to assess the distribution of acetylated microtubules (Ac-MT) in cultured *Helisoma* neurons. Shortly (~2 hr) after plating, axonal remnants of neuron B5 contained a large number of Ac-MTs distributed in bundles along the length of the axon. These MTs constituted a minority (~10-20%) of the total MTs. Membrane veils at the distal attachment point of the axonal stump never contained any Ac-MTs, although they contained a distribution of total MTs consistent with an incipient growth cone. In the early stages of neurite outgrowth, neurites less than 200-300 μm long never contained any Ac-MTs, although they were filled with MTs as they grew out. With longer culture times, and consequently longer lengths of neurites, there was a reappearance of Ac-MTs within the neurites. These Ac-MTs did not necessarily exist in bundles, but often as individual MTs within a matrix of many other non-acetylated MTs. Neither did the Ac-MTs begin at the soma and extend distally. Rather, Ac-MTs often existed as isolated short segments. At no stage did Ac-MTs appear in growth cones or membrane veils. Thus, Ac-MTs are rapidly deacetylated or depolymerized during axonal resection and re-expressed only in stabilizing neurites.

TIME-LAPSE IMAGING OF MIGRATING CELLS IN CORTICAL SLICES. Nancy A. O'Rourke, Michael E. Dailey, Stephen J. Smith* & Susan K. McConnell. Depts. of Bio. Sci. & Molec. Cell. Physiol., Stanford Univ., Stanford, CA 94305

We are using cultured slices of developing cerebral cortex as a model system for studying neuronal migration in organotypic, three-dimensional environments. Small injections of the fluorescent vital dye DiI were made in the ventricular zone of ferret cortical slices and labeled cells were followed using time-lapse imaging with a laser-scanning confocal microscope. We observed elongated, bipolar cells with thickened leading processes oriented toward the pial surface and thinner trailing processes extending toward the ventricular surface. This morphology strongly resembles that of migrating neurons described by Rakic in EM studies (1972, J. Comp. Neurol. 145:61). Time-lapse analysis of these cells revealed migratory movement toward the pial surface at rates up to approximately 18 $\mu\text{m/hr}$. The leading processes of these cells continually extended and retracted pseudopodia during migration. The cell soma often moved independently of the leading process, as has been shown in neuron-glia co-cultures by Hatten and colleagues (1987, J. Neurosci. 7:1928). However, in contrast to such co-cultures, migrating cell bodies in slices often showed sudden, rapid translocations, as if squeezing past an obstruction in the three-dimensional environment. It is important to directly confirm the neuronal identity of these migrating cells. Toward this end, we have labeled newly-generated neurons with BrdU in the same group of slices; labeled cells moved from the ventricular zone toward the cortical plate over several days in culture, a pattern suggestive of the migration of neurons in the cortex. Consistent with the possibility that migration in slices is guided by radial glia, anti-vimentin immunohistochemistry and DiI labeling revealed radial glia in the cultured slices. In one case, a migrating cell switched from one migratory path to another directly adjacent to it, as if jumping from one radial process to another. Such behavior has been observed in neuron-glia co-cultures and implied in EM studies. Thus, these slice cultures provide a promising system for examining the dynamic behavior of migrating neurons in the developing cortex.

ANTIBODIES AGAINST A ~300 kD HELISOMA ECM PROTEIN CAUSE GROWTH CONE COLLAPSE AND NEURITE RETRACTION FROM CULTURED NEURONS. J. D. Miller and R. D. Hadley. Dept. Anat. & Cell Biol., Med. Univ. of SC, Charleston, SC 29425.

We have previously identified a ~300 kD protein in the extracellular matrix (ECM) of *Helisoma* ganglia that is recognized by anti-laminin antibodies. *Helisoma* brain-conditioned media (CM) contains the ~300 kD ECM protein and supports outgrowth from cultured *Helisoma* neurons. Addition of anti-~300 kD Fab fragments to CM (100 $\mu\text{g/ml}$) inhibits neurite initiation from identified neurons B5 and B19. We have extended our observations to assess the effects of anti-~300 kD Fab fragments on neurites that have already initiated. Addition of anti-~300 kD Fabs (200 $\mu\text{g/ml}$) to cultures of actively growing B5 and B19 neurons induces growth cone collapse and neurite retraction within 2 hrs of Fab addition. Retraction continued for up to several hours, culminating in the formation of a static retraction bulb. Neurons treated with anti-~300 kD Fabs were fixed either during initial retraction of neurites or after retraction had occurred. Immunofluorescence of microtubules during early phases of neurite retraction revealed a tortuous, sinusoidal distribution of microtubules within collapsed growth cones. Conversely, retracted stumps were uniformly and intensely labeled, with no discernable microtubular structures. These results suggest the ~300 kD ECM protein functions in the adhesion between the culture substrate and growth cones, and that loss of this adhesion results in rapid growth cone collapse and retraction. The transient appearance of disorganized microtubules within actively retracting neurites may reflect a specific interaction between the ~300 kD protein and the cytoskeleton, or may be a general feature of neurite retraction phenomena. At later stages of retraction, the uniform distribution of label is likely due to microtubular depolymerization.

DEVELOPING LEECH NEURONS EXCHANGE CALCIUM VIA CNS GAP JUNCTIONS IN VIVO. L.R. Wolszon, V. Rehder, S.B. Kater and E.R. Macagno. Columbia Univ. Biology Dept., New York, NY 10027; Colorado State Univ. Dept. of Anatomy & Neurobiology, Fort Collins, CO 80523.

Communication among particular leech neurons during their initial phases of outgrowth is important for establishing their correct branching patterns. This is true for the Anterior Pagoda (AP) cells, which are found as bilateral pairs in 20 of the 21 segmental ganglia of *Hirudo medicinalis*. Gao and Macagno (*J. Neurobiol.* 18:295 [1988]) found that developing AP's in adjacent ganglia extend transient axons toward each other, that overlap for a few days before being retracted. These axons actually inhibit each other's growth during this period, because if one AP cell is deleted specifically during the time of overlap, its neighbor does not retract, but instead resumes growth and takes over the vacated territory. The overlapping axons therefore communicate the existence of each cell to the other.

Since preliminary data indicate that the overlapping AP axons are electrically coupled, we are looking for small signalling molecules or ions that might cross these gap junctions. To test whether Ca^{2+} can cross, we injected Fura-2 into two adjacent AP cells of an E11 embryo. We report here that locally elevating the Ca^{2+} level in one AP, by briefly focussing a UV beam on part of the cell, led to a Ca^{2+} wave that crossed into the adjacent AP. Both cells remained healthy during this procedure. Two observations indicate that the Ca^{2+} rose in the receiving cell via direct transfer across gap junctions, rather than from depolarization or receptor activation: 1) The increase in Ca^{2+} occurred after a long delay (20-60 min), and 2) We found no evidence of voltage-dependent Ca^{2+} channels in these cells. These data suggest that Ca^{2+} may play a role in conveying information about the presence of homologous neurons during development.

Properties of *Hirudo Retzius* neurons cultured in isolation and with reproductive ducts. K.A. French, S.M. Jordan*, L. Szczupak*, and W.B. Kristan, Jr. Department of Biology, U.C.S.D., La Jolla, CA 92093-0322.

Although all *Retzius* (Rz) neurons begin development identically, by adulthood Rz neurons in the segments containing the male (segment 5) and female (segment 6) reproductive ducts differ from their segmental homologs in several respects, including their response to ACh. Normally, Rz neurons in the reproductive segments [Rz(5,6)] innervate the reproductive ducts (RDs), while Rz neurons in standard mid-body segments [Rz(X)] diffusely innervate muscles and glands in the body wall; the distinctive properties of Rz(5,6) arise only if their normal targets are present during development. To understand the interaction between Rz(5,6) and the RDs, we have begun to study Rz neurons when they are cultured in isolation or in association with juvenile RD tissue.

Rz(5,6) and Rz(X) from adult leeches were cultured on concanavalin A substrate, using previously described techniques (Chiquet and Acklin (1986) *P.N.A.S.* 83:6188). These conditions also supported slices of juvenile male RD. Both Rz(X) and Rz(5,6) neurons that were co-cultured with RD slices were more likely to sprout neurites than were isolated Rz neurons, their total neurite length was greater, and the neurites had a more complex branching pattern. Outgrowth occurred primarily when the Rz axon hillock was placed directly in contact with the duct. Rz neurons cultured with, but not touching, RD slices grew like isolated Rz neurons. If embryonic RDs are transplanted into standard mid-body segments of embryonic leeches and the local Rz neurons innervate the ectopic tissue, these Rz(X) neurons similarly increase their structural complexity (French, et al., in press). Preliminary results indicate that co-culturing Rz neurons with flattener muscle less effectively stimulates neurite outgrowth, suggesting that at least part of the increased growth depends on properties specific to RDs.

Rz neurons cultured in isolation retained their responsiveness to exogenous ACh for at least 5 days, and the sign of the ACh response depended upon the segment of origin. We have now begun to study the ACh response of Rz(5,6) and Rz(X) that have been co-cultured with male RD slices to determine whether this physiological property responds to contact with the target, as does the pattern of neurite outgrowth. Supported by the March of Dimes and by NIH grant #25916 to WBK.

NEURAL PLASTICITY II

213.1

A NETWORK MODEL OF THE EFFECTS OF DEPRIVATION AND PHARMACOLOGICAL AGENTS ON THE RESPONSE PROPERTIES OF KITTEN VISUAL CORTEX. C. Law*, Leon N. Cooper. Center for Neuroscience, Brown Univ., Providence, RI 02912.

The Bienenstock, Cooper, Munro (BCM) model of synaptic plasticity has been successful in simulating the response properties of neurons in kitten visual cortex under various rearing conditions. This model has been extended from the single cell mean field approximation to a network of neurons with intracortical inhibition without altering the overall results. However, there are some modifications. For example, in network simulations of reverse suture, the length of time neurons were unresponsive to either eye varied. This is in agreement with experimental results. We are currently in the process of modeling the effects of various pharmacological agents on the plasticity of kitten visual cortex. The infusion of bicuculline (BIC) into the cortex was successfully modeled by a reduction of the efficacy of inhibitory connections. In agreement with experimental results BIC caused a reduction of orientation selectivity in modeled neurons, and blocked the ocular dominance shift usually seen during monocular deprivation.

213.3

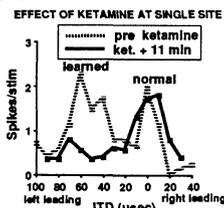

LEARNED AUDITORY RESPONSES IN THE BARN OWL'S OPTIC TECTUM ARE PREFERENTIALLY SUPPRESSED BY THE NMDA RECEPTOR BLOCKER KETAMINE. M.S. Brainard and E.L. Knudsen. Dept. Neurobiology, Stanford University, Stanford, CA 94305.

Space-specific neurons in the barn owl optic tectum (superior colliculus) are normally tuned to the interaural timing differences (ITDs) which are produced by sounds at the locations of their visual receptive fields. Neurons in owls raised with laterally displacing prisms become tuned for abnormal ITDs corresponding to the locations of their optically displaced visual receptive fields. We have found that these learned responses to abnormal ITDs are strongly suppressed by ketamine, a blocker of the N-methyl-D-aspartate (NMDA) type of glutamate receptor.

Owls were raised with prismatic glasses that displaced the visual field by 23° to the left or right. Beginning at 60 days of age, extracellular recordings were used to measure unit tuning for the ITD of sounds delivered via earphones. At some recording sites, units responded both to the ITD which was normal for that location in the tectum ("normal ITD"), and to the ITD which corresponded to the prismatically displaced visual receptive field ("learned ITD"). At those sites, responses to repeated presentations of normal and learned ITDs were monitored for a 20 minute control period, and then for up to 100 minutes following injection of ketamine HCL (10-25 mg/kg; IM).

Ketamine suppressed responses to learned ITDs by 40 to 90% during the 20 minute period following injection, with gradual recovery over the next hour. In contrast, ketamine had relatively little effect on the responses of units to normal ITDs (see Fig.). These results suggest that NMDA receptors participate differentially in mediating the response to the learned versus normal range of ITDs.

Functional Organization of the Primary Auditory Cortex in Adult Owl Monkeys: Parallel Improvements in Performance at an Auditory Frequency Discrimination Task. G.H. Recanzone, C.E. Schreiner, G.T. Hradek*, M.L. Sutter, R.E. Beitel*, and M.M. Merzenich. Coleman Laboratory and Keck Center for Integrative Neuroscience, Departments of Otolaryngology and Physiology, University of California at San Francisco, San Francisco, CA 94143

Electrophysiological experiments in several neocortical areas have shown that the representational 'maps', for example of sensory surfaces, are alterable in the adult mammal. Here we report representational changes in primary auditory cortex (AI) recorded in adult monkeys that were trained in a frequency discrimination task.

Five monkeys were trained to detect an increase in the frequency of the second tone of a stimulus pair presented sequentially in the free field. Stimuli both above and below discrimination threshold were presented on 20-50 trials on daily sessions. Different monkeys were trained at different comparison frequencies: 2.5, 3, 5, or 8 kHz. The behavioral performance of all monkeys progressively improved during several weeks of training. Unattended auditory stimuli matching those in the 5 kHz and 8 kHz task were presented to two control monkeys trained to perform a tactile task.

Three experimental and two control monkeys were then anesthetized with nembutal and the frequency representation in AI was defined by multiple unit recording in the middle cortical layers at locations separated by 200 μ m. The characteristic frequency (CF), Q10, Q40 and latency of the response at CF was defined from the neural responses to 675 tonal stimuli presented through ear bars. The location of each penetration was determined histologically. The cortical area at which neurons had a CF within the range of frequencies presented in the behavioral task was 2-8 times greater in monkeys that had been trained at that frequency range when compared to either the monkeys trained at a different frequency range or to the passive stimulation control monkeys that had received an equivalent number of auditory stimuli. These results demonstrate that the functional organization of AI in the adult primate is mutable and parallels an improvement in behavioral performance following an extended period of training. ADULT RATS EXPOSED TO COMPLEX ENVIRONMENTS HAVE A GREATER NUMBER OF SYNAPSES PER NEURON THAN INDIVIDUALLY HOUSED RATS. V.L. Kilman, A.M. Sirevaag & W.T. Greenough, Beckman Inst., Neurosci. Prog., Dept. Psych. & Cell & Struct. Biol., University of Illinois, Urbana-Champaign, Urbana IL 61801.

Synaptic and neuronal densities (Nv) were estimated in Layer IV of the Occipital cortex of adult male rats exposed to either a complex (EC), social (SC) or individually caged (IC) environment. Nv neurons has been reported previously (Hess et al., 1990 SFN abstract) and was estimated by an unbiased method using the nucleator and Vv. Nv synapses is now reported for the same animals and was estimated by both the unbiased method of the disector and the biased formula Na/D. For both the disector and the Na/D methods Nv synapses did not differ among EC, SC and IC rats. The number of synapses per neuron was estimated by the ratio of Nv synapses to Nv neurons. EC rats had an approximately 40% greater number of synapses per neuron than IC rats and 35% more than SC rats regardless of the method used to estimate synaptic density. These results are similar to the results for weaning age animals where EC rats had a 25% greater number of synapses per neuron than IC rats (Turner and Greenough, 1985). Despite the fact that the conclusion (EC rats have more synapses per neuron than IC rats) is identical for both the disector and the Na/D method, we do not recommend the use of the biased Na/D method. The influence of size, shape and orientation biases on Nv can not be reliably predicted in the Na/D method and it can not be assumed that identical conclusions will always arise when the two different methods are used. Furthermore, the amount of effort and time involved in obtaining the biased estimate is much greater than effort needed to obtain the unbiased disector estimate. Supported by HD-07333 and MH-35321.

CHANGES IN SHORT-TERM PLASTICITY OF RAPHE NEURONES AFTER MICROCUOT LESIONS AND TRANSMITTER INJECTIONS. P. Hinckel, Ch. Rusing* and M. Rusing*. Physiologisches Institut, Universität Giessen, Altweg 129, D-6300 Giessen, Federal Republic of Germany.

Neurones in the nucleus raphe magnus (NRM) have been shown to belong to the thermoafferent system. Beside thermal long-term adaptation (Hinckel et al., Soc. Neurosci. Abstr., 14, 606, 1988; 16, 344, 1990) during cold acclimatization (within weeks) warm-responsive NRM neurones show short-term adaptive behavior in the order of minutes.

In 30 guinea-pigs basic spike rate as well as peak activity of 34 warm-responsive NRM neurones increased within 10-40 min during constant cold stimulation of the receptive field of the cells. After interruption of the dorsal and rostral connexions of the NRM by microcuts the basic rate was not changed during the thermal skin stimulation, whereas the maximum spike rate increased again. Control lesions of lateral pathways did not show any effect.

Microiontophoretic application of serotonin and/or substance P on warm-responsive NRM neurones caused similar effects.

It is concluded that the thermal short-term plasticity of NRM neurones has two components. The cold-adaptive increase of peak activity is generated at a lower level, whereas the increase of tonic basal spike rate is mediated by higher pathway loops.

213.9

DIFFERENTIAL RETRACTION OF SNB DENDRITIC ARBORS WITH UNILATERAL TESTOSTERONE TREATMENT OF BC/LA MUSCLES. Mark N. Rand, Billie E. Loftinus*, and S. Marc Breedlove, Psychology Dept., U.C. Berkeley, Berkeley, CA 94720.

We previously reported that local, lateralized administration of androgen to the bulbocavernosus/levator ani complex (BC/LA) results in a local anabolic effect on these muscles (Rand & Breedlove, Soc. Neurosci. Abstr. 13:54, 1987), and that the dendritic arbors of motoneurons innervating androgen-treated muscles are 40% longer than those of motoneurons innervating BC/LAs given anti-androgen treatment ($p < 0.04$; Rand & Breedlove, Soc. Neurosci. Abstr. 15:377, 1989). The present study examined the effects of local steroid manipulation at the BC/LA on differential retraction in the three primary projection fields of SNB dendrites: ipsilateral, contralateral, and dorsal.

Adult male rats 90-120 days of age were castrated and implanted with two capsules, one containing testosterone (T), and the other hydroxyflutamide (hF), an anti-androgen. The capsules had a single diffusible surface and were sutured one on each BC/LA side so that the diffusible surface faced the muscle. After 30 days the capsules were removed and the lateral BC on one side was injected with 1 μ l of 2% cholera-toxin HRP (CT-HRP, list labs). Four days later the animals were sacrificed; the lumbar spinal cord was frozen-sectioned at 50 μ m and reacted with TMB to visualize the CT-HRP-filled motoneurons and their processes. These were then photographed, traced, and scanned into a microcomputer for analysis, all without knowledge of hormone treatment at the muscle. We found a significant effect by treatment in the contralateral projection field; dendritic arbors of motoneurons innervating hF-treated muscles were 44% shorter than those of T-treated muscles ($p < 0.03$, Scheffe's F-test). Differences in the dorsal and ipsilateral fields did not achieve significance. The percentage of dendritic retraction in the contralateral field was significantly greater than that of the ipsilateral field (29%; $p < 0.02$), demonstrating that unilateral T administration at the BC/LA results in uneven dendritic retraction in the SNB. These results are not consistent with the hypothesis that androgens increase the retrograde transport rate of CT-HRP.

QUALITATIVE CHANGES FOLLOWING HIPPOCAMPAL LESIONS IN INFANT RATS. E.J. Holmes, Lab. for Neurobehavior, Dept. of Psychology, Hampton University, Hampton, VA 23668.

Adult rats which received large, bilateral aspiration lesions of the hippocampal complex (HPC) in infancy have been reported by this author (EPA Proceedings, 1991, 62, p.53) to be significantly less impaired on a radial arm maze task than rats which received HPC lesions as adults and given equal periods of recovery time from surgery. To address the question of the basis for the "sparing of impairment," the brains of the animals receiving HPC lesions in infancy were examined for anatomical patterns of re-structuring or reorganization to explain the phenomenon. Most surprising was the noted degree of absence of qualitative changes in the brain material (~5 mos. after surgery) which could be used to explain the behavioral sparing. Moreover, no common pattern of change existed which could be attributed as an underlying factor. In many cases, however, there was an obvious migration of CA1 cells in the dorsal hippocampus to "fill in" the cortical lesion site and a proliferation of glial supportive material within the damaged HPC area. In addition, changes in associated "storage" areas which receive projections from the hippocampus, e.g., the mammillary nuclei, were notably unaffected. Thus, a sufficient qualitative anatomical explanation for this sparing of impairment following HPC lesions in infancy is still obscure and the search for a satisfying explanation is in progress.

L-LYSINE DEFICIENCY MAY INDUCE PLASTICITY IN THE NEURONS OF THE LATERAL HYPOTHALAMIC AREA. K. Torii¹, K. Hana², T. Ono³ and C.J. Wysocki⁴, ERATO, R&D Corp. of Japan, Yokohama; ²Shiga Med. Univ. Shiga; ³Toyama Med. Pharm. Univ., Toyama, Japan; ⁴Monell Ctr., Phila., PA, 19104.

When a L-lysine-deficient diet was offered to rats, the concentration of L-lysine (Lys) declined in plasma and brain. Subsequently, when offered Lys solution and solutions of other amino acids (AA), they specifically selected the Lys solution and their food intake and growth normalized. The present study determined both neural activity of the lateral hypothalamic area (LHA) to AA feeding and release of growth factors in serum during ingestion of a diet deficient in Lys followed by one replete in Lys. Physiological factors were bio-assayed using Hydra japonica, under varying methylglutathione levels. A multi-barreled microelectrode was implanted into the LHA stereotactically. After achieving Lys-deficiency, rats were given access to various AA in a licking apparatus constantly monitored for lick rate and volume. Within one day they showed a marked preference for Lys. The single unit activity of LHA neurons was recorded while the animal consumed fluids containing taste stimuli or AA. During Lys deficiency, LHA neurons became more sensitive to AA intake. Some neurons specifically responded only to Lys, suggesting that some neural plasticity was elicited by dietary treatment. A thousand-fold increase in serum inhibin was observed in rats fed a normal diet compared with the fasted state. Serum actinin levels increased just after feeding of a non-protein diet. However, levels of both peptides did not vary under Lys-deficiency. These facts indicate that ingestion of Lys-deficient or non-protein diets caused a change in serum (and possibly brain) levels of physiological factors, including actinin and inhibin. This release may elicit plasticity in the sensitivity of some LHA neurons to AA that could selectively drive ingestive behavior for particular AA, e.g., Lys, to maintain AA homeostasis.

213.10

GENE TRANSFER INTO APLYSIA NEURONS SHOWS SEROTONIN ACTIVATES TRANSCRIPTION VIA cAMP RESPONSE ELEMENTS (CRE): A POSSIBLE ROLE FOR CRE AS A SWITCH FOR THE LONG-TERM PROCESS. B.-K. Kaang, E. R. Kandel and S. G. N. Grant, HHMI & Columbia, N.Y., N.Y. 10032.

A major weakness in the molecular biological studies of mature neurons is the lack of systems for expressing cloned genes. We have devised a general neuronal expression plasmid (pNEX) that after microinjection provides high level expression of cloned genes in all neurons of adult *Aplysia*. With this DNA expression system, reporter genes (β -galactosidase and CAT) and *Aplysia shaker* K⁺ channel (see Furukawa et al., this meeting) were expressed in over 80% of injected neurons in ganglia and primary culture.

Different DNA constructs allow study of either constitutive or inducible expression. We have tested the hypothesis that serotonin can activate transcription through a CREB (cAMP responsive element binding protein) dependent pathway in sensory neurons of *Aplysia*. We first injected plasmids that contained the CREB binding site (CRE) driving the lacZ reporter into sensory neurons and found a dramatic increase in levels of lacZ expression following application of serotonin. This induction appeared to be at the transcriptional level and mediated by the CRE since: i) co-injected competitor wild-type CRE oligonucleotides, but not mutant oligonucleotides, blocked the induction, and ii) no induction was seen with a control plasmid that expressed lacZ from a constitutive promoter. These data, together with studies using inhibitors of macromolecular synthesis and injected CRE oligonucleotides (Dash et al., 1990), indicate that transcriptional induction, involving CREB, is necessary for long-term synaptic facilitation and that CREB may serve as a switch for turning on the long-term process.

The ability to efficiently express cloned genes and regulate reporter genes in *Aplysia* neurons now allows assessment of a range of neurobiological problems.

213.11

STRUCTURAL CORRELATES OF ASSOCIATIVE MEMORY IN *HERMISSENDA* NEURONS: THE ROLE OF SMALL G-PROTEINS. C. Collin, M. Sakakibara, D. McPhie, J.V. Sanchez-Andres, T.I. Nelson and D. L. Alkon. Neural Systems Section, NINDS, NIH, Bethesda MD, 20892

Associative conditioning causes functional and structural modifications of the type B photoreceptors of the sea snail *Hermisenda*, that lead to enhanced excitability and a reduction of the enclosing volume of the terminal dendritic arborization. Here we studied the signal transduction pathway that mediates the structural modifications. A small G-protein, cp20, that is phosphorylated by conditioning, has recently been purified from *Hermisenda* brain, and shown to regulate potassium currents when microinjected back into neurons.

We report that iontophoresis (-2 to -3 nA, 500 msec, 1 Hz pulses for ten minutes) or pressure injection of cp20 has also structural effects on lucifer yellow filled B photoreceptors analyzed with confocal microscopy. These changes are taking place in a post-mitotic and differentiated neuron and have a fast time course. Two hours after cp20 microinjections, a reduction of the dendritic enclosing volume was observed in more than 70% of the injected cells. This effect was not prevented by 10 μ M staurosporine pretreatment, a PKC blocker. Experiments with colchicine, an axonal transport blocker, did not interfere with the lucifer yellow labelling of the axons, indicating that under these injection conditions cp20 effects were not mediated by a block of axonal transport.

The results suggest the existence of a PKC dependent signalling pathway, that can be activated during classical conditioning, and causes the early regulation of potassium channels. Structural- and long term modifications involving this and other pathways, including cp20, may induce more permanent structural re-arrangements of the dendritic area.

DID MECHANISMS OF HYPERALGESIA EVOLVE FROM PRIMITIVE ADAPTIVE RESPONSES TO AXONAL INJURY? CLUES FROM NOICEPTIVE PLASTICITY IN AN INVERTEBRATE, *APLYSIA*. E.L. Walters. Dept. of Physiology & Cell Biology, Univ. of Texas Medical School, Houston, TX 77225.

Although hyperalgesia and allodynia are defined in human terms, various vertebrates and invertebrates display similar hypersensitivity near a wound. Nociceptive sensory neurons in *Aplysia* (which combine integrative functions that in mammals are distributed across primary sensory neurons and dorsal horn neurons) show increased excitability, receptive field expansion, and synaptic enhancement after injury to their receptive fields. It was shown previously that these effects can be produced by activity-dependent actions of extracellular modulators (ADEM) released during injury. Several arguments suggest that some mechanisms of nociceptive sensitization may have descended from mechanisms of cellular repair in sensory neurons of early common ancestors of existing phyla. To begin to test this idea, long-term plasticity within the VC sensory population was compared after noxious cutaneous stimulation (maximizing ADEM) and after sensory axons were crushed under complete anesthesia (minimizing ADEM). Although delayed in onset, axon injury caused the same set of central changes as nociceptive ADEM did: significant a) decreases in spike threshold, accommodation, and AHP, and b) increases in spike duration, synaptic efficacy, and afterdischarge.

214.3

DIFFERENTIAL EFFECTS OF LASER IRRADIATION ON AXOPLASMIC TRANSPORT IN SENSORY NEURONS AS COMPARED TO MOTOR NEURONS. U. Wesselmann and W. Z. Rymer. Dept. of Physiology & Rehabilitation Medicine, Northwestern University Medical School, Chicago, IL 60611.

In the quest for a reliable physical method to alter nerve function selectively and differentially a number of radiation sources have been studied over the last 30 years (ultrasound, microwaves, radiofrequency current). We have demonstrated recently that Nd:YAG laser irradiation selectively impairs neural impulse propagation in small slow conducting fibers, as compared to large diameter afferents (Wesselmann et al., *Physiol. Chem. Phys. & NMR*, 23, 1991, in press). In an attempt to clarify the ultimate fate of sensory and motor neurons after laser application to their peripheral axons, we have used HRP to retrogradely label DRG cells and motor neurons 7 days after laser irradiation (Nd:YAG laser, 70 mJ/pulse x 5 min) of their peripheral axons. The number of labeled DRG cells was significantly ($P < 0.003$) decreased on the laser-treated side (laser-treated: 2183 ± 513 vs control: 3937 ± 225 , $n=7$). Dimension analysis of the labeled DRG cells showed that the cell deficit on the laser-treated side was mainly due to a decrease in small neurons of the A-delta- and C-group (Wesselmann et al., *Exp. Neurol.*, 111, 251-262, 1991). In contrast the number of HRP labeled motor neurons was not altered to a significant ($P > 0.05$) extent (laser-treated: 767 ± 10 vs control: 808 ± 19 , $n=5$). Since the majority of A-delta and C-fibers have nociceptive function, the observed selective effects of laser irradiation on this fiber class, when radiating the whole nerve, might lead to potentially useful applications for the treatment of pain.

PHYSIOLOGICAL AND PSYCHOPHYSICAL STUDIES OF THE EFFECT OF CALCIUM CHANNEL BLOCKERS ON CORNEAL SENSATION R. W. Beuerman, H.W. Thompson*, A. Snow*, C. Breen*, LSU Eye Center, New Orleans, LA 70112.

The cornea supports the most densely innervated surface epithelium in the body. Stimulation of these free nerve endings evokes only sensations of irritation or pain. Ionic mechanisms of the electrical events following stimulation are not understood for free nerve endings. We investigated the decrease in neural stimulation in a rabbit model using hyperosmotic concentrations of sodium chloride. The amplitude of the integrated neural response showed a linear decrease for 0.5 M NaCl combined with caffeine (1mM-50mM) or pretreatment with verapamil (1 μ M-100 μ M). Theophylline, another xanthine, was only 50% as effective in suppressing the response. Psychophysical assessment of stimulus magnitude and duration was performed in a series of consenting volunteers using a visual-analog scale. In 11 subjects the pain response to 10^{-7} M capsaicin was significantly ($P=0.0012$) decreased by combining caffeine (50mM) with the capsaicin. In 20 subjects, pretreatment with verapamil (0.1mM) decreased the pain response (43.6 ± 5.73 to 36.9 ± 4.91). Although the duration of the sensation decreased 20-60%, the difference was not significant. These results suggest that calcium channels may be involved in the transducer action of the free nerve endings and that calcium channel blockers may be useful as topical analgesics. (NEI EY04074)

Delayed Activation of C-Fiber Nociceptors: A Novel Mechanism of Nociception Deborah M. White and Jon D. Levine Dept. of Anaesthesia & Pain Mgt, University of Sydney, St. Leonards, N.S.W., 2065 and Division of Neuroscience, UCSF, San Francisco, CA 94143.

We evaluated responses of C-fiber mechano-heat nociceptors (C-MH) to sustained mechanical stimuli and compared this response to sensitization of C-MH by prostaglandin E₂ (PGE₂). Action potentials of single C-MHs were recorded from the saphenous nerve of anesthetized rats (pentobarbital; 50mg/kg; i.p.). Calibrated von Frey hairs (VFH) of threshold and subthreshold force were applied for 5min. While threshold force VFHs activate C-MH immediately, subthreshold stimuli activate C-MHs ($n=36$) with a delayed onset which increases exponentially with decreasing force. We found that the delayed activation of C-MHs differs from sensitization in at least three aspects. Firstly, the delayed activation of C-MHs does not involve a decrease in mechanical threshold ($n=11$). Secondly, an i.d. injection of PGE₂, which decreased the mechanical threshold of C-MHs ($n=7$), had no effect on the latencies of the delayed activation. Also, the delayed activation of C-MHs is Ca²⁺-dependent since latencies were increased by Quin 2 ($n=6$), a calcium chelating agent, and decreased by A23187 ($n=6$), a calcium ionophore. We propose that the delayed activation of C-fibers is a novel mechanism of nociception that may explain the delayed sensations of pain induced by sustained mechanical stimuli.

A DOMINANT ROLE OF ACID PH IN INFLAMMATORY EXCITATION OF NOCICEPTORS IN RAT SKIN. P.W. Reeh*, K.H. Steen* and A.E. Hanisch*. Institute of Physiology and Biocybernetics, D-8520 Erlangen, FRG

A major role of local acidosis in long lasting excitation and sensitization of cutaneous nociceptors has recently been demonstrated (Steen et al. 1991, J. Neurosci. submitted). In inflamed tissue, acid pH meets with a mixture of inflammatory mediators. We have mimicked this condition in a rat skin-saphenous nerve preparation in vitro which allows direct application of chemicals to the isolated receptive fields at the corium side. Stimulant solutions used were: CO₂ saturated "synthetic interstitial fluid" (CO₂-SIF, pH 6.1), an "inflammatory soup" (IS) in submaximal concentration containing bradykinin, serotonin, histamine, prostaglandin E₂ (all 10⁻⁶ M) in neutral SIF, and a combination made of CO₂ saturated IS (CO₂-IS, pH 6.1). Mechano-heat sensitive C-fiber terminals (n=36) were treated for 5 min at 10 min intervals with these solutions: 20 units responded to CO₂-SIF, 12 to IS, 11 to both, whereas 27 (77%) units were excited by CO₂-IS. Thus, 7 of 16 units insensitive to either of the two solutions were stimulated by their combination. This increased effect of CO₂-IS was also expressed in a larger mean response magnitude: 152 spikes with the combination versus 45 spikes evoked by IS and 93 spikes by CO₂-SIF (n=25; p<0.002 resp. <0.02, Wilcoxon-test). During long term nociceptor stimulation (30 min) by either CO₂-SIF or IS, the discharge regularly and markedly increased when CO₂-IS was applied during the middle 10 min. There is a strong algogenic interaction between acid pH and inflammatory mediators. At equal and pathophysiologically relevant concentration, however, hydrogen ions play a dominant role. (DFG grant RE 704/1-5)

ANALYSIS OF SYNAPTIC TRANSMISSION IN THE SPINAL CORD EVOKED BY ACTIVATION OF DORSAL ROOT GANGLION NEURONS WITH CHEMICAL IRRITANTS. S. Jettini and L. Urban. Department of Vet. Anatomy and Neuroscience Program, Iowa State University, Ames, IA 50011, USA, Sandoz Institute for Medical Research, Gower Place, WC1E 6BN, London, UK.

The synaptic activation of dorsal horn (DH) neurons evoked by stimulation of dorsal root ganglion (DRG) neurons with high potassium and capsaicin was studied in a spinal cord slice - DRG preparation. Brief (1 min) perfusion of 50mM potassium to the DRG depolarized all sensory neurons (29±2.2 mV, mean ±SEM, n=32). In spite of the large depolarization, firing of action potentials was recorded in 11 of the neurons. By simultaneous intracellular recording from DRG and superficial DH neurons we established that all spinal cord neurons (n=30) that had a C-fiber input were synaptically activated when DRG neurons were stimulated by high K or capsaicin. Effect of capsaicin was dose dependent and when applied in 0.2 and 0.5µM repeatable excitatory effects were observed. In concentration of 10µM capsaicin effects were very long lasting (up to 45 min) and while in 3 cases neurons responded to repeated application in 2 no response was obtained when capsaicin was repeated. Following capsaicin-evoked desensitization, perfusion of high K to DRG depolarized DRG neurons but failed to synaptically activate DH neurons (n=5). High capsaicin failed to depolarize large DRG neurons (n=8). Perfusion of 0.5µM TTX to the DRG selectively blocked the Na spikes in large fibers (n=7) but even at 10µM concentration failed to block synaptic activation of DH neurons evoked by high K or capsaicin applied to DRG-compartment. In summary, our data demonstrate that primary afferents are depolarized by KCl and capsaicin. In addition, our data suggest that high potassium evokes synaptic responses in DH neurons by activating small unmyelinated fibers in TTX insensitive fashion. Work was supported by NIH Grant NS27751 and USDA Grant PL95-113.

RESPONSES OF SPINAL DORSAL HORN NEURONS IN RATS WITH AN EXPERIMENTAL PERIPHERAL MONONEUROPATHY Jennifer M.A. Laird & Gary J. Bennett. Neurobiology & Anesthesiology Branch, NIDR, NIH, Bethesda, MD 20892 U.S.A.

Rats with a constriction injury of one sciatic nerve show evidence of hyperalgesia, which is maximal 10 days after surgery (Bennett & Xie *Pain* 33:87, 1988). We have examined the responses of dorsal horn neurons at this time in 6 rats with a constriction injury of one sciatic nerve and in 3 rats in which the nerve was exposed but not ligated (sham-operated). In the acute experiments, extracellular recordings were made from all dorsal horn neurons encountered in the ipsilateral L₄-L₅ segments of the spinal cord of rats anesthetized with pentobarbital. Neurons with input from the sciatic nerve were located by stimulating the nerve proximal to the site of injury, or at a comparable location in the sham-operated animals.

In the nerve-injured animals less than half (46%; 31/67) of the neurons had a peripheral receptive field (RF) as compared with 98% (48/49) of neurons in the sham-operated animals. The proportions of cells with low, high and both low and high threshold inputs was significantly different in the two groups. Half of the neurons in the nerve-injured animals responded to tapping the injury site on the nerve (49%; 33/67); this response was rapidly adapting. Some of these neurons also responded to stimulation of a RF. None of the neurons recorded in the sham-operated animals responded to tapping the nerve. A small number (<5%) of neurons in the nerve-injured animals had abnormally prolonged stimulus-evoked discharges and high spontaneous activity; such cells were not seen in the sham-operated animals. The loss of peripheral RFs and responses to mechanical stimulation of the injury site are consistent with the known effects of the constriction injury on primary afferent neurons. However, substantial spontaneous activity is seen in the injured nerve, yet this was seen in surprisingly few dorsal horn neurons.

ATP-SENSITIVE K⁺ CHANNELS MEDIATE THE PURINERGIC IPSP IN NOCICEPTIVE DORSAL HORN NEURONES IN THE CAT SPINAL CORD. M.W. Salter, Y. DeKoningk¹ and J.L. Henry^{1,2}. Div. Neurosci., Hosp. for Sick Children, Toronto, Ont. M5G 1X8. Depts. ¹Physiol., ²Res. Anaes. and ³Psychiat., McGill Univ., Montréal, PQ H3G 1Y6.

Input from vibration-sensitive, large diameter primary afferent fibres evokes an inhibitory postsynaptic potential (IPSP) in nociceptive neurones in the dorsal horn. This IPSP results from a K⁺ conductance activated by adenosine acting through P₁-purinergic receptors. Recently, it has been reported that the K⁺ channels activated by adenosine in cardiac muscle are ATP-sensitive K⁺ channels (Kirsch et al. *Am. J. Physiol.* 259:H820, 1990). Therefore, we examined whether these channels might mediate the adenosine IPSP in nociceptive dorsal horn neurones. Intra- and extracellular recordings from neurones in the lumbar spinal cord were made using adult cats anaesthetized with α-chloralose. It was found that iontophoretically applied glibenclamide, a blocker of ATP-sensitive K⁺ channels, attenuated the inhibition of nociceptive neurones by vibratory stimulation. Glibenclamide also blocked this inhibition when administered *i.v.*; this effect was dose-dependent and 20 mg/kg caused about 50% blockade. In addition, the IPSP evoked by vibratory stimulation was blocked by injecting ATP directly into neurones during intracellular recording. These results indicate that the purinergic IPSP in nociceptive neurones is mediated by ATP-sensitive K⁺ channels. As this IPSP may be the physiological substrate for the analgesia produced by vibratory stimuli, activation of ATP-sensitive K⁺ channels in nociceptive dorsal horn neurones may be necessary to produce this analgesia. (Supported by the Canadian MRC, the FRSQ and the Nicole Fealman Fund.)

PERIPHERAL INFLAMMATION INDUCES EXPRESSION OF THE NERVE TERMINAL PROTEIN NT75 IN SPINAL NEURONS. S.S. Kanekar, T.C. Ritchie and J.D. Coulter. Neurosci. Prog. & Dept. of Anat., U. of Iowa, Iowa City, IA 52242.

In adult spinal cord, staining for NT75 with the S-7B8 antibody is restricted to nerve terminals concentrated in the superficial dorsal horn. Study of the origin of NT75 immunoreactivity (NT75ir) indicates that most neurons with terminations in the spinal cord are capable of expressing NT75ir, but that only certain populations, such as primary afferents, maintain high levels in their terminals. This implies some form of regulation of the level of NT75ir in different neural systems. To explore factors that affect NT75ir in rat spinal cord, Complete Freund's Adjuvant (CFA) was injected into the hindfoot to induce a small, localized area of inflammation. A strong hyperalgesic response to radiant heat was seen in the injected paw from 4hrs to 4 days, then declined and was abolished by 2 weeks. Rats were perfused 12hrs, or 1, 2, 4, 10 or 14 days after injection, and the spinal cord and dorsal root ganglia (DRG) were stained for NT75. No change was seen in NT75ir in spinal nerve terminals or in DRG cells. However, NT75ir was induced in a small number of spinal neurons. NT75 labeled neuronal perikarya, clustered in laminae IV-VI ipsilateral to CFA, were detectable by 12hrs after injection, peaked in number at 2 days, and were still evident at 14 days. NT75ir cells (1-15 cells/100 tissue sections) were present from L1 to S1 but were most dense at L3-L5. In contrast, staining for synaptophysin or substance P was not affected by CFA treatment. The change in NT75ir may be related to increased neural activity resulting from inflammation-induced hyperalgesia. However, NT75ir is modulated in spinal neurons, but not in DRG cells, implying that neuronal activation alone is not a sufficient stimulus to alter NT75, but that synaptic activity may be required. During development, NT75 expression corresponds closely to the formation of synaptic connections. Plasticity in expression of NT75ir in adults and the timing of its expression during development may imply a role in active nerve terminals. Supported by NS23783.

NOXIOUS SKIN HEATING OR SUBCUTANEOUS FORMALIN INJECTION INDUCE SEQUENTIAL TRANSCRIPTIONAL OPERATIONS IN RAT SPINAL NEURONS. M. Zimmermann, T. Herdegen, T. Tölle, W. Zieglgänsberger, R. Bravo, H. Physiologisches Institut der Univ. Heidelberg, FRG, Max-Planck-Institut für Psychiatrie, München, FRG, The Squibb Institute, Princeton, USA.

Long-lasting expression of immediate-early gene (IEG) encoded proteins was previously observed after electrical stimulation of sciatic A delta- and C-fibers (Herdegen et al., *Eur. J. Physiol.* 415, R93, 1990). We have investigated the induction of IEGs following stimulation of nociceptors. In anesthetized rats one hind paw was immersed in 52° C hot water. Formalin (2%) was injected in one hind paw of unanesthetized rats. The expression of c-JUN, JUN B, JUN D, c-FOS, FOS B and KROX-24 proteins was visualized by immunocytochemistry. The temporo-spatial patterns were similar in both experiments. Numbers of neurons labelled for c-FOS, c-JUN, JUN B and KROX-24 were at maximum after 2 h and then declined to basal levels between 8 h and 24 h. FOS B labelled neurons showed maximum numbers between 4 and 8 h and were still present after 24 h. JUN D had a delayed onset after 4 h, a maximum after 8 h and remained on this level for up to 24 h. Expression was most pronounced in the superficial dorsal horn, except for c-FOS and JUN D. Frequency of labelled neurons showed falling order for KROX-24, c-FOS, JUN B, JUN D, FOS B and c-JUN. This different expression may indicate that a limited number of AP-1 transcription complexes had formed. The sequential expression of IEG proteins may be meaningful in relation to long-term alterations of neuronal programs which could be a new dimension of neuronal processes of pain. Supported by Deutsche Forschungsgemeinschaft.

NMDA RECEPTOR INVOLVEMENT IN MECHANICALLY AND ELECTRICALLY EVOKED SPINAL REFLEXES IN NORMAL AND MONO-ARTHRITIC RATS. Nick A. Hartell and P. Max Headley. SPON: Brain Research Association. Department of Physiology, School of Medical Sciences, University Walk, Bristol, BS8 1TD, U.K.

NMDA receptors may mediate increased central excitability following peripheral tissue injury. We have used ketamine to assess this in 5 arthritic and 19 normal male Wistar rats. Rats were inoculated with Freund's Complete Adjuvant (50 µl s.c. into one hind paw) 4 days before the experiment. Under halothane anaesthesia, animals were spinalized at a low thoracic level and anaesthesia switched to α -chloralose. Percutaneous needle electrodes were used to record single motor unit responses to controlled noxious mechanical stimuli (15 sec), cycled every 3 min with percutaneously applied electrical stimuli, delivered at 2 and 0.3 Hz (1 msec duration; 5xT for evoking reflex spike). Prior to drug administration, similar strength mechanical stimuli evoked higher mean (\pm s.e.) motor unit firing rates in the arthritic (25.5 ± 1.7 Hz; n=6) than in the normal group (21 ± 3.1 Hz; n=11; P<0.05). There was no significant difference, however, in the potency with which ketamine ($1-8$ mg/kg⁻¹) depressed the responses to the noxious stimuli. In normal animals, 2 Hz electrical stimulation evoked 40% more spikes over 16 stimuli than did 0.3 Hz. No frequency-dependent increase in responses was observed in the arthritic rats; moreover, the response size at 0.3 Hz was only 40% of that in normals. Ketamine was similarly effective in depressing the responses to low and high frequency stimulation in arthritic rats, low frequency stimulation in normal rats and to mechanical stimulation in both normal and arthritic rats (52-60% control with 4 mg/kg⁻¹ i.v. ketamine). In normal animals, however, the wound up component of the response was reduced to 20% of control by 4 mg/kg⁻¹ i.v. ketamine. The results indicate that NMDA-mediated wind-up phenomena do not contribute to the changes of excitability seen in mono-arthritis. The disparity between increased mechanical and decreased electrical responsiveness in mono-arthritic rats remains to be examined.

NITROARGININE, A NITRIC OXIDE SYNTHASE INHIBITOR, ATTENUATES MORPHINE WITHDRAWAL. A.S. Kimes, D.B. Vaupel, M. Bruckner*, and E.D. London. Neuropharmacology Laboratory, NIDA Addiction Research Center, Baltimore, MD 21224.

Antagonists of the N-methyl-D-aspartate subtype of the glutamate receptor (NMDA-R) recently have been shown to reduce opioid withdrawal behavior (Rasmussen et al., *Eur. J. Pharmacol.* 197:9, 1991; Trujillo and Akil, *Science* 251:85, 1991). Recent studies have implicated nitric oxide (NO•) as a mediator of some NMDA actions in the nervous system (Garthwaite, *TINS* 12:60, 1991). N^o-nitro-L-arginine (N-Arg) is a potent inhibitor of NO• synthase in brain (Hecker et al., *Biochem. Biophys. Res. Comm.* 167:1037, 1990). To determine if NO• plays a role in NMDA-R involvement in opioid dependence, we studied the effect of N-Arg on naloxone-precipitated morphine withdrawal (NPMW). Four groups of rats received one 75 mg morphine pellet on day 1, and two more pellets on day 4; two groups received placebo pellets on the same schedule. On days 4-7, morphine groups received either 0, 1, 3 or 7.5 mg/kg N-Arg (i.p., b.i.d.); placebo groups received either 0 or 7.5 mg/kg N-Arg. On day 8, signs of NPMW were assessed for 15 min after an injection of naloxone (0.5 mg/kg, s.c.). N-Arg (7.5 mg/kg) significantly reduced jumping and hyperactivity and tended to decrease wet dog shakes, weight loss due to diarrhea and irritability in morphine-dependent rats, but had no effect in placebo-treated rats. Grooming, abnormal posturing, ptosis, erections and ejaculations were unaffected by N-Arg treatment. The results of this study support a role of NMDA-R in NPMW and suggest that the effect is mediated, at least partially, through NO• synthase.

215.1

INDUCIBLE EXPRESSION OF A HOMEODOMAIN PROTEIN, HOX 1.3, IN ADULT AND EMBRYONIC TRANSGENIC MICE.

P. Vos, R. De Santo*, S.-D. Zhang*, H. Arnheiter*¹, W. Odenwald*² Lab. of Neurochem., NINDS, NIH; ¹Lab. of Viral & Molec. Pathogenesis, NINDS, NIH Homeotic genes, a class of genes that code for DNA binding proteins, have been implicated as regulatory elements that control and coordinate the expression of other subordinate genes. Our inability to selectively control the expression of individual homeotic genes has made it difficult to identify candidate targets for these homeotic gene products in vertebrate systems. To test the *in vivo* function of Hox 1.3, a murine homeodomain protein, we have generated transgenic mice in which the levels of Hox 1.3 protein can be controlled by injecting interferon (IFN). These mice contain in their genome a transgene consisting of Hox 1.3 cDNA linked to an IFN inducible promoter, the murine Mx1 promoter.

In the absence of deliberate induction, the transgenic mice appeared normal. Baseline transgene expression was undetectable by Northern analysis in many organs of the transgenic mice. However, IFN induction led to a rapid accumulation of Hox 1.3 RNA in many organs (e.g., CNS, lung, liver). Furthermore, IFN injections of nontransgenic pregnant dams also induced transgene expression in embryonic mice pups. Fetal induction was detectable as early as day 11.5 of gestation using Northern analysis. The distribution of Hox 1.3 transgene expression in fetal mice was examined using *in situ* hybridization. The tissue distribution of induced transgene expression in embryos paralleled that seen in adults. Current efforts are directed towards using these transgenic mice as tools to probe the biofunction of Hox 1.3 during development and in adulthood. Tissue-specific cDNA libraries from transgenic and nontransgenic animals are being screened for potential targets of Hox 1.3 using subtractive hybridization methodologies.

BRAIN-SPECIFIC INCREASED EXPRESSION OF GLIA DERIVED-NEXIN IN TRANSGENIC MICE ALTERS BRAIN FUNCTIONS. F.M. Botteri¹,

I. Mansuy¹, C. Mondadori², G. Sansig³, H. van der Putten³, and D. Monard¹. ¹Friedrich Miescher-Institute, P.O.Box 2543; ²Pharmaceutical Research Department, Ciba-Geigy Ltd.; ³Biotechnology, Ciba-Geigy Ltd., CH-4002 Basel, Switzerland. Glia derived-nexin (GDN), also known as protease nexin I, is a serine protease inhibitor, that *in vitro* promotes neurite outgrowth from neuroblastoma cells, sympathetic and hippocampal neurons. *In vivo*, GDN is constitutively expressed in the olfactory system, where axonal regeneration and neurogenesis occur continuously throughout life, and it is also upregulated following lesion of the rat sciatic nerve. Therefore GDN could serve crucial roles in the process of axonal regeneration *in vivo*. To investigate biological relevance of GDN *in vivo*, we generated several strains of transgenic mice carrying a chimeric Thy-1-GDN gene, which directs the expression of high levels of rat GDN in the brain. Transgenic mice of one strain went through a whole series of behavior tests. In any of the observation tests used (global behavioral assessment, rotarod, motility) no differences were noted between transgenic mice and non-transgenic littermates. The transgenic mice, however, tended to have a slower acquisition rate in the Morris water maze, although this effect was observed in only 6/40 animals and might be attributed to differences in GDN expression among individuals of the same strain. A second strain is being tested to exclude a role for the specific chromosomal integration site of the transgene influencing the learning performance of the first strain. Immunohistochemistry and *in situ* hybridisation analyses are in progress to determine possible consequences of the overexpression of GDN on brain organisation.

215.2

THYMOSIN B10 GENE EXPRESSION IN TRANSGENIC MICE AND ITS REGULATION BY RETINOIC ACID. S.-

C. Chen*, D. I. Lugo, R. J. Smeyne, J. G. Corbin*, J. L. Hempstead*, V. R. Albert and J. I. Morgan. Roche Institute of Molecular Biology, Roche Research Center, Nutley, NJ 07110.

In previous studies, levels of thymosin B10 have been shown to be high in the embryonic nervous system but to decline dramatically after birth. In addition, the expression of this gene is up-regulated by the morphogen, retinoic acid, in a variety of neuroblastoma cell lines e.g., B104. Using a thymosin B10 cDNA as a probe, we have investigated the levels of B10 mRNA in B104 cells treated with retinoic acid, either in the presence or the absence of cycloheximide. The results indicate that protein synthesis is required during the first 5 hours of retinoid treatment for the increased expression of thymosin B10 mRNA. This suggests the involvement of intermediate transcription factors e.g., immediate-early genes, in the regulation of thymosin B10 gene expression by retinoic acid.

Using *lacZ* as a reporter, we have constructed transgenic mice that carry a B10-*lacZ* fusion gene and examined its expression during development. We observe high levels of expression of this construct in CNS, including hippocampus, spinal cord, cerebellum, olfactory bulb and olfactory neuroepithelium. Several other constructs, with different lengths of the thymosin B10 promoter, have also been used. These studies will help to dissect out the regulatory elements responsible for the developmental expression of the thymosin B10 gene and the modulation by retinoic acid.

215.4

IN VIVO TISSUE-SPECIFIC EXPRESSION OF A CHIMERIC CONSTRUCT CONTAINING 3.5 KB OF THE 5' FLANKING DNA FOR THE MOUSE TYROSINE HYDROXYLASE GENE. W.W. Morgan and Z.D. Sharp*. Dept. Cellular and Structural Biology and the Institute for Biotechnology, Univ. Texas Hlth. Sci. Ctr. at San Antonio, TX 78284-7762.

The expression of tyrosine hydroxylase (TH) is limited to catecholaminergic neurons located within the brain, the sympathetic chain ganglia and paraganglia and to adrenal medullary cells. This limited distribution suggests that the activation of the gene which encodes TH is regulated by very precise molecular genetic mechanisms. To investigate these processes, over 3.5 kb of the 5' flanking region of the mouse TH gene was cloned and sequenced. A chimeric construct was made by attaching this upstream DNA including the +1 initiation site to a reporter gene consisting of the coding sequence for bacterial beta galactosidase plus polyadenylation signals. The construct was introduced into fertilized zygotes of C57BL/6 mice, and transgenic mice were identified by PCR analysis of mouse DNA. Bacterial beta galactosidase enzymatic activities in the medulla oblongata were 2.6 and 0.6, in the adrenal 120.6 and 13.5 and in the liver 0.2 and 0.2 picomoles/ml/min/mg protein in transgenic versus control animals, respectively. These results show that the DNA sequences required for the *in vivo* tissue-specific expression of the TH promoter are located within the 5' region of the gene and are all within 3.5 kb of the +1 initiation site. Supported by DA00755 and GM43763 to WWM and DK38546 to ZDS.

ONTOGENY OF mRNA FOR DOPAMINE RECEPTOR SUBTYPES (D₁, D₂, D₃) IN THE RAT BRAIN. U.B. Schambra, G.E. Duncan, G.R. Breese, M.G. Fornaretto*, M.G. Caron and R.T. Fremeau, Jr. UNC, Chapel Hill, NC 27599 and Duke Univ. Med. Ctr., Durham, NC 27710.

The ontogeny of the expression of D₁, D₂, and D₃ dopamine receptor mRNA in the rat brain was assessed at 16 time points between gestational day (GD) 14 and postnatal day (PD) 130-140 by *in situ* hybridization. A differential developmental pattern of expression of the 3 dopamine receptor subtypes was observed. X-ray film autoradiography revealed that the D₁ receptor message was present at GD 14 whereas the D₂ receptor mRNA was first evident at GD 18. In contrast D₃ receptor mRNA was detectable at PD 5. At GD 14, the D₁ message was observed in the area of the developing striatum/olfactory tubercle, cingulate and pyriform cortex in both ventricular and intermediate zones. At GD 18, D₂ mRNA was initially observed in the area of the developing striatum/olfactory tubercle and substantia nigra whereas at PD 0, cells in layer V of the cingulate, parietal, and pyriform cortices were labeled. D₃ mRNA was first observed at PD 5 in the olfactory tubercle and island of Calleja with weaker signals in the parietal cortex and nucleus accumbens. Maximal levels of receptor mRNA were observed at PD 14 for both D₁ and D₃ and PD 10 for D₂ and thereafter all three mRNAs declined significantly with age. Our observation that D₁ receptor mRNA is expressed in the ventricular zone, a region of dividing neuroblasts and the intermediate zone, a region of migrating neurons, is consistent with previous studies suggesting that D₁ receptors regulate neurite outgrowth and growth cone motility. Supported by Training Grant #5-39056, and grants HD-23042 and NS-19576.

ELECTRICAL ACTIVITY REGULATES EXPRESSION OF mRNAs CODING FOR MYOD-RELATED TRANSCRIPTION FACTORS AND ACETYLCHOLINE RECEPTORS. A. Buonanno, R. Beers*, H. Brenner* and R. Eftumie* Unit on Mol. Neurobiol., LDN, NICHD, NIH, Bethesda, MD 20892

Electrical activity represses the expression of a repertoire of muscle genes during innervation; i.e., genes coding for nicotinic acetylcholine receptors (nAChR). We have analyzed the expression of members of the myoD family of *trans*-acting factors during muscle development, to determine if they may regulate transcription of genes down-regulated by innervation. Using Northern blot analysis, we found that initially myoD, myogenin and myf-5 mRNA levels decrease during a period that coincides with innervation (E17 to P7), and is followed by a diminution in nAChR mRNA levels that occurs after birth (P7). In contrast, mrf-4 levels begin to accumulate around birth. Denervation reverses the effects of innervation and leads to the accumulation of transcripts coding for the myogenic factors and receptor. Myogenin and myoD mRNAs increase dramatically (40 and 15-fold) 8h after denervation; the increase precedes the accumulation of nAChR α and γ subunit mRNAs which begins approximately 1d after denervation. Increases in myf-5 and mrf-4 mRNA levels, however, are small and occur after the accumulation of receptor transcripts. The effects of innervation are due largely to electrical activity because stimulation of denervated muscle with extracellular electrodes prevents the accumulation of mRNAs coding for myogenic factors and receptor. Next, we analyzed if the myogenic factors can regulate transcription of receptor genes. Using gel-shift assays and DNA footprinting we found that myogenin and MyoD bind to the nAChR α and γ subunit enhancers which contain two consensus "myoD binding sites". Functional studies showed that myogenin and myoD activate transcription from constructs containing either the α or γ subunit enhancer linked to the CAT reporter gene. Point mutations in the myoD binding sites of either enhancer abolish expression of the reporter gene in transfected C2C12 myotubes. It is interesting to speculate from our results that myogenin and/or MyoD coordinately activate transcription of nAChR genes during myogenic differentiation, and may also modulate transcription of a repertoire of skeletal muscle genes down-regulated by electrical activity.

DEVELOPMENTALLY-REGULATED mRNA CLONED FROM AN EMBRYONIC NEURONAL CULTURE

Y. Aizenman, R.J. Milner. Department of Neuropharmacology, Research Institute of Scripps Clinic, La Jolla, CA 92037.

To gain insight into brain development, we have used molecular cloning techniques to identify mRNAs that are expressed at particular stages of neural development. Primary neuronal cultures were prepared from 17-18 days old embryonic rat cortices in a defined medium. A cDNA library was constructed from cultures that were induced for 2-3 hours with thyroid hormone, a crucial hormone for brain development, in the presence of cyclohexamide. Several clones of interest were selected from this library by a subtractive hybridization procedure. Three of these clones hybridized to mRNAs that displayed regulated patterns of expression during development, with increased expression in RNA samples from embryonic brain as compared to adult. Two of these clones were expressed at a constant amount from embryonic day 14 to postnatal day 10. Their expression declined on postnatal day 15 and was further decreased on day 20. This time course, taken with the fact that these mRNA were cloned from a rapidly growing neuronal culture, suggests that the mRNAs might encode proteins involved in the process of neural development, such as neurite outgrowth. Partial DNA sequence analysis of these clones revealed that one of the clones encoded α 1 tubulin, whereas the other two clones, which hybridized to mRNAs of 4500 bases and 2200 bases, were not similar to any known molecules contained in the NBRF and GenBank databases. Supported by NIH grant NS22347.

215.6

EXPRESSION OF BC1 RNA IN DEVELOPING HIPPOCAMPAL NEURONS IN CULTURE. H. Tiedge*, G. A. Banker¹, and J. Broslus. Fishberg Research Center for Neurobiology, Mount Sinai School of Medicine, New York, NY 10029. ¹Department of Neuroscience, University of Virginia, Charlottesville, VA 22908.

BC1 RNA is a short non-translatable polymerase III transcript that is selectively expressed in the somata and dendrites of a subset of neurons in the adult rat nervous system [Tiedge et al. (1991) Proc. Natl. Acad. Sci. USA 88, 2093-2097]. The expression pattern and subcellular location of the RNA have been interpreted to indicate a possible functional role in postsynaptic domains of neurons, conceivably in the context of localized protein biosynthesis. In the present study, we have analyzed the expression of BC1 RNA in developing hippocampal neurons over a period of up to 4 weeks in culture. Neurons were isolated from 18 day-old rat embryos and maintained in culture as described earlier [Bartlett and Banker (1984) J. Neurosci. 4, 1944-1953]. Cultures were fixed at various time points and probed for selected target RNAs. Significant amounts of BC1 RNA were not detectable in hippocampal neurons until the end of the first week in culture. During this time, hippocampal neurons in culture establish their polarity: they extend first axonal, then dendritic processes [Dotti et al. (1988) J. Neurosci. 8, 1454-1468]. In contrast, SRP RNA, the 7SL RNA component of the ubiquitous signal recognition particle, was detectable after only 2 days in culture, the first time point taken, and continued to be expressed at substantial levels during all phases of development. Levels of BC1 RNA rose sharply at the beginning of the second week in culture, at a time when synaptic contacts become numerous. In contrast, no abrupt changes were observed in expression levels of SRP RNA. By the end of the second week in culture, high levels of BC1 RNA were detectable in the somatic and dendritic domains of most neurons, a pattern that persisted in mature neurons. SRP RNA, on the other hand, was predominantly localized to the perikarya of hippocampal neurons at all stages during development in culture. Our results indicate that BC1 RNA is not required for initial outgrowth of either dendrites or axons by hippocampal neurons in culture; however, the time course of BC1 expression may correlate with the formation, maturation or maintenance of synaptic connections.

SUBTRACTIVE HYBRIDIZATION TO IDENTIFY GENE PRODUCTS EXPRESSED DURING THE CRITICAL PERIOD FOR VISUAL CORTEX DEVELOPMENT. Shiv Prasad and Max Cynader, Department of Ophthalmology, University of British Columbia, 2550 Willow Street, Vancouver, B.C., Canada. V5Z 3N9

The developmental patterns of expression in the visual cortex for some known molecules have been previously examined by ligand binding autoradiography, immunocytochemistry and *in situ* hybridization. The results of these studies have indicated that such molecules can be expressed transiently in high abundance during the critical period for developmental plasticity of visual cortex.

We have isolated and characterized cDNA clones of mRNAs whose levels change in the kitten visual cortex during the critical period. Our approach has been to construct and analyse a subtractive cDNA library for the visual cortex of a 30 day old kitten subtracted with an adult cat. In total approximately 12,000 clones were screened, 200 of which hybridized to the subtracted probes. The positives were screened with individual clones to determine how many represented copies of each other. About 75% of the positive clones were found to be single copy and the rest represented either two or many copies. One of these represented 20% of the positives.

The individual clones from the subtractive library are being examined by Northern blot hybridizations to mRNAs from various tissues and developmental ages. The individual clones are also being sequenced to identify the primary structure. The inferred amino acid sequence of some of these clones have shown identity to some functionally identified molecules in the EMBL nucleotide and SWISS-protein data base. *In situ* hybridization using the individual cDNAs as probes will facilitate the exact localization of these transiently expressed transcripts in the developing visual cortex.

RAPID GLUCOCORTICOID MODULATION OF ASTROCYTE mRNAs AND PROTEINS. M. K. O'Banion*, D. A. Young*, E. W. Howard*, and M. C. Bohn. Departments of Medicine, Biochemistry, and Neurobiology and Anatomy, University of Rochester School of Medicine, Rochester, NY 14642.

Glucocorticoids (GC) affect the developing nervous system and are important to homeostasis in the adult brain. Glucocorticoid receptors are expressed in astrocytes and oligodendrocytes, as well as in neurons. This study was undertaken to begin to identify genes that are regulated by glucocorticoids in the brain.

The influence of GC on gene expression in primary cultures of type I astrocytes was studied using ultra-high resolution giant two-dimensional (2D) gel electrophoresis of the ³⁵S-labeled *in vitro* translation products of poly-A RNA isolated from cells treated for 3 h with corticosterone (10⁻⁶ M; CORT). Quantitative analysis of over 1500 *in vitro* translation products reveals 7 that change by more than 2-fold (6 increases, 1 decrease). Four of 6 increases are observed in cells treated with cycloheximide, suggesting that these arise by direct transcriptional activation. Two of these inductions are also observed in mouse fibroblasts treated with dexamethasone. These have been identified as glucocorticin (17 kDa, pI 4.8) and glutamine synthase (43 kDa, pI 7.0).

To determine whether the changes observed in levels of mRNAs correspond to changes in protein expression, 2D gels of ³⁵S-labeled whole cell proteins were also examined. Five proteins induced within 3 h by CORT correspond to the changes seen in *in vitro* translation products.

These data demonstrate that type I astrocytes express functional GC receptors that mediate changes in gene expression within 3 hours. These changes appear to include both primary inductions and secondary inductions, requiring protein synthesis. The future identification of these GC-regulated genes will help elucidate the role of glucocorticoids in the brain. [Supported by the J. P. Wilmont Foundation and NIH grants NS20832 and RRO4968.]

CHARACTERIZATION OF NOVEL DEVELOPMENTALLY-REGULATED PROTEINS IN EMBRYONIC RAT SPINAL CORD. D.H. Geschwind and S. Hockfield, Section of Neurobiology, Yale School of Medicine, New Haven, CT 06510.

We have previously used 2-dimensional electrophoresis to identify several proteins (DRPs) whose synthesis is regulated during cortical neurogenesis in the rat (*J. Neurosci.* 9:4304). To further characterize some of these proteins, 2-D electrophoresis was used to study their regulation in the spinal cord at times (E12 v. E21) roughly comparable to those used in the previous study of developing cortex. Experimental procedures were similar to those previously described (*ibid*). Several of the proteins that were down-regulated in the cortex between E14 and E21, demonstrated significant down-regulation in the spinal cord between E12 and E21. Several of these do not appear in the liver, lung or heart and thus appear to be CNS-enriched. One of the previously up-regulated proteins, 407, was up-regulated as seen in cortex. Two additional proteins that were up-regulated in spinal cord were not observed in the analysis of cortex. Also intriguing is a set of proteins that were up-regulated more than 100-fold in cortex, but that are not seen in spinal cord, lung, heart or liver and thus may be cortex-specific.

One of the cortical up-regulated proteins, 310, was up-regulated 4-fold in spinal cord, but partitioned primarily in the soluble fraction in spinal cord (>90%), while being more evenly distributed between particulate and soluble fractions in the cortex. We have further characterized 310 by protein microsequencing. Five stretches of sequence ranging from 7-18 amino acids indicate no significant homologies with other proteins in several databases, indicating that protein 310 is a previously uncharacterized, neural-enriched protein whose abundance increases during neurogenesis in cortex and spinal cord. The apparent neural-specific expression protein 310 and other DRPs, coupled with their regulation during the period of neurogenesis in spinal cord and cortex suggests that they may be involved in neurogenesis. Experiments are currently underway to further characterize them using antibody and oligonucleotide probes. *Supported by the NSF.*

BRAIN METABOLISM AND BLOOD FLOW III

216.1

A NETWORK-SIMULATION MODEL FOR STUDYING INTERREGIONAL CORRELATIONS BETWEEN REGIONAL RATES OF CEREBRAL BLOOD FLOW (rCBF). B. Horwitz, Lab. Neurosciences, Natl. Inst. on Aging, NIH, Bethesda, MD 20892.

Correlations between pairs of cerebral metabolic rates, obtained by positron emission tomography (PET), have been used to study patterns of functional associations among brain regions in humans. Recently, a computer simulation model was developed for partial validation of the correlation method (Horwitz, *Int J Biomed Comput.* 26:149-170, 1990). The current study presents a generalization of the model for simulating (O-15)water-cerebral blood flow PET studies, where multiple tasks can be performed within a single scanning session on a single subject. The model generates a set of simulated rCBF data upon which correlational analysis is performed. The model consists of n regions, in which blood flow in one region is a sigmoidal function of blood flow in some or all of the other regions, with the linking parameter called a functional coupling coefficient. The pattern of functional coupling coefficients is specified for each simulation. Random numbers provide the within-subject and between-subject variabilities seen in experimental data. It is shown how the model parameters can be determined using existing experimental data. Simulations are presented that demonstrate how correlational analysis provides information about neural relations that cannot be determined by analysis of changes in rCBF values alone, and how models like this can provide a link between PET data and cognitive neuroscience hypotheses of brain function.

216.3

IN VIVO MAPPING OF BLOOD OXYGENATION LEVELS IN RAT BRAIN BY MAGNETIC RESONANCE IMAGING. S. OGAWA AND T.M. LEE, AT&T Bell Labs, Murray Hill, NJ 07974

With high field MRI (magnetic resonance imaging), Blood Oxygenation Level Dependent (BOLD) contrast has been observed in rat brains. BOLD contrast with numerous dark lines in these images reflects the venous blood micro-vasculature of the brain under normoxic conditions. The contrast is sensitive to the physiological condition of the brain (1). By changing the depth of anesthesia with 0% to 3% halothane, the venous blood oxygenation was varied and the level at the sagittal sinus was measured from the blood water relaxation time in MRI. BOLD contrast as measured by image signal intensities in the cerebral cortex region showed linear (rather than exponential or gaussian) dependencies on the sagittal sinus oxygenation level. Image signals from the midbrain region did not necessarily fit to the linear relation. CFS signals in ventricles showed opposite correlations to the depth of anesthesia (the lower the dose of halothane, higher the signal intensity), indicating the more CSF movement in awake states than in anesthetized states. These relationships between the image contrast and the venous blood oxygenation can be used to calibrate changes in BOLD contrast, responding to changes in the physiological condition, in terms of local blood oxygenation and further to correlate with local oxygen consumption and/or CBF.

AN ALTERNATIVE OPERATIONAL EQUATION FOR SEQUENTIAL DOUBLE-STUDY METHOD USING RADIOLABELED DEOXYGLUCOSE. J.Y. Chang, M.D. Ginsberg, Cerebral Vascular Disease Research Center, University of Miami, Miami, FL 33101.

We have previously described a sequential double-study method with autoradiography and radiolabeled DG (Chang et al., *Soc Neurosci Abstr* 16:23,1990). The success of this method depends upon how accurately RC can be estimated. RC is defined as the ratio of the tracer concentration at the end of the first study to its remnant at the end of second study. Recently we have realized that the limited information embedded in the history of tracer concentration prohibits us from estimating all five rate-constant values accurately when the least-square best-fit method is used. Thus, RC may have been estimated incorrectly using the average rate-constant values. Results of our computer simulation suggest that the error of RC, estimated through the use of average rate-constant values, is 10.7, 7.0, 4.4, and 1.8% with the study length for rate-constant estimation is 120, 180, 240, and 360 min, respectively. Individual RC, however, can be easily estimated correctly, within 0.5%, from a set of tracer concentration values obtained from a 120-min study. Thus, to take the advantage of better RC measurement from each data set, we devised an alternative operational equation using the *average RC* for the sequential double-study method as

$${}^{1}CMR_{glc1} = \frac{C_p}{LC} \left(\frac{\bar{k}_1^* \bar{k}_3^*}{k_2^* + k_3^*} \right) \frac{\overline{RC}_{(k_1^*, k_2^*, k_3^*, k_1^*, k_2^*)} [C^{*1}(T_2) - C_s^{*1}(T_2 : T_1)]}{C_{e+m}^{*1}(T_1)}$$

instead of obtaining RC from the average rate-constant values as

$${}^{1}CMR_{glc1} = \frac{C_p}{LC} \frac{\bar{k}_1^* \bar{k}_3^*}{k_2^* + k_3^*} \frac{RC_{(k_1^*, k_2^*, k_3^*, k_1^*, k_2^*)} [C^{*1}(T_2) - C_s^{*1}(T_2 : T_1)]}{C_{e+m}^{*1}(T_1)}$$

CONTINUOUS CEREBRAL BLOOD FLOW MEASUREMENT BY A THERMAL METHOD. Datong Wei*, Mary Shea*, Gerald M. Saidel*, and Stephen C. Jones, Cerebrovascular Res. Lab., Cleveland Clinic Foundation, Cleveland, OH 44195 and Dept. of Biomed. Eng., Case Western Reserve Univ., Cleveland, OH 44106.

A continuous thermal perfusion measurement system was developed to study temporal variations of cerebral blood flow (CBF) with 0.5 mm diameter thermistors placed on the cortical surface. The system is optimally designed based on a distributed heat transfer model under requirements of probe size, sensitivity, resolution, and frequency response (*IEEE Trans. Biomed. Eng.* 37:1159-1172, 1990). *In vitro* tests indicate that the long-term drift of the system is less than the equivalent of 0.001°C, an estimated temperature change caused by perfusion change of about 5 ml/100g-min. The system can compensate for baseline temperature changes during measurement.

In vivo tests were performed on Nembutal anesthetized, artificially ventilated Sprague-Dawley rats both to refine the probe design and to investigate its use for measuring dynamic changes in CBF. Norepinephrine (0.1 - 0.5 mg) was injected as a bolus into the femoral vein repeatedly to cause transient CBF changes in response to changes in arterial blood pressure (ABP). The results from 8 rats demonstrated a significant difference ($p < 0.05$) between the flow response and the reference temperature changes. Five of these 8 rats demonstrated an autoregulatory response of CBF between 5 to 14 s after the onset of the ABP increase. The mean ratio of flow change to ABP change ranged from 0.003 to 0.0015 °C/mmHg. Two rats showed temporal blood flow variations with a cycling pattern. Fourier transform analysis showed that the cycles had a distinct frequency peak component between 0.06 to 0.12 Hz and from 0.002 to 0.009 °C in magnitude.

These results indicate that the system can be used to study the initial response of CBF to ABP changes and temporal CBF cycling in different steady-state conditions. (Supported by USPHS NIH grant NS 21538 and NSF grant BNS 9022190.)

216.5

INTRACELLULAR ION CONCENTRATIONS AND CAPILLARY BLOOD FLOW WITHIN THE RAT BRAIN NEOCORTEX: AN IN VIVO IMAGING APPROACH. A. Villringer, U. Dirnagl, A. Thiem*, G. Sixt*, K.M. Einhäupl*, Dept. of Neurology, University of Munich, 8000 Munich, Germany

In order to investigate coupling between brain cells and microvascular blood flow, we established a model for the simultaneous assessment of intracellular ion concentrations and blood flow in surrounding microvessels within the outer layers of the rat brain cortex in vivo.

Methods: The parietal cortex (dura mater removed) of anesthetized Wistar rats was observed through a closed cranial window using a Bio-Rad MRC 600 confocal laser scanning microscope (Ar/Kr Laser) attached to a Nikon Optiphot microscope with a x40 water immersion objective. Brain cell loading with AM-esters of ion sensitive fluorescent dyes was achieved by superfusion for 30 min (10µM in artificial CSF, washout 30min). To label the intravascular space dyes that do not pass the blood brain barrier were injected i.v., Dyes with differing optical characteristics were used for labeling of brain cells and intravascular space, respectively. When brain cells were loaded with Ca-Crimson (Ca-sensitive dye, exc max 596nm, Molecular Probes) Na-fluorescein (exc max 488nm) was used as marker of plasma, when brain cells were labeled with BCECF (pH sensitive, exc max 488nm, Molecular Probes) Texas Red (exc max 596nm), respectively.

Results: Simultaneous imaging of brain cells loaded with ion concentration sensitive dyes and blood flow in surrounding capillaries was achieved in optical sections at different depths beneath the brain surface. Ion concentration dependent signal was derived from depths up to 200µm (BCECF) or 100µm (Calcium Crimson), individual cells could be differentiated up to 50µm or 30µm, respectively. Intracortical capillaries were seen up to 250µm (fluorescein) or 150µm (Texas Red), erythrocyte flow (erythrocytes were visualized as negative contrast within the labeled plasma) could be followed up to 150µm (fluorescein) or 100µm (Texas Red) beneath the brain surface, respectively.

Conclusion: The presented model is a promising approach to study the interaction of brain cells and surrounding vessels.

216.7

REMODELING OF PIAL BLOOD VESSELS IN MICE AFTER BIRTH.

D.-B. Wang*, C.M. Rovainen and T.A. Woolsey. Depts. Cell Biology and Neurosurgery, Washington Univ. Sch. Med., St. Louis, MO 63110

The aim of this work is to follow the changes in patterns, diameters, densities, and flow velocities of blood vessels on the developing barrel cortex of postnatal mice. Mice were anesthetized with 1.2mg/gm urethane IP or Metofane. Rhodamine- or FITC-dextran and 1.3 µm YG latex beads were injected intracardially or intravenously. Pial blood vessels were imaged through closed cranial windows with an epifluorescence microscope, GenRad strobe lamp, and ICCD or SIT video cameras. In newborn mice pial capillaries formed a dense plexus over the surface of the cortex; venules were small, irregular and extensively connected with surface capillaries; arterioles had numerous anastomoses. By 7 days intraparenchymal capillary density increased (M.E. Spence); surface density decreased; surface venules and arterioles grew to accommodate the internal microcirculation. In adults few surface capillaries remained; pial venules were large and smooth-walled and drained internal radial venules; pial arterioles were large and lacked collaterals. At all ages the diameters of arterioles at branch points (N.Blocher) followed Murray's cube rule. Velocities were measured with strobe illumination of moving fluorescent beads at 400 Hz. Young (0-7 day old) mice and adults had the same distributions of Vmax in arterioles of the same sizes (6-50 µm), suggesting that peak wall shear rates were similar in developing and mature arterioles. These results show that pial vessels are dramatically remodeled during the growth and differentiation of the cortex. Flow and wall shear stress are hemodynamic factors that may help regulate the enlargement or regression of blood vessels during cortical maturation.

STUDIES ON CEREBRAL O₂ LEVELS, FREE FATTY ACIDS, AND DIACYLGLYCEROL POOLS IN RAT HIPPOCAMPUS AND BRAIN CORTEX DURING SUSTAINED SEIZURES. F. Visioli,¹ L. Rihn,² E. Rodriguez de Turco,³ N. Kreisman, and B. Bazan N.G.¹ LSU Eye Center and Neuroscience Center and ²Department of Physiology, Tulane University School of Medicine, New Orleans, LA 70112.

Cerebral blood flow (CBF) increases during early seizures but the increase progressively attenuates during late seizures, resulting in decreased cortical oxygenation at that time. Since changes in free fatty acids (FFA) and diacylglycerol (DAG) were shown during seizures, we hypothesized a correlation between FFA and DAG levels and cortical O₂. Male Wistar rats were anesthetized with pentobarbital, paralyzed, and ventilated. Seizures were induced by IV injections of pentylenetetrazol and relative changes in cerebral O₂ were monitored. Animals were killed by focused microwaves at different times and brain lipids were extracted and analyzed. There was an increase in both FFA and DG following the third seizure, and arachidonate (20:4) and stearate (18:0) showed the highest increase. Late seizures showed different responses: a rise in cerebral O₂ was associated with a lower release of FFA compared to early seizures, while a decrease in cerebral O₂ was associated with a higher production of FFA. DAG followed the same profile during late seizures, but they also were elevated during both ictal and interictal periods of early seizures. Accumulation of free 18:0 and 20:4, and 18:0- and 20:4-DAG indicates increased activity of phospholipases A₂ and C resulting in a higher turnover of inositol phospholipids. Either an enhanced acyl transferase activity and/or increased CBF decreases FFA during the interictal period, and a relative hypoxia during late seizures is associated with increased production and/or decreased reacylation of FFA and DAG. Supported by AHA 89-902 and NINDS NS23002.

EVIDENCE THAT VASCULAR RECRUITMENT IS NOT IMPORTANT IN HETEROGENEITY OF CEREBRAL BLOOD FLOW (CBF). S.C. Jones, J.L. Williams, and M. Shea. Department of Brain and Vascular Research, Cleveland Clinic Foundation, Cleveland, OH 44195.

Recently, we hypothesized that recruitment of cerebral blood vessels might contribute to temporal cycling (3-10 cycles/min) and spatial heterogeneity of CBF (*Am. J. Physiol.* 257: H473, 1989). In the present study, we injected different fluorescent plasma tracers intravenously at 2 times before decapitation for examination of temporal and spatial relationships of cerebral vascular perfusion. In 7 anesthetized rats, either FITC- or RITC-dextran was injected 45s before decapitation. The other tracer and ¹⁴C-iodoantipyrine were injected as a bolus 10s before decapitation. Immediately after decapitation, the head was immersed in chlorodifluoromethane (-40°C). While frozen, the brain was removed from the skull and sectioned. In each section, vascular fluorescence of both tracers was examined microscopically, and sections were placed on film for quantitative autoradiography and image analysis. CBF was calculated with the indicator fractionation technique. Maps of vascular fluorescence were overlaid on CBF autoradiograms.

In each rat, we examined 73±6 (mean±SE) large vessels (20-60 µm) in cerebral cortex. In every instance, both tracers were present in the lumens of large vessels. Large vessels were distributed equally in cortical areas of high and low blood flow (P and V, respectively; P/V = 1.1±0.2). In each rat, small vessels (≤12 µm) with fluorescence were counted in 25±2 randomly selected locations in cerebral cortex. The number of small vessels for tracer injected 45s and 10s before decapitation was similar (346±48 and 355±42 vessels/mm², respectively), and the selected locations were equally distributed in P and V. Our findings suggest that vascular recruitment is not an important mechanism in temporal cycling or spatial heterogeneity of blood flow in cerebral cortex. (Supported by NIH NS24343)

DEVELOPMENTAL CHANGES OF ENERGY RELATED ENZYMES IN CULTURED ASTROCYTES, OLIGODENDROCYTES, SCHWANN CELLS, AND NEURONS, by R.S. Rust, J.G. Carter*, D. Martin, J.M. Nerbonne, P. Lampe, M.E. Pusateri*, and O.H. Lowry*. Washington Univ. Sch. of Med., St. Louis, MO 63110.

Little information is available concerning developmental and cell-type variation in energy enzymes of nervous tissues. We studied 16 enzymes from 8 metabolic systems in cell culture. All enzymes increased as a function of time in culture (6-18d). Enzyme activity in mature astrocyte cultures (percentage of activity of brain homogenates) ranged from 9% (Glycerol-3PDH) to over 300% (G6PDH). Most astrocytic energy-yielding enzymes showed 25-100% of brain activity, but three NADPH generating dehydrogenases (G6PDH, 6PGDH, and IDH) were more than two-fold enriched. Surprisingly, CPK activity was as high in mature astrocytes as in brain, half as high in oligos, but only 7% or less enriched in Schwann cells, cortical or cervical ganglion (SCG) neurons. Glycogen phosphorylase and PGM were also high in astrocytes, 130% and 90% of brain, respectively. SCG neurons were enriched in PGM and 6PGDH compared to cortical neurons. Oligodendrocytes and Schwann cells show remarkable enzymatic similarity to neurons in culture. Trypsinization affected the expression of LDH (+) and BOAC (-). These data support a role for astrocytes in provision of energy and production of reducing equivalents in brain.

MATURATION OF RAT BRAIN MITOCHONDRIAL CREATINE KINASE. D. Holtzman and T. Wallimann*. Dept of Neurology, Harvard Medical School and The Children's Hospital, Boston, MA 02115; Inst. Cell Biol., ETH Honggerberg, Zurich, Switzerland.

Brain creatine kinase (CK)-catalyzed phosphorus flux from phosphocreatine to ATP was measured in the rat pup using the ³¹P-NMR saturation transfer (ST) technique. The results are compared to an *in vitro* measure of mitochondrial CK (MiCK) activity. As previously described in the mouse brain (Holtzman et al., *Dev Brain Res.* in press), rat brain CK-catalyzed phosphorus flux increases 3-4 fold between 12-18 days of age (p<.05). The MiCK isoform is not found in cerebral cortical tissue at 5 days. This isoform rises sharply between 12-17 days of age. This age period, in which the MiCK activity appears with *in vivo* and *in vitro* studies, is coincident with the appearance of a fraction of brain mitochondria which show contact sites between the inner and outer membranes (Holtzman et al., *J. Neurochem.*, 33:453, 1979). The capacity of cerebral cortical tissue to rapidly increase the rate of oxidative phosphorylation in response to increased energy demand also appears over this narrow age period (Holtzman et al., *J. Neurochem.*, 39: 274, 1979). These simultaneous developments in the physiology of brain ATP metabolism suggest that the MiCK isoform is important in closely coupling the rates of ATP synthesis to changes in ATP utilization in brain.

ION CHANNELS IN RAT MICROVASCULAR ENDOTHELIAL CELLS

D. Janigro, G.A. West*, E.L. Gordon* and H.R. Winn*
Dept. of Neurosurgery, Univ. of Washington, Seattle, WA

Endothelial cells play an obligatory role in mediating the response to endogenous vasodilators such as acetylcholine. However, no electrophysiological data are available on brain microvascular endothelial cells. We have therefore investigated the electrophysiological properties of cultured endothelial cells from intraparenchymal brain microvasculature by using the patch clamp technique. These cells appeared to express a variety of voltage- and receptor operated ion channels. Cell membrane depolarization failed to elicit any inward current even after full blockade of outward currents: the prominent feature was the activation of an outward almost ohmic potassium current. Whole cell and single channel recordings revealed an ATP-activated current inwardly rectifying in the depolarizing range. The ATP-activated channel appears to be permeant to cations, since its reversal potential was near 0 mV in symmetric KCl solutions. We also found evidence of ATP-sensitive potassium channels blocked by micromolar concentrations of glibenclamide. These electrophysiological features may play a role in the regulation of microvascular tone and blood-brain barrier permeability. Supported by NS 21076, AHA 88-WA-111 & AHA 881134

ADVENTITIAL GANGLION CELL-LIKE STRUCTURES IN THE MAJOR CEREBRAL ARTERIES OF THE CAT: AN IMMUNOHISTOCHEMICAL STUDY. T. Okuno¹, T. Itakura¹, K. Nakai¹, N. Komai¹, M. Ueno² and T. J.F. Leg² Dept. Neurol. Surg., Wakayama Med. Col., Wakayama 640, JAPAN¹ and Dept. Pharmacol., S.I.U., Sch. Med., Springfield, IL 62794, U.S.A.²

Adrenergic, cholinergic, GABAergic and peptidergic nerve fibers along cerebral blood vessels were found to originate from several sources such as the superior cervical, ciliary, sphenopalatine, otic and trigeminal ganglia. The present study aimed to elucidate the presence of adventitial ganglion cell-like structures (AGCLS) connected to perivascular nerve fibers in the cerebral pial arteries. Major cerebral arteries of adult cats weighing 2-3 kg were dissected and fixed by immersion in an ice-cold 3:1 mixed solution of Zamboni's and PLP fixative. The materials were processed for single or double labelling avidin-biotin peroxidase complex immunohistochemistry and observed under a light microscope. Two types of clusters of AGCLS immunoreactive (I) to choline acetyltransferase, glutamic acid decarboxylase (GAD) and calcitonin gene-related peptide (CGRP) were observed in the intracranial internal carotid arteries. Smaller ones (25-45 µm in diameter) composed of several ganglion cells were observed mostly along thick adventitial nerve fibers in the distal portion, and larger ones (150-250 µm in diameter) composed of 10-20 clusters of ganglion cells were more proximally located in the internal carotid artery. Some of GAD-I AGCLS were found to overlap with CGRP-I AGCLS. On the other hand, AGCLS in other cerebral pial arteries did not form clusters and were spindle in shape. The density of AGCLS was highest in the proximal portion of the middle cerebral artery. There were no AGCLS immunoreactive to tyrosine hydroxylase or vasoactive intestinal polypeptide in this study. The present results suggest a possibility that AGCLS play some role in the regulation of cerebral blood flow as an origin of either cholinergic, GABAergic or CGRPergic nerve fibers. INHIBITION OF SUCROSE INTAKE BY CHOLECYSTOKININ IN RATS WITH PYLORIC CUFFS. J.E. Cox, Dept. Psychology, Univ. Alabama at Birmingham, Birmingham, AL 35294.

This experiment examined the effectiveness of cholecystokinin octapeptide (CCK-8) in reducing intake of 30% sucrose when gastric emptying was blocked. Prior research has suggested that cholecystokinin satiety is enhanced by (1) concurrent presence of sucrose or glucose within the small intestine and (2) greater gastric retention after CCK-8 administration than after saline; both of these factors should be eliminated by inflation of a pyloric cuff. Female (N=8) and male (N=2) adult Sprague-Dawley rats, with pyloric cuffs inflated or deflated, were allowed 20 min access to 30% sucrose beginning 10 min after intraperitoneal injection of saline or 1, 2, or 4 µg/kg CCK-8. When cuffs were deflated, these doses of CCK-8 reduced intake by 22%, 40%, and 45%, respectively. With cuffs inflated, corresponding reductions were 18%, 32%, and 49%. At each dose, the effect of CCK-8 did not differ significantly between tests with cuffs inflated or deflated (P 's > .05). Thus, neither emptying of sucrose into the duodenum nor differential retention of ingested sucrose was necessary for the full expression of cholecystokinin satiety at the doses tested.

217.3

BLOCKADE OF THE ACTIONS OF ENDOGENOUS CHOLECYSTOKININ (CCK) BY INTRAGASTRIC ADMINISTRATION OF THE TYPE A CCK RECEPTOR ANTAGONIST MK-329 SIGNIFICANTLY INCREASES FOOD INTAKE IN RHESUS MONKEYS. T.H. Moran, P.J. Ameglio*, G.J. Schwartz and P.R. McHugh. Department of Psychiatry, Johns Hopkins University School of Medicine, Baltimore, MD 21205.

In order to determine the role of endogenously released cholecystokinin (CCK) in the control of daily food intake in rhesus monkeys, we examined the ability of various doses of the type A CCK receptor antagonist MK-329 to affect subsequent food intake. Four male rhesus monkeys weighing between 5 and 7 kg were maintained on a feeding schedule of 4 hr per day access to 1 gm food pellets delivered in response to lever pulls on an FR schedule. On test days, thirty minutes prior to the feeding period, monkeys received 5 ml intragastric infusions of various dosages (vehicle, 10, 32, 100 or 320 µg/kg) of MK-329. Subsequent intake was computer monitored so that the time that every pellet was taken was recorded. Administration of MK-329 resulted in dose related increases in food intake over the 4 hr feeding period beginning at 32 µg/kg and reaching a maximum increase of 42 % at the 100 µg/kg dose. Analyses of meal patterns revealed that blockade of type A CCK receptors resulted in significant increases in the size of the first meal (76 to 121 g) as well as decreased satiety ratios (intermeal interval / 1st meal size). These data demonstrate that endogenously released CCK acting at type A CCK receptors plays a significant role in both the patterning and amount of food intake in rhesus monkeys. (Supported by NIH grant DK19302.)

217.2

TRANSIENT, SELECTIVE ATTENUATION OF OLEATE AND CCK-INDUCED SUPPRESSION OF SHAM FEEDING BY INTRA-INTESTINAL CAPSAICIN. C.S. Tamura and R.C. Ritter. Dept. of VCAPP & Pharmacology-Toxicology Program, Washington State University, Pullman, WA 99164.

Previous work from our lab demonstrated that systemic capsacin treatment causes long lasting attenuation of suppression of sham feeding by exogenous CCK and some intestinal nutrients. These effects are also produced by vagotomy, suggesting they are due to vagal sensory damage. Capsaicin, however, causes neuronal degeneration in nonvagal sensory nerves and at multiple central nervous sites. In addition it releases peptides from some enteric neurons. To assess the involvement of intestinal neurons and fibers in nutrient-induced suppression of sham feeding, we studied rats during and subsequent to low dose intraintestinal capsaicin infusion (500µg/ml; 10ml). Intraintestinal infusion of capsaicin suppressed sham feeding by 51.6±2.5%. Capsaicin-infused rats exhibited no signs of systemic capsaicin toxicity and were indistinguishable from controls except with regard to food intake. Intestinal capsaicin did not elevate plasma CCK concentrations. However, MK329, a CCK-A receptor antagonist attenuated capsaicin-induced suppression of sham feeding. Intestinal capsaicin attenuated oleate-induced suppression of sham feeding 48 and 96 hours after intestinal infusion. Reinstatement of oleate-induced suppression of sham feeding occurred by one week post capsaicin. Also, preliminary results indicate that intestinal capsaicin transiently attenuates CCK-8-induced suppression of sham feeding. These results suggest 1) that a capsaicin-sensitive substrate within or near the small intestine participates in suppression of sham feeding by nutrients and exogenous CCK and 2) that stimulation of the substrate may release endogenous, non-endocrine CCK.

217.4

INVOLVEMENT OF CHOLECYSTOKININ IN THE PARABRACHIAL NUCLEUS (PBN) IN THE CONTROL OF FOOD INTAKE: ANATOMICAL AND BEHAVIORAL STUDIES. R.D. Hofbauer*, K.A. Semrad, H.S. Wheat*, J.J. Howard*, C. Cozzari*, B. K. Hartman and P.L. Faris. Dept of Psychiatry, Div. of Neuroscience Research, University of Minnesota, Minneapolis, MN, 55455

Research from our laboratory has been focused on the anatomy and function of CCK in the PBN. Three questions are currently being addressed: (1) Does CCK act at the level of the PBN to suppress food intake? Following recovery from implantation of chronic indwelling, unilateral cannulae terminating in the area of the PBN, each animal received local microinjections of saline, 4.4 and 22 picomoles of sulfated CCK-8 on three separate test days according to a counter-balanced design. Food intake was reduced by CCK-8. Ongoing studies are investigating the effects of receptor-specific CCK antagonists; (2) What is the anatomical source of the CCK endogenous to the PBN which is likely to be involved in food intake control? CCK in the PBN is known to arise from both intrinsic and extrinsic sources predominantly from cells in the nucleus tractus solitarius (NTS; e.g. Herbert and Saper, JCN 293:1990). To localize the precise site within the PBN of the terminus of this projection, we have conducted a series of retrograde pathway tracing/IHC experiments. Discrete injections of fluorogold (10-20 nl) were made into subregions of the PBN containing CCK fibers. Sections through the NTS were then processed using CCK immunohistochemistry (IHC). Results to date suggest that the effectiveness of the direct injections of CCK in suppressing food intake was due to activation of CCK receptors located either postsynaptic to axon terminals arising from non-NTS sources or in another adjacent brain area. These anatomical results are being confirmed using an anterograde tracer; and (3) What is the anatomical relationship between CCK and CGRP cells in the NTS and their projections to the PBN? Double label IHC for simultaneous visualization of CCK and CGRP indicates the existence of two distinct populations of cells containing these neuropeptides. Current studies are investigating the differential localization of afferent terminals from these cells. Supported by NS12311 (BKH); Hamline U. Lund Fnd. (RDH); MH47189 (PLF);

217.5

INTRAVENTRICULAR INSULIN INCREASES SENSITIVITY TO CHOLECYSTOKININ (CCK) IN RATS. C.A. Riedy*, M. Chavez*, D.P. Figlewicz-Lattemann and S. C. Woods. Dept. Psychology, Univ. Washington, Seattle, WA.

Insulin acts at the CNS to reduce food intake and body weight. To determine if insulin might act by increasing sensitivity to satiety agents, we first determined a maximally subthreshold dose of insulin which, when infused via osmotic mini-pumps into the 3rd ventricle (IVT), has no effect on food intake or body weight. Doses from 1 μ g/day and higher reduced food intake and body weight whereas lower doses did not. Naive male Long-Evans rats were given CCK-8 or vehicle ip at doses from 0.25 to 8 μ g/kg. Rats were then infused with IVT insulin (0.5 mU/day) or its vehicle and all received the same doses of CCK-8 again. Rats receiving IVT insulin did not differ in 30-min meal size or body weight over the experiment. Rats receiving insulin were significantly more sensitive to ip CCK-8 than controls. 30-min meal size was reduced at a lower dose (0.5 μ g/kg) in insulin than control (2 μ g/kg) rats and the effect at 8 μ g/kg was significantly enhanced (-72.8% with insulin vs. -30.2% with vehicle). These results demonstrate that insulin, while having no effect by itself, enhances the meal-suppression effects of CCK. This effect may account for some of insulin's ability to reduce body weight.

217.7

SEROSAL GASTRIC APPLICATION OF BENZALKONIUM CHLORIDE ENHANCES THE SATIATING POTENCY OF BOMBESIN. I.C. Kirkham, C. Walsh, J. Gibbs and G.P. Smith. The NY Hospital-Cornell Medical Center, White Plains, NY 10605 USA.

Our previous work suggests that the stomach is an important site mediating the satiety actions of exogenous, peripherally administered bombesin (Kirkham et al., 1991). Bombesin (BN)-like immunoreactivity and BN receptors are located in intrinsic nerves of the stomach. To determine the importance of these neurons to BN satiety, we examined the satiating potency of BN following selective ablation of the gastric myenteric plexus as produced by the cationic surfactant, benzalkonium chloride (BAC), using the technique of Fox et al (1983).

Adult male Sprague-Dawley rats (n=10) were laparotomized and a 0.062% BAC solution was applied to the whole serosal surface of the stomach (by brushing at 5-min intervals over 30 min). At 8, 15 and 28 days after surgery, BN was injected i.p. (5 μ g kg⁻¹), 5 min prior to 30-min feeding tests (40% v/v BioServ). A separate group of non-BAC treated rats (n=6) were similarly tested. Intakes were compared to those after i.p. saline at 7, 14 and 27 days.

In control animals, BN suppressed liquid food intake by 35-40% in each test. By contrast, at day 8, BAC-treated rats were considerably more sensitive to the intake-suppressing effects of the peptide: intake was reduced by approximately 87%. However, BN suppressed intake by 54% and 49% when tested at days 15 and 28, respectively. Thus, the response of BAC-treated rats to exogenous BN normalized over the course of this experiment.

The initial, 2-fold increase in responsiveness to BN in the BAC-treated rats may be evidence of the induction of denervation supersensitivity. The mechanisms underlying this supersensitivity and the apparent recovery of normal sensitivity to BN in these animals remain to be determined.

217.9

INVOLVEMENT OF THE NUCLEUS OF THE SOLITARY TRACT IN MEDIATING THE EFFECTS OF BOMBESIN ON FEEDING: BEHAVIORAL AND ELECTROPHYSIOLOGICAL EVIDENCE. F.W. Flynn. Psychology Dept. and Neuroscience Program, Univ. of Wyoming, Laramie, WY, 82071

The nucleus of the solitary tract (NST) is a possible site that mediates the behavioral effects of bombesin (BN)-like peptides based on the presence of BN-like peptide binding sites and immunoreactive neurons, as well as behavioral data. To further examine the role of the NST, bilateral cannulae were aimed at the rostral (lateral) NST of male rats (n=10). Meal-related parameters and activity were monitored every 1 min for 1 hr following the injection. Rats were administered injections of saline (0.15 M), 0.5 ng, 1.0 ng, and 5.0 ng BN. Injections of 1 ng and higher reliably suppressed food intake and the reduction reflected a reliable decrease in meal size, $p < .05$. Next, to begin to identify the neuronal mechanisms that relate to the behavior-controlling effects of BN, 2 tungsten microelectrodes were attached to a cannula with a removable injector. The assembly was positioned in the NST of Urethane anesthetized rats. Spontaneously active neurons were isolated from the multiunit signal and then BN (5ng in 0.3 μ l) or isotonic saline was delivered through the injector into the NST. BN injections had an excitatory effect on single unit activity and in addition, units that were previously silent became active following the local BN injection. These results indicate that the NST is involved in mediating the effects of BN on food intake and that the behavioral effects of BN involves a change in the excitability of NST neurons. (Supported by RO1 NS-24879)

217.6

CHOLECYSTOKININ-INDUCED SATIETY DEPENDS UPON ACTIVATION OF 5-HT₁ RECEPTORS. B.Poeschla,* J.Gibbs, G.P. Smith, and C.Shamolan. E.W. Bourne Behavioral Research Lab., Cornell Univ. Med. Coll., White Plains, NY 10605.

To investigate the dependence of the satiety action of cholecystokinin upon serotonergic function we examined the effects of systemic pretreatment with 5-HT antagonists of varying selectivity for 5-HT₁, 5-HT₂ and 5-HT₃ receptor subtypes, on the suppression of solid food intake induced by systemic cholecystokinin octapeptide (CCK-8) in 3-h-fasted rats. We similarly tested a 5-HT_{1A} agonist (8-OH-DPAT) that decreases central serotonergic function via a presynaptic autoreceptor mechanism. On average, CCK-8 reduced food intake in the 30 minutes after food presentation by 51 ± 4% at 4 μ g/kg (n=11 experiments) and 73 ± 3% at 6 μ g/kg (n=2 experiments) compared to controls. 8-OH-DPAT (0.06 and 0.12 mg/kg), the 5-HT₁/5-HT₂ antagonist metergoline (0.06 and 0.10 mg/kg), and the 5-HT_{1C/2} antagonist mianserin (5.0 mg/kg) significantly attenuated or blocked CCK-8-induced satiety, while the 5-HT_{1A/1B} antagonist (-) pindolol had no effect. The 5-HT₂ antagonist ketanserin (1.0, 3.0 and 10.0 mg/kg) had no effect on the action of CCK-8, but reversed the anorectic action of the 5-HT₂ agonist DOI. The 5-HT₂ antagonists MDL-72222 (1.0 and 4.0 mg/kg), ICS 205-930 (2.5 and 5.0 mg/kg), and ondansetron (4.0 mg/kg) had no effect on CCK-8 induced satiety. None of the treatments with 5-HT antagonists or 8-OH-DPAT increased food intakes when given alone without CCK-8. These results indicate that the satiety action of exogenous CCK is dependent on activation of 5-HT₁ (possibly 5-HT_{1C}) receptors, probably at a central site. 5-HT₂ and 5-HT₃ receptors are not required.

POTENT BOMBESIN RECEPTOR ANTAGONIST D-PHE⁶-BOMBESIN(6-13)-METHYL-ESTER STIMULATES FOOD INTAKE IN RATS. R.D. Reidelberger, G. Varga*, T. Castonguay, D.H. Coy*. VAMC and Dept. Biomed. Sci., Creighton Univ. Sch. of Med., Omaha, NE 68105; Dept. of Med., Tulane Univ., New Orleans, LA 70112.

Bombesin-like peptides (BN) inhibit feeding in several species when administered peripherally or centrally. We used the potent BN receptor antagonist D-Phe⁶-bombesin(6-13)-methyl-ester (BME), which is highly selective for the pancreatic BN receptor subtype, to examine the role of endogenous BN in control of food intake. Effects of the C-terminal decapeptide of gastrin releasing peptide (GRP-10: .17, .5, 1.5, 4.5 nmol/kg-h iv), GRP-10 (4.5 nmol/kg-h iv) plus BME (400 nmol/kg-h iv), and BME (400 nmol/kg-h iv) alone, on solid food intake were determined in ad libitum fed rats (n=9-11) during the dark period. We have previously shown (Varga et al. *Peptides*, 1991) that in unanesthetized rats, 400 nmol/kg-h of BME completely blocks the maximal pancreatic amylase response to GRP-10 (0.5 nmol/kg-h). The minimal effective dose of GRP-10 for suppressing feeding was 4.5 nmol/kg-h; cumulative 1- and 2-h intakes were significantly decreased by 65 and 38%, respectively. BME completely blocked this effect of GRP-10. BME alone significantly stimulated 3-h cumulative food intake by 43%. **Conclusions:** 1) BME is a potent antagonist of the effects of exogenous GRP-10 on food intake; 2) these results suggest that satiety is mediated in part by bombesin-like peptides acting at peripheral pancreatic-type BN receptors.

217.10

POST-PRANDIAL CHANGES IN BOMBESIN-LIKE IMMUNOREACTIVITY IN THE GASTROINTESTINAL TRACT AND BRAIN

C. Katch¹ and Z. Merali^{1,2}. ¹School of Psychology and ²Department of Pharmacology, University of Ottawa, Ottawa, Ontario, K1N 6N5.

Exogenously administered bombesin (BN) elicits a satiety-like state in experimental animals and in man. BN-like immunoreactivity (BLI) has been demonstrated in discrete regions of the brain and gut of the rat, dog, pig, cat, guinea pig and man. In order to explore whether endogenous BN-like peptide(s) are involved in the mediation/modulation of the satiety response, we monitored changes in endogenous BLI within the brain and/or gut, in response to meal ingestion. Seven pairs of male Sprague-Dawley rats (300-350 g) were food deprived for 12 hr and only one from the pair allowed to eat *ad libitum* for a period of 35 min. The animals were sacrificed, brains and gut segments rapidly dissected, weighed and processed for radioimmunoassay (RIA). Blunt brain dissection was employed to harvest the hypothalamus, cerebellum, medulla, pons, neocortex, striatum, olfactory bulbs, hippocampus, midbrain and pituitary. Gut tissue isolated included the oesophagus, fundus, antrum, duodenum, jejunum, ileum, colon and adrenal glands. RIA was performed using rabbit antibody specific for the C-terminal fragment of bombesin and cross-reacted with gastrin-releasing peptide (GRP₁₈₋₂₇). Within the gut, a significant increase in BLI was detected in the antrum ($p < 0.05$). In the brain, the most notable changes were the post-prandial increases in BLI at the hypothalamus ($p < 0.05$) and hippocampus ($p < 0.05$). This finding is of interest as we have also found the greatest increases in BN-like binding sites at the hippocampus, in a parallel autoradiographic study. These rapid meal-related changes in the levels of BLI and their binding sites lend further support for BN's suggested role as a satiety peptide. (Supported by MRC).

217.11

ANALYSIS OF NEUROPEPTIDE Y-INDUCED FEEDING: DISSOCIATION OF Y_1 AND Y_2 RECEPTOR EFFECTS ON MEAL PATTERNS. J. T. Alexander*, C. B. Dietz*, G. Brennan and S. F. Leibowitz. The Rockefeller Univ., N. Y., N. Y. 10021.

Computer-assisted, minute-to-minute analyses of meal patterns were performed on rats after paraventricular nucleus (PVN) injection of neuropeptide Y (NPY), the selective Y_1 receptor agonist [Leu¹,Pro⁴] NPY, and the selective Y_2 receptor agonist NPY 13-36, at a dose of 100 pmol. Analyses of 12-hour nocturnal feeding patterns after PVN peptide or saline injections, in rats maintained on pure diets of protein (P), carbohydrate (C) and fat (F), revealed: 1) with NPY, a selective increase in C intake (+13.1 Kcal) during the first meal (increase in feeding time, not rate); little change in F intake; and a significant decrease in P intake (-3.2 Kcal) during the second meal. With no subsequent changes apparent, this pattern of effects, increased C and decreased P in the diet, can be seen for up to 9 hours after NPY injection with no change in total meal number; 2) with [Leu¹,Pro⁴] NPY, a selective, although somewhat smaller (+7.7 Kcal), increase in C intake and feeding time (not rate) during the first meal after injection as well as 9 hours later, with little change in P or F intake; and 3) with NPY 13-36, a significant decrease in P intake (-6.7 Kcal), feeding time but not rate, during the first meal as well as after 9 hours; a small transient decline in C intake (-3.2 Kcal) during meal 1; and no change in F intake. These findings indicate that the effect of the complete NPY molecule is on meal size and feeding time, rather than on feeding rate or meal number, and it is characterized by a selective increase in C and a decrease in P intake. The results obtained with the selective receptor agonists suggest that this stimulatory effect on C intake is mediated via Y_1 -type receptors, whereas the suppressive effect on P intake may be mediated via Y_2 -type receptors.

217.12

EATING ELICITED BY PERIFORNICAL HYPOLAMIC NEUROPEPTIDE Y INJECTION IS ABOLISHED IN STREPTOZOTOCIN-DIABETIC RATS. B.G. Stanley, S.M. Yee*, M.J. Rosenthal* & M.W. Gunion*. Dept. of Psychology, Univ. of California, Riverside, CA 92521; GRECC, Sepulveda VAMC, Sepulveda, CA 91343.

To determine whether the powerful eating response elicited by perifornical hypothalamic (PFH) injection of neuropeptide Y (NPY) might be dependent upon circulating insulin, NPY's effectiveness was tested in streptozotocin (STZ)-diabetic rats. Groups of rats were treated with either: 1) STZ (50 mg/kg, i.p.); 2) citric acid vehicle; or 3) STZ, followed by daily insulin injections (Lente, 1 U, s.q.). The induction of diabetes in the STZ group was confirmed by marked hyperglycemia, hypoinsulinemia, hyperphagia, polydipsia and body weight loss. These effects were partially normalized by daily insulin injection. Subjects were subsequently given PFH injections of NPY (78 pM/0.3 μ l) or artificial CSF vehicle, and food intake was measured 1, 2 and 4 hr postinjection. The results confirm that in the control group, PFH injection of NPY elicits eating (e.g., 1.1 g for CSF versus 6.5 g for NPY, one hr postinjection), and demonstrate that this eating response is abolished in diabetic rats (e.g., 2.2 g for CSF versus 2.3 g for NPY), as well as in diabetic rats with partial insulin replacement (e.g., 1.2 g for CSF versus 2.8 g for NPY). These findings suggest that circulating insulin and/or glucose may play a critical role in the eating response elicited by PFH injection of NPY.

CHANGES IN THE HEAD VELOCITY SENSITIVITY OF VESTIBULAR NEURONS DURING VOLUNTARY CANCELLATION OF THE VESTIBULO-OCULAR REFLEX. K. E. Cullen, C. Chen-Huang and R. A. McCrea. Comm. on Neurobiol., Univ. of Chicago, Chicago, Ill. 60637.

In this study, we recorded single unit activity in the vestibular nuclei of alert squirrel monkeys who had been trained to generate smooth pursuit eye movements (SP) and to cancel their vestibulo-ocular reflex (VOR) by fixating a visual target.

Vestibular neurons were first classified on the basis of their behavior during spontaneous eye movements and sinusoidal SP, VOR and VORc. Secondary vestibular neurons were identified by short latency (0.9-1.3ms) activation following stimulation of the ipsilateral vestibular nerve. Two types of ipsilateral head movement sensitive, secondary neurons were recorded: 1) neurons that were only sensitive to head movements (*vns*) and 2) neurons which were also sensitive to contralateral eye movements and that paused during saccades, position-vestibular pause neurons (*PVPs*). Although there was no difference in the head velocity sensitivity of the *vns* during VOR and VORc, the head velocity sensitivity of most *PVPs* decreased during VORc. Two other types of non-secondary neurons were also studied, 1) neurons whose behavior mirrored that of the *PVPs* (*type IIs*) and 2) gaze velocity type neurons whose eye and head movement sensitivities were in the same direction, vestibular smooth pursuit neurons (*spns*). The modulation of both of these types of neurons was greater during sinusoidal VORc than during VOR.

The responses of these four types of neurons to a step in head acceleration (400°/s²) was also studied. The head velocity sensitivity of the *PVPs* was attenuated at short latencies (>40 ms) in trials during which the monkeys had been cancelling their VOR. In contrast the head velocity sensitivity of the *vns* and *type IIs* remained constant. Surprisingly, most *spns* did not respond to the head velocity transient for > 80 ms. Since the *PVPs* are likely 2° VOR neurons, it is likely that direct VOR pathways can mediate non-visual suppression of the VOR. Furthermore it appears that the *spns* specifically generate a smooth pursuit signal which can aid to cancel the VOR during predictable head movements.

218.3

CHANGES IN THE EYE POSITION SENSITIVITY OF BRAINSTEM NEURONS DURING SACCADIC EYE MOVEMENTS, SMOOTH PURSUIT AND THE VESTIBULO-OCULAR REFLEX. R. A. McCrea, K. E. Cullen and C. Chen-Huang. Comm. on Neurobiol., Univ. of Chicago, Chicago, Ill. 60637.

Single unit recordings were obtained from neurons in the vestibular, prepositus and abducens nuclei in alert squirrel monkeys who had been trained to generate sinusoidal smooth pursuit eye movements (SP) and to cancel their vestibulo-ocular reflex (VOR) by fixating a small visual target. The eye position sensitivity (EPS) of a neuron was assessed by measuring the firing rate (FR) during periods of steady fixation between saccades or by measuring the amplitude of the component of a unit's FR that was in phase with SP eye position.

In most of the brainstem neurons recorded, the relationship between FR & eye position was different during smooth pursuit and steady fixation. In the case of abducens motoneurons and prepositus neurons, and secondary vestibular neurons the estimates of EPS were usually similar, although EPS tended to be greater during SP.

The EPS of many type II vestibular neurons and gaze velocity type vestibular neurons was dramatically increased or decreased (> 2X) during SP, compared to steady fixation. In fact, some did not show changes in FR related to eye position during saccades, but were strongly related to eye position during smooth pursuit. The SP EPS of these cells was also studied during eye movements evoked by transient steps in head acceleration during target fixation that typically evoked an eye movement. Their FR was not related to the vestibularly evoked changes in eye position during the first 80 ms after the initiation of the head acceleration step.

These data suggest that the neural substrate for the velocity-position integrator operating during smooth pursuit eye movements is not identical to that which operates during the VOR or saccades.

218.2

SMOOTH EYE MOVEMENTS ELICITED FROM THE MONKEY PERI-ARCULATE AREA: TOPOGRAPHY AND RELATION TO SINGLE UNIT RESPONSES. J.P. Gottlieb, M.G. MacAvoy and C.J. Bruce. Section of Neurobiology, Yale Univ. Sch. of Med., New Haven, CT 06510

We studied the peri-arcuate representation of smooth-pursuit eye movement (SPEM) using microstimulation and single unit recording in three adult unanesthetized rhesus monkeys. Smooth eye movements (SEM) were elicited at 67 sites in 6 hemispheres, commonly with currents of 100 μ A or less. Penetrations in which SEM were elicited entered the cortex in a small area (at most 6 mm²) slightly lateral to the spur (or bend) of the arcuate sulcus. Individual sites were localized in the fundus or in the posterior bank of the arcuate sulcus. Sites located in the fundus had lower thresholds (e.g., 25-50 μ A) and yielded predominantly movements directed ipsilaterally. In contrast, sites in the posterior arcuate bank had higher thresholds (e.g., 75-100 μ A) and yielded a larger proportion of movements directed contralaterally and downward.

Single unit activity was recorded at 47 of the stimulation sites. Neuronal responses during SPEM were excitatory at 31 sites and inhibitory at 2 sites. Neurons at the remaining locations responded in relation to the angle of gaze (2 sites), to foveal visual stimulation (3 sites) or did not respond to the tasks we used (9 sites). The tracking direction correlated with the best neuronal response was determined for 22 of the neurons with excitatory SPEM-related activity. There was a high correlation between the neurons' best tracking direction and the direction of the elicited SEM at their sites (R=0.93), suggesting that this activity helps elicit SPEM under physiological conditions. SPEM-related neurons often have responses to visual motion presented during fixation (Gottlieb et al., *Soc. Neurosci. Abstr.*, 15:1203, 1989). Neurons with excitatory SPEM-related responses at SEM sites had ratios of visual motion to pursuit responses between 0.0-2.6 (median=0.4; n=10). We found no relationship between these ratios and the velocity or threshold of the elicited SEM at the site. The activity of SPEM-related neurons at SEM sites is thus not obligatorily related to pursuit movements, but can be interpreted in several ways by downstream oculomotor structures. DISRUPTION OF VISUAL FIXATION FOLLOWING INJECTION OF GABAERGIC DRUGS INTO THE FIXATION ZONE OF THE PRIMATE SUPERIOR COLLICULUS. D. P. Munoz and R. H. Wurtz. Laboratory of Sensorimotor Research, National Eye Institute, Bethesda, MD 20892.

Cells in the rostral pole of the superior colliculus (SC) are tonically active whenever an animal fixates a target of interest and pause immediately prior to the initiation of saccadic eye movements (Munoz et al., 1990, *Neurosci. Abstr.*, 16: 1084; Munoz and Guitton, 1989, *Rev. Neurol.*, 145: 567-579). This brain region may therefore play an important role in the control of visual fixation. To test this hypothesis, we altered the activity of cells in the rostral pole of the SC by injecting micro quantities of muscimol (a GABA agonist) or bicuculline (a GABA antagonist) while the alert monkey performed fixation and saccade tasks. Unilateral injections of muscimol (1-4 μ g) led to: 1) an increase in the frequency of saccadic eye movements; 2) loss of the ability to suppress the initiation of a saccade following the sudden appearance of a visual stimulus in the peripheral visual field; 3) higher speed and shorter duration saccades directed toward visual stimuli; 4) decreased latency to initiate visually guided saccades; and 5) increased frequency of express saccades (latency < 100ms). Unilateral injection of bicuculline (0.25 μ g) led to: 1) slower visually guided saccades with longer durations; and 2) increased latency to initiate voluntary saccades. Thus, muscimol-induced deactivation of cells in the fixation zone of the rostral SC made it harder for the monkey to suppress the initiation of saccades, while activation with bicuculline made it harder to initiate saccades.

These results are consistent with the hypothesis that activation of fixation-related cells in the rostral SC is necessary to maintain visual fixation, while a pause in the discharge of these cells is a prerequisite for the initiation of a saccade. Furthermore, the occurrence of express saccades may depend critically upon decreased activity of collicular fixation cells.

218.5

ATTENTION-RELATED RESPONSES IN THE SUPERIOR COLLICULUS OF THE MACAQUE. R. Gattass and R. Desimone. Lab. of Neuropsychology, NIMH, Bethesda, MD 20892.

Previous studies have reported that superficial layer cells in the superior colliculus (SC) give an enhanced response to a stimulus when it is the target for an eye movement. However, in a peripheral detection paradigm, no such enhancement was found when a stimulus was attended, in the absence of an eye movement (Mohler and Wurtz, '76). Because behavioral studies have found attentional deficits in the absence of eye movements following SC lesions or deactivation, we investigated this issue in a paradigm that is very sensitive to effects of attention. In a matching-to-sample paradigm, a sample was presented at one location, followed by a brief test stimulus at that (relevant) location and a distractor at another (irrelevant) location. While maintaining fixation, the monkey indicated whether the sample and test stimulus matched, ignoring the distractor. The relevant and irrelevant locations were switched from trial to trial. SC cells in the superficial layers tended to give enhanced responses when the attended test stimulus was inside the receptive field compared to when the (physically identical) distractor was inside the field. Thus, responses of SC cells appear to be modulated by directed attention, even in absence of eye movements, probably reflecting the properties of cortical cells projecting to the SC.

OCULOMOTOR SHORT-LEAD BURST NEURON POPULATIONS GENERATE EYE VELOCITY VECTORS IN LISTING'S COORDINATES. J.D. Crawford and T. Vilis. Depts. of Physiology and Ophthalmology, University of Western Ontario, London, Canada, N6A 5C1.

3-D eye velocity vectors and positions were recorded in 4 alert monkeys while the midbrain riMLF burst region was explored with single unit recording, microstimulation, and injection of the GABA agonist muscimol. This confirmed that torsional-vertical quick phase components are generated by 4 riMLF neuron populations (Vilis et al. 1989), but these populations also had a small influence on horizontal rotation. The directions of rotation generated by the 4 populations were: clockwise-up-left and clockwise-down-right in the right riMLF and counterclockwise-up-right and counterclockwise-down-left in the left riMLF. Thus, various combinations of activity in these four populations could potentially produce eye rotations about any axis.

During riMLF inactivation the vertical axes for horizontal saccades, presumably generated by the intact pontine PPRF, lost their normal torsional tilts, suggesting that each population encodes a component of velocity rather than rate of position change (Tweed and Vilis 1990). The remaining vertical axis was abnormally confined to Listing's plane. During unilateral riMLF stimulation intermingled vertical and horizontal components cancelled, and the eye rotated torsionally about an axis aligned with the primary gaze direction orthogonal to Listing's plane. These stimulation and inactivation axes did not align with the anatomical coordinates of the semicircular canals or eye muscles. This suggests that although burst neuron populations are not organized into torsional, vertical and horizontal pairs, they individually produce eye velocity vectors that are symmetrical about Listing's coordinates.

OCULOMOTOR INTERNUCLEAR NEURONS: THEIR ROLE IN HORIZONTAL EYE MOVEMENTS R.A. Clendaniel*, L.E. Mays and P.D.R. Gamlin. Departments of Psychology and Physiological Optics; University of Alabama at Birmingham; Birmingham, AL 35294

Antidromically identified oculomotor internuclear neurons (OINs) that project to the contralateral abducens nucleus were recorded in monkeys (*Macaca mulatta*) trained to make saccadic, smooth pursuit, and vergence eye movements. The identified OINs have all been located in or near the oculomotor nucleus, and the cells in the vicinity of the OINs display behavior which is consistent with that of medial rectus motoneurons. The OINs also have firing characteristics similar to the putative medial rectus motoneurons. OINs increase their activity for adduction of the ipsilateral eye, and they also increase their firing rate for convergent eye movements. The conjugate gain (k_c) of these cells ranged from 2.29 to 8.35 spikes/sec/deg (mean 4.83); similarly the vergence gain (k_v) of these cells ranged from 1.13 to 8.51 spikes/sec/deg (mean 4.46). These values are similar to those of putative medial rectus motoneurons.

A series of stimulation and reversible inactivation studies have been used to assess the effect OINs exert on the contralateral abducens neurons. Microstimulation in the region of identified OINs produces a small abducting twitch in the contralateral eye. Injections of 0.1 μ l of 10% lidocaine HCl result in hypometric abducting saccades and hypermetric adducting saccades for the eye contralateral to the injection site. These findings are consistent with the hypothesis that OINs provide an excitatory input to the contralateral abducens nucleus. Thus, OINs appear to send a signal to the abducens nucleus which is appropriate for conjugate eye movements, but inappropriate for disjunctive movements. (Supported by EYO3463 and P30 EYO3039)

VELOCITY AXES OF EYE ROTATION DURING VESTIBULAR AND OPTOKINETIC STIMULATION IN THREE DIMENSIONS IN THE MONKEY. V. Henn, N. Lida*, D. Straumann, Th. Haslwanter*, B.J.M. Hess. Neurology Dept., University Hospital, CH-8091 Zürich, Switzerland.

Chronically prepared rhesus monkeys were seated in the center of a three-axes turntable surrounded by an optokinetic sphere. The turntable or the sphere were given velocity steps about an earth-vertical axis. Animal position was systematically shifted in 15 deg steps from upright to supine or side down. Three-dimensional eye position was measured with an implanted magnetic search coil. Angular eye velocity was found to be collinear with the stimulation axis for horizontal, vertical or torsional nystagmus. However, for oblique directions, systematic deviations occurred, with axes tilted away from the torsional towards the horizontal or vertical directions. In oblique directions, dynamics of OKN or VOR (gain and time constants) were similar for the different directional components. Neither the direction nor the dynamics of nystagmus could be accurately predicted from vector additions of horizontal or vertical and torsional components. This suggests that the velocity storage mechanism works in three dimensions with anisotropic directional characteristics.

A MODEL OF SMOOTH PURSUIT PERFORMANCE ILLUSTRATES THE RELATIONSHIP BETWEEN GAIN, CUS AMPLITUDE, AND CUS RATE. L. Friedman, J.A. Jesberger*, and H.V. Meltzer. Lab. of Biological Psychiatry, Case Western Reserve University, Cleveland, OH 44106.

During smooth pursuit tracking, if gain is less than 1.0, position error accumulates. Catch-up saccades (CUS) correct for this position error. Two general strategies are possible: either to make many small CUS or to make few large CUS. The relationship between gain (G), CUS amplitude (A) and CUS rate (R) can be expressed as follows:

$$G = 1 - (AR/Vt)$$

where Vt = target velocity. The fit of this model was tested in 45 normal controls and 39 schizophrenics. Eye movements were recorded with infrared oculography, and digitized for offline analysis. Target velocity was 5°/sec. The fit of the model to empirical data, as assessed graphically and with non-linear regression (NLR) techniques, was excellent. For example, the model R^2 for predicting G from A and R was 0.87 for all subjects combined. The model was linearized [$\ln(1-G) = \ln(A) + \ln(R) - \ln(Vt)$] and tested with linear regression techniques. The model fit was highly significant ($F=203$, $df=1,82$, $p < 0.00005$). When NLR was allowed to fit the constant (Vt) the optimal value was 4.85 (conf. lim=4.65-5.05). The model also applies when gain > 1.0, when backup-up saccades (-A) correct.

218.10

SMOOTH PURSUIT AND OPTOKINETIC DEFICITS FOLLOWING CHEMICAL LESIONS TO THE CEREBELLAR UVULA S.J. Heinen and E.L. Keller. Smith-Kettlewell Eye Res. Inst., San Francisco CA, and Dept. of Elect. Eng. and Comp. Sci., Univ. of California, Berkeley, CA 95720.

The uvula (lobule IX of the cerebellar vermis) receives indirect input from the superior temporal sulcus and pretectum via the dorsolateral pontine nucleus, areas all involved in visual motion processing. Although previous studies had implicated the uvula in visual alterations of the velocity storage mechanism of optokinetic eye movements, we reported last year that some uvular cells respond during pursuit eye movements as well. The deficits produced by chemical lesions placed in this structure now provide further evidence for a role of the uvula in the execution of pursuit. Three monkeys were trained to smoothly track a small ramping target spot (randomly selected from 10, 20 or 40 deg/sec) and to suppress optokinetic following movements by fixating a stationary spot during the sweep of a large-field, textured background (moving over the same range of velocities). Lidocaine and ibotenic acid were used to temporarily disrupt neural activity and to destroy Purkinje cells respectively. We found that initial eye acceleration to the ramping spot in some cases was increased by 200% due to infusion of these agents. This increase was sometimes accompanied by an inability of similar magnitude to suppress optokinetic following movements. Lesions placed in other cortical, brainstem and cerebellar areas have all been reported to produce markedly lower pursuit responses, but the results of uvular lesions are unique in producing accentuated pursuit. This effect is probably a reflection of the removal of inhibitory Purkinje cell activity either directly or indirectly from the pursuit pathway.

EYE POSITION DEPENDENCY OF UNITS IN THE DORSOMEDIAL FRONTAL CORTEX. K. M. Lee and E. J. Tehovnik, Department of Brain and Cognitive Sciences, M.I.T., Cambridge, MA 02139

It has been discovered by electrical stimulation that the dorsomedial frontal cortex (DMFC) contains a systematic representation of orbital eye position. Not only do evoked contraversive eye movements go to a specific orbital position but also the position is mapped in the antero-posterior dimension of this area of the brain.

Electrical stimulation, however, cannot localize neuronal elements for this representation, since collateral fibers from cells in other regions of the brain or fibers of passage are likely stimulated. Therefore, in this study we used single-unit recording to find out if this map of eye position is indeed represented by the activity of units in the DMFC. Using a prolonged fixation paradigm where behaving monkeys fixate a target for up to 2000 msec, we found units whose firing frequency show eye position dependency. Most of these cells are more active when the animal is fixating at contralateral targets in head-centered coordinates than ipsilateral targets. This eye position dependency of firing is most prominent for up to several hundred msec after the animal has acquired the target. Furthermore, units in the posterior sites within the DMFC have their optimum eye position closer to the midline than those in the anterior sites do, which is consistent with the electrical stimulation result.

The units found in this study along with the electrical stimulation results suggest that the DMFC is an area of the brain where visual target position in head-centered coordinates is computed for visuomotor transformation in making eye movements.

PEPTIDES: BIOSYNTHESIS, METABOLISM AND BIOCHEMICAL CHARACTERIZATION V

219.1

NOVEL STRUCTURES IN THE GONADOTROPIN-RELEASING HORMONE FAMILY. D.A. Lovejoy*, S. Ngamvongchon*, N.M. Sherwood Biology Dept., University of Victoria, Victoria, B.C. Canada, V8W 2Y2. W.H. Fischer*, A.G. Craig*, J.E. Rivier* The Clayton Foundation Laboratories for Peptide Biology, The Salk Institute, La Jolla CA 92037.

The structural characterization of two novel forms of gonadotropin-releasing hormone (GnRH) is reported here. These structures expand the GnRH family of neuropeptides to seven members. In addition, confirmation of His⁵, Trp⁷, Tyr⁸-GnRH (chicken GnRH-II) by sequence analysis in cartilaginous fish, bony fish, and reptiles indicates that this neuropeptide is present in all major vertebrate groups and has been conserved for over 400 million years.

Each form of GnRH was purified by reverse-phase HPLC from extracts prepared from spiny dogfish (*Squalus acanthias*), Thai catfish (*Clarias macrocephalus*) and American alligator (*Alligator mississippiensis*) brains. The sequence was determined by automated Edman degradation after cleavage of the pGlu residue using bovine pyroglutaminyl aminopeptidase. Confirmation of the sequence and presence of the amidated Gly¹⁰ residue was established by mass spectral analysis.

Sequence comparisons of the six forms of GnRH present in the brains of jawed vertebrates suggest the molecule evolved along two lines. One lineage is characterized by Trp⁷ and hydrophobic⁸ residues whereas the other possesses Leu⁷ and hydrophilic⁸ residues. We suggest that this structural dichotomy in GnRH may be the basis of functional differences.

219.3

USE OF A RETROVIRAL VECTOR FOR EXPRESSING ANTISENSE RNA OF PROOPIOMELANOCORTIN IN AT-20 CELL LINE. S. Scampinato, M. Canossa* and S. Ferri*. Dept. of Pharmacology, University of Bologna, 40126 Bologna, Italy.

Recent studies have demonstrated that gene expression in mammalian cells can be suppressed by nucleic acid sequences complementary to endogenous transcripts. This approach is based on the assumption that these "antisense" sequences can hybridize to primary RNA transcripts and prevent normal gene expression. However, one of the major problems emerged concerns the use of techniques that allow an efficient transfer of antisense constructs. Recently, recombinant retroviruses have been employed as vectors to stably transfer genes into a variety of cells. Therefore, with the aim to investigate their ability to produce antisense RNAs of neuropeptide genes we have examined their possible expression in cell lines. In this study we have evaluated the expression of an antisense RNA sequence of 940 bp, complementary to mouse proopiomelanocortin (POMC) mRNA, in a murine neuroendocrine cell line (AtT-20) that highly expresses this gene. A cDNA of mouse POMC (940 bp) was ligated in "antisense" orientation to the promoter in a retroviral vector (pJDOL⁻) and transfected into a cell line of helper cells (ψ cre). Mature virions, collected in the medium, were titrated and used to infect AtT-20 cells. We found that infected cells express POMC antisense RNA by a sensitive solution assay. The values obtained from six different plates were between 5 and 20 pg/ug total RNA. Therefore, retroviral vectors may represent an useful tool to introduce and express antisense sequences to neuropeptide genes in cell lines.

219.2

GASTRIN-RELEASING PEPTIDE (GRP) IS NOT THE MAMMALIAN HOMOLOG OF BOMBESIN. S.R. Nagalla*, B.W. Gibson*², J.R. Reeve Jr.*³, and E.R. Spindel¹. ¹Div of Neurosci, Oregon Rgl Primate Res Ctr, Beaverton, OR 97006, ²Dept of Pharmaceutical Chemistry, UCSF, San Francisco, CA 94143, ³Ctr for Ulcer Res and Education, UCLA, Los Angeles, CA 90073.

Bombesin-like peptides are potent growth factors, paracrine hormones and neurotransmitters. Based on amino acid homology, the 27-amino acid gastrin-releasing peptide (GRP) and its C-terminal decapeptide (GRP-10) since their discovery have been considered the mammalian homologs of amphibian bombesin. HPLC analysis of extracts of frog (*Bombina orientalis*) stomach revealed the presence of two peaks of bombesin-like immunoreactivity, consistent in size with GRP and GRP-10. The amino acid sequence of the smaller immunoreactive peak was determined, in part, by liquid secondary ion mass-spectrometry. Mixed oligonucleotides probes complementary to this sequence were used to screen a *B. orientalis* stomach cDNA library. Sequence analysis of hybridizing clones revealed a 970 bp cDNA encoding an amphibian GRP. Homology between frog and mammalian GRPs was high and frog GRP-10 is identical to rat GRP-10. Northern blot analysis showed high levels of GRP mRNA present in frog stomach and brain. Northern blot and *in situ* hybridization also showed the presence of frog bombesin mRNA in stomach and brain but with a different distribution than that of the frog GRP mRNA. Thus in *B. orientalis*, GRP and bombesin are separate entities encoded by distinct mRNAs with different patterns of expression. Analysis of nucleic acid and amino acid homologies suggests that bombesin and GRP diverged prior to the vertebrate radiation. This evidence raises the possibility that mammals may also have an as yet undiscovered gene encoding a "true" mammalian bombesin distinct from the well characterized gene for GRP.

219.4

EXPRESSION OF A HUMAN PROENKEPHALIN β-GALACTOSIDASE FUSION GENE IN TRANSGENIC MICE. David Borsook, Haim Rosen*, Karl Herrup, Holly Dressler*, Michael Comb, and Steven Hyman, Molecular Neurobiology Laboratory, Massachusetts General Hospital, Harvard Medical School, Boston MA 02114

Peptide gene expression is thought to occur via cis regulatory elements contained within the gene. However for genes with complex patterns of expression such as the human proenkephalin gene, it has proved difficult to map such elements by mutagenesis and transfection into tissue cells, perhaps because no available cell line can adequately model the variety of neurons in which the gene is expressed. Using fusions expressing the easily visualized histochemical marker β-galactosidase, we are in the process of mapping regulatory elements required for cell type specific expression of the proenkephalin gene. We present data of the expression of a proenkephalin β-galactosidase fusion gene in various brain regions of the mouse. The initial transgenic mice were made by injecting a construction containing 3 kilobases (kb) of human proenkephalin 5' flanking sequence fused to the *E. coli lac-z* transcription unit and 1 kb of proenkephalin 3' flanking sequence including sequences required for polyadenylation. The transgenic animals appeared morphologically and behaviorally normal. To determine expression of the fusion gene, brains from animals were stained for β-galactosidase activity using the chromogenic substrate X-gal, and then counterstained with neutral red. In the founder lines produced, levels of expression were seen in most brain regions corresponding with the expected distribution of the endogenous gene. However, no expression was seen in the basal ganglia. Furthermore, correct expression was seen in the reproductive organs of male (testis and epididymus) and female (ovary, oviduct and uterus) with high levels of expression were seen in pregnant or superovulated animals as well as at the utero-placental junction in pregnant females. Examination of other somatic tissue was negative for β-galactosidase staining with X-Gal. Examination of further constructs to explain these discrepancies and to map tissue specific regulatory elements is in progress.

219.5

DETECTION OF NEUROPEPTIDE HETERONUCLEAR RNA'S BY IN SITU HYBRIDIZATION USING SINGLE STRANDED DNA PROBES PRODUCED BY ASYMMETRIC PCR. P.J. Brooks, S.P. Kleopoulos*, C.V. Mobbs, and D.W. Pfaff The Rockefeller University, New York, NY

In situ hybridization using intron derived probes is a powerful method to examine changes in gene expression at the single cell level. Because of the low abundance of heteronuclear (hn) RNA, previous authors (Fremeau and Roberts, 1986, Herman et al, Soc. Neurosci. Abst. 526.5, 1990) have used single stranded RNA probes for such studies. We have explored the use of single stranded, internally labelled DNA probes produced by a modified asymmetric PCR procedure to detect low abundance hnRNAs.

Small (200-300 bp) regions of introns from the preproenkephalin (PPE) and oxytocin (OXY) genes are amplified from plasmids or genomic DNA by conventional PCR. Probe labelling is carried out by 50 cycles of linear amplification of the antisense strand of the PCR product in the presence of the C-terminal PCR primer and labelled dNTPs, producing internally labelled copies of the antisense DNA strand. Typically, between 40-85% of the radiolabel (we have used either H3, 125I, or 32P) is incorporated into DNA using these conditions. Probe specificity is confirmed by Southern blot hybridization. Our initial results indicate that these probes retain all of the features of single stranded RNA probes (high sensitivity, choice of specific activity) but are easier to produce and use. Using *in situ* hybridization with high specific activity 32P labelled probes, both PPE and OXY hn RNAs are detectable with appropriate regional distributions after overnight exposure to X-ray film. With H3 labelled probes, cell nuclear localization of OXY hn RNA can be detected in magnocellular neurons of the PVN and SON after 3 weeks exposure to nuclear emulsion. We are presently using this approach to study the regulation of both mRNAs under different experimental conditions.

IDENTIFICATION AND CHARACTERIZATION OF ENKEPHALIN-DEGRADING AMINOPEPTIDASE AND NEUTRAL ENDOPEPTIDASE IN APLYSIA CALIFORNICA. W. Bawab*, P. Crine* and L. DesGroseillers, Department of biochemistry, University of Montreal, Montreal, Canada, H3C 3J7.

We are investigating the role of enzymes in the inactivation of neuropeptides in *Aplysia*. Using [³H]leu-enkephalin (YGGFL) as substrate, we have identified two different neuropeptide degrading enzymes in kidney, heart, ovotestis, central nervous tissues and hemolymph. The most abundant enzyme in these preparations cleaves leu-enkephalin at the Tyr¹-Gly² bond, as determined by HPLC analysis of metabolites. In the kidney, this aminopeptidase activity was detected both in membrane-bound and soluble fractions. The Km value of this aminopeptidase in kidney plasma membranes for the leu-enkephalin substrate is 2.4 μM. Using specific enzyme inhibitors, we showed that this enzyme is a metalloprotease, with a profile of inhibition similar to the one of mammalian aminopeptidase N: amastatin was the most potent inhibitor, while bacitracin, bestatin and puromycin were about 100 to 1000 times less potent. However, the aminopeptidase activity was unaffected by thiol-, serine-, and acid protease inhibitors, as well as by neutral endopeptidase and angiotensin converting enzyme inhibitors. Inhibition of aminopeptidase activity by amastatin allows us to detect a second metabolite, Tyr-Gly-Gly, suggesting that an endopeptidase cleaves the Gly²-Phe³ bond of Leu-enkephalin. The presence of this metabolite was abolished by neutral endopeptidase (NEP) inhibitors HACBO-Gly, thiorphan and phosphoramidon, and by the divalent cation chelating agent 1-10 phenanthroline, suggesting that this enzyme is similar to the mammalian NEP. The presence of both the aminopeptidase and the NEP suggests that these enzymes may contribute to the extracellular degradation of *Aplysia* neuropeptides.

GENE EXPRESSION OF PROHORMONE CONVERTASES IN THE CNS AND PERIPHERY. R. Day, M.K.-H. Schafer, S.J. Watson, M. Chrétien, N.G. Seidah*, Clinical Research Institute of Montreal, Montréal, Québec, Canada, H2W 1R7 and Mental Health Research Institute, University of Michigan, Ann Arbor, MI, USA, 48109.

Recent advances in the molecular characterization of processing enzymes have demonstrated a subtilisin-like enzyme family in mammalian tissues to be responsible for the endoproteolytic processing of inactive precursors to biologically active peptides, via selective cleavage of basic residues. The neuroendocrine tissue distribution of two of these enzymes, PC1 and PC2, has been demonstrated (Seidah et al, Mol Endo, 5, 111, 1991). The cellular expression of Furin, a structurally related enzyme carrying a putative transmembrane domain, (like the yeast enzyme Kex2), is unknown in rat brain. The present study sets 3 objectives: (1) defining the cellular expression pattern of Furin, PC1 and PC2 in the rat CNS and select endocrine tissues, (2) identifying neuropeptide precursors as specific candidates for processing, (3) determination of the codistribution of PC1, PC2 and Furin with the other enzymes known to be involved in processing, i.e., carboxypeptidase E (CPE) and peptidyl-glycine α-mono-oxygenase (PAM). *In situ* hybridization studies using ³⁵S-labelled cRNA probes were carried out on frozen rat brain, pituitary and adrenal tissue sections. In the brain PC2 is more abundant and more widely distributed than PC1. PC1 and PC2 were preferentially expressed in neural and endocrine tissues, and were always coexpressed with CPE, however, coexpression with PAM was not always observed. For example, PC1, PC2, CPE and PAM are coexpressed in the supraoptic and paraventricular nuclei, but only PC1, PC2 and CPE are expressed in the cerebellum. Furin's distribution was ubiquitous, however, surprisingly high levels of Furin mRNA were expressed by non-neuronal brain tissues such as ventricular ependyma and choroid plexus. CPE was coexpressed in these cells with Furin. Other examples showing the distinct nature of PC1, PC2 and Furin will be shown. We conclude that Furin is a processing enzyme important to all cells and is most likely unique to the constitutive secretory pathway, whereas PC1 and PC2 are expressed in cells with a regulated secretory pathway.

219.6

PROCESSING AND SORTING OF THE ELH PROHORMONE IN AIT-20 CELLS P. A. Paganetti*, L. J. Jung* and R. H. Scheller, Howard Hughes Medical Institute, Stanford University, Stanford CA 94305

In the bag cells of *Aplysia*, proteolytic processing and sorting of the egg-laying hormone (ELH) precursor is highly regulated. Following the first endoproteolytic cleavage at a unique tetrabasic site, the two intermediates are packaged in distinct sets of vesicles. Within the vesicles further processing results in multiple physiologically active products. These two vesicle classes are then sorted to distinct targets in the cells. Atrial gland cells express the peptide A precursor which is 88% homologous at the nucleotide level with the ELH precursor.

Transfection studies suggest that similar processing and sorting events occur in the bag cell neurons and pituitary cells (Jung and Scheller, Science 251: 1330-35, 1991). Pulse/chase experiments indicate that the first cleavage of the ELH precursor in AIT-20 transformants occurs at the tetrabasic site in the late Golgi, similar to the bag cells. Mature ELH is colocalized in DCVs with endogenously expressed ACTH. In contrast to bag cells, no staining is observed with antibodies directed against the NH₂-fragment, possibly indicating the involvement of a degradative pathway. All these results suggest that much of the information required for correct processing and sorting of ELH precursor is contained within its structure.

To further study the details of these sorting events, we have constructed deletions of the ELH cDNA at the tetrabasic site. We are currently analyzing the processing of mutant ELH and peptide A precursors in AIT-20 transformants.

REGULATION OF PEPTIDYLGLYCINE α-AMIDATING MONOOXYGENASE (PAM) ACTIVITY BY DIETARY COPPER. G.P. Mueller, T.A. Ford* and M.L. Failla*, Dept. of Physiology, Uniformed Services University of the Health Sciences, Bethesda, MD 20814 and Vitamin and Mineral Nutr. Lab., USDA, Beltsville, MD 20705.

PAM (EC1.14.17.3) is the copper (Cu) dependent enzyme catalyzing the two-step formation of bioactive α-amidated peptides from their inactive glycine-extended precursors. We previously observed that Cu deficiency dramatically decreased body Cu stores yet failed to alter concentrations of amidated peptides in brain, pituitary or intestine. Here we examined the effects of dietary Cu deficiency on PAM activity in male and female rats. Sex difference and the effects of Cu deficiency on PAM activity (assayed *in vitro* under optimal conditions) were most clearly evident in the anterior pituitary (AP). In control animals, PAM activity in the AP of males was nearly double that observed in females (2.8 ± 0.2 vs 1.8 ± 0.1 pmol/μg protein/hr). Severe Cu deficiency (depressed growth, enlarged hearts, low tissue Cu) induced by feeding low Cu diet (0.7 μg/gm) to dams beginning at 13 days gestation and weaning pups to the same diet, increased PAM activity in the AP nearly 2-fold in both sexes at 7 weeks of age. Similar though less dramatic differences in PAM activity were observed in atrium and hypothalamus. High levels of PAM activity in serum were not affected by Cu status or gender. These findings suggest the expression of PAM is influenced by gender and increased to maintain peptide amidation in Cu deficient states.

219.10

REGULATION OF STRIATAL CCK mRNA BY GLUTAMATE, X.Z. Ding¹, M.Olasmaa¹, E.Costa¹ and I.Mocchetti², ¹F.G.I.N. and ²Dept of Anatomy and Cell Biology, Georgetown Univ. Washington, DC20007

Stimulation of dopaminergic (DA) D₂ but not D₁ receptor increases striatal CCK mRNA content. In the striatum, D₂ receptors are located on dendrites and cell bodies but also on the glutamatergic axon terminals of corticostriatal afferent neurons. Therefore, the release of glutamate could be modulated upon D₂ receptor stimulation, and this transmitter could in turn regulate striatal CCK mRNA. This hypothesis was tested by measuring changes in the striatal CCK mRNA elicited by specific glutamatergic and DA receptor agonists and antagonists. The activation of NMDA receptor by a single injection of NMDA (10nmol, i.c.v.) elicited a 70% increase in striatal CCK mRNA content. A single injection of MK-801 (1mg/kg, i.p.), a selective non-competitive NMDA antagonist, produced a 30% decrease in striatal CCK mRNA content 8 hours after the injection. This decrease was time and dose-dependent. A 50% decrease was observed after 7 daily MK-801 injections. To better characterize the interaction between glutamatergic and D₂ receptors in the regulation of CCK mRNA, MK-801 was injected concomitantly with bntropine, an indirect DA receptor agonist which increases DA content in synaptic clefts by blocking DA reuptake, or BHT-920, a specific D₂ agonist. Both DA agonists induce a two fold increase in CCK mRNA, which is partially reversed by MK-801. Hence the regulation of striatal CCK mRNA content might be modulated by both DA and NMDA receptors. This hypothesis is supported by the finding that the lesion of DA striatal afferent by 6-OHDA, which per se decreases striatal CCK mRNA, prevents the increase of CCK mRNA induced by NMDA.

219.11

METRAZOLE (MTZ) SEQUENTIALLY ACTIVATES C-FOS, PROENKEPHALIN (Penk) AND TYROSINE HYDROXYLASE (TH) GENE EXPRESSION IN RAT ADRENAL. Y.S. Zhu, S.O. Franklin*, T. Huang* and C.E. Inturrisi, Dept. of Pharmacology, Cornell Univ. Med. College, New York, NY 10021.

It has been postulated that the immediate-early genes, e.g., c-fos, may function as "third messengers", which act on late-effector genes to modify gene expression. In the present report, we have studied the effects of MTZ on c-fos, preproenkephalin (Ppenk) and TH mRNA levels in rat adrenal gland. One hour after MTZ, adrenal c-fos mRNA levels increased about 5-7 fold and return to control by 6 hr. At 1 hr after MTZ, adrenal Ppenk mRNA was increased 2-fold and TH mRNA doubled. In contrast to c-fos mRNA, both Ppenk (5-fold) and TH (2-3 fold) mRNA were significantly increased at 6 hrs. These MTZ-induced increases in c-fos, Ppenk and TH mRNAs were significantly reduced (by 41%, 76% and 37%, respectively) after hypophysectomy (hypox). ACTH treatment of hypox rats (for 7 days) failed to restore the MTZ-induced c-fos mRNA levels, while Ppenk and TH mRNA levels were partially restored in these animals. Furthermore, ACTH treatment completely blocked the MTZ-induced increase in c-fos mRNA but not the increase in Ppenk and TH mRNA in control (sham) rats. These results suggest (1) there is a linkage between neuronal excitation by MTZ and c-fos, Penk and TH gene expression in the adrenal; (2) glucocorticoid may, at least in part, modulate this system; (3) ACTH treatment can differentially affect expression of these genes. (Supported in part by DA01457.)

DIFFERENTIAL EFFECTS OF TYPICAL AND ATYPICAL NEUROLEPTICS ON NEUROTENSIN GENE TRANSCRIPTION. K.M. Merchant, P.R. Dobner and D.M. Dorsa. GRECC, VA Medical Ctr; Depts. of Medicine, Pharmacol., and Psychiatry, Univ. of Washington, Seattle, WA 98195; Dept. Mol. Genetics & Microbiol., Univ. of Mass., Worcester, MA 01655.

The present study characterized and compared the effects of a classical (haloperidol) and an atypical (clozapine) neuroleptic on the expression of neurotensin/neuromedin N (NT/N) mRNA in rat neostriatum using *in situ* hybridization analysis and quantitative solution hybridization. NT/N mRNA levels in the dorsolateral striatum were rapidly (within 30 min) and reversibly increased by a single dose of haloperidol (1 mg/kg, i.p.) but not clozapine (20 mg/kg, i.p.). Maximal induction following haloperidol occurred at 7 hr after drug administration, at which time NT/N mRNA levels were an order of magnitude higher than basal levels. Hybridization with an intron-derived probe showed that the increases in mature NT/N mRNA levels were preceded by an increase in intron-containing NT/N gene transcripts located in neuronal nuclei of the striatum. These data strongly indicate that haloperidol increases the transcription of NT/N gene and/or stability of its primary transcripts in the dorsolateral striatum. Unlike the effects in the caudate-putamen, both clozapine and haloperidol induced a small but significant increase (40-45%) in NT/N expression in the shaft region of the nucleus accumbens. These results suggest a functional diversity in striatal NT neurons. (Supported by Washington Institute for Mental Illness and NS 20311)

RESPONSE-SPECIFIC LEARNING IN APLYSIA: FREQUENCY-DEPENDENT EFFECTS OF DIRECTIONAL SIPHON MOTOR NEURONS. C. Hickie and E.T. Walters. Dept. of Physiology & Cell Biol., Univ. of Texas Medical School, Houston, TX 77225.

Six identified siphon motor neurons account for the flaring response of the siphon to tail stimulation (4 LFSB cells) and constricting response to head stimulation (RDS and LDS1). Each motor neuron is activated at high frequency by stimuli used in conditioning, and the LFSB cells show a prolonged increase in background firing after conditioning. We examined the effects of motor neuron firing on siphon response plasticity and found: (1) Tonic background firing facilitates siphon movements produced by high frequency test bursts (1 sec, 12-30 Hz, normalized to motional threshold) in each motor neuron (cf. Frost et al. J. Neurobiol. 19:297, 1988); (2) In the absence of background activity, movements produced by motor neuron test bursts were facilitated by a preceding test burst, but the LFSB cells showed greater and longer-lasting interburst facilitation than LDS1, or RDS which showed the least facilitation; (3) Following a single 2 sec, 40 Hz conditioning burst, LFSB neurons could produce enhanced movements for at least 10 min. These results suggest that patterns of motor neuron firing may contribute to both the induction and expression of response plasticity. We are now examining response plasticity induced by re-driving motor neurons with activity patterns recorded during conditioning.

220.3

NEURONS IN THE J CLUSTER OF THE CEREBRAL GANGLION PRODUCE MODULATORY EFFECTS ON SENSORY NEURONS IN THE PLEURAL GANGLIA OF APLYSIA. J.L. Raymond and J.H. Byrne. Dept. of Neurobiology and Anatomy, Univ. of Texas Medical School, Houston, TX 77225.

Changes in the biophysical and biochemical properties of sensory neurons (SNs) in the pleural ganglia of *Aplysia* have been correlated with behavioral plasticity of the tail-withdrawal reflex. Here we report that neurons in the J cluster of the cerebral ganglion produce effects in the SNs that mimic changes that have been associated with modulation of the reflex. We refer to these cells as J_m neurons.

Brief stimulation of J_m neurons produced hyperpolarizing and depolarizing responses in SNs in the pleural ganglion. In some preparations, a slow EPSP was produced in a SN by stimulation of a J_m cell. These EPSPs were associated with an increase in the excitability of the SNs. The effect on excitability generally persisted for less than 2 min, but outlasted the EPSP. In other preparations, IPSPs or mixed (E-I or I-E) responses were observed. Often a single action potential in a J_m neuron was sufficient to produce a PSP in a SN, and, in one case, a discrete fast IPSP was observed, indicating that the connections may be monosynaptic.

The J cluster contains mechanoafferent neurons innervating the head and neck regions of the animal (Rosen et al., 1979). The properties of the J_m neurons resembled those of the mechanoafferent neurons in the J cluster and in other ganglia. Specifically, they were not spontaneously active, had little spontaneous input, and exhibited rapid accommodation. Moreover, the efficiency of their connections to the pleural SNs depressed rapidly. The J_m cells generally received fast and slow excitatory input from cerebral nerves C1-C3 and from the cerebral-buccal connective and received inhibitory input from pedal nerves P7-P9.

These data suggest that the J_m neurons may be elements of a modulatory pathway involved in the behavioral plasticity of the tail-withdrawal reflex. In particular, they may contribute to modulation of the reflex produced by tactile stimulation of anterior parts of the animal.

220.2

LONG-TERM HYPEREXCITABILITY OF CEREBRAL MECHANOSENSORY NEURONS IN APLYSIA INDUCED BY AXON INJURY. A.L. Clatworthy and E.T. Walters. Dept. of Physiology & Cell Biol., Univ. of Texas Medical School, Houston, TX 77225.

Walters, Alizadeh and Castro (submitted) found that crush of pleural (VC) sensory neuron axons, under conditions in which synaptic transmission and spike activity were severely reduced, induced a delayed but persistent decrease in sensory spike threshold, accommodation and afterhyperpolarization, and an increase in spike duration, synaptic transmission and afterdischarge. To test the generality of these effects we crushed all cerebral (and pedal) nerves on one side of the animal under ice-cold MgCl₂ anesthesia. Six to 8 days later, cerebral (J,K) sensory neurons on the crushed side (52 pairs, 9 animals) displayed a decrease in spike threshold (0.7 vs 1.3 mA, p<.05), accommodation (5.3 vs 1.8 spikes in 1 sec, p<.05), and an increase in spike duration (2.9 vs 2.5 ms, p<.05). No differences in sensory neuron excitability were observed among neurons with uncrushed axons in these animals, sham-operated animals and naive animals, suggesting that axonal injury is required to induce the plasticity. Similar results were obtained for 25 pairs of pleural sensory neurons from 5 animals, although the magnitude and number of alterations tended to be greater in the pleural cells. We are currently examining whether any synaptic or morphological changes are induced in cerebral cells by axonal injury.

EFFECTS OF HABITUATION ON NEURONAL ACTIVITY IN APLYSIA ABDOMINAL GANGLION DURING THE GILL-WITHDRAWAL REFLEX. Chun X. Falk, Jian-young Wu, Larry B. Cohen. Dept. of Physiology, Yale U. Sch. of Med., New Haven, CT 06510.

Previous experiments indicated that habituation results in a decrease in the number of active neurons responding to the siphon touch. In the present experiments we made optical recordings during the 1st, 4th, 10th, 20th, 30th and 40th habituation trials and during control trials before habituation and after a 20 min recovery period. Using control trials, neurons were grouped into those that were activated by the touch, those that were inhibited by the touch and those with activity apparently unrelated to the stimulus. During habituation, the activity of almost all the neurons in the activated group decreased, but at different rates. Some neurons stopped responding to the stimulus by the 4th habituation trial, while others in this group continue to be excited in the 40th trial. Some of the inhibited neurons were less inhibited after habituation. In about half of the preparations there was increased activity among the cells that did not respond to touch. Thus, when the responses to habituating stimuli are examined in many neurons, there is substantial diversity. Supported by NIH grant #NS08437.

220.5

COMPARISON OF NEURONAL ACTIVITY IN THE APLYSTIA ABDOMINAL GANGLION DURING RESPIRATORY PUMPING AND THE GILL WITHDRAWAL REFLEX. Jian-young Wu, Larry B. Cohen and Chun X. Falk. Dept. of Physiology, Yale Univ. School of Medicine, New Haven, CT.

We used optical recording to monitor the neuronal activity during spontaneous gill contractions (respiratory pumping) and during the gill-withdrawal reflex elicited by a light touch to the siphon skin. We estimate that about 300 neurons are active during spontaneous contractions and that approximately 70% of these neurons are also active during the gill-withdrawal reflex. Many neurons had different activity patterns during spontaneous contractions and the gill-withdrawal reflex. In addition, when the gill-withdrawal reflex was elicited just after a spontaneous contraction, the evoked neuronal activity was altered in comparison with the activity elicited between spontaneous contractions. In different preparations we have seen both dramatic suppression or enhancement of activity. These results showed that complex neuronal events with some shared neurons are associated with both kinds of gill withdrawal behaviors. Thus further efforts to distinguish the neurons which generate or coordinate behaviors with gill movements remain interesting. Supported by NIH grant NS08437.

220.7

PAIRING-SPECIFIC TRANSFORMATION OF GABA-MEDIATED SYNAPTIC INTERACTION IN HERMISSENDA. D.L. Alkon, J.V. Sanchez-Andres, C. Collin. Neural System Section, NINDS, NIH, Bethesda MD 20892.

Previous experiments have demonstrated that GABA is the likely transmitter released by presynaptic hair cells into post-synaptic type B photoreceptors. Other observations have shown that a single pairing of depolarization of the B-cell with GABA iontophoresis produces long-lasting (>10 min) depolarization and increased resistance of the B-cell (Matzel and Alkon, Brain Res. 1991). Here we examine the ionic and pharmacological basis of these GABA-mediated responses. Current-clamp and two microelectrode voltage-clamp experiments demonstrated that 1) GABA-A receptors on the B-cell, in response to hair cell release of GABA open Cl⁻ channels, 2) GABA-B receptors briefly open Na⁺ channels and open K⁺ channels over a prolonged time course. If GABA applied iontophoretically or released by depolarization-induced firing of the presynaptic hair cell is paired with a depolarizing light stimulus to the B-cell, the GABA response thereafter remains transformed (for hours) as follows: 1) the GABA-A and GABA-B induced hyperpolarization are markedly reduced, 2) GABA-B mediated reduction of K⁺ current and depolarization now predominate in the B-cell response. The net effect of pairing is to transform a predominantly hyperpolarizing to a predominantly depolarizing GABA-mediated synaptic effect received by the postsynaptic B-cell from the presynaptic hair cell. This is a new type of synaptic function which seems ideally suited for associative learning.

220.9

IDENTIFYING THE NEURONS INVOLVED IN *C. ELEGANS* MALE MATING BEHAVIOR. K. Liu and P. Sternberg*, HHMI, Division of Biology, Caltech, Pasadena, CA.

Mating behavior in *C. elegans* is a male specific behavior and mediated at least in part by the 79 male-specific neurons, most of which reside in a set of copulatory structures which comprise the male tail. As this system is not amenable to electrophysiology, we have set out to examine the role of these neurons via the successfully used technique of cell ablation. And since cells comprising a common copulatory structure are often generated by a common precursor, we have chosen to follow a lineal approach. That is, male specific post embryonic blast cells which give rise to male copulatory structures and/or neurons are ablated and the resulting phenotype (mating defect), if any, is determined by observation. Given a defect, the progeny of that blast cell are then systematically ablated until the neuron(s) responsible for the phenotype are identified.

Using this approach, we have identified the copulatory structures underlying each of the previously reported steps in male mating behavior:

structure ablated	resulting defect
V rays	response to hermaphrodite
T rays	turning around hermaphrodite
hook	location of vulva
spicules	insertion of spicules into vulva

We are currently trying to identify the individual neurons which control these behaviors. For example, using this approach we have determined that the hook sensory neurons HOA and HOB are required for vulval location while the closely related interneuron PVZ is not. Similarly, the sensory/motor neurons SPCL/SPCR are required for spicule insertion while the sensory neurons SPVL/SPVR are not.

220.6

Dissecting the Memory for Sensitization in *Tritonia*. G. D. Brown and A. O. D. Willows. Friday Harbor Laboratories, Friday Harbor, WA 98250.

Previous experience with noxious chemical stimuli produces sensitization of the *Tritonia* escape swim. Sensitization is manifest in behavioral changes such as a decrease in the latency to swimming, an increase in the strength of swim movements, and an increase in the number of cycles per swim episode. Because the neural circuitry which underlies escape swimming is comparatively well understood and the memory for sensitization can be traced to these circuit elements, *Tritonia* can be used to study how a memory codes for a complex set of behavioral changes.

Using a head-attached preparation we have shown that the stimuli which produce sensitization in *Tritonia* also produce an increase in the firing rate of dorsal swim interneurons (DSI's). Double labeling experiments in which DSI's were labeled with an intracellular dye and tagged 5-HT antibodies support earlier evidence that DSI's contain serotonin, a neurotransmitter thought to be important for sensitization in other animals. Increasing the rate of DSI firing by intracellular current injection in reduced preparations results in a strengthening of functional connections made by the interneuron C2 onto its followers. [Brown and Getting, unpublished] We have found that increasing DSI activity also caused an increase in the spontaneous firing of putative motor neurons in the swim neural circuit. Neural correlates of the latency change occurring as a result of sensitization have not been found in the isolated brain preparation indicating that peripheral sensory systems may be necessary for sensitization of latency.

In a tail-attached preparation, stimulating a DSI before application of a swim stimulus causes changes in the swim pattern comparable to those seen in behavioral experiments, thus increased DSI activity is a sufficient condition for sensitization.

220.8

ROLE OF IDENTIFIED SEROTONERGIC NEURONS IN GENERATING ROTATIONAL BEHAVIOR IN *HELISOMA* EMBRYOS. T.J. Diefenbach*, N.K. Koehncke* and J.L. Goldberg. Dept. of Zoology, Univ. of Alberta, Edmonton, Alta., Canada T6G 2E9.

Embryonic neurons C1 differentiate early in *Helisoma* embryogenesis and have been implicated as regulators of neural development. Since these neurons first express serotonin at a stage corresponding to the onset of cilia-driven rotational behavior, we tested the hypothesis that neuron C1 also plays a role in the generation of this embryonic behavior. Embryonic neurons C1 were localized in live embryos using the fluorescent serotonin analogue 5,7-dihydroxytryptamine and sequential fluorescence-DIC microscopy. Intracellular recordings revealed spontaneous action potential activity in these neurons as early as stage E20. Together with data on serotonin immunoreactivity, functional serotonin uptake and neurite projections, these electrophysiological data suggest that embryonic neuron C1 releases serotonin. Using time-lapse video microscopy, embryonic rotational behavior was characterized in terms of its behavioral components, developmental changes and responses to exogenous serotonin. Rotation consisted of a slow tonic component that was interrupted by brief periods of accelerated rotation (surges). Quantitative analysis of rotation rate and surge frequency revealed that both of these parameters were maximal at stage E25. Application of serotonin induced a dose-dependent, reversible increase in rotation rate that was blocked by the serotonin antagonist, mianserin. Furthermore, application of mianserin alone abolished the expression of rotational surges, leaving the slow tonic component intact. These results support the hypothesis that embryonic neuron C1 not only regulates neural development, but also acts as a cilio-excitatory motor neuron which generates rotational surges.

Supported by NSERC of Canada.

MALE MATING FACTORS MEDIATE BLOCKING OF SEX PHEROMONE PRODUCTION AND SEXUAL RECEPTIVITY IN FEMALES OF A MOTH, *HELI COVERPA ZEA*. I.G. Kingan¹, A.K. Raina^{1*}, W. Bodnar^{2*} and D.E. Hunt^{2*}. 1, USDA ARS, Insect Neurobiology and Hormone Lab, BARC-East, Bldg. 225, Beltsville, MD 20705; 2, Dept. of Chemistry, Univ. of Virginia, Charlottesville, VA 22901.

The production of sex pheromone in the females of several moths has been shown to be under the positive control of a neuropeptide, termed pheromone biosynthesis activating neuropeptide (PBAN; Raina et al., Science, 244:796, 1989). The production of pheromone is followed by the "calling" behavior associated with the release of pheromone, attraction of a male moth, and mating. Similarly, mating in several moths has been shown to lead to a precipitous decline in pheromone production and sexual receptivity for varying periods of time. This decline could be associated with mechanical stimulation or with chemical factors transferred during mating. In earlier studies, we showed that the decline in pheromone after mating of the corn earworm moth *Helicoverpa zea* (formerly *Heliothis*) is likely to be associated with soluble factors from the male accessory gland, sites of production of the seminal secretions, that are transferred during mating. In order to understand the mechanisms by which male-derived factors cause depletion of sex pheromone and loss of sexual receptivity in females, we have purified and begun to characterize two, apparently related accessory gland factors, that when injected into females cause a depletion of PBAN-evoked pheromone accumulation. The factors are basic peptides, each is ca. 6600 Daltons in molecular weight (determined by electrospray tandem mass spectrometry) and contains a disulfide linkage. We refer to these peptides as pheromonostatic factors (PSFs). Partially purified extracts of accessory glands, containing the PSFs, have been tested in a "mating assay" and shown to render the females "unattractive" as well as to block receptivity to the sexual advances of pheromone-primed males.

EVIDENCE FOR A PROPOSED COMPUTATIONAL PROPERTY OF REMOTE DENDRITIC INHIBITION OBTAINED DURING INHIBITORY CONTROL OF CRAYFISH ESCAPE BEHAVIOR. E.T. Vu and F.B. Krasne. Neuroscience Program, Department of Psychology, and Brain Research Institute, University of California, Los Angeles, CA 90024.

The functional consequences of placing inhibition remotely from the axon spike initiation zone have been a subject of increasing interest. While studying inhibitory control of the lateral giant command neurons for crayfish tail flip escape behavior, we have come to appreciate a novel and generally important reason for such inhibition: When inhibition must interact with excitation in a "competitive" fashion, with each process being able to override the other by an increase in strength (as is the case for many processing tasks in the nervous system), then inhibition should be distal. In contrast, when computational requirements dictate that inhibition should be absolute, inhibitory synapses should be placed proximally.

Biological evidence for this notion was obtained. In crayfish, a form of inhibition that is active when lateral giant escape must be absolutely prevented was shown to produce an entirely proximal shunt of excitation to the command neurons for this behavior, while a different form of inhibition used to down-modulate but not eliminate this behavior was found to produce an exclusively distal shunt in the same neurons.

Supported by USPHS grant NS08108 (FK) and a Predoctoral NSF Fellowship (EV).

POSTEMBRYONIC GROWTH OF THE CRAYFISH ESCAPE CIRCUIT. D.H. Edwards, R.A. Fricke, L. Barnett, and P.R. Nagappan.

Department of Biology, Georgia State University, Atlanta, GA 30303.

Both 1 cm juvenile and 10 cm adult crayfish employ the tailflip response triggered by the lateral giant (LG) interneuron to escape from attacks directed at the abdomen. The response is reliable in small crayfish, whereas larger crayfish habituate to repeated stimuli. LG in both animals receives monosynaptic inputs from primary afferents and disynaptic inputs from mechanosensory interneurons through depression-prone chemical synapses from the same afferents. LG is reliably excited by the monosynaptic electrical input in juvenile crayfish, whereas that input is insufficient in adults, and so defers to the later, depression-prone input. We asked why the relative strengths of these inputs change during growth.

The soma is twice as large in 10 cm adults than in 1 cm juveniles, while the major dendrite's length and diameter both increase by 3 times. The axon grows 10-fold in length and 5-fold in diameter. Although the membrane time constant increases from 8.6 ms to 21 ms, the input resistance falls from 742 k-ohms to 167 k-ohms at the initial axon segment. Simultaneous recordings in adult LG neurons show that whereas both mono- and disynaptic PSPs have similar amplitudes in the dendrite, the phasic monosynaptic PSP is much smaller in the initial axon segment. In juvenile crayfish, the monosynaptic PSP is usually larger than the disynaptic PSP in the initial axon segment. Electrical models of large and small LGs show that LG becomes a low-pass filter for synaptic inputs during postembryonic growth. Supported by NIH Research Grant NS26457.

NEUROGLIA AND MYELIN III

CHARACTERIZATION OF IMMORTALIZED SCHWANN CELL LINES EXPRESSING MYELIN PROTEINS. J.A. Small*, K. Toda*, E. Yavin, and R.H. Quarles*. Laboratory of Molecular and Cellular Neurobiology, NINDS, NIH, Bethesda, MD 20892.

Cell culture systems for studying the expression of myelin proteins are complex. Primary cultures of rat Schwann cells do not express myelin components in the absence of axonal contact. Our laboratory has recently described a Schwann cell line, immortalized by continuous passage, that expresses myelin-associated glycoprotein (MAG) at levels found in adult sciatic nerve (Goda, et al., 1991, J. Neurochem., 56: 1354-1361). The MAG expressed in these cells had biochemical properties similar to MAG in sciatic nerve.

This cell line and similarly derived ones have been further characterized. Myelin-specific gene expression was determined at the RNA and protein levels. Cell lines S16 and S42 were found to express MAG and PO at both the RNA and protein level. The level of MAG was greater than or equal to that found in sciatic nerve, while the level of PO was much lower. Myelin basic protein (MBP) or its RNA could not be detected. Proteolipid protein (PLP) RNA was found, but no protein was detected. In addition, glial fibrillary acidic protein (GFAP), normally expressed in nonmyelinating Schwann cells, was expressed in these cell lines. Cell line S16Y does not express myelin proteins or GFAP.

The cell lines have been tested for their transfection efficiency. Plasmids containing the chloramphenicol acetyl transferase (CAT) gene driven by a variety of strong eukaryotic promoters were used. Transfection efficiency was high for all three cell lines in transient expression assays. Cells could also be stably transfected with the bacterial neo gene, using Geneticin (G418) eukaryotic antibiotic selection. Transfected cell colonies maintained the myelin expression pattern of the parental cell line.

These cell lines will be very useful tools for studying regulation of gene expression of myelin proteins.

PURINE NUCLEOSIDES AND NUCLEOTIDES STIMULATE ASTROCYTE PROLIFERATION *IN VITRO* AND ASTROGLIOSIS *IN VIVO*.

M.P. Rathbone, S. Hindley*, J.W. Gysbers*, B. Gabel*. Depts. Biomed. Sci. and Medicine, McMaster Univ. Health Sci. Center, Hamilton, Ont., Canada L8N 3Z5

Extracellular adenosine (Ado), guanosine (Guo), ATP and GTP stimulate the proliferation of astrocytes, microglia and brain capillary endothelial cells *in vitro*^{1,2,3}. The mitogenic effects of Ado and Guo are mediated through adenosine A₂ receptors and increased intracellular cAMP¹, whereas ATP and GTP activate purinergic P₂_U receptors and increase phosphoinositide metabolism. Hypoxic, "sick" and dying cells release high concentrations of soluble nucleosides. Do these stimulate the reactive proliferation of microglia, astrocytes and blood vessels *in vivo*? Ten μ L of Guo, Ado, (both 1 mM), ATP and GTP (both 500 μ M) were each infused into one cerebral hemisphere of rat brains over 2h. Simultaneously the contralateral hemisphere was infused with saline (10 μ L). The purines, but not control injections, stimulated marked reactive astrogliosis within 48 h. Astroglial reaction was also present in sub-pial and perivascular regions characteristic of Scherer's secondary structures observed around malignant astrocytomas. Microglia, which proliferate early and secrete IL-1, may augment the purinergic effects. Purines released in brain injury or neuronal death may stimulate glial response to injury. ¹Rathbone, M.P. et al., (1990) Soc. Neurosci. Abs. 16:1000; ²Norenberg, M.D. et al., (1990) Soc. Neurosci. DIFFERENTIATED IMMORTAL CELL LINES DERIVED FROM RAT BRAIN ASTROCYTES. C.F. Deschepper¹, E.H. Radany², V. Bigornia¹, K.R. Zaks¹, J.M. Bishop², F. Besnard³ and M. Brenner³. ¹Dept of Physiology and ²J.W. Hooper Foundation, U.C. San Francisco, CA 94143 and ³Laboratory of Molecular Biology, NINDS, Bethesda MD 20892

A common strategy to immortalize cells from rodent brains has been to infect primary cell cultures derived from embryonic animals with retroviral constructs. Apparently, this approach was mostly successful in immortalizing the more proliferative and less differentiated cells. As an alternative approach, we constructed a plasmid where a 2 kb fragment from the 5' region of the human GFAP gene was placed in front of oncogenic sequences from the SV40 early region. Using calcium-phosphate precipitation, this plasmid was cotransfected with a plasmid conferring resistance to G418 into astrocyte primary cultures derived from neonatal rats. After drug selection, 16 individual clones were isolated and maintained in culture. At least 6 of these cell lines expressed GFAP at the time of their 10th passage in culture, as determined by ICC and Western blot analysis. Pulse-chase analyses determined that these cells synthesized and secreted some of the proteins normally secreted by type I astrocytes, including transferrin, angiotensinogen and α_2 -macroglobulin. These results indicate that this approach may be useful to generate immortal astroglial cell lines with the phenotypic characteristics of mature astrocytes. Supported in part by HL29714 and HL 38774.

ASTROCYTE CELL CYCLING *IN VITRO*: G1/S TRANSITION REQUIRES MULTIPLE ISOPRENOIDS. T.J. Langan and M.C. Slater, Dept. of Neurology, SUNY Sch. Med., Buffalo NY 14222

Astroglial cultures were used to compare the relationships to cell cycling of dolichol-linked glycoprotein synthesis, and of availability of mevalonate, the precursor of cholesterol, dolichol and other isoprenoid lipids. With shift-up to 10% serum (time 0) after 48 h of serum depletion, the proportion of cells in S phase (bromodeoxyuridine immunofluorescence) remained under 15% for 12 h, then increased by 20 h to 72 \pm 10%; DNA synthetic rates (thymidine incorporation) increased 5-fold. S phase transition was prevented by addition at 10-12 h of tunicamycin, an inhibitor of transfer of saccharide moieties to dolichol. Mevinolin, an inhibitor of mevalonate biosynthesis, also blocked cycle progression at this time, but had no effect on net glycoprotein synthesis. Removal of mevinolin after a 24 h exposure delayed S phase until 48 h, following recovery of sterol synthesis, even though kinetics of glycoprotein synthesis were unaffected. Tunicamycin removal after 24 h spared sterol synthesis, but caused delay of S phase until 72 h, following recovery of glycoprotein synthesis. The G1/S transition occurring after hydroxyurea release was unaffected by mevinolin, tunicamycin or cycloheximide. Thus, in these cultured developing astroglia, mevalonate and its isoprenoid derivatives have at least two cell cycle-specific roles: dolichol-linked glycoprotein synthesis is required before the G1/S transition, at a time when a distinct mevalonate requirement is also apparent.

221.5

A COMPARISON OF OLIGODENDROCYTE AND SCHWANN CELL PROTEINS AND THE FUNCTIONAL CIS-ACTING ELEMENTS WHICH THEY BIND IN THE MBP PROMOTER REGION. L.G. Wrabetz*, S. Shumas*, M.L. Feltri*, J. Grinspan, D. Bozyczko*, F.A. McMorris, D. Pleasure, and J. Kamholz. Department of Neurology, University of Pennsylvania School of Medicine, and The Wistar Institute, Philadelphia, PA 19104.

During myelination, both oligodendrocytes(OL) and Schwann cells(SC) coordinately express a set of myelin-specific proteins including myelin basic protein(MBP). Others have shown that in development, MBP gene expression is regulated at the level of initiation of transcription. We have previously shown that the start site of MBP transcription is identical in OL and SC, suggesting that the MBP promoter region is the same in both cell types. MBP promoter-CAT fusion transient transfections demonstrate that the 150 base pair region upstream of the MBP gene contains sequences which are sufficient to promote CAT expression in a tissue-specific and orientation-dependent manner in both cell types. However, the 5' extent of cis-acting elements necessary for this expression differs in OL and SC, and therefore, the cis-acting regions necessary for MBP gene expression in OL and SC are also different.

We now extend these observations using enhancer trap experiments to examine the function of oligonucleotides spanning the OL and SC cis-acting regions. These experiments confirm that a different cis-acting element within this 150 base pair region enhances basal promoter activity in OL as compared to SC. Secondly, band-shift assays of OL and SC nuclear extracts with the oligonucleotides containing one or the other of these cis-acting elements demonstrate that each oligonucleotide binds proteins from both OL and SC. However, the oligonucleotide/protein complexes differ in mobility from OL as compared to SC. These results suggest that both the cis-acting elements and the trans-acting factors which bind them during initiation of MBP gene transcription differ in OL and SC.

Regulation of Myelin Gene Expression in C6 Cells. R. C. Wiggins and G. W. Konat.* Dept. Anatomy, West Virginia University School of Medicine, Morgantown, WV 26506.

A model system of rat glioma C6 cells grown in defined medium was used to investigate the mechanisms involved in the regulation of myelin proteolipid protein (PLP) and myelin associated glycoprotein (MAG) genes. Treatment of cells with cAMP-stimulating agents or ascorbic acid upregulated both the PLP and MAG genes, although the timing and extent differed. Retinoic acid upregulated the expression of PLP gene, but downregulated the expression of MAG; whereas, SV40 T antigen downregulated PLP and upregulated MAG. The dissimilarity of PLP and MAG gene responses to these agents indicates the existence of different regulatory mechanisms for the activation of these genes. Thus, the expression of myelin genes and their modulation in C6 cells extends the applicability of these cells as a convenient *in vitro* model system for study of the elementary mechanisms of myelin gene regulation. This research was supported by PHS grants NS13799 and DA04072 and the WVU Medical Corp and NIH BRG 2S07RR05433.

INSULIN-LIKE GROWTH FACTOR I GENE EXPRESSION IS INDUCED IN ASTROCYTES DURING DEMYELINATION. S. Komoly*, H.deF. Webster, and C.A. Bondy*. NINDS and NICHD, NIH, Bethesda, MD 20892.

We have studied the effects of experimental demyelination and remyelination on IGF-I and IGF-I receptor expression in the mouse brain using *in situ* hybridization and immunocytochemistry. Weanling male mice were fed diets containing 0.5% cuprizone for 8 weeks. In this model, myelin loss is restricted to specific white matter areas and remyelination occurs following cessation of treatment. In control animals IGF-I mRNA was undetectable in white matter, but in treated mice high levels of both IGF-I mRNA and peptide were expressed by astrocytes in the areas affected by myelinolysis. During recovery, IGF-I expression decreased rapidly as oligodendroglial expression of myelin-related genes increased. During early recovery there also was a transient increase in IGF receptor mRNA and peptide immunostaining of oligodendroglia-like cells in the affected areas. This highly specific pattern of IGF-I induction in astrocytes localized in demyelinating areas supports a physiological role for IGF-I in the regulation oligodendrocyte and myelin metabolism *in vivo*.

221.6

EFFECT OF PDGF TREATMENT ON GALACTOCEREBROSIDE AND PLP MRNA EXPRESSION IN CULTURES OF RAT OLIGODENDROGLIA. J.B. Grinspan, L.G. Wrabetz* and J. Kamholz. Dept. of Neurology, University of Pennsylvania, Philadelphia, PA 19104.

We have previously demonstrated that platelet derived growth factor (PDGF) causes proliferation of O2A cells and accumulation of galactocerebroside (GalC) positive oligodendroglia (OL) in cultures of rat cerebral white matter (CWM) (Grinspan et al, J.Neurosci. 10: 1866, 1990). In order to extend these studies, we have compared the expression of PLP mRNA with that of GalC and A2B5 in these rat CWM cultures in the presence and absence of PDGF using *in situ* hybridization and immunohistochemistry. At 3, 7 and 14 days after plating in the absence of PDGF, the number of GalC positive OL in these cultures are approximately the same as the number of cells expressing PLP transcripts. Grain counts of PLP expressing cells demonstrate that each cell contains less than 10 grains. The number of A2B5 and GalC positive cells increases in cultures grown for either 3 or 10 days in the presence of PDGF, although the number of GalC positive cells is still approximately the same as that of the PLP expressing cells at both times. Grain counts of the PLP expressing cells demonstrate, however, that most cells contain many more than 10 grains after 3 days of PDGF treatment and more than 50 grains after 10 days in PDGF. These studies show that GalC expression, as detected by surface labelling, appears at the same time as that of PLP mRNA expression, as detected by *in situ* hybridization, suggesting that OL maturation and PLP gene expression occurs contemporaneously *in vitro*. Furthermore, OL that mature in the presence of PDGF accumulate large amounts of PLP transcripts per cell. These studies, taken together with our previous data, suggest that PDGF promotes the survival of GalC positive OL in these cultures, and that subsequent OL maturation is associated with the accumulation of myelin transcripts.

221.8

CHARACTERIZATION OF A MAJOR ASTROCYTIC PHOSPHOPROTEIN SUBSTRATE FOR CALCIUM-DEPENDENT REGULATIONS: PEA-15.

H. Chneiweiss*, H. Araujo*, J. Cordier*, A. Sobel and J. Glowinski*. INSERM U114, 75231 PARIS Cedex 05, FRANCE.

Communication between cells involves phosphorylation as an important molecular mechanism. Astrocytes express membrane receptors capable of responding to extracellular signals. Activation of receptors induces intracellular reactions leading to phosphorylation of specific proteins. Thus, search for major phosphorylated proteins may lead to the discovery of unknown regulatory processes.

We have characterized a novel cytosolic astrocytic phosphoprotein with an apparent molecular mass of 15kDa. It is a major phosphorylation substrate, binding 1.5% of 32P incorporated onto proteins in astrocytes grown in primary culture. Two-dimensional gel electrophoresis of PEA-15 (phosphoprotein enriched in astrocytes of 15kDa) allowed to recognize three isoelectric variants between pI 5.3-5.4, the more basic, unphosphorylated, form yielding the two more acidic forms by phosphorylation in a Ca²⁺-dependent manner.

Phorbol esters and Ca²⁺ ionophores increase the phosphorylation of PEA-15, whereas specific inhibitors of Ca²⁺-dependent kinases such as staurosporine antagonize this effect. In brain slices PEA-15 is observed throughout all post-natal ages analyzed without great variations of its expression. PEA-15 can also be found in other cellular populations, although the main contribution remains astrocytic.

These results suggest a major involvement of PEA-15 in Ca²⁺-dependent regulatory processes in the astrocyte.

221.10

AXON-REGULATED SCHWANN CELL PROTEIN HOMOLOGOUS TO A GROWTH ARREST-SPECIFIC GENE. H.W.Müller, P.Spreyer*, G.Kuhn*, O.Hanemann*, C.Gillen* and H.Schaal*. Molecular Neurobiol. Lab., Dept. Neurology, Univ. of Düsseldorf, D-4000 Düsseldorf, FRG.

A cDNA-library from crushed rat sciatic nerve was differentially hybridized with mRNA expressed in regenerating and intact nerve (Spreyer et al., EMBO J. 9, 1990, 2479). We have isolated a 1.8kb cDNA clone which codes for a 17kD protein with 91.7% homology to the growth arrest-specific membrane protein gas3 (Manfioletti et al., Mol. Cell Biol. 10, 1990, 2924). Steady state mRNA levels are very much higher in sciatic nerve than in other tissues, and expression in sciatic nerve is confined to Schwann cells. After nerve injury, transcript levels rapidly declined in nerve segments distal to the site of lesion, but recovered upon nerve regeneration. In contrast, in distal stumps of permanently transected nerves, the mRNA level remained very low. Substantial amounts of mRNA could be reinduced only upon anastomosis of the transected nerve stumps. Reinduction of the transcript correlated with the spatio-temporal pattern of axonal elongation through the distal segment. Our results indicate an intriguing axonal regulation of the mRNA encoding a membrane-bound "gas" protein in peripheral nerve with putative functions related to Schwann cell growth and differentiation.

SCIP MARKS A PROLIFERATIVE SCHWANN CELL PROGENITOR AND ACTS AS A TRANSCRIPTIONAL REPRESSOR OF THE MYELIN GENES. E.S. Monuki, R. Kuhn*, and G.E. Lemke. Molecular Neurobiology Laboratory, The Salk Institute, La Jolla, CA 92037.

SCIP is a member of the POU domain transcription factor family that is transiently expressed during a narrow window of glial development in both the central and peripheral nervous systems. In developing rat Schwann cells (SC), SCIP mRNA is expressed at high levels prior to peak myelin gene expression, during the proliferative period that occurs as pre-myelinating SC differentiate into myelinating SC. SCIP mRNA is not expressed at high levels in fully-differentiated myelinating SC, but is transiently induced following peripheral nerve transection, during the proliferative period that occurs as these cells dedifferentiate back into pre-myelinating SC. Thus, elevated SCIP expression appears to mark specifically these proliferative transition periods in SC differentiation. In cultured SC, agents that raise intracellular levels of cAMP are strong inducers of this proliferative progenitor phenotype characterized by elevated SCIP expression.

In transient cotransfection assays, SCIP acts as a repressor of myelin-specific genes. This repression appears to be the function of two distinct domains in the SCIP protein: 1) the POU domain, encoding the DNA binding domain, and 2) an amino-terminal repression domain. Mutations that inactivate either of these domains inhibit the ability of SCIP to repress the P₀ promoter, a myelin-specific gene promoter that contains multiple SCIP binding sites as detected by gel shift and DNaseI footprinting analyses. These data indicate that the transcriptional regulatory properties of SCIP are distinct from those of previously-characterized POU proteins, and suggest that SCIP acts as a transiently-expressed repressor of the myelin genes during proliferative periods in SC differentiation.

221.12

A NOVEL MYELIN PROTEIN IS ENCODED BY THE HOMOLOG OF A GROWTH ARREST SPECIFIC GENE. U. Suter*, A. A. Welcher, M. De Leon*, G. J. Snipes* and E. M. Shooter. Department of Neurobiology, Stanford University School of Medicine, Stanford, CA 94305-5401

We have isolated a rat cDNA, SR13, which is strongly downregulated in the initial phase after sciatic nerve injury. This cDNA encodes a glycoprotein which shares striking amino-acid similarities with a previously purified myelin protein and is specifically precipitated by a myelin-specific antiserum. Immunohistochemistry experiments using peptide-specific polyclonal antibodies localize the SR13 protein to the myelin sheath of the sciatic nerve. Northern and Western blot analysis of different rat tissues revealed that SR13 protein is predominantly expressed in the rat sciatic nerve while a weak signal is detectable in the brain. Computer-aided sequence analysis identified a pronounced homology of SR13 to a growth arrest specific mRNA (Gas-3) which is expressed in resting but not in proliferating 3T3 mouse fibroblasts. SR13 is similarly downregulated during Schwann cell proliferation in the rat sciatic nerve. The association of the SR13 as well as the Gas-3 mRNA with non-proliferating cells in two different experimental systems suggests a common role for these molecules in maintaining the quiescent cell state. Supported, in part, by the American Paralysis Association.

NEUROGENESIS: TISSUE CULTURE MODELS

222.1

DEVELOPMENT AND CHARACTERIZATION OF A SECOND HUMAN NEURONAL CORTICAL CELL LINE, HCN-2. L.D. Hester, G.V. Ronnett and S.H. Snyder. Johns Hopkins University School of Medicine, Dept. of Neuroscience, Baltimore, MD 21205.

Previously, a cell line was successfully established from human cortical material obtained at the time of hemispherectomy (*Science*, 248:603-605, 1990). A similar methodology was employed to develop a cell line originating from material obtained from a patient with Rasmussen's encephalitis. This cell line, HCN-2, appears polygonal in shape and divides with a doubling time of approximately 36 hours. HCN-2 can also be induced to differentiate with the addition of nerve growth factor (NGF), the phorbol ester TPA, and isobutylmethylxanthine (IBMX). As with HCN-1, differentiation dramatically slows cellular division and induces the outgrowth of neurites over 3-4 days. In both undifferentiated and differentiated states, HCN-2 demonstrates immunoreactivity to neuron specific enolase (NSE), vimentin, neurofilament, and no immunoreactivity for glial fibrillary acidic protein (GFAP), and S-100 protein. These cells contain small amounts of somatostatin, vasoactive intestinal peptide, cholecystokinin, GABA, and glutamate. None or little immunoreactivity could be seen for neuropeptide Y, members of the enkephalin family, or substance P. HCN-2 represents a second line of human cortical neuronal cells established by our previously described methodologies.

222.3

NEUROTRANSMITTER EXPRESSION IN DIPLOID CELLS CULTURED FROM ADULT HUMAN BRAIN AT AUTOPSY. J.P. Blass, W.R. Markesbery, J.T. Duffy, R.K-F. Sheu, C-S. Rhim, L. Ko, and R.S. Black. Burke Med. Res. Inst., Cornell Univ. Med. Coll., White Plains, NY 10605 and *Dept of Neurology, U of Kentucky, Lexington, KY 40536-0230.

The serial culture from adult human brain obtained at autopsy of diploid cells which contain neurofilaments (NF-H and NF-M) and neuron-specific enolase has been presented previously (Blass et al, *Trans Amer Soc Neurochem* 22:227, 1991). These cells also contain tau proteins and GFAP. We now report that these cells also contain neurotransmitter markers. Tyrosine hydroxylase was identified by immunocytochemistry with both a monoclonal and a polyclonal antibody, and by Western blotting. Immunocytochemical studies also demonstrated the presence of glutamic acid decarboxylase and probably of GABA, and of serotonin but not of choline acetyltransferase. Immunocytochemical studies indicated the presence of met-enkephalin, neurotensin, and neuropeptide Y, possibly of somatostatin, but not of substance P. Immunocytochemical reactivity to a neurotransmitter or marker enzyme, when present, was in essentially all cells and in essentially equal intensity. These studies extend evidence that these cells cultured from autopsy human brain synthesize molecules normally associated with neurons as well as with glia, and suggest that these cells are relatively undifferentiated compared to neurons expressing a single neurotransmitter phenotype.

222.2

BIOCHEMICAL AND IMMUNOCYTOCHEMICAL CHARACTERIZATION OF HUMAN FETAL ORGANOTYPIC CENTRAL NERVOUS TISSUE CULTURES W. C. Hatch*, M. Tricoche*, F.-C. Chiu*, J. Vincent, W. D. Lyman* Dept. of Pathology, Albert Einstein College of Medicine Bronx, NY 10461

Objective: CNS explant organotypic tissue cultures (OTC) derived from human fetal brain allow the study of complex interactions between CNS cell types which is not possible in dissociated tissue culture systems. This study describes the identification of CNS cell types present in OTC and the kinetics of gene expression as a measure of tissue growth and viability.

Methods: Human fetal OTC grown in 24-well Primaria plates were analyzed at 2, 7, 14, 21, 28 and 32 days in culture. Immunocytochemistry and histochemistry identified CNS cell types using antibodies and lectins to detect neurons (NF68, NGF receptor [NGFr]), astrocytes (GFAP), oligodendrocytes (GC), and microglia (RCA, EBM11, non-specific acetate esterase [NSAE]). Cultures harvested at each time point were analyzed for CNS specific protein expression using NF, GFAP, GC, and EBM11 antibodies by Western blotting.

Results: Immunocytochemistry and histochemistry has identified CNS cell types staining positive for NGFr, GFAP, EBM 11, GC, and NSAE in these CNS explant cultures up to 32 days in culture. RCA stained microglia like cells and blood vessel up to day 14, but detection decreased by day 21. Western blot analysis suggests that levels of NF and GFAP proteins increase up to 32 days in culture.

Conclusions: These immunohistochemical results suggest the CNS OTC model derived from human fetal brain is composed of all the major CNS cell types which undergo growth and protein expression for up to 32 days *in vitro*. This model may allow the examination of developmental and neuropathologic processes including the interaction of HIV-1 with the developing CNS. Supported by USPHS grants MH 47667, MH 46815, and DA 05583.

222.4

ALTERED GLIAL CELL DEVELOPMENT IN THE TRISOMY 16 MOUSE. M.A. Barry, B.K. Krueger and P.J. Yarowsky. Depts. of Physiology and Pharmacol. & Exp. Ther., Univ. of MD Sch. of Med., Baltimore, MD 21201.

Trisomy of mouse chromosome 16 (MMU 16;Ts16) is a potential animal model for Down Syndrome (DS) because it contains several of the genes located on human chromosome 21 which is trisomic in DS. Studies of neuronal development in Ts16 indicate abnormal neurogenesis, a decrease in neuron density and premature neuron death. Gliogenesis and glial cell maturation was examined in primary cultures of the cerebral cortex from Ts16 and euploid mice. The development of oligodendrocytes (GalC⁺) from glial progenitor (O2A) cells (GFAP/A2B5⁺) was studied by immunofluorescence. Cells from E15-E16 Ts16 and euploid fetuses were maintained in DMEM/F-12 with 10% fetal calf serum for up to 30 days *in vitro* (div). During the first 12 div the numbers of both Ts16 and euploid O2As increased; however, the Ts16 cultures contained 2-3 times as many O2As as the euploid cultures. From 15-20 div the number of euploid O2As decreased whereas the number of Ts16 O2As continued to increase. Coincident with the decrease of O2As in euploid cultures, oligodendrocytes began to appear. In contrast, no oligodendrocytes were observed in the Ts16 cultures up to 30 div. The results suggest that overexpression of one or more genes on MMU16 alters the normal program for oligodendrocyte development from O2A progenitor cells. Supported by NIH and NSF.

222.5

GENERATION OF NEURONS AND ASTROCYTES FROM PROGENITORS OF THE ADULT MAMMALIAN CNS.

B.A. Reynolds and S. Weiss, Neuroscience Research Group, University of Calgary, Calgary, AB, Canada.

We report the presence of an adult CNS, epidermal growth factor (EGF) responsive multipotent progenitor which, *in vitro*, gives rise to neurons and astrocytes. Striata were dissected from adult mice (25-30gms), enzymatically dissociated and plated (300-500 cells/ml) in a defined serum-free media containing 20 ng/ml of EGF. Division of single progenitor cells (10-15/ml) was first observed after 2 days *in vitro* (DIV). By 5-7 DIV the proliferating cells had formed a sphere (neurosphere) which lifted off the plastic substrate and floated in suspension. Indirect immunocytochemistry of the neurospheres at 5-7 DIV revealed that the cells contained nestin-immunoreactivity (IR), an intermediate filament protein found in CNS neuroepithelial stem cells; neuron specific enolase (NSE)- or glial fibrillary acidic protein (GFAP)-IR was not detected. Single neurospheres (5-7 DIV) were transferred to poly-L-ornithine coated coverslips (in EGF-containing serum-free media). Attached neurospheres continued to proliferate and cells began to migrate from the sphere. After a further 14-21 DIV, neurofilament (160kDa)-, NSE- and GFAP-IR was present in the neurospheres and associated cells. These results demonstrate that the adult mammalian CNS contains progenitor cells which can be induced to proliferate and differentiate into neurons and astrocytes.

Supported by the Medical Research Council of Canada.

222.7

GROWTH FACTORS INFLUENCE THE FATE OF EPIDERMAL GROWTH FACTOR-GENERATED EMBRYONIC PROGENITOR CELLS IN VITRO. A.L. Vescevi, B.A. Reynolds and S. Weiss, Neuroscience Research Group, Univ. of Calgary, Calgary, AB, Canada and *National Neurological Institute, Milan, Italy.

Neurotrophic factors may act in concert to regulate the proliferation and differentiation of progenitor cells of the CNS. E14 striatal cells were plated (10^5 cells/ml) in defined, serum-free media containing epidermal growth factor (EGF; 20 ng/ml). EGF-responsive progenitors began to proliferate after 2-3 days *in vitro* (DIV) and by 5 DIV had formed a sphere of cells (neurospheres) which lifted off the substrate and floated in suspension. Indirect immunocytochemistry of the spheres at 5-7 DIV revealed that the cells were nestin-immunoreactive (IR) characteristic of CNS stem cells; these cells were negative for neuronal and glial cell markers. Neurospheres were mechanically dissociated and reseeded as single cells in defined medium, in the absence or presence of EGF or basic fibroblast growth factor (bFGF). In the absence of growth factors, single cells rarely survived for more than 1-2 DIV. In the presence of EGF, 10-40% of the cells formed new neurospheres; remaining cells either differentiated into neurons or glia or died. In the presence of bFGF, a unique pattern of proliferation and differentiation of the progenitor cells was observed. These findings suggest that EGF and bFGF can influence the fate of embryonic, EGF-generated progenitor cells.

222.9

EXPRESSION OF B-50 (GAP-43) DURING DIFFERENTIATION OF P19 EMBRYONAL CARCINOMA CELLS. E.R.A. Jap Tjoen San, M. Mercken, A.B. Oestreicher, P. Schotman, S.W. de Laat and W.H. Gispen, Rudolf Magnus Institute and Hubrecht Laboratory, University of Utrecht, Padualaan 8, 3584 CH Utrecht, The Netherlands and *Born Bunge Foundation, University of Antwerp and Innogenetics, Gent, Belgium.

The murine embryonal carcinoma cell (EC) line P19 is a pluripotent stem cell line, capable of differentiating into derivatives of each of the three primary germ layers, ectoderm, mesoderm or endoderm. B-50 (GAP-43) belongs to a set of neuronal specific proteins which expression is enhanced in early stages of neuron development. We have studied expression of the growth associated protein B-50 (GAP-43) in the development of P19 EC cells into neuronal or mesodermal structures.

Neuronal differentiation was induced by culturing P19 EC cells in suspension in the presence of 10^{-6} M retinoic acid (RA) for five days and subsequent plating of aggregates, resulting in heterogeneous cultures of neurons, glia and fibroblasts. Expression of B-50 was measured by Western blotting for protein and Northern blotting for mRNA levels. Undifferentiated cells express B-50 protein in low detectable amounts. Aggregation in the presence of RA, increased B-50 expression. During neuronal development, B-50 expression was further enhanced. In the heterogeneous cultures, B-50 immunofluorescence was highly restricted to neurons. Thus, B-50 appeared to be a useful neuronal marker in this system. The levels of expression followed the differentiation of P19 EC cells into neurons.

222.6

EMBRYONIC NEUROSPHERES: CONTINUAL PROLIFERATION OF CNS PROGENITOR CELLS IN SUSPENSION. J.S. Williams, B.A. Reynolds and S. Weiss, Neuroscience Research Group, Univ. of Calgary, Calgary, Canada.

We describe the continual proliferation of undifferentiated CNS progenitor cells that can be subcloned, harvested and induced to differentiate into neurons and astrocytes. E14 striatal cells were plated (10^5 cells/ml) in defined, serum-free media containing epidermal growth factor (EGF; 20 ng/ml). EGF-responsive progenitors began to proliferate after 2-3 days *in vitro* (DIV) and by 5 DIV had formed a hollow sphere of cells (neurospheres) which lifted off the substrate and floated in suspension. Indirect immunocytochemistry of the spheres at 5-7 DIV revealed that the cells were nestin-immunoreactive (IR) characteristic of undifferentiated CNS stem cells; cells in the sphere were negative for markers of differentiated CNS cells (e.g. NFM (160kDa), NSE and GFAP). Neurospheres could be removed from suspension and plated intact onto poly-L-ornithine-coated coverslips where they readily attached and could be induced to differentiate into neurons and astrocytes. Alternatively, neurospheres could be mechanically dissociated into single cells and reseeded in defined EGF-media; 10-40% of the subcloned cells formed new neurospheres. Removal of EGF at any stage resulted in cessation of proliferation. This methodology may be applied towards generating large numbers of cells for neuronal transplantation from minimal fetal tissue.

Supported by the Medical Research Council of Canada.

222.8

NEURONAL DIFFERENTIATION OF EMBRYONIC STEM CELLS K.S. O'Shea, Dept. of Anatomy & Cell Biology, Univ of Mich., Ann Arbor, MI 48109

Murine embryonic stem (ES) cells differentiate into a variety of cell types both *in vitro* as well as when injected into blastocysts to form chimeras. In the current study, a number of approaches were employed to examine the ability of ES cells to attain a neuronal phenotype *in vitro*. Briefly, ES cells (E14, M. Hooper) were cultured in bacteriological grade plastic in DMEM:F12 containing the N2 supplement. After 18h, aggregates were added to 24 well plates and differentiation monitored. For studies of the ability of chemical inducers, e.g., retinoic acid (RA) to promote differentiation, cell suspensions were added directly to 24 well plates. Medium was changed at 72h intervals. When maintained in complete medium also containing leukemia inhibitory factor (LIF), ES cells remain undifferentiated and proliferate rapidly. When removed from their substrate and aggregated overnight, then plated at low density in modified N2 medium, neurons were the predominate cell type present after a 3-4 week culture period. Culture in the presence of RA (10^{-6} - 10^{-7} M) produced a rapid shift (4-5 days) in morphology to a neuronal phenotype. On appropriate substrates there was extensive neurite outgrowth as verified by staining with neuron specific antibodies.

Supported by grant FO6 TWO1674 from the Fogarty International Center.

A CELL LINE DERIVED FROM THE NEUROEPITHELIUM EXPRESSES A NOVEL FORM OF HEPARAN SULFATE PROTEOGLYCAN (HSPG) WHICH IS DEVELOPMENTALLY REGULATED. V. Nurcombe*, G. Binmore* and A.W. Goodwin, Dept. of Anatomy, University of Melbourne, Australia 3052.

We have been isolating and characterizing HSPGs from a cell line, designated 2.3D, derived from the immortalization of E10 mouse neuroepithelium with the *c-myc* oncogene (Bartlett et al., PNAS [1988] 85:3255). 2.3D subcellular fractions containing HSPGs were isolated using anion-exchange and molecular sieve chromatography, and subjected to SDS-PAGE before and after treatment with nitrous acid or glycosaminoglycan lyases. This particular cell line appears to secrete approximately 90% of its PGs as a single species of HSPG of $M_r = 460$ kDa. The core molecule has a $M_r = 45$ kDa and significant homology at the amino acid level with another known basement membrane HSPG core molecule of much larger molecular weight (Noonan et al., JBC [1988] 263:16379) as well as stretches of unique sequence. These data indicate that the nervous system expresses developmentally regulated sets of PGs in a neurotrophically-controlled fashion.

223.1

FINE-STRUCTURAL CHARACTERISTICS OF IDENTIFIED SEPTO-HIPPOCAMPAL NEURONS SURVIVING AXOTOMY. G.M. Peterson, T. Naumann and M. Frotscher. Inst Anatomy, Univ Freiburg, F.R.Germany and Dept Anatomy & Cell Biology, East Carolina Univ Sch Med, Greenville, NC, USA.

Previous studies have indicated that axotomized septohippocampal neurons undergo severe degeneration, presumably due to the loss of nerve growth factor supplied by the target region. Here we demonstrate that a substantial number of septohippocampal neurons survive axotomy and display fine-structural characteristics of intact nerve cells. Rats received intrahippocampal injections of Fluoro Gold to retrogradely label septohippocampal neurons. One week following tracer injection, the fimbria was transected bilaterally. After varying survival times of up to 10 weeks, the animals were fixed by transcardial perfusion and 100 μ m thick sections were cut on a Vibratome. Retrogradely labeled septohippocampal neurons were visualized under a fluorescence microscope and were intracellularly injected with Lucifer Yellow (LY) to reveal the dendritic arbor of the cells. Following photoconversion of LY to an electron dense product, these identified septohippocampal neurons were subjected to light and electron microscopic analysis. Our results show that a large number of septohippocampal neurons survived even 10 weeks after axotomy. These cells displayed a normal endoplasmic reticulum and numerous input synapses on their cell bodies, but had severely shortened dendrites. These data show that septohippocampal neurons undergo some atrophic or degenerative changes following axotomy, but that many of them survive and maintain synaptic inputs for extended periods of time. (Supported by the Humboldt Foundation and Deutsche Forschungsgemeinschaft).

223.3

EXTENT OF RETROGRADE DEGENERATION OF CORTICOSPINAL AXONS 20 WEEKS AFTER T-9 SPINAL CORD TRANSECTION. M.K. Garver, E.R. Feringa and R.L. McBride. VA Medical Center and Medical College of Georgia, Augusta, GA 30910.

We used the anterograde transport of tritiated protein to determine the extent of retraction of injured corticospinal axons proximal to a T-9 spinal cord transection. We transected the cord of 10 7-week-old female rats; 7 non-transected rats were controls. After 18 weeks, we injected 50 μ Ci of 3 H proline bilaterally into motor cortex and 14 days later perfused the rats with formalin. The cord was cut transversely into blocks and processed for liquid scintillation counting. Counts of adjacent blocks were not significantly different: 55 \pm 7 DPM/mg tissue (caudal border of sample 21 mm rostral to transection), 63 \pm 7 (13.5 mm), 59 \pm 7 (6 mm). Labeling increased slightly close to and within the glial scar: 72 \pm 8 (4 mm), 78 \pm 10 (2 mm), 85 \pm 9 (0 mm). Since labeling did not decrease caudally, most axotomized corticospinal neurons incorporated proline into proteins and transported them down the axon. There was no evidence of substantial retrograde degeneration of the axons from the transection site at 20 weeks after lesion. Supported by the VA and MCG.

223.5

THE DEVELOPMENTAL TIME COURSE OF AXOTOMY-INDUCED MOTONEURONAL DEATH IN THE HORMONE-SENSITIVE SPINAL NUCLEUS OF THE BULBOCAVERNOSUS (SNB). J.L. Lubischer & A.P. Arnold, UCLA Brain Research Inst. and Dept. Psychol., Los Angeles, CA 90024

Motoneurons are more likely to die after axotomy early in development than after axotomy in adulthood. The developmental time course of this sensitivity to axonal injury roughly follows the time course of synapse elimination, suggesting that these cells are in a net regressive mode, incapable of an adult-typical response to axonal injury. Synapse elimination in the levator ani muscle (innervated by SNB motoneurons via the pudendal nerve) is delayed relative to other muscles, and can be altered by hormonal treatment. We asked whether susceptibility to axotomy-induced death is also delayed in the SNB, or is instead dissociated from synapse elimination in the normal development of this system.

The pudendal nerve was cut unilaterally in anesthetized male rats at various ages between postnatal day 1 (P1) and adulthood. Rats were perfused at P50 (or 3 weeks after axotomy for adults). The number of SNB motoneurons on the side of the axotomy was counted and divided by the contralateral number to determine percent cell survival. SNB motoneurons begin to show the ability to survive axotomy between P7 and P14, later than reported for other motoneurons (between P1 and P7). The adult pattern of survival is seen by P21:

	P1	P4	P7	P14	P21	P28	P42	adult
mean % survival	3.9	4.3	5.0	42.4	87.2	78.3	87.1	85.7
(SEM)	(1.5)	(1.8)	(1.0)	(5.1)	(3.6)	(6.3)	(3.6)	(4.3)

These results are consistent with a relationship between synapse elimination and sensitivity to axonal injury. Preliminary data, however, indicate that androgen treatment, which delays synapse elimination in the LA, does not alter the time course of axotomy-induced SNB cell death, suggesting that we can dissociate these developmental phenomena experimentally.

Supported by NIH grant HD15021 and an NSF Graduate Fellowship.

223.2

EFFECT OF T-3 SPINAL CORD HEMISECTION ON SURVIVAL OF TWO POPULATIONS OF SPINOCEREBELLAR NEURONS. T.M. Wallace*, D.S. Feldman, E.R. Feringa and R.L. McBride. VA Medical Center and Medical College of Georgia, Augusta, GA 30910.

We studied the relationship between distance from axotomy and survival of spinocerebellar neurons. In seven-week-old female rats, spinocerebellar neurons were retrogradely labeled by cerebellar injection of True Blue. Five days later, the spinal cords were hemisected at T-3. After 10 weeks, the rats were perfused. The cord caudal to the lesion was cut transversely into 30 μ m sections. Based on survival, there appeared to be two populations of neurons in Clarke's column. Rostral to T-12 only 15% of the labeled neurons ipsilateral to the hemisection survived; caudal to T-12 77% survived. The transition zone between low and high survival was narrow, suggesting that factors other than distance were determining survival. Labeled ventral horn spinocerebellar neurons, found only in lumbar and sacral segments, were decreased by 48% contralateral to the hemisection. Neuron loss in both the ventral horn and Clarke's column at and caudal to T-12 was inversely proportional to the distance from the lesion. Supported by the VA and MCG.

223.4

TOPOGRAPHY OF RETROGRADE HORSERADISH PEROXIDASE (HRP) LABELING OF CORTICOSPINAL NEURONS AFTER SPINAL CORD TRANSECTION. V.C. Livingston*, E.R. Feringa and R.L. McBride. VA Medical Center and Medical College of Georgia, Augusta, GA 30910.

Ten weeks after T-9 spinal cord transection, many rat corticospinal neurons do not retrogradely label with HRP; failure to retrogradely label with Fluoro-Gold occurs much later. To determine if the failure to label was due to the time interval between HRP placement and sacrifice, and if loss of labeling occurred in the same neurons as with Fluoro-Gold, the spinal cords of 27 7-week-old female rats were transected at T-9. Ten weeks later, a pellet of HRP was placed into a new transection at T-2 in these and 25 controls. Rats were sacrificed 1, 2, 3 or 5 days later. In both control and transected rats, labeling decreased as survival time increased (control vs transected, 1 day: 859 \pm 54 vs 565 \pm 53; 2 days: 689 \pm 111 vs 466 \pm 61; 3 days: 583 \pm 34 vs 353 \pm 52; 5 days: 546 \pm 76 vs 349 \pm 53). The decreased labeling in transected rats always occurred in the hindlimb area of motor cortex (as with Fluoro-Gold), and was not related to survival time after HRP placement. Supported by the VA and MCG.

223.6

ORGANIZATION OF DORSAL ROOT GANGLION NEURON (DRGN) LOSS 20 WEEKS AFTER HINDLIMB AMPUTATION IN RATS. B.E. Smith*, J.K. Williams, Jr., E.R. Feringa and R.L. McBride. VA Medical Center and Medical College of Georgia, Augusta, GA 30910.

Twenty weeks after hindlimb amputation in rats, we compared the resulting loss of sciatic DRGNs with the loss of DRGNs supplying either the common peroneal or tibial nerves. DRGN somata were retrogradely labeled in 7-week-old female rats by soaking the proximal end of the cut right sciatic nerve (10 rats), common peroneal nerve (8 rats) or tibial nerve (7 rats) in True Blue for one hour. Five days later, we amputated the right hindlimb of half the rats in each group. Twenty weeks later the rats were perfused with formalin. Labeled DRGNs were counted on frozen sections. Amputation resulted in a loss of 49% of L-4, L-5 and L-6 DRGNs supplying the sciatic nerve; most of the loss was in L-5. The number of labeled tibial L-5 DRGNs decreased by only 29% while labeled common peroneal L-5 DRGNs decreased by 53%. Neurons supplying particular anatomical regions were more affected by injury than others. The determinants of the death are not clear. Supported by the VA and MCG.

MK-801 Inhibits Axotomy Induced Cell Death in the Clarke's Nucleus of the Rat C. Sanner and M.E. Goldberger, Dept. of Anatomy and Neurobiology, Medical College of Pennsylvania, Philadelphia, PA. 19129.

It was shown in our previous studies that L1-S2 dorsal rhizotomy of the spinal cord prior to hemisection at T9, prevents axotomy induced cell death in Clarke's Nucleus (CN). This implied that dorsal root afferents may be cytotoxic to axotomized neurons since their removal promoted cell survival. In this study we have attempted a non-surgical deafferentation of CN neurons by administering MK-801 daily to T9-10 hemisectioned rats. The rats were divided into groups corresponding to five post-operative intervals. We compared each group of MK-801 injected rats with axotomized controls that received saline only. We found that the saline rats showed an ipsilateral cell loss of CN neurons that increased in magnitude over time until there was 30% or greater cell loss by 8 weeks. The MK-801 animals however, showed no cell loss over the same five time points. These results suggest that axotomy induced cell death in CN may be partially mediated by glutamate and its effect on CN NMDA receptors. Supported by grant NS24707.

AXOTOMY ENHANCES GAP-43 mRNA LEVELS IN ADULT RAT RETINAL GANGLION CELLS. P.S. Jones and A.J. Aguayo, Center for Research in Neurosciences, Montreal General Hospital and McGill University, Montreal, Quebec, Canada H3G 1A4

Optic nerve (ON) transection near the eye leads to increased GAP-43 immunoreactivity in some but not all surviving retinal ganglion cells (RGCs) examined in retinal whole mounts (Doster et al., *Neuron* 6: 1-20, 1991). RGCs were immunoreactive from 6 to 21 days after injury and there was a marked increase in the levels of axonally transported GAP-43 in the ON. Neither of these changes were apparent when the ON was interrupted intracranially, approximately 8 mm from the eye. We have now used *in situ* hybridization to investigate GAP-43 mRNA in radial sections of the retina after axotomy near to and far from the RGC somata. A radiolabeled DNA probe corresponding to the first 500 base pairs of the rat cDNA clone pG43-1.2 (courtesy of Dr. J.H.P. Skene) was used for these studies. Retina were examined at 3, 5, 12, and 21 days after axotomy. We detected an increase in the hybridization signal over approximately 5% of the pre-axotomy cell number of RGCs. Similar increases occurred both after sectioning the ON intraorbitally (0.5 mm from the eye) and when the ON was cut 8-9 mm from the eye. With either of these axotomy locations, the enhanced signal was first observed in RGCs 3 days after injury and lost between 12 and 21 days. We conclude that: a) axotomy alone, without subsequent fiber elongation, can induce an elevation of GAP-43 mRNA in these CNS neurons; b) differences in GAP-43 immunoreactivity and axonal transport previously observed after intraorbital and intracranial axotomy do not reflect the changes in mRNA regulation that follow the injury of RGCs near and far from their somata.

223.11

EFFECTS OF PROTEINASE INHIBITORS ON RETROGRADE CHANGES IN AXOTOMIZED RETINAL GANGLION CELLS. G.A. Robinson and A.J. Aguayo, Center for Research in Neuroscience, Montreal General Hospital and McGill University, Montréal, Québec, Canada H3G 1A4.

Optic nerves (ONs) were unilaterally and intraorbitally transected in adult female Sprague-Dawley rats <1 mm from the eye. Immediately after axotomy, an Elvax pellet containing either leupeptin, an inhibitor of cysteine and serine proteinases, or E-64, an inhibitor of cysteine proteinases, was placed either in contact with the ON stump or under the sclera near the optic disk. Empty pellets or those containing leupeptin or E-64 were inserted into control eyes with intact ONs. Empty pellets were inserted into control eyes with cut ONs. One to four weeks after axotomy, control and experimental retinas were studied using a battery of antibodies to structural proteins and by electron microscopy (EM).

Neurofilament (NF) antibodies revealed that axotomy alone severely reduced the number of retinal ganglion cell (RGC) axons while inducing focal swellings in a small number of axons. Both leupeptin and E-64 greatly increased the frequency of these swellings and further reduced the number of axons that survived axotomy. EM analysis revealed that the axonal swellings contained large accumulations of NFs. Antibodies to NFs did not show differences in phosphorylated epitopes between swollen and not swollen segments of axons. These results suggest that both proteinase inhibitors may exacerbate cytoskeletal alterations in injured RGCs. It is not known if the NF accumulation in the swellings is related to the slowed transport of this and other proteins observed in the proximal stump of cut ONs (McKerracher et al., 1990, *J. Neurosci.* 10: 2834) or to an inhibition of NF breakdown in injured axons.

223.8

PHOSPHORYLATION OF NEUROFILAMENTS (NF) IN THE AXOTOMIZED SPINAL DORSAL NUCLEUS OF CLARKE (DNC) NEURONS. S.Hong, P.J.Reier and G.Shaw, Depts. Neurological Surg. and Neuroscience, Univ. Florida Coll. Med., Gainesville, FL 32610.

It has been suggested that a persistence of cell body-associated (CB-A) NF phosphorylation within the CNS may be linked to the imminent death of injured neurons. To address this issue further, we have examined whether CB-A persistent phosphorylation is associated with retrograde cell death in the DNC. Previous studies have shown that these neurons undergo substantial degeneration within 5-10 weeks after spinal cord transection. Immunocytochemistry was performed using a specific monoclonal antibody (RT97, Boehringer) against the phosphorylated epitopes of the NF heavy subunit. DNC axotomy was performed by creating a hemisection cavity at the T₉-T₁₀ spinal level. By 5 days post-injury (p.i.), reactive, swollen DNC neurons were seen; however, phosphorylated NF were only demonstrated in the cell bodies of a few axotomized DNC neurons caudal to the level of injury. By 2 weeks p.i. more cells in the DNC were stained by RT97. In addition, some contralaterally located neurons (e.g., Rexed lamina VII) exhibited intense RT97-immunoreactivity. By 10 weeks, when most DNC neurons have died, only a modest number of RT97-positive cells were seen in the DNC. These results suggest that phosphorylation of perikaryal NF may coincide with cell death in the DNC, though this process seems to be secondary to other neuronal responses to injury (e.g., chromatolysis). Hence, phosphorylation of CB-A NF may be a useful index of imminent cell death. Such a marker could be useful in demonstrating post-injury degeneration in other, more diffuse neuronal populations in the spinal cord, as well as elsewhere in the CNS. This work was supported by NIH PO1-NS 27511.

223.10

RETROGRADE EFFECTS OF AXOTOMY BY CUT OR CRUSH OF THE ADULT RAT OPTIC NERVE. M. Berkeleer*, G.M. Bray and A.J. Aguayo, Centre for Research in Neuroscience, McGill University, 1650 Cedar Avenue, Montréal, Québec, H3G 1A4.

To investigate the anatomic effects of different types of axotomy on retinal ganglion cells (RGCs) and their fibers in the optic nerve (ON) and retina, we compared retrograde changes after cutting or crushing the ON intracranially, 8-10 mm from the posterior pole of the eye.

One week after ON cut, a central core of degenerating myelinated fibers (MFs) and macrophages extended 4-5 mm from the injury site towards the eye but at 1 mm from the eye, myelinated fibers (MFs) appeared normal in ON cross-sections examined by light microscopy (LM). At 4 weeks, however, many MFs had degenerated in the ON close to the eye. Within the retina, fiber bundles were decreased in size, although the extent of axonal loss was qualitatively less than in the ON, and RGC cell bodies expressing RT-97 immunoreactivity were prominent.

Crush injury 8-10 mm from the eye caused a slower, more homogeneous retrograde change. At one week, severe MF breakdown was restricted to the site of crush and extended only 1 mm towards the eye; no degenerative changes were observed by LM 3 mm proximal to the injury site. Four weeks after ON crush, there were few degenerating MFs in the ON 1 mm from the eye, axonal changes were not detectable in the retina, and only occasional RGC cell bodies expressed RT-97 immunoreactivity.

Thus, cutting the ON triggers different retrograde changes in the axotomized RGCs and their axons than interrupting the ON by crush injury. Conditions at the lesion site and substrates in the ON and retina may influence the extension of these changes towards the RGC somata.

223.12

OLFACTORY BULB REMOVAL CAUSES INCREASED PROLIFERATION AND REDUCED SURVIVAL OF PRIMARY OLFACTORY NEURONS. S. Biffo*, M. Sassoe-Pognetto* and A. Fasolo, Dip. Biologia Animale, Univ. Torino, V. A. Albertina 17, 10123 Torino, Italy.

Olfactory neurons (ON) located in the olfactory epithelium project their axons to the olfactory bulb. Bulbectomy (BX) causes the death of ON followed by the restoration of their number from a stem cell compartment. However, in the absence of their target ON do not fully differentiate and retain an immature phenotype (expression of B-50/GAP43, absence of OMP).

In order to assess whether the effect of target deprivation on ON was due to either a block of differentiation and normal turnover or accelerated turnover and shorter survival, adult rats were unilaterally bulbectomized and 35 days later, when the number of ON recovered normal levels, injected with bromodeoxyuridine (BrdU). Rats were then sacrificed at various intervals following the injection and the expression of carnosine, calmodulin m-RNA (expressed both in immature and differentiated ON) and BrdU incorporation were analyzed by a novel technique combining *in situ* hybridization and immunohistochemistry.

In the BX side of the olfactory epithelium little or no expression of carnosine was seen. Conversely, ON expressing calmodulin m-RNA were abundant both in the control and in the BX side. At 1 day following BrdU injection ON that incorporated BrdU were much more abundant in the BX side. Strikingly at 35 days following BrdU injection ON double labelled for both calmodulin m-RNA and BrdU incorporation were seen only in the normal side whereas no BrdU positive neurons were present in the BX side.

These data indicate that the OB is fundamental both for the survival and differentiation of ON. (Financial contribution from CNR, MURST).

ANALYSIS OF PRECEREBELLIN GENE EXPRESSION IN THE DEVELOPING MOUSE BRAIN. D.I. Lugo, Y. Urade*, J.D. Oberdick* and J.L. Morgan. Roche Institute of Molecular Biology, Roche Research Center, Nutley, NJ 07110.

The cerebellin precursor, precerebellin has been cloned from a human cDNA library. Previous immunocytochemical data had localized the hexadecapeptide primarily to Purkinje neurons of the cerebellum and to cartwheel neurons of the dorsal cochlear nucleus. In the present study we have utilized a ~1000 base cerebellin-specific riboprobe to study the spatial and temporal expression of cerebellin mRNA during mouse development by in-situ hybridization histochemistry. Surprisingly, within the cerebellum, cerebellin mRNA was confined to granule cells and neurons of the deep cerebellar nuclei and not to Purkinje cells. Additional areas of cerebellin gene expression included various areas of the cerebral cortex, the thalamus, hypothalamus, parabigeminal nucleus, vestibular nuclei, dorsal and ventral cochlear nuclei and the reticular formation. Cerebellin transcripts can first be detected at postnatal day 2.5 in the external granular layer of the cerebellum and in thalamus. The relative levels continue to increase as the granule cells migrate to form the internal granular layer. In the adult, high levels remain in the cerebellum and the thalamus. Recently, a gene highly homologous to precerebellin (pseudocerebellin) has been cloned. In-situ hybridization experiments are underway to study its sites of expression and determine if the cerebellin peptide previously localized to Purkinje cells, is the product of this homologous gene.

224.3

A COMPARATIVE ANALYSIS OF THE POST-TRANSCRIPTIONAL REGULATION OF THREE CEREBELLAR MARKER MRNAs. L. Sangameswaran¹, Y. Urade², J. Oberdick³, J.I. Morgan³. ¹Dept. of Pathology, Indiana Univ. Sch. of Med., Indianapolis, IN 46202-5120; ²Towa City Corp.-Nishinotohin, Nishinotohin, Nakagyo-ku, Kyoto 604, Japan; ³Dept. Neurosciences, Roche Inst. of Molec. Biol., Nutley, NJ 07110

Using rodent cerebellum as a model, we have isolated a set of markers, cerebellin, L7 and PEP-19, to address the question on the molecular and cellular mechanisms that play a role in the assembly of nervous system. All of them have been shown to be localised in the Purkinje neurons of the cerebellum. Previous studies indicated that cerebellin levels are diminished in the cerebella of the murine mutants, weaver and staggerer, suggesting that synaptic activity could regulate cerebellin biosynthesis. However, PEP-19 mRNA regulation seems to be under the influence of factors intrinsic to Purkinje neurons.

In the present study, a comparative analysis of the regulation of mRNA of the three markers has been attempted. Northern analyses were performed with tissues obtained from neurological mutant mice, with genetically determined cerebellar anomalies. Further, paradigms where either of the two inputs to the Purkinje neurons, climbing or parallel fibres, is impaired by chemical lesions were employed to investigate the levels of mRNA specific for each of the three markers. The results of these experiments with implications on the post-transcriptional regulation of these three polypeptides will be discussed.

224.5

HB-GAM IMMUNOREACTIVITY IN THE DEVELOPING RAT CEREBELLUM. K. Wewetzer*, H. Rauvala*, K. Unsicker Dept. Anatomy and Cell Biology, University of Marburg, Robert-Koch-Str. 6, 3550 Marburg, F.R.G. and Dept. Medical Chemistry, University of Helsinki, Finland

The heparin-binding growth associated molecule (HB-GAM) is a 18 kD protein which was recently purified from rat brain and promotes neurite outgrowth in vitro. We have studied the distribution and function of HB-GAM in the postnatal cerebellum using a polyclonal antiserum raised against the native peptide. HB-GAM-immunoreactivity was found to be associated with cell processes rather than cell bodies. Through all stages examined, the molecular layer was labeled. Immunoreactivity was also associated with Bergmann glia-like processes located in the external granular layer. Immunoreactivity in the adult cerebellum was mainly restricted to the molecular layer. Together these results suggest that HB-GAM in the cerebellum might have a function in the context of cell migration and axon growth. In vivo studies aiming to perturb cell migration along radial glial cells, axon growth and fasciculation are under way.

224.2

DIFFERENTIAL GENE EXPRESSION IN DEVELOPING AVIAN CEREBELLUM. P.L. Jeffrey, J.W. Sentry* and R.C. Henke*. Developmental Neurobiology, Children's Medical Research Foundation, P.O. Box 61, Camperdown NSW 2050, Australia.

To complement our immunological studies identifying and characterizing developmentally regulated neural antigens, we have constructed cDNA libraries from poly A⁺ mRNA isolated from embryonic day 8 (ED8) and ED18 chick cerebellum in the plasmid vector pUEX1. (+/-) screening of these libraries with SScDNA from ED8 and ED18 cerebellum and liver poly A⁺ mRNA have shown that 5.8% of the ED8 cerebellum cDNA clones are brain specific and developmentally expressed early in the cerebellum. Conversely 2.2% of the ED18 cerebellum cDNA clones are brain specific and expressed late in cerebellum. One late expressed brain specific clone 2352 bp in length hybridizes to a message of 2.4 kb. In cerebellum it is first detected at ED12 reaching maximum at ED20 and continuing through adulthood. In forebrain it appears later (ED16) peaks at postnatal day 7 and continues being expressed through to the adult. The translated sequence demonstrates 75% identity at the amino acid level to human, rat and mouse myelin basic protein, 18.5 Kd MBP (lacking exon 2). Other developmentally expressed clones are being characterized. By a combination of differential screening and screening the cDNA libraries with subtracted cRNA probes from directional libraries, we aim to isolate and characterize cerebellum specific, developmentally expressed genes.

224.4

GRANULE CELL ANTISERUM IDENTIFIES A BRAIN-SPECIFIC cDNA IN AN EXPRESSION LIBRARY DERIVED FROM NEONATAL HETEROZYGOUS WEAVER CEREBELLA. M. Kambouris*, L. Sangameswaran, S.R. Dlouhy*, L.C. Triarhou, B. Ghetti & M.E. Hodes*. Dept. Med. Molec. Genetics, Dept. Pathol. (Neuropathol.) & Med. Neurobiol. Pgm, Indiana Univ., Indianapolis, IN 46202.

An antiserum was raised against a protein extract of cerebellar granule cells (GC). Western blot analyses showed that the antiserum cross-reacts with a number of different proteins with molecular weights ranging from 26 to 100 kDa. A 26 kDa protein detected by the antiserum is missing from *wu/wu* cerebella. Immunocytochemical analyses of normal cerebellum by light and electron microscopy showed positive immunoreactivity in the cytoplasmic compartment of GC and in neuronal processes of the GC layer neuropil, as well as in the molecular layer. The antiserum was used to screen a cDNA expression library made from postnatal day 0 *wu/+* cerebella. Twenty immunopositive clones were obtained. In order to determine which of these twenty clones is a GC marker, northern blot analyses were performed with *wu/wu* and *+/+* cerebellar total RNA. At least one of the clones hybridized to RNA transcripts that appear to be missing in *wu/wu* but present in *+/+* cerebellar RNA. This suggests that the insert may encode a GC marker. Another clone detects two RNA transcripts, indicating regulation by alternative splicing. Both transcripts are brain-specific. Further characterization of these clones, including sequence analysis, is in progress. (Supported in part by USPHS PO1-NS27613 and RO1-NS14426).

224.6

DEVELOPMENTAL DISTRIBUTION OF MAP2 IMMUNOREACTIVITY IN THE CHICK EMBRYO SPINAL CORD. H.S. Keirstead, D.S. Henshel, D.M.S. Webster¹ and J.D. Steeves. Department of Zoology and ¹School of Rehabilitation Medicine, University of British Columbia, Vancouver, BC, V6T 1Z4.

Microtubule-associated protein 2 (MAP2) is a family of three cytoskeletal elements that have been localized to dendrites and certain somata in differentiated neurons. The relative abundance of these related forms changes during development, suggesting that MAP2 may be involved in the control of dendritic outgrowth and the stabilization and maintenance of dendrites. We have examined the developmental distribution of MAP2 immunoreactivity in chick embryo spinal cord from embryonic day 9 (E9) through to hatching (E21). At E9, MAP2 immunoreactivity appears in the neuropil at all levels of the spinal cord gray matter. Motor neuron cell bodies begin to be immunoreactive at E14, followed by interneuron cell bodies at later stages of development. The number of immunoreactive cell bodies at any given level of the spinal cord increases with development. By E21, virtually all motor neurons and many interneuron cell bodies are labelled. Furthermore, the proportion of cell body to neuropil labelling within the spinal cord increases in a rostral-caudal gradient. This developmental profile may reflect the stabilization of dendritic fields in the developing spinal cord.

AGE RELATED CHANGES IN PROTEIN SYNTHESIS IN THE MURINE LUMBAR SPINAL CORD. H.L. Stewart, S. Chaube*†, J.A. Birk*††, N.C. Mills*, M.H. Droge. Department of Biology, Texas Woman's University, Denton TX 76204. Department of Biological Sciences, University of North Texas, Denton TX 76203†, Department of Academic Computing, Texas Woman's University, Denton TX 76204††.

The objective of the current project was to characterize cell protein production in an effort to develop a valid assay for circuit viability as well as a biochemical assessment of development. To this end, samples consisting of 200-300 µm thin transverse sections of lumbar spinal tissue were incubated in medium containing ³⁵S-methionine and examined for: 1) precipitable counts via scintillation counting and 2) protein patterns via electrophoresis using PAGE-gels containing SDS. Additional tissue samples were stained via acetylcholinesterase histochemistry for identification of cholinergic neurons. Peaks and valleys of protein production associated with specific ages were examined and increased synthesis of proteins with molecular weights was found. Antibody probes are being used to identify specific proteins that may contribute significantly to such peaks. Preliminary data suggest that changes in size and density of cholinergic neurons at the sampled intervals in culture are clearly reflected in total cell protein profile. Ultimately, we hope to correlate protein profiles with the morphological features and pattern generating capabilities of *in vitro* spinal circuitry.

EARLY DIFFERENTIATION OF NEURONS AND PHOTORECEPTORS IN THE EMBRYONIC ZEBRAFISH EPIPHYSIS. S.W. Wilson and S.S. Easter Jr. Dept of Biology, University of Michigan, Ann Arbor, MI 48109.

At 24h, the embryonic zebrafish brain contains a small number of discretely located neurons with axons that establish a simple scaffold of tracts. One group of the early projecting neurons is located in the developing epiphysis. The presence of this projection, long before the eyes assume visual function, suggests that the epiphysis may be involved in early light mediated behaviour. We are investigating the differentiation of cells within the epiphysis using immunocytochemistry and electron microscopy (EM). We find that by 22h, several cells are already immunoreactive for opsin on their medial surface; by 24h, these cells stain throughout; and by 48h, well developed outer segments are evident with EM. We have also screened monoclonal antibodies (FRets) raised against adult retina. By 24h one of these, FRet 43, labels a few cells that are coincident with the opsin containing cells in the medial region of the epiphysis. Retrograde labelling of the epiphysial projection neurons shows that they are laterally located. In addition, several of the epiphysial cells are GABA positive by 25h. We are currently double labelling embryos to resolve the exact relationship between the different cell types.

We thank R. Bremiller, K. Larison and R. Molday for antibodies. Supported by NIH EY00168 to SSE.

EFFECTS OF REDUCING MATURATIONAL DISPARITY ON SEGREGATION OF NORMAL AND ECTOPIC RETINAL INPUTS. K.T. Yee and R.D. Lund Department of Neurobiology, Anatomy and Cell Science, School of Medicine, University of Pittsburgh, Pittsburgh, PA 15261

A common feature in mammalian visual systems is the segregation of inputs from the two eyes. This can also be experimentally induced in the frog tectum following introduction of an ectopic eye. In contrast, segregation of normal and ectopic inputs does not occur when ectopic retinæ are transplanted into neonatal rat hosts, even though specificity for normal optic target regions is exhibited.

We have examined whether this is due to maturational disparity of host and transplant inputs in two experiments: 1) pairs of stage-matched retinæ (embryonic day 12 (E12) mouse and E13 rat retina) were co-transplanted into postnatal day 1 rat hosts and 2) E12 mouse retinæ were transplanted into fetal hosts. Animals survived to 1 month of age. Transplant connectivity was revealed with antibodies specific for mouse tissue. In some hosts with double transplants, the projection from the transplanted rat retina was also labeled by tracer application to the transplant. In rats that received grafts as fetuses, the normal host projection was similarly labeled.

Our results show that projections from double retinal transplants overlap in the superior colliculus, and that at least the mouse retina innervates regions which do not receive input from single grafts. Transplant axons in fetal hosts integrate extensively with host optic axons, coursing through the superior colliculus in the stratum opticum where normal optic axons travel. In both experiments, projection patterns differ from those shown by single transplants placed into neonatal hosts. Therefore, reduction of maturational disparity alters the pattern of target innervation compared to postnatal hosts, but not does not produce segregation of optic inputs.

FETAL EYE AND HOST SUPERIOR COLLICULUS CONNECTED BY A PERIPHERAL NERVE BRIDGE: COMPARISONS OF FETAL AGE AND DONOR SOURCE. B.H. Hallas, L. Guarino*, M.R. Wells, M. LaCorte*, R. Cebelenski, B. Kim* and M.F. Zanakos. NY College of Osteopathic Medicine, NY and Veterans Administration, Northport, NY

Previous studies have shown that when fetal eye/peripheral nerve bridge complexes are used to "reconstruct" the damaged visual system, fetal retinal ganglion cells grow through the bridge and well into the host. The pattern of synapse formation is organized and quite extensive. The present studies expand on this technique to investigate the role of various fetal ages as well as the differences between homograft and heterograft nerve and eye donor animals. Sprague-Dawley or Wistar albino rats were used as donors and/or recipients (thereby establishing homografts or xenografts for the nerves). The immature eyes were also either from one or the other species. In all experiments, the eyes were removed from fetal or prenatal (3 day) rats and attached to a 3 cm segment of tibial nerve by use of gelled cyanoacrylate. The eye with attached nerve was inserted into the anterior eye chamber of an adult rat host (with optic nerve cut) while the free nerve end was inserted through a burr hole in the cranium into the contralateral superior colliculus. One month to one year post-implantation of the eye/peripheral nerve complex, either HRP or WGA/HRP was injected into the host eye. Twenty-four hours post injection, the eye/bridge complex and host brain was processed for HRP histochemistry. Bulk labelled axons and HRP filled cells were demonstrable in the contralateral superior colliculus in all animals. Homograft bridges with homograft eyes demonstrated the best labelling (65%) while 60% of the heterograft bridges and 55% of heterograft eyes showed labelled axons and neurons. While PN3 eyes provided good results, E18 eyes generally demonstrated more labelling and pattern formation.

225.4

ALERTING AND ORIENTING RESPONSES MEDIATED BY INTRACEREBRAL RETINAL TRANSPLANTS. P.J. Coffey* and R.D. Lund. Department of Psychology, University of Sheffield, England and Department of Neurobiology, Anatomy and Cell Science, University of Pittsburgh, Pittsburgh, PA.

Normal retinæ project to a number of brain regions, each subserving a specific visual response. Retinæ transplanted over the midbrain of neonatal rats connect with many of the same regions and these mediate pupilloconstriction, conditioned suppression and photophobic responses. The heaviest transplant input is to the superior colliculus, a region normally involved in alerting and orienting responses. In this series of experiments we examined the alerting and searching patterns in rats when a light was presented to their normal eye or retinal implant. When a visual stimulus is presented in a dark chamber, a rat typically inhibits its ongoing behavior and orientates toward the light source. Whereas presentation of the light in normal rats resulted in an inhibition of ongoing behavior often followed by a specific orientation towards the light, visual stimulation of the transplant resulted in the inhibition of ongoing behavior with undirected orientation behavior. These results suggest that the alerting response, thought to be mediated through the colliculus, can be driven by implant illumination. The orienting response may be confounded by the lack of topographic organization in the transplant-host projection.

225.5

MORPHOLOGY OF THE TERMINAL ARBORS OF RETINAL TRANSPLANT-DERIVED PROJECTIONS IN EYELESS MUTANT AND NORMAL MICE. G.M. Horsburgh, R.D. Lund and M.H. Hankin. Dept of Neurobiology, Anatomy, and Cell Science, University of Pittsburgh School of Medicine, Pittsburgh, PA 15261.

We have previously shown that fetal retinae transplanted to the midbrain of neonatal rodents are capable of projecting to appropriate visual nuclei in the host brain where they form synapses and can mediate light-driven responses. In order to further understand the anatomical substrates for these specific projections and functional responses, the morphology of the retinal transplant-derived terminal arbors was examined using the anterograde neuronal tracers Biocytin and Dil.

In the present study we address two primary issues. First, how does the morphological development of retinal transplant-derived terminals in normal recipient mice compare with that of normal retinal terminals? Second, eyeless mutant mice (or^1) - in which the visual nuclei never receive retinal input - were used as recipients to determine whether the absence of prior optic innervation affects the development of transplant-derived terminal arbors.

Following large deposits of tracer in the transplant, the overall pattern of arborization within the visual nuclei appeared similar in normal and mutant hosts. However, transplant-derived projections tended not to occupy the full extent of the normal visual terminal fields. Following small deposits of tracer, the arbors of individual transplant-derived axons could be examined. The ramification of these arbors appeared similar in complexity to normal retinal terminals, and were comparable in genetically normal and mutant hosts.

These findings indicate that projections of transplanted retinae form morphologically normal terminal arbors despite the the ectopic locations of the transplants and the delayed arrival of their projections in the targets.

225.7

EFFECT OF LESIONS OF THE OLIVARY PRETECTAL NUCLEUS ON THE DIRECT AND CONSensual PUPILLARY REFLEXES M.J. Young, H. Klassen and R.D. Lund, Dept. Neurobiology, Anatomy & Cell Science, Univ. Pittsburgh Sch. Medicine, Pittsburgh, PA 15261.

It is well established that the olivary pretectal nucleus is central to the pupillary constriction response in rats. In order to determine the anatomical substrate of the consensual pupillary reflex in Long-Evans (L-E) rats, unilateral heat lesions of the olivary pretectal nucleus were performed, and the effect of these lesions on both the direct and consensual pupillary reflexes was determined.

Rats (aged 6 weeks) received unilateral heat lesions of the olivary pretectal nucleus. They were allowed to recover for 7-14 days. The degree of direct and consensual pupilloconstriction in response to a range of illumination intensities was then determined. After several trials, the animals received unilateral intravitreal injections of 30% HRP to verify the extent of the lesion. The rats were then perfused, and processed for HRP-TMB and Nissl stains.

It is apparent that unilateral lesions significantly increase the threshold of stimulus required to elicit both direct and consensual pupilloconstriction compared to controls. However, even complete unilateral lesions of the olivary pretectal nucleus fail to completely abolish either the direct or consensual pupillary reflex. This suggests that one component of the consensual reflex depends on bilateral innervation of the olivary pretectal nucleus, but not solely on this pathway.

Supported by NIH grant EY 05283.

DEVELOPMENTAL REGULATION OF THE L7 GENE IN THE MOUSE CEREBELLUM AND RETINA. A.S. Barrabi, J. Oberdick*, R.J. Sneyten, J.L. Morgan* and E. Mugnaini. Neuromorphology Lab, U-154, Univ of Conn., Storrs, CT. 06269 and *Dept. of Neurosci., Roche Inst. Mol. Biol., Nutley, NJ 07110.

A central issue in contemporary developmental neurobiology is the elucidation of the mechanisms that orchestrate the assembly of the nervous system. One approach to this problem is to study the transcriptional regulation of specific, informative, genes at the cellular and molecular levels. Previous studies have been aimed at identifying genes that show restricted expression in the CNS, particularly in Purkinje neurons of the cerebellar cortex.

The L7 gene is expressed only in cerebellar Purkinje cells and rod bipolar cells of the neural retina (Oberdick et al., 1989, 1990; Berrebi et al., 1991). In the present studies we examined the developmental pattern of L7 expression to determine whether the gene is coordinately regulated in these two structures.

In the cerebellum, Purkinje cell immunoreactivity (iR) is first detected in late embryogenesis. At E17, two discrete parasagittal bands are present on each side of the midline. By P0, L7-iR is most evident in 3 bilateral clusters or bands of Purkinje cells. The number of sharp bilateral bands increases from 3 to 5 by P4. On P9, all Purkinje cells display strong L7-like iR.

In retina, all rod bipolar neurons are completely immunonegative prior to P7. At P7, very faint staining of rod bipolar cell bodies is evident. However, by P8 all rod bipolars are densely immunostained, with no evidence of banding. At this stage, their fine radial processes, which traverse the inner plexiform layer (IPL), are also faintly labeled, as are their endings in the deepest regions of the IPL. By P9, intense immunolabeling of the radial processes and endings of rod bipolar cells is observed. The developmental sequence of L7 expression in the retina is essentially unchanged when animals are born and reared in complete darkness.

The disparity in both the time of onset and spatial progression of immunoreactivity in the cerebellum and retina suggests that induction of the L7 gene is controlled by different events in these two structures.

LOCAL MYOPIA PRODUCED BY PARTIAL VISUAL-FIELD DEPRIVATION IN TREE SHREW. Thomas I. Norton and John T. Siegart, Jr.* Department of Physiological Optics, School of Optometry/The Medical Center, Univ. of Alabama at Birmingham, AL 35294.

In many mammalian and avian species, deprivation of form vision during postnatal development produces axial elongation of the eye and a resultant myopia. This is mediated by direct retino-choroidal/scleral mechanisms; it occurs in tree shrew despite blockade of ganglion cell action potentials by TTX (Norton et al., *Invest. Ophthalmol. Vis. Sci.* 30: 32, 1989). To examine the local specificity of these mechanisms, we deprived tree shrews of form vision in either the nasal (N = 5) or temporal (N = 5) hemifield of one eye with a translucent half goggle. After 3 to 4 weeks the deprived region of the eye, measured 20°-30° off-axis, was significantly myopic (-8.7 ± 2.9 D [mean ± S.D.]) (streak retinoscopy) and elongated (0.14 ± 0.06 mm) (A-scan ultrasonography) compared to the control eye. In the non-deprived region, there was no significant refractive difference (-1.6 ± 3.2 D) or elongation (0.02 ± 0.06 mm). These results extend to mammals the previous reports of local myopia in avians (e.g. Wallman et al., *Sci.* 237: 73, 1987). Such a within-eye change implies that the neurobiological mechanisms which normally coordinate the axial length of the eye with its focal length are extremely local in their ability both to detect the absence of a clear retinal image and to rapidly alter ocular development. CHICK EMBRYO RETINA CELLS METABOLIZE AND RESPOND DEVELOPMENTALLY TO RETINOLIDS IN VITRO. D. L. Stenkamp*, J. K. Gregory*, and R. Adler. Depts. Ophthalmology and Neuroscience, Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205.

In addition to visual transduction, vitamin A appears to affect retinal development and differentiation through still poorly understood mechanisms. We are investigating these effects in RPE/glia-free cell cultures in which retinal precursor cells differentiate as either neurons or photoreceptors, the latter being opsin-immunoreactive and showing photomechanical responses to light. Our studies suggest that retinoids do not have a mitogenic effect, but do affect retinal cell survival and differentiation. While increases in neuronal numbers were small, retinoids (retinol >11-cis retinal >retinoic acid) caused marked increases in number of photoreceptors and also potentiated their photomechanical responses. HPLC analysis showed that cultures hydrolyze retinyl acetate and reduce exogenous retinal to retinol. Oxidation of retinol or retinal to retinoic acid was not detected. *In vitro* differentiation of retinal neurons and photoreceptors therefore includes a capacity for developmental responses to vitamin A, and expression of metabolic activities which may be important for these responses and for visual transduction. DEVELOPMENTAL EXPRESSION OF GLUTAMIC ACID DECARBOXYLASE (GAD 65) mRNA IN THE MOUSE RETINA. Vijay Sarthy. Dept. of Ophthalmology, Northwestern Univ. Med. Sch., Chicago, IL 60611.

Immunocytochemical studies show that GAD is present in horizontal cells in the developing rodent retina, although there is no evidence that these cells use GABA as a synaptic transmitter. We have used *in situ* hybridization to examine whether GAD 65 mRNA is expressed by horizontal cells during retinal development. In the adult retina, labeled cells were found in the inner nuclear layer (INL) and the ganglion cell layer (GCL). In the INL, all labeled cells were located close to the boundary of the INL and the inner plexiform layer (IPL) suggesting these are labeled amacrine cells. In the developing retina, lightly labeled cells were first detected at embryonic day 15 (E-15). Beginning at E-20, strong labeling was observed in the INL and GCL. The labeled cells in the INL formed a band at the interface of INL and IPL. In the GCL, the majority of labeled cells were present at the IPL/GCL boundary. At the postnatal stages examined (P1-P14), labeled cells were found at the INL/IPL and IPL/GCL boundary. In the GCL, there was a decrease in the number of labeled cells between P-1 and P-10. The intensity of cell labeling reached adult-like by P-7. In summary, we did not find GAD 65 mRNA-containing horizontal cells in either adult or developing mouse retina. Supported by EY-03664.

TAURINE IN DEVELOPING RABBIT RETINA. G. Battista* and N. Lake. Depts. Physiology & Ophthalmology, McGill University, Montreal, Canada H3G 1Y6.

The retina of a newborn rabbit is not fully mature in terms of morphology, chemical composition or capabilities. It has been suggested by Redburn et al [IOVS 31:1620A,1990] that the release of GABA from horizontal cells (HC) plays a trophic role in postnatal (PN) organization of cone terminals. GABA then disappears from HC after PN day 5, and their inhibitory transmitter remains unknown. We have observed that HC in the adult rabbit contain high levels of taurine, another amino acid with potent neuroinhibitory effects. The present study examined PN changes in retinal taurine levels and localized taurine immunoreactivity (T-IR). Taurine is present at birth (1.13 $\mu\text{mol}/\text{mg}$ DNA) and increases four-fold by maturity. At PN1 to PN3 T-IR is in radial glial cells whose processes span the retina. Neurons also show T-IR, but apparently as an accompaniment to differentiation/maturation, since T-IR is not seen in neuroblasts, or relatively undifferentiated neurons, but tracks the maturation gradients: posterior pole to periphery, inner to outer retinal layers. Adult T-IR is in receptors, HC, amacrine, ganglion cells and the inner plexiform layer. From the earliest day examined, prominent T-IR is seen in HC and their lateral processes. These cells develop precociously compared to their neighbouring neuroblasts. In contrast to GABA-IR, T-IR persists in HC through to adulthood. Taurine may have roles related to development, and in adults, it may be a HC or amacrine inhibitory transmitter. Supported by MRC Canada

POSTNATAL DEVELOPMENT OF TYPE A HORIZONTAL CELL TOPOGRAPHY IN THE CAT RETINA. J.S. Tootle and J.W. Bledsoe III. Neurobiology Research Center and Department of Physiology and Biophysics, University of Alabama at Birmingham, Birmingham, AL 35294.

The topography of type A horizontal cells (HCs) in the retina of the adult cat has been described (Wässle et al., Proc. R. Soc. Lond. B, 203:269,1978) but the ontogenetic events which give rise to the precise tiling observed at maturity have not been reported. In the present study we used a commercial (Sigma) monoclonal antibody to the 28 kD calcium binding protein calbindin to stain all the type A HCs in retinas taken from kittens at postnatal day 5 (P5), P7, P10, P27, P36 and in 2 retinas from adult cats. These data were supplemented by additional retinas taken at ages ranging from P0 to P33 for which significant fractions of the type A HCs were labeled. The general topographic features of this cell type in the adult retina were present at all ages studied and included: a peak density in the area centralis; a decline in density toward the periphery which was most rapid along the vertical meridian and slowest in nasal retina along the horizontal meridian. The densities of type A HCs near the area centralis did not differ markedly between ages but more peripherally there was a monotonic decrease in cell density with age. Nearest neighbor analysis showed that the regularity of the type A HC matrix was already adult-like at birth when the X/S.D. of nearest neighbor distances measured in the periphery ranged from 3.8-5.3. These results show that the mechanisms which generate the tiling of the retina by the type A HCs do so prenatally and that the general topography present at birth is preserved as cell densities are reduced during postnatal growth.

MORPHOLOGICAL CHARACTERIZATION OF TYROSINE HYDROXYLASE (TH) IMMUNOREACTIVE NEURONS IN THE DEVELOPING RABBIT RETINA. Giovanni Casini and Nicholas C. Brecha, Depts. of Anatomy & Cell Biology and Medicine, UCLA and VAMC-West Los Angeles, Los Angeles, CA.

TH cells represent a class of wide-field amacrine cells thought to exert modulatory functions in the processing of visual information. In the present study, retinas at different postnatal ages were processed as whole mounts for TH immunohistochemistry. In newborn retinas (PD 0), TH cells display very weak immunoreactivity. In most cases, one thick primary process, often with second-order ramifications, is present. Varicosities are not observed. At PD 6, variable characteristics are found, including third-order ramifications and a few varicosities, with no evident correlation between degree of maturation of TH neurons and their position in the retina. At PD 12 (eye opening), TH cells have 2 to 5 primary processes, a complicated network of TH fibers begins to form in lamina 1 of the inner plexiform layer (IPL), and processes with small varicosities can be seen in lamina 3. Many growth cones are present. From PD 12 to PD 26, the network of TH fibers attains a high degree of complexity (with varicosities arranged in ring-like structures), processes enter lamina 5 of the IPL and growth cones disappear. After PD 26, TH neurons are similar in appearance to those in the adult. These observations indicate that the transmitter phenotype of dopaminergic neurons is established before birth. Their maturation is well advanced at the time of eye opening, but mature characteristics are not seen until after the first month of age. Supported by EY04067 and VA Medical Research Funds.

225.12

HORIZONTAL CELLS IN THE MARSUPIAL RETINA. A.M. Harman and L.D. Beazley. Dept. of Psychology, University of Western Australia, Nedlands, W.A. 6009, Australia.

We have previously shown that cells in the marsupial retina are generated in two separate phases (Harman and Beazley, Neuroscience 28: 219-232, 1989). Here we classify horizontal cells in the marsupial retina and determine in which phase they are generated. Adult retinas were examined from two species, the quokka wallaby and the brush-tailed possum. Many small crystals of HRP (Sigma) were pressed into the retinal surface and, following incubation in DMEM culture medium, retinas were processed with cobalt enhanced diaminobenzidine. Two types of horizontal cell are seen in the marsupial retina, one with and one without an axon. The cell type with an axon has many fine dendrites with an average dendritic length of about 100 μm and an axonal arborisation. Dendrites in the axonless cells are 300-400 μm in length and each cell has 3-5 dendrites in the quokka and 8-10 in the possum. Immunohistochemical processing of other retinas revealed that calbindin immunoreactivity is restricted to the horizontal cells with axons. To establish birth dates of these two types of horizontal cell, animals were injected with tritiated thymidine during either the first or second phase of retinal cell generation. Animals were grown to maturity, retinas were processed as above to reveal horizontal cells and then sectioned horizontally in plastic (Historesin, Reichert-Jung) at 3 μm and processed for autoradiography. Both types of horizontal cell were found to be produced in the first phase of retinal cell generation.

225.14

CHOLINE ACETYLTRANSFERASE (ChAT) IMMUNOREACTIVITY IN THE EMBRYONIC OPOSSUM RETINA. L. Camargo* & J.N. Hokoç. ¹Dept. Histologia e Embriologia & ²Instituto de Biofísica CCF. UFRJ. BRAZIL.

Immunocytochemical localization of ChAT in the opossum retina revealed, as in other mammals, two major populations of cholinergic neurons. One with cell bodies in the inner nuclear layer and dendrites arborizing in sublamina 2, another with the soma in the ganglion cell layer and dendrites reaching sublamina 4 of the inner plexiform layer (IPL). In this report we follow the time course of differentiation of these cells and compare this information with other events of development. Retinal sections from opossums 12-67 postnatal days were incubated in anti-ChAT serum (Hersh) and the reaction was visualized by the PAP method. The first ChAT(+) cell bodies were seen at P31 and immunoreactive processes and strata at P40. At P50 the ChAT(+) pattern is very similar to the adult. The onset of ChAT expression was the same at the inner nuclear and ganglion cell layers. In the north american opossum retina, the development of IPL is completed at P17 and the formation of conventional synapses at P30. Thus, in this animal ChAT phenotype is expressed after the establishment of synaptic contacts in the IPL.

POSTNATAL DENDRITIC MODIFICATION IN AN IDENTIFIED POPULATION OF HAMSTER RETINAL GANGLION CELLS. R.J.T. Wingate* and I.D. Thompson* (SPON: Brain Research Association). University Lab. of Physiology, Oxford University, Parks Road, Oxford OX1 3PT, U.K.

We have used a combination of fluorescent retrograde tracers and *in vitro* intracellular techniques to follow the dendritic development of retinal ganglion cells with an aberrant, uncrossed projection from nasal retina. These cells are characterised by a preferential postnatal elimination which leaves a small adult population of mainly sparse, type III dendritic morphologies. By making an injection of rhodamine latex microspheres into the ipsilateral optic pathway, cell bodies in this aberrant population can be labelled. After an appropriate survival time, retinas were lightly fixed, removed and placed under a compound microscope with a fixed stage and UV epifluorescence. Labelled cell bodies were selectively impaled with a glass micropipette and injected with Lucifer Yellow by iontophoresis to reveal their complete dendritic arbors. At postnatal day 1 (P1), arbors are uniformly small and sparse. Rapid dendritic growth and elaboration occur throughout the period of cell death so that by the end of this period (P13), diverse and complex cell morphologies are present. The adult morphology that characterises this population arises by a dramatic dendritic pruning coincident with eye opening (P16). This loss of complexity appears greater than the simple retraction of spines and transients that accompanies normal retinal ganglion cell maturation. The effect of an activity blockade on this regressive event was examined by the intraocular application of tetrodotoxin.

Developmental interactions between α and β cell dendritic arborizations in the cat retina. S. Deplano*, G.M. Ratto* and S. Bisti. Lab. of Neurophysiol. CNR, 56100 Pisa, Italy and Inst. of Comparative Anatomy, University of Genova, 16126 Genova, Italy.

In the adult retina of the cat the dendritic fields of a well-defined physiological class of ganglion cells form a mosaic-like structure with little overlap between cell territories. It has been suggested that this pattern results from complex shaping interactions taking place during development between cell dendrites of the same class. No interactions seem to occur between cells of different classes. The aim of the present study was to test the possibility that also dendrites of different cell classes interact. We have analyzed the effect of a small lesion to the retina of a two days old kitten and observed that after degeneration of ganglion cells whose axons were severed, a restricted region of the retina remained depleted of cells. Cells located near the borders of the depleted zone showed an abnormal elongation of dendrites projecting towards the bare area. By means of a computer aided system we analyzed the whole population of cells at the two borders and, in agreement with previous data, we found that the effect was most prominent at the border and progressively decreased to eventually disappear while moving away to a distance of approximately 500 μ m. The distance from the border, however, is not the only factor to influence the degree of asymmetry: with comparable distances, the vicinity of an α cell reduces the projection of the β cell dendrites toward the empty area. We suggest that the organization of the adult retinal pattern may be influenced also by interactions occurring between dendrites of different classes of ganglion cells.

CELL GENERATION, DEATH, AND RETINAL GROWTH DURING THE PROTRACTED DEVELOPMENT OF THE CALIFORNIA MOUSE. A.A. Dos Santos and D.B. Sengelaub. Program in Neural Science, Dept. of Psychology, Indiana University, Bloomington, IN 47405.

The California mouse (*Peromyscus californicus*) and the Syrian hamster (*Mesocricetus auratus*) are closely related cricetid rodents who differ dramatically in developmental duration and rate. Like all developmental features, retinal development in the California mouse is protracted, but the events and their consequences are strikingly similar to those seen in the hamster, resulting in virtually identical retinal morphologies. We are studying the protracted development of the California mouse to determine how generational and post-generational events interact in the development of retinal morphology.

Mice were pulse-labeled with tritiated thymidine on one of days 18 through 28 postconception (PC; day of birth=PC33), the period of retinal ganglion cell layer (RGCL) generation. Pups were killed prenatally (PC30), postnatally (PC36,41,46), or as adults (PC92) to assess the effects of cell generation, death and retinal growth. As in hamster, RGCL generation proceeded with both center-to-periphery and temporal-to-nasal progressions. Initial (PC30) distributions of labeled cohorts differed from their adult distributions, indicating that post-generational events sculpt individual cohorts. As in hamster, the distribution of labeled cells changed differently for each cohort during the period of cell loss. After cell death, the distributions of labeled cells changed similarly, suggesting an alteration by a mechanism common to all cohorts such as retinal growth. While similar to hamster, the protracted development of the California mouse allows a greater resolution of the temporal and spatial patterns of cell generation, death, and retinal growth that sculpt its hamster-like retinal morphology.

RADIALLY ASYMMETRIC GROWTH OF FISH RETINAS WITH SPECIALIZED AREAS. S. S. Easter, Jr. Dept. Biology, U. Michigan, Ann Arbor, MI 48109; and Vision, Touch, and Hearing Res. Centre, U. Qld., Brisbane, Australia.

The goldfish retina adds new ganglion cells at its margin, with the result that generations of cells occupy concentric retinal annuli, old centrally, young peripherally. Young and old retinas all subtend an optical field of about 180 degrees, so a cell's receptive field is initially peripheral and later moves centrally. The goldfish retina is homogeneous, but other fish have a small temporal area, with high cell density, for high acuity vision. How do they keep a specialized area in temporal retina while growing all around the retinal margin?

I have exploited the fact that each new generation of ganglion cells sends its axons together into the optic nerve. Retinas with attached optic nerves were obtained from sand perch, leather-jackets, and dragonets, which have a specialized area, and goldfish, gobies, and humbugs, which do not. They were fixed in paraformaldehyde. Dil was applied to 1-5 locations in the cross section of the nerve; it labeled generations of optic fibers and, via retrograde diffusion, their somata of origin, which were viewed in whole-mounts.

Labeled annuli in those retinas without specialized areas were roughly concentric around a nearly central optic papilla, consistent with radially symmetric growth. In those retinas with specialized areas, the labeled annuli were very asymmetric. The oldest annuli, labeled through fibers radiating from the central end of the elongate optic papilla, lay in temporal retina. The specialized area was within this early annulus, indicating that it was formed from the oldest retina. More peripheral annuli were skewed oppositely; they nested very close to the old annuli in peripheral temporal retina (indicating little late retinal growth temporally), but ballooned out widely in dorsal, ventral, and especially nasal retina (indicating substantial late retinal growth in these sectors).

In summary, radially asymmetric retinal growth maintains the specialized area in roughly the same part of the retina throughout life.

AGE-RELATED CHANGES IN SPATIAL DENSITY OF RETINAL CELLS IN ALBINO RATS. W. Krebs and I. Krebs*. Dept. of Cell Biology and Anatomical Sciences, The City University New York Medical School, New York, NY 10031.

The spatial densities of retinal neurons have been determined in electron micrographs of tangential serial sections through the retina of laboratory albino rats 4 to 28 weeks of age. Retinal samples were taken 500 μ m from the rim of the optic disk (see: Krebs, Krebs and Worgul: Rad Res 123:213,1990).

Between weeks 6 and 12, the cell density of the pigment epithelium dropped from 2,000 to 1,500 cells/mm²; of photoreceptor cells, from 500,000 to 400,000 cells/mm²; of horizontal cells, from 800 to 600 cells/mm²; and of bipolar cells, from 70,000 to 60,000 cells/mm². The densities of amacrine cells (20,000/mm²), ganglion cells (9,000/mm²), and radial glial (Müller) cells (10,000/mm²) did not change in the age range examined. The data imply that the retina of the laboratory rat may not be mature before the age of 6 weeks.

RETINAL TARGET GENESIS DURING THE PROTRACTED DEVELOPMENT OF THE CALIFORNIA MOUSE. D.A. Schaefer* and D.B. Sengelaub. Program in Neural Science, Indiana University, Bloomington, IN 47405.

The California mouse (*Peromyscus californicus*) and the Syrian hamster (*Mesocricetus auratus*) are closely related cricetid rodents who differ dramatically in developmental duration and rate. Like all developmental features, retinal development in the California mouse is protracted, but the events and their consequences are strikingly similar to those seen in the hamster, resulting in virtually identical retinal morphologies. We are examining the neurogenesis of thalamic and midbrain retinal targets in the California mouse for similar evidence of protraction with a preservation of developmental patterns.

Mice were pulse-labeled with tritiated thymidine on one of days 9 through 30 postconception (PC; day of birth=PC33). Labeled cells were counted at adulthood (PC90) in the superior colliculus and the dorsal and ventral lateral geniculate. As in hamster, neurogenesis of the California mouse retinal targets commenced coincident with, or just prior to, retinogenesis (PC16-17). Cell generation extended over a significantly longer period than in hamster (11-12 days), with neurogenesis peaking at PC20-21 and declining rapidly thereafter. In all structures, large neurons were generated earliest and smaller, glial-like cells became more abundant after PC24. Generation began and ended earlier in the superficial gray layer of the colliculus than in the deeper laminae. Evidence of a lateral-to-medial pattern in cell generation was observed in the dorsal and ventral geniculate, consistent with the spatial pattern reported in hamster (Crossland and Uchwat, '82). Thus, as in retina, development of the retinal targets in the California mouse is protracted relative to the hamster, but the temporal and spatial patterns of neurogenesis are similar.

QUANTITATIVE ANALYSIS OF LOCAL REGENERATION IN THE RETINA OF THE GOLDFISH. K. J. Lindsey and P. F. Hitchcock. Ophthalmology; Anatomy and Cell Biology; The Neuroscience Program, University of Michigan, Ann Arbor, MI 48105

Local retinal damage in the goldfish is repaired by local regeneration (Hitchcock, P.F., [1990], Neuroscience abstracts). To quantitate this regeneration and gain insights into its control, we, 1) compared the planimetric density of cells (#/mm²) in regenerated retina to adjacent, intact retina, and 2) taking advantage of the large changes in cell density with retinal growth (from high to low), compared the density of regenerated cells in a subset of animals: 5 small fish and 2 large ones. The data were expressed as the ratio of the planimetric densities.

Patches of retina, 0.5-1.5mm on a side, were excised using a trans-scleral surgical approach. Animals survived 5 months. Cells were counted in 5 μ m sections.

The regenerate:intact ratio (n=14) was 0.85. The small:large ratio for the intact retinas (excluding rods whose density doesn't change with growth; Johns, [1977] J. Comp. Neurol., 176:331) was 2.1. The small:large ratio for the regenerated patches was 1.4. The smaller small:large ratio for the regenerated patches is due to a relatively higher cell density within the large retinas. The data indicate that within each eye the density of the regenerated cells tends to approximate that of the surrounding, intact retina. EY07060; EY07003; T32 MH14279.

SYNAPTIC CONTACTS INCREASE AS MATURE DENDRITES GROW IN THE RETINA OF THE GOLDFISH. Peter F. Hitchcock, Departments of Ophthalmology & Anatomy and Cell Biology, The University of Michigan, Ann Arbor, MI 48105

As the goldfish retina expands, the dendritic arbors of 'mature,' large-field ganglion cells grow by a simple increase in the length and girth of individual dendritic segments, without a change in the dendritic architecture (Bloomfield and Hitchcock, [1991] *J. Neurosci.*, 11: 910-917). These arbors are in a neuropil that continually adds new synapses, but maintains a constant afferent neuron:ganglion cell ratio. I sought answers to two questions: 1) are synapses added to arbors as they enlarge, and 2) is the addition of new synapses related to the changes in the arbor geometry?

Ganglion cells from large, old (n=2) and small, young fish (n=3) were intracellularly labeled with HRP and serially sectioned for electron microscopy. Synapses were tallied from a 1-in-10 series of sections for each arbor.

On average the large arbors were 1.7X longer, had 2.5X more surface area, and were 3.9X greater in volume than the small arbors. The larger arbors were contacted by 2.7X more bipolar synapses and 1.7X more amacrine-cell synapses than the small ones. This indicates that these arbors receive more synapses from each presynaptic neuron as they grow, and the addition of bipolar and amacrine-cell synapses may reflect different aspects of the arbor's changing geometry. EXPRESSION OF HOMEBOX mRNAs IN ADULT GOLDFISH RETINA. E. Levine, R. Druger, and N. Schechter, Departments of Biochemistry and Psychiatry, SUNY at Stony Brook, NY 11794.

Unlike visual systems of higher vertebrates, the goldfish visual pathway displays continuous growth and differentiation throughout life. Homeobox gene products have been implicated as potential regulators of embryogenesis and central nervous system development. We have begun studies to determine if homeobox gene products are involved with the regulation of gene expression in the goldfish retina. The PCR was used to obtain portions of the homeobox from cDNAs derived from adult retina. Clones were isolated and sequenced and their predicted amino acid sequences showed greater than 90% homology to four previously cloned homeobox genes. The pattern of expression of these clones in various tissues is being investigated by northern hybridization. Another clone had 60% amino acid homology to an invertebrate homeobox and less than 20% homology to any vertebrate homeobox. We suggest that this clone represents a novel vertebrate homeobox. Preliminary northern data shows this clone to be expressed in a tissue specific manner. Since the goldfish displays a remarkable capacity for optic nerve regeneration after injury, we are investigating the role of homeobox gene expression during regeneration. REGENERATION: MOLECULAR CORRELATES

226.1

TRANSIENT C-FOS EXPRESSION AND DENDRITIC SPINE PLASTICITY IN PARTIALLY DEAFFERENTED HIPPOCAMPAL GRANULE CELLS. D.E. Hillman and S. Chen, Dept. Physiol. & Biophys. NYU Med. Ctr., New York, NY 10016.

A marked plasticity of dendritic spines and synaptic sites in the inner molecular layer occurs following partial deafferentation of dentate granule cells. (*Soc Neurosci Abst.*(1988) 14:1133). Within two hours of unilateral lesion to the entorhinal cortex or within of rats, the immediate-early gene, c-fos, was activated ipsilaterally in granule cell nuclei of the dentate gyrus. Beta adrenergic blocker, propranolol, completely negated the c-fos response indicating expression of this c-fos gene through norepinephrine. By 24 hours of deafferentation, the dendritic endoplasmic reticulum (normally extending into the spine neck as a single tube) elaborated into complex folds. The complex spine apparatus was associated with a widened spine neck and frequently cradled a multivesicular body with a coated patch on the surface. As previously described, ribosomes lined the ER and were also free in the spine head and dendritic shaft (Steward, O & Reeves, TM, *J. Neurosci* 8:176-84). By 3 days, the undifferentiated dendritic spines began to extend around boutons and the synaptic sites enlarged, became perforated and had irregular boundaries. We conclude that immediate-early genes, such as c-fos, are important links in signaling late-response genes for generating building blocks needed in plasticity and reorganization of remaining synaptic connections. 226.2

JUN, FOS, MYO D1, AND MYOGENIN PROTEINS ARE INCREASED IN SKELETAL MUSCLE FIBER NUCLEI AFTER DENERVATION. J. Weis, Inst. of Pathology, Aachen Univ., W-5100 Aachen, Germany

After denervation of skeletal muscle, mRNA levels of the c-jun and c-fos protooncogenes are increased (Besse-reau et al., *New Biol.* 2, 375, 1990). The increase of c-fos was interpreted as part of a muscle fiber "dedifferentiation" process following denervation. This hypothesis was supported by the finding that fos represses myogenic differentiation of cultured cells induced by the myogenic factor MyoD (Lassar et al., *Cell* 58, 659, 1989).

We used immunohistochemistry to assess the expression of c-jun and c-fos as well as MyoD1 and the homologous factor myogenin in normal and denervated muscle. Rat diaphragms were denervated and analyzed after periods of 90 min to 8 d. An increase of fos, jun, MyoD1, and myogenin immunoreactivity was found after 2 - 2.5 d of denervation. MyoD1 and myogenin immunoreactivity was mostly confined to muscle fiber nuclei, whereas fos and jun antisera stained muscle fiber as well as some interstitial cell nuclei in denervated muscle. After 8 days of denervation, clusters of smaller cells, presumably satellite cells, showed strong staining for MyoD1 and myogenin.

These results suggest that a genetic program which includes expression of genes that are involved in proliferation (jun, fos) as well as myogenic differentiation (MyoD1, myogenin) is activated in skeletal muscle fibers after denervation.

226.3

EARLY MOLECULAR RESPONSES TO AXOTOMY AND DEAFFERENTATION: CHOLINERGIC NEURONS. M. Weiser, H. Baker, T. Wessel and T.H. Joh, Lab. Molec. Neurobiol. Cornell Univ. Med. Coll., Burke Med. Res. Inst., White Plains, NY 10605

Cholinergic neurons of the horizontal limb of the diagonal band (HLDB) have axons which travel rostrally to terminate within the olfactory bulb and are axotomized by olfactory bulb decentralization. Cholinergic interneurons within the corpus striatum (CS) receive afferent modulation from catecholaminergic neurons of the substantia nigra pars compacta (SNc). Removal of this dopaminergic input is achieved by transection of the medial forebrain bundle and results in partial deafferentation of the cholinergic interneurons in the CS. To compare the acute effect of axotomy versus deafferentation on gene expression for choline acetyltransferase (ChAT) and c-Fos mRNAs and proteins, Sprague-Dawley rats were examined by immunohistochemistry and *in situ* hybridization. Following unilateral olfactory bulb decentralization, no alterations in ChAT or c-Fos levels were observed in the axotomized neurons of the HLDB between 1 and 24 hours. In contrast, neurons in the piriform cortex which receive afferents from the olfactory bulb and are deafferented by this lesion, exhibited a large increase in c-Fos. In addition, cholinergic interneurons in the CS partially deafferented by a transection of the catecholaminergic neurons of the SNc showed a large induction of c-Fos between 1 and 2 hours. These data suggest that deafferentation, not axotomy, results in c-Fos induction in these cholinergic systems. Supported by MH44043 and AG08702.

226.4

EARLY MOLECULAR RESPONSES TO AXOTOMY AND DEAFFERENTATION: CATECHOLAMINERGIC NEURONS. T.H. Joh, M. Weiser, T. Wessel, and H. Baker, Cornell Univ. Med. Coll., Burke Med. Res. Inst., White Plains, NY 10605

A micro-knife lesion placed rostral to the substantia nigra transects the medial forebrain bundle (MFB) and axotomizes both the catecholaminergic neurons of the substantia nigra pars compacta (SNc) and deafferents the GABAergic neurons of the substantia nigra pars reticulata (SNr). In addition, catecholaminergic neurons in the locus ceruleus (LC), far removed from the site of injury, are also axotomized by this lesion. To determine the acute alterations in gene expression in response to axotomy and deafferentation, the distribution of and temporal changes in the mRNA and protein levels for tyrosine hydroxylase (TH) and c-Fos were examined in adult male Sprague-Dawley rats by immunohistochemistry and *in situ* hybridization. Following a unilateral lesion of the MFB, the axotomized neurons of the SNc exhibited no alteration in TH or c-Fos levels between 1 and 24 hours. In contrast, a dramatic increase in c-Fos protein occurred with maximum expression at 6 hours in the deafferented neurons of the SNr. Furthermore, a large increase in c-Fos protein was seen in the axotomized neurons of the LC also reaching a maximum at 6 hours. The transient expression of c-Fos in the LC was followed at 24 hours by an increase in TH mRNA. These data suggest that the neuronal response to axotomy and deafferentation is not stereotyped but is both region and phenotype specific.

THE EXPRESSION OF TGF-B1 MRNA INCREASES DURING WALLERIAN DEGENERATION IN THE PNS. S.S. Scherer* and S.B. Jakowlew. Dept. Neurol., Univ. Penn. Sch. Med., Philadelphia, PA 19104, and Lab. Chemoprevention, NIH, Bethesda, MD 20892.

Transforming growth factor (TGF)-B1 inhibits cellular proliferation of many cell types, but is mitogenic for Schwann cells (Ridley et al., J. Cell Biol. 109:3419). Since Schwann cells are well known to proliferate during Wallerian degeneration, we investigated whether the possibility that TGF-B1 might be involved in this proliferative response. The sciatic nerves of adult rats were either ligated and transected (to prevent axonal regeneration) or crushed (to allow axonal regeneration), and RNA was isolated from distal nerve-stumps at 1, 4, 8, 12, and 24 days post-lesion. Ten ug of total RNA from each time point was separated on agarose-formaldehyde gels, transferred to nylon membranes, and individual blots were hybridized with a cDNA probe for TGF-B1, then sequentially rehybridized with a cDNA probe for nerve growth factor receptor (NGFR) and the major myelin glycoprotein Po. In transected nerves, the levels of TGF-B1 and NGFR mRNA in the distal nerve-stump increased to a maximal extent by 4 days post-transection and remained at this level for at least 24 days, while the level of Po mRNA decreased in a reciprocal pattern. The steady state levels of TGF-B1 and NGFR mRNA increased in the distal nerve-stump of crushed nerves, too, but then decreased by 24 days post-crush, while the level of Po mRNA increased at 24 days post-crush in a reciprocal pattern. This decline in TGF-B1 and NGFR mRNA and increase in Po mRNA coincided with the remyelination of regenerated axons. We are currently performing immunocytochemistry to localize TGF-B1 in transected and crushed nerves.

ANALYSIS OF THE RNA LEVELS OF SR13 (GAS-3) IN RAT SPINAL CORD AFTER SCIATIC NERVE TRANSECTION AND COMPLETE FREUND'S ADJUVANT (CFA)-INDUCED INFLAMMATION. M.M. Divish*, M. De León, R. Nahin and M.A. Ruda. Neurobiology and Anesthesiology Branch, NIDR, NIH, Bethesda, MD 20892

We are interested in studying the molecular changes associated with axonal injury and nerve regeneration. Previously we reported the isolation of a cDNA clone named SR (sciatic repressed) 13 from a rat sciatic nerve cDNA library that was found to be repressed in the sciatic nerve three days after nerve crush. Further characterization of this cDNA found that it is the rat homolog of the growth arrest gene 3 (gas-3) (Welcher et al, submitted). In the present study we analyzed the mRNA expression of SR13 in the rat spinal cord after two kinds of manipulation 1) sciatic nerve transection and 2) peripheral inflammation and hyperalgesia produced by unilateral hindpaw injection of CFA. Three days after treatment, the L4-5 segments of the spinal cord were collected and the RNA was extracted ipsilaterally and contralaterally. The RNA was fractionated in a formaldehyde agarose gel, northern blots were performed following standard techniques, and the membranes hybridized with 32P-labeled SR13 cDNA. RNA blot analysis demonstrated that the SR13 cDNA recognized a 1.8 kb mRNA species in the spinal cord similar (although less abundant) to that found in the sciatic nerve. We found that both nerve transection and CFA-induced inflammation triggered at least a two-fold induction of SR13 mRNA by day 3 after treatment on the ipsilateral side of the spinal cord as compared with the contralateral, untreated side. The mRNA level returned to normal by day 10. Our results suggest that both nerve transection and inflammation signal the regulation of SR13 (gas-3) in the central nervous system and that this response is uniquely different from that observed in the peripheral environment at the site of the injury.

RNA POLYMERASE ACTIVITY IN DORSAL ROOT GANGLION NEURONS AFTER NERVE CRUSH. M. R. Wells and U. Valdivya. Nerve Regeneration Research Laboratory, VA Med. Center, Northport, N.Y. 11768 and Depts. of Neurology and Psychiatry, SUNY, Stony Brook, N.Y. 11794.

After crush injuries to the sciatic nerve, dorsal root ganglion neurons undergo a complex series of metabolic changes which include phasic increases in RNA synthesis approximately one week apart. We wished to determine if these increases in RNA synthesis are accompanied by corresponding changes in RNA polymerase (RNAP) activity. Male, Wistar-Furth rats were subjected to unilateral crush lesions of the sciatic nerve at the level of the sciatic notch. At 12 hours, 1, 2, 3, 4, 5, 7, 8, 9, 11, 14, and 30 days after nerve crush, animals were perfused with buffered isotonic sucrose and the L5 lumbar ganglia removed bilaterally. RNA polymerase activity over nucleoli and nucleoplasm in neurons was measured autoradiographically on frozen sections by the method of Moore (Exp. Cell Res. 111: 317,1978) and compared the activity of sections from normal animals placed on the same slide. Compared to the unoperated side and normal controls, L5 ganglia from the side of the nerve crush showed a biphasic increase in RNAP activity consisting of two peaks between 1 to 5 days and 8 to 14 days after injury. Changes of similar magnitude occurred in both nucleolar (RNAP I) and non-nucleolar (RNAP II & III) RNA polymerase activity, although RNAP I appeared to peak first. There were no significant changes in RNA polymerase activity on the unoperated side compared to normal at any time point. The results suggest that RNA polymerase activity may be one mechanism through which the metabolism of injured neurons is controlled. Supported by the Veterans Administration.

226.6

GROWTH-ASSOCIATED GENE EXPRESSION DURING NEURONAL REGENERATION IS A FUNCTION OF THE AMOUNT OF AXON LOST. T.C. Mathew and F.D. Miller. Dept. of Anat. and Cell Biol., Univ. of Alberta, Edmonton, Alberta, CANADA.

We have previously demonstrated that the regeneration of sympathetic neurons is associated with increased expression of τ 1 α -tubulin mRNA. To elucidate the signals responsible for inducing a growth response following axonal injury, we have examined the expression of τ 1 mRNA following axotomy proximal to (a close cut) and distal to (a long cut) the superior cervical ganglion (SCG) of adult rats. The peak induction of τ 1 mRNA in the SCG occurred 5 days following either a long cut or a short cut, as indicated by Northern blot analysis. To determine the magnitude of this response on a per neuron level, we developed the following experimental paradigm. Sympathetic neurons that project from the SCG to the iris via the internal carotid nerve (ICN) were retrogradely labelled by injection of fast blue into the anterior chamber of the eye, while those that project via the external carotid nerve (ECN) to the pinna of the ear were retrogradely labelled with fluorogold. Following labelling, postganglionic axons that project to the iris were long cut by enucleating the eye, while those that project to the ear were short cut by transecting the ECN close to the ganglion. In situ hybridization analysis of fast blue versus fluorogold-labelled neurons in the same ganglia (done to minimize intersection variability) demonstrated that the peak level of expression of τ 1 mRNA was two- to three-fold higher in neurons axotomized close to their cell bodies as opposed to those transected distally. These results suggest that neurons are capable of monitoring the severity of the axonal damage, and of responding appropriately.

226.8

IDENTIFICATION OF GENES TRANSCRIPTIONALLY REGULATED AFTER SCIATIC NERVE CRUSH. M. De León*, A. A. Welcher*, U. Suter*, M. A. Ruda* and Eric M. Shooter*. *Neurobiology and Anesthesiology Branch, NIDR, NIH, Bethesda, MD, 20892 and *Department of Neurobiology, Stanford University, California, 94305-5401

The local environment at the sciatic nerve crush injury site may play an important role in modulating the neuronal response to axotomy. In order to characterize the molecular response present in this region, we have analyzed a group of genes that were found to be transcriptionally regulated after sciatic nerve crush. cDNA libraries were constructed from either the nerve segment distal to the crush site or the corresponding contralateral uninjured nerve of the same animal at day three after crush. These cDNA libraries were screened by differential hybridization and several transcriptionally repressed and induced sequences were isolated. In the contralateral segment library we found 30 colonies containing sequences that were repressed after sciatic nerve crush. Among these we found five sequences that were dramatically repressed and included creatine kinase (muscle type M), Myelin basic protein, Myelin P0 and a novel cDNA named SR-13, that after further characterization and sequencing, was found to be the rat homolog of growth arrest gene 3 (gas-3) (Welcher et al, submitted). Screening of the ipsilateral distal library resulted in eleven sequences found to be induced, including the rat homolog of vimentin. We also found a novel sequence called Distal Induced 12 (DI12) that showed homology at the nucleotide level with the Human FK506-binding protein. Northern blot analysis confirmed the regulation shown by these sequences after axonal crush. The observed pattern of complex regulation suggests that the local environment at the site of injury plays an important role during neuronal injury and regeneration.

226.10

CYTOSKELETAL GENE EXPRESSION FOLLOWING AXOTOMY IN THE PNS IN YOUNG VERSUS AGED ALBINO RATS. S.L. Cassar, C.A. Leonard and W. Tetzlaff. Neuroscience Research Group, University of Calgary, Calgary, Alberta, Canada, T2N 4N1.

Peripheral nerves regenerate more slowly in aged versus young adult animals. We investigated whether or not changes in cytoskeletal gene expression in facial motoneurons following axotomy were less pronounced in aged versus young rats. Adult Sprague-Dawley rats aged 4, 16 and 23 months underwent a left-sided facial nerve transection. At 14 days post lesion the animals were sacrificed and cryostat sections through the facial nerve nucleus underwent *in situ* hybridization. We noted a consistent decrease in the expression of neurofilament mRNA, as well as a consistent increase in the levels of alpha-tubulin mRNA in axotomized facial motoneurons, as compared to undamaged contralateral control facial motoneurons. This response was quantitatively similar across all age groups.

These results demonstrate that, following axotomy, the gene expression of neurofilament and alpha-tubulins in aged mammalian motoneurons are similar to those seen in young adults. This indicates that the slower regeneration rate of injured peripheral nerves seen in aged animals is not due to a less vigorous gene expression response.

DOPAMINERGIC RECOVERY FOLLOWING A UNILATERAL NIGRAL LESION IN THE RAT. J.S. Lamberti*, S.Y. Felten, S.B. Schwarzkopf, D.L. Felten. Dept. of Neurobiology and Anatomy, Univ. Rochester Sch. of Med., Rochester, NY 14642.

Unilateral injection of 6-hydroxydopamine (6-OHDA) into rat substantia nigra has been shown to produce degeneration of the nigrostriatal dopaminergic pathway. While recovery has been demonstrated, its mechanisms and time course remain unclear. In this study we examined striatal dopamine (DA) concentrations at various times following a unilateral nigral lesion.

69 eleven week old male Fischer rats received either a left nigral injection of 8 µg 6-OHDA, sham injection of 4 µL saline, or no treatment. All animals underwent rotometry following 5 mg/kg amphetamine infusion, with lesioned animals demonstrating at least 7 rotations/min. Animals were then sacrificed and left dorsal striatum was removed for analysis at 10, 30, or 90 days post lesion. DA concentrations in lesioned animals were 5.3%, 21.1%, and 10.0% of controls at those time periods respectively (t-test p<.05), while control and sham groups showed no significant differences. Anatomical studies are presently underway to determine the extent to which this pattern of recovery is due to metabolic regulation or regenerative sprouting. This work was supported by grants NIH AG06060 and NIMH MH40381.

NEUROPEPTIDE CHANGES IN THE RAT LUMBAR DORSAL HORN AFTER SCIATIC DEAFFERENTATION INDUCED BY INJECTION OF THE SCIATIC NERVE WITH PRONASE. A. El-Bohy and C.C. LaMotte. Section of Neurol. Surgery, Yale Univ. Sch. of Med., New Haven, CT. 06510.

Sciatic deafferentation was induced by injecting the sciatic nerve of anesthetized rats with proteolytic enzymes (10-20mg Pronase). The effects of this chemical deafferentation were examined in two animal groups, i.e., short term (10-13 days) and long term (4-6 months) after injection, using a computerized densitometry analysis system. The L1-L5 segments and C5 control segments were removed, sectioned, and immunostained. The density of the label in the dorsal horn was measured for each section and the results were compiled for the segments L1-3 and L3-5. Using a paired t-test, we found a highly significant decrease in CGRP and SP on the pronase side at both the L1-3 and L3-5 levels in both the short term and the long term rats. In the long term group, the loss of CGRP staining was significantly less than that in the short term animals, indicating partial recovery. A similar trend was observed for SP. The results also indicated that recovery was greater in the L1-3 than that in the L3-5 levels for both peptides. The large decrease in CGRP and SP seen in short term animals reflects the large contribution of the sciatic nerve to the lumbar dorsal horn. The partial recovery of peptides may parallel sprouting of primary afferents from other nerves, such as the saphenous nerve, as we have demonstrated in previous studies. (Aided by grants from the Paralyzed Veterans of America Spinal Cord Research Foundation #880, the Eastern Paralyzed Veterans of America, and NIH Grant NS28876).

PREFERENTIAL GROWTH OF ADULT SENSORY NEURONS ON SECTIONS OF LESIONED PERIPHERAL NERVE IS NOT DEPENDENT ON NGF.

(1) K.S. Bedi, (2) J. Winter(*), (3) M. Berry and (3) J. Cohen (*). (1) Dept. of Anatomy, University of Queensland; (3) Div. of Anatomy and Cell Biology, UMDS, Guy's Campus, London, and (2) Sandoz Inst. Med. Res., London.

In adult rats the axons of DRG neurons regenerate within damaged peripheral nerves. We have investigated whether cultured DRG neurons from adult rats could be induced to grow on various CNS and PNS tissue sections. Cryostat sections were prepared from freshly frozen rat tissues including lesioned and non-lesioned cerebrum, cerebellum, peripheral and optic nerves and picked up on coverslips. Dissociated adult rat DRG neurons were cultured with or without NGF on the tissue sections for 3-5 days. Neurites were visualized by immunostaining with antibodies to GAP-43 and neurofilaments. Only sections from lesioned peripheral nerves supported neurite outgrowth. This was independent of the presence of exogenous NGF. The neurite growth was largely parallel to the long axis of longitudinally-sectioned nerves. This tissue culture model system mimics the situation seen in regenerating sensory peripheral nerves *in vivo* and offers a unique opportunity to examine underlying mechanisms.

226.12

REGULATION OF β -PREPROTACHYKININ mRNA AND SUBSTANCE P IN RAT DRG NEURONS AFTER NEONATAL SCIATIC NERVE LESION. F. Nothias, A. Tessier, W. Battisti, M-F Chessex¹ and M. Murray. Dept. of Anat. & Neurobiol., Med. Coll. of Penn., Philadelphia, PA 19129; ¹Dept. of Pharmacol., Univ. of Penn., Philadelphia, PA 19104.

Previous studies using sciatic nerve (SN) section have shown that in adult rat DRG neurons, SP and its mRNA decrease and do not recover if regeneration is prevented. In neonates, large numbers of DRG neurons die after SN axotomy but recovery of SP-immunoreactivity (SP-IR) in the dorsal horn (DH), mediated by dorsal roots, is observed by 60 days, even if regeneration is prevented. We tested the hypothesis that this developmental effect is related to a permanent increase of SP synthesis and its gene expression in the remaining DRG neurons. Sixty days after neonatal SN axotomy, L4 and L5 DRG sections were used for *in situ* hybridization histochemistry using preprotachykinin (PPT)^{35S}-cRNA probes, and immunocytochemistry for SP. Contralateral DRG served as controls. In the control and operated DRG, both PPT-mRNA hybridization and SP immunostaining were observed in medium and mostly small size neurons. SP-IR in both DH is comparable, but the total number of PPT-mRNA and SP-IR labelled neurons is lower in operated DRG than in control. The mean levels of hybridized PPT-mRNA and SP-IR per neuron in DRG ipsilateral to the lesion, were, however, comparable to the control. These data show that after neonatal sciatic axotomy, PPT-mRNA and SP-IR recover in DRG neurons but do not exceed that observed in controls, and suggest that both transcriptional and post-transcriptional regulation are different than when SN axotomy is made in the adult. Supported by grants, NIH NS 24707, VA, VSAMRDC 51930002, and AFM.

POTENTIAL ELECTRICAL SIGNALS ASSOCIATED WITH AXOTOMY R.C. Berdan, J. Easaw, and R. Wang. Department of Physiology, University of Alberta, Edmonton, Alberta, Canada T6G 2H7.

Recent molecular studies have found that neurons may undergo rapid changes in gene expression in response to axotomy. We are examining the possibility that changes in membrane potential associated with injury may represent one of the signals associated with axotomy that triggers regeneration. We have recorded intracellularly from identified neurons B5 from the mollusc, *Helisoma*, during axotomy. Axotomy was associated with a short injury discharge and a rapid membrane depolarization. Repolarization took place within 15 minutes. The magnitude of the depolarization recorded in the soma was a function of distance from the site of injury. Superfusion of saline containing elevated potassium onto buccal neurons mimicked the change in membrane potential associated with axotomy. Buccal neurons B5 that were axotomized, organ cultured for 5 days in the presence of elevated potassium (5-50 mM), and then filled with Lucifer yellow and examined by fluorescence microscopy, appeared to exhibit more extensive neurite outgrowth. Isolated neurons B5 cultured in defined culture medium (Liebovitz) containing elevated potassium (5-50 mM), however, did not extend neurites. Using the whole-cell patch clamp technique, both a low-voltage-activated (LVA) and a high-voltage-activated (HVA) calcium currents were detected in neurons B5 after 24 hours in culture. After culturing in depolarizing medium containing 25 mM potassium for 6 days the LVA channel could no longer be detected and the amplitude of the HVA channel current was suppressed approximately 10 fold. This observation indicates that expression of calcium channels may be altered following treatments that alter membrane potential. Together these results are consistent with the hypothesis that membrane depolarization may represent one of the signals associated with axotomy.

226.16

A SIGNAL SEQUENCE MEDIATES THE RAPID RETROGRADE TRANSPORT OF PROTEINS FROM THE AXON INTO THE NUCLEUS.

R. Schmied,* M. Smedman,* and R. T. Amborn. Anatomy and Cell Biology, Columbia University, New York, N. Y. 10032

We have discovered a new feature of retrograde transport that may explain how external signals, e.g. growth factors, cause long-term changes at the presynaptic terminal. Since such changes require transcriptional activation in the nucleus, a signal must be conveyed from the periphery to the cell body. We searched for this signal using neurons of *Aplysia*. When a neuron is placed in culture, the cut axon seals to form a terminal swelling from which neurites emerge. Material injected into this swelling has direct access to the axon.

We coupled the nuclear import signal peptide of the SV-40 T antigen, and then rhodamine, to human serum albumin. The construct (rHSA-sp) was injected into the terminal of neurons *in vitro*. 24h later, all the rHSA-sp was found in the nucleus. Cells 20min to 3h after injection revealed that the rHSA-sp moved rapidly through the axon. Significantly, all transport was in the retrograde direction and none was toward neurites or growth cones. Injected rHSA did not move and rHSA-sp containing a single a.a. substitution in sp, which reduces its efficiency for nuclear import, was transported poorly. Thus, the nuclear import signal peptide is responsible for binding to the retrograde transport system. Microtubules are also involved, since nocodazole blocked transport of both forms of rHSA-sp.

To identify endogenous proteins that might use this transport system, we conjugated soluble proteins from adult nerves to biotin and exposed these proteins to isolated intact neuronal nuclei using a nuclear import system. The nuclei were washed, fixed, and probed with streptavidin-Texas Red. Many nuclei were fluorescent, indicating that they had imported nerve proteins. These findings show that a retrograde transport system in *Aplysia* neurons recognizes an evolutionarily conserved signal peptide that directs axonal proteins to the nucleus. This system may link the needs of the terminal to the biosynthetic machinery in the cell soma.

SEAL FORMATION IN EARTHWORM MEDIAL GIANT AXON FOLLOWING TRANSECTION STUDIED BY COMPLEX IMPEDANCE SPECTROSCOPY. T.L. Krause, H.M. Fishman* and G.D. Bittner. Univ of Texas, Austin, *Univ of Texas Medical Branch, Galveston.

The medial giant axon of the earthworm *Lumbricus terrestris* recovers from transection by reestablishing its resting membrane potential and DC cable impedance (input resistance) with a time course of about 1 hr. Complex (AC) impedance spectroscopy (0.5 to 1000 Hz) provides additional information about conducting structures in the current path prior to and following axonal transection. AC impedance data (400 freq pts) were rapidly acquired (1-2 sec) using two intracellular microelectrodes, 80-200 μ m from the site of transection, in ion-channel blocked axons. Upon transection the impedance decreased dramatically, becoming largely ohmic in character. This was indicative of current flow through the low resistance path created by the transection. Subsequent impedance data acquired at regular intervals were well fitted with an RC model. These curve fits showed temporal changes in both resistance and capacitance consistent with formation of an electrical barrier. At 30 min or more, following transection, the AC impedance was found to be similar to that obtained prior to injury. Thus, the temporal changes in axonal complex impedance suggest that a membranous barrier (seal) forms during recovery from transection. TESTOSTERONE EFFECTS ON AXONAL REGROWTH FOLLOWING SCIATIC NERVE INJURY. K.A. Kujawa and K.J. Jones. Dept. Cell Biology and Anatomy, The Chicago Medical School, North Chicago, IL 60064 and Depts. Physical Therapy, and Anatomy & Cell Biology, Univ. of Chicago, Chicago, IL 60612.

Systemic administration of testosterone propionate (TP) accelerates both the rate of axonal regeneration and functional recovery from facial paralysis induced by facial nerve crush in the hamster. In this study, the hypothesis that TP affects the regenerative properties of spinal motoneurons as well as tested using fast axonal transport of radioactively labeled proteins to assess sciatic nerve regeneration. Adult male rats were castrated under anesthesia. 3-5 days postoperative (dpo), the animals were re-anesthetized and each subjected to a right sciatic nerve crush. One-half the animals immediately received subcutaneous implants of TP, with the others sham-implanted with blank capsules. Postoperative times ranged from 3-7 d. 18 h prior to sacrifice, stereotaxic injections of 3 H-amino acids into the ventral horn at spinal segments T13-L1 were done. Following sacrifice, the radioactivity in 1-mm segments of the right sciatic nerve was determined, and plotted as a function of postoperative time. The furthest distance point at which the radioactivity was ≥ 2 S.D. above background levels defined the outgrowth distance of the fastest growing axons. Thus far, the results indicate that at 5 dpo, the average outgrowth distances in the crush plus TP vs. crush alone groups were 10 mm \pm 0.53 and 6 mm \pm 0.6, respectively. This represented a TP-induced 40% increase in the outgrowth distance. Supported by NS28238 (KJJ).

CASTRATION OF ADULT MALE RATS INCREASES ASTROCYTE REACTIVITY (GFAP) IN THE MOLECULAR LAYER OF THE DENTATE GYRUS. J.R. Day, N.J. Laping, M. Lampert-Etchells*, T.H. McNeill, and C.E. Finch. Andrus Gerontology Center, University of Southern California, Los Angeles, CA 90089.

Increased glial fibrillary acidic protein (GFAP) mRNA and immunoreactivity (IR), as indices of astrocyte reactivity, are apparent in aging, neurodegeneration, deafferented regions and after brain injury. Recently, this laboratory showed that GFAP-IR and mRNA increase in the hippocampus 21 days after castration in unlesioned and entorhinal cortex lesioned (ECL) adult male rats (Day et al., Mol Endocrinol 4:1995). This study quantified the GFAP-IR increase with western blots and determined if gonadal steroid replacement would inhibit the increase in GFAP-IR in the hippocampus. Western blots confirmed that GFAP-IR in the hippocampus increased 21 days after castration (38%, $P < 0.0001$) and that the increase in GFAP-IR 2 days after ECL was enhanced by castration (54%, $P < 0.03$). Four groups of rats ($n=3$) were given subcutaneous silastic implants containing either testosterone (T), estradiol (E2), dihydrotestosterone (DHT), or an empty implant (CAST) on the day of castration. Additional rats served as intact controls. 21 days after castration, rats were perfused and brains were processed for GFAP immunocytochemistry. By videoimage analysis, the area occupied by GFAP-IR (including the soma) was determined within a fixed perimeter containing an individual astrocyte from the dentate molecular layer. This analysis revealed that the area of GFAP-IR increased 36% ($P < 0.03$) CAST vs intact controls. T, E2, DHT implants all suppressed this castration-induced increase to control values ($P < 0.01$). These results indicate that GFAP-IR in adult male rats is responsive to gonadal steroids. We suggest that the increase in astrocyte reactivity after long-term castration is the result of astrocyte hypertrophy and not proliferation (Supported by USPHS Grant AG-07909).

CHRONIC LEVODOPA AND RECOVERY OF NIGROSTRIATAL DOPAMINE NEURONS IN MPTP-TREATED YOUNG MICE. K. Steece-Collier, J.R. Sladec, Jr., S.Y. Felten, D.L. Felten. Department of Neurobiology and Anatomy, University of Rochester, Rochester, NY 14642.

The nigrostriatal dopamine (DA) system in young C57BL/6 mice can recover following damage from the neurotoxin MPTP. This is an excellent model for studying the potential toxicity of levodopa or DA itself on neuronal plasticity. Levodopa has been shown to stunt neurite outgrowth and reduce viability of embryonic nigral neurons. We investigated possible damage of recovering DA neurons by levodopa in MPTP treated mice. Two days after MPTP treatment (4 x 20mg/kg) mice were divided into 3 groups: MPTP/no injection; MPTP/ saline injection; and MPTP/levodopa injection. Levodopa (200mg/kg) or saline was injected twice daily for 5 weeks. HPLC analysis of nucleus accumbens and dorsal and ventral caudate revealed no differences in DA concentration between the 3 treatment groups. A trend toward a selective increase in DA turnover was observed following levodopa treatment in subcompartments of caudate but not in nucleus accumbens. It is possible that levodopa does not damage DA neurons recovering from MPTP in young mice. However, neurochemical analysis by itself is inadequate to assess the anatomical integrity of DA neurons, since upregulated metabolism in surviving cells could compensate for death or injury of neighboring DA neurons. We are assessing this possibility with quantitative morphological methods utilizing immunocytochemistry for tyrosine hydroxylase and GAP43. Supported by United Parkinson Foundation, PO1 NS24032, and R37 AG06060.

TESTOSTERONE EFFECTS ON AXONAL REGENERATION FOLLOWING FACIAL NERVE CRUSH IN FEMALE HAMSTERS. E. Emeric*, K.A. Kujawa and K.J. Jones. Dept. Cell Biology and Anatomy, The Chicago Medical School, North Chicago, IL 60064 and Depts. Physical Therapy, and Anatomy and Cell Biology, Univ. Illinois at Chicago, Chicago, IL 60612.

We have previously demonstrated that testosterone propionate (TP) accelerates the rate of regeneration following facial nerve crush in castrated and intact male hamsters. In this study, we examined the effects of TP and the nonaromatizable form, dihydrotestosterone (DHT), on axonal regeneration in intact females following facial nerve crush. Following anesthetization, adult female hamsters were subjected to right facial nerve crush. One-half the animals immediately received subcutaneous implants of TP or DHT, with the others sham-implanted with blank capsules. Postoperative times ranged from 3-7 d. 18 h prior to sacrifice, stereotaxic injections of 3 H-amino acids into the right facial nuclear groups were done. Following sacrifice, the radioactivity in 1-mm segments of the right facial nerve was determined, and plotted as a function of postoperative time. The furthest distance point at which the radioactivity was ≥ 2 S.D. above background levels defined the outgrowth distance of the fastest growing axons. The results indicate that either TP or DHT accelerates the rate of axonal regeneration in females, albeit to a lesser extent than in the males (10% vs. 30%). This may be due to inherently faster regeneration rates in intact females when compared with intact males. Supported by NIH NS-28238 to KJJ.

MOTOR FUNCTIONAL RECOVERY AND ACHR CONCENTRATION REFLECT SEX DIFFERENCES IN REGENERATION. J. Kume and F.L. Strand. Department of Biology and Center for Neural Science, New York University, New York 10003.

Sex steroids have been shown to affect the non-androgen sensitive muscle, the extensor digitorum longus (EDL) (Kume, J. and Strand, F.L. Soc. Neuroscience, Nov. 1990). The present study explored the relationship between acetylcholine receptor (AChR) concentration and motor recovery in the EDL, after nerve crush in castrated and normal rats. Male and female rats were divided into 3 groups: nerve crushed; castrated, nerve crushed; and castrated with subsequent LHRH antagonist administration (BIM-21009, Biomeasure, Inc., 5mg/kg, s.c.), nerve crushed. In a second experiment, castrated male and female rats were subcutaneously implanted with silastic implants filled with either testosterone propionate or estradiol benzoate. Under anesthesia, the peroneal nerve was crushed at the site of innervation. AChR concentration was found by radiolabelled binding of 125 I- α -bungarotoxin. Motor tests were done on rats used for AChR assays. Digit Distance 1-5 (DD1-5), peroneal functional indices, and % toespread recovery were measured. We found previously that nerve crush increases AChR concentration especially in castrated animals (in this earlier study, LHRH antagonist was the castrating agent used for males only, females were surgically castrated). At 9 days post-crush, a sex difference between castrated groups appears, males having 28% higher AChR concentration than females. This difference is not seen in rats with normal steroid levels. When relating this difference to motor function recovery tests, male sex hormones appear to exert a positive effect on % toespread recovery at day 2 in males, whereas female sex hormones play a negative role in females. (Supported by NIMH grant # MH18882-03.)

COLLAGEN NERVE GUIDES PROMOTE PHYSIOLOGICAL RECOVERY OF A 2cm MEDIAN NERVE DEFICIT IN MONKEYS. S.J. Archibald, C. Kranup, L. Wraga, S.T. Li and R.D. Madison, ¹Departments of Surgery (Neurosurgery) and ²Neurobiology, Duke University Med. Ctr., Durham, N.C. 27710, ³Research Service V.A. Hospital, Durham, N.C. 27710, ⁴Department of Clinical Neurophysiology, Rigshospitalet, Copenhagen, Denmark and ⁵Colla-Tec, Inc., Plainsboro, N.J.

We have recently shown that collagen nerve guide conduits permeable to macro-molecules up to 68kd support and maintain axon regeneration in nerve deficits of 5mm in the median nerve of *Macaca fascicularis* (Archibald et al., J. C. N., 306 (4):685-696, 1991.) Nerve deficits of more than 2cm clinically, are usually repaired with nerve grafting techniques. This study compares motor and sensory physiological recovery following the repair of a 2cm deficit of the median nerve in *Macaca fascicularis*. Adult male monkeys received bi-lateral median nerve section at the wrist and removal of a 2cm segment of nerve, followed by either: A) Sural nerve cable graft repair (n=8 nerves), B) Entubulation repair with 2mm I.D. nerve guide conduits (n=8 nerves). Serial evoked EMGs of the abductor pollicis brevis and sensory nerve conduction studies were performed bi-weekly up to 154 days following surgery and at monthly intervals thereafter.

Evoked EMG activity was first detected between 56-126 days and 98-182 days in the graft and entubulation repair procedures respectively. At 322 days average EMG amplitude of the graft repair and the entubulation repair procedures had returned to 55.5% (+/- st.dev.17.9) and 39.7% (+/- st.dev.22.8) of baseline respectively, no significant statistical difference can be demonstrated between the two procedures at this time point. Supported by NS-22404-06 and Colla-Tec, Inc.

CARBON FILAMENT IMPLANTS SUPPORT AXONAL REGROWTH ACROSS TRANSECTED RAT SCIATIC NERVE. S. Savers, M. Dauzvardis, and T. Khan, Rehab. R&D Center, Hines VA Hospital, Hines, IL 60141.

Current methods of peripheral nerve repair often result in unsatisfactory restoration of function. In some situations, a significant loss of nerve tissue may result in a gap too wide for end-to-end anastomosis. In this case, a nerve graft is necessary to bridge the gap. Although a nerve autograft would be the preferred method of repair, problems occur with obtaining donor nerve. An alternative is to use an artificial nerve graft as a bridge. In our laboratory, we have shown that small diameter carbon filaments can support and give directionality to growing rat fetal spinal cord explants (*Neurosci. Lett.* 118:172-176, 1990). We have also shown that carbon filaments implanted into the transected adult rat spinal cord can promote axonal growth across the transection site (*Brain Res.* 541:139-145, 1991). In the present study, we evaluated the feasibility of using carbon filament implants in the repair of peripheral nerve.

Young adult rats were anesthetized and the left sciatic nerve was cut. The proximal and distal ends were inserted into the ends of a silicone tube containing approximately 10,000 carbon filaments (5 µm diameter) 5 mm in length. The nerve stumps were held in place with a small amount of cyanoacrylate adhesive applied between the epineurium and the tubing. The right sciatic nerve served as a control. After 60 days, the rats were anesthetized and both the left and right sciatic nerves were crushed distal to the injury. WGA-HRP (0.3 µl of a 2% solution) was injected into the crush site of each nerve. After 24 h, the animals were sacrificed and perfused. The spinal cords were removed, fixed, sectioned, reacted for WGA-HRP, and segments L2-S5 were observed for labeled cells.

Preliminary results have shown labeled cells on the left half (injury side) of the spinal cord. Numerous labeled cells were always seen on the right (control side) of the spinal cord. These early studies suggest that carbon filament implants are capable of supporting axonal regrowth in peripheral nerve.

CULTURED SYNGENEIC ADULT SCHWANN CELLS SEEDED IN SYNTHETIC GUIDANCE CHANNELS ENHANCE SCIATIC AND OPTIC NERVE REGENERATION. V. Guénard¹, T.K. Morrissey², N. Kleitman², R.P. Bunge², P. Aebischer¹, ¹Division of Biology and Medicine, Brown University, Providence, RI 012912 and ²The Miami Project to Cure Paralysis, University of Miami School of Medicine, Miami, FL 33136.

Upon injury in the PNS, Schwann cells (SCs) within the distal nerve segment regain some of their developmental properties, including the ability to attract and guide regenerating axons. Peripheral and central nerve regeneration through permissive guidance channels could be enhanced by pre-forming an organized SC cable oriented along the longitudinal axis of the guidance channels. Permissive guidance channels were seeded with virtually pure cultures of SCs isolated from adult Fisher rat sciatic nerves and suspended in a 30% solution of Matrigel® in culture medium at a final density of either 40 or 80 x 10⁶ cells/ml (SC-40, SC-80 channels). Matrigel®-filled channels were used as controls. Channels were implanted for 3 weeks in transected rat sciatic nerves across an 8 mm nerve gap. Matrigel®-filled channels and SC-80 channels were also implanted for 8 weeks in transected rat optic nerves across a 1 mm gap. In the sciatic nerve, cables with nerve microfascicles bridged the nerve stumps in all channels. Cables regenerated through SC-80 channels were larger, contained significantly more myelinated axons and showed less microfasciculation as compared to cables regenerated through Matrigel®-filled channels. The number of myelinated axons in SC-40 channels was between that in Matrigel®-filled channels and SC-80 channels. In the optic nerve, regenerated nerve cables bridged the nerve stumps in all animals. However, nerve microfascicles with myelinated axons were observed only in SC-80 channels. Axons originated from retinal ganglion cells as observed with fast blue retrograde tracing. These studies indicate that cultured syngeneic adult SCs can favorably influence nerve regeneration in both PNS and CNS structures.

227.2

An Artificial Nerve Graft Combines Schwann Cells & Acellular Components to Enhance Peripheral Nerve Regeneration. Rob Keeley, Tanya Atagi, Lawrence Eng, Joseph Rosen.

A study was done to compare two artificial nerve grafts (ANG) in a rat model using the peroneal branch of the sciatic nerve. A 10 mm gap was created in one peroneal nerve and a graft composed of a porous conduit filled with a 0.8% collagen matrix implanted (Coll-ANG), while the contralateral nerve was repaired with an identical graft except for live schwann cells suspended in the matrix to support neurite outgrowth (SCC-ANG). Schwann cells were harvested from 2-day old syngeneic neonates. Fourteen rats were set up and evaluated bi-weekly with a rat walking test to measure functional recovery. After 4.5 months the animals were anesthetized deeply for electrophysiological analysis of the regenerated nerves, then sacrificed for qualitative and quantitative histological comparison. In addition, 15 control animals were implanted comparing SCC-ANGs to dead schwann cell-collagen grafts, to saline-filled conduits, and to sutured autografts, with results pending.

Walking pattern analysis demonstrated the SCC-ANG to enhance functional recovery from 60 to 110 days post-implantation over the Coll-ANGs (p<.005). Electrophysiological data demonstrated superior compound action potentials in the SCC-ANG repairs (p<.05). Quantitative histology revealed statistically higher axon counts for SCC-graft repairs (p<.01) and larger fiber diameters (p<.05). Qualitative histology demonstrated the SCC-ANG to have better organization (p<.01) than the Coll-ANG.

This study demonstrates that living schwann cells can be harvested, grown in cell culture, and incorporated into an ANG, and that this SCC-ANG improves nerve regeneration.

CARBON FILAMENT IMPLANTS PROMOTE AXONAL REGROWTH IN THE TRANSECTED SPINAL CORD OF THE NEONATAL RAT. M. Dauzvardis, T. Khan, and S. Savers, Rehab. R&D Center, Hines VA Hospital, Hines, IL 60141.

In the adult mammalian central nervous system (CNS), damaged axons fail to regrow to their former target sites largely due to influences of the CNS microenvironment. Glial scarring and the lack of appropriate trophic signals are among these factors. Recent evidence from *in vitro* and *in vivo* experiments in our laboratory indicate that small diameter carbon filaments are capable of supporting the growth of damaged spinal cord axons and directing these processes across a site of spinal cord transection. In the present study, we sought to determine whether carbon filaments implanted into the transected spinal cord of the neonatal rat would result in even greater trans-lesion growth than was observed in our previous adult transection model.

Three day old rat pups, sustaining complete spinal cord transection and receiving carbon filament implants (10,000 filaments, 0.5 cm long, 5 µm diameter) (n=7), were compared to animals sustaining total spinal cord transections without implants (n=3).

Lesions were made at the T7-T8 spinal cord level under hypothermic anesthesia, following laminectomy, using a #11 scalpel blade and a fine wire hook. Both groups received bilateral injections of 2% WGA-HRP (0.05µl) in the somatosensory cortex 30 days after surgery.

While none of the sections taken from the spinal cords of surgical control animals demonstrated any label caudal to the lesion site, labeled axons were found below the lesion site in the spinal-cords of 3 out of 7 of the animals receiving carbon filament implants. Regrowing axons were found to take a lateral or ventral course around the implant, while others appeared to travel through it.

Carbon filament implants appear capable of promoting significant axonal regrowth in the transected spinal cord of the neonate.

Supported by Rehab. R&D Center, Hines VA Hospital, Hines, IL.

VENTRAL ROOT REGENERATION THROUGH GLIAL CELL-SEEDED SEMIPERMEABLE GUIDANCE CHANNELS M.L. McCormack¹, T.K. Morrissey², N. Kleitman², R.P. Bunge², and P. Aebischer¹ Brown Univ.¹ and The Miami Project, Univ. of Miami² Semipermeable guidance channels have been shown to be successful in supporting regeneration of ventral root axons across 4 mm gap injuries but insufficient when 10 mm gap injuries are involved. To determine intraluminal modifications that might enhance the supportive properties of these channels, glial cells seeded in a laminin-containing gel matrix were tested as potential outgrowth-promoting substrates for ventral root axons *in vivo*. Outbred early postnatal rat-derived astrocyte (AC) and olfactory bulb cell lines (ROB) (a gift of Dr. J. Jacobberger), outbred and inbred adult rat-derived primary Schwann cells (SC) were used as cellular substrates for regenerating axons. The various cell types were entubulated within the gel matrix so that a centrally-located cable of cells arranged longitudinally within the gel was formed down the length of an acrylic copolymer semipermeable guidance channel. The seeded channels were then used to bridge 10 mm gaps in the L5 ventral root of adult male albino rats. Eight animals received ROB implants, 9 received AC implants, 10 received outbred SC implants, and 3 received inbred SC implants. Regeneration was assessed at 4 weeks post-implantation. Successful regeneration (cables containing myelinated and nonmyelinated axons at the channels midpoint) was achieved only with the SC-seeded guidance channels. Furthermore, there was a marked difference in the success of the syngeneic grafts (100%) as compared to the allogeneic grafts (20%). This data suggests that Schwann cell-seeded semipermeable guidance channels can support regeneration of ventral root axons across large deficit injuries. In addition, syngeneic SC grafts are superior to allogeneic grafts for successful regeneration.

227.7

REGENERATION ACROSS PERIPHERAL NERVE ALLOGRAFTS WITH TEMPORARY OR CONTINUOUS CYCLOSPORIN A IMMUNOSUPPRESSION. R. Midha, S.E. Mackinnon and P.J. Evans. Peripheral Nerve Research Lab., University of Toronto, Toronto, Ontario, Canada, M5S 1A8.

Peripheral nerve reconstruction would benefit from the use of nerve allografts, however life-long immunosuppression for non-vital organ transplantation is controversial. This study compares regeneration across peripheral nerve allografts in rats immunosuppressed with either temporary or continuous cyclosporin A. One hundred and fifty Lewis rats received 2 cm nerve grafts from allogeneic AC1 or syngeneic Lewis donors, repaired to the sharply transected posterior tibial nerve of the hosts. Cyclosporin A (CyA) at 5 mg/kg/day subcutaneously is the sole immunosuppressive agent, given temporarily (12 weeks) or continuously from one day pre-graftment to sacrifice. The graft recipients have been randomly allocated to the following groups: allogeneic grafts with continuous CyA for 12 (n=10), 18 (n=20) and 30 (n=20) weeks; allogeneic grafts with temporary CyA for 18 (n=20) and 30 (n=20) weeks; negative controls with allogeneic grafts and no CyA sacrificed at 12, 18 and 30 weeks (n=10, each); and positive controls with syngeneic grafts and no CyA sacrificed at 12, 18 and 30 weeks (n=10, each). Functional regeneration across the nerve grafts is being serially assessed by walking track analysis, performed every second week. Endpoint evaluations will include histologic, morphometric, and electrophysiologic determinations.

227.9

TRANSPLANTS OF TARGET AND NON-TARGET NEURAL TISSUE SUPPORT REGENERATION OF AXOTOMIZED DORSAL ROOT AXONS IN NEONATAL RATS. E. Rinn, A. Adams*, J. Gomez*, and B.S. Bregman. Dept. of Anat. & Cell Biol., Georgetown Univ., Sch. Med., Washington, DC 20007

Transplants of fetal spinal cord tissue support the survival and growth of immature axotomized brainstem-spinal neurons in a target-specific manner. Although these descending axons initially grow into both target and non-target transplants, they subsequently withdraw from the non-target tissue. The aim of the current study was to determine the requirements of dorsal root ganglion (DRG) neurons, which are mature at birth, for axonal regrowth after central axotomy at birth. DRG neurons survive central axotomy at birth. Embryonic target (spinal cord (SC) E14) or non-target (cortex (CX) or hippocampus (HC) E18) transplants or non-neuronal extracellular matrix, (ECM, matrigel), were placed into hemisectioned lumbar spinal cord of neonatal rats (3 or 8 dpn). The L4 - L6 dorsal roots were cut and placed onto the transplant. Controls received no transplant. An antibody against calcitonin gene-related peptide (CGRP) was used to examine the regeneration of dorsal root axons at 1 week and 4 weeks after axotomy. Dorsal root axons regenerated into SC, CX, and HC transplants and ECM by 1 week and remained extended throughout the transplants at 4 weeks. The growth within the SC transplants was robust; highly branched fibers extended throughout the transplants. The regrowth of dorsal root axons into CX and HC transplants was less extensive; the fibers were thicker and less branched than in the SC transplants. ECM also supported regrowth of dorsal root fibers but the axons were disorganized, thick and mostly unbranched. Since both target and non-target transplants permitted the regeneration of dorsal root axons, non-specific growth cues may be provided. Mature neurons may require less precise growth cues for regeneration than immature neurons. Supported by NIH grants NS19259, NS27054 and NS01356 to BSB.

INSULIN-LIKE GROWTH FACTOR-II INCREASES REGENERATION OF MOTOR AXONS IN RATS. S.L. Near¹, L.R. Whalen¹, J.A. Miller³, J.F. Masken² and D.N. Ishii². Dept. of Anatomy and Neurobiology¹, and Dept. of Physiology², Colorado State Univ., Ft. Collins, CO 80523; Amgen³, Thousand Oaks, CA 91320.

Insulin-like growth factors (IGFs) can increase neurite growth in sensory, sympathetic and motor neurons *in vitro*, and IGF-II gene expression upregulates in denervated muscle during nerve regeneration (Ishii, Proc. Natl. Acad. Sci. USA 86: 2898, 1989). We tested the hypotheses that IGF-II can increase motor nerve regeneration in rats, and that endogenous IGF-II helps to support spontaneous regeneration.

Sciatic nerves were crushed (0.4 mm lesion), and miniosmotic pumps were implanted to continuously release either vehicle or IGF-II. After three days, the ventral roots at spinal cord level L4 were electrically stimulated, and evoked potentials were recorded to locate the most distal site of motor axon regeneration below the site of crush. The regeneration distance was statistically increased ($P < 0.05$) in the group treated with IGF-II. Moreover, this distance was reduced about 30% in rats treated with an anti-IGF-II antiserum. We conclude that exogenous IGF-II can increase the regeneration of motor axons, and infer that endogenous IGF-II plays a role in spontaneous regeneration. (Supported in part by NIH grant RO1 NS24787)

TOWARDS BANKING PERIPHERAL NERVES. P.J. Evans, D.C. Awerbuch, R. Midha, S.E. Mackinnon. Peripheral Nerve Lab., University of Toronto, Toronto, Canada, M5S 1A8.

We studied the possibility of storing peripheral nerves for later use in reconstructive procedures. The goal of preservation is to maintain an optimal nerve graft conduit through which proximal regenerating fibres can bridge and subsequently reinnervate distal muscle targets.

A 3.0 cm syngeneic (Lew/Lew) sciatic nerve graft model in the rat was used. Following harvesting, nerve grafts were stored at different temperatures (5°C, 22°C, 37°C) and for different time periods (6 hrs, 24 hrs, 3 weeks) in Belzer/UW CCS solution. Following preservation, nerve grafts were micro-neurosurgically interposed and repaired to the right sciatic nerve of recipient animals.

Recovery was assessed monthly by walking track analysis to generate a Sciatic Function Index. At sacrifice (14 months), electrophysiological and histomorphological studies of nerve regeneration, as well as gastrocnemius muscle contractile function studies were performed.

In nerves stored at 5°C no statistical difference was seen between storage times. There was a statistically decreased number of myelinated nerve fibres that regenerated across nerves stored at 22°C and 37°C. Nerves stored at 37°C had statistically slower conduction velocities than those at 5°C and 22°C when stored for 24 hours and 3 weeks.

Within this model, nerve autografts can be successfully stored at 5°C for up to 3 weeks for later use in reconstructive procedures. Regeneration was statistically better in 5°C stored nerves versus 22°C and 37°C stored nerves. It is likely that the 3 week stored nerves merely provide a nonviable conduit for proximal regenerating fibres.

BIM 22015 ENHANCES MUSCLE FIBER DIAMETER IN PERONEAL NERVE CRUSH AND TRANSECTION MODELS. T.S. Lee, S.J. Lee, K.A. Williams and F.L. Strand. Department of Biology and Center for Neural Science, New York University, Washington Square, New York, New York 10003.

Sprague-Dawley male rats (175-200g) are subjected to peroneal nerve crush or nerve transection under ketamine (80mg/kg) and xylazine (5mg/kg) anesthesia. A #5 forceps is used for nerve crush, resulting in a 1mm wide lesion and a scissor is used for nerve transection. Starting at the time of surgery, ACTH 4-10 (10µg/48hrs i.p.) or an ACTH 4-10 analog (BIM 22015, 10µg/48hrs i.p.) is administered for 5 or 7 days for nerve crush, and 10 days for nerve transection studies.

Muscle fiber diameter was significantly increased with BIM 22015 treatment in both the nerve transection and nerve crush model. ACTH treatment resulted in muscle atrophy as compared to saline-crush at day 7. In the transected model BIM 22015 showed an enhancement of muscle fiber diameter in comparison to saline-crush. Previous studies have shown that the effects of these peptides on muscle fiber diameter is strikingly different. BIM 22015 affects muscle strength and speed whereas ACTH 4-10 affects muscle endurance.¹ ACTH 4-10 treated animals result in EDL muscle atrophy during regeneration whereas BIM 22015 treated animals do not. In addition, BIM 22015 seemed to enhance muscle fiber diameter by selectively affecting different muscle fiber types. This myotrophic property of BIM 22015 may have considerable clinical potential for diseases involving muscle atrophy.

EFFECTS OF MIANSERIN AND FLUOXETINE ON THE AXONAL REGENERATION OF CENTRAL CATECHOLAMINERGIC NEURONS. S. Nakamura. Dept. of Physiology, Fac. of Medicine, Kanazawa Univ., Kanazawa 920, Japan.

We have reported that the antidepressants maprotiline and desipramine, which are potent noradrenaline (NA) reuptake blockers, induce regeneration of NA axons in the rat cerebral cortex (Neurosci. Lett., 111:64, 1990). In the present experiments, two different antidepressants mianserin (MIA) and fluoxetine (FLU), which reveal little or no effect on NA reuptake blockade, were examined. Female Sprague-Dawley rats, 8-16 weeks of age were used. Under chloral hydrate anesthesia, 6-hydroxydopamine (6-OHDA) was locally infused into the symmetrical sites of two hemispheres. One to 2 weeks after 6-OHDA pretreatment, the same cortical site of one hemisphere was infused with either MIA (gift from Dr. Watanabe) or FLU (gift from Eli Lilly) by means of an osmotic minipump, and the corresponding cortical site of the other hemisphere was infused with saline. After more than 2 weeks from the start of drug infusion, the density of glyoxylic acid-induced fluorescent catecholamine fibers was increased in the MIA- but not Flu-infused cortex. Since MIA is known to increase NA release by blocking presynaptic inhibition, the antidepressant-induced regeneration of cortical NA fibers may be associated in part with enhanced noradrenergic transmission. Supported by the fund for medical treatment of the elderly (School of Medicine, Kanazawa University).

THE THERAPEUTIC POTENTIAL OF X-IRRADIATION IN LESIONED RAT SPINAL CORD. N.Kalderon and Z.Fuks*. The Rockefeller Univ and Sloan-Kettering Cancer Ctr., New York, NY 10021.

The potential of x-irradiation, at clinical doses (e.g. eradicating malignant cells), to alter the cellular environment and events and thereby change the consequences of injury to adult mammalian CNS are being examined. We showed that a timed specific x-irradiation resulted in prevention of formation and/or elimination of reactive astrocytes which also enabled some of the regenerative processes in lesioned olfactory bulb to maintain their courses (PNAS 1990 87:10058). Presented here are the beneficial effects of x-irradiation on hemisectioned rat spinal cord (examined 2-3 mos postinjury) as studied based on the bulb data. Radiation (20Gy) of lesioned cord only when delivered at a critical period (15-18 days) postinjury led to elimination of gliosis at the wound, prevention of degeneration and cavitation, structural healing, and, most importantly, significant regeneration of the severed corticospinal (CS) axons beyond the cut. The number of severed CS axons growing past the lesion site is determined by the retrograde double-labeling procedure; dyes were applied: dil at lesion time into the cut, and fast blue after the recovery period 8-10mm distal to the cut. Degree of double-labeled CS neurons in irradiated (n=4) was 12-33% compared to 0-2% in unirradiated (n=5) animals. Axonal regeneration correlates with the degree of structural healing at the cord; hence an improved radiation regimen should enable regrowth of most of the severed axons beyond the cut, achieving one crucial step towards functional recovery.

APPLIED DC ELECTRIC FIELDS AND PERIPHERAL NERVE REGENERATION: AN ANALYSIS OF CRITICAL FACTORS. M. E. McGinnis. Center for Paralysis Research, Sch. of Veterinary Med., Purdue Univ., West Lafayette, IN 47907.

Several recent publications have reported an enhancement of peripheral nerve regeneration by application of low level DC currents. A variety of stimulation protocols, field strengths, and assay techniques have been used to obtain positive results. I have used a similar variety of techniques and have never detected a positive effect of applied fields on peripheral nerve regeneration. This led me to directly repeat several of the published experiments reporting positive results. Again I was unable to detect an effect of the applied fields (Abst # 479.2, 1990). Here I report an analysis of the factors that seem to be critical: current levels, current density, field strength, polarization effects, field patterns, and assay techniques. I compare my techniques yielding negative results with those that show an effect of fields. An example of the results is a possible explanation of why Román *et al.* (Exp. Neurology 98: 222-232, 1987) reported a 5-fold increase in the number of myelinated fibers regenerating through a silicone chamber with a 10µA cathode, and why we find a 2-fold decrease in the number of myelinated fibers under the same circumstances. I find there is an inhibition of regeneration through the tube due to electrode products produced by the cathode, specifically OH⁻. This inhibition results in the formation of a neuroma-like structure just proximal to the cathode. Sections through the center of the tube just distal to the electrode show a lower number of fibers than controls, while sections 1 - 2 mm proximal have higher numbers than comparable control sections. Therefore, the apparent "positive" effect is dependent on the exact level of the histological sample and, ironically, is due to an inhibition of regeneration.

BLOOD REPERFUSION FOLLOWING D.C. ELECTRICAL FIELD TREATMENT IN THE DAMAGED RODENT SPINAL CORD. M.J. Politts, M.F. Zanakis and B.H. Hallas. Dept. of Surgery, Univ. of Saskatchewan, Saskatoon, Saskatchewan, American Biolinterface Corp., NY and New York College Osteopathic Medicine, NY.

Previous studies have demonstrated that DC electrical field application can result in increased axon populations in the damaged CNS. This process may involve axonal regeneration and/or a "sparing" of fibers. Since the changes occur rapidly, a vascular component is implicated. Thus, the following experiment was performed to determine the effects of DC electrical fields on reperfusion of damaged spinal cord. Adult rat spinal cords were lesioned using a 300 gm/cm weight drop. Animals were immediately implanted with TRAXON® CNS galvanic stimulators delivering 6µA at 3V DC throughout the length of the study. Control animals received inactive stimulators. The stimulating surfaces were positioned epidurally so that the cathode was located 5.0mm rostral to the lesion epicenter and the anode 5mm caudal. All animals were allowed to survive for 6 days and then sacrificed by transcardial perfusion of a Pelican Ink solution. Spinal cord frozen sections were cut 1.0mm rostral or caudal to the lesion epicenter, and blood vessels were counted in a blinded fashion. The results showed that the animals treated with active stimulators had a statistically significantly greater number of vessels both rostral and caudal to the lesion than control animals. The vessels concentrated in the dorsal funiculi in all active stimulator animals. These data strongly implicate that reperfusion of damaged tissues is an early result of electric field treatment, and may be associated with the survivability or "sparing" of axons following CNS damage. Longer term evaluations are currently being performed.

ELECTROMAGNETIC FIELDS MODIFY NEW PROTEINS SYNTHESIZED IN RAT SCIATIC NERVE Betty F. Sisken, Martin Blank* and W. Kurtz*. Center for Biomedical Engineering and Dept. of Anatomy and Neurobiology, Univ. of Kentucky, Lexington, KY 40506; Dept. of Physiology, Columbia Univ., New York, NY 10032 and Bietic Research, Inc. Lyndhurst, NJ.

Stimulation of nerve regeneration in adult rats by pulsed electromagnetic fields (PEMF, 0.3 mT, pulsed for 20 msec at a repetition rate of 2 Hz, 4 hrs/day) after a crush or transection lesion has been reported. The mechanisms underlying the PEMF effects were investigated using transected rat sciatic nerves. The experimental animals were restrained and treated with PEMF for 4 hours/day for 5 days; the sham control animals were restrained but not treated. Two weeks later the transected and untransected segments of sciatic nerves from sham control and PEMF-treated rats were incubated in ³⁵S-methionine in methionine-depleted culture medium for 4 hours at 37°C. The nerve sediments were analyzed by Protein Databases Inc., NY on 2D gels. The new polypeptides found were derived primarily from Schwann cells and fibroblasts found in the isolated nerves. Analyses of nerves from control and experimental animals indicated the presence or absence of new polypeptides in PEMF-treated nerves, and differences in the distribution of polypeptides based on molecular weight class as a function of transection and PEMF treatment.

THIN-FILM MICROELECTRODE ARRAY FOR PERIPHERAL NERVE RECORDING AND STIMULATION

Gregory T. A. Kovacs*, Christopher W. Stormont*, Carl R. Belczynski, Khoi D. Nguyen*, and Joseph M. Rosen* Stanford University Departments of Electrical Engineering and Surgery and the Palo Alto Veterans Administration Medical Center

A microelectrode array capable of recording from, and stimulating peripheral nerves at prolonged intervals after surgical implantation has been demonstrated. The microelectrode array, fabricated on a silicon substrate perforated by via holes, is implanted between the ends of a surgically severed nerve. Regenerating tissue fixes the array in place to provide a stable mapping between the microelectrodes and the axons in the nerve. Processes were developed for the fabrication of thin-film iridium microelectrodes, micromachined via holes, and silicon nitride passivation layers. All fabrication methods were designed to be compatible with standard active microelectronic circuit fabrication processes to allow for on-chip signal processing circuits in future designs. Devices with arrays of 64 via hole/microelectrode sites distributed over a 1mm² surface area were implanted bilaterally in the peroneal nerves of 9 male Sprague-Dawley rats. At post-operative durations of up to 13 months, the implants were surgically exposed and electrical probe needles used to make contact to probe points connected to the microelectrodes on the array. The arrays were used to record from and, in some cases, stimulate the nerve at up to 13 months post-operatively. While the initial design of these devices was not refined for optimal nerve regeneration, it allowed the demonstration of the basic principle and the durability of devices fabricated with the processes developed for this purpose. Optimization of the design in terms of minimal impact on nerve regeneration and electrical selectivity is currently underway.

RECONSTITUTION OF SYNAPSES FOLLOWING SURGICAL TREATMENT FOR INFANTILE HYDROCEPHALUS. J.P. McAllister, P.M. Hale*, R.A. Morano*, D.V. Shroff* and R.M. Kriebel. Depts. of Anatomy, Temple Univ. School of Medicine and Phila. Coll. Osteopathic Medicine, Philadelphia, PA 19140.

Controversy persists regarding the clinical decision of when to surgically decompress hydrocephalic children. To address this issue systematically, the present study was designed to analyze quantitatively the neuropil of hydrocephalic animals before and after ventriculoperitoneal (VP) shunting. Obstructive hydrocephalus was induced in 10 day old kittens by intracisternal injection of kaolin; VP shunts were placed in hydrocephalic animals at early (6-8 days post-kaolin) and late (10-15 days post-kaolin) stages of ventriculomegaly. Normal animals served as age-matched controls. Hydrocephalic animals were sacrificed at times corresponding to the immediate pre-shunt period, and about 7 days after shunt placement. Tissue from primary visual cortex was processed for electron microscopy and the number of synapses per unit area determined for superficial and deep laminae. To date, preliminary data indicate that in layers V and VI the number of synapses decreases 60% in hydrocephalic animals. While individual variations exist that appear to be related to the success of decompression, shunting largely restores the number of synapses in deep cortex (7% and less than 1% below control values for early and late shunts, respectively). Thus, early and late decompression seems equally effective in promoting recovery.

227.19

DISTRIBUTION AND CHARACTERIZATION OF RESPONSES TO LIGHT IN REINNERVATED HAMSTER SUPERIOR COLLICULUS. Y. Sauvés, M. Rasminsky and D.A. Carter. Centre for Research in Neuroscience, McGill University, 1650 Cedar Ave., Montreal, Quebec, Canada H3G 1A4.

Axotomized rodent retinal ganglion cells (RGCs) can regrow axons for several cm into a peripheral nerve graft (PNG) apposed to the stump of the transected optic nerve and inserted into the CNS. The regenerated axon terminals form well differentiated, persistent and functional synapses with target neurons in the superior colliculus (SC) (Vidal-Sanz et al, J. Neurosci. 7:2894, 1987; Carter et al, J. Neurosci. 9:4042, 1989; Keirstead et al, Science 246:255, 1989). The extent and organization of SC reinnervation can be assessed physiologically by recording responses to light in the SC.

In adult hamsters examined 16-30 weeks after insertion of a PNG routed from the eye to the lateral aspect of the ipsilateral or contralateral SC, invasion of a substantial area of the SC by regenerated RGC axons was suggested by the finding of unitary responses to light within areas of the SC as large as 750 μ m x 500 μ m. Innervation of the SC by multiple regenerated RGC axons could be inferred from the observation of unique receptive fields for each of the visually responsive units. In some cases recordings were made from more than 20 different units, some of which could be identified as postsynaptic neurons rather than as RGC axon terminals by suppression of their responses to light by iontophoretic application of GABA. The visual fields of nearby SC units were frequently clustered, suggesting a tendency of axons regenerated from nearby RGCs to project together. However, the visual fields found for some closely spaced SC units identified as postsynaptic neurons were more widely separated than those found in recordings from the SC of intact animals in which a displacement of 20 μ m represents a displacement of 1° in visual space.

FUNCTIONAL RECOVERY AND NEURONAL RECONNECTIVITY IN OLFACTORY TRANSPLANT AND OLFACTORY BULBECTOMIZED RATS. ^{1,2}K.R. Hendricks*, ^{2,3}L.E. Westrum, ²J.N. Kott, ¹M.E. Hanson*, and ¹J.B. Simpson. Depts. of ¹Psychol., ²Neurol. Surg., and ³Biol. Struct., University of Washington, Seattle, WA 98195.

Recovery of function in rat and mouse after olfactory bulb (OB) transplants (OBT) and olfactory bulbectomies (OBE) is a controversial topic. We are examining the anatomical correlates involved in functional recovery. One day old Sprague-Dawley rats received unilateral OBE followed immediately by either an embryonic OBT or a gelfoam pack. At weaning, the rats were taught to find hidden pieces of cookie. When cookie-finding was reliable, the contralateral, normal OB was removed from all rats. Beginning one week after the second surgery, testing of cookie-finding was resumed. Some rats from both groups were immediately able to find the cookie. All rats in these two groups were able to find the cookie within 5 weeks, behaviorally demonstrating return of olfactory function. Histology was used to verify that the OBT had not been rejected (OBT material was labeled with tritiated thymidine) and that the lesions were complete. Olfactory Marker Protein (OMP)*, an olfactory nerve (ON) specific marker, combined with standard fiber and cell staining was used to show which brain regions were penetrated by ON fibers. Innervation of brain tissues by the ON was only achieved when the OBT or OBE occurred neonatally. The primary target of ON fibers in the lesion rats was the olfactory peduncle (OP; a target and relay area for OB and not ON efferents in the normal olfactory system). In one case, ON fibers innervated the nucleus accumbens as well. In the OBT rats, ON fibers innervated both the OBT tissue and the OP. The results suggest that in the absence of the secondary OB neurons in this pathway, the ON extends and connects directly to the "tertiary" neurons suggesting a mechanism for functional recovery. We are currently investigating the synaptic connectivity in OBT and OBE preparations. (Supported by NIH Grant NS 09678, and NS 07144. L.E.W. is an affiliate of the CDMRC). *OMP was kindly provided by Dr. F. L. Margolis.

TRANSPLANTATION: NEW TECHNOLOGY

228.1

FLUORESCENT LABELING OF FETAL CELLS FOR TISSUE CULTURE AND NEURAL TRANSPLANTATION. C. Paramore*, S. Meadows, R. D. Madison, and D. A. Turner. Neurosurgery and Neurobiology, Duke Univ. Med. Ctr., Durham, NC 27710 and Durham VAMC.

One of the challenges in the field of neural transplantation is the absolute identification of grafted neurons in the host. A fluorescent marker to localize transplanted neurons in both physiological and anatomical preparations would be ideal. Potential benefits of labeling would include identification of cell type, identification of processes, and analysis of graft migration. We have used tissue culture as a model to test the feasibility of several fluorescent dyes for this application.

Fetal rat brain tissue (E12, E17) was harvested, mechanically dissociated, and incubated in the presence of the fluorescent labels rhodamine dextran amine and carboxy-fluorescein ester (CFSE). The cells were washed twice with medium, then plated on poly-L-lysine coated coverslips in 35 mm dishes at 37°C and 5%CO₂. Cultures were viewed and photographed live or after fixation with 4% paraformaldehyde at intervals up to one week. Cells labeled with rhodamine dextran were initially bright, but faded with time. Cells without processes appeared heavily labeled, while those with neurite-like processes were faint. At levels of 5 μ M, CFSE appeared toxic, as no processes arose from the cultured cells; however, at 0.05 μ M neurons were noted to put forth processes equal to controls, and the processes were well-labeled with dye.

We conclude that CFSE may be a suitable label for grafting of fetal rat brain cells, though longer periods in culture are being studied to determine the durability of the label. Parallel studies are being carried out on other labels, including Dil and latex nanosphere beads loaded with fluorescent dyes. Supported by B.S. Turner Foundation and the Alzheimer's Disease Association.

PATTERNS OF THE ARBORIZATIONS MADE BY RETINAL GANGLION CELL AXONS REGENERATING INTO THE SUPERIOR COLLICULUS OF ADULT HAMSTERS. D.A. Carter*, G.M. Bray, and A.J. Aquayo. Centre for Research in Neuroscience, McGill University, 1650 Cedar Avenue, Montreal, Quebec, Canada, H3G 1A4.

Axotomized retinal ganglion cells (RGCs) in adult hamsters can regrow through peripheral nerve (PN) grafts and form persistent functional synapses in the superior colliculus (SC) (Carter et al., J. Neurosci. 9: 4042, 1989; Keirstead et al., Science 246: 255, 1989). We have now investigated the terminal arbors formed by RGC axons that penetrate the SC. To establish the retinal origin of the arbors studied, [³H]-amino acids were injected into PN-grafted eyes. After 48 hours, HRP was applied into a small incision made in the graft near the SC; 12 hours later, the SCs were removed and incubated with DAB to visualize the fine details of the injury-filled terminal arbors. Forty-seven arbors labelled with both HRP and [³H]-amino acids were studied from 6-9 months after the PN grafts were inserted into the SC. Double-labelled axons extended into the SC for up to 1 mm and remained confined to the retino-recipient layers of the SC. Their course was either directed towards the pial surface or followed a horizontal plane. These patterns resembled those of many normal RGC-SC arbors. However, many of the branches formed by the regenerated arbors were shorter than those of controls and their boutons were more densely clustered. In spite of these differences, many of the regenerated arbors had normal numbers of boutons.

227.22

EVOKED SYNAPTIC POTENTIALS FROM REGENERATING DORSAL ROOT AXONS WITHIN INTRASPINAL FETAL SPINAL CORD TISSUE TRANSPLANTS. J.D. Houle, R.D. Skinner and K.L. Turner. Dept. of Anatomy, Univ. of Arkansas Med. Ctr., Little Rock, AR 72205

The apposition of injured dorsal roots (DR) into an intraspinal transplant of fetal spinal cord tissue results in the regeneration of sensory axons from the root, which can be promoted by co-grafting a nitrocellulose substratum treated with nerve growth factor (NGF). The present study tested whether these regenerating axons could form functional synaptic contacts with transplant and/or host neurons. Two to six months after transplantation, apposed DRs were cut and placed on hooked wires for electrical stimulation.

A ball tip electrode recorded cord dorsum potentials from the dorsal transplant surface and host spinal cord. A micropipette filled with 2 M NaCl was advanced through the transplant near the DR entry zone at 100 μ m intervals. Negative intramedullary field potentials evoked by DR stimulation were maximal 400-700 μ m below the dorsal surface, shifting to positive deeper into the transplant. Regions of maximum negativity indicated greatest density of active synapses. Single units were identified along the microelectrode tract by their negative spike potentials, sharp threshold, and temporal facilitation. Regenerated sensory axons were visualized by CGRP immunoreactivity. The results demonstrate structural and functional integration of regenerated nerve fibers with both transplanted and host spinal neurons.

Supported by NIH grant NS-26380.

228.2

ANATOMICAL AND PHYSIOLOGICAL LOCALIZATION OF PRELABELED GRAFTS. G.K. Pyapali*, D.A. Turner and R.D. Madison. Neurosurgery and Neurobiology, Duke Univ. Med. Ctr. and Durham VAMC, Durham, N.C., 27710.

Neural grafting into CNS may restore function of the brain following pathologic insult. The anatomical and physiological analysis of grafted tissue could be facilitated with fluorescent labeling of grafted cells, ensuring that the graft is visible both at the time of physiological recording and during anatomical analysis. In this study we assess prelabeling dissociated fetal CNS cells with various fluorescent dyes and following the fate of these dyes after grafting, using both physiological and anatomical techniques.

Dissociated rat fetal cells (E12, E17-E20) were grafted into adult host hippocampus. The fetal cells were incubated with one of a number of fluorescent compounds (rhodamine beads, Cascade Blue beads, rhodamine-dextran-amine, Dil and carboxyfluorescein) at the time of the dissociation. The labeled cells were stereotactically placed as a suspension into normal and lesioned host hippocampal. The pre-labeled grafts were located using fluorescence optics 4-6 weeks later within live, *in vitro* hippocampal slices of the grafted host. Neurons within the graft were injected with Lucifer yellow. The rhodamine labels were the best in terms of intensity of labeling, percent of cells labeled, preference for labeling live cells, low toxicity and visibility in live slices. The processes of labeled cells were moderately integrated into the host hippocampus, as labeled by rhodamine-dextran-amine and Lucifer yellow.

The ability to prelabel the dissociated cell suspensions prior to grafting facilitates the identification of grafts for analysis of integration of grafted neurons. This technique will also improve our understanding of the survival, differentiation and migration of grafted neurons and their potential to restore function in the lesioned CNS. Supported by ADRDA and VAMC Research.

228.3

A CULTURED MULTIELECTRODE-CELL APPARATUS TO PROBE CNS INJURY. M.F. Zanakis, A. Feller*, B.H. Hallas, P.A. Femano*, D. Schwartz*, M. Sussman* and R. Cebelenski, H. Yoon* and M.R. Wells. American BioInterface Corp., NY, NY College of Osteopathic Medicine, NY, and Veterans Administration, Northport, NY.

Earlier experiments demonstrated that a multielectrode cable (MEC) could be constructed where fetal neurons (probes) could be cultured and monitored *in vitro*. These probes, along with the supporting MEC assembly, will be used for implantation into a damaged host CNS structure (such as the spinal cord). The synapse of damaged host neurites on the fetal probe cells will provide an opportunity to indirectly monitor host neuronal activity. With signal processing, monitoring host activity may allow us to more clearly understand the interconnections between these structures, and may ultimately allow us to stimulate musculature which was denervated by spinal cord injury. We have performed experiments using both rodent cardiac myocytes as well as dissociated fetal rat cortical cells as "test" and "actual" probe cells, respectively. The MEC surface is a group of 10 μ diameter Pt/Ir lead wires encased in a polystyrene matrix. The MEC surface is polished and then prepared for cell adhesion by propane firing of the surface followed by layering of a protein mixture. The MEC assembly, varying from 30 to 200 electrodes, was tested on a support structure which includes the electrode lead wires, a channel scanner/selector and preamplifiers. Constant temperature is maintained and video imaging of the MEC surface (to identify cells) is provided. *In vitro* electrophysiological results through the MEC, verified by standard extracellular electrophysiological techniques, indicate that the MEC can provide good signal fidelity of cultured cells, while maintaining good cell viability. Stability testing indicates that probe cells on the MEC surface can survive implantation into the host CNS if the MEC surface is protected.

AN ENCAPSULATED PC12 CELL LINE RELEASES LEVODOPA CONSTITUTIVELY *IN VITRO*. T.R. Flanagan, M.P. Lavoie*, F.A. Kaplan, W.J. Bell*, M.A. Palmatier, F.T. Gentile*, and P.R. Sanberg. Cellular Transplants, Inc., Providence, RI 02906.

Immunoisolation of xenogenic cells allows a means of exploring their potential for cellular replacement therapies. Immunoisolation methods have been developed to produce polymer encapsulated PC12 cells for the treatment of experimental Parkinsonism. Suspensions of PC12 cells are co-extruded with a polymer solution to encapsulate cells within a hollow fiber. These fibers are designed with molecular weight perm-selectivities to restrict host immunoglobulin and complement access to encapsulated cells while permitting metabolite diffusion.

Encapsulated PC12 cells provide an interesting experimental system for characterizing changes in the aggregate properties of cell populations when compacted in a three dimensional array. It is well documented that PC12 cells synthesize, sequester, and also constitutively release dopamine. Previous studies have described surface-contact and density-dependent physiological responses among PC12 cells. Following encapsulation, PC12 cells exhibit evoked release of dopamine and also release of dopamine metabolites. Under basal release conditions, an encapsulated broadly available PC12 cell line primarily releases two dopamine derived metabolites; homovanillic acid (HVA) and 3,4-dihydroxyphenylacetic acid (DOPAC). Under basal release conditions these encapsulated cells also release substantial amounts of the dopamine precursor levodopa. Thus, this cell line may provide a product for a constitutive local release of levodopa when implanted into Parkinsonian models.

While the basal release of metabolites from encapsulated cells cultured *in vitro* is a limited model for predicting the physiological performance of these encapsulated cells *in vivo*, we feel that this cell line offers an attractive system to study pharmacological manipulations which could optimize basal and evoked release of dopamine from this broadly available PC12 cell line after encapsulation.

228.7

PHYSICO-CHEMICAL CHARACTERIZATION AND MICROIMMUNO-CYTOTOXIC CHALLENGE OF MEMBRANE FOR CELL OR TISSUE TRANSPLANTATION. E.A. Kaplan, T.E. Hazlett*, M.P. Lavoie*, F.T. Gentile*, P.R. Sanberg, and L. Christenson. Cellular Transplants, Inc. Providence, RI 02906

Transplantation of endocrine or transmitter-secreting cells immunoisolated within a permselective polymeric membrane represents a novel therapeutic modality. In order to characterize the membrane transport properties, the rejection coefficients (R) of marker molecules of varying molecular weights (M) were measured with stirred filtration cells.

Marker Molecule	M	R(±10%)
Dextran	2,000,000	0.98
Bovine serum albumin	67,000	0.94
alpha-Chymotrypsinogen	24,000	0.25
Cytochrome C	12,500	0.12
Vitamin B12	1,400	0.05

Molecules the size of immunoglobulins do not cross the membrane, while molecules even larger than dopamine are freely permeable. Diffusive transport of dopamine in the membrane was determined in separate experiments: $D_{mem}/D_{H2O} = 0.85 \pm 0.05$. We then incubated capsules containing PC12 cells with an IgM antibody specific for the Thy-1.1 surface marker (clone HO-22-1) at titers 1:1, 1:4, and 1:8. Control wells contained unencapsulated PC12 cells, PC12 cells in capsules in which pin-holes had been deliberately created in the walls, and in capsules with incomplete seals. Samples were incubated with the antibody for periods of 2 hours, 3 days, and 8 days to allow the antibody to bind, at which time fresh rabbit complement (1:4, 1:20, 1:40) was added to the wells for 2 hours. Cell viability was assessed by uptake of propidium iodide (PI) using fluorescent microscopy. Controls exposed to anti-Thy-1.1 and complement took up PI at all time points measured, indicating that their cell membranes were damaged by the antibody and complement. In contrast, PC12 cells encapsulated in intact capsules showed the same viability as did capsules maintained for the same period of time. Cells encapsulated within this polymeric membrane are protected from complement-dependent, antibody-mediated cytotoxicity, while allowing passage of vital nutrients. NIH grant 1 R43 NS28992-01

228.4

ENCAPSULATED PC12 CELLS AMELIORATE SPONTANEOUS AND DRUG-INDUCED BEHAVIORS IN THE 6-OHDA LESIONED RAT. D.F. Emerich, P.E. McDermott*, L. Christenson, M.A. Palmatier, F.A. Kaplan, T.R. Flanagan, M.P. Lavoie*, B.R. Frydel*, F.T. Gentile* and P.R. Sanberg. Cellular Transplants, Inc., Providence RI 02906.

Encapsulation of dopamine-secreting cells into a permselective polymer membrane has been proposed as a possible treatment for Parkinson's disease (PD). This technique provides an effective immunoprotective barrier for the encapsulated cells and permits the use of allogeneic or xenogeneic tissue without the need for immunosuppression of the recipient. Encapsulated PC12 cells ameliorated apomorphine-induced rotational behavior in 6-OHDA lesioned rats following implantation into the denervated striatum (Winn et al., *Soc. Neurosci. Abstr.*, 16:39, 1990). In the following studies we further characterized the extent of behavioral recovery following implantation of encapsulated PC12 cells.

PC12 cells were coextruded into a polymer fiber, sectioned into 4 mm lengths and cultured *in vitro* to establish a basal level of dopamine metabolite release using HPLC. Following unilateral 6-OHDA lesions of the substantia nigra animals were tested for apomorphine-induced (0.1 mg/kg s.c.) rotational behavior and on a battery of sensorimotor and limb use tests. Lesioned rats exhibited a pronounced motor asymmetry in all tasks. Six weeks following surgery, animals received intrastriatal implants of encapsulated PC12 cells or empty, non PC12-containing capsules. At 2 and 4 weeks post-implantation those animals receiving PC12 implants exhibited a significant (50%) reduction in the number of apomorphine-induced rotations as well as a significant normalization of the asymmetries observed using the sensorimotor and limb use tests. There were no beneficial or detrimental changes observed following implantation of empty capsules. This study further supports the previous evidence that implantation of encapsulated neurotransmitter-secreting cells may provide a useful treatment for PD and other human degenerative diseases characterized by secretory cell dysfunction.

IMMUNOCYTOCHEMICAL ANALYSIS OF ALLOGENEIC AND XENOGENIC PC12 CELL IMPLANTS INTO STRIATUM. B.R. Frydel*, D.F. Emerich, P.E. McDermott*, F.A. Kaplan, M.A. Palmatier, L. Christenson, H. Duncan, and P.R. Sanberg. Cellular Transplants, Inc., Providence, RI 02906.

Transplantation of encapsulated dopamine-secreting cells has been proposed as a treatment for Parkinson's disease PD (Aebischer et al. *Exp. Neurol.* 111:269,1991). PC12 cells encapsulated within polymeric membranes survive for extended periods of time and reverse the behavioral deficits in both rodent and primate models of PD (Aebischer et al., *Soc. Neurosci. Abst.* 16:393,1990). Because PC12 cells are tumor-derived, there is the potential for tumor formation if the cells escape from the capsule or the capsule is mechanically damaged during implantation. The following studies examined the survival and possible tumor formation of unencapsulated PC12 cells implanted into the striata of rats (allograft) and guinea pigs (xenograft). PC12 cells were suspended in RPMI at a concentration of either 10⁴, 10⁶, or 10⁸ cells/4 μ l and were stereotactically injected into rat and guinea pig striata. Animals were sacrificed at 1, 4, or 12 weeks following surgery and their brains were processed and stained for tyrosine hydroxylase (TH), dopamine beta hydroxylase (DBH), glial fibrillary acidic protein (GFAP), a cell surface marker for PC12 cells (Thy-1), Nissl substance, and hemodeserin. All rats injected with PC12 cells developed tumors within 1-2 weeks, with an associated 50% mortality. All surviving rats exhibited a massive growth of PC12 cells upon necropsy. In contrast, guinea pigs with PC12 cell implants survived at all time points with no observed mortality. Histological analysis showed that at one week after implantation 75% of animals had small clusters of cells, at 4 weeks 10% had some surviving cells, and at 12 weeks no surviving cells were observed. At 12 weeks post-implantation there remained a modest glial response. The survival of PC12 cells was not found to be dependent on the initial concentration implanted. These data suggest that PC 12 cells do not survive unencapsulated in a xenogeneic host. Furthermore, the use of encapsulated PC12 cells may be a viable and safe approach for treating human disease such as PD.

228.8

PC12 CELLS ENCAPSULATED IN AN IMMUNOISOLATORY POLYMER MEMBRANE SURVIVE FOR EXTENDED PERIODS *IN VITRO*. M.A. Palmatier, F.A. Kaplan, W.J. Bell*, F.T. Gentile*, T.R. Flanagan and P.R. Sanberg. Cellular Transplants, Inc., Providence RI 02906

Encapsulation of allogeneic or xenogeneic cells in an immunoisolation synthetic thermoplastic polymer membrane provides a tool for the exploration of cellular replacement therapies without immunosuppression of the recipient. For example, implantation of PC12-containing capsules alleviates parkinsonian behaviors in animal models (Winn et al. *Soc. Neurosci. Abst.* 16:39, 1990).

Using a co-extrusion process PC12 cells can be encapsulated in a hollow polymer fiber with a perm-selective membrane. The fiber can be cut into segments and the ends sealed to form capsules which can be incubated *in vitro*. The present study was designed to determine the growth characteristics of encapsulated PC12 cells during extended *in vitro* culture.

PC12 capsules were incubated *in vitro* and MTT assays (Mosmann, J. *Immuno. Methods* 65:55, 1983; Uludag and Sefton, *Biomaterials* 11:708, 1990) were done at various times to determine the metabolic activity of the surviving cells. After 6 weeks *in vitro*, 4 mm long capsules loaded at 15 million cells per ml displayed the same metabolic activity as capsules assayed one week after fabrication (equivalent to approximately 15,000 unencapsulated cells). Two cm long capsules loaded at 5 million cells per ml showed gradually increasing metabolic activity over 6 weeks, approximately equivalent to 15,000 unencapsulated PC12 cells at 1 week and 40,000 unencapsulated PC12 cells at 6 weeks. Metabolic activity in the 2 cm long capsules, equivalent to approximately 40,000 unencapsulated PC12 cells, remained stable over the period from 6 to 15 weeks *in vitro*.

Encapsulation of PC12 cells in capsules of a synthetic polymer membrane provides a method for immunoisolating these cells, yet allows uncompromised metabolic activity of these encapsulated PC12 cells *in vitro*.

229.1

IMPLANTATION OF THE IMMORTALIZED HIPPOCAMPAL CELL LINE HIB5 INTO DEVELOPING AND MATURE BRAIN SITES: CHARACTERIZATION, EPIGENETIC INFLUENCE, AND IMPLICATIONS TOWARD FUNCTIONAL RECOVERY. M. G. Cunningham*, P. J. Renfranz, and R. D. G. McKay. Department of Brain and Cognitive Sciences, M.I.T., Cambridge, MA, 02139.

Immortalized cell lines were established from embryonic day 16 rat hippocampal primary cultures in order to address developmental issues and to assess the capacity of such cell lines to serve in brain cell replacement in disease states. The HiB5 cell line, one of a number of nestin-positive cell lines established, was reintroduced into the developing brain, specifically, the postnatal-day-2 hippocampus and cerebellum. A stereotaxic technique was used for implantation along with a combination of cell labeling techniques. HiB5 cells demonstrated a striking ability to integrate into both these sites and appeared to localize to neurogenetically active regions within them. The morphologies assumed by the implanted cells were indistinguishable from those of endogenous neurons and glia that are being generated at the time of the implant. HiB5 cells were also implanted into the hippocampus and cerebellum of young and aged adults and showed much less integration and differentiation. Nevertheless, many of the implanted HiB5 cells survived beyond three months. Present studies are being conducted to determine whether these cells take on functional roles, and to investigate the potential of such cell lines in reestablishing specific cell populations in lesioned brain sites.

TRANSPLANTATION OF POLYMER-ENCAPSULATED NGF-RELEASING CELLS PREVENTS LESION-INDUCED REDUCTION IN CHAT EXPRESSION BY SEPTAL CELLS. D. Hoffman¹, X. Breakfield², P. Short² and P. Aebischer¹. ¹Division of Biology and Medicine, Brown University, Providence, Rhode Island; ²Department of Neurology, Massachusetts General Hospital, Boston, Massachusetts.

The delivery of nerve growth factor (NGF) to the lateral ventricle of a fimbria-fornix lesioned rat prevents the lesion-induced reduction in choline acetyltransferase (ChAT) expression by medial septal cells. The use of cell lines genetically engineered to produce NGF as a means of delivery poses the inherent threats of tumor formation and/or immune rejection. Transplantation of cells isolated within a permselective polymer capsule separates the cells from the host tissue and allows exchange of oxygen, nutrients, neurotransmitters, and other factors, while providing mechanical support and immunoprotection. Rat fibroblasts genetically engineered to produce NGF (R208N.8) were suspended at a density of 1×10^6 cells/ μ l in a laminin-containing hydrogel, and surrounded by a permselective poly(acrylonitrile/vinyl chloride) membrane. Empty capsules and encapsulated control fibroblasts (R208F) were used as controls. The capsules were placed in culture with PC12 cells. Encapsulated fibroblasts remained viable after 2 weeks in vitro. R208N.8 capsules induced neurite extension from PC12 cells beginning at 4 days, while empty capsules and R208F capsules elicited no response. Unilateral aspirative fimbria-fornix lesions were performed in adult rats, and an empty or R208N.8 capsule was implanted into the ipsilateral lateral ventricle. After 2 weeks, ChAT(+) cells were evaluated in the medial septum. A significant prevention of ChAT(+) cell reduction was observed in rats receiving R208N.8 capsules, similar to that induced by NGF-releasing polymer rods. No undue reaction to the implants was noted, and viable fibroblasts were observed within the implanted capsules. These studies suggest that encapsulated genetically engineered cells may provide an efficient means for future applications involving delivery of neurotrophic factors.

HSV-1 VECTOR-MEDIATED GENE TRANSFER: GENETICALLY MODIFIED POST-MITOTIC CELLS IMPLANTED INTO RAT STRIATUM EXPRESS A FOREIGN GENE.

B.A. SABEL¹, A. VICK^{1*}, V. HÖLLT^{2*}, AND A. GELLER³.

Inst. Med. Psychol.¹ and Inst. Physiol.² Univ. Munich Med. School, Munich, FRG, and Dana Farber Cancer Inst.³, Harvard Med. School, Boston, MA, USA.

Herpes Simplex Virus (HSV-1) vectors (Science 241, 1667, 1988; PNAS, USA 87, 1149, 1990) are the only available method to deliver genes into postmitotic cells such as neurons; retrovirus vectors require a round of mitosis for integration. A potential gene therapy approach for Parkinson's Disease is to deliver genes into neurons using HSV-1 vectors and transplant these neurons into the adult brain. This strategy requires that the transfected neurons survive intracerebral implantation and stably express a foreign gene.

To develop such a system we used a HSV-1 vector (pHSVlac) expressing *E. coli*- β -galactosidase (β -gal); to optimize conditions for subsequent implantation, we examined infection parameters in culture using PC12 cells and cerebral cortex cells from rat embryos (E14). The highest infection rate was obtained by exposing cells to 10 infectious particles/cell at 37°C for 3 h. Infected cells were transplanted into the striatum of adult male rats (250-280g) by unilateral injection (5 μ l, 2 x 10⁴ PC12 cells or 3.3 x 10⁴ cortical cells). Expression of β -gal was assayed 1-5 days after implantation; perfused brains were sectioned at 50 μ m with a freezing microtome, and β -gal was detected using X-gal or immunohistochemistry with rabbit anti- β -gal-antibodies. Numerous β -gal-positive cells were observed near the injection site using both assays. Thus, we have shown that pHSVlac infected cells survive implantation and express a foreign gene for at least 5 days. The long-term survival of the transplanted cells and stable expression of β -gal are currently under study.

RAT ASTROCYTES CONTAINING A MOUSE NGF TRANSGENE ENHANCE THE SURVIVAL OF BOTH YOUNG POSTNATAL AND ADULT ADRENAL CHROMAFFIN CELLS GRAFTED INTO THE ADULT RAT STRIATUM. L.A. Cunningham, J.T. Hansen, M. P. Short¹, M.C. Bohn. Dept. of Neurobiology and Anatomy, University of Rochester Medical School, Rochester, NY 14642 and ¹Molecular Neurogenetics Unit, MGH, Harvard Medical School, Boston, MA 02114

Our previous studies demonstrated that primary rat astrocytes infected with a retroviral vector harboring a mouse β -NGF transgene support the survival and neuronal differentiation of young postnatal adrenal chromaffin cells in intrastriatal grafts. The aim of the present study was to determine whether these effects were dependent upon adrenal age. Suspensions of partially purified chromaffin cells were prepared from postnatal day (PD) 12 or 90 rat adrenal medulla and grafted into the adult 6-OHDA-lesioned rat striatum alone (AC), or at a 1:1 ratio with either normal (AC + AS) or genetically altered astrocytes (AC + ASN.8). Surviving chromaffin cells were identified by tyrosine-hydroxylase immunoreactivity (TH-IR) two weeks after grafting.

Table 1. Number of surviving TH-IR chromaffin cells *p<0.01

	AC	AC + AS	AC + ASN.8
PD12	1234 \pm 197*	552 \pm 97	3075 \pm 77
PD90	---	551 \pm 325	2782 \pm 750*

The genetically altered astrocytes enhanced the survival of both PD12 and PD90 chromaffin cells ~3-6 fold over control groups (Table 1). Histological evaluation revealed that PD12 chromaffin cells display extensive neurite-outgrowth when co-grafted with the genetically altered astrocytes, whereas PD90 chromaffin cells remain endocrine in morphological phenotype. Thus, the effect of the genetically altered astrocytes on chromaffin cell neurite-outgrowth, but not chromaffin cell survival, appears to be dependent on adrenal age.

TRANSPLANTATION OF AN IMMORTALIZED CELL LINE (A7) INTO THE RAT BRAIN. M. Iseno¹, H. M. Geller², M. Polterak¹ and W. J. Freed¹. ¹NIMH, Neuroscience Center at St. Elizabeths, Washington D. C., 20032, ²Dep. of Pharmacology, UMDNJ-Rutgers Medical School, Piscataway, NJ 08854

The A7 cell line is an astrocyte-like cell from the rat optic nerve immortalized by retroviral transfer of the SV40 large T antigen (H. M. Geller and M. Dubois-Dalco, J. Cell Biol. 107: 1977-1986, 1988). To investigate the properties of these cells as possible source of tissue for brain transplantation, A7 cells were transplanted into rat brains and the graft-host interaction was examined immunohistochemically. In 26 adult rats, dissociated A7 cells (25,000 cells in 5 μ l) were transplanted stereotaxically into the hippocampus. After 2, 6 and 8 weeks, the brains were examined using indirect immunofluorescence staining. Survival of the transplanted cells was confirmed with Hematoxylin and eosin staining and with staining by an antibody against SV40 large T antigen. The cells grew focally and did not invade the surrounding brain tissue. In 3 of 26 animals, well encapsulated clumps of cells, which were probably displaced during the injection, were found in the subarachnoid space. After transplantation, the A7 cells retained immunocytochemical properties observed in culture. GAP-43 and N-cadherin, which were not expressed by A7 cells in culture, were strongly expressed throughout the graft and in surrounding brain tissue. This suggests integration of the A7 cells into the host brain structure and invasion of host neuronal elements into the graft area. No T lymphocyte infiltration was observed, although MHC class 1 immunoreactivity was enhanced in the host tissue. These results suggest extensive interactions between transplanted A7 cells and host brain tissue, and suggest that this cell line may induce growth or anatomical alterations in surrounding regions of the host brain.

TRANSPLANTATION OF PRIMARY GLIAL CELLS THAT PRODUCE DOPA AFTER RETROVIRAL TH GENE TRANSFER IN THE RAT MODEL OF PARKINSON'S DISEASE.

C. Lundberg*, P. Horellou*†, P. Brundin*#, K. Victorin*, P. Kalén*,

P. Colin*†, J.F. Julien*†, A. Björklund and J. Mallet*† (SPON: European Neuroscience Association) Dept. of Medical Cell Res. and # Restorative Neurology Unit, Univ. of Lund, Sweden, † Laboratoire de Neurobiologie Cellulaire et Moléculaire, CNRS, Gif-sur-Yvette, France

Dissociated striatal and mesencephalic cells from E15 rat fetuses were grown in the presence of 10% FCS, i.e. conditions allowing glial cell division. The cells were infected using recombinant retroviruses in which the human TH-1 gene was placed under the control of either a CMV or a LTR promoter. The infected cells were cultivated for four weeks in the presence of 10% FCS. The production of DOPA was assayed by HPLC analysis of supernatants collected over a 24 hr incubation period. Most of the cells were found to be GFAP positive, suggestive of an astrocytic nature, and many showed TH immunoreactivity. Four dishes (each approx. 5 million cells) exhibiting the highest DOPA production were selected for transplantation.

About 450 000 cells/rat were implanted as a cell suspension into the striatum in rats with unilateral 6-OHDA lesions. Two weeks after grafting apomorphine-induced turning (but not amphetamine-induced turning) was reduced by an average of 45%. Microdialysis, through a probe placed in-between the three transplant deposits, was performed about three weeks after transplantation. From both types of cells dopamine overflow was detected in the perfusate, and it was increased after addition of depolarizing concentration of KCl. DOPA, by contrast, remained low during baseline conditions and after KCl, suggesting that DOPA released from the transplanted cells was rapidly decarboxylated by the host striatum.

The same gene transfer methods are now also being explored with the GABA synthesizing enzyme. Glutamate decarboxylase cDNA has been expressed in various cell lines using the retroviral vector containing a CMV promoter. Cells showing high levels of GABA production are being characterized *in vitro* and transplanted to the ibotenic acid lesioned striatum of adult rats.

PRIMARY FIBROBLASTS GENETICALLY MODIFIED TO PRODUCE NERVE GROWTH FACTOR EMBEDDED WITHIN A COLLAGEN MATRIX ACT AS A PERMISSIVE GRAFT FOR AXONAL REGENERATION *IN VIVO*. M.D. Kawaja and F.H. Gage. The Department of Neurosciences, U.C.S.D., La Jolla, CA 92093-0624.

Grafts of a collagen matrix containing primary skin fibroblasts genetically modified to produce nerve growth factor (NGF) may serve as a unique graft environment for regenerating septal axons following fimbria-fornix (FF) ablation. Septal axons stained for acetylcholinesterase (AChE) were found within the deafferented hippocampus of female Fischer 344 rats with grafts of collagen/NGF-producing fibroblasts; the density of these fibers was variable among the different animals and was higher after eight weeks than at four weeks. In those rats that received grafts of collagen/control non-infected fibroblasts, the deafferented hippocampus was often devoid of AChE-positive fibers; a few axons were occasionally seen in the medial-most hippocampus. Data concerning the ultrastructural features of collagen/fibroblast grafts at eight weeks after unilateral FF lesion and implantation revealed that all grafts contained numerous fibroblasts with elongated processes passing along dense bundles of collagen. Capillaries, astrocytes and their processes, and blood-borne cells (e.g., plasma cells, lymphocytes) were also seen. In the NGF-producing grafts, variable numbers of small unmyelinated axons were surrounded by astrocytic processes. Axons were also closely associated with Schwann cells or the basal lamina of capillaries, while others were found within the graft extracellular matrix. In control grafts, small numbers of unmyelinated axons were associated predominantly with Schwann cells; few axons were found in the extracellular matrix of the grafts. These data reveal that this new grafting material - NGF-producing primary fibroblasts within a collagen matrix - can provide a conducive environment for regenerating cholinergic axons from the medial septum. Further, this unique grafting material allows for an ultrastructural assessment of the cellular and matrix substrates preferred by regrowing NGF-sensitive axons within the adult rat brain. Supported by AGO8514 and NS28212.

IN VITRO AND IN VIVO CHARACTERIZATIONS OF PRIMARY FIBROBLASTS GENETICALLY MODIFIED TO PRODUCE ACETYLCHOLINE. L.J. Fisher, M. Schinstine, K.L. Eagle, K.S. Chen and F.H. Gage. Dept. Neurosci., Univ. of California, San Diego, La Jolla, CA 92093-0624.

In animal models of cognitive impairments, cholinergic-rich fetal neurons implanted within the brain have been found to reduce learning and memory deficits. Genetically modifying cells may be an alternative method for obtaining donor cells for intracerebral grafting which synthesize and release desired products. In the current work, primary skin fibroblasts from Fischer 344 rats were infected with a retroviral vector containing the cDNA for *Drosophila* choline acetyltransferase (dChAT), the enzyme which catalyzes the conversion of choline and acetyl-CoA to acetylcholine (ACh). Following selection, the ChAT activity of the primary fibroblasts was 2326.7 nmoles ACh/hr/mg protein. *In situ* hybridization and immunohistochemistry conducted on cells *in vitro* revealed that both dChAT message and protein was produced from the transgene. The ChAT enzyme was biologically active, catalyzing the formation of ACh within these cells. Approximately 16% of the ACh synthesized by the transduced cells was released into the extracellular medium. Administering the ACh precursor choline to the transduced cells *in vitro* was found to influence the production of ACh. Choline chloride levels ranging from 100 μ M-500 μ M increased extracellular ACh levels 75% to 288%. These ACh-producing fibroblasts have been implanted within the hippocampus of fimbria-fornix lesioned Fischer 344 rats. Some rats examined at 3 weeks post-grafting have been found to contain surviving grafts with fibroblasts which appeared to show positive immunoreactivity for dChAT. Currently, we are conducting experiments to assess whether ACh continues to be synthesized and released by the dChAT-expressing cells following implantation. This work is supported by AGO8514, UC President's Fellowship (M.S.). L.J.F. is a NINDS Javits Junior Clinical Investigator.

IN VITRO STRATEGIES FOR IDENTIFYING TRANSPLANTED PRIMARY CNS TISSUE AND NEURONAL CELL LINES. S. M. Onifer, L. A. White, S. R. Whittemore, and V. R. Holets. The Miami Project and Dept. of Neurological Surgery, University of Miami, Miami, FL 33136.

To address the fate of primary CNS tissues or genetically engineered cell lines after transplantation into the CNS, the transplanted cells must be labeled so as to be distinguished from the host neuropil. We reasoned that an optimal label could be chosen by first examining its fate *in vitro*. Using 11 different labels, we determined which labels were maintained *in vitro* by neurons and non-neuronal cells derived from fetal medullary raphe nuclei and by RN33B cells, a temperature-sensitive neuronal cell line derived from fetal medullary raphe (see White and Whittemore). Labeled RN33B cells were grown in clonal culture or in co-culture so as to model how the labeled cells might behave *in vivo*. The appropriate labels for fetal raphe neurons and RN33B cells were then examined *in vivo* after transplantation into the CNS.

In vitro, raphe neurons were most reproducibly labeled with the fluorescent dye DiI. Other labels were toxic or less effective. Labels in non-neuronal raphe cells were rapidly diluted. Retroviral infection with the *E. coli* β -galactosidase gene optimally labeled undifferentiated RN33B cells over multiple passages. The gene was expressed by RN33B cells at non-permissive temperatures and in co-culture. *In vivo*, DiI-labeled raphe neurons, many of which were 5-HT immunoreactive, were visualized up to 1 month after intra-spinal transplantation. β -galactosidase-positive RN33B cells were visualized up to 2 weeks after intra-hippocampal transplantation. These results suggest that to determine the most appropriate labeling approach for identifying transplanted cells, it is advisable to first examine its properties *in vitro*. Supported by The Miami Project and NS26887.

Effect of Cytokines on Transgene Expression from the Moloney Murine Leukemia Virus LTR (MoMLV) and Collagen α 2(I) Promoters in Fibroblasts. M. Schinstine, L. Ray, and F. H. Gage, Dept. of Neurosciences, UCSD, La Jolla, CA 92093.

Recently we have shown that MoMLV transgene expression is reduced in quiescent fibroblasts (Schinstine et al., submitted). In addition to becoming quiescent, fibroblasts transplanted into the CNS have mononuclear phagocytes associated with the core of the graft. These cells secrete many types of cytokines, including IL-1 β , TGF β 1, and TNF α . The current study was undertaken to determine if these molecules can influence, and possibly be used to modulate, transgene expression.

Different reporter genes driven by the MoMLV or the collagen α 2(I) promoter were transduced into primary dermal fibroblasts. The expression of the MoMLV-driven reporter gene was greatest in fibroblast cultures containing proliferating cells. Fibroblasts maintained in a postconfluent state for 7 days exhibited a ~50% decrease in reporter gene activity. The activity of the reporter gene driven by the collagen promoter was comparable in cultures containing growing or quiescent fibroblast. Thus, it appears that MoMLV-driven transgene expression decreases in quiescent cells, whereas collagen promoter-driven expression remains stable. Cytokines were used to test their influence on transgene expression in cultures containing quiescent cells. IL-1 β (10 u/ml) and TNF α (120 ng/ml) did not affect transgene expression driven by MoMLV. TGF β 1 decreased transgene expression by ~50%. In comparison, IL-1 β caused a 25% reduction in transgene expression driven by the collagen promoter. TNF α and TGF β 1 administration caused a ~200% and ~300% increase in transgene expression, respectively. These results indicate that cytokines differentially effect the MoMLV and collagen promoters. Data on the expression of cells that have been implanted into the brain will be presented.

Supported by AGO8514 and an UC President's Fellowship to M.S.

INTRAHYPOTHALAMIC GT1 CELLS DIFFERENTIATE AND STIMULATE REPRODUCTIVE DEVELOPMENT IN HYPOGONADAL MICE. A.-J. Silverman, J.L. Roberts, K.W. Dong*, G.M. Miller & M.J. Gibson, Dept. Anat.& Cell Biol., Columbia Univ., New York, NY, 10032; Dept. Med. and Fishberg Ctr. Neurobiol., Mt. Sinai Sch. Medicine, New York, NY, 10029.

Bilateral injections of GT1-7 cells were made into the anterior medial hypothalamus of adult mutant hypogonadal (hpg) mice, which fail to produce GnRH. GT1 cell lines are immortalized neurons developed by genetically targeted tumorigenesis, that produce and secrete GnRH in culture. Neuronal-appearing cells with a plexus of fibers innervated the host brain at 1wk. Cells were immunoreactive to GnRH antibodies LR1, 1076 (detect precursor and product), and EL14 (which reacts with product only), suggesting complete processing of the GnRH prohormone in grafted cells. Numerous differentiated cells were seen in the hpg host brain at 5wk. Significant gonadal development in response to GT1-7 cells was evident in all 3 male hpgs studied 10 wk after grafting, with testes wts: 19.2, 20.4, and 33.8 mg (vs. untreated 7.6 mg). Two hpg female mice responded to GT1-7 implants with vaginal opening within 1wk, reflecting ovarian stimulation; at 10wk one hpg had significant uterine development (36.0 mg). We conclude that GT1 implants in hpg mice provide a powerful model to evaluate the utility of cell lines for neuronal transplants. Support: NS20335 (MJG) & HD19077 (MJG).

A NEURONAL CELL LINE DERIVED FROM MEDULLARY RAPHE. L.A. White & S.R. Whittemore. The Miami Project, Univ. of Miami School of Medicine, Miami, FL 33136.

Following infection of dissociated E13 rat medullary raphe cells with a retrovirus encoding the temperature-sensitive (ts)-mutant of SV40 large T antigen, a clonal cell line, RN33B, was isolated by serial dilution. At 33°C, RN33B cells divide with a doubling time of 36 hrs and show nuclear T antigen, vimentin, A2B5, and nestin immunoreactivities. RN33B cells are immortal, but not transformed as they will not grow in soft agar. At non-permissive temperature (39.5°C), T antigen immunoreactivity is markedly decreased and the cells cease mitotic activity. At 39.5°C, RN33B cells differentiate with phase bright cell bodies and "neuritic-like" processes. Immunohistochemical staining, northern blots, and Western blots showed that differentiated RN33B cells express vimentin, A2B5, nestin, and also neuron-specific enolase, neurofilament protein, and the NGF receptor, but not astrocytic or oligodendrocytic-specific cell antigens. Ultrastructurally, differentiated RN33B cells contain both microtubules and smaller caliber filaments. Differentiated RN33B cells returned to 33°C express T antigen, but do not de-differentiate and begin dividing. Class I MHC expression was detected only on undifferentiated RN33B cells, although IFN- γ could induce class I, but not class II MHC antigen expression on differentiated RN33B cells. Our results suggest that differentiated RN33B cells have many of the properties of mature CNS neurons. In addition, RN33B cells survive following transplantation into the CNS (see, Onifer et al.), suggesting that ts-neuronal cell lines may potentially be useful in replacing damaged neurons *in vivo*. Supported by The Miami Project to Cure Paralysis and NS26887.

229.13

ASTROCYTES AS CELLULAR VEHICLES FOR GENE THERAPY IN THE BRAIN. E.F. La Gamma, G. Weisinger, R.E. Strecker and N.J. Lenn. Depts. Pediatrics & Neurobiology, Psychiatry and Neurology, SUNY at Stony Brook, NY 11794-8111.

Genetically modified astrocytes can be transplanted into the central nervous system. Astrocytes may be the preferred cellular vehicle for gene replacement therapy via brain transplantation since they divide in culture, are region specific, possess a release mechanism, secrete growth factors, and migrate several millimeters from the transplant site. We have stably transfected neonatal rat astrocytes and selected for growth in G418 selective media for 3 weeks. RSV-driven and enkephalin promoter driven chloramphenicol acetyl transferase activity was demonstrated *in vitro* and again *in vivo* after 3 more weeks following transplantation into striatum. The transplanted astrocytes were also identified histologically by GFAP staining. In addition, we have demonstrated changes in transacted gene expression *in vitro* using dopaminergic agonists. This suggests another potential advantage of astrocytes over neuronal fibroblasts as transplant therapy in human disease entities such as Parkinson's Disease. Current work is in progress using the retroviral vector for the tyrosine hydroxylase gene LThRN (provided to us by F. Gage and K. O'Malley) to further evaluate this approach in the Parkinsonian rat behavioral paradigm. We speculate that genetically modified astrocytes can be used for studying other expressed proteins as well.

229.14

EXPRESSION OF PLASMID DNA IN RAT BRAIN CELLS *IN VITRO* AND *IN VIVO*. S.S. Jiao, G. Acsadi*, A. Jani*, P.L. Felgner* and J.A. Wolff*. Dept. of Pediatrics & Medical Genetics, Waisman Center, University of Wisconsin, Madison, WI 53705 and Vical Inc., San Diego, CA 92121.

This study demonstrated that plasmid DNA was able to persist in rat brain cells *in vivo* for one to two months. A new cationic lipid formulation which contains equimolar concentrations of DOTMA [N1-(2,3-dioleoyloxy)propyl]-N, N, N-trimethyl-ammonium and cholesterol was used to transfect reporter genes into fetal brain cells in culture with increased efficiency than the previously described cationic lipid formulation, Lipofectin (BRL). Suspended or clumped neocortical cells obtained from E17 fetuses had the greatest levels of luciferase activity after transfection of pRSVL, which contains the luciferase reporter gene. Using double immunohistochemical labelling, gene expression was localized both to glial and neuronal cells after transfection of fetal brain cells with pRSVLac-Z which contains the *E. coli* β -galactosidase reporter gene. Both glial and neurons were transfected with approximately equal efficiency. The transfected cells were also transplanted into the caudates of adult rats. One to two months after transplantation, the expression of the reporter genes were still found in the host brains. The ability for brain cells transfected with simple plasmids to have persistent expression of a foreign gene has implications for intracerebral viral infections and gene therapy of brain disorders.

THE AVIAN ALPHA₆ SUBUNIT OF INTEGRIN IS EXPRESSED IN THE DEVELOPING NERVOUS SYSTEM AND MUSCLE.

Michael Artinger*, M. Cullen and M. Bronner-Fraser, Developmental Biology Center, University of California, Irvine, CA 92717

The distribution of the alpha₆ subunit of integrin was examined in the trunk region in 2 to 8 day old avian embryos. Alpha₆ was first observed after neural tube closure and somite formation. As the somite differentiates into the dermomyotome and sclerotome, alpha₆ immunoreactivity was noted on prospective myotomal cells. At the same time, low levels of alpha₆ reactivity were observed in neuro-epithelial cells of the neural tube. Alpha₆ expression persisted in myotomal cells and later was present on myoblasts in the limb, as well as in the apical ectodermal ridge. In the developing neural tube, alpha₆ immunoreactivity became prominent near the lumen and in the ventrolateral portions of the neural tube, co-distributing with neurons and axons. Its expression was prominent in commissural neurons as they extended processes toward the floorplate via the basal lamina. Alpha₆ immunoreactivity was expressed on a subpopulation of neural crest cells around the dorsal aorta at later stages of neural crest cell migration; these were presumably sympathoadrenal cells. It was prominent in the ventral roots and first appeared in the dorsal root ganglia shortly after their formation. Expression was developmentally regulated and appeared to peak at embryonic days 5 to 6, decreasing thereafter. Alpha₆ co-localized with $\beta 1$ integrin, suggesting that they form alpha₆-beta₁ heterodimers. Our results show that the alpha₆ subunit of integrin is expressed throughout the developing nervous system and muscle. In the periphery, these regions are rich in laminin, which is thought to be its ligand. (supported by HD15527)

ASSOCIATION OF MULTIPLE FORMS OF HUMAN N-CADHERIN WITH BRAIN SYNAPTOSOMES. Duane D. Bronson*, Robert A. Reid*, and John J. Hemperly. Becton Dickinson Research Center, Research Triangle Park, NC 27709.

The establishment, maintenance, and modification of synaptic connections are critical to the proper functioning of the nervous system. The molecules involved in these processes, particularly cell adhesion molecules, are the subject of intensive study. We have prepared antibodies and DNA probes to the human calcium-dependent adhesion molecule N-cadherin and used them to identify the molecule in the synaptosomal fraction of human brain. Unlike in tissue culture cells, and in contrast to our studies of human L1 antigen and transmembrane forms of the neural cell adhesion molecule N-CAM, N-cadherin appears to be tightly associated with cytoskeletal elements. Moreover, antibodies prepared against a recombinant form of N-cadherin expressed in bacteria recognize two polypeptides (130 Kd and 100 Kd) in brain and in cell lines. The nature of these polypeptides and their relationship to each other and to other cadherins are being investigated.

230.2

T-CADHERIN, A GPI-ANCHORED CADHERIN IN THE NERVOUS SYSTEM, IS COMPETENT TO MEDIATE CELL ADHESION. D.J. Vestal and B. Ranscht. La Jolla Cancer Research Foundation, La Jolla, CA 92037.

The cadherins are a family of calcium-dependent cell-cell adhesion molecules. The adhesive function of cadherins depends, in part, on the interaction of their highly conserved cytoplasmic domain with components of the cytoskeleton. This laboratory has identified a new member of the cadherin family, T-cadherin, that lacks the conserved cytoplasmic sequences (Ranscht and Dours-Zimmermann, in press). T-cadherin is a prominent component of many neuronal cell types and is detected in the paths of growing commissural and motor axons. This expression pattern is consistent with a possible role in nerve guidance.

In order to investigate if T-cadherin is competent to mediate adhesive interactions, T-cadherin cDNA was expressed in CHO cells. Transfected cells express both the 95 kda mature T-cadherin protein and an additional 110 kda polypeptide. The heterologously expressed T-cadherin is GPI-anchored, as determined by the incorporation of ³H-ethanolamine and by the release of both polypeptides from the cell surface by treatment with PI-PLC. In cellular aggregation assays, T-cadherin induces calcium-dependent homophilic cell-cell adhesion. A variant T-cadherin cDNA has been identified (see Sacristan and Ranscht, this issue) which encodes T-cadherin polypeptides with similar biochemical and adhesive properties. The ability to promote cell-cell adhesion in the absence of the conserved cytoplasmic region, that links other cadherins with the cytoskeleton, implies that T-cadherin uses an alternative mechanism for generating adhesive interactions.

230.4

CHARACTERIZATION AND DEVELOPMENTAL EXPRESSION OF A T-CADHERIN VARIANT IN THE CHICKEN NERVOUS SYSTEM. M. Sacristan* and B. Ranscht. La Jolla Cancer Research Foundation, La Jolla, CA 92037.

Cadherins are a multigene family of calcium-dependent cell-cell adhesion molecules that are suggested to play an important role in tissue morphogenesis. This laboratory has identified a new cadherin, T-cadherin, that lacks the conserved cytoplasmic region and, instead, is anchored to the cellular plasma membrane through a glycosylphosphatidylinositol glycan (Ranscht and Dours-Zimmermann, in press). We now report the characterization of a variant form of T-cadherin, Tcadv, that is encoded by a cDNA differing in the 3' region from the originally reported clone, Tcad. In the open reading frame for Tcadv, the carboxyterminal Leu of Tcad is changed into Lys and followed by five additional amino acids. To investigate if the expression of the two T-cadherin forms is regulated during chick neural development, mRNA from chick brain between embryonic day 2 and two days after hatching was analyzed by RNase protection with probes specific for Tcad and Tcadv. mRNAs for both T-cadherin forms were expressed, at strikingly different levels, at all times examined. Tcadv was prevalent at embryonic day 2, while Tcad predominated, in a ratio of >10:1, at all later developmental stages. mRNA levels for both Tcad and Tcadv increased continually between embryonic day 4 and day 16 and appeared to be down regulated thereafter. The accumulation of Tcad over Tcadv mRNA appears to correlate with neuronal differentiation and was also observed in pure cultures of neurons. These observations indicate that the expression levels of the two T-cadherin forms are differentially regulated during neural development. The location of Tcad and Tcadv mRNAs at the single cell level will be examined by *in situ* hybridization.

230.5

NEURAL CELL ADHESION MOLECULE REGULATION IN CULTURED CHICK MYOTUBES. *J.M. Lyles, W. Amin* and C.L. Weill*. Department of Neurology, Louisiana State University Medical School, New Orleans, LA 70112.

The neural cell adhesion molecule, NCAM, is a cell surface glycoprotein that influences neuro-muscular adhesion in developing muscle. Since NCAM levels and molecular forms change during muscle development, the factors that affect NCAM regulation were investigated in primary, embryonic chick muscle cultures. Primary muscle cultures grew better and fibroblast proliferation was reduced in serum-free medium on reconstituted basement membrane, Matrigel. Serum factors enhanced the relative level of NCAM (per ug protein on myotube day 5) determined by ELISA, suggesting that growth factors regulate NCAM expression. Several purified factors which enhanced relative NCAM levels were: 1) nisoldipine (a calcium ion agonist), 2) insulin-like growth factor II (IGFII), 3) nerve growth factor (NGF), 4) veratridine (a sodium ion channel agonist) and 5) thyroxine (T4). Ineffective factors were vasoactive intestinal peptide, calcitonin gene-related peptide, acidic fibroblast growth factor, basic fibroblast growth factor, IGF I, dibutyl cyclic GMP and dibutyl cyclic AMP. Therefore, extracellular factors and intracellular ions appear to regulate NCAM expression in developing muscle.

MOLECULAR STRUCTURE AND FUNCTIONAL TESTING OF HUMAN L1. *M.L. Hlavin and Y.P. Lemmon*. Departments of Neurosurgery and Neuroscience. Case Western Reserve University School of Medicine, Cleveland, OH 44106.

The L1-like cell adhesion molecules are members of the immunoglobulin superfamily that have been implicated in axon growth and guidance. We have isolated the related molecule from human brain and found that, like its counterparts in rodents and chick, it also supports neurite growth *in vitro*. Additionally, we have cloned and sequenced the entire coding region for human L1. It has a very high degree of homology to mouse L1, 92% at the amino acid level. Although overall homology to chick L1 is substantially less, 40% at the amino acid level, certain regions are highly conserved. A domain by domain comparison of the mouse, chick, and *Drosophila* sequences to human L1 indicates that the L1 Ig domain 2 and Fn domain 2 are strongly conserved between species and thus are likely functionally important. The Ig 2 domain possesses a highly negatively charged region suggesting a significant functional region; similarly, a highly positively charged region was found in the Fn domain 3. We found 100% identity of the mouse cytoplasmic region to human L1, further supporting previous reports of the highly conserved nature of this region and suggesting an important function such as cytoskeleton interaction or cellular regulation.

DOMAIN	Ig 1	Ig 2	Ig 3	Ig 4	Ig 5	Ig 6	Fn 1	Fn 2	Fn 3	Fn 4	Fn 5	CP

BRAVO, A NOVEL CELL-SURFACE MOLECULE FOUND IN A RESTRICTED PATTERN ON OPTIC FIBERS OF THE DEVELOPING NERVOUS SYSTEM, IS CLOSELY RELATED TO NgCAM AND L1.

J.F. Kayyem, Enrique J. de la Rosa, J.M. Roman*, U. Schwarz* and W. J. Dreyer*. CalTech, Pasadena, CA 91125 and Max Planck Inst., Tübingen, Germany D7400.

Cell-surface molecules play an essential role in guiding axons to their targets. We have developed a method to generate monoclonal antibodies (mAbs) which recognize cell-surface molecules of defined molecular weight that are expressed during the development of the chicken retinotectal system. The antigen distribution on optic fibers recognized by one of these mAbs, Bravo, is restricted to retinal ganglion cell axons in the retina, and absent from these same axons in the tectum.

The complete derived sequence of Bravo has been obtained. It reveals a close relationship to the neural members of the immunoglobulin superfamily, with closest relationship to chicken NgCAM and mouse L1. Like NgCAM and L1, Bravo contains six immunoglobulin domains, five fibronectin type III repeats, a transmembrane domain and a highly conserved but functionally uncharacterized cytoplasmic region. Like the other neural members of the Ig superfamily, Bravo carries the HNK-1 carbohydrate epitope, and specifically like L1 and NgCAM, Bravo is found predominantly in the form of a heterodimer, an intact chain cleaved in identical locations in all three molecules into two non-covalently associating parts. These data present an interesting view of retinotectal optic fiber outgrowth: As optic fibers grow in dense fascicles towards the optic nerve exit, they express both the known cell adhesion molecule NgCAM, and the closely related Bravo. As these fibers pass through the optic chiasm, Bravo is reduced on their surfaces, coincidentally in the same place and time that these fibers noticeably defasciculate, presumably to allow independent target seeking by individual axons. The possible role that Bravo's expression and topological restriction plays in the fasciculation and subsequent defasciculation of optic fibers is currently under investigation.

DEVELOPMENTAL AND CELL-SPECIFIC CHANGES IN N-CAM EPITOPES. *Y. Yan, W-W. Chung and C. Lagenaur*. Dept. of Neurobiology, Anatomy and Cell Science, University of Pittsburgh, Pittsburgh, PA. 15261.

N-CAM exists in three major isoforms in the CNS; varied glycosylation may account for further N-CAM heterogeneity. In this study, three monoclonal antibodies (12F11, 12F8 and 8A2) were used to study N-CAM expression *in vivo* and *in vitro*. Western blots of brain membranes from E14, P0 and adult mice were examined. Diffuse bands around 200 kD were observed with all antibodies at E14 although 12F11 stained weakly. In adult, polyclonal anti-N-CAM stained the three major isoforms of CNS N-CAM. The 12F8 antibody recognizes polysialic acid on N-CAM and showed little staining in adults. Interestingly, 12F11 stained the 180 and 140 kD forms of N-CAM but not the 120 kD form. The 8A2 antibody also failed to stain the 120 kD N-CAM, but did stain 140 and 180 kD forms. The anti-8A2 also weakly stained a number of unidentified proteins. Cultured mouse neocortex was stained with each antibody. Anti-12F8 stained neurons and their processes as well as some astroglia. Anti-12F11 stained some neurons but did not stain glia. Most strange was the anti-8A2 which stained the substrata of the cultures leaving an unstained "ghost image" in areas occupied by cells. These studies further define the developmental changes in N-CAM expression and the differing expression of particular forms of N-CAM by various neural cell types. Supported by NIH NS25543.

ISOLATION AND CHARACTERIZATION OF A 135 kDa MEMBRANE GLYCOPROTEIN FROM HUMAN BRAIN

E. Berglund, S.R. Carlsson*, R.S. Johansson, and T. Stigbrand**. Dept. of Medical Biochemistry and Biophysics and Dept. of Physiology, Umeå University, S-901 87 Umeå, Sweden.

We have purified a 135 kDa membrane glycoprotein from human brain cortex using lentil lectin affinity chromatography and immunoaffinity chromatography with a specific monoclonal antibody, CF3 (Berglund, E. et al., (1987) J. Neurochem., 48(3),809-815, Berglund et al., (1991) Eur. J. Biochem., in press). The polypeptide core is estimated to be 115 kDa by N-glycanase digestion. The glycoprotein is anchored to the plasma membrane through glycosylphosphatidylinositol as shown by digestion with phospholipase C and liposome incorporation. Quantitative enzyme-linked immunosorbent assay (ELISA) and immunohistochemistry techniques were used to determine the location of the 135 kDa protein in human brain. The 135 kDa glycoprotein is most abundant in the gray matter of frontal cortex and cerebellum, i.e. areas dense in dendritic and unmyelinated axonal processes. In contrast, the subcortical white matter, pons and medulla display only low levels of the 135 kDa protein. Amino acid sequence analysis of the amino terminus and of an internal peptide obtained by V8 protease digestion of the 135 kDa protein, revealed a strong similarity to three previously described glycoproteins from chicken (contactin and F11) and mouse (F3) brains. These glycoproteins belong to the immunoglobulin superfamily and are implicated in cell adhesion phenomena in the developing brain. Gp135 may be the human counterpart to one or several of these glycoproteins.

230.10

A RETINAL CELL SURFACE PROTEIN UNEQUALLY DISTRIBUTED ON OPTIC FIBERS

J. Vielmetter, J. F. Kayyem, R. Lane, J. Roman*, U. Schwarz*, and W. Dreyer*. Caltech, Pasadena CA 91125 and Max-Planck-Institut für Entwicklungsbiologie, Tübingen D-7400, Germany

Most scientists now agree that the proper establishment of axonal projections in the nervous system is achieved in part by an address system of cell surface recognition molecules. These address molecules are expected to be distributed unevenly both in space and in time during embryogenesis. One candidate for such a molecule was detected with the monoclonal antibody 10-22A8. In the chick retina, at embryonic stages E7 to E8, it stains the optic fibers of the nasal retina while staining the temporal fibers little if at all. Preliminary sequence information of a cDNA clone coding for a portion of this protein reveals that its closest homology is to the fibronectin Type III repeat of LAR (leukocyte antigen related, human) and DLAR (neuron specific, *Drosophila*), two members of the family of membrane bound tyrosine phosphatases. Determination of the entire coding sequence will reveal more information on protein domains with known functions and will establish whether this is in fact a novel member of the tyrosine phosphatase family of cell surface receptors. Additional histological studies, as well as *in vitro* and *in vivo* functional assays will be required in order to assess the significance of the striking difference between the staining of nasal vs. temporal axons in the developing retina at stages E7 to E8.

230.11

MONOCLONAL ANTIBODY BM88 DEFINES A NEURON SPECIFIC SURFACE ANTIGEN INVOLVED IN NEURITE OUTGROWTH. E. Patsavoudi*, V. Vlazakis* and R. Matsas. Lab. of Biochemistry, Hellenic Pasteur Institute, Athens 115 21, Greece.

BM88 antigen is a neuron specific surface protein present in the central and peripheral nervous system and composed of two 22KD polypeptide chains (E. Patsavoudi, C. Hurel and R. Matsas, 1989, *Neuroscience* 30 463-478). The immunoaffinity purified antigen has properties typical of an amphipathic membrane protein and is not glycosylated (E. Patsavoudi, C. Hurel and R. Matsas, 1991, *J. of Neurochemistry* 56 782-788).

The functional properties of this antigen were investigated in antibody mediated perturbation experiments using primary cultures. To this purpose an immunoaffinity and Fab fragment preparation of a polyclonal antibody raised against the BM88 antigen were prepared. When dissociated cells from brain of 19 day old rat embryos were cultured for 6h and 24h in a defined medium in the presence of the antibody, an inhibition of neurite outgrowth of these cultures was observed in a dose dependent manner. Our results strongly suggest that the BM88 antigen plays and important role in the promotion of neurite outgrowth.

230.13

GALACTOSE-BINDING PROTEINS ISOLATED FROM THE LEECH CNS ARE COMPLEMENTARY, *IN VITRO*, TO A GALACTOSE-CONTAINING EPITOPE ON LEECH SENSORY AFFERENTS. R.N. Cole and B. Zipser, Department of Physiology, Michigan State University, East Lansing, MI 48824.

Carbohydrate recognition between cell surface glycoconjugates and carbohydrate-binding proteins (CBPs) is postulated to regulate neuronal pathfinding and target recognition. Previously, we demonstrated that a carbohydrate epitope on the surface of leech sensory afferents mediates the defasciculation of the sensory afferents into the synaptic neuropile of the CNS. This work predicted the presence of a CBP in the leech synaptic neuropile. We have now isolated three CBPs with apparent MWs of 37, 35, and 16 kD from crude membrane fractions of the leech CNS. They bind to an asialofetuin affigel column and are eluted by alpha-methyl-galactose or galactosamine, but not by xylose or alpha-methyl-mannose. These galactose-binding proteins have similar MWs and binding characteristics as the vertebrate galactose-binding proteins CBP-35 and CBP-16 (*J. Biol. Chem.* 258: 10657), which belong to the family of thiol dependent (S-type) lectins (*J. Biol. Chem.* 263: 9557).

In vitro, these galactose-binding proteins are complementary to a carbohydrate epitope on a subset of sensory afferents found on leech lips. The lip afferents, chemo- or heat detectors, express a galactose-containing epitope, as inferred from the sugar-binding specificity of the mAb Lan2-3a. Galactosamine inhibits the binding of mAb Lan2-3a to the lip afferents and elutes mAb Lan2-3a from an asialofetuin column. Molecular cloning and functional studies will determine whether the leech galactose-binding proteins are S-type lectins and whether they interact with the Lan2-3a epitope *in vivo*.

230.15

DIFFERENT DOMAINS OF J1/TENASCIN PROMOTE CEREBELLAR GRANULE CELL MIGRATION AND NEURITE OUTGROWTH. K. Husmann*, M. Schachner and A. Faissner* Dept. Neurobiology, Swiss Federal Institute of Technology, Zürich, Switzerland and *Dept. Neurobiology, University of Heidelberg, Heidelberg, Germany.

J1/tenascin is a hexameric extracellular matrix molecule which is involved in neuron-glia recognition. To study its role in astrocyte-mediated neuronal migration, five monoclonal antibodies were used in an *in vitro* assay to determine cerebellar granule cell migration (modified from Lindner et al., *Nature*, 305: 427, 1983). Rotary shadowing electron microscopy was used to determine the immunoreactive domains of J1/tenascin. The antibodies J1/t1, 4 and 5 bound to the fourth or fifth fibronectin type III repeat, while J1/t2 reacted with the tenth or ninth and tenth repeat and J1/t3 with a proximal EGF-like repeat (for J1/t1 and 2 see Lochter et al., *J. Cell Biol.*, in press). Only antibodies 1, 4 and 5 inhibited granule cell migration (by 55%). To study which of the domains are involved in extension of granule cell neurites, granule cells were cultured on a J1/tenascin-polyornithine substrate and the influence of J1/tenascin on neurite extension was measured in the presence of the antibodies. As for hippocampal neurons (Lochter et al., *ibid.*) only J1/t2 inhibited the stimulatory effect. We conclude that J1/tenascin influences neurite outgrowth and neuronal migration by different domains in the fibronectin type III repeats.

230.12

DEVELOPMENTALLY AND SPATIALLY REGULATED EXPRESSION OF HNK-1 EPITOPE ON A NOVEL PI-ANCHORED GLYCOPROTEIN, PI-GP150 Y. Yoshihara, S. Oka*, Y. Watanabe* and K. Mori Dept. of Neuroscience, Osaka Bioscience Inst., Suita, Osaka 565 Japan

Cell surface adhesion and recognition molecules play critical roles in a variety of developmental events. HNK-1 carbohydrate antigen is a common epitope expressed on such molecules involved in cell-cell interactions in the nervous system. We purified and characterized from rat brain a novel phosphatidylinositol (PI)-anchored 150 kD glycoprotein with HNK-1 epitope. The molecule (PI-GP150) was detected by combination of PI-specific phospholipase C treatment of brain membranes and Western blot analysis with monoclonal antibody HNK-1. The expression of HNK-1 epitope on PI-GP150 was developmentally and spatially regulated. In newborn rats, HNK-1 epitope was expressed on PI-GP150 throughout the brain. The level of HNK-1-positive PI-GP150, however, decreased after postnatal day 7 only in hindbrain, and became completely absent in adult myelencephalon and metencephalon, while constitutive expression of HNK-1 epitope on PI-GP150 was observed in telencephalon. This developmental change results in formation of the rostro-caudal gradient of the HNK-1 epitope expression on PI-GP150 in adult brain.

230.14

REGIONAL AND TEMPORAL VARIATIONS OF CARBOHYDRATE DISTRIBUTION IN THE EMBRYONIC CHICK BRAINSTEM.

I. Lopez-Colberg and J.A. Wallace. Dept. of Anatomy, Univ. of New Mexico Sch. of Med. Albuquerque, New Mexico 87131.

Analysis of cell surface carbohydrates in central and peripheral neural tissue has revealed that certain neuronal subsets possess oligosaccharides that vary in composition or amount during development. The function of these oligosaccharides is unknown but it is postulated that they may serve as recognition signals during the processes of neuronal migration and synaptogenesis. In this study we examined the pattern of cell surface carbohydrates in the embryonic chick brainstem at ages related to active cell migration and pathway formation. To investigate the spatial and temporal distribution of sugar moieties in the chick brainstem, paraffin sections of the brainstem were screened with a battery of fluorescinated lectins. Lectins are glycoproteins of non-immune origin that bind to specific oligosaccharide residues. Our study demonstrated that only Peanut agglutinin (PNA) and Concanavalin A (Con A) exhibited regional and temporal variation in their binding during embryonic chick brainstem development. PNA staining was especially interesting in that it bound to areas known to contain differentiating and migrating serotonergic (5-HT) neurons. Work is in progress using an affinity isolation technique to enrich for 5-HT cells by their potential binding to peanut agglutinin. Supported by MBRS grant RR08139.

VARIABLE MEMBRANE GLYCOPROTEINS IN DIFFERENT GROWTH CONE POPULATIONS. S. Quiroga*, H. Li*, K.H. Pfenninger. Cell. & Struct. Biol., Univ. Colo. Sch. Med., Denver, CO 80262

The question of whether growth cones generated by different neurons contain distinctive membrane glycoproteins was examined. Growth cones (GCPs) were isolated from defined regions of fetal or early postnatal rat brain and their membrane proteins analyzed by two-dimensional PAGE and Western blotting using wheat germ agglutinin (WGA) as a probe. The results indicate substantial pattern diversity for the different growth cone populations. Some WGA-binding proteins are uniformly present in the GCP fractions while others appear unique to a specific brain region. gp93 is a 90-97 kDa glycoprotein complex present in all GCPs analyzed. The complex covers a pI range from about 4.9 to about 6.4 and consists of at least twelve different species, probably isoelectric variants, in GCPs from whole fetal brain. Neuraminidase digestion simplifies the gp93 pattern only partially, indicating that variable sialic acid content explains the molecular diversity to some extent. In GCPs from different brain regions the sets of gp93 species are different and characteristic. This suggests that gp93 may be involved in selective cell-cell interactions. gp93 has been purified and experiments are being carried out to study the heterogeneity of the oligosaccharide and polypeptide chains included in the complex. (Supported by NIH grant NS24676.)

INTERACTIONS BETWEEN NEURONAL HEPARAN SULFATE PROTEOGLYCANS AND PROTEINS OF THE EXTRACELLULAR MATRIX. C. S. Stupp, M. E. Herndon*, and A. D. Lander, Dept. of Biology & Dept. of Brain & Cognitive Sciences, M.I.T., Cambridge, MA 02139.

Proteoglycans (PGs) are believed to play roles in complex neural cell behaviors such as cell attachment and neurite outgrowth. Biochemical analysis of PGs from cultured cells may provide clues about the roles of specific PGs in cell behavior. Therefore, membrane-associated PGs were isolated from PC12 cells that had been metabolically labelled with $^{35}\text{SO}_4$ and the core proteins of these PGs were biotin-labelled. SDS-PAGE analysis following heparitinase digestion confirmed the presence of a major heparan sulfate proteoglycan (HSPG) with a core protein M_r of ~60kd (Gowda, et al., JBC 264:11436). The effects of phosphatidylinositol-specific phospholipase C on Triton X-114 partitioning of this HSPG indicate that it is a lipid-anchored membrane component. The data suggest that this PG is identical to a rat brain PG whose expression is developmentally regulated (HSPG M12; Herndon and Lander, Neuron 4: 949). To investigate the possibility that this PG is a receptor for the extracellular matrix, PG binding to purified matrix proteins was measured by affinity coelectrophoresis (Lee and Lander, PNAS 88:2768). The PC12 PG preparation showed a single, heparitinase-sensitive affinity for each protein tested. The order of affinities was collagen > laminin >> fibronectin (FN). Interestingly, this order correlates with the relative levels of adhesion displayed by PC12 cells toward substrata treated with these molecules. The low affinity observed for binding of PC12 HSPG to FN ($K_d > 1\mu\text{M}$) contrasts sharply with the behavior of HSPG M12 isolated from newborn rat brain, which contains a subfraction exhibiting high affinity ($K_d \sim 10\text{nM}$) for FN. These data are consistent with the idea that PGs can exhibit functional (e.g. binding) diversity sufficient to influence neuronal cell-matrix interactions. Supported by NIH grant NS26862 (ADL) and NRSA predoctoral support (CSS and MEH).

230.19

A GENERAL COMPONENT OF ADULT BRAIN EXTRACELLULAR MATRIX, THE T1 CHONDROITIN SULFATE PROTEOGLYCAN. Mineo Iwata and Steven S. Carlson, Dept. of Physiology and Biophysics, University of Washington, Seattle, WA.

We have identified a large chondroitin sulfate proteoglycan (T1-PG) that has the characteristics of a general extracellular matrix component of rat brain (Iwata and Carlson, Abst. Soc. Neuro., 16:496, 1990). This proteoglycan was identified with a mAb to a rare chondroitin sulfate epitope (T1). The T1-PG is immunocytochemically localized throughout the brain in white and gray matter. Like ECM components from other tissues, the T1-PG requires denaturing conditions to be solubilized from brain tissue. The T1 antigenicity appears to be secreted by cultured rat newborn cerebellar cells. Digestion of the T1-PG with chondroitin ABC lyase yields to core sizes of 210Kd and 250Kd.

The T1-PG appears to be distinct from the well-known spacefilling proteoglycans, versican and aggrecan. We generated an antibody against a common consensus sequence in the hyaluronic acid binding loop region (HABL) of these proteoglycans. This antibody crossreacts with monkey smooth muscle versican and calf nasal cartilage aggrecan with core sizes of 447Kd/528Kd and 447Kd, respectively. This anti-HABL antibody also recognizes two major core proteins of the putative rat brain versican with molecular weights of 361Kd and 447Kd. This putative versican is extracted by non-denaturing detergents. Anti-HABL does not detectably bind to purified T1-PG. Furthermore, the following biochemical characteristics of T1-PG are found to differ from the putative brain versican: (1) T1-PG has a higher density on dissociative CsCl gradient. (2) It is tightly associated with the detergent-insoluble fraction of adult brain. (3) It has the T1 epitope; versican does not. (4) It is disulfide-linked to a 100Kd protein. (5) Its core size is smaller.

230.21

A neuronal surface, sub-population specific proteoglycan in mouse and *Drosophila melanogaster* nervous systems. C. Williams*, L. Reiter*, D. Hinton*, S. Benzer and C.A. Miller, Dept. of Pathology, U.S.C. School of Medicine, Los Angeles, CA 90033. Dept. of Biology, California Institute of Technology, Pasadena, CA 90025.

Monoclonal antibody (MAb) 6A2 labels an antigen localized to somal surfaces of neurons comprising the spinocerebellar system, and to a sub-population of non-pyramidal neurons in the cerebral cortex of human CNS, (Hinton et al, 1988, J. Comp. Neurol. 267:398). The immunoreactivity disappears in amyotrophic lateral sclerosis (Williams et al, 1990, Ann. Neurol. 27:215). We are now comparing the corresponding antigen (Ag) in the murine and *Drosophila melanogaster* nervous system. Ag 6A2 has a similar distribution in the murine and human CNS. Ultrastructurally, in mouse it lies in the extracellular space adjacent to neuronal surface membranes and in fly retina, in the intrareticular space. Affinity-purified mouse cerebellar and fly head homogenates reveal on immunoblots, 630kDa, and 400kDa proteins respectively. After incubation with chondroitinase ABC, both antigens showed increased migration on polyacrylamide gels, and the murine Ag 6A2 immunoreactivity with MAb 1B5, which labels chondroitin sulfate 'stubs'. The lectin, Jacalin, was immunoreactive with both antigens verifying the presence of O-linked oligosaccharides. The restricted distribution of Ag 6A2 to functionally distinct cellular subpopulations may be of importance in the formation and maintenance of these systems.

230.18

IMMUNOHISTOCHEMICAL LOCALIZATION OF THE GLYCOSAMINOGLYCAN (GAG) CHONDROITIN-4-SULFATE (CS-4) IN THE NORMAL ADULT RAT SPINAL CORD. F.J. LIUZZI, Dept. of Anatomy and Neurobiology, Eastern Virginia Med. Sch., Norfolk, VA 23501.

A chondroitin sulfate proteoglycan (PG) containing mainly CS-4 has been localized in adult rat brain by Aquino and colleagues (*J. Cell Bio.* 187:211, 1984). The PG has a widespread distribution and is present in neurons as well as astrocytes. More recently, an *in vitro* study showed that type-2 astrocytes express CS-4 but not CS-6 while type-1 astrocytes express neither form (Gallo and Bertolotto, *Exp. Cell Res.* 99:1117, 1990).

In light of the latter *in vitro* data, and the recent proposal that CS is inhibitory to axonal growth in the adult mammalian CNS by virtue of its localization in white matter and its purported absence in gray matter, it was decided to examine CS-4 localization in the adult rat spinal cord using a monospecific antibody to this GAG. The results of this work show that CS-4 is widely distributed not only in the spinal cord white matter but also in the gray matter. The GAG is ubiquitous in the gray matter and is found within neurons. In the white matter CS-4 is found in longitudinally oriented astrocytic processes and is particularly prominent at nodes of Ranvier, a finding that supports the idea that type-2 astrocytes form the nodal processes.

This work was supported by a grant from the NIH (NS24309).
