The bombesin-like peptides gastrin-releasing peptide (GRP) and neuromedin-B (NMB) are important in regulating a number of biological activities including secretion, smooth muscle contraction, and modulation of neuronal activity. The bioactivities associated with these peptides are mediated by high-affinity binding to receptors, GRP-R and NMB-R, present on the surface of many target cells. cDNA clones encoding GRP-R and NMB-R have been isolated from mouse swiss 3T3 fibroblasts and rat esophagus respectively. The two receptors show 56% amino acid identity, and encode seven putative transmembrane domains characteristic of the G-protein coupled receptor superfamily. Ligand binding studies have shown that while both receptors bind both ligands, GRP-R has higher affinity for the GRP ligand in contrast to NMB-R which prefers NMB. In this study a series of chimeric GRP-R and NMB-R have been constructed. These constructs were first assayed for function in oocytes and then stably transfected into BALB 3T3 fibroblasts. Ligand displacement studies using bombesin receptor agonists and antagonists have been used to examine domains involved in high affinity ligand binding.

CHARACTERIZATION AND FUNCTIONAL EXPRESSION OF A HUMAN SUBSTANCE P RECEPTOR cDNA. Y. Takeda, K.B. Chou, J. Takeda, B.S. Sachais and J.E. Krause. Department of Anatomy & Neurobiology, Washington University School of Medicine, St. Louis, MO 63110.

Substance P (SP) brings about its diverse biological actions by activating a G-protein coupled receptor, which in turn results in the stimulation of particular effector systems. Recently, the rat SP receptor was cloned and molecularly characterized, and was shown to be a member of the G-protein coupled receptor superfamily. In this work we have also molecularly characterized the human SP receptor. RNA was isolated from the IM-9 immunoblast cell line, and a partial receptor fragment was generated by the polymerase chain reaction (PCR). The 5' and 3' extents of the coding region were determined by genomic cloning and sequence analysis, and a full coding region containing cDNA was generated by PCR. The human SP receptor displayed greater than 94% identity to the rat receptor. The human SP receptor cDNA was inserted into the vector, pM², in which cDNA expression is controlled by the Harvey murine sarcoma virus LTR. Receptor expression was characterized in transiently transfected COS-7 cells using a filtration assay with [¹²⁵I]-Tyr¹-SP as ligand. [¹²⁵I]-Tyr¹-SP specifically bound to transfected cells with high affinity (K_d=0.24 nM), at a level of 151,000 sites/cell. The potency of tachykinin agonists on the displacement of [¹²⁵I]-Tyr¹-SP was as follows: SP > physalaemin > SP methyl ester > neuropeptide γ > neurokinin A = neuropeptide K = neurokinin B > senktide; this is consistent with the binding site being an NK-1 type tachykinin receptor subtype. SP stimulation of transfected cells resulted in the transient production of IP₃ as measured by a radioreceptor assay. These results demonstrate that we have cloned and functionally expressed the human SP receptor.

GR82334, A PHYSALAEAMIN ANALOGUE WHICH IS A SELECTIVE NK-1 RECEPTOR ANTAGONIST. R.M.Hagan*, I.J.M. Beresford*, S.J.Ireland*, C.C. Jordan* and P. Ward*. Department of Neuropharmacology, Glaxo Group Research, Ware SG12 0DP, U.K.

GR82334 {[D-Pro⁹[spiro- γ -lactam]Leu¹⁰,Trp¹¹]-PHY(1-11)} is an analogue of the non-mammalian tachykinin physalaemin (PHY) containing the (S)-spiro-lactam bicyclic conformational constraint which confers antagonist activity at NK-1 receptors (see Ward et al., J. Med. Chem., 33, 1848-1851, 1990). GR82334 behaved as a reversible competitive antagonist in vitro at NK-1 receptors in guinea-pig ileum, guinea-pig trachea and U-373MG human astrocytoma cells (pK_B values 7.64, 7.23, 7.55 respectively) but had no agonist or antagonist activity at NK-2 or NK-3 receptors at concentrations up to 10 μ M. In the neonatal rat hemisectioned spinal cord preparation, GR82334 antagonised ventral root depolarisation-induced by the NK-1 agonist, substance P methylester (SPOMe). However, GR82334 exhibited reduced potency (approximately 10-fold) in this preparation compared to other NK-1 receptors, suggesting NK-1 receptor heterogeneity. In anaesthetised rats, GR82334 (0.1-2.5 μ mol/kg i.v.) inhibited plasma protein extravasation in skin evoked by an NK-1 agonist, δ Aval[Pro⁹,N-MeLeu¹⁰]SP(7-11) (GR73632), or by electrical stimulation of the fibularis nerve. In mice, GR82334 (1 nmol) given intrathecally, was able to antagonise the hind-limb scratching response induced by concurrent administration of SPOMe, causing a 41-fold rightward shift in the dose-response curve to SPOMe. In conclusion, GR82334 is a potent antagonist at NK-1 receptors in peripheral and CNS tissues both in vitro and in vivo.

STRUCTURE-ACTIVITY STUDIES OF TRUNCATED NEUROPEPTIDE Y ANALOGUES IN BRAIN AND PERIPHERAL TISSUES. J.C. Martel¹, H. Satoh¹, Y. Dumont¹, A. Cadieux², M. T-Benchekroun², A. Fournier³, S. St-Pierre³ and R. Quirion¹. (1) Douglas Hosp. Res. Ctr., McGill Univ., Montréal, Canada, H4H 1R3, (2) Dept. Pharmacol., Sherbrooke Univ., Sherbrooke, Canada J1K 2R1, (3) INRS-Santé, Pointe-Claire, Canada, H3R 1G5.

Truncated neuropeptide Y analogues of the [1-4-aca-18-36]-NPY type, were tested for their ability to inhibit rat vas deferens contraction, to induce the contraction of the rat descending colon and to inhibit [¹²⁵I]PYY binding in rat forebrain membranes. Substitutions of the tyrosine (Tyr) residue in position 1 by either phenylalanine (Phe), cyclohexylalanine (Cha), D-Tyr, N-Me-Tyr, Tyr-O-Me, Tyr-O-Et, 1p-nitro-Phe, p-Iodo-Phe, p-Chloro-Phe, and 3-5-Bromo-Phe produced analogues having two-three times lower potencies than pNPY in the rat vas deferens (EC₅₀: 50-150 nM). These same analogues were only slightly weaker than pNPY in the rat forebrain binding assay. However, in the rat descending colon, most behaved as weak agonists (EC₅₀: 1-2 μ M); the analogues Tyr-O-Et, p-Iodo-Phe and 3-5-Bromo-Phe being completely inactive. Taken together, these results indicate that the tyrosine residue in position 1 is more critical for receptor activation in the rat colon than in the rat vas deferens and CNS binding assay. In addition, analogues substituted in position 1 by either Tyr-O-Et, p-Iodo-Phe and 3-5-Bromo-Phe may prove useful to differentiate NPY receptor classes in various peripheral tissues. Supported by the MRCC.

79.4

REGULATION OF SUBSTANCE P RECEPTOR mRNA EXPRESSION BY cAMP AND GLUCOCORTICOIDS IN HUMAN AND RAT CELL LINES. J.E. Krause, J. Takeda, J.D. Cremins and R. Raddatz. Department of Anatomy & Neurobiology, Washington University School of Medicine, St. Louis, MO 63110.

We have examined the effects of various hormones and second messenger systems on substance P receptor (SPR) mRNA expression in model human astrocyte (U373 MG) and rat glial (LRM55) cell lines. These cell contain NK-1 type tachykinin ligand binding sites based on pharmacological criteria, and thus were appropriate to examine the mechanisms regulating SPR mRNA expression. Cell lines were treated with pharmacological agents, and total RNA was isolated and SPR mRNA levels were assessed using nuclease protection methods. β -Actin mRNA levels served as a control. Both cell lines express authentic SPR mRNA which is detectable as a ~4.0 kb species on Northern blots or as 677 or 588 base pair protected species in protection assays. In both cell lines, the stimulation of intracellular cAMP levels by treatment with forskolin, dibutyryl cAMP and/or isobutylmethylxanthine resulted in a time and concentration dependent 300 to 400% increase in SPR mRNA levels, with a lag time of 1 hr for onset. Phorbol ester, cGMP and increased intracellular Ca²⁺ levels were without effect. These cAMP effects may be exerted via a cAMP response element present in the 5' flanking region of the SPR gene (Hershey et al., JBC 266:4366, 1991). A variety of steroid hormones were also examined; cortisol selectively decreased SPR mRNA levels in a time and concentration dependent manner with 40% and 70% reductions observed after two and twenty hours of treatment, respectively. Estradiol, progesterone and testosterone were without effects. These studies suggest that SPR mRNA regulation can occur both as a result of changes in intracellular second messengers and in the hormonal milieu.

79.6

ELECTROPHYSIOLOGICAL DEMONSTRATION OF NK₃ RECEPTORS IN THE RAT SUBSTANTIA NIGRA PARS COMPACTA *IN VITRO*. K.D.KEEGAN*, G.N.WOODRUFF AND R.D.PINNOCK. PARKE-DAVIS RESEARCH UNIT,ADDENBROOKES HOSPITAL SITE, HILLS ROAD, CAMBRIDGE, CB2 2QJ, U.K.

Electrophysiological studies show a weak action of substance P (SP) on dopamine (DA) neurons of the substantia nigra (SN) *in vitro*. In this study, we have used specific ligands for the different tachykinin receptors to characterise the receptor type involved in the tachykinin response in the SN, pars compacta. 350 μ m slices of rat brain were cut and recordings were made by conventional electrophysiological techniques. Senktide (1-1000 μ M) excited 13 of 49 DA neurones in the SN in a dose dependent manner (ED₅₀ 41.2 \pm 9.9 nM n=5). Senktide responses were prolonged (10 to 30 minutes before recovery) and there was a marked desensitization of the response to high doses (1 μ M) of senktide. The NK1 receptor agonist [Sar⁹,Met(O₂)¹¹]SP1-11 and the NK2 receptor agonist [β Ala⁹]NKA4-10 were inactive on senktide sensitive neurones (n=6). The majority (95%) of senktide sensitive neurones were also sensitive to neurotensin. The results in this study demonstrate that a subpopulation of neurotensin sensitive dopamine neurones in the substantia nigra are sensitive to the NK3 receptor agonist senktide. The inactivity of the NK1 and NK2 receptor agonists suggests that only NK3 receptors are present on these neurones.

79.8

QUANTITATIVE LOCALIZATION OF NEUROPEPTIDE Y Y1 RECEPTORS IN RAT BRAIN AS REVEALED USING THE SELECTIVE AGONIST [LEU³¹,PRO³⁴]-NPY. Y. Dumont¹, A. Fournier², S. St-Pierre² and R. Quirion¹. (1) Douglas Hospital Res. Ctr., McGill University, Montréal, Québec, Canada, H4H 1R3 (2) INRS-Santé, Pointe-Claire, Québec, Canada, H3R 1G5.

We have investigated the distribution of the neuropeptide Y Y1 receptor subtype in various areas of rat brain using receptor autoradiography and membrane preparations and [¹²⁵I]PYY (25pM) as radioligand. Various competitors including pNPY, PYY, NPY_{2-36}}, NPY_{13-36}} and [Leu³¹,Pro³⁴]-NPY displaced specific [¹²⁵I]PYY binding sites in various regions with different affinity and Hill coefficients below unity. This suggests the heterogeneity of [¹²⁵I]PYY labelled sites. The selective Y1 receptor agonist [Leu³¹,Pro³⁴]-NPY was found to be especially useful to discriminate between Y1 and non-Y1 sites having markedly greater affinity (>1000) for the first class of sites. Competition data revealed that 60-65 % of the overall population of NPY binding sites was of the Y1 type in cortical areas while they represented only 20-30 % in the cerebellum and olfactory bulb. Very low proportions (10-20 %) of Y1 sites were detected in the hippocampus and striatum. The nature of non-Y1 sites remains to be established but may include more than one class of receptors. Supported by the MRCC.

79.9

NEUROPEPTIDE Y RECEPTOR-MEDIATED RESPONSES IN DIFFERENTIATED PC12 CELLS. D.A. DiMaggio, J.M. Farah, Jr. and T.C. Westfall. Dept. of Pharmacol. Physiol. Sci., Saint Louis Univ. Sch. of Med., St. Louis, MO 63104 and G.D. Searle & Co., Chesterfield, MO 63198.

The presence of neuropeptide Y (NPY)-selective receptor subtypes (NPY1 and NPY2) has been demonstrated on the basis of differences in pharmacologic potency and binding of C-terminal fragments at sites within sympathetic neuroeffector junctions. In the present study, we have used PC12 rat pheochromocytoma cells, which synthesize NPY and express Y1 receptors, in order to study cellular aspects of NPY function concomitant with catecholamine (CA) neurotransmission. PC12 cells were treated with factors which induce cellular differentiation for 5-7 d. In dexamethasone (dex)-treated PC12 cells, the Y1 selective agonist (leu³¹, pro³⁴)-NPY (LP-NPY), but not NPY 13-36, was shown to inhibit forskolin-evoked cAMP in a dose-dependent and PTX-reversible manner. LP-NPY was shown to inhibit binding of NPY 1-36 to intact dex-treated cells, whereas C-terminal fragments of NPY were without effect. In contrast, in PC12 cells differentiated with nerve growth factor (NGF), both LP-NPY and NPY 13-36 were shown to inhibit evoked cAMP in a PTX-sensitive manner, with additive effects. Inhibition of evoked cAMP by NPY 13-36 was attenuated following withdrawal of NGF 24 h prior to experiments. Additionally, both LP-NPY and 13-36 were shown to inhibit binding of NPY 1-36 to intact, NGF-treated PC12 cells. Interestingly, in both NGF- and dex-treated PC12 cells, LP-NPY was shown to enhance nicotine- and K⁺-evoked CA release, while long C-terminal fragments of NPY were shown to inhibit evoked CA release in NGF-treated cells. The data provided by these sympathoadrenomedullary models suggest that NGF treatment of PC12 cells induces expression of Y2 receptors, and that modulation of CA release by NPY may not be mediated through cAMP.

79.11

THE VIP ANTAGONIST [D-Phe²]-VIP INHIBITS PACAP SIGNAL TRANSDUCTION AT TYPE II BUT NOT TYPE I RECEPTORS. B.D. Shivers¹, T.J. Görcs², D.H. Coy², A. Arimura² and P.E. Gottschall¹. ¹U.S.-Japan Biomedical Research Laboratories, Tulane University Hebert Center, Belle Chasse, LA 70037 and ²Peptide Research Labs, Department of Medicine, Tulane University Medical Center, New Orleans, LA 70112.

Pituitary Adenylate Cyclase-Activating Polypeptide (PACAP) belongs to the vasoactive intestinal polypeptide (VIP)/glucagon/secretin family of proteins, and stimulates adenylate cyclase in cultured rat pituitary cells, neurons and astrocytes. Two related peptides of 38 or 27 residues, PACAP38 and PACAP27, arise from the PACAP precursor and bind to two, distinct high affinity sites whose abundance varies across tissues. While only the PACAPs bind with high affinity to the first site (Type I), the PACAPs and VIP bind with similar affinities to a second site (Type II) that may represent the VIP receptor. To determine if VIP antagonists distinguish between Type I and II receptors, we assayed binding in rat tissues enriched in Type I (brain) and Type II (liver) binding sites. Type I binding sites (K_d = 0.64 nM) were measured in 6 brain regions: Bmax hypothalamus > hippocampus > septum > brainstem > cerebellum > cortex. Hypothalamic binding capacity (38 pmol/mg protein) was 3-fold greater than that measured in cortex. The order of potency for 4 VIP antagonists in displacing 200 pM [¹²⁵I]PACAP27 from Type II binding sites in liver was: [D-Phe²]-VIP > [4-Cl-D-Phe⁶, Leu¹⁷]-VIP >> [Ac-Tyr¹, D-Phe²]-GRF (1-29 Amide) = [D-Phe², Nle²⁷]-GRF (1-29 Amide). In the hypothalamus, 2 μM [D-Phe²]-VIP displaced only 7% of [¹²⁵I]PACAP27 but displaced 99.9% of [¹²⁵I]PACAP27 in liver. In liver, unlabeled PACAP27 was 10-fold more potent than VIP which, in turn, was 10-fold more potent than [D-Phe²]-VIP in displacing [¹²⁵I]PACAP27 from the predominant Type II site. Our results show that [D-Phe²]-VIP distinguishes between these two binding sites and, hence, is useful for elucidating the roles of PACAP and VIP in the brain and peripheral tissues. (Supported by NIH AM-09094 and Takeda Chemical Co. to A.A. and DK-30167 to D.H.C. [4-Cl-D-Phe⁶, Leu¹⁷]-VIP was the gift of J. Rivier of the Salk Institute in La Jolla, CA.)

DRUGS OF ABUSE—COCAINE: TRANSPORTERS AND TOXINS

[¹²⁵I]RTI-55: A HIGH AFFINITY LIGAND FOR THE DOPAMINE TRANSPORTER. J.W. Boja, A. Patel, F.I. Carroll, M.A. Rahman, A. Philip, A.H. Lewin, R. Vaughan, T.A. Kopaitic and M.J. Kuhar. Molecular Pharmacology Laboratory, NIDA Addiction Research Ctr, P.O. Box 5180, Baltimore, MD 21224. *Research Triangle Institute, Research Triangle Park, NC 27709.

The iodinated cocaine analog RTI-55 (3β-(4-iodophenyl)-tropane-2-carboxylic acid methyl ester) has nanomolar affinity for the dopamine transporter. Both saturation and kinetic studies in rat striatal membranes indicated that [¹²⁵I]RTI-55 bound to both a high and low affinity binding site with affinities of approximately 50 times that previously reported for [³H]cocaine. Similar results were observed with solubilized dog striatal membrane fractions. Competition studies with various monoamine uptake inhibitors and various receptor binding agents, indicated [¹²⁵I]RTI-55 had a pharmacological profile in the rat striatum consistent with that of the dopamine transporter. However, competition studies in the frontal cortex and pons-medulla indicated that [¹²⁵I]RTI-55 also may bind to the serotonin transporter in these regions. These results suggest that [¹²⁵I]RTI-55 is the most potent ligand for the dopamine transporter thus far discovered. Its high specific activity and lack of quenching makes it a superior ligand for autoradiography. It also binds with high affinity *in vivo* and therefore has application in PET and SPECT scanning.

79.10

A POTENT NEW SYNTHETIC ANALOG OF VASOPRESSIN WITH RELATIVE AGONIST SPECIFICITY FOR THE PITUITARY

J. Schwartz, D. Jefferys and G. Kupryszewski. Department of Physiology and Prince Henry's Institute of Medical Research, Monash University, Melbourne, Australia; Baker Medical Research Institute, Melbourne; and Institute of Chemistry, University of Gdansk, Gdansk, Poland.

The physiological actions of vasopressin (AVP) are mediated by two well-characterized classes of receptors, referred to as V₁ (vasoconstrictor) and V₂ (antidiuretic). AVP is also a potent secretagogue of corticotropin (ACTH) at the pituitary (pit), and the receptor that mediates this action is not as well characterized. In many respects it resembles the classic V₁ receptor; this includes the observation that all synthetic analogs with full agonist activity at the pit have been vascular V₁ agonists as well, even if the vascular activity is less. The aim of this study was to synthesize a prototypical pit vasopressin agonist, specifically one with no vascular agonist activity.

The analog deamino-D-3-(3'-pyridyl)-Ala², AVP was synthesized by solid phase methods and assessed for biological activity by conventional bioassays. It is a weak (1/381 as AVP) agonist at V₂ receptors in the antidiuretic bioassay. It is an antagonist of the vasoconstrictor response to AVP in the V₁ bioassay (pA₂ = 6.22, and no measurable agonist activity). Despite its antagonist activity at vascular V₁ receptors, the analog is a full, relatively potent agonist at pit AVP receptors. Its potency stimulating ACTH secretion by ovine pit cells *in vitro* is 1/34 that of AVP, and it is similarly potent in sheep *in vivo*. These data indicate that analogs of AVP can be synthesized with relative agonist specificity for the pit, and thus add further evidence that the pit receptor is distinct from the V₁ vasoconstrictor receptor. Supported by the NH & MRC of Australia and the Polish Scientific Research Committee.

UREIDOACETAMIDES: POTENT AND SELECTIVE CHOLECYSTOKININ B RECEPTOR ANTAGONISTS IN THE RODENT BRAIN. A. Doble, P. Bertrand, A. Böhme, M. Reibaud, J.D. Bourzat, M. Capet, C. Guyon, F. Manfré, C. Cotrel, J.C. Blanchard. Rhône-Poulenc Rorer, CRVA, 13, quai Jules Guesde, 94400 Vitry-sur-Seine, France.

The octapeptide cholecystokinin (CCK) is one of the most abundant neuropeptides in the mammalian brain, where it is thought to be involved in feeding behaviour and in anxiety. Two subtypes of CCK receptors, CCK_A and CCK_B, have been identified in the central nervous system. This report describes a novel family of CCK_B antagonists, the ureidoacetamides. In radioligand binding experiments with [³H]-CCK_B and membrane preparations from guinea-pig cortex, these compounds show affinity for this receptor subtype in the low nanomolar range, the most potent having a K_i of 0.6 nM. Nanomolar affinity was also observed for gastrin receptors in the rat stomach. Their affinities for CCK_A receptors in guinea-pig pancreas are higher than 10⁻⁶ M. No activity was observed at a wide variety of other neurotransmitter receptors. Ureidoacetamides, at low concentrations (10 - 50 nM), antagonize the excitatory effect of CCK_B on rat hippocampal neurons *in vitro*, measured using extracellular recording techniques. CCK_A-mediated responses in the guinea-pig ileum were not inhibited by these CCK_B antagonists. Ureidoacetamides may thus be useful in exploring the role of CCK in the central nervous system.

80.2

A COCAINE ANALOG AND A GBR ANALOG BOTH LABEL THE SAME PROTEIN IN RAT STRIATAL MEMBRANES. A. Patel, J.W. Boja, J. Lever, R. Lew, R. Simantov, F.I. Carroll, A.H. Lewin, A. Philip, Y. Gao, R. Vaughan and M.J. Kuhar. NIDA/ARC, Baltimore, M.D. 21224. *Johns Hopkins University, Baltimore, M.D., *Research Triangle Inst., Research Triangle Park, NC 27709.

Several GBR analogs have been used as photoaffinity probes to identify the dopamine transporter/cocaine receptor in brain. Because of the evidence that cocaine is a noncompetitive inhibitor of 3H-GBR 12935 (Berger et al, Eur J Pharmacol. 176(1990) 251-252), we examined whether or not cocaine binds to the same protein as GBR 12935 and the other GBR photoaffinity probes. In parallel experiments, both [¹²⁵I]DEEP and [¹²⁵I]RTI-82 (3β-(p-chlorophenyl) tropane-2β-carboxylic acid, 4'-azido-3'-iodophenyl ethyl ester) were used to photoaffinity label a site identified as the dopamine transporter/cocaine receptor according to its pharmacological properties. The molecular weights of the labeled proteins were examined by SDS-PAGE and autoradiography. Both probes were incorporated into a broad band of identical mobilities, suggesting a glycoprotein of approx 80,000 Da. Thus, it appears that the GBR analogs bind to the same protein as cocaine does. Work is in progress to discern if both labels reside in the same peptide fragments upon enzymatic digestion.

80.3

COCAINE RECEPTOR PROBES IN HUMAN AND NONHUMAN PRIMATE BRAIN: IN VITRO CHARACTERIZATION AND IN VIVO IMAGING. B.K. Madras, M.A. Fahey*, M.J. Kaufman, R.D. Spealman, J. Schumacher*, O. Isacson, A.L. Brownell*, G.L. Brownell* and D.R. Elmaleh*. Harvard Medical School, New England Regional Primate Research Center, Southborough, MA 01772-9102, Massachusetts General Hospital, Boston, MA 02114.

The phenyltropane analogs of cocaine, CPT (WIN 35,065-2) and CFT (WIN 35,428), are high affinity ligands for cocaine recognition sites on the dopamine transporter. In membranes of human caudate-putamen and nucleus accumbens, the pharmacological specificity of [³H]CFT binding sites was similar to that reported in cynomolgus monkey caudate-putamen. The rank order of potency of these drugs, CFT, GBR 12909 > WIN 35,065-2 > (-)-cocaine > bupropion, also corresponded to their rank order of potency for inhibiting dopamine uptake. The *in vivo* distribution of tracer doses of [¹¹C]CPT and [¹¹C]CFT was monitored in cynomolgus monkey. High resolution positron emission tomography (PET) revealed high uptake of [¹¹C]CFT and [¹¹C]CPT in the caudate-putamen with striatal:cerebellar ratios > 2. These studies suggest that CFT and CPT or other phenyltropane analogs may be suitable for development of imaging probes for monitoring presynaptic dopamine nerve terminals in Parkinson's disease and other neurodegenerative disorders. Supported by grants from the Parkinson's Disease Foundation, and USPHS grants DA06303, DA00499, RR00168, MH14275, DA00088.

80.5

RADIATION INACTIVATION STUDIES OF THE DOPAMINE TRANSPORTER PROTEIN. S. P. Berger, E. S. Kempner* and S. M. Paul. NIH, Bethesda, MD 20892.

Recently we reported a complex interaction of cocaine with the dopamine transporter protein inasmuch as cocaine was a non competitive inhibitor of [³H]GBR-12935 binding to the transporter. Madras and colleagues have likewise reported that dopamine reuptake inhibitors structurally unrelated to cocaine bind to a "subpopulation" of the two sites labeled by [³H]2 beta-carbomethoxy-3 beta-(4-fluorophenyl)tropane (CFT, also designated WIN 35,428, a cocaine analogue). To further explore the question of whether the molecular mechanism of cocaine's interaction with the dopamine transporter differs from other dopamine reuptake inhibitors we have utilized a technique called radiation inactivation to determine the molecular weight of protein(s) important to the binding of dopamine reuptake inhibitors to the transporter protein. From the amount of radiation needed to inactivate binding of tritiated dopamine reuptake inhibitors molecular weights of involved proteins can be calculated based on the following assumptions. According to "target" theory inactivation is an "all or none event" i.e., one radiation "hit" results in destruction of the target protein and larger targets are more likely to be "hit" by a given amount of radiation. As the amount of radiation increases the amount of functional activity (binding to the dopamine transporter) decreases in an exponential fashion enabling one to calculate a molecular weight target size. Data will be presented comparing the target sizes obtained with [³H]CFT to [³H]mazindol and [³H]BTCF (a PCP analogue that binds with high affinity to the dopamine transporter protein). Preliminary data to be discussed suggests a higher target size for [³H]CFT.

EVIDENCE FOR THE INVOLVEMENT OF THE N-METHYL-D-ASPARTATE (NMDA) RECEPTOR IN THE EFFECTS OF COCAINE. Y. Itzhak, I. Stein and D.C. Mash. Depts. of Biochemistry & Molecular Biology, Pharmacology and Neurology, University of Miami School of Medicine, Miami, FL 33101.

Seizures and lethal-convulsions in human cocaine users are now recognized as concomitant with cocaine-related death. The present study was undertaken in order to investigate a possible association of the NMDA type of the glutamate receptors in the toxic effects of cocaine. *In vivo* experiments indicated that the potent noncompetitive and selective NMDA receptor antagonist, MK-801, abolishes completely the convulsive effect of cocaine in mice and also reduced the mortality by 50-60% as compared to control cocaine-treated mice. In a series of *in-vitro* experiments, the binding of the competitive and selective NMDA receptor antagonists, [³H]CPP and [³H]CGP-39653, to brain membranes derived from rats treated with cocaine (40mg/kg/day for 7 days) or saline was examined. Results indicated approximately 50% decrease in the number of CPP and CGP-39653 binding sites in brain membranes from cocaine-treated rats as compared to saline-treated rats. The protective effect of MK-801 on cocaine-induced convulsions and the down-regulation of the NMDA receptor following repeated exposure to cocaine, strongly support the hypothesis that the glutamatergic system has a prominent role in cocaine toxicities.

80.4

COMPARATIVE PET STUDIES OF THE BINDING OF CARBON-11 LABELED COCAETHYLENE AND COCAINE IN BABOON BRAIN. J.S. Fowler, N.D. Volkow, R.R. MacGregor*, S.L. Dewey, S.J. Gatley*, J. Logan*, D. Schlyer* and A.P. Wolf*. Brookhaven National Laboratory, Upton, NY, 11973.

Cocaethylene (CE), the ethyl homolog of cocaine, is a metabolite of cocaine (COC) which is present in blood and neurological specimens of individuals co-administering cocaine and alcohol (Hearn et al, J. Neurochem. 56: 698, 1991 and Jallow et al, Life Sci. 48: 1787, 1991). CE has potency similar to cocaine at the dopamine reuptake site causing speculation that its presence may play a role in cocaine abuse and toxicity. We have compared the uptake and clearance of [¹¹C]COC and CE (5-8 mCi, 4-6 µg) in regions of interest (ROI) of baboon brain over a 50 min period along with the amount of unchanged tracer in arterial plasma (CP) from which the steady state distribution volumes (DV, (cc/g)) were calculated as the slope of a plot of $\int_0^T \text{ROI}(t)/\text{ROI}(T)$ vs $\int_0^T \text{Cp}(t)/\text{ROI}(T)$ (Logan et al, J. Cereb. Blood Flow Metab. 10: 740, 1990). Absolute uptake and clearance of the two compounds in striatum were indistinguishable. Debenzoylation of CE in plasma was slower than COC as determined by *in vitro* incubation of [¹¹C]CE and COC with plasma. The ratio of the plasma integral of CE:COC at 30 min was 0.98 for one baboon and 1.2 for the other. Plasma free fractions were also similar. DVs for the two baboons were 7.2 and 7.9 for CE and 6.7 and 7.7 for COC in the striatum and 4.6 and 5.2 for CE and 4.1 and 4.5 for COC in the cerebellum. These studies demonstrate a striking similarity in the initial uptake and clearance of CE and COC in baboon brain. Supported by DOE/OHER and NIDA.

QUANTITATIVE IN VITRO AUTORADIOGRAPHY OF COCAINE BINDING SITES IN RAT AND HUMAN BRAIN. N. Volkow, J. Fowler, R. Hitzemann, A. Wolf*, K. Dillon* and #A. Bigon. Brookhaven National Laboratory, Upton, NY 11973 and #Lawrence Berkeley Laboratory, Univ. of California, Berkeley, CA 94720.

The neuroanatomical distribution and pharmacological identity of cocaine binding sites were examined by quantitative autoradiography of tritiated cocaine (N.E.N, 32Ci/mmol) in sections of rat and human brain obtained postmortem. Using 10nM tritiated cocaine with or without excess (100µM) unlabeled cocaine to assess non-specific binding, we found the optimal conditions for autoradiography were a 30min incubation at room temperature in phosphate buffered saline (PBS) followed by 2X1 min washes in ice cold PBS. Sections were apposed to tritium sensitive film for 8 to 16 weeks alongside with tritium standards. A video-camera based computerized image analysis system was used to quantitate the autoradiograms. The highest density of binding sites in the human brain was found in the caudate and putamen. Moderate to low levels of displaceable binding were found in the anterior and medial thalamic nuclei, the hippocampus and the cortex. Binding in basal ganglia was fully displaceable by the dopamine uptake blockers GBR12909 and nomifensine. Binding in the hippocampus was displaceable by the serotonin uptake inhibitors fluoxetine and imipramine. High density of binding was also observed in the rat dorsal raphe nucleus, which was fully displaceable by fluoxetine but not by desipramine, a norepinephrine uptake blocker. These data suggest that cocaine binds to dopaminergic as well as serotonergic uptake sites in human and rat brain.

NEW EVIDENCE LINKING PCP NEUROTOXICITY IN RATS WITH PCP PSYCHOSIS IN HUMANS. J.W. Olney, MA Sesma, J. Labruyere*, MT Price. Washington Univ., St. Louis MO 63110 & Univ. of MO-St. Louis, MO 63121.

In rodents NMDA antagonists, including phencyclidine (PCP), ketamine and MK-801, induce pathomorphological changes in cingulate-retrosplenial (C-RS) neurons consisting of vacuole formation, mitochondrial dissolution and an abnormal expression of heat shock protein (HSP). These changes are readily prevented by co-administration of muscarinic cholinergic antagonists. In humans, it is known that PCP is a psychotogen and that humans anesthetized with ketamine frequently manifest psychotic symptoms which can be prevented or diminished by co-administration of benzodiazepines (e.g. diazepam). We have now found that diazepam, and other GABA-mimetics (e.g. pentobarbital), prevent all pathomorphological effects of NMDA antagonists, including the expression of HSP (see Sesma et al., NS Abstr., '91). This establishes a link between the neurotoxic (rat) and psychotomimetic (human) properties of NMDA antagonists, and suggests that the circuitry involved may include NMDA receptors which, by activating inhibitory GABAergic interneurons, modulate the release of acetylcholine from axonal endings on C-RS neurons. Blockade of the NMDA receptor would inactivate the GABAergic interneuron and disinhibit acetylcholine release, causing cholinergic hyperstimulation of the C-RS neuron (as the proximate cause of injury). Psychotic symptom formation would follow as a psychological reflection of the dysfunctional state induced in neural networks integrally associated with the injured C-RS neurons. Our findings provide neuroscience for the first time with morphological correlates of psychotic symptom formation, including identification of specific transmitter systems and specific CNS neurons involved. In addition, our data suggest that anticholinergic and GABA-mimetic drugs (alone or in combination) can prevent both the neurotoxic and psychotomimetic side effects of PCP, ketamine or other NMDA antagonists, thereby improving their safety as neuroprotective drugs. EFFECTS OF 2,4,5-TRIHYDROXYMETHAMPHETAMINE ON THE CENTRAL SEROTONERGIC AND DOPAMINERGIC SYSTEMS. M. Johnson, J.W. Gibb, G.R. Hanson, R.L. Foltz* and H.-K. Lim*. Dept. Pharmacology and Toxicology, and Center for Human Toxicology, University of Utah, Salt Lake City, UT 84112.

2-Hydroxy-4,5-methylenedioxyamphetamine (2-OH-MDMA) is a metabolite of 3,4-methylenedioxyamphetamine (MDMA) in the rat brain. We predicted that 2-OH-MDMA can be dealkylated to produce 2,4,5-trihydroxymethamphetamine (THM). The effects of THM on the central serotonergic and dopaminergic systems were examined in order to determine whether THM accounts for MDMA-induced neurotoxicity. Male Sprague-Dawley rats (180-250 g) were injected i.c.v. with 50 µg, 100 µg or 200 µg THM and killed 5 days later. Transmitter concentrations and *in vitro* tryptophan hydroxylase (TPH) activity were measured with HPLC-EC. Tyrosine hydroxylase (TH) activity was determined with a radioisotopic method. THM reduced TPH activity in a dose-dependent manner reaching 50%, 70% and 10% of control in the cortex, neostriatum and hippocampus, respectively, after a 200-µg dose. The decreases in serotonin concentration were less in the side contralateral to the THM injection. THM (50 µg, 100 µg or 200 µg) increased TPH activity from 123% to 144% of control in the dorsal raphe; in the median raphe, only the 50-µg dose increased TPH activity (132% of control). THM reduced neostriatal TH activity to 21% of control but had no effect in the nigra. These results suggest that THM is a potent neurotoxin which destroys dopaminergic and serotonergic nerve terminals. (Supported by USPHS grants DA 00869, DA 04222 and DA 05860)

STUDIES ON N-MONOMETHYL-1-(4-METHOXYPHENYL)-2-AMINOPROPANE, AN ANALOGUE OF METHAMPHETAMINE. T.D. Steele*, A. Martello and G.A. Ricaurte. Dept. of Neurology, Johns Hopkins School of Medicine, Baltimore, MD 21224.

N-Monomethyl-1-(4-methoxyphenyl)-2-aminopropane (PMMA) is a ring-substituted methamphetamine analogue that has surfaced in the illicit drug market. Behavioral studies in animals indicate that while PMMA produces significant central effects, it does not appear to be a simple amphetamine-like stimulant (Glennon et al., *Pharm. Bioch. Beh.* 31:9-13). This study assessed the neurotoxic potential of PMMA, and compared it to that of 1-(4-methoxyphenyl)-2-aminopropane (PMA) and 3,4-methylenedioxyamphetamine (MDMA). Rats were injected with PMMA (20, 40 and 80 mg/kg; s.c.) twice daily for 4 days. One week later, they were examined for their content of brain monoamines. PMMA produced a dose-dependent depletion of 5-HT, with the highest dose reducing hippocampal 5-HT by approximately 50%. Comparison to PMA and MDMA revealed that PMMA and PMA produced comparable 5-HT-depleting effects, but that these were not as pronounced as those induced by MDMA. Striatal DA was not affected by any of the compounds. These findings suggest that PMMA, like PMA and MDMA, possesses 5-HT neurotoxic activity. Further, they suggest that para substitution may be an important determinant of the selective 5-HT neurotoxic action of certain amphetamine analogues.

METHAMPHETAMINE (MA) INDUCES DOPAMINE (DA) DEPLETIONS AND 6-HYDROXYDOPAMINE (6-OHDA) FORMATION IN RATS INJECTED 4 TIMES IN A 3 HR PERIOD. L.S. Seiden and G. Vosmer. Univ. of Chicago, Pharm/Phys. Sci., Chicago, IL 60637.

Male Long-Evans hooded rats were injected (4 x) with 5, 10 or 20 mg/kg of MA (1 inj/hr). Following the 4th injection, the rats were either sacrificed immediately or at .5, 1, 2 hrs or 14 days after the last injection. 6-OHDA was found in the posterior striatum in rats receiving 10 mg/kg and sacrificed immediately or 2 hrs after the 4th injection. These results are consistent with a prior report (Seiden & Vosmer, 1984) in which 6-OHDA was detected after a single injection of MA (100 mg/kg). In the present study the proportion of rats exhibiting MA-induced 6-OHDA formation was greater and the levels higher than in the original study, possibly due to differences in the rat strain, route of administration, or dissection of the striatum. As in the original study, rats sacrificed 2 weeks after the last injection showed depletions of DA and 5-hydroxytryptamine (5HT) in the striatum and 5HT in hippocampus. MA induced the formation of 6-OHDA in both hooded rats and Sprague-Dawley rats. Both strains, irrespective of injection regimen, showed similar neurotoxicity in that both DA and 5HT were depleted 2 and 8 weeks after the last MA injection. We examined the ability of MK-801, a competitive antagonist at the n-methyl-D-aspartate receptor, to block the formation of 6-OHDA because MK-801 can block MA-induced neurotoxicity (Sonsalla et al., *Science*, 1989). The results of this experiment suggested that MK-801 blocked the MA engendered formation of 6-OHDA. These results also suggest that 6-OHDA is involved in the neurotoxicity of MA, but calcium channel blockade by MK-801 may be involved as well. This research is supported by RSA #10562 (L. Seiden); NIDA #DA-00250.

METHAMPHETAMINE CYTOTOXICITY STUDIED IN CULTURED RAT VENTRAL MIDBRAIN NEURONS. J.F. Cubells, D. Sulzer and S. Rayport. Dept. Psychiatry, Ctr. Neurobiol. & Behav., Columbia Univ.; Dept. Neuropathology, NYS Psychiatric Institute, NY 10032.

Methamphetamine (METH) and other psychostimulants are known to exert cytotoxic effects on dopaminergic neurons. To investigate subcellular mechanisms of cytotoxicity, we used postnatal ventral midbrain cultures that contain at least 10% dopaminergic neurons. To exclude confounding excitotoxic effects, 500 µM kynurenic acid was included with METH. We assessed the viability of neurons after incubation in 100 µM METH for 5 days using casein-AM/ethidium homodimer staining (Live/Dead Assay[®], Molecular Probes). There was no significant neuronal loss; however, we found vacuolar structures in the cytoplasm of METH-treated neurons, similar to those observed previously with 3,4-methylenedioxyamphetamine (Won et al., *Soc. Neurosci. Abstr.*, 16:304, 1990). We took advantage of the selective cytoplasmic staining resulting from the cleavage of casein-AM by cytoplasmic esterases to membrane-impermeable casein; vacuolar structures either did not stain or stained lightly, suggesting that they derive from membrane-delimited organelles. To examine the possibility that the vacuoles arise from endocytic structures, we incubated cultures with fluorescent latex microspheres (1 µL/mL; Luma-Fluor); both neurons and glia showed extensive punctate labelling. We never observed vacuolar structures containing microspheres, regardless of whether cultures were labelled prior to or during METH exposure. On that basis, vacuolar structures are unlikely to be endosomes or lysosomes. To assess the possibility that the vacuoles originate from mitochondria, we will present results using the mitochondrial dye 4-Di-2-ASP and a monoclonal antibody (a generous gift of A. Miranda, Dept. Neurol., Columbia Univ.) to cytochrome c oxidase complex subunit IV, a marker of the inner mitochondrial membrane.

INGESTIVE BEHAVIOR: MOLECULAR

GALANIN GENE EXPRESSION IN THE HYPOTHALAMUS OF LEAN AND OBESE ZUCKER RATS AT DIFFERENT AGES AND AFTER FOOD DEPRIVATION.

M. Jhanwar-Uniyal, S.C. Chua, Jr.* and S.F. Leibowitz. The Rockefeller University, New York, N.Y. 10021.

The neuropeptide galanin (GAL) induces food intake, specifically of fat, when injected into the paraventricular nucleus (PVN). It also has an inhibitory effect on the release of insulin and corticosterone. The present investigation examined whether GAL gene expression is altered in the hypothalamus of genetically controlled obese rats, which have abnormal endocrine balance, lipid metabolism, eating behavior and body weight. GAL mRNA levels in the hypothalamus of Zucker lean and obese rats were measured at different ages (11, 24 and 40 wks) and under satiated versus food deprivation (FD) conditions.

Quantitative Northern blot analysis of the hypothalamus, in addition to circulating hormone measurements, indicate that: a) GAL mRNA in the obese rats, relative to their lean littermates, is significantly lower ($P < 0.05$) at puberty (11 wks), no different at 24 wks, and reliably higher at 40 wks ($P < 0.05$); b) levels of hypothalamic GAL mRNA increase significantly after 48 hrs food deprivation, although only in obese rats at 11 ($P < 0.05$) and 24 ($P < 0.05$) wks of age and not at 40 wks of age; c) GAL mRNA levels are positively correlated with body weight and BMI in the lean and obese rats at 11 and 24 wks of age; and d) Zucker obese rats exhibit decreased circulating levels of aldosterone, in addition to an increase in insulin and glycerol levels, insulin resistance, body weight and BMI. These results reveal disturbances in hypothalamic GAL gene expression which may be associated with the physiological and endocrine changes observed in Zucker obese rats.

CENTRAL INSULIN ADMINISTRATION INHIBITS INCREASED HYPOTHALAMIC EXPRESSION OF NEUROPEPTIDE Y mRNA INDUCED BY FASTING. M.W. Schwartz, AJ Sipols†, DP Flegelwicz‡, SC Woods‡, SE Kahn*, D. Porte, Jr.*, G. Sanacora‡, JD White§ and DG Baskin† Depts of Medicine, †Biological Structure, and ‡Psychology, Seattle V.A. Medical Center, Univ. of Washington, Seattle, WA, and §Dept. of Medicine, S.U.N.Y., Stony Brook, NY

Hypothalamic insulin administration suppresses food intake, whereas neuropeptide Y (NPY) has the opposite effect. Since fasting lowers circulating insulin levels and increases NPY synthesis in the hypothalamic arcuate nucleus (ARC), insulin could act to inhibit ARC NPY gene transcription. To test this hypothesis, we quantified the effect of 72 hr of food deprivation on expression of preproNPY mRNA in the ARC of male Long-Evans rats receiving 3rd ventricular injections (5 µl/12 hr) of either saline vehicle (n=5) or insulin (160 ng; n=4), compared to vehicle-treated, free feeding controls (n=6). Coronal sections of rat brain (six 15 µm sections per animal) were analyzed by *in situ* hybridization using an oligonucleotide probe complementary to preproNPY mRNA. Hybridization was quantified by computerized image analysis (hybridization area x density; mean ±SE) of resultant autoradiographs. Fasting in vehicle-treated rats increased ARC levels of preproNPY mRNA to $178 \pm 20\%$ those of fed controls ($p < 0.05$ by ANOVA). In contrast, ARC levels of preproNPY mRNA in fasted, insulin-treated animals were unchanged from those of fed controls ($99 \pm 14\%$), significantly lower than vehicle-treated, fasted animals ($p < 0.05$). Thus, central insulin administration blocked the effect of fasting on expression of mRNA for NPY in the ARC. Conclusion: Reduced circulating insulin levels may be the mechanism by which fasting stimulates ARC NPY gene expression. Inhibition of ARC NPY gene expression may be the physiological basis for the central action of insulin on food intake and body weight regulation.

ACTIVITY-INDUCED ANOREXIA DOES NOT AFFECT THE EXPRESSION OF HYPOTHALAMIC NEUROPEPTIDE mRNAs. J. Licinio, M.-L. Wong, P. W. Gold* and J. Glowa. Clin. Neuroendocrinology Branch, Bldg 10/3S231, NIMH, Bethesda, MD 20892.

Hypothalamic neuropeptides, such as CCK, CRH, GAL, NPY, and POMC, play an important role in the acute regulation of ingestive behavior and food intake. The levels of those peptides have been found to be abnormal in human eating disorders, suggesting that they may contribute to the pathophysiology of those disorders. In this study we examined the effects of chronic activity-induced anorexia in male Sprague-Dawley rats on the levels of neuropeptide gene expression, measured by *in situ* hybridization histochemistry.

PEPTIDE	LOCATION	CONTROL	ACTIVITY	
CCK	PVN	50123 ± 348	50301 ± 322	NS
	Hippocampus	18196 ± 633	17586 ± 692	NS
	Basal Ganglia	18397 ± 831	17711 ± 928	NS
CRH	PVN	40088 ± 1349	39266 ± 801	NS
GAL	ARC	37198 ± 534	37282 ± 254	NS
NPY	ARC	45007 ± 1740	44636 ± 1179	NS
POMC	PVN	41229 ± 442	42113 ± 946	NS
	ARC	42956 ± 785	44402 ± 1338	NS

Disintegrations/min/mg wet weight of tissue, mean ± SEM

We found that in a behavioral paradigm resulting in profound changes in energy expenditure, appetitive behavior, and body weight in male rats, there were no long-term alterations in the levels of expression of hypothalamic neuropeptide mRNAs.

81.5

INCREASED HYPOTHALAMIC CORTICOTROPIN-RELEASING FACTOR (CRF) mRNA IN SHORT-TERM STARVATION BUT NOT SHORT-TERM RESTRAINT STRESS. R. Briones-Urbina*, T. Hattori and S.F. George. Dept. Pharmacology, Univ. of Toronto, Toronto, Ont. CANADA M5S 1A8.

Centrally administered CRF produces behaviors similar to those caused by stress, including suppression of feeding. CRF peptide levels and mRNA are also increased following multiple stressors. However, differences in the response to starvation stress and other physical stressors has not been established. We studied hypothalamic CRF mRNA levels following short-term sustained starvation and short term restraint stress in adult male Sprague Dawley rats. Animals were housed in environmental rooms with 12h light-dark cycles and handled daily at the onset of dark. On the test day, at the onset of dark, groups of animals were: 1) handled as usual 'control'; 2) 'starved' for 4 hrs; 3) 'stressed' for 10 min every hr for 4 hrs; 4) 'starved-stressed' as per 2) and 3). All animals were sacrificed at the end of the 4 hours and their tissues rapidly frozen. Northern blotting analysis (total hypothalamic RNA) was performed using a 48 base synthetic ³²P-labelled oligonucleotide complementary to amino acids 22-37 of CRF. A 1.4 Kb band compatible with CRF mRNA was seen, but no differences in intensity were detected among the groups. *In situ* hybridization used the same probe labelled with ³⁵S. Equally increased levels of mRNA were seen in the paraventricular nucleus of the hypothalamus (PVN) in the 'starved' and 'starved-stressed' groups, but not in the 'stressed' group as compared to controls.

We report increased levels of CRF mRNA in the PVN of rats following 4 hrs of starvation at the onset of dark (time of maximal feeding) with no changes in rats that underwent intermittent restraint stress for the same 4 hours. It is suggested that different mechanisms may drive the peptide responses to these two types of stressors.

81.7

C-FOS-LIKE IMMUNOREACTIVITY IN CAUDAL HINDBRAIN FOLLOWING FEEDING SUPPRESSIVE INTRASTOMACHAL NUTRIENT INFUSIONS OR EXOGENOUS CCK-8 INJECTION. R.C. Ritter and J.T. Maund*. Department of VCAPP, Washington State University, Pullman, WA 99164

Exogenous CCK and intestinal infusions of some nutrients suppress food intake via an action on capsaicin-sensitive, vagal sensory neurons. To evaluate the distribution of hindbrain neurons activated by intestinal nutrients or exogenous CCK, we used a polyclonal, affinity purified antibody (Oncogene Science) against the 4 to 17 residues of human fos to identify c-fos-like immunoreactive neurons in the nucleus of the solitary tract (NST) and area postrema (AP) following CCK-8 injection or intestinal nutrient infusions. All infusions were isotonic, pH 7.4. Exogenous CCK-8 (2 or 4 µg/kg), oleate (0.065 or 0.13 kcal/ml), maltose and maltotriose (0.13 or 0.26 kcal/ml) all caused similar patterns of c-fos expression in the NST and AP. Neither control injections nor intraintestinal saline infusion induced c-fos. Furthermore, intraintestinal trypsin inhibitor, which elevated circulating CCK to levels comparable to those produced by exogenous CCK-8 also did not induce c-fos. We also examined the effect of CCK injection and oleate infusion on c-fos expression in the caudal hindbrains of capsaicin-pretreated rats. Expression of c-fos immunoreactivity in response to either treatment was attenuated or abolished following capsaicin-pretreatment. These results indicate 1) that both intestinal nutrient infusions and exogenous CCK activate neurons in the primary sensory vagal projections of the hindbrain, 2) that hindbrain c-fos induction by intestinal nutrients probably is not due to direct action of circulating CCK on the NST or AP and 3) that induction of NST and AP c-fos immunoreactivity by at least some nutrients depends on stimulation of capsaicin-sensitive neurons. Supported by NINDS Grant NS20561.

81.4

INCREASED C-FOS IMMUNOREACTIVITY IN THE ARCULATE NUCLEUS OF FASTED RATS. D. G. Baskin and M. W. Schwartz. Depts. Medicine and Biological Structure, Univ. Washington, Seattle, WA 98195, and V. A. Medical Center, Seattle, WA 98108

The adaptive response to food deprivation involves modulation of the expression of genes encoding neuropeptides in the hypothalamic arcuate nucleus (AN). Since nuclear transcription factors such as *c-fos* may regulate neuropeptide gene transcription, we hypothesized that fasting would activate expression of *c-fos* in AN neurons. To test this hypothesis, male rats were fasted for 48 hrs. with water ad lib (N = 2). Controls received food as usual (N = 3). Brains were perfused with 4% paraformaldehyde in PB for 20 min, removed and immediately put in cold 25% sucrose buffer overnight. Coronal cryostat sections (25 µm) were immunostained free floating (ABC peroxidase) with *fos* polyclonal antibody (M. Iadarola, NIH). Numbers of immunoreactive cells in the AN sections were counted bilaterally by computer image analysis (MCID) and expressed as positive cells per AN section side. *Fos* immunoreactivity was observed in perikaryal nuclei of AN neurons in both fed and fasted groups. However, the number of neurons with *fos*-like immunoreactive nuclei was doubled (p<0.05, t-test) in the fasted (240 ± 38) compared to fed rats (119 ± 28). The results indicate that fasting stimulates expression of *c-fos* in AN neurons. This response may mediate the changes in neuropeptide gene expression which occur in the AN during fasting.

81.6

EXPRESSION OF FOS IN THE RAT BRAIN FOLLOWING SYSTEMIC INJECTIONS OF CHOLECYSTOKININ. D.Y. Chen, Y. Gu, M.F. Gonzalez, and J.A. Deutsch*. Department of Psychology, UCSD, La Jolla, CA 92093

The expression of *fos*, the protein produced by the *c-fos* proto-oncogene, was mapped in the brain of rats following intraperitoneal injections of cholecystokinin (10 µg/kg, Bachem) or control injections of normal saline. Male Sprague-Dawley rats were tested 15-hours-fasted. Two hours after the injections the rats were perfused and their brains extracted and sectioned using a vibrating microtome. The sections were reacted for *fos* immunocytochemistry using commercially available *fos* antibody (Microbiological Associates) and ABC reagents (Vector Lab). Following injections of CCK *fos* expression was observed in neurons of the solitary nucleus, extending from the commissural part to about 1mm rostral to this level. More *fos*-positive cells were found at the commissural level than in the more rostral aspects of the nucleus where *fos* induction was present. However, the intensity of the *fos* staining was stronger in the anterior region. Intense *fos* expression was also found bilaterally in the parvocellular region of the paraventricular nucleus of the experimental animals.

These findings suggest that the decreases in food intake induced by exogenous CCK exert their actions on the areas of the solitary nucleus and the paraventricular nucleus that exhibited *fos* expression. Since the commissural solitary nucleus receives sensory information from the gastrointestinal tract via the vagus nerve, the present data support previous research concerning the functions of this site in eating regulation. On the other hand, we also have found that the same structures that express *fos* in response to CCK also express *fos* in response to lithium chloride injections at doses that produce reductions in eating comparable to those induced by CCK.

81.8

EXPRESSION OF C-FOS PROTEIN IS INDUCED IN SPECIFIC BRAIN NEURONS BY METABOLIC INHIBITORS THAT INCREASE FOOD INTAKE. S. Ritter, N.Y. Calingasan, T.T. Dinh and J.S. Taylor*. Department of VCAPP, Washington State University, Pullman, WA 99164-6520.

To further elucidate neural pathways important for glucoprivic and lipoprivic feeding, we examined the distribution of c-fos protein in rat brain after 2-deoxy-D-glucose (2DG)- and mercaptoacetate (MA)-induced inhibition of glucose and fatty acid metabolism, respectively. 2DG (200 and 600 mg/kg), MA (600, 800 and 1200 µmol/kg) and vehicle solutions were infused remotely in the absence of food 1-4 hr prior to sacrifice. MA increased c-fos immunoreactivity markedly in the area postrema/nucleus of the solitary tract (AP/NTS), dorsal motor nucleus of X (DMV), lateral parabrachial area (LPB) and central nucleus of the amygdala (CNA) and slightly in the locus coeruleus (LC). Staining was greatly attenuated or abolished by abdominal vagotomy. 2DG increased immunoreactivity in the AP/NTS, DMV, LPB, LC and paraventricular nucleus (PVN) and the staining was not significantly altered by vagotomy. Results are consistent with lesion data suggesting (1) that 2DG and MA stimulate feeding by enlistment of different neural substrates, (2) that the vagus nerve, LPB and CNA, but not the PVN, participate in MA-induced feeding and (3) that 2DG feeding is nonvagal but requires neurons in the AP/NTS region. Supported by PHS #RO1 DK40498.

81.9

EXPRESSION OF *FOS* IN THE RAT BRAIN FOLLOWING SYSTEMIC INJECTIONS OF LITHIUM CHLORIDE. Y. Gu, M.F. Gonzalez, J.A. Deutsch* and D.Y. Chen. Department of Psychology, UCSD, La Jolla, CA 92093

The expression of *fos*, the protein produced by the *c-fos* proto-oncogene, was mapped in the brain of rats following intraperitoneal injections of lithium chloride (LiCl) (3 and 0.65%) or control isotonic injections of saline (4.14 and 0.9%). Male Sprague-Dawley rats were used as subjects. These doses of LiCl have been shown to have an emetic effect and to produce conditioned taste aversion learning. Two hours after the injections the rats were perfused and their brains extracted and sectioned using a vibrating microtome. The sections were reacted for *fos* immunocytochemistry using commercially available *fos* antibody (Microbiological Associates) and ABC reagents (Vector Lab). Following injections of 3% LiCl *fos* expression was observed in nucleus of the solitary tract, the supraoptic and paraventricular hypothalamic nuclei, and the basolateral nucleus of the amygdala. Injections of 0.65% LiCl also induced *fos* in the same structures, but the intensity of expression and the number of positive neurons were significantly less in all of these structures, specially in the supraoptic nucleus and the basolateral amygdala. Normal saline did not induce *fos* expression in any region. However, hypertonic 4.14% saline induced *fos* in all the structures except the basolateral amygdala, but in a much weaker fashion.

These results, including the expression of *fos* in a dose-related fashion following LiCl injections, suggest that *fos* immunocytochemical procedures can be used to map some of the structures that are stimulated by the emetic effects of LiCl, and possibly other emetic agents. The mechanisms involved in the induction of *fos* by LiCl remain to be elucidated.

81.11

COEXISTENCE OF INCREASE IN NEUROPEPTIDE Y (NPY) WITH THE BEGINNING OF HYPERPHAGIA IN THE OBESE ZUCKER RAT. B. Beck, A. Buriel, R. Bazin*, J.P. Nicolas, C. Buriel. INSERM U.308, Mécanismes de Régulation du Comportement Alimentaire. 54000 NANCY and *INSERM U.177. PARIS (France)

Neuropeptide Y (NPY) has been detected in the central nervous system and particularly in the hypothalamus. Numerous cell bodies have been located in the arcuate nucleus. When centrally injected, it strongly stimulates food intake and we have previously shown that the adult obese Zucker rat with a well-established hyperphagia is characterized by higher NPY concentrations in different hypothalamic areas involved in the regulation of food intake. We therefore hypothesized that NPY might play a role in the development of obesity and hyperphagia. To confirm this hypothesis, we measured NPY in several microdissected brain areas of 16 lean (L) and 15 obese (O) suckling Zucker pups (16 days old) and a few days after weaning (30 days old rats) when hyperphagia takes place. The results were analyzed by two way ANOVA and revealed a significant effect of age ($p < 0.001$) in the arcuate nucleus - median eminence (ARCME), paraventricular nucleus (PVN) and lateral hypothalamus (LH) and a significant effect of genotype ($p < 0.01$) in the ARCME. Between 16 and 30 days of age NPY increased by 58% (L) and 100% (O) in the ARCME, by 134% (L) and 124% (O) in the NPV and 49% (L) and 74% (O) in the LH. NPY in the ARCME which was not different between lean and obese rats at 16 days significantly increased at 30 days in the obese rat (60.6 ± 3.1 (O) vs 49.5 ± 2.3 (L) ng/mg protein; $p < 0.01$). These results showed therefore that NPY levels are increased in the obese Zucker rat in an area where it is synthesized. This increase in NPY occurred concomitantly with the increase of food intake. They support our hypothesis of a role of NPY in the development of hyperphagia in the obese Zucker rat.

81.10

HYPOTHALAMIC NEUROPEPTIDE Y GENE EXPRESSION: ANALYSIS IN LEAN AND OBESE ZUCKER RATS IN RELATION TO AGE AND NUTRITIONAL STATE.

S.F. Leibowitz, M. Jhanwar-Uniyal and S.C. Chua, Jr.*. The Rockefeller University, New York, N.Y. 10021.

Hypothalamic injection of neuropeptide Y (NPY) stimulates food intake, particularly of carbohydrate, and also releases insulin and corticosterone. Moreover, NPY-like immunoreactivity in hypothalamic nuclei is found to vary in association with the diurnal cycle and nutritional state, while NPY gene expression is altered in genetically controlled obese mice and rats with abnormal neuroendocrine function. To examine further a potential role for this peptide in the development or maintenance of obesity, the present study examined the levels of NPY mRNA in the hypothalamus of Zucker lean and obese rats, at different ages (11, 24, and 40 wks) and under satiated versus food-deprived (FD) conditions.

Quantitative Northern blot analysis of the hypothalamus, in addition to measurements of circulating hormones, indicate that: a) hypothalamic NPY mRNA levels in the obese rats, relative to their lean littermates, are normal at the time of puberty (11 wks) but are significantly higher at maturity (24 and 40 wks); b) levels of NPY mRNA, in both lean and obese rats, increase similarly after 48 hrs food deprivation in 11- and 24-wk-old rats, but at 40 wks of age are resistant to change after deprivation; c) Zucker obese rats at all ages exhibit decreased circulating levels of aldosterone, in addition to increased insulin and glycerol levels, insulin resistance, body weight and BMI. These findings, revealing abnormal neurochemical patterns primarily after puberty, indicate that hypothalamic NPY neurons may be involved in the maintenance, but possibly not the development, of obesity in these genetically controlled animals.

EFFECT OF THE 5-HT_{1A} AGONIST FLESINOXAN ON THE 5-HT SYSTEM: ELECTROPHYSIOLOGICAL STUDIES IN THE RAT CNS. C. de Montigny, C. Ortemann* and P. Blier. Neurobiological Psychiatry Unit, McGill University, Department of Psychiatry, Montreal, Quebec, Canada H3A 1A1

Flesinoxan (FLE) is a high-affinity ($pK_i = 8.8$) and selective 5-HT_{1A} ligand. The present *in vivo* electrophysiological studies were undertaken to determine the effect of FLE on the 5-HT system in the rat brain.

A two-day treatment with FLE (5 mg/kg/24 h, s.c.) delivered by an osmotic minipump reduced markedly the firing activity of dorsal raphe 5-HT neurons. There was a partial recovery after 7 days, and a complete one after 14 days of treatment. At this point in time, there was a 3-fold shift to the right of the dose-response curve of the effect of intravenous LSD on 5-HT neuron firing activity, indicating a desensitization of somatodendritic 5-HT autoreceptors.

The agonistic activity of FLE, applied by microiontophoresis onto dorsal hippocampus pyramidal neurons, was found to be 15 times greater than that of gepirone, another 5-HT_{1A} agonist. Furthermore, both FLE and gepirone applied concurrently with 5-HT, readily blocked its effect on the same neurons, indicating that FLE, as gepirone, acts as a partial agonist at postsynaptic 5-HT_{1A} receptors in this region of the rat forebrain.

A 14-day treatment with FLE (5 mg/kg/24 h, s.c.) did not modify the responsiveness of dorsal hippocampus pyramidal neurons to microiontophoretic applications of 5-HT or FLE, nor to endogenous 5-HT released by the electrical stimulation of the ascending 5-HT pathway.

The present results indicate that FLE is a potent agonist of both somatodendritic 5-HT_{1A} autoreceptors and postsynaptic 5-HT_{1A} receptors and that, at the latter, it acts as a partial agonist. The fact that its long-term administration induces a desensitization of somatodendritic, but not of postsynaptic, 5-HT_{1A} receptors would predict that it might be an effective anxiolytic/antidepressant in humans.

82.2

EFFECT OF REPEATED ELECTROCONVULSIVE SHOCK TREATMENT ON THE FUNCTION OF SEROTONIN NEURONS. P. Blier and C. Boucharid*. Department of Psychiatry, McGill University, Montreal, Canada H3A 3A1.

The present studies were undertaken to assess the effect of repeated electroconvulsive shocks (ECS) on the sensitivity of somatodendritic 5-HT_{1A} autoreceptors in the rat dorsal raphe *in vivo*, using microiontophoresis, and on the function of 5-HT terminals in the guinea pig hypothalamus *in vitro*, using superfusion of slices preloaded with [³H]5-HT. Sprague-Dawley rats and guinea pigs received, under halothane anesthesia, six ECS (150 V, 10 ms, 50 Hz for 1 s) over two weeks and the experiments were carried out two days later. In a first series, a reduced hypothermic response to the 5-HT_{1A} agonist 8-OH-DPAT (0.5 mg/kg, s.c.) was observed in ECS-treated rats, as previously reported by other investigators. In a second series, the firing activity of rat 5-HT neurons and their responsiveness to microiontophoretically-applied 5-HT and 8-OH-DPAT was unaltered following ECS. In a third series, the electrically-evoked release of [³H]5-HT (20 mA, 2 ms, 3 Hz for 2 min) from guinea pig hypothalamic slices was not altered following ECS. In addition, the attenuating effect of the 5-HT_{1D} autoreceptor agonist 5-carboxyamido-tryptamine, and the enhancing effect of the 5-HT_{1D} autoreceptor antagonist methiothepin as well as that of the 5-HT₂ agonist 2-methyl-5-HT on [³H]5-HT evoked release were unchanged in slices of ECS-treated guinea pigs.

These results indicate that, following repeated ECS, 1) the sensitivity of somatodendritic 5-HT_{1A} autoreceptors in the rat dorsal raphe is normal, 2) terminal 5-HT_{1D} autoreceptors in the guinea pig hypothalamus are normosensitive and still tonically activated, and 3) the capacity of 5-HT₂ receptors to enhance 5-HT release is not affected. In conclusion, repeated ECS does not alter the function of 5-HT neurons and, consequently, the hypothesia induced by systemic 8-OH-DPAT is unlikely to result from the activation of somatodendritic 5-HT_{1A} autoreceptors on dorsal raphe 5-HT neurons.

82.3

EEG SPECTRAL ANALYSIS OF VARIOUS HIGH AFFINITY SIGMA LIGANDS IN RATS. F.C. Tortella and L. Robles, Neuropharmacol. Br., Walter Reed Army Inst. Res., Washington, DC 20307.

The present study attempted to assess the *in vivo* pharmacology of high affinity sigma ligands by evaluating changes in EEG function in freely-moving rats. Using the technique of computer-derived EEG spectral analysis we have previously reported differential EEG responses for the sigma/PCP ligand (+)-SKF10047 (a dual peak EEG spectra) and the sigma/DM ligand dextromethorphan (a slowing of the spectral pattern) (Tortella & Robles, Neurosci. Abst., 1989). Subsequently, a series of high affinity sigma ligands have been studied. In adult SD rats the *iv* administration of (+)-3-PPP (5 mg/kg) produces an EEG response characterized by a distinct increase in spectral power restricted to the 6-7 Hz frequency band. In contrast, 2.5 mg/kg DTG or haloperidol (HAL) produces similar EEG responses measured as a distinct increase in spectral power focused about the 2.5-3.5 Hz frequency bands. Thus, generation of EEG spectral fingerprints reveals an *in vivo* differentiation among sigma compounds which 1) supports the possibility of multiple sigma recognition sites and 2) questions the heuristic classification of HAL as a sigma antagonist.

82.5

EFFECT OF TRIMIPRAMINE STEREOISOMERS ON ^{45}Ca UPTAKE IN SYNAPTOSOMES FROM RAT FRONTAL CORTEX. G. Beauchamp*, P.-A. Lavoie and R. Elie*. Département de pharmacologie, Université de Montréal, Montréal (Québec), Canada H3C 3J7.

Depolarization-induced and $\text{Na}^+\text{-Ca}^{2+}$ exchange-induced uptake of ^{45}Ca were studied in synaptic terminals of rat frontal cortex, a limbic system brain region. Net K^+ -induced ^{45}Ca uptake, a specific index of voltage-dependent calcium channel function, was the difference between uptake (after 10 sec) in high- K^+ choline and low- K^+ choline media: *in vitro*, racemic trimipramine (T) inhibited this process with an IC_{50} of 57 μM , and (+)-T ($\text{IC}_{50} = 18 \mu\text{M}$) was more potent ($p < 0.05$) than (-)-T ($\text{IC}_{50} = 91 \mu\text{M}$). At 2 μM and 20 μM , T inhibited ^{45}Ca uptake by 16% and by 38% respectively; the steady-state brain concentrations of T in patients could fall within this range, and cause such a degree of calcium channel inhibition. The possible role of calcium channel inhibition in the therapeutic effect of T is strengthened by the parallel order of potency of T stereoisomers in the clinic (La Presse Médicale, 69, 1425, 1961) and in calcium channel inhibition. Net $\text{Na}^+\text{-Ca}^{2+}$ exchange-induced ^{45}Ca uptake was the difference between uptake (after 10 sec) in low- K^+ choline and low- K^+ sodium media: (+)-T ($\text{IC}_{50} = 159 \mu\text{M}$) and (-)-T ($\text{IC}_{50} = 153 \mu\text{M}$) did not differ in inhibitory potency, and no effect on $\text{Na}^+\text{-Ca}^{2+}$ exchange would be expected at therapeutic steady-state brain T concentrations.

CLOZAPINE INCREASES C-FOS EXPRESSION IN LIMBIC BUT NOT BASAL GANGLIA NUCLEI: COMPARISON WITH HALOPERIDOL AND SELECTIVE D1 AND D2 RECEPTOR ANTAGONISTS. G.S. Robertson and H.C. Fibiger. Division of Neurological Sciences, Dept. of Psychiatry, University of British Columbia, Vancouver, Canada V6T 1Z3.

The mechanisms by which the atypical neuroleptic, clozapine, produces its unique therapeutic effects in the treatment of schizophrenia without having the motoric side effects characteristic of typical antipsychotics remain unclear. Recently, it has been reported that expression of the proto-oncogene *c-fos*, which encodes a 55-kilodalton phosphoprotein, Fos, is increased in the striatum by haloperidol. Hence, we have examined the effects of clozapine, haloperidol and selective D1 (SCH 23390) and D2 (raclopride) antagonists on Fos immunoreactivity in the forebrain. Haloperidol (0.5, 1 mg/kg) and raclopride (1, 2 mg/kg) increased Fos immunoreactivity in neurons of the striatum (STR) and nucleus accumbens (NAC). In contrast, clozapine (10, 20 mg/kg) increased Fos immunoreactivity in the NAC, medial prefrontal cortex and septum but not the STR. SCH 23390 (0.5, 1 mg/kg) had no effect on Fos immunoreactivity in the prefrontal cortex and septum while it reduced Fos immunoreactivity in the striatum and NAC. Destruction of mesencephalic dopaminergic neurons with 6-hydroxydopamine abolished the increase in Fos expression in the STR and NAC produced by haloperidol and raclopride, and also blocked the clozapine-induced increase in the NAC. These results suggest that haloperidol increases Fos expression in the STR and NAC by blocking D2 dopamine receptors and that a selective action on *c-fos* expression in the limbic system may contribute to clozapine's unique therapeutic profile.

CLOZAPINE POTENTLY INHIBITS SHAM FED SUCROSE: D₁ RECEPTORS MAY BE NECESSARY FOR SWEET TASTE REWARD IN THE RAT.

L.H. Schneider, J.H. Dokko*, J.D. Davis*, J. Gibbs and G.P. Smith, Cornell University Medical College, Dept. of Psychiatry, Bourne Lab, White Plains, NY 10605 and *Dept. of Psychology, University of Illinois, Chicago, IL 60680.

PURPOSE: The antipsychotic efficacy of clozapine (CLOZ), an 'atypical' neuroleptic, may be due to its potent blockade of the newly characterized D₁ dopamine (DA) receptor [Van Tol et al., *Nature*, 350:610 (1991)]. We wanted to determine whether CLOZ would reduce the rewarding potency of sham fed sucrose at doses without motor effects, as do selective D₁ or D₂ receptor antagonists and haloperidol [Schneider, *Annals NYAS*, 575:307 (1989)].

METHODS: Effects of CLOZ on intake of 40% (1.2M) sucrose and rate of licking during 30 min of sham feeding were determined in 11 male, Sprague-Dawley rats after 4.75h food deprivation. CLOZ or vehicle (0.1M citric acid) was administered *ip* at -20 min.

RESULTS: CLOZ ID_{50} for intake was determined for each rat and ranged from 1 to 6 mg/kg (see Table).

CLOZAPINE (mg/kg)	0	1	1.5	2	3	5	6
Intake (ml/30 min)	31.2	17.5	12.5	17.0	14.5	14.0	15.5
	(11)	(2)	(1)	(4)	(2)	(1)	(1)

CONCLUSIONS: The potent inhibitory effect of CLOZ (ID_{50}) on the sham fed intake of sucrose is consistent with the hypothesis that D₁ receptors are necessary for the central rewarding effect of the orosensory stimuli of sucrose. [Supported by: NIH R29 NS24781 (LHS) and NIMH RSA MH00149 (GPS)]

82.6

DEXAMETHASONE-STIMULATED BRAIN ORNITHINE DECARBOXYLASE ACTIVITY IS PREVENTED AFTER LONG BUT NOT SHORT-TERM LITHIUM CHLORIDE TREATMENT. G.M. Gilad, V.H. Gilad, R. Li* and R.J. Wyatt. NPB, NIMH Neuroscience Center at St. Elizabeths, Washington, DC 20032.

Ornithine decarboxylase (ODC), the enzyme catalyzing the formation of putrescine in the first step of polyamine biosynthesis, is known to increase after various brain traumas, stressful stimuli, and glucocorticoid hormone treatments. In peripheral tissues hormone-stimulated ODC activity can be prevented by acute lithium treatment. Here we report that, unlike peripheral tissues, hormone (dexamethasone 3-5 mg/kg, *i.p.*)-stimulated ODC activity in rat hippocampus could be prevented by daily lithium injections (LiCl 106 mg/kg, *s.c.*) for 14 d, but not by a single LiCl injection (212 mg/kg, *s.c.* or *i.p.*) given 24 h prior to, together with, or after hormone treatment. The data indicate that the effect of lithium on hormone-induced ODC response in the brain is both concentration and time dependent, and implicate polyamines in the mechanism of lithium action.

82.8

EFFECT OF TREATMENT WITH ECS AND DESIPRAMINE ON 5HT_{1A} RECEPTORS IN RAT BRAIN. GN Pandey, SC Pandey*, L. Isaac, JM Davis. Illinois State Psychiatric Institute, Chicago, Illinois 60612

It has been reported that 8-OH-DPAT-induced hypothermia is attenuated by chronic ECS or desipramine (DMI) treatment, thus suggesting down-regulation of 5HT_{1A} receptors in brain. We determined the effects of both acute and chronic ECS or DMI administration on 5HT_{1A} receptors in rat cortex and hippocampus brain region. Rats were administered ECS (75 mA for 0.2 seconds) or DMI (10 mg/kg *ip*) once daily for 14 days for chronic and 1 day for acute studies. Rats were sacrificed after 24 hours of the last treatment for chronic studies and 1 hour after treatment for acute studies. 5HT_{1A} receptors were measured by binding techniques using ^3H -8-OH-DPAT as the radioligand. We observed that chronic but not acute ECS or DMI treatment caused significant decrease in the B_{max} of ^3H -8-OH-DPAT binding in rat cortex, where 5HT_{1A} receptors are presumably located pre- and postsynaptically, but had no significant effect on ^3H -8-OH-DPAT binding in hippocampus, where the 5HT_{1A} receptors are presumably located postsynaptically. Thus, our results indicate that both chronic ECS and DMI cause down regulation of presynaptic 5HT_{1A} receptors but do not alter postsynaptic 5HT_{1A} receptors. No effects of acute or chronic treatment were observed on K_d of [^3H]-8-OH-DPAT binding to 5HT_{1A} receptors either in cortex or hippocampus. These results thus suggest that changes in presynaptic 5HT_{1A} receptors caused by antidepressants may be related to their mechanism of action.

82.9

A SINGLE DOSE OF REDUCED HALOPERIDOL (RHAL) PRODUCES A POTENT AND LONG LASTING INHIBITION OF [³H]DEXTROMETHORPHAN (DM) AND SIGMA LIGANDS BINDING TO MOUSE AND GUINEA PIG BRAIN. J. M. Musacchio and M. Klein*. Dept. Pharmacology, N.Y.U. Medical Center, New York, NY 10016.

The administration of haloperidol (HAL) inhibits the binding of (+)-[³H]SKF-10047 to the haloperidol-sensitive sites in mouse brain. This effect requires the repeated administration of high doses of HAL and is not produced by one day treatment (Itzhak & Alerhand, FASEB J. 3:1668, 1989). This has been confirmed by several laboratories and uniformly attributed to "receptor" down regulation. Thus, HAL has been labeled a "sigma receptor agonist".

The possibility that the DM₁/σ₁ site might not be a neurotransmitter receptor (Life Sci. 48:543, 1991) and other considerations, lead us to test the effects of RHAL. Administration of 1.9 mg/kg of HAL for 7 days to C57BL/6 mice produced no effect, whereas RHAL inhibited the binding of [³H]DM and (+)-[³H]-PPP by 25 and 38% respectively. Two days after a single dose of RHAL binding was inhibited by 15 and 30% respectively.

We found that guinea pigs were much more sensitive than mice: a single s.c. injection of 0.1 mg/kg of RHAL produced a marked inhibition of binding to the DM₁/σ₁ site, which was easily detectable even 10 days after the injection. Thus, RHAL could be or produce a neurotoxic metabolite that might explain tardive dyskinesia and other side effects of chronic neuroleptic administration. Supported in part by USPHS grants MH-29591, NS-23926 and Research Scientist Award MH-17785.

82.10

SKF38393 OR PILOCARPINE INJECTED INTO VENTROLATERAL STRIATUM ELICIT TD-LIKE BUT NOT PRIMED DYSTONIA-LIKE ORAL MOVEMENTS IN RATS ADMINISTERED CHRONIC HALOPERIDOL. G. D. Ellison and U. Liminga*. Department of Psychology, UCLA, 405 Hilgard Ave., Los Angeles, CA 90024

Oral movements (OMs) in rats administered continuous haloperidol (HAL) gradually develop smooth, small OMs with a peak energy at 1-3 HZ, the same energy spectrum reported for tardive dyskinesia (TD) in humans, whereas rats given HAL in weekly, large injections develop a "primed dystonia" syndrome characterized by large OMs with steep onset slopes and peak energy at 4-6 HZ.

In order to study the location of the altered pattern generator underlying these effects, rats pretreated with HAL using these two drug regimens for at least 9 months were implanted with bilateral cannula in ventrolateral striatum (VLS) and substantia nigra (SN). It was found that microinjections of SKF38393 or pilocarpine into VLS led to increased OMs which had an exaggeration of the characteristic OM form of rats pretreated with continuous HAL, but this was not true of those pretreated with intermittent HAL. In contrast, bilateral buccuculline into SN did not alter OM form in either group.

These findings indicate that while these two syndromes following chronic HAL may have different neurochemical substrates, both can be altered by injections of a D1 dopamine or a cholinergic agonist into VLS.

ALZHEIMER'S DISEASE: GENETICS AND GROWTH FACTORS

83.1

HIGH RESOLUTION DETECTION OF POLYMORPHISMS IN SPECIFIC GENES AND ITS APPLICATION TO NEUROLOGICAL DISEASE. S.E. Poduslo. Dept. of Neurology, Texas Tech University Health Sciences Center, Lubbock, TX 79430.

In the past, polymorphisms have been detected by hybridization of DNA probes to genomic DNA (Southern hybridizations). This approach can find moderately frequent polymorphisms. We have developed a more sensitive technique that allows detection of single base changes in genes (Poduslo, Dean, Kolch and O'Brien, "Detecting high-resolution polymorphisms in human coding loci by combining PCR and single strand conformation polymorphism (SSCP) analysis," *Am. J. Human Genetics*, in press, 1991). Sequences of interest are amplified and simultaneously radio-labeled by the polymerase chain reaction. The samples are then denatured and subjected to electrophoresis for SSCP analysis. In addition, if restriction enzymes that cut frequently (with four base pair recognition sequences) are used in digests of the amplified DNA, multiple genetic variations can be resolved after electrophoresis. Alternatively digested non-radio-labeled samples can also be resolved after electrophoresis. Using this strategy we have detected a Hae III polymorphism in the c-kit proto-oncogene (4q11-21), which is linked to other chromosome 4p markers. We found a 2 bp deletion in the insulin-like growth factor I receptor gene located on 15q25-26. We have also found a Hae III polymorphism in proteolipid protein (xq21.3-q22) that we are characterizing. Thus, these techniques are sufficiently sensitive to detect single base changes and allow the placement of DNA segments or genes on the linkage maps of human chromosomes. Such an approach will facilitate the identification of candidate genes involved in human disease (e.g., Alzheimer's Disease). (Supported by the Alzheimer's Institute and the South Plains Foundation)

83.3

COLLABORATIVE LINKAGE ANALYSIS OF CHROMOSOMES 19 AND 21 LOCI IN FAMILIAL ALZHEIMER DISEASE. M.A. Pericak-Yance*, J.L. Haines*, P.H. St. George-Hyslop*, J. Rebut*, C. Haynes*, R. Tanzi*, L. Yamaoka*, J.F. Gusella*, A.D. Roses*. ¹Neurology Div., Duke Univ. Med. Ctr., Durham, NC 27710; ²Molecular Neurogenetics Lab., Mass. Gen. Hosp., Boston, MA 02129; and ³Tanz Neuro-science Institute, Univ. Toronto, Canada M5S 1A8.

Familial Alzheimer disease (FAD) is a debilitating disorder. The exact genetic etiology remains unknown. FAD loci on chromosome 21 (Ch 21) and chromosome 19 (Ch 19) have been suggested. Two-point analyses on 59 FAD families were performed for markers APP, D21S1/D21S11, D21S59, D21S13, D21S16, D19S13, BCL3, ATP1A3, and APOCII. Results summed over all 59 families excluded close linkage to all markers; only D21S1/D21S11 (+1.26 @ 30 cM), and D21S13/D21S16 (+0.88 @ 30 cM) had lod scores over 0.50. Multipoint analysis of Ch 21 gave a peak location score of +2.30 near D21S1/D21S11; a similar analysis of Ch 19 was negative. Dividing families into early and late onset groups, lod scores above 0.5 were found for D21S1/D21S11 (+3.05 @ 15 cM), D21S13/D21S16 (+0.74 @ 30 cM) (early onset), and ATP1A3 (+0.69 @ 15 cM) (late onset). Affecteds only analysis of ATP1A3-D19S13 multipoint gave a peak location score of +4.4 (near ATP1A3) in the late onset families. Updated analyses, including CA repeat polymorphism data, are in progress.

83.2

IMMEDIATE-EARLY GENE EXPRESSION IN ALZHEIMER'S DISEASE. H.Endo¹, J.M.Stephens², P.H.Pekala², G.A.Higgins¹, S.Kittur¹. ¹Mol. Neurobiol., NIA/NIH, Baltimore, MD, 21224; ²Dept of Biochem., East Carolina Univ., Greenville, NC, 27858.

We have studied immediate early-gene expression of *c-fos*, *c-jun* and *jun-B* in Alzheimer's disease (AD). The purpose of the present study was to determine if any of these immediate early-genes were activated in AD when compared to control brains. RNA was isolated from 5 AD and 4 control individuals with no neurological disorder. The postmortem interval ranged from one and a half hour to twelve hours. Northern blot analysis was performed and the intensities of the bands was analysed by laser densitometry. Transcript size were as follows; 2.2 kb for *c-fos*, 3.2kb and 2.7kb for *c-jun* and 2.1kb for *jun-B*. *C-fos* mRNA was decreased by 37% in AD brain ($p=0.0576$) compared to control brain. *C-jun* mRNA was decreased by 41% but this finding was not statistically significant. *Jun-B* mRNA was significantly decreased by 55% in AD brain ($p<0.01$). This immediate early-gene expression seems to be involved in long-term adaptive responses and in cell plasticity processes that may play a role in AD.

83.4

CO-EXPRESSION OF BRAIN-DERIVED NEUROTROPHIC FACTOR (BDNF) AND LOW AFFINITY NGF-RECEPTOR (p75^{NGFR}) GENES IN HUMAN BASAL FOREBRAIN NEURONS: ALTERATIONS IN ALZHEIMER'S DISEASE. C. E. Byrne¹, H. S. Phillips², E. J. Mufson³ and G. A. Higgins¹. ¹Mol. Neurobiol., NIA/NIH, Baltimore, MD 21224; ²Dept. Dev. Biol., Genentech, S. San Francisco, CA 94080; ³ Rush Medical Ctr., Chicago, IL 60612.

NGF, BDNF and NT-3 bind the low affinity NGF-R (p75^{NGFR}), but additional factors, such as the *trk* family of proto-oncogenes may also be required for high affinity neurotrophin signal transduction. High resolution *in situ* hybridization was used to determine the distribution of neurotrophins and their receptor elements in the human brain, including a comparison of BDNF, p75^{NGFR} and *trk* mRNAs between tissue from normal aged individuals and Alzheimer's disease (AD) patients. In the normal aged human CNS, BDNF mRNA is widely expressed in cortical regions. In AD, we confirmed that BDNF mRNA was abolished within hippocampal (Phillips *et al.* submitted) and entorhinal neurons. BDNF and p75^{NGFR} mRNA levels were both reduced in the nucleus basalis in AD. These results indicate that BDNF and p75^{NGFR} mRNAs are co-localized within neurons of the nucleus basalis in the human, and suggest that expression of these molecules may be coordinately down-regulated in AD.

83.5

VASCULAR ENDOTHELIAL GROWTH FACTOR: A HEPARIN BINDING GROWTH FACTOR WITH A DIFFERENT DISTRIBUTION THAN BASIC FIBROBLAST GROWTH FACTOR IN NORMAL BRAIN AND ALZHEIMER'S DISEASE.

Corona RJ, Chorsky R*, Baird A*, Gonzalez AM*, Patel L* and Stopa EG. Department of Pathology, SUNY Health Science Center, Syracuse, New York and Department of Molecular and Cellular Growth Biology, The Whittier Institute, LaJolla, California. Vascular endothelial growth factor (VEGF) is a specific and potent mitogen for vascular endothelial cells, that has been recently isolated from conditioned media of bovine pituitary follicular stellate cells. Like bFGF, VEGF also has heparin-binding properties. In previous studies, we have shown that basic fibroblast growth factor (bFGF) is increased in Alzheimer's Disease (AD) and appears to be associated with the heparan-sulfate like proteoglycans bound to B/A4 amyloid (Biochem. Biophys. Res. Commun. 171,690-696, 1990). In the present study, we examined VEGF in 4% paraformaldehyde fixed samples of prefrontal cortex and hippocampus from control (n=6) and Alzheimer brains (n=7) in order to assess the possibility that VEGF might be a brain growth factor. A specific polyclonal antibody (AB-61) directed against the amino terminus of VEGF revealed widespread VEGF-like immunoreactivity within neurons and their processes in both prefrontal cortex and hippocampus. Unlike bFGF, only weak VEGF-like immunoreactivity was seen in astrocytes. In the AD cases studied, there was no obvious association with the B/A4 amyloid containing neuritic plaques or neurofibrillary tangles. Our observations suggest that VEGF may be a novel brain growth factor. The different distribution of VEGF-like immunoreactivity relative to bFGF suggests that factors other than passive binding to the heparan-sulfate like proteoglycans may be important in the development of the heparin-binding growth factor alterations observed in Alzheimer disease. Supported by AG09301, NS 28121.

83.7

LOSS OF NGF RECEPTOR IN ALZHEIMER'S DISEASE: AN AUTORADIOGRAPHIC STUDY. O. Strada¹, E.C. Hirsch¹, F. Javoy-Agid¹, S. Lechéry², M. Ruberg¹, J.J. Hauw² and Y. Agid¹. (1) INSERM U289 and (2) Laboratoire de Neuropathologie R. Escourolle, Hôpital de la Salpêtrière, 75013 Paris, France.

Basal forebrain cholinergic neurons, known to be trophically affected by NGF, degenerate in Alzheimer's disease (AD). NGF binding has so far not been analyzed pharmacologically in the human forebrain, however. We analyzed the expression of the high affinity NGF receptor, by autoradiography using 125I-NGF 2.5S in the caudate nucleus, putamen, ventral striatum, substantia innominata and nucleus tegmenti pedunculopontinus in 6 Alzheimer patients and 5 controls. This was compared to acetylcholinesterase (AChE) activity in the same areas.

In control brains, high levels of 125I-NGF 2.5S binding were observed in the basal forebrain and striatum (from 0.32 to 0.49 fmoles/mg of tissue equivalent). No specific binding was observed in the nucleus tegmenti pedunculopontinus. Saturation study revealed a 25-40 pM Kd value in the striatum and basal forebrain. NGF binding sites were heterogeneously distributed in the striatum with patches of low NGF receptor density corresponding to the acetylcholinesterase poor striosomes, surrounded by a NGF receptor richer matrix (30%; p>0.05). In Alzheimer brains, a large decrease of NGF receptor density was observed in the caudate nucleus, putamen, ventral striatum and substantia innominata. These results indicate a selective vulnerability of neurons expressing NGF receptor in AD. Interestingly the decrease of AChE activity was less severe than the loss of NGF receptors.

83.9

COMPLEMENT mRNA UP-REGULATION DURING RESPONSE TO DEAFFERENTING LESIONS. S. A. Johnson, G. M. Pasinetti, M. Lampert-Etchells, N. Laping, C. Zarow and C. E. Finch. Andrus Ctr. and Dept. of Biol. Sci. Univ. So. Cal., Los Angeles, CA 90089

Activated complement (C) components are selectively associated with senile plaques, dystrophic neurites and tangled neurons in AD cortex and hippocampus (McGeer et al., Can. J. Neurol. Sci. 1989; 16, 516). This and other data on brain C derives from immunohistochemical studies; C mRNA has not been documented in the adult brain. The C system, a cytotoxic arm of the immune system, responds to bacteria and malignant cells, as well as to membrane fragments, aggregated protein and other abnormal structures. Cytotoxic mechanisms include depositing large transmembrane pores, the membrane attack complex, while promoting anaphylaxis and chemoattraction of phagocytic cells. We used northern blot and in situ hybridization to examine expression of various C mRNAs in AD and in rat brain lesion models of AD. C expression in AD is presented in a companion abstract (Lampert-Etchells et al.). We find elevated C1q b-subunit and C4 mRNAs in hippocampus after perforant path transection and in striatum after frontal cortex ablation. The time course of C mRNA increase is similar to GFAP and SGP-2, astrocyte mRNAs that increase during synaptic reorganization after afferent lesion. In situ hybridization with C anti-sense probes after decortication shows specific signal initially in the wound cavity (18 hrs). At 3d intense signal is seen only in striatum, the target of the ablated cortical neurons, where synaptic reorganization occurs for several days post-lesion. Combined C in situ hybridization and immunocytochemistry with OX-42, a microglial specific antibody, shows numerous C expressing microglia in the striatum. Further experiments on the role of C in synaptic plasticity are in progress. Supported by a LEAD award (AG-7909) to CE Finch.

IMMUNOHISTOCHEMICAL STUDY OF FIBROBLAST GROWTH FACTOR RECEPTOR IN BRAINS OF THE RAT AND HUMAN. I. Toyama*, O. Yasuhara*, A. Matsuo*, K. Hanai*, M. Isebe*, Y. Oomura*, PL. McGeer††, H. Kamo††† and H. Kimura*. Institute of Mol Neurobiol. Shiga Univ Med Sci, Otsu, †Toyama Med Pharm Univ, ††Takeda Hospital, Japan, †††Univ of BC, Vancouver, Canada

The immunocytochemical localization of presumed receptors for fibroblast growth factor (FGF-R) was studied in mammalian brain using an antibody to the 136-152 amino acid sequence. The synthetic haptenic antigen was conjugated to carrier poly-L-glutamate with water soluble carbodiimide and injected into rabbits. The best antiserum was able to detect 7.8 ng of the haptenic peptide, but did not react even with 2.0 µg of poly-L-glutamate or glutamate. Immunohistochemical staining in rat brain revealed a positive reaction mainly on neuronal cell surfaces, and less intensely on surfaces of glial cells and blood capillaries. Brain regions rich in the positive structures were the hippocampus, hypothalamus, substantia nigra and cerebral cortex. Since we have previously shown that acidic FGF is abnormally expressed in reactive astroglia surrounding senile plaques of Alzheimer diseases (*Dementia*, in press), we examined for the expression of FGF-R in human brain. In cerebral cortices of both Alzheimer cases and age-matched controls, immunopositive structures were observed mainly in neuronal cells of deeper cortical layers and in a few capillaries. The positive neuronal staining, however, appeared to be decreased in both density and intensity in Alzheimer cases as compared with controls.

The present study indicates that FGF-R may be down-regulated in cortical neurons with a concomitant hyper-production of FGF in reactive astrocytes surrounding cortical senile plaques.

ALZHEIMER'S AND NORMAL BRAIN CONTAIN mRNA FOR COMPLEMENT COMPONENTS C1qB, C3 and C4. M. Lampert-Etchells*, S.A. Johnson, C.E. Finch. Andrus Gerontology Center and Dept. of Biological Sciences, University of Southern California, Los Angeles, CA 90089.

In Alzheimer's disease (AD) brain, immunohistochemistry demonstrates complement components associated with plaques, tangles, and dystrophic neurites. The presence of these components suggests activation of the classical pathway. (McGeer, et al. 1989. Can. J. of Neurol. Sci. 16:516). A previous study in this laboratory identified a complement lysin inhibitor mRNA elevated in AD hippocampus (May, P.C. et al. Neuron, 5:831-839). In order to understand the origin and possible role of these gene products in the Alzheimer's disease process we analyzed complement specific mRNA gene expression in the brain by Northern and *in situ* hybridization techniques.

By Northern analysis using cRNA probes from coding regions, we detect 1.0kb C1qB RNA, 5.6kb C3 RNA and 5.5 kb C4 RNA in Alzheimer's and normal frontal cortex. *In situ* analysis of Alzheimer disease tissue from frontal cortex demonstrates increased hybridization of C1q and C4 probes in the outer layers of the cortex. Extensive plaques and tangles are seen in these same layers by Bielschowski silverstaining. Microscopically, clusters of grains are seen over large neuron-like cells and also over small cells in the cortex as well as the hippocampus. Ongoing studies address cell types expressing complement and the location of complement mRNA expressing cells in relation to Alzheimer's pathology. Supported by Alzheimer's Association IIRG-88-069 and Lead award AG-7909 to C.E. Finch.

DETECTION OF COMPLEMENT mRNAs IN HUMAN BRAIN BY NORTHERN HYBRIDIZATION ANALYSIS AND POLYMERASE CHAIN REACTION. D.G. Walker and P.L. McGeer. Kinsmen Lab., Dept of Psychiatry, Univ. of B. C., Vancouver, B.C., Canada, V6T 1W5.

Complement proteins associated with the classical pathway have been detected immunohistochemically in Alzheimer disease (AD) brain tissue (McGeer et al, Can J Neurol Sci 16:516, 1989). To determine whether complement proteins can be locally synthesized, we examined temporal cortex mRNAs for appropriate transcripts. C3 and C4 mRNAs were detected by Northern hybridization in all brains tested. These included 5 AD cases, 4 cases without neurological disease, and 1 case of carcinoma with brain metastases. C1q, C3, and C4 mRNAs were detected in the same extracts by the reverse transcription polymerase chain reaction (PCR) technique. Intron-spanning sequences for probe synthesis were selected from the Genbank data base so that amplification of genomic DNA could be excluded. Semi-quantitative PCR analysis of complement mRNA levels of C3 and C4 were made by measuring ³²p dCTP incorporation into amplified material at a stage where amplification was occurring at an exponential rate. There was a 4.27 fold increase in expression of C3 mRNA (p=.053) and a 9.33 fold increase in expression of C4 mRNA (p=.026) by ANOVA analysis. C9 mRNA was detected only variably by PCR. Since cells of monocytic origin can synthesize some complement proteins, microglia are a possible source for production in brain.

EFFERENT NEURONS OBSERVE THE COMPARTMENTAL ARCHITECTURE OF THE SUPERIOR COLLICULUS. R.-B. Illing* (SPON: European Neuroscience Association), Unit for Morphological Brain Research, Univ.-HNO-Klinik, W-7800 Freiburg, Germany.

The superior colliculus (SC) shares a compartmentalized architecture with several other brain structures. The intermediate collicular layers are characterized by several sets of neurochemically defined compartmental domains. Various collicular efferents terminate in a clustered pattern such that some sets of terminal clusters lie in register with certain neurochemically defined patterns, while other pairings assume a complementary or non-matching relationship.

To determine if collicular efferents originate from neurons having a distinct spatial position with respect to compartmental domains, axonal tracing with fluorochromes (Fluorogold or Fast Blue) was combined with intracellular Lucifer yellow injections and acetylthiocholine histochemistry to visualize efferent cells and acetylcholinesterase (AChE)-rich compartments in single sections of the rat SC. Descending collicular neurons of the intermediate layers backfilled from the dorsolateral bundle were situated mostly outside AChE-rich patches but tended to reside at the edges of the AChE-rich domain; particularly small perikarya were occasionally clustered inside the patches. Cell bodies with ascending axons to the intralaminar thalamic nuclei had a preference for the space outside AChE-rich patches. The dendrites of many efferent cells ran straight into AChE-rich neuropil, but others apparently selected their input from domain border regions.

I propose that the compartmental architecture of the SC provides a matrix to which not only efferents but also major collicular efferents are specifically related. A subpopulation of efferent neurons appears to be situated in strategic position at domain borders, with the geometry of their dendritic trees coordinated with the heterogeneous environment.

PROJECTIONS OF VESTIBULOSPINAL AXONS TRAVELLING OUTSIDE THE VENTRAL FUNICULI IN THE CAT. A. Donevan, I. MacDonald*, P.K. Rose, Department of Physiology, Queen's University, Canada, K7L 3N6.

Recent studies using the anterograde tracer PHA-L have shown that the medial and descending vestibular nuclei project to the upper cervical spinal cord via multiple funicular pathways including the lateral funiculi (LF), dorsolateral funiculi (DLF) and the dorsal columns (DC). (Donevan et al., J. Comp. Neurol. 302: 1-14, 1990). These pathways were not included in classical descriptions of vestibulospinal tracts. In the present study we have used serial reconstructions of single collaterals stained with PHA-L to map the termination zones of the "new" vestibulospinal pathways.

The terminal field of each collateral was closely related to the funicular location of its parent axon. For example, most collaterals arising from either ipsilateral or contralateral LF axons projected in a narrow band across lamina VII or dorsal lamina VIII, usually as far medial as the central canal. All contralateral DLF axon collaterals had terminations in lamina IV, while some projected ventrally to lamina V or dorsally to laminae III and II. The small number of DC axon collaterals examined had a characteristic widespread termination crossing multiple laminae, as dorsal as lamina II and as ventral as lamina VIII. The notable absence of a significant number of boutons in the ventral horn from any of the collaterals indicates that these vestibulospinal axons do not play a direct role in the control of head movement. Rather, they appear to be involved in the modulation of somatosensory processing or the transmission of segmental reflexes in the upper cervical spinal cord. (supported by MDAC, and MRC)

DIAZEPAM IN MEDULLARY RETICULAR FORMATION REDUCES EVOKED EMG RESPONSES IN BACK AND NECK MUSCLES; PROGESTERONE ENHANCES THE EFFECT. S. Schwartz-Giblin, A. Robbins and D.W. Pfaff, Rockefeller University, N.Y., N.Y. 10021.

Contraction of the deep back muscle, lateral longissimus (LL) contributes to the vertebral extension of lordosis during reproductive behavior in the female rat. Under urethane anesthesia (1.4g/kg), sites in the nucleus gigantocellularis (Gi) which receive inputs from the midbrain central gray (Robbins et al., Exp Brain Res, 1990), activate LL EMG and dorsal neck EMG with 1/sec trains (300 msec long) of biphasic pulses at 250 Hz. The test stimulus consists of 20 trains; repeated tests are at intervals of at least 10 min. In ovariectomized rats, a 32 gauge cannula containing 20-80 ng crystalline diazepam (1:100 diazepam:dextrose) is inserted through a guide cannula to which a bipolar stimulating electrode is attached. The electrically-evoked EMG response in either LL or neck is reduced at 5, 15, 30 and 60 min after diazepam in the reticular formation compared to the mean of 3 predrug controls and to the effect of a dextrose cannula (post hoc Tukey, $p < .01$). With dextrose, the response is reduced at 60 min. Progesterone (1mg, i.p.) 1 hr after local diazepam further reduces EMG responses at 15 min ($p = .05$) but has no effect when given after local dextrose. Drug and hormonal modulation occurred when the current (≤ 60 uA) was 1.2-1.5 x threshold. Large EMG units recruited last by reticulospinal fibers are the first to be inhibited when diazepam is put into Gi. Given that progesterone facilitates lordosis, it is important that the potential for progesterone to decrease medullary reticulospinal drive on axial muscles is state dependent; it depends upon GABA_A receptor modulation by diazepam in Gi.

84.2

THE DISTRIBUTION OF GLYCINERGIC BRAIN STEM NEURONS PROJECTING TO THE SPINAL CORD. A RETROGRADE TRACING STUDY USING ³H-GLYCINE.

J.C. Holstege*, C.M.H. Bongers*, H. Goedknegt*, W. Taat* and M. Godschalk, Dept. of Anatomy, Erasmus University Medical School, P.O. Box 1738, 3000 DR Rotterdam, The Netherlands.

Recently we found a glycinergic projection from the ventro-medial lower brainstem to spinal motoneuronal cell groups by combining anterograde transport of WGA-HRP with glycine immunocytochemistry at the ultrastructural level in rat (J.C. Holstege and C.M.H. Bongers, Eur. J. Neurosci. Suppl. 3 (1990) p. 96). In order to verify this projection and to determine whether additional projections were present, the (presumed transmitter-specific) retrograde transport of ³H-glycine from the spinal cord was used.

In several rats, 20-60 μ Ci. of ³H-glycine was injected in the lower cervical spinal cord under deep pentobarbital anesthesia. After 2 days survival, the rats were re-anesthetized and perfused transcardially with 250 ml. saline followed by 750 ml. of 3% glutaraldehyde and 1% paraformaldehyde in phosphate buffer. The brainstems were removed and frozen sections were cut, mounted on glass slides and processed for light microscopic autoradiography by dipping in liquid emulsion using 6 weeks exposure.

Preliminary results showed retrogradely labeled neurons in four areas: 1) medial of the trigeminal nucleus at the level of the caudal half of the inferior olive mainly on the ipsilateral side, 2) large cells in the nucleus gigantocellularis mostly on the contralateral side, with labeled axons of large diameter immediately crossing to the MLF on the ipsilateral side of the injection, 3) weakly labeled neurons in the ventro-medial reticular formation immediately dorsal and, to a limited extent, rostral of the inferior olive and 4) neurons bilaterally in the medial vestibular nucleus. In addition to the retrogradely labeled cells, anterogradely labeled terminals were also seen, especially in the medial part of the caudal brainstem.

It may be concluded that the retrograde transport technique with ³H-glycine is "glycine-specific" since retrogradely labeled cells were found only in the areas mentioned above, while other cell groups known to project to the spinal cord (e.g. the lateral vestibular nucleus and the cell groups in the dorso-lateral pons) were not labeled. The anterograde labeling, on the other hand, may be aspecific.

THE ROLE OF Gp Ia AND CUTANEOUS AFFERENTS IN ACTIVATING THE LUMBOSACRAL MOTOR CENTRAL PATTERN GENERATOR. J.W. Commissiong, NIH-NINDS-CNB, Bldg.10/5N214, Bethesda, MD. 20892.

Seven (PN7) and 14 (PN14) day old rats were spinalized at T6 under ether anesthesia. The PN7, but not the PN14 group recovered co-ordinated stepping function in the hindlimbs. At 16-18 of age, or later, a laminectomy was done in the unanesthetized, intercollicular decerebrate rat, and recordings were made from L2-L6 ventral nerve filaments, while stimulating Gp Ia afferents in the L4 dorsal root. In the unoperated control (UOC), PN7 and PN14 groups, the highest percentage of motoneurons was activated in the L4 segment. In the PN7 group, unlike the UOC and PN14 groups, a high percentage of motoneurons was activated in the L3 and L5, as well as in the L2 and L6 segments. The widest divergence of cutaneous afferents within the L2-L6 segments also occurred in the PN7 group. Functional recovery in the PN7 group may be related to a wide distribution of Gp Ia and cutaneous afferents within the lumbosacral motor central pattern generator. The mechanism by which peripheral, afferent signals to the generator, initiates patterned discharges in motoneurons, and causes coordinated stepping, is still unclear.

BACK MUSCLE EMG RESPONSES EVOKED BY CUTANEOUS FLANK NERVES IN RATS: EFFECTS OF SPINAL TRANSECTION, ANESTHESIA AND STEROID HORMONES. D.A. Holtzman, D.W. Pfaff and S. Schwartz-Giblin, Rockefeller University, N.Y., N.Y. 10021.

This study examines EMG responses in the lateral longissimus muscle to cutaneous flank nerve stimulation in ovariectomized (OVX) rats. When anesthetized with a low surgical dose of urethane (1.0 g/kg) 24 h after complete spinal transections (between T1 and T2), 15 of 19 OVX rats were capable of producing the same early (11-30 ms) and late (50-120 ms) responses to ipsilateral stimulation as CNS-intact rats. However, at this anesthetic level, only 6 of 18 transected rats had early and late flank nerve-evoked responses following contralateral stimulation, whereas all CNS-intact rats showed these responses ($p < .05$). It appears that descending information facilitates back muscle responses to contralateral cutaneous inputs. As early as 3 min after 1 mg (i.v.) of progesterone, the EMG response to unilateral flank nerve stimulation is decreased in CNS-intact, OVX rats (13 of 17) with 1.4 g of urethane/kg [Schwartz-Giblin and Pfaff (1990) J. Neurophysiol.]. This effect was not seen with the lower anesthetic dose in 4 of 4 CNS-intact or in 5 of 7 transected rats in the present study. No effect of estrogen (pretreatment or acute) was found in transected rats. Depression of unilateral cutaneous reflexes by progesterone appears to be state-dependent, consistent with studies by others which show reduced excitability of multisynaptic reflex pathways by anesthesia and potentiation of GABA_A synapses by progesterone.

INITIAL STUDIES ON THE MODIFICATION OF SPINAL STRETCH REFLEXES IN SPINAL CORD INJURED PATIENTS. R.L. Segal and S.L. Wolf. Div. Phys. Ther., Depart. Rehab. Med., Atlanta, GA 30322.

This abstract reports the findings from studies aimed at reducing hyperactive biceps spinal stretch reflexes (SSR) in spinal cord injured (SCI) patients using operant conditioning. Ten subjects (2 have withdrawn) have participated or are participating in the study. Subjects were randomly assigned to control (N=5) or treatment (N=5) groups. For both groups the first 6 sessions (baseline) and last 4 sessions (follow-up) involve no operant conditioning. The middle 24 sessions involve operant conditioning for the treatment group, while the sessions are the same as baseline and follow-up for the control group. Of the three subjects who have completed treatment, one subject did well (SSR decreased by almost 60%). A second subject was also doing well until the 10th treatment session when he contracted a urinary tract infection. Interestingly, this subject modulated the SSR downward within a session, but not below baseline levels. A third subject showed no ability to modulate the SSR. Two subjects have finished as control subjects and demonstrated relatively stable SSR's. Supported by the AMERICAN PARALYSIS ASSOCIATION.

AN IMPORTANT AREA FOR RESPIRATORY RHYTHMOGENESIS IN THE MEDULLA OF THE FROG *RANA CATESBEIANA*: AN *IN VITRO* STUDY USING THE HEMISECTED BRAINSTEM. HA McLean; SF Perry*; N Kogo & JE Remmers. Dept. of Medical Physiology. University of Calgary. Calgary, AB, Canada. T2N 4N1.

In the isolated brainstem of the frog, respiratory-related motor output is recorded from the rootlets of the cranial nerves V, IX, X and XII using suction electrodes. Two kinds of periodic activity are present: one related to lung ventilation and one related to buccal ventilation. Midsagittal section of the brainstem left the motor output associated with lung ventilation unchanged but abolished that associated with buccal ventilation. The hemisected brainstem responded to changes in superfusate pH by increasing the burst frequency of the motor output in a linear fashion with decreasing pH values from 8.6 to 7.6.

We have attempted to locate an area important for generating or modulating the motor output associated with lung ventilation. Microinjections (10 nl) of glutamate (100 and 10 mM) and GABA (100 mM) into a discrete area in the medulla resulted in respective increases and decreases in the frequency of the respiratory motor output. Microinjections of these neurotransmitters into other areas of the medulla, rarely influenced the motor output. The area yielding the largest number of positive responses was marked by injection of rhodamine labeled microspheres. Histological analysis revealed that this area lies 200 - 500 μ m below the ventral surface near the exit of the VI cranial nerve, and appears to be in the reticular formation just caudal to the level of the IX motor nucleus. Supported by AHFMR.

BILATERAL MAUTHNER LESIONS CAUSE INCREASES IN EMG MEASURES OF ESCAPE RESPONSES. M. B. Foreman and R. C. Eaton. Center for Neuroscience, University of Colorado, Boulder, CO 80309-0334.

In earlier work, we showed that electromyographic (EMG) recordings from the trunk musculature can account for kinematic parameters of the Mauthner (M-) initiated escape response of goldfish. A long term goal is to look for EMG parameters specifically associated with the firing of the M-cell. In this work we compare EMG recordings from animals in which one or both M-cells were electrolytically lesioned with normal and sham-lesioned animals. We here focus on an unexpected finding: four principal measures of the EMG size increased from 200 - 271% during escapes in fish without M-cells. The variability of these EMG parameters also increased. In contrast, these parameters changed from only 0 - 38% for non-M responses in fish with one M-cell remaining. Thus, we suspect that bilateral M-cell lesions cause damage to ancillary networks, possibly involving PHP cells, that may be much less affected by unilateral lesions. When intact, these networks appear to actively suppress non-essential motor output during escape responses. As in previous studies there was a significant increase in response latency associated with M-cell loss. Interestingly, despite the large increase in EMGs, there were no significant differences in other kinematic parameters associated with lesions of the M-cells. [Supported by NIH grant NS22621].

MAP OF BRAINSTEM NEURONS ACTIVATED BY CHEMICAL STIMULATION IN THE RAT PERIAQUEDUCTAL GRAY AS REVEALED BY THE EXPRESSION OF THE C-FOS PROTEIN. J. Sandkühler & T. Herdegen II. Physiologisches Institut, Universität Heidelberg, Germany.

Activation of efferents of the midbrain periaqueductal gray (PAG) may produce a wide variety of behavioral, somatosensory and vegetative responses. Here we have used the expression of the proto-oncogene *c-fos* encoded FOS protein as a cellular marker of brainstem neurons which are activated by micro-injections of bicuculline (GABA_A receptor antagonist, 200 pmol in 50 nl) into PAG sites of pentobarbital anesthetized rats. The animals were perfused 90 min after the injections and the nuclear FOS protein was detected by immunocytochemistry (FOS-IR, avidin biotin method, primary antibody at 1:6000) in free floating 50 μ m frontal sections through the brainstem.

After bicuculline injections into dorsal sites of the rostral PAG, FOS-IR was elevated above levels in sham treated (NaCl injected) animals bilaterally in the: -dorsal part of the rostral PAG, -throughout the caudal PAG, -commissural part of the solitary tract ncl., -rostral ventrolateral medulla, -medial vestibular ncl., -ncl. locus coeruleus, -rostral ventromedial medulla, -superior colliculus, -periventricular gray, -medial hypothalamus, -supraoptic ncl., -suprachiasmatic ncl. and -zona incerta. Preliminary results suggest that the injections into ventrolateral sites of the PAG produce a clearly different pattern of FOS-IR within the PAG and the brainstem.

These results provide a direct, functional substrate for the diversity of output functions of the PAG overlapping with known anatomical efferent connections. The putative role of proto-oncogenes such as *c-fos* for longterm adaptive changes of neuronal function suggest that efferents of the PAG may be involved in the plasticity of brainstem neurons. SUPPORTED BY A GRANT FROM THE DEUTSCHE FORSCHUNGSGEMEINSCHAFT (SA 435).

TRANSMITTERS IN INVERTEBRATES: COELENTERATES, ANNELIDS, ARTHROPODS

85.1

NEUROPEPTIDES IN COELENTERATES: STRUCTURE, LOCALISATION, BIOSYNTHESIS AND ACTION. C.J.P. Grimmelikhuijzen¹, D. Darmer², C. Schmutzler³, H.-P. Nothacker³, K. Carstensen³, R.K. Reinscheid³, K.L. Rinehart² and I.D. McFarlane². ¹Center for Molecular Neurobiology, Martinistr. 52, 2000 Hamburg 20, FRG, ²School of Chemical Sciences, University of Illinois, 1209 W. California St., Urbana, IL 61801, ³Department of Applied Biology, University of Hull, Hull HU6 7RX, UK.

Coelenterates have the simplest nervous system in the animal kingdom and were probably the first animal group that evolved a nervous system. Until recently, the nature of neurotransmitter substances in coelenterates has remained unknown. By means of several radioimmunoassays, we have now isolated 13 novel neuropeptides from sea anemones and 2 from hydromedusae. These peptides are all related and contain the C-terminus Lys-X-NH₂ or Arg-X-NH₂, where X represents Ala, Asn, Ile, Phe, Pro or Trp. Three peptides contain an N-terminal L-3-phenyllactyl residue which protects against degradation by nonspecific aminopeptidases. The neuropeptides are located in different sets of neurons in sea anemones. Each neuropeptide has a characteristic action. The precursor protein for the sea anemone neuropeptide Antho-RFamide (<Glu-Gly-Arg-Phe-NH₂) has been cloned. In *Calliactis parasitica* it harbors 19 copies of immature Antho-RFamide (Gln-Gly-Arg-Phe-Gly) together with 7 other, novel, putative neuropeptide sequences. The precursor of *Anthopleura elegantissima* contains 15 copies of Antho-RFamide and 18 other, putative neuropeptides.

THERMAL AND CHEMICAL INPUTS DIFFERENTIALLY AFFECT SEROTONIN NEURONS THAT EXPRESS FEEDING BY THE MEDICINAL LEECH. I.R. Groomer* and C.M. Lent. Dept. Biology, Utah State Univ. Logan UT 84322-5305.

Hirudo medicinalis ingest mammalian blood. The physiological components of this behavior are activated by serotonin-containing neurons, and we have found that either thermal or chemical stimulation of the prostomial lip synaptically excites serotonergic Retzius cells (RZ) throughout the CNS. Thermal effects have a more rapid onset and chemical stimulation evokes long-lasting excitation of RZ. Atropine (1 μ M) inhibits the thermal excitation of RZ (82%) and 1mM kynurenic acid decreases the chemical excitation by 85%. These data suggest that acetylcholine is the transmitter released from neurons in the thermosensory pathway, while glutamate mediates chemical excitation of RZ. Leech ingestive behavior depletes ganglionic serotonin by 28% (Lent et al. J. Comp. Physiol. A 168:191-200, 1991), and these two sensory pathways differentially affect central and peripheral serotonin stores. Thermal stimulation depletes 20-25% of the serotonin from the CNS, but does not deplete it from body wall. Chemical stimulation does not deplete central serotonin, but reduces the levels of this monoamine in the body wall by 28%. These data suggest distinct physiological and biochemical roles for thermal and chemical inputs to RZ during the expression of stereotyped ingestive behavior.

CARBACHOL AND SEROTONIN-ENHANCED RUBIDIUM UPTAKE RATE IN LEECH GLIA. M.C. Foster, C.M. Castiglia*, and A.J. Saubermann, Dept. of Anesthesiology, SUNY at Stony Brook, Stony Brook, NY 11794-8480.

Glia have receptors for carbachol (CARB) and serotonin (SER). Functions of these neurotransmitters (NT) in glial cells are not clear. It has been suggested that they may modify extracellular K clearance. The extent to which CARB and SER alter K metabolism in leech CNS was studied by electron microprobe analysis. Rb was substituted for K in order to study its uptake into neurons and glia. Leech (*Hirudo Medicinalis*) ganglia were perfused 60 s in 4 mM Rb Ringers' with and without CARB or SER, then frozen, cryosectioned, and analyzed for water content and concentrations of K, Rb, Na, Mg, P, Cl, and Ca in neurons and glia. In neurons, SER caused a small, dose-dependent increase in Rb uptake; CARB had little effect. In glia, both SER and CARB caused a dose-dependent increase in Rb uptake; Rb (mmol/Kg dry wt) was 28 ± 2 (control); with 5, 50, and 500 μ M NT, Rb was 36 ± 3 , 53 ± 3 , and 70 ± 3 (CARB), and 52 ± 4 , 63 ± 3 , and 89 ± 11 (SER). These results suggest that SER and CARB may help regulate K metabolism. (Supported by NIH NS21455.)

THE MECHANISM OF AN EXCITABILITY CHANGE INDUCED BY MUSCARINIC RECEPTORS IN AN IDENTIFIED INSECT MOTONEURON. B.A. Trimmer and J.C. Weeks. Institute of Neuroscience, University of Oregon, Eugene, OR 97403.

In larval *Manduca sexta*, the identified motoneuron, PPR, receives direct cholinergic input from proleg mechanosensory neurons. In addition to eliciting fast unitary EPSPs via nicotinic receptors, stimulation of these afferents can evoke slow, long-lasting (5-20 s) depolarizations (sEPSPs) of muscarinic pharmacology. Both the sEPSP, and muscarinic agonists such as oxotremorine-M (oxo-M), lower the spike threshold of PPR. To investigate the mechanism of this change in excitability we used a single electrode voltage clamp to monitor currents evoked by muscarinic agents. The main current activated by oxo-M is slow and long-lasting, allowing us to characterize its voltage dependence using slowly ascending (40 s) voltage ramps applied at the soma. This inward current is largest near PPR's normal resting potential (-50 mV), and declines with depolarization or hyperpolarization. The current is TTX-insensitive but is reversibly abolished when all external Na is replaced with N-methyl-D-glucamine. These findings suggest that a major component of the muscarinic current is carried by Na but is independent of the voltage-gated Na channel. To help analyze the regulation of this current, we injected various agents into the soma of PPR through the voltage clamp electrode. Injection of GTP γ S causes a prolongation of PPR's response to oxo-M and a persistent activation of the muscarinic current, effects that are consistent with the action of a G-protein. These data suggest that the excitability of PPR can be regulated by muscarinic modulation of a Na-dependent inward current via a G-protein.

A GENETIC ANALYSIS OF THE *FMRFamide* GENE REGION IN *DROSOPHILA*. M.A. O'Brien, M. Roberts*, and P.H. Taghert. Dept. of Anatomy and Neurobiology, Washington University Med. School, St. Louis, MO 63110.

We are using *Drosophila* molecular genetics to investigate the functions of modulatory neuropeptides. The gene of interest encodes a complex precursor protein with many diverse *FMRFamide*-related sequences. We are in the process of creating mutations in the gene in order to investigate the development and physiology of animals that lack its expression. Deletions were created in the 46C region, the cytological locus for the *FMRFamide* gene, using X-rays. One of these deficiency stocks, Df(2R)X3, has a visible deletion extending from 46C-E that includes the *FMRFamide* gene. Using cosmid and phage clones of surrounding genomic regions, the proximal breakpoint of the Df(2R)X3 deletion was mapped by Southern blot analysis to ~20kb upstream of the gene. Another deficiency stock, Df(2R)X1, does not delete the gene and its proximal breakpoint was mapped to within ~15kb downstream of the *FMRFamide* gene. Together, these 2 deletion stocks define a small ~40kb genomic interval that includes the *FMRFamide* gene; they were used to screen for point mutations. Because the phenotype of a *FMRFamide* gene mutation cannot be predicted, we began by screening for lethal phenotypes among ~1300 EMS mutagenized chromosomes. Seventeen lethal alleles mapping to the Df(2R)X3 were obtained with EMS mutagenesis. Five of these map to the small ~40kb interval defined by X3 and X1 breakpoints. Complementation analyses revealed that these 5 lethal mutations segregate into 2 complementation groups; therefore, at least 2 genes with lethal mutant phenotypes are likely to reside in this defined interval. We are in the process of determining if either is the *FMRFamide* gene. To account for the possibility that a *FMRFamide* gene mutant does not have a lethal phenotype, we are also mobilizing a P element from a position ~25kb upstream from the *FMRFamide* gene and screening for insertions into the gene as well as new deletions. These molecular genetic approaches should provide a novel means of studying neuropeptide function *in vivo*. This work was supported by NIH Grant # NS08460 and #NS21749.

THE STEROID HORMONE, 20-HYDROXYECDYSONE, CONTROLS GANGLIONIC FUSION DURING DEVELOPMENT OF THE MOTH, *MANDUCA SEXTA*. I.M. Amos and K.A. Masca. Graduate Program in Neuroscience and Dept. of Entomology, Univ. of Minnesota, St. Paul, MN 55108.

Manduca sexta is a holometabolous insect whose adult pterothoracic ganglion is formed when the larval meso- and metathoracic ganglia fuse with the first and second abdominal ganglia. The first gross morphological evidence of ganglionic fusion is apparent during the first few hours after pupal ecdysis. The pterothoracic ganglion is recognizable in its adult form 7 days later. As the various ganglia begin to fuse, the level of 20-hydroxyecdysone (20-HE) also slowly rises for the third and final time. We investigated whether the changing levels of 20-HE that occur shortly before and after pupal ecdysis regulate pterothoracic ganglion formation.

Normally there are two relatively small peaks of 20-HE that occur prior to pupation, and a third rise that begins at pupal ecdysis. In order to manipulate 20-HE levels, animals were ligated below the prothoracic segment. This isolated the various ganglia from the prothoracic glands, the only known source of ecdysone (20-HE precursor). Animals ligated after the first peak of 20-HE did not form pupal cuticles and showed no evidence of ganglionic fusion. Animals ligated after the first 20-HE peak and subsequently infused with physiological levels of 20-HE, mimicking the second peak, formed perfect pupal abdomens. No signs, however, of ganglionic fusion were evident. When animals, which had been induced to form a pupal cuticle, were again infused with 20-HE to mimic the post-pupation rise, the ability to form the pterothoracic ganglion was restored. This is the first study to demonstrate that all three fluctuations in 20-HE, during the larval to pupal transition, are required for the initiation of a developmental process.

MOLECULAR ANALYSIS OF *FMRFamide* GENE EXPRESSION IN *DROSOPHILA*. L. E. Schneider and P. H. Taghert. Dept. of Anatomy and Neurobiology, Washington University Medical School, Saint Louis, Mo 63110.

The *Drosophila FMRFamide* gene encodes a single detectable transcript that is expressed in a small, stereotyped pattern of ~100 central neurons. To study the molecular mechanisms that underlie this restricted pattern of expression we have generated a P element construct containing the *FMRFamide* gene fused to a β -galactosidase reporter gene. The construct contains 8 kilobases of the *FMRFamide* gene: 5 kilobases of upstream sequence, the short untranslated first exon, the entire intron, and the first 70 base pairs of the open reading frame. We have isolated two independent transformed lines with this construct. At all stages of development, the pattern of expression in animals that are homozygous for the construct is nearly identical to the expression of the endogenous gene. This suggests that the regulatory elements that are necessary for the appropriate pattern of *FMRFamide* gene expression are included in this construct. To determine whether expression in individual groups of neurons is directed by distinct DNA elements or, conversely, whether all neurons require the same regulatory elements, we are generating additional constructs that delete the intron or portions of the upstream sequence. These constructs will allow a more precise definition of the regions of the *FMRFamide* gene that direct expression to the appropriate subset of neurons. This work was supported by NIH grant #NS21749

PROCTOLIN MODULATION OF MUSCLE EXCITABILITY IN THE LARVAL HOUSEFLY IS MIMICKED BY PHORBOL ESTERS. L.D. Acevedo, D.N. Mbungu* and M.E. Adams. Entomology Dept, Univ of California, Riverside, CA 92521.

The neuropeptide proctolin is a cotransmitter for one of the motor neurons innervating the longitudinal ventrolateral muscles (6A and 7A) of the larval housefly, *Musca domestica*. Repetitive motor neuron activity or direct proctolin application leads to the appearance of calcium action potentials in normally inexcitable muscle targets, suggesting that the peptide modulates a voltage-sensitive calcium current (Duce and Adams, *Soc. Neurosci. Abstr.* 15:25). We find that the proctolin-activated muscle action potential is enhanced by bath application of 0.5-1 μ M Bay K 8644 and is inhibited by 5 nM nifedipine; both effects are reversible. Thus, these insect muscle calcium channels are pharmacologically similar to vertebrate L-type channels.

We have studied the mechanism by which proctolin activates the muscle action potential by examining activators and inhibitors of different second messenger pathways. The phorbol ester PMA (phorbol 12-myristate 13-acetate) evoked an action potential similar to that elicited by proctolin, and which was blocked by nifedipine. The response to PMA was reversible and the muscle did not respond to the inactive 4 α analog of PMA. Staurosporine, an inhibitor of protein kinases A and C, suppressed both the spontaneous and proctolin-induced action potentials. Membrane permeable analogs of cAMP and cGMP, and IBMX, did not evoke action potentials. Our data suggest that protein kinase C is involved in the generation of the proctolin-induced potential, which results from a dihydropyridine-sensitive calcium current.

COMPLETE PROCESSING OF A SYNTHETIC PROHORMONE OF AKH I RECONSTITUTED *IN VIVO*. R.C. Rayne* and M. O'Shea. Neurosciences Interdisciplinary Res. Centre, University of Sussex, Brighton, Sussex BN1 9QG, U.K.

We have chemically synthesized the complete prohormone of AKH I and developed an *in vitro* assay in which all *in vivo* post-translational events in precursor processing are reconstituted. AKH I is an amidated 10 residue insect hormone synthesized by the neuroendocrine cells of the glandular corpus cardiacum (CC). The AKH I prohormone consists of one copy of AKH I, a gly-lys-arg processing site and a 28 residue C-terminal peptide. The prohormone first forms a homodimer precursor which is then processed into two AKH I molecules and a dimer of the 28 residue C-terminal peptide. The C-terminal peptide contains a processing site (arg-lys) which is unused. To study processing of the synthetic precursor *in vitro*, extracts from the CC were incubated with synthetic and biosynthetically radiolabelled precursor. The *in vitro* system generates sequentially AKH-gly-lys-arg, AKH-gly-lys, AKH-gly and finally the bioactive form, AKH-NH₂. It may therefore allow us to isolate and characterise all enzymes involved in *in vivo* processing of AKH I precursor. Also, structural studies (NMR and X-ray crystallography) of the synthetic prohormone are in progress in order better to understand the influence of precursor structure on processing.

MULTIPLE RECEPTORS MEDIATE THE MODULATORY EFFECTS OF SEROTONERGIC NEURONS IN A SMALL NEURAL NETWORK. B. Zhang and R. M. Harris-Warrick. Section of Neurobiology and Behavior, Cornell University, Ithaca, NY 14853.

The gastro-pyloric receptor (GPR) cells are a set of cholinergic/serotonergic mechanosensory neurons that modulate the activity of neural networks in the crab stomatogastric ganglion (STG). Stimulation of these cells evokes a variety of slow modulatory responses in different STG neurons that are mimicked by exogenously applied 5-HT; these responses include tonic inhibition, tonic excitation, induction of rhythmic bursting and induction of bistable plateau properties.

We used pharmacological antagonists to show that these four classes of modulatory response are mediated by at least four distinct 5-HT receptors in the STG. GPR- and 5-HT-induced inhibition of the pyloric constrictor (PY) cells was selectively antagonized by gramine. Tonic excitation of the lateral pyloric (LP) cell was blocked by cinanserin. Induction of rhythmic bursting in anterior burster (AB) cell and the electrically-coupled pyloric dilator (PD) cells was antagonized by cinanserin and atropine at concentrations that do not block muscarinic cholinergic receptors in the STG. Induction of plateau potentials in the dorsal gastric (DG) cell was not blocked by any of the drugs we tested. These results show that a modulatory sensory neuron can use 5-HT to evoke multiple modulatory responses via multiple 5-HT receptors. They also provide further evidence that the GPR cells use 5-HT as a neurotransmitter. Supported by NIH #NS 17323.

THE ACTIONS OF L-GLUTAMIC ACID ON MOTONEURONS OF THE LOBSTER CARDIAC GANGLION. H. Hashemzadeh-Gargari and J. Freschi. Neurology Dept., Emory University, Atlanta, GA 30322.

Although in the mammalian nervous system, glutamate is exclusively an excitatory neurotransmitter, in invertebrates it may be either excitatory or inhibitory. For example, in the crustacean stomatogastric ganglion, glutamate may cause either a Na⁺-dependent excitatory response or inhibitory responses mediated by Cl⁻ or K⁺ conductances. We studied the effects of glutamate on lobster cardiac ganglion neurons voltage-clamped with two microelectrodes. We found that glutamate caused a depolarization and increase in bursting of the motoneurons (follower cells), and under voltage-clamp this effect was mediated by a dose-dependent increase in conductance leading to an inward current. The response to L-glutamate was mimicked by quisqualic acid and L-aspartate (quisqualate > glutamate > aspartate). Kaicnic acid, N-methyl-D-aspartate, glutamate diethyl ester, and D-glutamate were not effective. The antagonist kynurenic acid, over a concentration range of 0.1 to 1 mM, inhibited the response. The response was not modified by spermine (polyamine site) nor by glycine. The reversal potential of the glutamate-evoked current was between -20 and 0 mV, and the response was blocked in Na⁺-free saline. We conclude that these neurons contain glutamate receptors, similar to mammalian non-NMDA receptors, that activate a cation current, carried by K⁺ and Na⁺. The physiological response appears identical to that produced at muscle glutamate receptors of crustaceans and insects (Supported by NIH NS-22628).

FMRFAMIDE-RELATED PEPTIDES FROM CRAYFISH PERICARDIAL ORGANS. A. J. Mercier, I. Orchard, M. Skerrett and V. TeBrugge. Dept. of Biol. Sci., Brock University, St. Catharines, Ont., L2S 3A1, and Dept. of Zoology, University of Toronto, Toronto, Ont., M5S 1A1.

The pericardial organs of crayfish contain high amounts of FMRFamide-like immunoreactivity (FLI), suggesting a hormonal role for FMRFamide-related peptides (Mercier, Orchard & TeBrugge, J. exp. Biol. 156: 519-538, 1991). The present study was undertaken to determine the amino acid sequences of such peptides. Extracts of pericardial organs from *Procambarus clarkii* were fractionated on two sequential reversed-phase HPLC columns (a C18 column, followed by a Phenyl column), using 0.1 % TFA and gradients of acetonitrile. The peak fraction from the phenyl column (containing the highest amount of FLI) was found to contain two peptides with the sequences NRNFLRF-NH₂ and DRNFLRF-NH₂. We have named these peptides "NF1" and "DF2", respectively, due to their similarities with identified peptides from lobster PO's, peptides "F1" (TNRNFLRF-NH₂) and "F2" (SDRNFLRF-NH₂) (Trimmer et al. J. Comp. Neurol. 266: 16-26). Synthetic forms of peptides NF1 and DF2 increased the rate and amplitude of contraction of isolated crayfish hearts, as did the peak fraction from the phenyl column. DF2 increased the size of EPSP's in phasic extensor muscles; effects of NF1 on this preparation are being studied. The results support a neurohormonal role for FMRFamide-related peptides in crayfish. INTRACELLULAR AND EXTRACELLULAR RECORDINGS OF POSTERIOR HYPOTHALAMIC NEURONS IN VITRO: RESPONSES TO HYPOXIA AND HYPERCAPNIA. G.H. Dillon and T.G. Waldrop. Dept. of Physiology & Biophysics, Univ. of Illinois, Urbana, IL 61801.

Several studies have suggested posterior hypothalamic (PH) neurons modulate cardiorespiratory responses to stimulation of central and/or peripheral chemoreceptors. The present studies were conducted to examine responses of PH neurons *in vitro* to hypercapnia and hypoxia. 400 µm slices were taken from 150-250g, male Sprague-Dawley rats. Slices were placed in a recording chamber and perfused with nutrient media equilibrated with 95% O₂/5% CO₂. Extracellular and intracellular (whole-cell patch) recordings were obtained and responses to hypercapnia (7% CO₂/93% O₂) and hypoxia (5% CO₂/95% N₂ or 10% O₂/5% CO₂/85% N₂) were examined. EXTRACELLULAR RESULTS: 31% of PH neurons studied were excited by elevated CO₂. 84% of PH neurons were stimulated by hypoxia (0% or 10% O₂); the response to hypoxia was shown to be dose-dependent. Only 13% of PH neurons were stimulated by both hypoxia and hypercapnia. In addition, stimulation in response to hypoxia or hypercapnia was observed during synaptic blockade. INTRACELLULAR RESULTS: Input resistance of studied cells was 173±17.4 MΩ. Neurons studied in response to hypoxia had a resting V_m of -51.8±4.1 mV. 67% of these cells depolarized and increased their discharge during the hypoxic bout; hyperpolarization and a decrease in activity followed the stimulation. PH neurons studied in response to elevated CO₂ had a resting V_m of -49.8±3.8 mV. Hypercapnia increased the firing rate of 42% of those cells studied in the whole-cell patch configuration. Results of these studies suggest: 1) PH neurons modulate responses to both hypercapnia and hypoxia, but via separate subpopulations of cells, 2) the posterior hypothalamus may be a site of central hypercapnic and hypoxic chemoreception (Supported by NIH 38726; American Heart Association).

VAGAL INPUT TO THE VENTRAL RESPIRATORY GROUP (VRG) OF THE RAT. F. Hayashi*, S.K. Coles, R. Behnia*, and D.R. McCrimmon. Depts. of Physiology & Anesthesia, Northwestern University, Chicago, IL 60611.

Neuronal candidates for mediating the Breuer-Hering reflex prolongation of expiration (E), were identified in the rostral VRG of anesthetized, paralyzed, and vagotomized rats (n=12). Intracellular recording of VRG neurons was used to identify synaptic potentials (PSPs) elicited by low intensity stimulation (.5-100 Hz, .05-.1 ms, 5-20 µA) of the vagus nerves. Antidromic stimulation of the vagus and superior laryngeal nerves and of the spinal cord was used to identify axonal projections of recorded neurons. Sixteen non-antidromically activated E neurons were recorded and divided into two groups: 1) those which rapidly depolarized in early E (E-Dec, n=12) and 2) those exhibiting progressive depolarization during E (E-Aug, n=4). EPSPs were observed in 4 E-Dec neurons (latency = 2.2-4.0 ms) and IPSPs in 1 E-Dec neuron (latency = 5.2 ms). PSPs were not observed in E-Aug neurons. During tetanic stimulation E-Dec neurons depolarized and discharged tonically. In contrast, E-Aug neurons ceased firing. Twenty-five non-antidromically activated inspiratory (I) neurons were recorded and divided into three groups: 1) those which progressively depolarized throughout I (I-Aug, n=18), 2) those which rapidly depolarized during early I (I-Dec, n=5), and 3) those which depolarized during late I (n=2). EPSPs (latency of activation=2.2 and 2.6 ms) were seen in two I-Aug neurons, but only one IPSP (latency=5.4 ms) was observed. All I neurons decreased their discharge rate during tetanic vagal stimulation. These results are consistent with the hypothesis that vagal afferents paucisynaptically excite a subset of E-Dec neurons in the VRG that, in turn, inhibit I neurons, thereby delaying the onset of the next inspiratory cycle.

ACETYLCHOLINE (ACh) RELEASE IN THE MEDIAL PONTINE RETICULAR FORMATION (mPRF) PREDICTS RESPIRATORY FREQUENCY. R. Lydic, H.A. Baghdoyan, and Z.Lorinc, Dept. of Anesthesia, Penn State Univ., College of Medicine, Hershey Pa 17033.

Studies using *in vivo* microdialysis recently suggested that respiratory frequency during the carbachol-induced REM sleep-like state (DCarb) was accompanied by enhanced ACh release (*FASEB J.* 5:A734, 1991). We now report that levels of ACh release in the mPRF predict respiratory frequency during DCarb and during quiet wakefulness (W). To date, we have studied 4 intact, unanesthetized cats instrumented for polygraphic and respiratory recordings and trained to sleep in the laboratory. A microdialysis probe (2mm tip, 20kDa molecular cutoff) was placed in the mPRF for collecting dialysate samples during wakefulness and during the DCarb state produced by microinjecting carbachol (4.0µg/0.25µl) into the contralateral mPRF. Dialysis samples were analyzed for ACh using HPLC and a BAS electrochemical detector (LC-4B). A statistically significant increase ($p < 0.0001$) was observed in ACh release (mean pmoles \pm S.D.) during DCarb (0.71 \pm 0.29) as compared to W (0.42 \pm 0.08). Respiratory frequency in breaths/min declined to an average of 30 during DCarb from 38 in W. Regression analyses revealed that levels of ACh release accounted for most of the variance in respiratory frequency during both DCarb ($r^2=0.97$) and W ($r^2=0.91$). Thus, state-dependent changes in respiratory frequency can be expressed as a function of endogenous ACh release in non-respiratory regions of the mPRF known to regulate REM sleep. Support: Department of Anesthesia, MH-45361(HAB), HL-40881(RL).

CARBONIC ANHYDRASE IN BRAINSTEM RESPIRATORY CHEMOSENSITIVE REGIONS. Y. Pan, K. Nauss, D.G. Bernard, R.M. Douglas, and C.O. Truoth, Dept. of Physiol. & Biophysics, Coll. of Med., Howard Univ., Washington, D.C. 20059.

Regions of respiratory chemosensitivity that respond to cerebrospinal fluid (CSF) pH changes and inspired carbon dioxide have been described on the ventral medullary surface (VMS). The present investigation was undertaken to determine the presence and distribution of carbonic anhydrase (CA) in the rat brainstem as studied by histochemical and immunocytochemical methods. Histochemical staining of soluble and membrane-bound CA was found to be more intense in nerve fibers than in neuronal cell bodies. The intensity increased with age from newborn to adult. Immunocytochemical staining of soluble CA was intense in the cytoplasm of neurons and glia especially in the endothelium of blood vessels and within the marginal glia. In the adult rat, CA is ubiquitous throughout the medulla with greatest intensity being at the VMS and in the dorsal medulla in and around the Nucleus Tractus Solitarius and Cuneate Nucleus. In the neonate there was a paucity of clearly stained neuronal and glial elements. SUPPORT: - NIH-NIGMS Grant # 806GM08016 AND NIH Grant PH 55-T 32 GM-07800.

MUSCLE SYMPATHETIC NERVE AND HEMODYNAMIC RESPONSES DURING HYPOVENTILATION INDUCED HYPERCAPNIA IN HUMANS

David E. Anderson*, Virend K. Somers*, Mary P. Clary*, Christine A. Sinkey*, Erling A. Anderson, NIA, Baltimore MD; and U of Iowa, Iowa City IA

Respiratory inhibition and increased arterial pressure (AP) have been reported during preavoidance stress in dogs and during daily activities in humans. Hypoventilation increases arterial carbon dioxide (pCO_2) which could stimulate chemoreceptors and increase muscle sympathetic nerve activity (SNA) and AP. We sought to determine whether increased AP during hypoventilation induced hypercapnia is associated with increased SNA.

We measured AP, heart rate, oxygen saturation, end tidal CO_2 , forearm vascular resistance, (FVR, plethysmography), SNA (microneurography) and central venous pressure (CVP) in 6 sitting subjects. Measurements were taken during: 1) baseline; 2) hypoventilation (6-8 breaths/min; normal tidal volume) and 3) recovery (8 min each; data mean \pm SE).

	Control	Hypoventilation	Recovery
pCO_2	34 \pm 0.1	42 \pm 3.0*	34 \pm 1.0
MAP (mmHg)	94 \pm 6	105 \pm 7*	97 \pm 6
CVP (mmHg)	0.1 \pm 1.9	6.0 \pm 1.3*	2.2 \pm 1.7
HR (bpm)	70 \pm 2	67 \pm 2*	70 \pm 4
SNA (units)	622 \pm 175	682 \pm 195	658 \pm 203
FVR (units)	43 \pm 8	39 \pm 9	42 \pm 8

Hypoventilation increased pCO_2 and caused marked increases in AP and CVP without vasoconstriction in the forearm. Despite increased AP and CVP, SNA did not decrease. Thus, hypoventilation observed during daily activity promotes increased AP which 1) fails to produce the expected baroreflex inhibition of SNA and 2) is not mediated by sympathetic vasoconstrictor activity to skeletal muscle.

EVIDENCE FOR A ROLE FOR TONIC RELEASE OF AN EXCITATORY AMINO ACID AT THE CAUDAL-SUBRETROFACIAL AREA IN THE CONTROL OF VENTILATION. J.E. McManigle*, W.H. Panico*, S. Pineo*, A.M.T. Da Silva*, K.L. Dretchen and R.A. Gillis*. Georgetown Univ., Washington, D.C. and Uniformed Services Univ. of Health Sci., Bethesda, MD.

Neurons in the caudal-subretrofacial area (cSRFA) of the ventrolateral medulla of the cat exert a major role in the control of ventilation (*Neurosci. Abstr.* 16: 298, 1990). Microinjection of excitatory amino acids (EAA) receptor agonists into the cSRFA produces decreases in respiratory activity. For example, using concentrations of 50 and 100 mM of L-glutamate and microinjecting 20 nl/side results in apnea. Nearly identical effects are noted with microinjection of N-methyl-D-aspartate (NMDA) (0.78 mM) and (RS)-alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) (0.05 mM), agonists for the NMDA and non-NMDA receptors, respectively. To determine whether tonic release of an EAA occurs at the cSRFA and exerts control over ventilation, we evaluated the effects of dihydrokainate, an inhibitor of glutamate and aspartate reuptake (*J. Neurochem.* 32: 121, 1979). Dihydrokainate (10 to 100 ng/20 nl) microinjected bilaterally into the cSRFA (located approximately 3 mm rostral to obex, 4 mm lateral to midline and 1.5 mm below the ventral surface) of chloralose-anesthetized cats while monitoring tidal volume (V_t), respiratory rate (f), blood pressure (BP) and heart rate (HR), produced significant reductions in V_t (20.2 \pm 2.8 ml to 14.5 \pm 1.9 ml, $p < 0.05$) (N=6). This occurred without significant changes in f, BP and HR. Pretreatment with a specific antagonist of non-NMDA receptors, namely, 6-cyano-7-nitroquinoxaline -2, 3 - dione (CNQX), counteracted the respiratory depressant effect of dihydrokainate. These results suggest that tonic release of an EAA occurs at the cSRFA and exerts an inhibitory effect on ventilation that is mediated through activation of a non-NMDA EAA receptor.

PROSTAGLANDIN H-SYNTASE (PGHS) IMMUNOREACTIVITY AND ENZYME ACTIVITY IN THE LATE GESTATION OVINE BRAIN. J.L. Norton, S.L. Adamson*, A. D. Bocking*, T. Zakar*, D. Olson* and V. K. M. Han*. MRC Group in Fetal and Neonatal Health and Development, The Lawson Res. Inst., London, and Mt. Sinai Hosp., Toronto, ON, Canada.

PGHS is the rate limiting enzyme in prostaglandin (PG) biosynthesis. PGs may play a role in the regulation of breathing *in utero*. To determine if PGs are synthesized in the developing brain, we have used immunocytochemistry (ICC) to identify PGHS immunoreactive (IR) neurons, and a specific enzyme assay to measure PGHS activity in different brain regions. ICC was performed on Bouin's fixed tissue sections from fetal ovine brains (120-130 d gestation, n=3), using avidin-biotin-peroxidase technique with specific antiserum against ovine PGHS. PGHS enzyme activity was determined in microsomes from different brain regions by measuring the PGE_2 production in the presence of 10 mM arachidonate. PGHS-IR neurons and fibers were observed in the gracile and cuneate nuclei, dorsal vagal nucleus and raphe obscurus of the medulla, reticular formation of the pons, superior colliculi of the midbrain, lateral hypothalamus, dentate gyrus and CA3 regions of the hippocampus, and widely distributed in the gray matter of different regions of the cerebral cortex. PGHS enzyme activity (pg PGE_2 /mg prot/4 min) in different brain regions were as follows: cortex (frontal) 1967.8, medulla 474.4, pons 191.4, superior colliculus 3101.5, cerebellum 108.7, and hypothalamus 601.8. PGHS enzyme activity of the different regions correlate well with the number of PGHS-IR neurons in each region. These findings indicate that functional PGHS-IR neurons are present in specific regions of the late gestation ovine brain, and suggest a role for locally synthesized PGs in the regulation of fetal breathing.

CENTRAL CHEMOSENSORY CONTROL OF TONIC CARDIO-RESPIRATORY AND MOTOR RESPONSES IN A PRIMATE MODEL OF BRAIN INJURY. R.M. Millis*, D.G. Bernard, C.O. Truoth, and D.H. Wood*. Dept. of Physiol. & Biophysics, & Neurol., Coll. of Med., Howard University, Washington, D.C. 20059.

Hypoxic brain injury was produced in primates by slow infusion of physiological saline into an epidural balloon catheter (1cc/min). Mean arterial blood and airway pressure and intracranial pressure (ICP) were measured continuously in spontaneously breathing baboons (3-6kg) anesthetized with ketamine hydrochloride. Arterial blood gas tensions were measured by respiratory mass spectrometry. Cerebral perfusion pressure (CPP) was calculated. Results showed that ICP > 30cm H_2O was associated with decreased CPP, simultaneous, periodic vasopressor response, hyperventilation, and muscle rigidity in four of ten animals studied. Administration of sodium bicarbonate intra-arterially reversed the muscle rigidity and periodic responses, and increased arterial plasma bicarbonate levels. Periodic vasopressor, ventilatory and motor responses may be mediated by central chemosensory reflexes, and rapidly reversed by sodium bicarbonate. SUPPORT: MBRS 206 GM 08016.

Immunocytochemical identification of catecholaminergic neurons in the vasopressor areas of the medulla oblongata in the swine. S. D. Wang, R. H. Lin*, H. T. Horng*, J. C. Liu*, J. S. Kuo* and C. Y. Chai*. Dept. of Biology and Anatomy, National Defense Medical Center, Dept. of Medical Res., Taichung Veterans General Hospital, Institute of Biomedical Sciences, Academia Sinica, Taiwan, R.O.C.

The aim of this study is using immunocytochemical techniques to determine the anatomical relationships of catecholamine neurons with our previously defined vasopressor areas in the dorsal (DM) and ventrolateral (VLM) regions of medulla oblongata and also the region in between, the parvocellular reticular nucleus (PVC) of Swine. The immunoperoxidase and immunofluorescence are used to identify the distribution of immunoreactive neurons, nerve fibers and terminal processes of catecholaminergic nature in the above regions. The distribution of catecholamine-synthesizing enzyme i.e., dopamine-beta-hydroxylase (DBH) and phenylethanolamine N-methyltransferase (PNMT) are examined in the brain sections of the medulla oblongata. The results show that noradrenergic (DBH-positive and PNMT-negative) and adrenergic (DBH-positive and PNMT-positive) neurons exist in DM, VLM and PVC coincided with the areas functionally active for pressor responses. This suggests that in swine the DM, VLM and PVC contain a mixed population of catecholaminergic neurons which may contribute to the vasopressor responses on chemical and electrical stimulation.

CENTRAL OPIOIDERGIC MECHANISMS IN THE ROSTRAL VENTROLATERAL MEDULLA CONTRIBUTE TO THE HYPOTENSIVE RESPONSE OF PROPRANOLOL IN THE SPONTANEOUSLY HYPERTENSIVE RAT. R. L. Tackett and L. R. Portis. Department of Pharmacology and Toxicology, Cardiovascular Pharmacodynamics Laboratory, College of Pharmacy, University of Georgia, Athens, GA 30602.

Previous experiments in our laboratory have demonstrated that the hypotensive response to centrally administered propranolol is associated with an increase in central norepinephrine and beta endorphin levels. These findings, thus, suggest an interaction between catecholaminergic and opioidergic systems in the antihypertensive action of propranolol. The rostral ventrolateral medulla (RVLM) represents a possible neuroanatomical site for the interaction of catecholaminergic and opioidergic neuronal systems in the regulation of cardiovascular responses. The present study was designed to determine if opioidergic mechanisms in RVLM are involved in the hypotensive actions of propranolol. Male spontaneously hypertensive rats were anesthetized with pentobarbital, ventilated artificially and instrumented for recording arterial pressure and heart rate. Bilateral microinjection of propranolol (0.25 nmole) in RVLM resulted in a significant decrease in arterial pressure of 46% at 45 min. Bilateral injection of naloxone (20 nmole) into RVLM did not alter blood pressure or heart rate. However, naloxone pretreatment significantly attenuated the hypotensive response produced by microinjection of propranolol into RVLM. These data support the involvement of RVLM opioidergic systems in the hypotensive actions of propranolol.

IMMUNOHISTOCHEMICAL STUDY OF NEUROPEPTIDE Y IN THE BULBOSPINAL TRACT. C. J. Tseng, H. C. Lin*, S. D. Wang and C. S. Tung*. Departments of Pharmacology, Physiology and Anatomy, National Defense Medical Center, Taipei, Taiwan, R.O.C.

Neuropeptide Y (NPY), a 36 amino acid polypeptide, has been shown to be a co-transmitter with adrenaline and noradrenaline in many sympathetic nerves. Our previous studies suggested that NPY may be crucial in cardiovascular regulation. In the present study, we proposed to establish an immunohistochemical techniques to stain the Tyrosine Hydroxylase (TH), Dopamine β Hydroxylase (DBH), Phenylethanol-N-Methyl-Transferase (PNMT) and NPY in neurons or nerve terminals of the rat brainstem and spinal cord. By using these techniques, we also determined the effects of C₁ area lesions on NPY nerve terminals in the intermediolateral column (IML). Our results demonstrated that many catecholamine- and NPY-containing neurons exist in medulla, such as the nucleus tractus solitarius, area postrema, A, and C₁ areas. Their terminals are also found in the IML. After unilateral microinjection of 6-hydroxydopamine (6-OHDA) into the C₁ area, the catecholamine- and NPY-containing neurons were disappeared and their terminals diminished in the IML. On the other hand, following administration of 6-OHDA intrathecally, the catecholamine- and NPY-containing neurons and terminals extinguished or decreased both in the brainstem and spinal cord. These results indicate that most of the NPY and catecholamine immunoreactivity found in the IML were projected from the rostral ventrolateral medulla, and they may hold an important functional role in the bulbospinal pathway to regulate the cardiovascular function.

LASER-DOPPLER FLOWMETRY MEASUREMENT OF SYMPATHETIC CUTANEOUS VASODILATION. M. C. Koss and M. Kawarai*. Univ. of Okla. Hlth. Sci. Ctr., Okla. City, OK 73190.

This study was undertaken to determine if laser-Doppler flowmetry could effectively measure neurally evoked sympathetic cutaneous vasodilation in anesthetized cats after pretreatment with anti-adrenergic drugs: 1) acute guanethidine administration, 2) chronic monoamine depletion and 3) α -adrenoceptor blockade with prazosin and yohimbine. We also addressed the question of a casual relationship between neurally evoked vasodilator and sudomotor responses. Guanethidine produced a depression of basal cutaneous blood flow whereas α -adrenoceptor blockade did not. In all groups, preganglionic sympathetic nerve stimulation produced intensity-dependent increases of digital skin blood flow along with sympathetic-cholinergic sudomotor responses. Vasodilator responses were not altered by i.v. propranolol or atropine, however, evoked sudomotor responses were blocked by atropine. Low doses of hexamethonium (1.5 mg/kg, i.v.) selectively abolished cutaneous vasodilation but not concomitantly evoked sudomotor responses. These results demonstrate that cutaneous digital vasodilation can be measured in cats following removal of either pre- or postjunctional vasoconstrictor mechanisms. Neither muscarinic nor β -adrenoceptor mechanisms appear to be involved. Cutaneous vasodilation does not appear to be a consequence of concomitant sudomotor activation. (Supported by KAO Corp.)

N-ACETYLGLUCOSAMINE (NAGA) PRODUCTION BY DEVELOPING WHITE MATTER ASTROCYTES IN THE FETAL RABBIT. T. Bass¹, P. Gurtner², and F. J. Liuzzi³. Depts. of Pediatrics¹, Neurosurgery², and Anatomy & Neurobiology³, Eastern Virginia Medical School, Norfolk, VA 23507.

Developing CNS tracts are thought to be compartmentalized by extracellular matrix proteins (ECMP) produced by astrocytes. NAGA, a major constituent of many of these ECMP has a high binding affinity for various plant lectins. We used the tomato lectin, *Lycopersicon esculentum* (LE) to identify NAGA producing astrocytes and to document developmental patterns of appearance in the fetal rabbit.

New Zealand White rabbit pups were sacrificed after delivery by caesarean section at 22 to 32 days gestation. Other pups were allowed to deliver vaginally and were sacrificed at 2 and 4 postnatal days. All brains were fixed in Zamboni's fixative and paraffin embedded sections were incubated with biotinylated LE which was detected with peroxidase conjugated streptavidin and aminoethylcarbazole chromagen.

NAGA positive astrocytes were found in and between developing white matter tracts and were concentrated at their margins. The numbers of NAGA positive astrocytes increased with increasing gestational age. This study suggests a developmental regulation of ECMP production by astrocytes which may in turn influence white matter development.

SCHWANN CELLS FAIL TO REMYELINATE AXONS FOLLOWING INJURY IN CULTURE IN DIFFERENTIATION SUPPORTING MEDIUM. C. Fernandez-Valle, P. M. Wood, and M. B. Bunge. The Miami Project, Univ. of Miami Sch. of Med., Miami, FL 33136.

Ascorbate dependent acquisition of basal lamina (BL) on the Schwann cell (SC) is required for initial myelin formation in vitro. To better understand this linkage we asked whether SCs could use previously deposited BL to form myelin after injury. Well-myelinated axon fascicles in rat dorsal root ganglion neuron-SC cultures were crushed to cause myelin breakdown and reformation. Axons were injured on one side of the culture; the opposite side served as a control. Cultures were maintained for 3-5 weeks after crush (sufficient for initial myelin formation) in: 1) myelinating (M) medium containing ascorbate, 2) M medium lacking ascorbate, and 3) M medium lacking ascorbate but with protease inhibitors (PIs) to minimize BL loss. Sudan black staining was used to visualize myelin; electron microscopy was performed to determine axon size, presence of BL, and myelin thickness. We were surprised to find that SCs did not appear to myelinate axons following injury, even in M medium in which they could have formed new BL; in fact, BL was lost and did not reform on the injured side, in contrast to the uninjured side where BL persisted. BL was lost after injury in medium lacking ascorbate as well and PIs did not prevent this BL loss. A time course study of myelin disappearance showed an initial rapid degradation into myelin ovoids (1-5 days) but many SCs contained myelin debris 3 weeks after injury. In sum, conditions favoring SC BL formation (and thus myelination) are not present after injury in these cultures of purified populations of neurons and SCs. Possibly the slow clearance of myelin debris limited the SC's ability to reform BL. (Supported by NIH 09923 and The Miami Project).

Exogenous Purified Basal Lamina Components Cause Abnormal Schwann Cell Ensheathment of Sympathetic Neurites in Culture. V. J. Obremski and M. B. Bunge. The Miami Project, University of Miami School of Medicine, Miami, FL 33136

We have used a tissue culture system of superior cervical ganglion neurons (SCGNs) and Schwann cells (SCs) to model development of unmyelinated nerve. SCs in SCGN+SC cultures do not completely differentiate; SC basal lamina (BL) deposition is patchy and neurite ensheathment is poor. Previous experiments have shown that a diluted extract of BL, Matrigel, improves these two parameters. Could this effect be due to a specific component of Matrigel? SCGN+SC cultures were supplemented with one of three BL components (known to be in Matrigel), laminin, type IV collagen, or heparan sulfate proteoglycan, or with all three. Surprisingly, all four different additions, like Matrigel, improved the two parameters we examined; more BL was deposited on SCs and ensheathment was increased.

However, these cultures do not resemble normal nerve. The SCs appear hypertrophic with numerous processes. Some SC ensheathment is exaggerated; multiple wraps of SC cytoplasm may be seen on a single neurite, or two processes may envelop a neurite and then proceed beyond it for some distance. Other processes do not ensheath neurites, but instead run parallel to them. Our earlier work had shown that the addition of fibroblasts (Fbs) to SCGN+SC cultures most closely models unmyelinated nerve; we had hypothesized that Fbs might contribute one of the three molecules tested to SC BL. We now suggest that while this might be the case, Fbs must also contribute another factor that promotes normal SC function. (Supp. by NIH 09923 & The Miami Project. Gifts of molecules from A. Charonis, E. Tsilibary, J. Hassell)

LAMININ ISOFORMS IN THE NEURAL RETINA: POTENTIAL MODULATORS OF CELLULAR DIFFERENTIATION. D.D. Hunter, A. Torio*, R. Libby*, and W.J. Brunken¹. Neuroscience Program, Tufts Univ. Sch. of Med., Boston, MA 02111 and ¹Biology Dept., Boston College, Chestnut Hill, MA 02167.

The development of the neural retina follows a stereotyped time course that begins with an undifferentiated neuroepithelium populated by multipotential progenitor cells and ends with a highly differentiated tissue containing diverse cell types. The identities of the factors that guide this differentiation have remained elusive; a likely location for such factors, however, is the extracellular space in which retinal cells develop. We have shown that the extracellular matrix component s-laminin is present in the neural retina, that s-laminin expression parallels the differentiation of rod photoreceptors, and that photoreceptors specifically interact with s-laminin *in vitro*. In marked contrast, laminin (A/B1/B2) is absent from s-laminin-rich areas of the neural retina. These data suggest that s-laminin acts in a manner quite unlike laminin (A/B1/B2) during the development of the neural retina.

We have now begun to address the role of s-laminin in the neural retina more directly. First, we have implemented an *in vitro* system to ask whether the interaction of precursor cells with s-laminin induces a photoreceptor lineage. When precursor cells are exposed to an s-laminin-rich matrix, many begin to express the photopigment rhodopsin, suggesting that s-laminin may participate in this lineage. Second, we have used *in situ* hybridization histochemistry to ascertain the cellular source of s-laminin in the neural retina, both in adulthood and during development, in order to more precisely define the role of s-laminin in the acquisition and maintenance of an adult phenotype. Finally, we have used s-laminin affinity chromatography to isolate a putative s-laminin receptor. Together, these results provide support for our hypothesis that s-laminin is a component of the process that induces undifferentiated precursor cells to follow a rod photoreceptor lineage.

epi-1 MUTATIONS CAUSE DEFECTS IN BASAL LAMINAE, AXON OUTGROWTH, AND TISSUE DEVELOPMENT IN C. ELEGANS. D.H. Hall and E.M. Hedgecock*. Albert Einstein College of Medicine, Bronx, N.Y. 10461 and Johns Hopkins University, Baltimore, M.D. 21218.

Five mutant alleles of the gene *epi-1* were isolated in the nematode *C. elegans* on the basis of their disruption of gonadogenesis, due to improper epithelialization of the uterus. Molecular and genetic data suggest that *epi-1* may encode a laminin A chain (J. Yochem and I. Greenwald, pers. comm.). The primary defect in *epi-1* appears to involve loss of integrity in the basal laminae. Electron microscopy of *epi-1(rh165)* animals shows that many laminae break down into loose fragments, form multiple stacked sheets, or condense into gobs of extracellular material. In many areas, tissues adhere to neighboring tissues abnormally, for the lack of a basal lamina to keep them separated. The pharynx is surrounded by a distinctly thicker basal lamina which remains intact in *epi-1*. The pharynx is still well formed, resulting in a well fed "monster" with many somatic cell types disoriented and/or malformed. Germ cell development is primitive in *rh165*, while somatic cells achieve adult fates. Milder *epi-1* alleles are fertile, but *rh165* is sterile. Nerve cords and the nerve ring show local mispositions, but most neurites remain in organized fascicles. Synaptic contacts are still common within the nerve ring, but are reduced in number elsewhere as many axons fail to reach appropriate targets. In *C. elegans*, another laminin gene, *unc-6*, is required for guidance of axons along the dorsal/ventral axis (Hedgecock et al., *Neuron*, 2: 65-80, 1990; Ishii, Wadsworth, Stern, Culotti & Hedgecock, pers. comm.). No visible disruptions of the basal laminae are noted in *unc-6*. The defects in axon guidance in *epi-1* do not appear to be global, although local errors in dorsal/ventral guidance and cell position are noted.

87.4

DIFFERENTIATION IN THE SKATE RETINA. WJ Brunken, MD Murphy*, TK Waters* & DD Hunter¹ Boston College and Tufts University¹ Boston Ma

The retina develops along a stereotyped path with a reasonably consistent pattern from species to species. Specifically, ganglion and amacrine cells develop first, followed by neurons of the outer retina including photoreceptors. Retinal progenitors are multipotent and maintain their remarkable plasticity until their last mitosis. Environmental and cell-cell interactions are likely to be critical in guiding the ultimate fate of progenitors. We have identified previously one such factor, s-laminin in the outer retina; here we focus on other factors, transmitters, which may be important in cell induction. Retinal development extends over 4 months in the skate, making it a good system for the study of cell induction.

First, we used BrDU to obtain birthdates of retinal neurons. Neurogenesis begins in the central-most region of the retina and continues as a wave to the retinal margin which lags behind by several weeks. Ganglion and amacrine cells are born first followed closely by photoreceptors and then horizontal and bipolar cells.

Interestingly, unlike other species, there is a long lag in the differentiation of postmitotic cells in this retina. We have used several markers of differentiation: 5HT, TH, GAD, rhodopsin, protein kinase C and GFAP immunoreactivities. Rods are born in stage 3 but do not make rhodopsin until late stage 5 (4 weeks later); of the transmitter markers 5HT appears first in early stage 4; TH in late stage 4, and GAD in late stage 5. Bipolar genesis is late (stage 5) and correlates with the end of ganglion cell death. Maturation of bipolar cells (PKC+) does not occur until stage 6 (hatching). GFAP positive Müller cells are the last to appear. The correlation of bipolar cell birth with the end of ganglion cell death and the early appearance of the biogenic amine transmitters suggests a trophic effect on retinal development while the coincidence of GAD at the end of synaptogenesis suggests that it may be involved in the termination of growth.

NEURONAL MIGRATION ON LAMININ IN VITRO APPEARS TO DEPEND ON NEURITE OUTGROWTH. S. Liang*, J. M. Tew, Jr. and K. A. Crutcher, Department of Neurosurgery, Univ. of Cincinnati, Cincinnati, OH 45267.

Neuronal migration is an important morphogenetic event in the development of the nervous system. Available evidence indicates that migration *in vivo* depends on neuronal/glia cell interactions (Rakic, 1972; Gasser and Hatten, 1990) and extracellular matrix factors such as laminin (Liesi, 1985). We found that laminin, when used as a substrate to culture chick embryonic sympathetic neurons, stimulates migration whereas more adhesive substrates, i.e., poly-L-lysine and poly-ornithine, do not. Time-lapse videomicroscopy demonstrates that neuronal migration on laminin correlates with neurite extension. Translocation of neuronal perikarya occurs in the direction of previously extended neurites or advancing growth cones. Such movement is often accompanied by retraction of trailing neurites. The net result of migration often is the aggregation of perikarya. Although anti-laminin antibodies result in a reduced rate of migration, the primary effect appears to be due to retraction of neurites. In addition, inhibition of neurite extension, through addition of 1,2-dioctanoyl-sn-glycerol (Weeks et al., 1990), delays migration for several hours until neurite formation is resumed. These results indicate that migration of primary neurons *in vitro* is supported by laminin and does not require interaction with other cells. The apparent dependence of neuronal motility on neurite extension *in vitro* suggests that directional migration may normally depend on neurite guidance *in vivo*. Furthermore, the fact that such motility in culture results in aggregation of neuronal perikarya may reflect a mechanism by which ganglion formation occurs *in vivo*.

ADHESION MOLECULES AND THE MIGRATION OF LHRH NEURONS IN THE OLFACTORY NERVE DURING DEVELOPMENT. R. B. Norgren, Jr. and R. Brackenbury. Depts. of Psychiatry and Anatomy and Cell Biology, Univ. Cincinnati Coll. Med., Ohio 45267

Immunocytochemical results suggest that luteinizing hormone-releasing hormone (LHRH) neurons migrate from the olfactory epithelium to the olfactory nerve in several species of mammals [Schwanzel-Fukuda, 1990] and in chicks [Norgren, 1991]. As the migrating LHRH neurons appear to be restricted to the medial half of the olfactory nerve in chicks, we were interested in whether adhesion molecules define the migratory path of the LHRH neurons. Thus far, we have examined the distribution of N-CAM, N-cadherin and fibronectin in the olfactory system of the developing chick. Intense immunostaining for N-CAM was observed in the olfactory epithelium and in an early outgrowth of olfactory nerve of an E4 chick. In addition, a band of anti-N-CAM immunostaining was observed in the most superficial portion of the telencephalon; however, this staining was less intense than that observed in the adjacent olfactory nerve. Although these results indicate high levels of N-CAM immunostaining in portions of the olfactory system, the staining does not appear to be limited to regions where LHRH neurons are observed. Although only a few LHRH neurons are found in the olfactory epithelium of an E4 chick, the entire olfactory epithelium expresses high levels of N-CAM. Similarly, N-cadherin staining was observed in the olfactory nerve, but did not appear to be restricted to the medial half of the nerve. Since N-CAM and N-cadherin staining were found in both the medial and lateral halves of the developing chick olfactory nerve, it seems unlikely that these cell adhesion molecules play a decisive role in the migration of LHRH neurons within the medial half of olfactory nerve although they may play a permissive role. Fibronectin staining was absent in the olfactory epithelium and nerve, but was observed in the surrounding mesenchyme indicating that this extracellular matrix molecule is probably not directly involved in the migration of LHRH neurons. We are currently examining additional cell adhesion and extracellular matrix molecules in the developing chick olfactory system. This work was supported by BRSG S07 RR05408-29 (RBN).

POLYSIALIC ACID ON NEURONAL CELL ADHESION MOLECULES INHIBIT ADHESION AND MIGRATION. A. Harel, J. Silver, U. Rutishauser and D. Roufa. GliaTech, Inc. Beachwood, OH 44122 and Dept. of Neurosciences & Genetics, Case Western Reserve University, Cleveland, OH 44106.

Traumatic injury to adult rat brain results in the formation of a glial-fibroblastic scar. Similar injury to newborn rat brain does not lead to a fibroblast-containing scar (Rudge et al., 1989 Exp. Neurol. 103:1). Brain neuronal cell adhesion molecule (NCAM) undergoes developmentally regulated changes in its polysialic acid (PSA) content. Embryonic brain NCAM contains three-fold more PSA than adult brain NCAM (Rothbard et al., 1982 JBC 257:11064). We examined the effect of NCAM's PSA content on neuronal, glial and fibroblast adhesion and migration. Alternating stripes of laminin (LN) and high PSA NCAM (NCAM-H) or low PSA NCAM (NCAM-L) were blotted onto nitrocellulose coated tissue culture dishes. A cell suspension of either meningeal fibroblasts or astrocytes was added and examined for adhesion to the substratum and migration. Both fibroblasts and astrocytes attached to LN or NCAM-L but not to NCAM-H. Cells did not migrate onto NCAM-H containing stripes for at least 6 days. The effect was dose dependent and fibroblasts were more sensitive than astrocytes to NCAM-H. Treatment of NCAM-H coated plates with neuraminidase resulted in removal of the inhibition. These results demonstrate that the extent of NCAM polysialylation affects cell migration and thus may contribute to the difference in scar formation between adult and embryonic brain.

NEURAL CREST-DERIVED CELLS DO NOT ACQUIRE A NERVE-RELATED LAMININ RECEPTOR UNTIL AFTER THEY MIGRATE INTO THE GUT. V. M. Tennyson, M. J. Howard, H. D. Pomeranz, T. P. Rothman, and M. D. Gershon. Dept. Anat. & Cell Biol., Columbia Univ., P & S, N.Y., NY, 10032.

The enteric nervous system is formed by derivatives of the neural crest. These cells are unable to colonize the terminal gut of the lethal spotted (*ls/ls*) mouse. An excess of laminin accumulates in the mesenchyme of the presumptive aganglionic *ls/ls* bowel; therefore, we have proposed that crest-derived cells in the gut may cease migrating and extend neurites when they encounter laminin. The current experiments were carried out as a partial test of this hypothesis. EM immunocytochemistry revealed that abnormal accumulations of amorphous laminin-immunoreactive material ("puffs") are present in the outer gut mesenchyme of the presumptive aganglionic *ls/ls* bowel by day E14 and enlarge by day E16. In both avian and murine bowel, crest-derived cells within the gut acquire the immunoreactivity of a 110/120 kDa laminin-binding protein (present on the surfaces of ganglia and nerves) that they do not express at earlier stages of migration. Laminin-binding protein immunoreactivity appeared to be expressed by developing neurons just before neurofilament immunoreactivity could be detected. In contrast to controls, no cells become laminin-binding protein-immunoreactive in the terminal colon of the *ls/ls* mouse. Laminin-binding protein was found by EM immunocytochemistry to be a surface protein, which is present on crest-derived cells, and is preferentially located at sites where these cells make contact with puffs of laminin. Results are consistent with the hypothesis that acquisition of a neural laminin receptor by crest-derived cells enables these cells to extend neurites in response to laminin. The absence of this receptor on crest-derived cells prior to their arrival at their site of terminal differentiation may enable them to migrate through laminin-containing regions of the embryonic mesenchyme without responding prematurely as neurons. Supported by NIH grants HD 17736, NS 15547, and HD 21032.

DEVELOPMENT & ULTRASTRUCTURE OF PURKINJE NEURONS IN DISSOCIATED CELL CULTURES. M.E. Dunn, K. Schilling, J.J. Morgan, & E. Mugnaini. Neuromorphology Lab, UConn, Storrs, CT 06269 & Neuroscience Dept., R.I.M.B., Nutley, NJ 07110.

Purkinje neurons (PCs) grown in culture undergo plastic changes when grown under conditions known to inhibit electrical activity. The present study was conducted to elucidate the fine structure and synaptic organization of PCs developing in electrically active cultures. Cerebellar cells obtained from E15 mouse embryos were grown in culture for up to 3 weeks before they were fixed and embedded for electron microscopy. Identification of PCs was obtained with antisera to L7, Calbindin, PEP-19, and Parvalbumin. PCs were distinctly immunostained at 1 week, but obtained their most characteristic morphological features at 2 and 3 weeks. At 2 weeks, PC bodies were uniquely covered with somatic spines which contained microfilaments and formed synaptic junctions with boutons. At 3 weeks, spines were mostly present on terminal branches of large dendrites. A large dendritic stem often gave rise to the axonal process after ceasing to emanate spines. This neurite formed boutons with a dense axoplasm and pleomorphic vesicles. The large cell bodies contained an organelle rich cytoplasm, including an extensive hypolemmal cisterna. Subsurface cisterns with a narrow lumen were not present in PCs at 3 weeks, although they were found in other large neurons provided with numerous axosomatic synapses and interpreted as deep nuclear neurons. Stellate and granule neurons were also identified in these cultures by immunocytochemical and morphological criteria. In conclusion, most of the ultrastructural features of PCs and other cerebellar neurons in vivo are reproduced in dissociated cultures despite the absence of a layered organization. Supported by NIH grant NS-09904 & DFG grant SCH1271/2-2.

87.10

LAMININ AND MEROSIN PROMOTE NEURONAL MIGRATION, BUT ARE ANTI-ADHESIVE. A. L. Calof¹ and A. D. Lander². ¹Dept. of Biology, University of Iowa, Iowa City, IA 52242 and ²Dept. of Brain and Cognitive Sciences, Mass. Institute of Technology, Cambridge, MA 02139.

We have used cultures of a proliferative neuroepithelium, the olfactory epithelium (OE) of the embryonic mouse, as a model system for studying how molecules of the extracellular matrix (ECM) regulate migration, motility and adhesion of central nervous system neurons and their progenitors. Neuronal cells of the OE, which undergo extensive migration during normal development were shown to be highly migratory in culture as well. Migration of OE neuronal cells was found to depend strongly on substratum-bound ECM molecules, being specifically stimulated and guided by laminin (or the laminin-related molecule merosin) in preference to fibronectin, type I collagen, or type IV collagen. Motility of OE neuronal cells, examined by time lapse video microscopy, was high on laminin-containing substrata, but negligible on fibronectin substrata. Interestingly, quantitative assays of adhesion of OE neuronal cells to substrata treated with different ECM molecules demonstrated no correlation, either positive or negative, between migratory preferences of these cells and the strength of cell-substratum adhesion. Furthermore, experiments in which cell-substratum adhesion was measured on substrata containing combinations of ECM proteins uncovered the finding that laminin and merosin are anti-adhesive for OE neuronal cells, i.e. cause these cells to adhere poorly to substrata that would otherwise be strongly adhesive. Evidence was obtained that this anti-adhesive effect is due to a direct cellular response to laminin, which alters the way in which neuronal cells respond to adhesive molecules, rather than to an interaction of laminin with other ECM molecules. In further support of this idea, laminin was found to inhibit the formation of focal contacts by OE neuronal cells. Experiments to identify the site(s) on laminin responsible for stimulating motility and mediating anti-adhesivity are in progress. Supported by a grant from the Whitaker Health Sciences Fund.

AN IN VITRO MODEL OF OLFACTORY RECEPTOR NEURON DEGENERATION AND DIFFERENTIATION. S.K. Pixley. Dept. Anat. & Cell Biol., Univ. of Cincinnati Coll. Med., Cincinnati, OH 45267.

Previous work *in vivo* shows that if connection with the olfactory bulb is lost, olfactory receptor neurons (ORNs) degenerate, then are replaced by division and differentiation of neuronal stem cells. Differentiation is marked by expression of the olfactory marker protein (OMP), detected by immunostaining.

We show that, in dissociated cell cultures of newborn Sprague-Dawley rat nasal mucosal tissues, OMP+ neurons were present at 1-3 days after plating, but not at 4, 10 and 15 days post-plating. Non-OMP+ neurons were present throughout. If nasal cells were plated onto non-neuronal cells from the olfactory bulb, OMP+ cells were present at 1-3 days and absent at 4 and 10 days post-plating. Surprisingly, at 15 days post-plating, numerous OMP+ cells appeared in the co-cultures. Also present at 15 days were sustentacular cells (SUS-1+) and dark basal cells (keratin+). OMP+ neurons had a typical ORN morphology. Immunostained cells were found in large, multi-cellular clumps that often had fluid-filled cavities. We are investigating bulb-specificity and whether neurogenesis is involved. This *in vitro* system models *in situ* neuronal differentiation. (Grant support: Amer. Paralysis Assoc. #PB1-8803-1; NIH P01-DC00347-06).

MIGRATORY MECHANISMS OF GRAFTED FETAL ASTROCYTES. J.J. Bernstein, G. Tadvalkar and W. Goldberg. Lab. CNS Inj. Regen., DVA Med. Ctr. Wash., DC 20422 & Depts. Neurosurg. Physiol. George Wash. Univ. Sch. Med. Wash., DC 20037.

Fetal astrocytes grafted into lesioned adult host spinal cord migrate centimeters from the site of implantation. Fourteen day gestation purified, cultured rat spinal cord fetal astrocytes (E14) were incubated with rhodamine labeled microbeads, grafted in aspiration pockets in the fasciculus gracilis (FG) of the third cervical spinal segment (C3) of adult rats and followed for 7 days. The cells migrated approximately 5.2 mm/7 days and were observed rostrally in C1FG. The fetal astrocytes also migrated caudally, laterally and ventrally into the FG, fasciculus cuneatus, and the dorsal, lateral and ventral horns of the spinal cord. In an *in vitro* model, 10⁵ cultured E14 fetal spinal cord astrocytes were seeded on wafers of hydrated collagen I. The fetal astrocytes migrated through the wafer and digested the collagen I fibrils. Immunohistochemistry revealed that the astrocytes contained plasminogen activators (tissue, tPA, and urokinase, uPA) which result in thrombolysis and cell digestion. The fetal astrocytes also contained guanidinobenzoate (GB), a serine protease, associated with tumor metastasis and migration. GB cleaves the cells attachment to fibronectin and releases the cell from the substrate to allow for migration. These characteristics of fetal astrocytes were part of the molecular mechanisms for migration of these cells during development and after neural grafting into mature CNS.

GNRH CELLS IN THE HYPOGONADAL MOUSE FORM FUNCTIONAL CONNECTIONS DESPITE THEIR BIOSYNTHETIC DEFICIENCY. J. Livne, M. J. Gibson, and A. J. Silverman. Dept. of Medicine, Mt. Sinai Sch. of Med., New York, N. Y. 10029 & Dept. of Anat. & Cell Biol., Columbia Univ., New York, N. Y. 10032

The hypogonadal (hpg) mouse has an undeveloped reproductive tract due to a truncated GnRH gene, resulting in failure to synthesize GnRH. Cells in the OVL1 region of the hpg brain have low levels of GnRH mRNA but are devoid of the neuropeptide. The normal distribution of GnRH transcribing cells suggests that in spite of their failure to synthesize the peptide, GnRH cells migrate properly to their residence areas in the CNS. To elucidate the extent of differentiation of the mutant GnRH cells we have performed an *in situ* hybridization study in mice which were given injections of the fluorescent tracer Fluoro-Gold (FG). Only cells terminating on fenestrated capillaries, such as those of the hypophysial portal system in the median eminence (ME), can capture and concentrate systemically delivered FG. We have therefore hypothesized that the finding of FG in cells containing GnRH mRNA, will indicate that GnRH cells in the hpg brain are capable of innervating their proper target. The experimental procedure for detection of GnRH mRNA and FG in the same cell was performed as follows: Normal and hpg adult males were given 3 i.p. injections of 40 mg/Kg FG and perfused. Sections through the septal-POA-AHA extent were processed for standard *in situ* hybridization with [³⁵S] labeled oligonucleotide complementary to the GnRH coding region. The slides were analyzed to identify GnRH transcribing cells which accumulate FG. In brain sections from 2 hpg males 54.5% and 64% of the GnRH transcribing cells were double labeled with FG, while in 1 normal brain 61.2% were double labeled. We have demonstrated that GnRH transcribing cells in the hpg brain concentrate FG. This finding suggests that mutant GnRH cells are capable of elaborating functional connections with their major target, the ME, in the absence of their principal secretory product. NS 20335

VOLTAGE-DEPENDENT CALCIUM CHANNELS (VDCCs) AFFECT NEURON MIGRATION: A LASER MICROSCOPIC STUDY IN CEREBELLAR SLICE PREPARATIONS. H. Komuro and P. Rakic, Section of Neurobiology, Yale University School of Medicine, New Haven, CT 06510

Molecular and cellular mechanisms underlying neuronal migration are not well understood. In the present study we have examined the effects of various blockers of voltage-sensitive channels on the movement of postmitotic cells in brain slice preparations. Slices 400 to 800 μ m in thickness were dissected from the cerebellum of 7-14-day-old mice, stained for 30 min in 25 μ g/ml solution of carboxyanin dye (DiI) and maintained in a CO₂ incubator for 2 hrs in MEM. The migration of postmitotic cells was followed for several additional hours using a laser scanning confocal microscope and positions of their leading tips recorded every 10 min on a attached color video printer. In the control slices, granule cells migrated along Bergmann glial fibers at the rate of 10-20 μ m/h over a distance of up to 100 μ m, some of them reaching Purkinje cell layer within 6 hours, which is comparable to the rate *in vivo*. However, the addition of L or N type blockers of VDCCs to the slice medium (e.g. ω -conotoxin or Cd⁺⁺) suspended migration. In contrast, blocking of L subtype of VDCCs by nifedipine or a sodium channel by tetrodotoxin did not affect the movement, suggesting that N type of VDCC's may be essential for proper neuronal migration.

Supported by NIH grant NS22807

EVIDENCE FOR RAPID MIGRATION OF NEWLY BORN CELLS IN THE ADULT RAT DENTATE GYRUS. H.A. Cameron, E. Gould, D.C. Daniels* and B.S. McEwen Lab. of Neuroendocrinology, Rockefeller Univ. N.Y., N.Y. 10021

Unlike the majority of neuronal populations which undergo neurogenesis during a discrete developmental period, granule cells continue to be added to the rat dentate gyrus for at least 1 year postnatally (Kaplan, M.S. and Bell, D.H. 1984. J. Neurosci. 4:1429-41). Although the birth of new granule cells in the adult dentate gyrus has been well established, it is presently unknown whether these cells undergo local cell division or migrate shortly after birth. Adult (6 mos) female rats were injected with ³H-thymidine (5.0 μ Ci/gm body wt.) and perfused either 1, 6, or 24 hours after injection. The tissue was processed for autoradiography and counterstained with cresyl violet. Light microscopic examination of ³H-thymidine labelled tissue from each time point revealed labelled cells of varying morphologies; some cells appeared to be glia (irregularly shaped small cell bodies) whereas others showed characteristics of granule cells (round or oval medium cell bodies). With time, the proportion of ³H-thymidine labelled cells in the hilus steadily diminished while that of ³H-thymidine labelled cells in the granule cell layer increased. These results provide evidence that newly born cells in the dentate gyrus migrate from the hilus to the granule cell layer within 24 hours of DNA synthesis. Combined immunohistochemical and autoradiographic studies to determine when these newly born cells express neuronal/glia specific markers (glial fibrillary acidic protein, vimentin / neuron specific enolase, neurofilaments) are ongoing.

NORADRENERGIC INNERVATION OF THE REGENERATED RAT CEREBELLUM AFTER POSTNATAL X-IRRADIATION. P.E. Kunkler*, and W.J. Anderson. Department of Life Sciences, Indiana State University, Terre Haute, IN. 47809

In previous studies, our laboratory indicated that fractionated x-irradiation in rat pups begun at postnatal day 1 (PN1) through PN5 resulted in an alteration in the number and distribution of noradrenergic fibers throughout the molecular layer and the regenerated external granular layer (EGL). The present study was performed to determine the timing sequence of the alterations and to identify which if any cell types were the target of the noradrenergic fibers. Long Evans hooded rats were bred, and at birth were assigned to six conditions: x-irradiated at postnatal day 1 with 1 to 5 daily doses (150r each) and control animals for each age group. Rat pups were sacrificed at daily intervals after x-irradiation and at 10, 21 and 30 days of age. All animals were prepared for either routine histology or immunohistochemical staining. In the x-irradiated groups, sacrificed at 24 hr after the last treatment, numerous noradrenergic fibers were present throughout the regenerated EGL. At 10 days of age the expanding molecular layer had numerous fibers within its deep portion with some continuing up to the EGL. The fibers of the higher x-irradiated animals (5X) tend to run in a longitudinal plane within the developing cerebellum, while control and low dose x-irradiation fibers projected radially in the molecular layer in the sagittal plane. The fiber projections were reminiscent of the Bergmann glia radial projections. At longer survival times the fibers were associated with ectopic cells within the molecular layer. Occasional ectopic cell nest were seen with a dense plexus of noradrenergic processes scattered within. This suggests that the noradrenergic fibers may play a role in the formation of ectopic cells and that x-irradiation may alter the directional orientation of the these fibers.

CELL-SPECIFIC SORTING IN THE SUBVENTRICULAR AND INTERMEDIATE ZONES OF THE EMBRYONIC RAT NEOCORTEX. S.A. Bayer and J. Altman. Indiana-Purdue University, Indianapolis, IN 46205 and Purdue University, West Lafayette, IN 47907.

The embryonic rat neocortex was studied at daily intervals after the dams were given a single injection of tritiated thymidine (5 μ Ci/gram body wt.). Within 24 hrs after injection, bands of heavily labeled cells are seen in the intermediate zone (superior bands, sb) and in the subventricular zone (inferior bands, ib). Three of the bands are postulated to be composed of cortical neurons because their appearance and disappearance can be correlated with the known timetables of neurogenesis of layers VI-II. Layer VI neurons sojourn in the early-appearing sb1 just below the cortical plate, layer V neurons appear next in sb2 in the lower intermediate zone, then layers IV, III, and II neurons sojourn successively in ib1 in the lower subventricular zone. Two bands, sb3 and ib2 cannot be linked to any neuronal population and are postulated to contain glia. These data suggest that neurons destined for cortical layers VI-II, interrupt their migration to the cortical plate to accumulate in cell-specific bands, or sojourn zones. The subventricular and intermediate zones may be considered as "staging areas" for different classes of neocortical neurons. (Support: NIH Grants NS27613 and NS23713)

ANTI-ASTROTACTIN ANTIBODIES DISRUPT THE CYTOSKELETAL ORGANIZATION OF MIGRATING GRANULE NEURONS. G. Fishell and M.E. Hatten. Dept. of Pathology and Center for Neurobiology, College of Physicians and Surgeons, Columbia University, 10032.

During CNS development, neurons migrate from proliferative zones to specific cortical laminae along radial glial processes. *In vitro* studies indicate that migrating neurons form a specialized adhesion site, 'the interstitial junction', between the neuronal cell soma and the glial fiber. The neural glycoprotein astrotactin provides one neural component of these specialized neuron-glia adhesions. The observation that fine cytoskeletal elements project into the 'interstitial junction' suggested that astrotactin may provide a link between the site of neuron-glia adhesion and the cytoskeleton of migrating neurons (Gregory et al, 1988). To examine this possibility, neurons were treated with 1.0 mg/ml of anti-astrotactin antibodies and examined by correlated video and electron microscopy. For comparison, in separate experiments neurons were treated with 1.0 mg/ml anti-NCAM antibodies. Video microscopy provided evidence that, in the presence of anti-astrotactin antibodies, neurons ceased migration and adopted a posture characteristic of stationary neurons. Correlated electron microscopic analysis revealed a disorganization of cytoskeletal elements into tangles of filaments in the area rostral to the neuronal nucleus. In contrast, neurons treated with antibodies against NCAM were indistinguishable from untreated cultures. These observations raise the possibility that astrotactin, as well as mediating adhesion to the glia fiber on the cell surface, provides a linkage to the neuronal cytoskeleton on the cytoplasmic side.

88.7

ROLE OF THE CYTOSKELETON IN GLIAL-GUIDED NEURONAL MIGRATION. R.J. Rivas,*G. Fishell, and M.E. Hatten. Department of Pathology and Center for Neurobiology and Behavior, Columbia University, New York, NY 10032.

Glial-guided neuronal migration is a critical step in the development of cortical regions of the mammalian brain, ushering young neurons from proliferative zones to the positions where they establish synaptic connections. To study cytoskeletal involvement in neuronal migration, migrating granule neurons in microcultures prepared from early postnatal cerebellum were analyzed by confocal microscopy. Optical sectioning (0.6 μ m steps) through the neuronal cell body and leading process of fixed neurons with migration "profiles" shows a morphology highly polarized in the direction of migration. Indirect immunofluorescence with tubulin antibody revealed a cage-like network of microtubules which are concentrated in the rostral portion of the cell body and extend into the leading process. Mitochondrial (DiOC6(3)) and Golgi staining (rhodamine wheat germ agglutinin) showed that these microtubule-associated organelles are also concentrated in the rostral portion of the cell body. Staining for actin with rhodamine phalloidin revealed bright fluorescence which appeared associated with the cell body plasma membrane. Current experiments are directed towards understanding the relationship of the neuron-glial adhesion molecule, astrotactin, to the cytoskeleton.

PATTERNS OF SYMPATHETIC PREGANGLIONIC NEURONAL MIGRATION IN SPINAL CORD OF EMBRYONIC RATS. J.A. Markham and J.E. Vaughn. Div. of Neurosciences, Beckman Res. Inst. of the City of Hope, Duarte, CA 91010.

Preganglionic neurons were retrogradely labeled by microinjections of HRP into the sympathetic chain ganglia of rats on embryonic days 13-16 (E13-16). Observations at E13 $\frac{1}{2}$ indicated that preganglionic and somatic motor neurons were initially intermixed in the primitive motor column of the ventral thoracic spinal cord. However, by E14, preganglionic motor neurons were segregated dorsolaterally from somatic motor cells. On E15, the two subclasses of motor cells were located in separate columns with the preganglionic cells being positioned more dorsally than the somatic motor neurons. In addition, by E15, the alignment of the dorsal-most preganglionic cells had changed from a dorsoventral to a predominantly mediolateral orientation. By E16, the preganglionic autonomic motor column was located well within the intermediate gray matter, and a number of its constituent cells were found in increasingly more medial positions. These results, in conjunction with previous observations, suggest that the migration of preganglionic neurons in the embryonic rat spinal cord can be divided into three distinct phases: a primary movement from the ventricular zone to form a single primitive motor column together with somatic motor neurons; a secondary dorsal translocation of the preganglionic neurons resulting in the formation of separate autonomic and somatic motor columns; and a tertiary medial movement of certain preganglionic cells giving rise to the medially-located autonomic nuclei. Spatiotemporal considerations suggest that different migratory pathways may be utilized during these phases. Examples of substrates that may form the different routes are radial glia, early forming fiber pathways and medially-directed dendrites of other preganglionic neurons (see companion presentation by Phelps *et al.*) Supported by grants NS25784 and NS18858 from NINDS.

PREGANGLIONIC NEURONS EXHIBIT NORMAL MIGRATION PATTERNS IN CULTURED SLICES OF EMBRYONIC RAT SPINAL CORD. R.P. Barber, J.A. Markham, P.E. Phelps and J.E. Vaughn. Division of Neurosciences, Beckman Research Institute of the City of Hope, Duarte, CA 91010.

The use of organotypic cultures of CNS slices as a tool for studying developmental phenomena has gained prominence with the development of better culturing techniques and materials. Using a modification of this preparation, we have shown that spinal cord slices from embryonic day 14 (E14) rats grown *in vitro* on a rocker table contain neurons that express ChAT, GAD or neurofilaments for 3 wk in culture. It is known that at E14 *in vivo* there is only a single primitive column of mixed motor neurons (autonomic and somatic) in the ventral thoracic spinal cord. By E15, there is a dorsal translocation of autonomic neurons into the intermediate gray matter, and by E17, the separation of autonomic and somatic neurons is complete. This is followed by a medial translocation of some preganglionic neurons to form the medially-located autonomic nuclei. To determine if these translocations occur *in vitro*, the ventral roots and autonomic chain ganglia of E14 embryos were injected with a fluorescent tracer before sectioning and explanting the spinal cord slices. After 72 h in culture, there was a substantial dorsal translocation of cells into the intermediolateral cell column, as well as a medial migration of some preganglionic neurons. Thus, the migration of preganglionic motor neurons appears to occur *in vitro* in much the same pattern as it does *in vivo*. These preliminary results pave the way for future experimental studies of migratory pathways *in vitro* to explore the substrates that are necessary for these translocations to occur. Supported by grants NS25784 and NS18858 from NINDS and funds from the Sadie and Norman Lee Endowment.

MIGRATION OF THORACIC PREGANGLIONIC NEURONS IN THE CHICK AND RAT. C.J. Forehand and E.B. Ezerman. Dept. of Anat. and Neurobiol., Univ. of Vermont, Burlington, VT 05405.

Motor neurons project axons through the ventral root while their somata are migrating from the ventricular zone to the motor columns (Farel & Bemelmans, *Neurosci. Lett.* 18:133, '80). Rat and chick thoracic preganglionic axons also project axons peripherally while their somata are migrating; we have taken advantage of this phenomenon to study the migration of these neurons in the spinal cord.

An *in vitro* labeling paradigm was utilized to study the migration of thoracic preganglionic neurons in 4-10 day (D4-D10) chicken embryos and 13-17 day (E13-E17) rat embryos. Neurons were retrogradely labeled from the sympathetic chain with fluorescently-tagged dextran amines in living *in vitro* preparations of the thoracic body wall, spinal column, and sympathetic chain.

Preganglionic neurons that project to the chain at early time points (D4/1/2-5 in the chick, E13/1/2-15 in the rat) appear to arise from the ventral aspect of the ventricular zone and migrate first laterally and then dorsally. In the chick, this lateral migration is extremely limited; the dorsal migration begins just as the neurons leave the ventricular zone. In the rat, these early neurons migrate first to the lateral edge of the cord, and then dorsally. Preganglionic neurons that project to the chain at later time points (D6-7 in the chick, E16-17 in the rat) appear to arise from a more dorsal region of the ventricular zone and migrate laterally at their appropriate dorsoventral level. At D4 in the chick and E13 in the rat, there is no indication of a ramus projecting to the presumptive area of the sympathetic chain. Also at these times, none of the neurons retrogradely labeled from the ventral root are found outside of the lateral motor column. Thus the dorsal migration of these cells may be signalled by the periphery once the axons enter the chain.

SUBSTRATES UNDERLYING THE MIGRATORY PATTERNS OF SYMPATHETIC PREGANGLIONIC NEURONS IN EMBRYONIC RAT SPINAL CORD. P.E. Phelps, R.P. Barber, and J.E. Vaughn. Div. of Neurosciences, Beckman Research Inst. of the City of Hope, Duarte, CA 91010.

Previous results indicate that precursors of preganglionic neurons follow a circuitous route in achieving their final spinal cord locations. For certain preganglionic cells, this can involve both a secondary dorsal and a tertiary medial translocation (see Markham and Vaughn, companion presentation). Since the substrates these cells use for their translocations are not known, we initiated the following two studies. To investigate possible dorsal migration pathways, ChAT-immunocytochemical preparations of thoracic spinal cord were double-labeled with TAG-1/SNAP (from M.Yamamoto) to examine relations between preganglionic neurons and axons of early-forming association cells. On E14, TAG-1 positive fibers were detected just dorsal to the primitive motor column, and by E15.5, such elements were directly apposed to the lateral border of preganglionic neurons, suggesting that they could provide a dorsal migration route. To initiate studies of possible medial migration pathways, ChAT-immunocytochemical preparations of upper lumbar cord were selected because medially-located preganglionic cells, or central autonomic neurons, are most numerous at this spinal level. These studies revealed that the tertiary medial translocation of preganglionic neurons began by E15.5, and that many of these neurons are located medially by E18. Since some preganglionic neurons appear to migrate medially, they probably utilize a radially-oriented migratory pathway. Current investigations are focused on whether radial glial cells or, alternately, transverse dendritic bundles of early-forming lateral preganglionic neurons might provide such a substrate for the medial translocation of the neurons that come to reside in the central autonomic region. Supported by NS25784 and NS18858.

A GOLGI STUDY OF DEVELOPING GLIAL CELLS IN THE RABBIT LUMBAR SPINAL CORD. S.A. Scoville*¹, D.E. Scott² and F.J. Liuzzi³ Departments of Neurosurgery^{1,2,3} and Anatomy and Neurobiology^{2,3} Eastern Virginia Med. Sch., Norfolk, Va 23501

Spinal cords from embryonic rabbits ranging from E22-E31, early post-natal and adults were processed using a modified rapid Golgi procedure of Del Rio Hortega. The development of one glial type was traced from E22, at which time its soma was either bordering on, or oriented towards the central canal with one primary radial process extending toward the pial surface. This cell type appeared to migrate away from the central canal and by E26 some of these cells appeared to transform within the developing gray matter into stellate cells without radial processes. These cells exhibited increasing complexity and attained an adult-like morphology by PN 2. Other developing glial cells have been identified and characterized. These include white matter astrocytes, both stellate and radial, as well as tanyocytes. In addition, the developmental relationships of glial cells with the vasculature and myelination were examined.

This work was supported in part by research funds from the Department of Neurosurgery, EVMS.

INHIBITION OF NEURAL CREST CELL MIGRATION BY THE MESENCHYME OF PRESUMPTIVE AGANGLIONIC SEGMENTS OF MUTANT GUT T. P. Rothman and M. D. Gershon. Dept. Anat. & Cell Biol., Columbia U., P & S, NY, NY 10032.

The terminal bowel of the lethal spotted (*ls/ls*) mouse becomes aganglionic because the presumptive aganglionic tissue is not colonized by viable neural or glial precursors. Crest-derived cells of *ls/ls* animals are able to colonize control segments of bowel *in vitro*, but no source of crest-derived cells is able to colonize the last 2 mm of *ls/ls* colon. Collagen type IV, laminin, and hyaluronic acid accumulate in the mesenchyme of the abnormal *ls/ls* gut. The current experiments were carried out to test 2 hypotheses: (i) that crest-derived cells enter the presumptive aganglionic *ls/ls* bowel, but die; (ii) that crest-derived cells fail to colonize abnormal *ls/ls* gut because pathways that lead these cells from the crest to bowel are defective. Crest-derived cells leave segments of gut and re-migrate in host embryos when bowel that has already been colonized is back-transplanted into a crest migration pathway. Segments of duodenum or terminal colon were dissected from control or *ls/ls* embryos (E13-14) and back-grafted between the neural tube and somites of quail embryos (E2; adjacent to somites 8-24). Host cells were distinguished from mouse cells by demonstrating the quail nuclear marker and NC-1 immunoreactivity was used as a crest marker. No murine cells migrated out of presumptive aganglionic *ls/ls* gut to reach neural structures in host embryos. Quail crest-derived cells entered control segments of bowel. In contrast, the grafts of presumptive aganglionic *ls/ls* tissue could not be colonized by crest-derived cells of host origin, and often appeared to obstruct their migration. It is concluded that crest-derived cells cannot be liberated by back-transplantation from presumptive aganglionic *ls/ls* bowel, and that this tissue cannot be colonized by crest-derived cells, even when it is placed in a crest cell migration pathway. The results indicate that aganglionosis arises in *ls/ls* mice because an inherent abnormality of non-neuronal elements of the bowel wall inhibit migration of crest-derived cells. Supported by HD 21032, HD 20470, and NS15547.

MYOTOMAL CELLS PLAY A ROLE IN GUIDING THE MIGRATION OF THE LATERAL LINE PRIMORDIUM IN ZEBRAFISH. W.K. Metcalfe and J.T. Graveline*. Institute of Neuroscience, U. of Oregon, Eugene, OR 97403.

We are interested in learning how cells migrate along precise pathways during embryonic development. We have chosen the developing lateral line of zebrafish to study this question because it is a simple system in which a dramatic cell migration takes place within the skin of the embryo. The sensory organs of the zebrafish midbody lateral line are derived from a primordium that migrates along a stereotyped pathway within the skin. The pattern of the lateral line sensory organs, as well as the path of the peripheral sensory nerve, are determined by the path of migration of this primordium, but what guides the primordium?

We observe that the lateral line primordium fails to migrate along the trunk of embryos homozygous for the *spadetail* mutation. In these embryos, trunk myotomes are malformed, suggesting that myotomal patterning may play a role in directing the migration of the primordial cells. To test this idea, we caused focal disruptions of a few trunk myotomes prior to the onset of primordium migration either by heat shock during myotome formation, or by laser ablation of early myotomal cells. Both of these manipulations resulted in local disruptions of the path of migration of the primordium. Thus, although the primordium migrates within the skin, its migration pathway appears to be dependent upon some feature of the underlying myotomes. Supported by NIH grant NS27122.

PROCESS OUTGROWTH, GROWTH CONES AND SPROUTING II

EFFECT OF SERUM OR INTEGRIN RECEPTOR BLOCKADE ON NEURITIC OUTGROWTH FROM ADULT AND EMBRYONIC MOUSE RETINAL EXPLANTS ON LAMININ. C.A. Bates and R.L. Meyer. Developmental Biology Center, UC Irvine, Irvine, CA 92717.

Laminin is an excellent substrate for the outgrowth of adult rodent optic neurites in culture, but it has been reported that laminin is ineffective in promoting neuritic outgrowth from embryonic retinal explants. One possibility is that serum in the media interferes with neurite extension on laminin in the embryonic retinal explant. To test this, we cultured adult and embryonic (E15) mouse retinal explants on laminin coated coverslips in serum containing and serum free media. Adult explants showed similar levels of neuritic outgrowth in serum and serum free media. In contrast, the E15 explants grew extensive haloes of neurites within 24 hours in serum free media and showed little or no neuritic outgrowth in media with serum. We then looked for differences in the laminin receptors in adult and E15 explants. Explants were cultured in media containing GPI40 (C. Damsky), an antibody which blocks the laminin binding integrin B1/B3 subunit. GPI40 had little effect on the outgrowth of neurites from adult explants. In contrast, it completely blocked the extensive neuritic outgrowth from E15 explants for at least 5 days in culture. This demonstrates that embryonic optic neurites do respond positively to laminin in the absence of serum and suggests that the positive response of adult neurites to laminin may involve receptors other than the B1/B3 integrin subunits. Supported by NS26750 (RLM) & HD07029 (CAB).

MATURATION OF EMBRYONIC AVIAN RETINAL GANGLION CELLS IN VITRO. N. Morissette* and S. Carbonetto. Center for Research in Neuroscience, Montreal General Hospital Research Institute and McGill University, Montreal, Quebec, Canada H3G 1A4.

Integrins are a superfamily of adhesive molecules several of which mediate neurite growth *in vitro* and nerve regeneration *in vivo*. Integrin function in chick retinal ganglion cells (RGCs) is down-regulated between embryonic days 6 and 12. To help study this regulation, we undertook to establish an *in vitro* system in which changes in integrin function parallel those *in vivo*. Primary cultures of neural retinal cells were grown on laminin substrates and neurite outgrowth of RGCs was assessed. Secondary cultures were prepared by replating primary cultures on laminin substrates. Preliminary data indicate that early (5-7 days) embryonic chick RGCs will lose their laminin integrin function following maturation in primary retinal cultures and that their neurite outgrowth in secondary retinal cultures is similar to that of RGCs allowed to mature to the same absolute age *in ovo*. Similar to RGCs in primary cultures, chick RGCs which mature *in vitro* remain capable of extensive neurite outgrowth on rat astrocytes suggesting that non-integrin receptor activities on their surfaces (e.g. N-cadherin) are intact. This avian retinal system could prove to be useful in studies of integrin regulation that would be difficult to accomplish *in vivo*.

Molecular Cloning of the Rat Integrin alpha1- Subunit: A Receptor for Laminin and Collagen. M.I. Ignatius¹, T.H. Large¹, M. Houde², J.W. Tawil², A. Barton¹, S. Carbonetto², and L.F. Reichardt¹, 1Dept. of Physiology and HHMI, UCSF, San Francisco, CA 94143; 2Neurosciences Unit, McGill University, Montreal General Hospital; 1650 Cedar Avenue, Montreal, Quebec Canada H3G 1A4

Integrin heterodimers mediate a variety of adhesive interactions, including neuronal attachment to and process outgrowth on laminin. We report here the cloning and primary sequence of an Mr200k integrin alpha subunit that associates with the integrin beta 1 subunit to form a receptor for both laminin and collagen. Similarities in ligand-binding specificity, Mr, N-terminal and internal sequence make this a strong candidate for the rat homologue of the human VLA-1 integrin alpha subunit. The full length rat alpha 1 cDNAs encode a protein containing a putative signal sequence and a mature polypeptide of 1152 amino acids, with extracellular, transmembrane and cytoplasmic domains. Several structural features are conserved with other integrin alpha chains, including (a) a sequence motif repeated seven times in the N-terminal half; (b) potential divalent cation binding sites in repeats 5, 6 and 7, and (c) alignment of at least 15 of 23 cysteine residues. This rat alpha 1 sequence also contains a 200 amino acid 1 domain, inserted between repeats 2 and 3, that is homologous to 1 domains found in the same position of other integrin subunits (alpha 2, Mac-1, LFA-1, GP150). The rat integrin alpha 1 subunit has several unique features, though, including a 38 residue insert between two Ca²⁺/Mg²⁺ binding domains that contains 4 cysteines and a potentially novel protease cleavage site, that can account for unique functions of this integrin.

LOCALIZATION AND CHARACTERIZATION OF 110 KD LAMININ BINDING PROTEIN IMMUNOREACTIVITY IN ADULT AND LESIONED BRAIN. M. Jucker, H.K. Kleinman, L.C. Walker, P. Bialobok*, L.R. Williams, D.K. Ingram. Gerontology Res. Ctr., NIA, NIH, Baltimore, MD 21224; NIDR, NIH, Bethesda, MD 20892; Neuropathol. Lab, J. Hopkins U., Baltimore, MD 21205; Fisons Corp., Rochester, NY 14624; Upjohn Co., Kalamazoo, MI 49001.

A 110 kD laminin-binding protein (110 kD LBP) isolated from newborn mouse brain extract has been identified. This protein recognizes a neurite-outgrowth promoting 19-amino acid synthetic peptide (PA22-2) derived from the laminin A chain (Kleinman et al., submitted). Antibody to 110 kD LBP strongly immunostains fibers and distinct cell populations in adult rat forebrain, in particular cortical pyramidal neurons with apical dendrites and hippocampal mossy fibers (Jucker et al., *Brain Res.*, in press). Similar immunoreactivity was found in newborn rats, adult mice, and adult nonhuman primates. Preliminary ultrastructural analysis of rat cortical pyramidal neurons revealed intracellular staining. Dual immunolabelling demonstrated colocalization of laminin-like (monoclonal 2E8 anti-laminin, gift of E. Engvall) and 110 kD LBP-like immunoreactivity in cortical pyramidal neurons. Western blot analysis of Triton soluble rat brain extract under reducing conditions revealed bands at 110 and 100 kD. However, using the pellet fraction, antibody recognized a dominant 140-150 kD band. Fimbria-fornix transection, stab wound and ischemia in rat induced intense 110 kD LBP-like immunostain of reactive glial cells. Ongoing time-course analysis revealed immunopositive reactive glial cells as early as 2 days after injury which persisted as long as 64 days. In rats subjected to transient ischemia by means of 4-vessel occlusion, the 110 kD LBP-positive glial cells in early postischemic periods served as a predictor for regions with permanent neuron loss. Distinct localization of the immunostain in adult and lesioned forebrain suggests that 110 kD LBP-like molecules might have an important function in brain and may be involved in the CNS response to injury.

INTERACTIONS OF SYMPATHETIC NEURONS WITH LAMININ DOMAINS. L. C. Plantefaber and A. D. Lander, Dept. of Brain and Cognitive Science, MIT, Cambridge, MA 02139

The interactions of neurons with laminin (LN) are believed to be mediated by multiple LN domains and to utilize several types of receptors. To assess the roles of LN domains, we are taking the following approaches: We are comparing the adhesive and neurite outgrowth activities of LN with merosin (MN), a LN variant that contains an M-chain in place of the LN A-chain. We are also testing the functions of isolated domains using proteolytic fragments of LN (E1', E3, E4, E8), a recombinant fragment containing the C-terminal 863-amino acid globular domain (G), and two 16-amino acid peptides, one containing the IKVAV A-chain sequence (present in E8, and proposed to represent a binding site), and the other representing the homologous region of the MN M-chain. The results indicate that MN supports greater adhesion and neurite outgrowth by chick sympathetic neurons than LN. In contrast, MN and LN were found to be equally adhesive for a fibroblast line, suggesting that binding sites recognized by neurons in the M-chain may differ functionally from those in the A-chain. Although only one LN fragment (E8) supported neurite outgrowth, both E8 and G supported neuronal adhesion, with LN>G>E8. Only weak adhesion to E1', E3 and E4 was observed. Adsorption of the synthetic LN- and MN-derived peptides to the substratum also promoted neuronal adhesion: However, addition of these peptides to the culture medium failed to block, at concentrations up to 0.5 mM, adhesion to LN or MN. In fact, the LN-derived peptide increased adhesion to E8 in a dose-dependent manner. Addition of this soluble peptide to culture medium did not, however, increase neuronal adhesion to albumin- or vitronectin-treated substrata. These data support the view that multiple sites, especially within the E8 and G domains, mediate the neuronal response to LN. (Supported by the Muscular Dystrophy Association)

MEROSIN BUT NOT LAMININ IS EXPRESSED IN THE MAMMALIAN CNS. E. Engvall*, D. Earwicker*, M. Manthorpe, S. Varon, T. Hagg, La Jolla Cancer Research Foundation and Department of Biology, University of California San Diego, La Jolla, CA.

Laminin and merosin, two members of the laminin family, possess each two 200 kD light chains (B₁ and B₂) and one 400 kD heavy chain (A or M). Both have potent in vitro neurite-promoting activity. In adult rat and rabbit brains, immunostaining with chain-specific monoclonal antibodies revealed laminin (A chain) only in association with blood vessels while merosin (M chain) was seen associated with neuronal fibers in a number of brain regions. B₁ and B₂ chain staining was seen in association with blood vessels and in almost all neuronal cell bodies. The expression of mRNA for merosin and laminin chains in different CNS regions was also determined. Adult rats (Sprague-Dawley) and rabbits (New Zealand White) were perfused transcardially with ice-cold PBS, their brains dissected out and selected regions were immediately frozen on dry ice and stored at -70°C. mRNA was prepared and used in reverse transcriptase-polymerase chain reaction to amplify conserved regions of the M and A chain RNA. Essentially no A chain mRNA was detectable in any of the CNS regions but M chain mRNA could be detected in almost all brain regions. In conclusion, merosin is the major laminin-like molecule of the adult mammalian CNS as it is in the adult PNS. Support: DHHS grants DK 30051 and NS 16349.

NEURONAL RESPONSE TO MICROFILAMENT DISRUPTION VARIES ACCORDING TO ADHESION MOLECULE SUBSTRATE. A. Abosch and C. Lagenaar, NACS Dept., Univ. of Pittsburgh School of Medicine Pgh, PA 15261.

Microfilaments, which form a major component of the cytoskeleton, are especially prevalent in the motile regions of growth cones, and are believed important in neurite outgrowth, particularly in extension of lamellipodia and filopodia. Different cell adhesion molecules, including L1, P84, NCAM, and laminin (LN), have been shown to promote neurite outgrowth from CNS neurons. These various adhesion molecules do not necessarily engage the same intracellular mechanisms to achieve this similar outcome (Bixby et al., 1991). This study assessed the contribution of microfilaments to the process of neurite outgrowth evoked by several adhesion molecules. Dissociated cell cultures of P5 murine cerebellum showed exuberant neurite growth on the substrates L1, P84, and LN. Cortical cells from P0 mice grew well on L1, P84, and NCAM. Most cells on L1 extended two neurites, oriented 180° apart. Fewer cells emitted only one process. Somata were fusiform (length/width=2). Addition of cytochalasin B (CB) to these cultures caused disruption of phalloidin-stained microfilaments, and a reduction to 1 in number of neurites extended by most cells. CB-treated neurites were curved and significantly longer than control. Somata were round (length/width=1). Cells grown on P84 extended curved neurites. Upon addition of CB, cells continued to extend neurites, but in a more tightly curved fashion. A number of cells were noted in CB-treated cultures bearing highly arborized neurites. These cells stained with tetanus toxin, and were not seen in control cultures. On NCAM, addition of CB blocked neurite extension, but did not interfere with attachment of cells to substrate. On LN, CB caused a marked inhibition of neurite outgrowth initially, with eventual production of thicker neurites. These findings provide striking evidence of the differences in intracellular response subsequent to the binding of different cell adhesion molecules.

DIFFERENTIAL EFFECTS OF LAMININ AND MEROSIN ON INTEGRIN-MEDIATED CNS NEURITE GROWTH AND REGENERATION. J. Cohen*, Division of Anatomy and Cell Biology, UMDS, Guy's Campus, London, SE1 9RT. (SPON: Brain Research Association).

Laminin (LN) is unique amongst extracellular matrix molecules in its ability to promote extensive neurite outgrowth by neurons in vitro. In the case of embryonic chick and rat retinal ganglion cells (RGC), the ability to extend neurites on LN is lost during development at the time when, in vivo, RGC axons encounter their target. LN exists in several isoforms, the products of a multi-gene family. One of these, merosin (M) is a 300kD A-chain homologue present in vivo in only a few sites, including peripheral nerve endoneurium and muscle basal lamina, consistent with a role in axon growth. As a culture substratum for RGC, merosin-containing LN (M-LN) not only duplicates the neurite promoting effects of A-chain containing LN (A-LN) but also is able to support the survival of, and induce neurite outgrowth from, older RGC that fail to grow on A-LN. Antibody blocking studies show that at all embryonic ages chick RGC neurite outgrowth on both A- and M-LN is mediated by neuronal αβ1 integrin heterodimers. These findings suggest that RGC use different αβ1 dimers in interactions with A-LN and M-LN, and that M-LN, but not A-LN, supports RGC regeneration.

IDENTIFICATION OF A NEURONAL THROMBOSPONDIN RECEPTOR. Michael F. DeFreitas, Kurt Gehlsen** and Louis F. Reichardt, Department of Physiology and HHMI, University of California, San Francisco 94143 and * La Jolla Institute for Experimental Medicine, La Jolla CA 92037.

Thrombospondin (TS) is an extracellular matrix (ECM) protein found throughout the developing nervous system, particularly in the spinal cord, dorsal root ganglia, and in the cerebellum (O'Shea and Dixit, (1988) JCB 102: 2737). TS has been shown to be important in cerebellar granule cell migration (O'Shea et al. (1990) JCB 110: 1275) and to support attachment and neurite outgrowth from embryonic chick retinal neurons (Neugebauer et al. (1991) Neuron 6: 345). This neurite outgrowth is inhibited by antibodies to the integrin beta1 subunit.

To understand the basis of neuronal interaction with TS, we are using primary neurons, neuronal cell lines, and function-blocking antibodies to determine which receptors are involved. Our data show that for primary neurons and a neuronal cell line, adhesive interactions with TS are partially inhibited by antibodies to the integrin beta1 subunit. This implies that at least one of the receptors utilized by neurons to bind TS is an integrin heterodimer. Integrins are a large family of heterodimers which mediate interactions with ECM proteins. We are currently using function-blocking antibodies to the integrin alpha subunits that associate with beta1 to identify the specific alpha/beta heterodimer(s) which interact with TS.

EFFECT OF DIFFERENT ADHESION MOLECULES AS SUBSTRATES FOR OUTGROWTH OF MAP2 AND NEUROFILAMENT POSITIVE PROCESSES FROM CULTURED CORTICAL NEURONS. W.-W. Chung, J.S. Lund, and C. Lagenaar, Department of Neurobiology, Anatomy and Cell Science, Center for Neuroscience, University of Pittsburgh, PA 15261.

In many differentiated CNS neurons, the dendrites express MAP2 (microtubule-associated-protein 2) while the axon expresses neurofilament (NF) (Pennypacker et al., Exp. Neurol. 111:25-35). In these studies we investigated the expression of these molecules in the first processes to grow out from the dissociated neocortical neurons of newborn mice. We used polyclonal antibody to MAP2 (gift from I. Fisher) and mouse monoclonal antibody (RT97) to NF. The cells were grown in a 1:1 combination of N1 medium (Bottenstein et al., Exp. Cell Res. 125:183-190) and BME with Earle's salt and 10% horse serum. The substrates for growth were purified L1, N-CAM, and P84 molecules; polylysine was used as an inert control substrate. The growth of MAP2 positive processes was similar on all substrates; and they were the first processes to grow out. By 6 hours some processes also expressed NF in addition to MAP2. All cultures showed some processes having only NF by 40 hours, and by 3 days the majority of NF positive processes lacked MAP2. Most of the cells that grew on L1 and N-CAM were neurons, while many more glial cells attached with the neurons on P84 and polylysine. At 17-22 hours cultures on L1 showed more and longer NF positive processes than cultures grown on N-CAM; cultures on P84 and polylysine showed fewer, shorter NF positive processes. Our conclusion is that all these neuronal cell adhesion molecules allowed differentiation of axon and dendrites; L1 and N-CAM encouraged the rate of axonal growth relative to dendritic growth in comparison to P84 and polylysine. STRUCTURE-FUNCTION RELATIONS OF THE NEURAL RECOGNITION MOLECULES L1 AND N-CAM. F. Appel*, T. Frei*, F. von Bohlen und Halbach*, J. Holm*, D. Barthelst*, W. Willeit*, J.-F. Conscience* and M. Schachner, Dept. Neurobiology, Swiss Federal Institute of Technology, Zürich, Switzerland, and Institute of Genetics, University of Cologne, Cologne, Germany.

L1 and N-CAM have been implicated in several types of neural cell interactions, such as neuron-neuron adhesion, neurite extension and fasciculation, neuronal cell migration, and triggering of second messenger systems. Both molecules belong to the L2/HNK-1 carbohydrate and immunoglobulin families and express fibronectin type III repeats. To identify structural domains which may be involved in distinct functions, we have generated molecular fragments by recombinant DNA technology and antibodies directed against these, and have used them in *in vitro* assays designed to probe for the different functions. Both the immunoglobulin-like domains and the fibronectin type III repeats of L1 and N-CAM mediate cerebellar neuron adhesion and neurite outgrowth in substrate-bound form. When added in soluble form to cerebellar explant cultures, immunoglobulin-like domain I of N-CAM decreases neurite fasciculation and granule cell migration, whereas domains III and IV increase neurite fasciculation. The other immunoglobulin-like domains and the fibronectin type III repeats do not induce morphological changes in these explant cultures. Thus, the domains influence cellular behaviour differently depending on whether they are offered as substrate or as soluble competitors. Furthermore, antibodies against individual epitopes induce different effects in substrate-bound or soluble form. Thus, a monoclonal antibody reacting with the fibronectin type III repeats of L1 inhibits neurite outgrowth on substrate-bound L1, while it enhances neurite outgrowth when substrate-bound. That signal transduction mechanisms are involved in evoking the different cellular responses is indicated, for instance, by the observation that immunoglobulin-like domains, but not the fibronectin-type III repeats of N-CAM, stimulate phosphatidylinositol turnover in cerebellar neurons. Our observations indicate that L1 and N-CAM are composed of "cassettes" of functional domains that subservise distinct cellular functions.

DIFFERENTIAL EXPRESSION OF ADHESION MOLECULES ON SUBPOPULATIONS OF SENSORY NEURON GROWTH CONES. M.G. Honig, Dept. of Anat. and Neurobiology, Univ. of Tennessee-Memphis, Memphis, TN 38163.

We are interested in understanding how, during development in the chick hindlimb, some sensory neurons grow along cutaneous nerves to the skin while other sensory neurons grow with motoneurons to innervate muscle. As one approach to this issue, we have begun to characterize the expression of adhesion molecules on the growth cones of cutaneous afferents as compared to muscle afferents. To do this, we use a tissue culture system since, in contrast to sectioned material, this allows us to visualize immunofluorescent labelling on individual growth cones. The expression of NCAM and L1 was assessed with antibodies described previously by Landmesser, Rutishauser and colleagues (Dev. Biol. 130: 645; Neuron 4: 655). In DRG explant cultures, we found a fairly wide range in the level of expression of NCAM and L1 on different growth cones. Moreover, the levels of expression of NCAM and L1 appeared to be correlated. In some experiments, we made explant cultures from embryos in which either cutaneous or muscle afferents had been retrogradely labelled with dil, and examined the expression of adhesion molecules on the dil-labelled growth cones that extended out of these explants. We found that cutaneous growth cones tended to express lower levels of L1, of NCAM, and in particular, of the heavily sialylated form of NCAM, than did growth cones of muscle afferents. Thus, cutaneous and muscle afferents appear to differ in the expression of various adhesion molecules and this may be related to how they interact with other axons during outgrowth into the limb. CARBOHYDRATE EPITOPES DELINEATE FUNCTIONAL ORGANIZATION IN THE LEECH SENSORY AFFERENT SYSTEM. K. Zipsar* and B. Zipsar, Dept. of Brain and Cognitive Sciences, MIT, Cambridge MA. 02139 and Dept. Physiology, Michigan State Univ., East Lansing, MI 48824.

Leech peripheral afferents convey information of several sensory modalities which is integrated into leech feeding behavior. Sensory afferents can be identified by three different galactose-containing epitopes. We investigated how the distribution of these three carbohydrate epitopes on subsets of sensory afferents is correlated with the functional organization of the sensory afferent system. Using antibody labeling, we found that lip afferents, which transduce chemical and heat stimuli, are divisible into two subsets by two different carbohydrate epitopes. In contrast, the gut afferents (presumptive stretch detectors) lack the lip-associated epitopes and express a third carbohydrate epitope, not found on lip afferents.

Each sensory afferent subset has a distinct CNS projection pattern. We found that the two subsets of sensory afferents, which express the lip-associated carbohydrate epitopes, have overlapping presynaptic projections. In contrast, sensory afferents which express the gut-associated carbohydrate epitope have a segregated presynaptic projection. If the different presynaptic projections input into different sensory processing networks, then the carbohydrate identity of sensory afferent subsets could serve to delineate functional pathways. Another epitope common to all sensory afferents, the mannose-containing Lan3-2 epitope, mediates an early step in the generation of sensory afferent presynaptic projections. It remains to be seen if the galactose-containing epitopes found on subsets of sensory afferents mediate subsequent steps in the generation of their CNS projections.

L1/NGCAM SUBSTRATE ENHANCES NEURITE OUTGROWTH FROM MESENCEPHALIC TYROSINE HYDROXYLASE-POSITIVE NEURONS IN CULTURE. M. Poltorak, K. Shimoda and W.J. Freed, NIMH Neuroscience Center at St. Elizabeths, Washington, DC 20032.

The neuron-glia cell adhesion molecule (L1/NGCAM) is involved in neuronal development and regeneration. L1/NGCAM is implicated in the molecular basis of neuronal cell migration as well as in axonal elongation during formation of major fiber tracts. We have evaluated neurite outgrowth from dopaminergic (tyrosine hydroxylase-positive) neurons grown *in vitro* on different substrates. Cultures of ventral mesencephalon from rat embryos (E13) were plated on plastic dishes coated with the following substrates: L1/NGCAM, L2/HNK1 and MAG antigens from mouse brains, laminin, fibronectin, poly-L-lysine, DRG peptide and plastic alone. After 3, 4 and 6 days *in vitro*, the cultures were stained using an antibody against tyrosine hydroxylase (TH), and the length of TH-positive neurites was measured by computer assisted image analysis in a double blind fashion. After 3 and 4 days in culture the TH positive neurites were significant longer when grown on L1/NGCAM as compared to all other substrates studied. At 6 days laminin and fibronectin as well as L1/NGCAM showed positive effects on neurite outgrowth as compared to the poly-L-lysine coating. These data indicate that L1/NGCAM may be involved in differentiation or axonal elongation from substantia nigra dopaminergic neurons.

AN EARLY STEP IN THE GENERATION OF SENSORY AFFERENT PRESYNAPTIC PROJECTIONS IN THE CNS IS MEDIATED BY A MANNANOSE-SPECIFIC RECOGNITION. J. Song*, S.B. Heisey and B. Zipsar, Dept. of Physiol., Mich. State Univ., E. Lansing, MI 48824.

Leech peripheral sensory afferents express the mannose-containing Lan3-2 epitope on their cell surface. Previously, we showed that a mannose-specific recognition involving the Lan3-2 epitope is essential for the normal generation of sensory afferent presynaptic projections. Here, we further examine details of sensory afferent development under normal and experimentally perturbed conditions. Normally, sensory afferents originate in a precise temporal order in six bilaterally arrayed sensilla in the skin of embryonic midbody segments. The third sensilla afferents differentiate first and project as fasciculated axons over a 100 µm distance into the CNS. Upon entering the CNS, sensory afferents then suddenly defasciculate and amorphously spread through a 15 µm diameter of ipsilateral neuropile. Subsequently via an undetermined molecular mechanism, sensory afferents regroup into a highly structured pattern of presynaptic projections. We found that inhibiting the mannose-specific recognition using either Lan3-2 Fab fragments or mannose-BSA does not affect sensilla structure and peripheral fasciculation. In contrast in the CNS, sensory afferents stop defasciculating and therefore no longer amorphously permeate the neuropile; instead, they continue to elongate in densely fasciculated tracts. Thus, the transition from a structured peripheral axon tract to a structured CNS pattern of presynaptic projections involves a necessary intermediate state of amorphous sensory afferent growth depending on mannose-specific recognition.

LECTIN BINDING AFFECTS NEURITE OUTGROWTH AND FASCICULATION IN SENSORY GANGLIA EXPLANTS. Y. Sheh*, S. Mehta*, L. Hsu, Dept. of Biology, Seton Hall Univ., S. Orange, NJ 07079; Dept. of Chemistry, Rutgers Univ. Piscataway, NJ 08854.

Both initiation of axonal elongation and subsequent neurite fasciculation are mediated by the adhesive properties of glycoproteins on the neuronal cell surface and the extracellular matrix. To identify the specific glycoconjugates involved in neuritogenesis, we have surveyed the effects of numerous lectins on neurite outgrowth from sensory ganglia explants. Lectins were applied onto collagen-coated surfaces or incorporated into growth medium with or without the neurite-promoting phorbol ester 12-O-tetradecanoylphorbol-13-acetate (TPA). Various effects were elicited by the presence of lectins. *Triticum vulgare* (WGA) was found to significantly promote neurite outgrowth. Mannose-binding lectins such as *Lens culinaris* (LCA) or *Pisum sativum* (PSA) affected fasciculation by causing a marked shortening and thickening of neurite bundles. Another lectin, *Ricinus communis* (RCA), did not promote ganglia development and caused explants to detach from the underlying surface. (Supported by NS 21262 and Research Council of SHU)

LOCALIZATION OF HIPPOCAMPAL NEURONS TO CHEMICALLY MODIFIED SILICON NITRIDE SURFACES. J.M. Corey¹, B.C. Wheeler¹ and G.J. Brewer². ¹Neuroscience Program, University of Illinois, Urbana, IL 61801 and ²Southern Illinois University School of Medicine, Springfield, IL 62794.

Synaptic specificity of CNS neurons would be more easily studied *in vitro* by limiting the number of cells and connections formed by localized somae and processes. We previously localized hippocampal neuronal somae to specific locations on coverslips using differential adhesion. Regions of polylysine were ablated from coated coverslips by exposure to a UV laser (100 mW/cm²; 193 nm) through a quartz mask with a pattern of square grid networks. As many as 94 % of the neurons complied to one of the networks.

More recent work, adapted from Kleinfeld et. al (J Neurosci, 8 (1988): 4108), has allowed us to chemically modify the surfaces of coverslips and electrode arrays to effect cell localization. As an insulator, silicon nitride was deposited on cover slips and electrode arrays by a plasma-enhanced chemical vapor deposition process. Photoresist was used to establish a pattern to which the cells would adhere, and hydrophobic 16-carbon alkane chains were bound to the remaining surface by reflux in 5% hexadecyltrichlorosilane solution. The photoresist was removed, leaving a pattern of silicon nitride to which was bound hydrophilic diaminoalkyltrimethoxysilane. Embryonic rat hippocampal cells were dissociated and grown in serum-free media on these surfaces. Compliance to the amino-silane pattern was above 95%. This method of patterning has several advantages over the polylysine method described above. First, the hydrophilic pattern with hydrophobic surround constitutes a greater difference in adhesivity, resulting in better restriction of processes. Secondly, the cell patterning step can be done with a conventional mask aligner using a UV lamp (i.e., without the expensive laser). Third, the resulting pattern has greater shelf life than the one to two day period of patterned polylysine. This ability to localize a few cells to specific locations on electrode arrays should permit recording from neuronal networks with simple, visible connections.

PATTERNED NEUROBLASTOMA ATTACHMENT AND OUTGROWTH ON COVALENTLY MODIFIED/CHARGE INJECTED SUBSTRATES. R.E. Valentini, J. Ranieri*, T. Vargo*, J. Gardella*, J.P. Aebischer. ABC Section, Brown University, ¹Dept. of Chem., SUNY at Buffalo. Fluorinated ethylenepropylene copolymer (FEP) with embedded positive charges enhances neurite outgrowth as compared to negatively charged or uncharged FEP. In the present study, FEP surfaces were refunctionalized with hydroxyl (OH) or amine (NH₂) groups to determine how these negatively (O⁻) and positively (NH₃⁺) charged (at physiologic pH) surface groups influence outgrowth in the presence or absence of embedded charges. Covalent addition of OH groups was achieved in a flow-through glow discharge chamber using methanol/hydrogen vapor. A phototooled nickel mask restricted modification to 25 adjacent strips (300 x 1000 μm) spaced 500 μm apart. NH₂ groups were bound by reacting the OH-rich regions with aminopropyltriethoxysilane. Covalent monolayer modification was verified using surface-sensitive spectrophotometric techniques. FEP was charged to a potential of +1500 V with a corona poling triode array, a technique which does not alter surface chemistry. Mouse neuroblastoma (Nb2a) cells were plated onto covalently modified FEP in 10% FCS/DMEM. Nb2a cells attached preferentially, and at similar densities, to OH and NH₂ modified strips. Nb2a cells featured a flatter morphology on NH₂ versus OH groups. The level of Nb2a differentiation on electrically charged FEP was greater than that on uncharged FEP. Neurites rarely extended into unmodified FEP regions. Neurites from occasional cells that attached on unmodified regions were longer than those on OH or NH₂ strips. These results suggest that enhanced differentiation is due primarily to positive charges embedded below the surface and that charged surface groups exert a greater influence on cell attachment and morphology.

MODIFICATIONS OF MOLECULES ON THE SURFACE OF MERKEL CELLS AND SUBSEQUENT EFFECTS ON NEURONAL INTERACTIONS. Wesslia P. Hynicka* and Randall N. Pittman. Department of Pharmacology, Univ. of Pennsylvania School of Medicine, Philadelphia, PA. 19104

Merkel cells in the rat buccal pad epidermis are the natural targets for a subpopulation of trigeminal ganglion sensory neurons. Merkel cells contain NGF and are thought to provide trophic support for sensory neurons. Sensory neurons and sympathetic neurons from the superior cervical ganglion innervate the rat buccal pad at about the same time in development; however, the sympathetic neurons innervate blood vessels and the sensory neurons innervate Merkel cells in the epidermis. In culture, sensory neurons grow onto Merkel cells and branch extensively following contact; however, sympathetic neurons will not grow onto Merkel cells in culture and growth cones often collapse and retract following contact with Merkel cells. The molecular mechanisms underlying the selective contact or avoidance of Merkel cells in culture by the two types of neurons is being studied by modifying molecules on the surface of the Merkel cells. Preliminary results indicate that modification of o-linked sugars on the Merkel cell surface decreases interactions of sensory neurons with Merkel cells but does not change the interactions of sympathetic neurons. Treatment of the Merkel cells with very low concentrations of trypsin increases the number of contacts made by sympathetic neurons but does not alter the number of contacts made by sensory neurons. Studies are underway to characterize components on Merkel cells that are involved in the contact or avoidance phenomena observed with sensory and sympathetic neurons. Supported by the Whitaker Foundation.

89.18

THE MAGNITUDE OF SUBSTRATE ELECTRICAL CHARGE MEDIATES THE DEGREE OF NEUROBLASTOMA DIFFERENTIATION. S.A. Makohliso*, R. F. Valentini, R. Bellamkonda*, P. Biancani and P. Aebischer, Brown University, Providence, RI 02912.

Positively charged polymer substrates elicit greater neurite outgrowth from mouse neuroblastoma (Nb2a) cells than negatively charged or uncharged substrates. The structural and adhesive properties and levels of cell attachment are similar for all materials, suggesting that trapped charges are exerting the effect. The present study investigated a possible relationship between the amount of trapped charges and the degree of Nb2a differentiation observed. Fluorinated ethylenepropylene (FEP) films were fabricated into positively charged electrets using a corona charging procedure. This process injects charge into the polymer bulk without modifying the surface properties. FEP films with projected surface voltages of 500, 1000 and 3000 V were prepared. Detailed analysis revealed that all films retained their original surface chemistry and morphology. Charge levels were monitored throughout the study with a non-contacting electrostatic voltmeter. Charged and uncharged substrates were plated with Nb2a cells in serum-containing media. Differentiation of attached cells was assessed 24, 48, 72, 96 hr after plating, by quantifying the number of cells whose neurite lengths equaled or exceeded the cell's diameter. Differentiation on the various substrates was lowest on uncharged FEP, peaked on the 1000 V substrates and decreased on 3000 V FEP. Five hundred and 3000 V FEP displayed similar levels of outgrowth. All charged substrates displayed neurites of similar length, which were longer than those on uncharged FEP. Attachment levels were similar for all charged and uncharged materials. These results suggest a relationship between the extent of neuroblastoma differentiation and the magnitude of projected surface charge.

89.20

TISSUE PLASMINOGEN ACTIVATOR MESSENGER RNA IN THE DEVELOPING MOUSE CEREBELLUM AND IN NG105-15 CELLS. G.C. Friedman* and N.W. Seeds. Neuroscience Program, Dept. Biochem/B/Genetics Univ. of Colorado HSC, Denver, CO 80262.

Tissue plasminogen activator (tPA) has been implicated in neurite outgrowth and cell migration in the developing nervous system. NG105-15 neuroblastoma cells induced to undergo neurite outgrowth with 1 mM dB-cAMP showed a 2.5 fold increase in tPA mRNA levels as compared to morphologically undifferentiated uninduced cells. Northern blot analysis of total RNA from developing cerebella revealed that tPA mRNA levels are extremely low at embryonic day 17. tPA mRNA levels increased 4-fold by postnatal day 1 and maintained this level thru day 7; these levels progressively decreased with age into adulthood, where they were 40% of the P1 levels. A major species of mRNA was seen at approximately 2.8kb and a minor species, most evident in E17 and P1 cerebella, was seen at 3.4kb. The nature of this higher Mr species is under investigation. *In situ* hybridization was performed on whole brain sections. The cerebellum was the only region that showed significant binding with an tPA anti-sense riboprobe. In the P14 cerebellum specific binding was seen in the molecular layer just superficial to the internal granular layer. The intensity of binding decreased with development, in parallel with the northern blot results. These findings indicate that tPA mRNA levels are highest at the time of active cell proliferation, migration and differentiation in the nervous system.

89.22

INVESTIGATIONS INTO THE ROLE OF TISSUE TYPE PLASMINOGEN ACTIVATOR IN CEREBELLAR GRANULE NEURON MIGRATION. J.H. Ware and R.N. Pittman. David Mahoney Institute of Neurological Sciences and Dept. of Pharmacology, University of Pennsylvania School of Medicine, Philadelphia, PA 19104.

We are investigating the role of proteases in the development of the nervous system. Some published data are consistent with the hypothesis that tissue-type plasminogen activator (tPA) plays a role in the migration of cerebellar granule neurons, while other data are inconsistent with this hypothesis. In an effort to clarify what role, if any, tPA plays in this event, we are using ³H-thymidine to pulse-label cerebellar slice explants, which contain proliferating granule neuron precursors. The explants are then cultured for 72 hours in serum free or serum containing medium augmented with various protease inhibitors or antibodies. Autoradiographic visualization of the labelled neurons is being used to determine the effects of inhibiting proteases on granule cell migration.

A second approach being used to clarify the role of tPA in neural development is to characterize tPA's expression as a function of cerebellar development. While it is clear that cultured cerebellar granule neurons can secrete tPA and it will bind with high affinity to their surfaces, it has not been shown that granule neurons manufacture tPA *in vivo*. We are investigating this possibility by performing *in situ* hybridization histochemistry on sections of postnatal day 7-17 rat brains, using a riboprobe transcribed from a rat tPA cDNA. Supported by NS22663.

89.23

DEVELOPMENTAL REGULATION OF RAT UROKINASE PLASMINOGEN ACTIVATOR IN THE CENTRAL NERVOUS SYSTEM. Anne Marie L. Inglis, Angela J. DiBenedetto*, and Randall N. Pittman, Dept. of Pharmacology, Univ. of Pennsylvania School of Medicine, Philadelphia, PA 19104.

Growth cones of cultured rat sensory and sympathetic neurons release urokinase plasminogen activator (uPA). *In vitro*, some of this released uPA binds locally to the bottom surface of the neuron in discrete patches next to the substrate. Inhibition of uPA activity increases neurite outgrowth about 2-fold. This effect appears to be direct rather than through inhibition of plasmin generation. The available evidence suggests a role for uPA in the development of the nervous system, and experiments in the lab are designed in an effort to elucidate this role. We have initiated studies examining the developmental regulation of both uPA activity and mRNA levels in the central nervous system of the rat. In the cortex, uPA activity increases to a peak at postnatal day 15 and then declines, reaching a steady-state during adulthood. We have cloned a rat uPA cDNA and are presently sequencing it. Northern blot analysis is being used to determine the developmental profile of uPA mRNA. In addition, the rat uPA cDNA is being cloned into a mammalian expression vector and will be used to generate recombinant rat uPA for functional and biochemical studies. Supported by NS22663.

NEURITE OUTGROWTH INDUCED BY A SPECIFIC PROTEASE INHIBITOR (Z-LEU-LEU-LEU-AL) IN PC12 CELLS: CHARACTERIZATION AND PURIFICATION OF THE TARGET MOLECULE. Y.SAITO*, S.TSUBUKI¹, H.ITO¹, T.HAMA² AND S.KAWASHIMA¹, Dept. Enzyme Biochem, Tokyo Metropol. Inst. Gerontol. Tokyo 173. ¹Dept. Chem, Aoyama-Gakuin Univ, Tokyo 157. ²Dept. Neurosci, Mitsubishi-Kasei Life Sci. Inst. Tokyo 194, Japan.

Our previous study have shown that, among many protease inhibitors examined, only a leupeptin analogue, Ac-Leu-Leu-Nle-al(ALLNal) initiates neurite outgrowth in PC12h cells. This inhibitor also increases the cellular level of both AchE and TH. The neuritegenesis induced by the inhibitor is different in some aspects from that induced by NGF, dbcAMP, bFGF and high K⁺. These findings provide evidence that the protease inhibitor and other known neurotrophic factors elicit neurite initiation by different mechanisms and suggest the existence of a novel molecule which modulates neurite initiation in PC12h cells. Recently we reported that benzyloxycarbonyl (Z)-Leu-Leu-Leu-al has 50-fold stronger potencies to initiate neurite outgrowth than that of ALLNal. To determine the target molecule, Leu-Leu-Leu-al was immobilized and used as a ligand for affinity chromatography. Proteins of 33,35 and 180K were isolated specifically from the cytoplasmic fraction of PC12h cells and the conditioned medium contained none of these proteins at all. 33K and 35K were eluted with citrate buffer (pH3), while 180K was isolated with 6M urea (pH7). 2D-electrophoresis showed that 33K and 35K were acidic proteins, and amino acid analysis by pico-tag revealed that 33K had similarity to 35K. The same proteins were identified in the brains of postnatal 1 day rat, but the amounts started to decrease from the brains of postnatal 14 day rat. This suggests that these proteins are involved in some process in brain development such as neuritegenesis. Further analysis of these proteins will provide unique insights into the regulation mechanism of neurite initiation and outgrowth.

PROCESS OUTGROWTH, GROWTH CONES AND SPROUTING III

90.1

A ROLE FOR OLIGODENDROCYTES IN THE STABILIZATION OF OPTIC NERVE AXON NUMBERS. R.J. Colello¹, J. Kapfhammer, and M.E. Schwab, Brain Research Institute, University of Zürich, CH-8029 Zürich, Switzerland

The stabilization of axon numbers in the rat visual system occurs at a time when differentiating oligodendrocytes appear and begin myelination. As this glial cell type expresses the neurite growth inhibitors NI-35 and NI-250 upon differentiation (Caroni and Schwab, 1989), we examined whether oligodendrocytes may have a role in stabilizing this fiber projection.

To test this hypothesis, oligodendrocyte development was suppressed in the retinofugal pathway of rats by X-irradiating the optic nerves at P0, P2, and P4, a time when oligodendrocyte precursors proliferate. EM and immunohistochemical analysis of irradiated optic nerves at P15 showed that the absence of oligodendrocytes and myelin was complete. Optic fiber numbers were then determined for normal (myelinated) nerves and X-irradiated (unmyelinated) nerves. In some instances, an intravitreal injection of FGF was given to the pups at P10 in order to enhance neurite growth and sprouting.

Axon counts showed that the total fiber number in the optic nerve of irradiated animals was up to 30% higher than that of normals. Further, counts at three locations along the length of the irradiated optic nerves showed fluctuations of up to 27%, while axon numbers in normals fluctuated at most 8%.

These results indicate that, in the absence of oligodendrocytes and myelin, optic fibers are able to form sprouts. This suggests that oligodendrocytes have a role in preventing sprouting and stabilizing the number of fibers in a pathway.

90.3

SUBSTRATES FOR REGENERATING GOLDFISH RETINAL AXONS *IN VIVO*. GABY STROBEL AND CLAUDIA A.O. STUERMER; Faculty of Biology, Univ. Konstanz, Germany.

In contrast to mammals, retinal ganglion cell (RGC) axons in fish regenerate successfully. Fish CNS myelin and optic nerve oligodendrocyte-like cells, offered as substrates to RGCs in culture, proved to be growth permissive and not inhibitory as in mammals (Bastmeyer et al., J. Neurosci. 11, 1991). This study aims at identifying elements of the fish optic nerve used as substrates by regenerating goldfish RGC growth cones *in vivo*.

Regenerating RGC axons were labeled by intraretinal applications of HRP, 6 d after optic nerve transection. Individual HRP labeled growth cones were identified in DAB reacted semithin sections and serially ultrathin sectioned. HRP labeled growth cones were seen in close association with myelin debris and glial cells. These cells appeared, by ultrastructural criteria, to be immature oligodendrocytes or microglia. None of the growth cones examined was found to contact astrocytes or the basal lamina ensheathing the optic nerve fascicles.

Thus *in vivo*, regenerating fish RGC growth cones may grow on myelin and immature oligodendrocytes or microglia of the injured fish optic nerve.

90.2

GROWTH OF ADULT RAT RETINAL AXONS ON GOLDFISH OLIGODENDROCYTE-LIKE CELLS *IN VITRO*. M. BASTMEYER¹, M. BÄHR² and C.A.O. STUERMER¹; ¹Faculty of Biol., Univ. Konstanz; ²MPI Dev. Biol., Tübingen, Germany.

Cross species *in vitro* assays were used to test the response of adult mammalian retinal ganglion cell (RGC) axons to oligodendrocyte-like cells of fish. Rat oligodendrocytes inhibit the regrowth of neurites (Schwab and Caroni, J Neurosci 8, 1988). They also cause collapse of fish RGC growth cones (Bastmeyer et al, J Neurosci 11, 1991). Fish oligodendrocyte-like cells, however, were found to support the growth of regenerating fish RGCs (Bastmeyer et al, Soc Neurosci Abstr 16, 1990).

Here we asked whether RGCs of adult rats would regenerate when cocultured with goldfish oligodendrocyte-like cells. We cocultured adult rat retinal explants (7 d after optic nerve crush) and glial cells from regenerating goldfish optic nerve/tract at a compromise temperature of 28°C. Oligodendrocyte-like cells were identified with the monoclonal antibody 6D2 against fish myelin proteins (Jeserich and Rauen, Glia 3, 1990).

Regenerating rat RGC axons grew in high density on the surface of goldfish oligodendrocyte-like cells after 9-12 d *in vitro*, but failed to grow on oligodendrocyte-free regions. The vigorous and lengthy growth of regenerating rat RGC axons on fish oligodendrocyte-like cells at 28°C is comparable to that seen on mammalian Schwann cells at 37°C.

Thus, fish optic nerve/tract oligodendrocyte-like cells have growth promoting properties which support not only the growth of fish RGC axons but also the growth of axotomized adult rat RGC axons.

90.4

THE EXPRESSION OF BASEMENT MEMBRANE MOLECULES ON CULTURED SCHWANN CELLS AND THEIR ROLE IN NEURITE OUTGROWTH. B. Seilheimer and W.D. Mathew, Dept. Neurobiology, Harvard Medical School, Boston, MA 02115.

We have analyzed the expression of Schwann cell (SC) basement membrane (BM) antigens and have investigated the ability of several purified monoclonal antibodies (mabs) to perturb neurite outgrowth (NO) onto cultured SCs. Dissociated dorsal root ganglia (DRG) from P1 rats were Percoll-fractionated in order to obtain pure populations of SCs and neurons. These studies analyzed the expression of antigens in three different cultures: (1) pure SCs; (2) pure neurons; and (3) pure N/SC co-cultures. The antibodies tested resulted from tolerizing mice to adult spinal cord and then immunizing with sciatic nerve.

Immunohistochemistry revealed the distinct pattern typical of SCBM staining *in vivo* and *in vitro*. Purified SCs also expressed the antigens on their surface but at low levels. Pure neuronal cultures were negative. Hence, contact with neurites promotes the accumulation of these antigens on Schwann cell surfaces—a characteristic trait of BM proteins. To test antibodies for their ability to perturb neurite growth onto established SC monolayers, the mabs were added after the neurons had attached (3-4 hrs). After 48 hours the cultures were processed for neurofilament staining to assess NO. One mab, PC1A6, was found to reduce NO dramatically. Furthermore, neuronal cell bodies and SCs tended to aggregate, indicating that this antibody interfered with substrate attachment. This data supports the fact that BM molecules are important in axon growth and, in addition, may play a role in SC adhesion and/or migration.

90.5

THY-1 SELECTIVITY INHIBITS NEURITE OUTGROWTH ON MATURE ASTROCYTES R.L. Morris, M.C. Tiveron*, B. Pliego-Rivero*, E. Barboni* and A.M. Gormley*, Lab of Neurobiology, NIMR, Mill Hill, London NW7, UK.

Thy-1, the smallest member of the immunoglobulin superfamily, is totally excluded from growing axons during normal development. However, it is a major and ubiquitous component of the surface of mature neurons, and could contribute to the fate of axons attempting to regenerate in adult nervous tissue. To determine the effect of Thy-1 on axonal growth, we have turned to neural cell lines which are Thy-1-negative, and for which neurite outgrowth is, by molecular criteria, axonal in character. Clones stably expressing Thy-1 (obtained by transfection using beta-actin promoter) show a severe inhibition of process outgrowth on a monolayer of astrocytes, but not on other cellular substrates (including embryonic glia and Schwann cells). Analysis of the site on Thy-1 interacting with astrocytes, and that responsible for mediating a transmembrane signal which suppresses process outgrowth, will be presented. We suggest that the interaction of Thy-1 on the surface of mature neurons with astrocytes contributes to a down regulation of axonal growth in an astrocytic environment.

90.7

ASTROGLIA DURING GROWTH AND DIFFERENTIATION OF NERVE TERMINALS IN CULTURE. A. J. Waclawik, H.M. Sobkowitz and B. K. August*, Dept. of Neurology, Univ. of Wisconsin, Madison, WI 53706

Interactions between neuronal growth cones and astroglia were studied in organotypic cultures of the fetal (15 dg) mouse spinal cord. Primary 24-48 hr outgrowth consists of bundles of nerve fibers extending radially whose growth cones are lead by flat translucent glial cells. Ultrastructurally, these cells cover the collagen substrate, carrying nerve fibers and growth cones atop. Secondary outgrowth proceeds slowly as a band of tissue, within which nerve fibers, intermingled with glial cells, grow both radially and circumferentially. Ultrastructurally, this outgrowth is stratified. The myriad neuronal growth cones are restricted to the outermost surfaces open to the feeding solution or substrate. In the central part, however, presynaptic and synaptic terminals, inextricably associated with astrocytic processes, prevail. With time, multiple glial lamellae, (each ca 60 nm thick) interconnected by tight junctions, form an elaborate glial barrier which encases all neuronal structures except neuronal growth cones, which become almost extinct. In the explant-within the intricate network of nerve cells and their fibers interspersed with glial cells--all growth ceases. The 48-hour labelling with ^3H thymidine, between 7-9 DIV, revealed labelled glial cells restricted almost exclusively to the rim of the outgrowth zone. Our results suggest that neuronal growth cones may mitogenically stimulate astroglial cells during active neuronal growth. The young astrocytes may consist of two populations: 1) the cells that enhance and lead neuronal growth (radial glia?) and 2) the cells that induce the differentiation of presynaptic terminals. (NIH grant NINCDS R01 DC00517)

90.6

CONCENTRATION-DEPENDENT EFFECTS OF ACTIVATORS OF PROTEIN KINASE C ON GLIAL-STIMULATED NEURITE OUTGROWTH. J. Qian and P. Levitt, Department of Anatomy and Neurobiology, Medical College of Pennsylvania, Philadelphia, PA, 19129.

Protein kinase C (PKC), one branch of the signal transduction cascade of the phosphatidylinositol system, has been shown to play multifunctional physiological roles. In present study, the role of protein kinase C in regulating the stimulating effect of glial cells on neurite outgrowth was investigated using an *in vitro* system, in which neurons derived from the embryonic rat spinal cord or hippocampus were grown for two days in media conditioned by different populations of CNS astroglia. Neurite outgrowth was examined by immunocytochemistry using an antibody against the high molecular weight neurofilament subunit (anti-NF-H), an axonal marker, and an antibody against microtubule-associated protein 2 (anti-MAP2), a dendritic marker. Two PKC activators, 12-O-tetradecanoyl-phorbol-13-acetate (TPA), a phorbol ester, and retinoic acid, a vitamin A analog, enhanced the outgrowth of axons when added into glial-conditioned neuronal cultures at low concentrations (nM levels), while at high concentrations (μM levels), inhibited the glial effect on neurite outgrowth. The addition of sphingosine, a potent PKC inhibitor, into these cultures also resulted in inhibition of neurite outgrowth. These results suggest that glial stimulation of axonal growth can be modified by manipulating the PKC second messenger systems. Supported by NIMH grant MH45507 and NIH grant NS24707.

INCREASED DENSITY OF PITUITICYTES AND MICROGLIA IN THE NEUROHYPOPHYSIS DURING AXONAL DEGENERATION AND SPROUTING. J. A. Watt and C. M. Paden, Dept. of Biology, Montana State University, Bozeman, MT 59717.

In a previous study we described compensatory collateral sprouting of intact magnocellular neurosecretory efferents following partial denervation of the neural lobe (NL) in rats (*Exper. Neurol.* 111; 9-24, '91). Ultrastructural analysis revealed a transient increase in the volume of NL occupied by glial elements with a peak at 5 days post surgery (PS). We report here the initial results from experiments designed to measure the contribution of pituitocytes (astrocytes) versus microglia to this increase and to determine whether it is the result of glial hypertrophy and/or hyperplasia. Glial cell numbers were determined by counting the total number of pituitocyte and microglial nuclei in plastic embedded coronal sections of NL stained with toluidine blue at 5, 10, 30 and 90 days PS. Cell counts of the pituitocyte population revealed a 30% increase in density over control values at 5 days PS. The density of pituitocytes remained elevated by 25% at 10 days PS and 23% at 30 days PS, but then decreased to a value 18% below that of intact controls by 90 days PS. Counts of the microglia population indicated increases in density of 34% over control values at 5 days PS, 29% at 10 days PS, 22% at 30 days PS and 39% at 90 days PS. Thus both glial types appear to respond rapidly to partial denervation of the NL, and this response is sustained during the initial period of axonal sprouting. In addition, these data suggest that a secondary microglial response occurs between 30 and 90 days PS. An investigation utilizing bromodeoxyuridine incorporation is currently underway to determine the extent to which glial hyperplasia contributes to these increases in cell density.

FORMATION AND SPECIFICITY OF SYNAPSES II

91.1

Immunocytochemical study of synaptophysin on synapse formation between dissociated fetal cerebral cortical cells. Masumi Ichikawa¹, Junko Kimura-Kuroda², Kotaro Yasui², Yoichiro Kuroda³, Depts. of ¹Anat. and Embryol., ²Microrbiol., ³Neurochem. Tokyo Metropolitan Institute for Neurosciences, Fuchu, Tokyo 183, Japan.

Synaptophysin localizing on synaptic vesicle membrane has been suggested to be a good marker for synapse. Synapse formation was examined immunocytochemically in the primary culture of dissociated cortical cells using anti-synaptophysin antibody. Dissociated cerebral cortical cells of fetal rats (14 days) were cultured *in vitro* (7-104 days). Synaptophysin immunoreactive (SP-IR) spots were observed in more than 14 days culture with fluorescent microscope. EM observation showed that the SP-IR spots represent the presynaptic terminals. Time-course of distribution of the SP-IR spots was examined. The spots could not be observed at 7 days *in vitro* (DIV). At 14 DIV, the SP-IR spots were recognized on cultured cells. Then, the density of the spots increased with DIV. At 42 and 104 DIV, the spots distributed densely on the cultured cells. These immuno-cytochemical studies suggest that the dissociated fetal cerebral cortical cells make considerable number of synapses at 14 DIV and that the synaptic density increases with day. At 42 and 104 DIV, synapses are formed densely on the cultured cells.

91.2

TRANSJUNCTIONAL ADHESION COMPLEXES (TACs) AND THE GENERATION OF SYNAPTIC SPECIFICITY. W.B. Pope, S.A. Enam, T.H.C. Tsui, & W.L. Klein, Northwestern University Institute for Neuroscience, Evanston, IL 60208.

Initial contact between potential synaptic partners is often mediated by neuronal filopodia. *In vitro*, filopodia form junctions that are maintained during high levels of filopodial motility. These junctions can lead to the formation of structurally identifiable synapses. Whole-mount electron micrographs have revealed that filopodia contact is mediated by transjunctional adhesion complexes (TACs) made up of extracellular microfibrils. Some of these extracellular microfibrils are associated with the cytoskeleton, and they can link the cytoskeletons of contacting neurons. This may account for the ability of filopodial contacts to withstand motile stress and enable filopodia to form nascent synaptic junctions. The molecular components of TACs are highly variable from one contact to the next. So far, three components of TACs have been identified. They are heparan sulfate proteoglycan (HSPG), purpurin, (both adhesive molecules) and AD2. All of these molecules are components of chick retinal adherons. AD2 is particularly interesting since it is nervous tissue specific and because it is present only during development. Furthermore, in fixed cultured retinal neurons AD2 expression is punctate yet evenly distributed throughout soma, neurites, growth cones, and filopodia. If cells are labeled and then fixed, however, AD2 becomes clustered in growth cones and points of neuritic contact. This suggests that AD2 is free to diffuse throughout most of the membrane excepting points of contact with the external milieu. Thus interaction between AD2 and the external environment may affect the regulation of AD2. Since the formation of TACs may be an initial event in synaptogenesis, further identification and characterization of adhesion components present in extracellular microfibrils should give insights into the generation of synaptic specificity.

91.3

NERVE-MUSCLE COMMUNICATION DURING SYNAPTOGENESIS. I. Chow and S.H. Young. Dept. of Biology, The American University, Washington, DC 20016 and Jerry Lewis Neuromuscular Research Center, UCLA Sch. of Medicine, Los Angeles, CA 90024.

The formation of a functional neuromuscular junction requires proper interaction between the pre- and post-synaptic components. Besides the influence of secreted soluble factors and electrical activity, direct communication between the cytoplasm of nerve and muscle cells from chick (Fischbach, Dev. Biol. 28, 407, 1972) and *Xenopus* (Allen & Warner, Neuron 6, 101, 1991) kept in culture has been described.

In this study, embryonic *Xenopus* muscle cells were manipulated into contact with the soma of neurons in 1- and 2-day old cultures. Lucifer Yellow or current pulses were injected into one of the cells. Passage of dye or current into the other cell indicating the presence of gap junctions was found in 26% of the cell pairs. These junctions appeared sporadically and only a small number of channels seemed to be open at a time. Chemical synapses were also detected in several of these cell pairs by recording miniature endplate potentials in muscle cells.

These results show that during development, direct cytoplasmic communication can occur, allowing the exchange of material between the two cells which may contribute to formation and stabilization of the synapse. Yet this coupling occurs at levels low enough to prevent "short circuiting" of the chemical transmission. (supported by grants from NIH).

91.5

REGENERATION AND SYNAPSE FORMATION BY IDENTIFIED INTERNEURONS OF HELISOMA. J.S. Roger, N.I. Syed, R.L. Ridgway, A.G.M. Bulloch, and K. Lukowiak. Dept. of Medical Physiology, University of Calgary, Calgary, Alberta, T2N 4N1, Canada.

The nervous system of the snail *Helisoma trivolvis* has been used extensively for studies of neuronal regeneration. Most of these studies, however, have been focused on neurons of the buccal ganglia. Following axotomy, these buccal neurons not only exhibit neurite outgrowth, but also reinnervate peripheral targets. In the present study, we used an identified network of interneurons (L.Pe.D.1, R.Pe.D.1, V.D.4) and follower cells located in the central ring ganglia. We tested the ability of these neurons to regenerate and establish appropriate synaptic contacts following axotomy.

Central ring ganglia were isolated from adult snails. All three neurons were axotomized by crushing the connectives between the left pleural and parietal ganglia and between the right pleural and parietal ganglia. These ganglia were then incubated in defined medium for 4 days. Following incubation, intracellular staining with Lucifer yellow revealed extensive neurite outgrowth of all three cells. Simultaneous intracellular recordings demonstrated the re-establishment of appropriate chemical synaptic connections. However, some new connections were observed not only after crush of the connectives, but also in control preparations in which no crushes were made. These results demonstrate the ability of adult *Helisoma* neurons to establish both appropriate and new synaptic connections following regeneration. Our *in vitro* model system therefore provides an opportunity to study the mechanisms underlying the specificity of synapse formation. Supported by MRC (Canada) and the Canadian Centre of Excellence in Neural Regeneration and Functional Recovery.

91.7

ECTOPIC MUSCLES AND THEIR INNERVATION IN OCTOPOD, A HOMEOTIC MUTATION OF THE MOTH, *MANDUCA SEXTA*. C.I. Miles and R. Booker. Section of Neurobiology and Behavior, Cornell Univ., Ithaca, NY 14853. Little is known about the role of innervation during the development and specification of insect muscle. We have addressed this issue by exploiting the homeotic mutation of *Manduca*, *Octopod* (*Octo*). Larval *Octo* animals have a pair of ectopic thoracic legs on the first abdominal segment. In addition to this ectodermal effect, *Octo* also induces ectopic mesodermal structures. Up to 4 ectopic muscles, often recognizable as thoracic coxal muscles, can occur in each ectopic leg. We have examined the innervation pattern of the ectopic muscles, using cobalt backfills and neurophysiological recordings. All of the muscles appear to be innervated by an abdominal motoneuron which normally innervates the ventralmost lateral external body-wall muscle, (VLE). In *Octo* animals it innervates the ectopic muscles as well as the VLE. We studied the developmental changes in these muscles at the larval-pupal transformation, using sectioned and stained material. Both sets of muscles degenerate at the larval-pupal transition. The ectopic muscles begin degenerating on the day after the onset of metamorphosis (day W1) and are completely degenerated 3 days later. This time course is similar to that of the thoracic and abdominal proleg muscles (Kent & Levine, 1988; Weeks & Truman, 1985). The VLE does not begin degenerating until two days after the ectopic muscles (day W3), along with other body-wall muscles. The ectopic leg muscles thus degenerate with other proleg muscles, while the VLE degenerates with the body-wall muscles. These results demonstrate that the *Octo* mutation affects both ectoderm and mesoderm, inducing ectopic muscles as well as epidermal leg structures. The ectopic muscles are innervated by a motoneuron that also innervates an abdominal body-wall muscle. Despite their common innervation, the two muscle types follow independent time-courses for degeneration, indicating that muscles respond independently to developmental signals at metamorphosis, rather than being triggered to do so by the motoneuron that innervates them. 91.4

SELF RECOGNITION INHIBITS GAP JUNCTION FORMATION: REGULATION BY CYTOPLASMIC CONTINUITY. P.B. Guthrie, R.E. Lee, V. Rehder, M.F. Schmidt, and S.B. Kater. Dept. Anatomy & Neurobiology, Colorado State University, Ft. Collins, CO 80523.

Identified cultured neurons from the snail *Helisoma* show a strong correlation between electrical coupling and freeze-fracture plaques (hexagonal arrays of intramembraneous particles assumed to be connexins, or hemi-junctions). Electrical coupling is always seen between pairs of neurons with actively growing neurites at the time of neurite overlap; plaques are always seen in fractures which pass between the overlapping neurites. Experimental measurement of electrical coupling between two neurons before and after cutting a subset of overlapping neurites suggests that electrical coupling is also distributed uniformly between the overlapping neurites. In contrast, electrical coupling is never seen when one of the neurons has stopped growing before neurites overlap; moreover, no plaques are observed in these cases.

Interestingly, plaques are never seen between neurites from a single neuron, even though the neurites overlapped during outgrowth. A form of self-recognition appears to be inhibiting the formation of gap junctions between sibling neurites.

Direct experimental evidence against self recognition of plasma membrane was obtained using isolated growth cones from a single cultured neuron. Such isolated growth cones will survive and grow for several days. In addition, new growth cones are generated at the severed neurite tips, which advance and often overlap the isolated growth cones from the same neuron. Experiments using the calcium indicator fura-2 show that microelectrode stimulation of the cell body results in elevated calcium levels in the stimulated neuron and in the previously isolated growth cones now physically contacted by newly formed growth cones from the stimulated neuron. No calcium rise was observed in isolated growth cones that showed no overlap. Electrophysiological measurements using two patch electrodes also showed significant electrical coupling between isolated but overlapped parts of the same neuron. The inhibition of electrical coupling between sibling neurites apparently depends on cytoplasmic continuity between the neurites, and is not inherent in the molecular composition of the membrane.

91.6

TERM1: A MOLECULAR LABEL FOR THE GROWTH CONES AND DEVELOPING SYNAPSES OF AN IDENTIFIED INTERNEURON. H. Reichert and T. Meier*. Dept. of Zoology, University of Geneva, CH-1211 Geneva, Switzerland.

The chemoaffinity theory (Sperry, 1963) postulates neuron-specific molecular labels, which are acquired by individual neurons and facilitate cellular reconnection between the growth cones and the targets of the labeled cells during synaptogenesis. To date, neuron-specific molecular labels of this type have not yet been found.

Here we report the discovery and biochemical characterization of a candidate molecule of this type, called TERM1 for terminal recognition molecule 1. This cell-specific molecular label is expressed on the growth cones and developing synaptic terminals of one pair of identified descending interneurons in the embryonic nervous system of the grasshopper. TERM1 is first synthesized in the labeled neurons at the 40% stage of embryogenesis. During axonogenesis, TERM1 becomes incorporated into the axonal growth cones of these neurons. Immunocytochemical studies show that the recognized epitope of TERM1 is located on the outer cell surface of the growth cones. In the subsequent synaptogenesis phase, the TERM1 label becomes concentrated on the membrane of the presynaptic terminals of these neurons. Postembryonically the expression of TERM1 disappears. The TERM1 molecular label is not expressed in any other of the millions of neurons in the nervous system of the developing embryo.

These findings suggest a molecular labeling system that is remarkably specific for individual neurons and may be important for establishing precise synaptic connectivity. (Supported by the Swiss NSF).

91.8

GROWTH CONE CHOICES OF DROSOPHILA MOTONEURONS IN RESPONSE TO MISMATCHED TARGETS. A. Chiba & H. Keshishian. Dept. of Biology, Yale Univ., New Haven, CT 06511

Individual motoneurons innervate specific bodywall muscles in the *Drosophila* embryo. RP3 innervates muscles 6 and 7, and RP1 innervates the adjacent muscle 13. We have designed complementary mismatches between the RP growth cones and their targets and have examined the morphology of dye-filled RP endings. The *rhomboid* mutation, which affects formation of specific muscles, deletes muscle 7. When observed at late stage 16, RP3 either innervates only muscle 6 (80%) or no muscle (20%). RP1 innervates muscle 13 normally. These results indicate that synaptic specificity is conserved after the deletion of a single muscle. We are also examining effects of muscle deletions on synaptic specificity using both the *numb* mutation and laser ablation in wild-type embryos. Conversely, an extra muscle 13 can be added when wild-type embryos are heat-shocked. RP1 innervates both muscle 13s, but RP3's innervation pattern remains intact. In all mismatch conditions examined, the innervation patterns of other neighboring muscles (e.g. muscle 12), as revealed by anti-peroxidase labeling, appear intact. These results are consistent with the idea that individual postsynaptic cells (muscles) bear unique labels to which presynaptic (motoneuronal) growth cones respond during synaptic target recognition.

91.9

FASCICLIN III EXPRESSION DURING SYNAPTIC TARGET RECOGNITION IN *DROSOPHILA*. T. N. Chang, A. Chiba, D. Jay[§] & H. Keshishian. Dept. Biol., Yale Univ., New Haven, CT 06511 and [§]Dept. Cell. & Dev. Biol., Harvard Univ., Cambridge, MA 02138

Fasciclin III (fas III) is a cell surface glycoprotein proposed to function as a homophilic adhesion molecule. We find that it is expressed both by a subset of motoneurons and on specific ventral muscle fibers during *Drosophila* embryogenesis. Fas III is expressed by motoneurons RP1, RP3, and RP4, which innervate three ventral muscle fibers via the SNb nerve branch. Expression on their growth cones persists until synapses have differentiated. Fas III is also expressed on the surface of muscle fibers 6 and 7, at the site where the synapse of RP3 is made. Expression on the target surface is first detected at stage 15, when the initial contacts occur, but disappears by stage 17, after synapse formation. We are using genetic and cellular approaches to assess the role of fas III during synaptic target recognition. First, we are examining a mutant which lack fas III but has apparently normal CNS and musculature, by dye filling RP growth cones. Also we are using chromophore-assisted laser inactivation in wild-type embryos to functionally inactivate fas III at specific times during development. This technique allows us to focally denature the fas III antigen and closely associated proteins without causing cell damage.

91.11

AN EARLY MARKER FOR ADULT MUSCLE PRECURSORS IN *DROSOPHILA*. P.K. Rivlin, R.S. Edgecomb, C. Ghetti[†] and A.M. Schneiderman. Section of Neurobiology and Behavior, Cornell University, Ithaca NY 14853.

As part of an ongoing study investigating the development of the neuromuscular system in *Drosophila*, we are following the fate of the ad epithelial cells (AC) of imaginal discs, the presumptive precursors of adult muscle (Poodry & H. Schneiderman, 1970, Roux's Archiv, 166:1). One powerful tool for producing cell-specific markers is P-element mediated enhancer detection. Transposants which show β -galactosidase staining in embryonic mesodermal derivatives (Bellen et al., 1989, Genes Dev 3:8288) were obtained from the Hughes P-element *Drosophila* Stock Center (Bloomington IN) and evaluated as potential markers for AC. The β -gal-staining pattern in whole mount preparations of third instar leg, wing and haltere discs was analyzed. Of six lines evaluated only one, WG1054 ("A79.1M2," Bellen et al. 1989) showed staining of AC. The β -gal-staining pattern in WG1054 discs resembles that seen in discs stained with peanut agglutinin (PNA) (Rivlin et al., 1990, Soc Neurosci Abstr 16:177). β -gal-positive AC are spindle shaped and border the basal surface of the disc epithelium. In leg discs, these cells are distributed throughout the basal lumen. The β -gal-staining pattern in the wing and haltere discs, however, includes cells not previously seen in PNA-stained discs. In wing discs, they reside within a posterior region fated to give rise to pleural plates, cuticular structures ventral to the wing (Bryant, 1975, J Exp Zool, 193:49). Their shape and position suggests that these cells are also AC. Fewer β -gal-positive cells are present in haltere discs; they have a distribution resembling that of wing discs. Although WG1054 shows no staining of adult muscle, we will use this marker to study the ontogeny of ad epithelial cells and to trace their migration out of discs towards their target sites. (NSF BNS90-09833, NIH 5-T32-NS07303, NIH 5-T32-GM07469)

91.13

SPECIFICITY OF SYNAPTOGENESIS DURING REGENERATION OF AN IDENTIFIED NEUROMUSCULAR JUNCTION IN *HELISOMA*. M. J. Zoran, J. L. Rotter^{*} and P. G. Haydon. Dept. of Zoology and Genetics, Iowa State Univ., Ames, IA 50011.

Novel chemical connections form between neurons not normally connected in the buccal ganglia of *Helisoma* following axotomy (Haydon and Kater, 1988; J. Neurobiol. 19, 636). Buccal neuron 19 (B19), which normally innervates the supralateral radular tensor (SLT) muscle of the buccal feeding apparatus, is restricted in its formation of chemical connections during regeneration *in vivo* and in cell culture. Neuron B19 never forms novel chemical connections with neuronal targets. However, recent cell culture studies have demonstrated that B19 is capable of forming appropriate neuromuscular connections in cell culture (Zoran et al., 1990; Dev. Biol. 138, 202). The possibility that neuron B19 might form inappropriate chemical connections with novel muscle targets remains. Therefore, the objectives of the present study were to identify other appropriate and inappropriate muscle targets of this motoneuron and to describe the specificity of synaptogenesis during regeneration of neuron B19.

Electrophysiological studies of neuromuscular preparations demonstrated novel connections between neuron B19 and its SLT muscle target. In similar recordings, no evidence of connectivity was detected between B19 and buccal retractor (BR), anterior jugalis (AJ), posterior jugalis (PJ) and odontophore (ODT) muscles. *In vivo* regeneration experiments were performed surgically by crushing the heterobuccal and ventrobuccal nerves which contain the axons of neuron 19. During regeneration, B19 exhibited highly stereotyped pathfinding ability. Dye fills revealed that the sprouting neurites of B19 were discriminate in their selection of appropriate pathways and extended within discrete tracts in the buccal nerves. Stimulation of neuron B19 at this time of regeneration evoked excitatory junctional potentials (EJPs) in the SLT muscle fibers and elicited SLT muscle contractions. No inappropriate neuromuscular connections were detected between B19 and other buccal muscles. Cell culture studies are in progress to determine whether B19 can form novel neuromuscular connections.

91.10

CELLULAR AND DEVELOPMENTAL CHARACTERIZATION OF TWO ENHANCER TRAP LINES WITH EXPRESSION IN SPECIFIC EMBRYONIC *DROSOPHILA* MUSCLES. E. W. Harkins and H. Keshishian. Biology Department, Yale University, New Haven, CT 06511.

The embryonic *Drosophila* neuromuscular system is stereotypic in muscle pattern, neuronal ending location and morphology, connectivity, and cotransmitter expression. We are using Enhancer Trap mutagenesis to address the hypothesis that molecules specific to subsets of muscles fibers help establish aspects of this stereotypy either during muscle pattern formation or during growth cone recognition events. We have isolated several mutants with muscle expression of the reporter gene (β gal) during embryogenesis. We have further characterized two lines that express β gal in a very small subset of fibers. Line 3068 has bodywall expression in a pair of ventral muscles (#17 and 28) and one pleural transverse muscle (#24), as well as in several sensory cells. In addition, it is expressed in 3-4 cells per segment in the CNS. Expression is first observed in non-muscle cells at embryonic stage 12, before myoblast fusion has begun. The mutant is recessive lethal and maps to 56F-57A by *in situ* hybridization to polytene chromosomes. Line 4624 is expressed in one ventral muscle fiber (#17) in segments A2-A7, and in another single fiber each in A1 and A8. Expression is segmentally repeated in a pair of mesectodermal cells, but is strongest in 3 anterior segments. There is also expression in trachea and in the gut. A developmental analysis of this line is in progress. The mutation is viable, and maps to the right arm of the third chromosome.

91.12

EXTRAGENIC SUPPRESSORS OF *UNC-55*: A GENE INVOLVED IN NEURONAL DIFFERENTIATION IN *C. ELEGANS*. Marion Clein^{*} and W. W. Walthall. Dept. of Biology, Georgia State University, Atlanta, GA. 30302-4010

The VD and DD motoneurons (*mns*) of the roundworm *C. elegans* share very similar genetic programs; as a result they use the same transmitter, GABA, and they are morphologically indistinguishable. They differ in their lineal histories and their target specificities. Mutations in the gene, *unc-55*, specifically affect the VD *mns* by altering their pattern of synapses so that they become identical to the DD *mns*. The phenotype exhibited by homozygous *unc-55* mutants is to coil with the ventral side innermost when attempting to move backward, forward movement is essentially normal. Genetic strategies combined with an analysis of locomotory behavior have been employed to aid in the identification of mutations in genes that interact with *unc-55*. A maze was designed to aid in this search. The maze, whose structure was inspired by the benzene ring, is effective in enriching for noncoiler phenotypes. Typically 95 to 100% of wild-type animals navigate the maze and find the food in a 15 to 20 hour period. However, due to a number of blind alleys, 5% of *unc-55* animals are successful. The maze was used to select noncoiler animals from the F2 generation of mutagenized *unc-55* strains. Two recessive, X-linked suppressors have been obtained. When separated from *unc-55* both exhibit difficulties in moving backward but neither are coilers. Genetic and cellular analyses of these alleles are being pursued. Supported by the NSF (BNS-8911523A01).

INCREASE OF c-FOS AND RAS ONCOPROTEINS IN THE DENERVATED NEUROPIIL OF THE RAT DENTATE GYRUS. L.L. Phillips and E.T. Belardo, Division of Neurosurgery, Medical College of Virginia, Richmond, VA 23298.

When the entorhinal cortical (EC) input to the rat dentate gyrus is destroyed, the process of sprouting and synaptogenesis begins within the denervated neuropil. The present study used immunohistochemistry to determine whether there is an increase in c-fos and ras within the denervated neuropil of the dentate gyrus during terminal growth and synapse formation. Rats were perfused with paraformaldehyde fixative at 1, 6 and 30 days after unilateral lesion of the EC, and brain sections were incubated with antibodies to either c-fos or ras oncoprotein. At 1 day postlesion light microscopic analysis showed a moderate increase in both c-fos and ras proteins over the denervated zone. However, at 6 days postlesion we observed a marked increase in denervated zone labeling for each oncoprotein relative to intact contralateral and naive controls. The c-fos label over the denervated molecular layer was generally uniform, with interspersed punctate reaction product. Neuroglia contained the highest levels of c-fos oncoprotein. Granule cell nuclei were reduced in c-fos labeling at 1 and 6 days postlesion when compared to naive controls. By 30 days postlesion increased neuropil c-fos labeling was not visible and granule cell c-fos label was predominantly nuclear, as seen in naive controls. Ras oncoprotein localization at 6 days postlesion was also uniform over the denervated zone, with intermittent punctate labeling. As with c-fos, this selective label was not seen at 30 days postlesion. No cell nuclei labeling was observed with antibodies to ras protein. Additional method and antibody controls showed labeling to be specific for each oncoprotein. These results show that both c-fos and ras are increased within the denervated neuropil of the dentate gyrus during sprouting and synapse formation, supporting oncoprotein mediated changes in gene expression and membrane signal transduction during synaptogenesis. Supported by NIH grant NS27225 to L.P.

ACTIVITY-DEPENDENT SYNAPSE ELIMINATION AT THE VERTEBRATE NMJ *IN VITRO*. P.G. Nelson, C. Yu*, R.D. Fields and S.C. Fitzgerald*. Lab. of Developmental Neurobiology, NICHD, NIH, Bldg. 36, Room 2A21, Bethesda, MD 20892.

Mouse myotubes in the center compartment of "Campanot" chambers were innervated by axons from sympathetic ganglion neurons in two bilaterally symmetrical side compartments, or from ventral spinal cord neurons. Axons from each side can be stimulated for several days through extracellular electrodes. The efficacy of synaptic connections was monitored by observing contractions of myotubes in response to stimulating neurons from either side compartment, and by repeated intracellular recordings of synaptic potentials.

Functional cholinergic connections develop and are stable for several weeks in culture. Following 3-5 days stimulation at 30 Hz for 2 sec. at 10 sec intervals, 30% - 50% of the synaptic connections were eliminated ($p < 0.001$, chi-square, $n = 520$ muscle fibers). By Hebbian postulates the stimulated afferents in unilaterally stimulated cultures should be selectively retained. However, the probability of elimination was equal for stimulated and unstimulated inputs in unilaterally stimulated cultures (innervated by either ventral spinal cord or superior cervical ganglion neurons). Thus, elimination at this nmj is an activity-dependent process, but it does not follow Hebbian rules of synaptic plasticity.

KINASE MANIPULATIONS DISRUPT ACTIVITY-DRIVEN RETINOTOPIC SHARPENING IN GOLDFISH TECTUM. John T. Schmidt, Dept. Biol. Sci., SUNY-Albany, NY 12222

Regenerating optic axons form side branches and synapses over a wide area, and retinotopically appropriate synapses are stabilized through the activation of NMDA receptors that detect the coincident activity of neighboring ganglion cells making synapses onto the same tectal cell. Calcium entering through NMDA receptor channels triggers LTP by activating C-kinase and Cam kinase, and these experiments test whether kinase activation is necessary for synaptic stabilization during sharpening. Intracocular (IO) or intracranial (IC) injections of the phorbol TPA (50 μ M x 2 μ l in Ringers, ~1 μ M after dilution), which activates and down regulates C-kinase, were made every other day during the sensitive period (19-35days postcrush), and the projections formed were recorded. IO-TPA prevented sharpening and resulted in multiunit receptive fields that averaged about 26° vs 11° in Ringer controls. IC-TPA also prevented sharpening (29° multiunit fields), but did not unsharpen the mature projection on the opposite tectum. IC injection of kinase inhibitors H7 or sphingosine (4 μ l x 10mM, 200 μ M after dilution) prevented sharpening (27 and 30° multiunit fields). HRP staining of these arbors shows abnormalities in branching. Thus active formation of retinotopic order (vs maintenance—Cline and Const.-Paton, 1990) is sensitive to kinase inhibitors. In retinal explant cultures TPA treatment decreases the rate of elongation of growing axons and increases the probability of retraction. This is important since an inability to grow could explain the failure to disrupt preexisting eye-specific stripes. During sharpening there is an increased capacity for LTP triggered by NMDA receptors, and these experiments support the idea of a parallel dependence of LTP and sharpening on kinase activation. (Supported by NIH grant EY03736).

A NOVEL METHOD FOR FORMATION OF NEURAL NETWORKS IN CULTURE. A.Kawana, H.P.C.Robinson*, K.Torimitsu and Y.Jimbo*. NTT Basic Res. Labs. Musashino, Tokyo, 180 Japan

Culture systems of vertebrate neurons provide a useful method for studying the physiology of neurons and neural circuits in a simplified, controlled environment. However, networks formed by conventional methods are too complex to allow meaningful investigation of their physiology. Here, we describe a novel method for the construction of patterned neural circuits in cell culture, in which both the position of neurons and the direction of their neurite outgrowth are controlled.

A silica glass substrate with 150 X 150 μ m wells connected by 50 μ m wide microgrooves of 10 μ m depth and 200 μ m length was employed. A metal mask with 150 μ m diameter holes at corresponding positions to the substrate wells was laid over the substrate. A suspension of dissociated rat hippocampal neurons was plated over the metal mask and incubated for 30 min. Then, 2 ml of culture medium was added and the metal mask was removed. The cell density in the wells was controlled by varying the density of the suspension. After 2 or 3 days, neurons within the same well form synaptic connections, following which the neurites grow out from the wells along the microgrooves to form inter-well synaptic connections. The capability of thus imposing spatial and temporal order on the process of synaptic wiring should facilitate studies of the functioning of cultured neural circuits. Monitoring of neural activity in this culture system by optical methods and by electrodes embedded in the substrate will be discussed.

CHRONIC NMDA RECEPTOR BLOCKADE PREVENTS THE FORMATION OF SPINOCEREBELLAR STRIPES. J.M. Alisky and D.L. Tolbert Department of Anatomy and Neurobiology and Surgery (Neurosurgery), St. Louis University School of Medicine St. Louis MO 63104.

During the period of 3 to 7 postnatal days (PNDs), developing spinocerebellar (SpCb) projections in rats segregate into 5 sagittally oriented stripes in the anterior lobe (Nunes and Sotelo, '85). To test the hypothesis that NMDA receptor activation is required for segregation of SpCb afferents, NMDA receptors were chronically blocked with the competitive antagonist aminophosphovaleric acid (APV). Elvax implants containing 0.1 M APV were placed on the surface of the anterior lobe of the cerebellum at 3 PND. SpCb projections were labeled with injections of WGA-HRP into the thoracic-lumbar junction of the spinal cord, and rats were sacrificed at 16, 19, 21 and 23 PNDs. In transverse sections of control cerebella, labeled mossy fiber terminals formed five sharply defined sagittally oriented stripes with no interstripe label. In APV treated rats, incipient stripes were present but they were not sharply delineated and many terminals were present in interstripe regions. Desegregation of stripes occurred predominantly in the apical portions of lobules II-IV, closest to the APV-elvax implant. Deeper in the lobules there was a transition zone of moderate segregation, and in the most basal portions of anterior lobules, there were normal stripes. These findings suggest that NMDA receptor activation is necessary for the establishment of spinocerebellar stripes. Supported by NIH Grant NS20227.

ELECTRICAL ACTIVITY REGULATES THE EXPRESSION OF SYNAPSE-SPECIFIC GENES DURING NEURONAL DEVELOPMENT.

G. Alvarez-Bolado^{1,2*}, M.C. Lebeau^{1*}, O. Braissant^{1*}, W. Wahli^{1*} and S. Catsicas^{1,2}. ¹Institut de Biologie Animale, Université de Lausanne and ²Glaxo Institute for Molecular Biology, Geneva, Switzerland.

During synaptogenesis, cell-cell interactions between neurons and their targets are thought to induce the expression of specific sets of genes. Our goals are to determine the nature of these interactions and to study the molecular mechanisms involved in this process of gene regulation.

We have constructed 2 cDNA libraries from chick retina mRNA extracted at embryonic day 9 (E9) and E15 (i.e. before and after the onset of synaptogenesis) and we have then performed a subtractive hybridization, using the E9 PCR-amplified library as a driver, to isolate cDNAs present at E15 but not at E9. Several clones corresponding to mRNAs developmentally regulated during synaptogenesis were isolated. One such clone was found to encode SNAP-25, a nerve terminal protein expressed in subtypes of synapses. Early lesion of the optic tecta had no effect on the expression of SNAP-25 by retinal ganglion cells. In contrast, blockade of electrical activity with intraocular injections of TTX strongly reduced SNAP-25 expression. Similarly, the expression of the presynaptic protein synaptophysin was strongly reduced following the TTX injection, whereas β -tubulin expression was unaffected. These data suggest that electrical activity regulates the expression of proteins involved in synapse structure and function.

FACILITATION AT THE NEUROMUSCULAR JUNCTIONS OF ALLOTTRANSPLANTED NEURONS IN THE CRAYFISH. K. M. Krause and S. J. Velez. Department of Biological Sciences, Dartmouth College, Hanover, New Hampshire 03755.

The superficial flexor muscle system of the crayfish *Procambarus clarkii* has been used to analyze the factors that affect neurons as they make precise connections with their target cells. We had previously reported that the isolated ganglion that contained the somas of these cells could be successfully transplanted from one crayfish to another: the neurons survived, grew and formed new synaptic contacts with the denervated target muscle; as revealed by junction potential (jp's) sizes, the contacts assumed normal characteristics by eight weeks (Krause et. al., Soc. Neurosci. Abstr. 16: 489, 1990). We followed the progress of regeneration of these allotransplanted neurons using microelectrodes to test for jp's and suction electrodes to record and stimulate the nerve. As criterion for the maturation of the contacts, we measured the facilitation properties of the synapses (jp size at 10 Hz/jp size at 1 Hz). We found that by ten weeks the entire muscle field becomes innervated by more than one axon. Nerve stimulation has revealed that the newly established contacts do not facilitate, which suggests that these connections are not maturing normally. The lack of development of normal facilitation characteristics might be the result of the reduced level of spontaneous activity found in the isolated ganglion.

HORMONAL REGULATION OF MOTOR UNIT SIZE AND SYNAPTIC STRENGTH DURING SYNAPSE ELIMINATION. C.L. Jordan, P. Pawson, A.P. Arnold, & A.D. Grinnell, Psychology and Physiology Departments, UCLA, Los Angeles CA 90024. Our previous anatomical studies have implied that androgen treatment of juvenile male rats prevents some synapse elimination in the levator ani (LA) muscle of rats. The present study confirms this implication physiologically by demonstrating that such androgen prevents some of the ontogenetic decline in motor unit size in this muscle. The size of LA motor units was estimated in androgen-treated and control rats at 7-28 days after birth by measuring the twitch tension of individual motor units relative to the twitch tension of the whole muscle. Synaptic strength was also evaluated by measuring the ratio of tetanic and twitch tensions produced by individual motor units relative to the ratio of the whole muscle. The results indicate: 1) between 7 and 21 days, the size of LA motor units declines from 10.8 to 4.2%, and androgen treatment prevents some of this decline (10.8 to 6.9%); 2) between 7 and 14 days, the tetanic/twitch ratio drops from about 4 to 1, indicating that nearly 75% of all LA synapses are below threshold at 7 days, but virtually all synapses are above threshold by day 14; 3) androgen does not alter the tetanic/twitch ratio of motor units at any age examined. Thus, androgen prevents the normal decline in the size of motor units without altering the apparent strength of synapses. Supported by NS08686 and HD15021.

COLD STRESS CAUSES A REVERSIBLE LOSS OF PHOTORECEPTOR SYNAPSES IN THE FLY'S OPTIC LOBE. L.H. Brandstätter and L.A. Meinertzhagen. Life Sciences Centre, Dalhousie University, Halifax, Nova Scotia, CANADA B3H 4J1.

Synaptic contacts turn over in the adult nervous system and this must entail both their spontaneous formation and loss. Both the formation and loss of contacts occur in the first neuropile, or lamina, of the optic lobe in the adult fly, amongst the population of afferent tetrad synapses of the photoreceptor terminals. The rates of formation and loss are hard to establish however from changes in net frequencies. We have found that cold stress causes the rapid loss of synaptic junctions, a loss which is reversible, and have started to use the reversible effects of cold as a tool to perform a stop-flow analysis of synaptic turnover. Adult (2-3d) flies, *Musca domestica*, reared at 23°C were exposed to 0°C for periods up to 12hrs. Following this, the frequency of tetrad synapses, measured from the frequencies of the single-EM section profiles of presynaptic ribbons in > 250 terminals in 3 experimental animals, decreased by 20-30% after 12hrs, whereas 2hrs of cold produced no decrease. The effect is reversible; 24hrs after the flies had returned to 23°C the value had increased, returning to normal control values (n=170, 2 flies). This increase is highly significant. We hope with this method to resolve the rate of synapse formation during warm recovery, as the first step to dissecting the dynamics of synapse turnover.

Supplementing synaptic changes we also find that, following cold exposure, the frequency of the profiles of the receptor terminal mitochondria decreases and their shape elongates; the frequency of the profiles of capitate projections, glial invaginations of enigmatic function into receptor terminals, also decreases. These changes too are reversible, but unlike the synaptic changes they are not completely restored to control values by 24hrs at 23°C.

DEVELOPMENT OF TWITCH/TETANUS RATIOS DURING SYNAPSE ELIMINATION IN THE RABBIT SOLEUS MUSCLE. K. S. Cramer and D. C. Van Eszen, Division of Biology 216-76, California Institute of Technology, Pasadena, CA 91125

The study of motor unit development and diversity is essential for understanding motor function at the muscular level. Our experimental model, the rabbit soleus muscle, is polyinnervated at birth and eliminates excess synapses over the first two postnatal weeks. It contains both fast and slow motor units, which, even at early ages, are known to be distinguishable physiologically by their twitch rise times. We examine here fast and slow motor unit development using a different measure, the twitch/tetanus ratio (TTR). We find that TTRs change during synapse elimination, and that these changes are different for fast and slow motor units.

In the 4-5 day rabbit soleus, the mean TTR is $.24 \pm .01$ (s.e.m.) for fast units and $.29 \pm .01$ for slow units. At this age the slow units have a significantly higher TTR than fast units ($p < .01$). By 13-15 days, however, we find that fast motor units have significantly higher ratios than slow motor units, with means at $.35 \pm .02$ and $.21 \pm .01$, respectively ($p < .0001$). A similar distribution has been described for 17-18 day rat soleus (Thompson and Astrow, Soc. Neurosci. Abstr. 16: 331, 1990). Thus, during synapse elimination, fast motor unit TTRs increase while slow motor unit TTRs decrease.

Previous studies have suggested that the ratio of mean motor unit tensions at polyinnervated versus singly innervated ages gives a useful estimate of the overall degree of polyinnervation for fast and slow muscle fibers at the early age. However, since TTRs change with age, this ratio yields conflicting estimates depending on whether the estimates are based on twitch vs tetanic tension. Consequently, more direct methods will be needed in order to obtain reliable measurements of polyinnervation by fiber type.

92.10

THE NUMBERS OF PHOTORECEPTOR SYNAPSES IN THE FLY'S OPTIC LAMINA REVEAL DAY/NIGHT (CIRCADIAN?) CHANGES. Elzbieta Pyza* and L.A. Meinertzhagen. Life Sciences Centre, Dalhousie University, Halifax, Nova Scotia, Canada B3H 4J1.

The receptor cells of the arthropod compound eye exhibit many circadian rhythms, most notably in the turnover of their photoreceptive membranes; do such rhythms also exist in their output region, the synaptic terminals? To address this question we have examined the frequencies of synaptic contacts in the first visual neuropile, or lamina, of the optic lobe in the fly *Musca domestica*. Two synapses have been compared: the afferent tetrad synapses formed upon two interneurons, L1 and L2, and their reciprocal feedback counterparts from L2, formed back upon receptor terminals; both were measured from the frequencies of presynaptic ribbon profiles in single EM sections.

In the L2 feedback synapses there is a remarkable change in frequency during the normal day/night cycle, with 80% more synaptic contacts in the night. Since this difference could be a function either of light or of a circadian rhythm, flies previously entrained to a reversed light/dark cycle were then reared in constant darkness for three days. The frequencies were also found to be higher in the fly's subjective night, which suggests a strong endogenous influence upon synaptic frequency. Compared with the values in constant darkness, there was no significant difference when the flies received 1hr of light (in either their subjective night or in their subjective day), relative unimportance of light exposure.

In the afferent tetrad synapses similarly there is a day/night change in frequency, but in that case the frequency is 20% lower in the night, and the relationship between the effects of light and possible circadian rhythms is more subtle. The functional significance of the changes in either of these synapses is not clear.

Supported by NIH grant EY 03592 and the Canadian Centre of Excellence in Neural Regeneration and Functional Recovery.

REGULATION OF PARASYMPATHETIC NERVE DENSITY BY SYMPATHETIC INNERVATION DURING DEVELOPMENT. Peter G. Smith and Chad E. Sharp*. Department of Physiology, University of Kansas Medical Center, Kansas City, KS 66103

The influence of sympathetic innervation upon development of parasympathetic nerve density was examined in the rat tarsal muscle, a smooth muscle target where both autonomic components are accessible for surgical manipulation. In preliminary studies, the specificity of acetylcholinesterase (AChE) histochemistry for parasympathetic nerves was determined. Ipsilateral superior cervical ganglionectomy 7 days prior to sacrifice resulted in a 39% decrease in AChE nerve density, indicating that sympathetic fibers contain this enzyme. Ipsilateral superior cervical ganglionectomy concurrent with ipsilateral pterygopalatine ganglion excision resulted in an essentially complete loss of AChE-positive fibers after 7 days, indicating that non-sympathetic AChE-positive fibers represent parasympathetic nerves originating in the pterygopalatine ganglion. The influence of sympathetic innervation on parasympathetic nerve density was investigated by bilaterally excising the superior cervical ganglia on postnatal day 5 and quantitating AChE-positive nerve density at 4 months of age. Tarsal muscles with persistent sympathetic denervation, as confirmed by absence of catecholamine histofluorescence, displayed a 46% reduction in AChE-positive nerve density as compared to acutely sympathectomized controls. It is concluded that sympathetic nerves act by direct or indirect means to enhance parasympathetic nerve proliferation within this target. Supported by NS23502.

RELATIONSHIP OF SYNAPSE DENSITY TO GROWTH IN A CRUSTACEAN MUSCLE. S.E. Huestis*, J.P. Walrod* and C.K. Govind. *Dept. Anatomy and Neurobiology, Colorado State University, Fort Collins, CO 80523 and Life Sciences Division, University of Toronto, 1265 Military Trail, Scarborough, Ontario, M1C 1A4 Canada.

Growth-related changes in synapse number and distribution were investigated for the single inhibitory and excitatory motor neurons innervating lobster (*Homarus americanus*) Distal Accessory Flexor Muscles (DAFM). Both the excitator and inhibitor release more neurotransmitter onto the most distal muscle fibers than onto the most proximal muscle fibers. To regulate differences in the amount of transmitter released, the inhibitor forms more synapses distally than proximally whereas the excitator forms similar numbers of synapses in the two regions with larger active zones on the distal fiber bundle. In the present study, inhibitory axon terminals were visualized with an antibody against the neurotransmitter, γ -aminobutyric acid (GABA), linked to horseradish peroxidase or a fluor. Axon terminal varicosities, the sites where most of the inhibitory synapses are located, were counted on individual muscle fibers. Varicosity number was normalized to muscle fiber surface area to measure the synapse density. During growth, the total varicosity number and muscle surface area increases, indicating that the inhibitor makes additional synaptic contacts to accommodate the increased muscle size. Therefore, synapse density in sexually immature animals (50-420 gm) remains constant. These studies suggest that the inhibitor forms new synapses to match the increased surface area of the muscle. After sexual maturity the muscle fiber area outpaces synapse addition. Although the relationship of excitatory synapse number to growth is unknown, the size of the excitatory active zone increases with growth on the distal muscle fiber. However, active zone size remains constant in the excitatory synapses on the proximal bundle as well as in all of the inhibitory synapses. The mechanisms used to regulate differences in the amount of transmitter released regionally may be similar to those used during growth.

92.15

DIFFERENTIAL PROLIFERATION OF AXOSOMATIC SYNAPSES IN THE NEONATAL RAT CILIARY GANGLION G.N. Robertson and P.C. Jackson. Department of Anatomy, Dalhousie University, Halifax, N.S., Canada B3H 4H7

During the development of autonomic ganglia the general pattern of connections changes such that neurons in the adult receive fewer inputs, yet more synapses, than those of the neonate. Physiological evidence suggests that some initial inputs are withdrawn, while the remainder consolidate their innervation through continued synaptogenesis. To determine the effect of this change upon synaptic populations, we examined the synapses between preganglionic neurons and cell bodies in the ciliary ganglion. Each preganglionic axon makes synapses with the cell body (Forehand, 1987, J. Neurosci. 7:3274). The number, structure and location of axosomatic synapses in the rat ciliary ganglion was examined at one, three and eight weeks of age. The number of synapses increased approximately four-fold between one and three weeks and changed little thereafter. We found four distinct types of synapse; one type completely accounted for the increase in total number.

In the neonate the synapses tended to be uniformly distributed over the cell body. By three weeks of age however, five times as many synapses were found under the perinuclear glial lamella (glial "cap"); elsewhere on the cell body the glial lamella was attenuated (glial "cover") and invested far fewer synapses. The frequency of synapse types within the total population was similar in both cap and cover regions. Thus not only is the glial cap a preferred region for synaptogenesis in early postnatal development, there is a differential proliferation of one specific type of synapse.

DISTRIBUTION OF DORSAL ROOT AFFERENT BOUTONS ON MOTOR NEURONS IN DEVELOPING MAMMALIAN SPINAL CORD. W.D. Snider, Li Zhang, S. Yusoof, A. Konstantinidou. Dept. of Neurology, Washington Univ. Med. School, St. Louis, Mo. 63110

The interactions between afferent axons and their specific target cells during development have not been well characterized. In order to address this issue in mammals we have utilized the simple system of monosynaptic contacts between group I muscle afferents and spinal motor neurons in the rat. We have labelled dorsal root afferents with DiI and spinal motor neurons with DiA. We show that dorsal root afferent axons enter the spinal cord at E15 in fasciculated bundles. Spatially separate bundles in the dorsal horn converge in the intermediate zone, then fan out to innervate various motor pools. In general, spatial relationships apparent in the intermediate zone are maintained on the way to the motor pools. Dorsal root axons destined for axial pools grow directly to their appropriate motor pool without the benefit of guidance by dendrites. Those destined for limb motor pools pass through a region densely populated by motor neuron dendrites. Whether contact with these dendrites is important in the development of appropriate specificity is not yet clear.

Starting at E17 dorsal root axons give off branches with increasing intensity through the first postnatal week. A striking feature of these branches is that they are invariably directed towards rather than away from motor neuron somata. Thus even though axons are in close proximity to dendrites which project for long distances dorsally or medially, the afferents grow towards the somata rather than growing distally along these dendrites. Higher order branching and bouton formation occurs almost exclusively in the area of the motor neuron somata and proximal dendrites, at least through PN5.

We conclude that dorsal root afferents have their initial interactions with the somata and proximal dendrites of their target motor neurons. This occurs despite the fact that motor neurons have elaborated extensive and lengthy dendrites prior to the arrival of dorsal root afferents. Whether this pattern is typical of other spinal afferent systems is currently under investigation.

SYNAPTOGENESIS IN IDENTIFIED SPIKING LOCAL INTERNEURONES OF THE LOCUST SCHISTOCERCA GREGARIA. Leitch, B., Laurent, G., & Shepherd, D.* University of Cambridge, UK.

The development of synapses on identified spiking local interneurons in the thoracic ganglia of embryonic locusts was examined using intracellular horseradish peroxidase (HRP) injection and electron-microscopy. In adult locusts, spiking interneurons of the midline group receive direct inputs onto a ventral field of branches from leg hair afferents and in turn makes output synapses from a dorsal field of branches directly upon leg motor neurons, nonspiking local interneurons and intersegmental interneurons. The aim of this study was to examine the development of these connections.

Formation of the major branches occurs during 55-70% embryogenesis and is followed at 70-80% by an elaboration of this branching. Subsequently, there is a period of maturation during which the number and length of the branches are pruned to produce the adult pattern. Mature synapses are first evident on the interneurons at 70-75% development coincident with the time of arrival of the majority of afferents into the CNS. At this stage most of the ventral synapses are outputs. By 85-90% development output synapses still predominate but, the ratio of outputs to inputs is reduced from 15:2 to 4:1. Dorsal branches have predominantly output synapses from 70% embryogenesis, onwards. The work was supported by a SERC (UK) Rolling Grant awarded to Prof. M. Burrows.

ISTHMOCTECTAL SYNAPSES IN DEVELOPING XENOPUS FROGS. S.B. Udin, M.D. Fisher*, & J.J. Norden. Dept. of Physiol., SUNY, Buffalo, NY 14214 and Dept. of Cell Biol., Vanderbilt Medical School, Nashville, TN 37232.

During the development of binocular maps in *Xenopus* tectum, axons which relay input from the ipsilateral eye via the nucleus isthmi undergo a prolonged period of shifting connections concomitant with the dorsofrontal shift of the eyes. Isthmoctectal axons arborize densely in the rostral region but also extend sparser branches into the caudal zone, which is occupied by retinotectal inputs with receptive fields in the monocular zone of the visual field. Establishment of matching binocular maps entails activity-dependent stabilization of isthmoctectal axons which exhibit firing patterns correlated with those of nearby retinotectal axons. Synaptic communication is hypothesized to be essential for this process. We therefore have used electron microscopy to investigate whether isthmoctectal axons make morphologically identifiable synapses during development and whether such synapses occur throughout the tectum.

HRP was injected into the left nucleus isthmi in order to fill isthmic inputs to the right tectal lobe. We found that all regions of the tectum contain morphologically identifiable synapses, along with many growth cones and structures that may be immature synapses. As in the adult, the synapses contain round, clear vesicles, have asymmetric specializations, and terminate on structures which appear to be dendrites. These results indicate that synaptically-mediated interactions may promote stabilization of appropriate isthmoctectal connections and withdrawal from inappropriate regions of the tectum during development.

PERIPHERAL INFLUENCE ON MUSCLE AFFERENTS AND MOTONEURONS. P. Wenner, C. Lance-Jones and E. Frank. Dept. of Neurobiology, Anatomy and Cell Science, Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA 15261.

How are neurons specified during development to make their appropriate connections? Previously we have found that the central projections of muscle spindle afferents are influenced by the location of their peripheral axons; thoracic sensory neurons forced to supply a limb make novel but functionally appropriate connections with limb motoneurons. In this study we specifically ask if muscle sensory neurons are influenced to make central connections with motoneurons directly by the muscle they supply; similarly, are motoneurons also influenced by their target muscle?

In order to answer these questions we created chicks which had a double complement of dorsal muscle in the thigh. The ventral half of the limb bud is replaced by a dorsal half from a similarly staged embryo (sl. 17-19), (Lance-Jones, 1986). Motoneurons and muscle afferents which would normally have innervated ventral muscle now innervate donor dorsal muscle; in the same animal dorsal motoneurons and muscle afferents project to their normal host dorsal muscles. Do dorsal motoneurons in these embryos receive direct input from afferents that would normally have been antagonistic, but are now supplying dorsal muscle? Furthermore, do ventral motoneurons receive direct input from normal dorsal afferents?

Muscle sensory input to lumbosacral motoneurons was assessed using intracellular recordings from isolated spinal cords. In normal embryos ventral motoneurons do not receive direct input from dorsal afferents, and dorsal motoneurons do not receive direct input from ventral afferents. In dorsal-dorsal duplications, normal dorsal motoneurons now do receive direct input from muscle afferents supplying dorsal muscle but traveling with ventral motoneurons, suggesting that muscle afferents recognize their specific motoneuron partners based on the peripheral muscle they supply. In the two best preparations to date, ventral motoneurons innervating dorsal muscle received strong direct input from normal dorsal afferents, suggesting that motoneurons are also influenced by their target muscle. (Supported by NSF to EF).

CHANGES IN PHENOTYPIC PLASTICITY OF SENSORY NEURONS DURING DEVELOPMENT. S.C. Mears, S. Donahue*, and E. Frank. Depts. of Neurobiology, Anatomy, & Cell Science and *Ophthalmology, University of Pittsburgh School of Medicine, Pittsburgh, PA 15261.

During development in tadpoles, populations of sensory neurons are influenced by their peripheral projections to make appropriate synaptic connections within the spinal cord. If a thoracic nerve is rerouted peripherally and joined to the adjacent brachial nerve, then sensory neurons in the thoracic ganglion, which in adult frogs contains no muscle spindle afferents, are made to innervate limb muscles. When this manipulation is performed in young tadpoles, the central axons of the rerouted afferents project into ventral laminae of the dorsal gray matter where they make synaptic contacts with limb motoneurons, something that thoracic sensory neurons never do in normal frogs. We find that this plasticity is lost as development proceeds. If the same manipulation is made at late tadpole stages, rerouted thoracic afferents do not form these ventral spinal projections. What factors underlie this loss of developmental potential?

One possibility was that mature sensory neurons lose their ability to innervate muscle spindles and arborize within ventral spinal laminae, even ones that are "committed" to being spindle afferents. We tested this idea by transplanting lumbosacral sensory ganglia, which do contain muscle afferents, to the brachial level in juvenile frogs, well after the period of developmental plasticity has ended. Peripherally, these transplanted ganglia formed stretch-sensitive endings in limb muscles and centrally they projected deeply into ventral laminae of the dorsal horn, just as normal spindle afferents do. Thus mature muscle afferents are still able to reform appropriate peripheral and central projections.

Alternatively, there may be some change either in the environment surrounding sensory neurons or in the neurons themselves that makes further phenotypic specification unlikely. For example, during this developmental period, white matter tracts in the spinal cord become refractory to further axon growth, and sensory neurons have stopped proliferating and are undergoing naturally occurring cell death. Current experiments are designed to discriminate between the effects of developmental age on the sensory neurons directly and on their environment by heterochronic transplantation of late stage thoracic ganglia into young tadpoles.

THE DISTRIBUTION OF AFFERENT AXONS AND THE SYNAPTIC FORMATION IN THE SINGLE AND COMBINED CULTURES OF POSTNATAL RAT CEREBRUM. T. SHIRAI*, T. SHIGA AND K. KITAO*. Dept. of Anat., Yamagata Univ. Sch. of Med., Yamagata 990-23, Japan.

We studied the pathway of afferent axons and the synaptic formation in the single and combined cultured cerebral explants to examine the role of afferent axons on the formation of synaptic organization. We cultured a slice of cerebrum alone and that of cerebrum with that of cerebrum, thalamus, cerebellum or spinal cord from rat at one day after birth in a CO₂ incubator for 21 days, and observed cerebral explants as follows: 1) We labeled cerebral afferent axons derived from neurons in the explants of another cerebrum, thalamus, cerebellum or spinal cord with DiI. These DiI labeled axons showed many varicosities and were distributed in the cerebral explants with several branchings. 2) We observed the cerebral explants with the electron microscope. Axo-somatic, axo-dendritic and axo-dendro-spinous synapses were found in the single and combined cultures of newborn cerebrum. These results indicate that the cerebrum of newborn rat may form the synaptic organization of the developed cerebral cortex in the organotypic culture.

SYNAPSE FORMATION BETWEEN DORSAL ROOT GANGLION AFFERENTS AND SPINAL CORD MOTONEURONS *IN VITRO*.

K. Sharma* and E. Frank. Dept. of Neurobiology, Anatomy and Cell Science, Univ. of Pittsburgh, Pittsburgh, PA 15261.

During development sensory neurons establish highly specific sets of synaptic connections with neurons in the spinal cord. For example, muscle spindle afferents make monosynaptic connections with motoneurons whereas cutaneous afferents do not, even though both cell types use glutamate as a transmitter. To begin to understand the mechanisms responsible for this specificity, we have sought to establish an *in vitro* system where the formation of specific connections can be studied in more detail than is possible *in vivo*.

Sensory and motor neurons from chick embryos are grown in a 3-compartment chamber system ("Campanot chamber") as originally adapted for sensory and spinal neuron culture by Nelson *et al.* (1989). Motoneurons retrogradely labeled *in ovo* with Dil are plated on a layer of E6 chick spinal astrocytes in the central compartment and small DRG explants are placed adjacent to the chamber walls in the two side compartments. An important modification of earlier methods is the use of low melting point agarose under the Teflon chamber walls and in the two side compartments to prevent bulk flow and cell migration between compartments.

Processes from sensory neurons begin to appear in the central compartment after 2 days and these neurites cover the entire compartment (2 mm wide) by 4 days. Early neurite growth in this culture system results in the development of synaptic connections within 5 days, a time at which retrogradely labelled motoneurons can still be identified. The extensive neurite growth also results in strong mono- and poly-synaptic connections with definitive motoneurons. By culturing different classes of sensory neurons in the 2 side chambers it should be possible to determine if these different classes have different synaptic affinities for motoneurons.

FORMATION AND SPECIFICITY OF SYNAPSES IV

93.1

SUBCELLULAR LOCALIZATION AND BIOCHEMICAL CHARACTERIZATION OF A NEUROMUSCULAR JUNCTION-SPECIFIC ANTIGEN. S.H. Astrow and W.J. Thompson. Dept. of Zoology, Univ. of Texas, Austin, TX 78712.

Last year we reported the identification of a subsarcolemmal, innervation-dependent component of the rat neuromuscular junction using a monoclonal antibody designated 3G2 (mAb 3G2). We have now examined in greater detail the localization of the antigen recognized by mAb 3G2 at adult junctions and within developing muscle fibers. At adult junctions, mAb 3G2 immunoreactivity lies beneath the acetylcholine-rich synaptic gutters, but is also present in sarcoplasmic protrusions located between, or at the edges of, the synaptic gutters. Deeper within fibers, mAb 3G2 immunoreactivity surrounds sole plate nuclei and enters the Z-lines. Overall, the pattern is similar to that reported by Sealock *et al.* (*Synapse*, 3:315) for the distribution of desmin. However, mAb 3G2 immunoreactivity is different from that for desmin in several respects: mAb 3G2 labels perijunctional Z-lines only (whereas an anti-desmin mAb reacts with both junctional and extrajunctional Z-lines, as expected), the expression of desmin is not substantially altered in denervated muscle fibers, and pre-adsorption of anti-desmin mAbs with an intermediate filament-enriched preparation removes anti-desmin immunoreactivity, whereas a similar pre-adsorption of mAb 3G2 is ineffective. In neonatal muscle fibers, mAb 3G2 immunoreactivity is found at myotendinous junctions where it forms a reticular network surrounding developing myofibrils. Differential extraction of muscle proteins, followed by Western blotting suggest that mAb 3G2 immunoreactivity is associated with a highly insoluble fraction of neonatal muscle.

INFLUENCE OF BASIC FIBROBLAST GROWTH FACTOR ON ACETYLCHOLINE RECEPTORS IN CULTURED MUSCLE CELLS. Zhengshan Dai* and H.B. Peng. Dept. of Cell Biology and Anatomy and Curr. in Neurobiology, Univ. of North Carolina, Chapel Hill, NC 27599.

The acetylcholine receptors (AChRs) in cultured *Xenopus* muscle cells consist of a high-conductance type and a low-conductance type. The low-conductance channels undergo a remarkable decrease in burst duration during development (Leonard *et al.*, *Science* 226:55,84; Rohrbough *et al.*, *J. Physiol.* 425:245,90). Recently we showed that basic fibroblast growth factor (bFGF), when locally applied, can mimic the effect of nerve in inducing a postsynaptic-type development. In this study, we examined whether this growth factor can influence the kinetics of AChRs. Patch clamp method was employed to record single AChR channel currents elicited by 200nM ACh from cultured *Xenopus* muscle cells. In control cultures, we observed a 3-fold decrease in burst duration of low-conductance channels between the first and second day in culture. In contrast, cultures treated with 1µg/ml bFGF at an early time (stage 23) showed only a 1.5-fold decrease in burst duration during the same period. Histogram analyses showed that the low-conductance channels were composed of a fast and a slow component and the decrease in burst duration is due to a shift in the population from the slow to the fast. bFGF appeared to slow down this shift by prolonging the lifetime of the slow channels. In older cells (stage 40) that already expressed predominantly short channels, bFGF treatment had no effect on the burst duration. These data suggest that bFGF may enhance the stability of low-conductance AChRs with long burst duration. This effect seems to parallel the stabilization of junctional AChRs at the innervated endplate. Thus, bFGF, or a related polypeptide growth factor, may mediate this and other innervation-induced changes in the postsynaptic membrane. 93.3

REGULATION OF POSTNATAL CHANGES IN SUBUNIT COMPOSITION OF ACETYLCHOLINE RECEPTORS AT NEUROMUSCULAR JUNCTIONS OF NORMAL AND MED MICE. C. Gary Reiness and Peter M. Colowitz* Dept. of Biology, Pomona College, Claremont, CA 91711

To study whether muscle activity regulates subunit composition of ACh receptors (AChRs) at developing neuromuscular junctions (nmjs), we stained random cryostat sections of biceps brachii muscles from normal mice and mice with motor endplate disease (med) with an antiserum specific for γ (embryonic) subunits of AChR (Gu and Hall, *Neuron*, 1:117 (1988)) and with rhodamine α -bungarotoxin to reveal all AChR clusters at nmjs.

In 3-6 d med or normal mice about half the nmjs stain for the γ subunit (84/173 med; 62/133 normal). By 10-12 d few nmjs contain the γ subunit (2/225 med; 0/157 normal). Thus AChRs at nmjs of both med and normal mice switch from embryonic to adult forms postnatally. Shortly after the onset of inactivity in the med mice (10-12d), there is a return of detectable γ subunits (15d, 12/112 nmjs; 18-20 d, 87/315 nmjs; >20 d, 26/122 nmjs). Since older med muscles are inactive but innervated, this finding shows that inactivity alone is sufficient to cause synthesis and insertion of embryonic AChRs. In normal mice there was also a transient reappearance of embryonic AChR at a small but significant fraction of nmjs at the end of the third postnatal week (15d, 0/77 nmjs; 18-20d, 19/504 nmjs; >20 d, 0/63 nmjs). We suggest that this may be caused by a brief period of inactivity in some fibers, endplates or regions of endplates in normal developing muscles.

TYROSINE PHOSPHORYLATION AT ACETYLCHOLINE RECEPTOR CLUSTERS INDUCED BY A VARIETY OF STIMULI IN CULTURED XENOPUS MUSCLE CELLS. L.P. Baker and H.B. Peng. *Curr. In Neurobiology & Dept. of Cell Biology and Anatomy, Univ. of North Carolina, Chapel Hill, NC 27599.*

Our recent work has demonstrated the effectiveness of basic fibroblast growth factor (bFGF)-coated beads in inducing acetylcholine receptor (AChR) clustering in cultured *Xenopus* muscle cells (*Neuron* 6:237, 1991). A tyrosin tyrosine kinase inhibitor blocks the formation of clusters by these beads, indicating the involvement of a specific receptor tyrosine kinase. Using two monoclonal antibodies against phosphotyrosine (PY20 and 4G10), we found by immunocytochemistry the distinct accumulation of phosphotyrosine at AChR clusters induced by a variety of stimuli, including nerve, beads, culture substrate ("hot spots"), and electric-field. External crosslinking of AChRs with biotinylated α -bungarotoxin followed by fluorescently conjugated avidin results in the formation of visible "microclusters" which do not exhibit this phosphotyrosine labeling. Using beads as temporally and spatially controllable stimuli, an early phosphotyrosine accumulation is observed in the absence of detectable rhodamine- α -bungarotoxin labeled AChRs at 10% of bead-muscle contacts within 15 minutes of bead application. AChR clustering becomes visible and colocalized with phosphotyrosine at 20% of bead-muscle contacts within 30 minutes. This colocalization increases in number as well as fluorescence intensity to reach a plateau level within 24 hours. These results suggest (1) AChRs in the diffuse or unclustered state are not tyrosine phosphorylated, (2) tyrosine phosphorylation is induced by the application of clustering stimuli and is a feature of AChR clusters in general, and (3) the accumulation of tyrosine phosphorylated protein(s) other than or in addition to the AChR may play a critical role in the initial formation of AChR clusters. COMPLEX EXTRACELLULAR MATRIX INCREASES VESICLE DENSITY IN SYNAPTIC PROFILES OF CULTURED SYMPATHETIC NEURONS. M. Loegering*, D. Higgins¹, and M.I. Johnson. Univ. of Ariz. Col. of Med., Tucson, AZ 85724 and SUNY², Buffalo, NY 14222.

Extracellular matrix plays an important role in the development and regeneration of neuromuscular junctions. This study explores its role in the development of synaptic varicosities by autonomic neurons. Embryonic rat superior cervical ganglion neurons were dissociated, plated onto a polylysine substratum and maintained in serum-free media. Non-neuronal cells were eliminated by treatment with antimitotic agents. Control cultures remained on defined media; experimental cultures received 50 μ g/ml of Matrigel (Collaborative Research, Inc.) in serum-free media. After three weeks in vitro the cultures were fixed with 2% glutaraldehyde and processed for electron microscopy. Varicosities photographed randomly at high power on the electron microscope were compared. Control boutons had 40.6 ± 6.2 vesicles per μ m² (mean \pm S.E.M.) vs 109.5 ± 16.5 vesicles per μ m² in the Matrigel treated cultures ($p < 0.005$). Quantification of the size of the profiles indicates that control varicosities are larger than those treated with Matrigel, suggesting that one mechanism by which vesicle density is increased may be induction of vesicle formation from the nerve terminal membrane. Preliminary studies also indicate that there is a clustering of varicosities on and near the soma of neurons treated with Matrigel [supported by grants NIH-NS15070 (MIJ), and NSF-BNS8909373 (DH)].

AN ACETYLCHOLINE RECEPTOR INDUCING ACTIVITY INCREASES THE NUMBER OF Na⁺ CHANNELS AND AChRs IN CHICK CULTURED MYOTUBES AND MYOBLASTS. G. Corfas and G.D. Fischbach. Dept. of Neurobiology, Harvard Medical School, Boston, MA.

ARIA, an AChR inducing activity purified from chick brain, promotes an increase in synthesis and insertion of AChRs in cultured myotubes. It has been proposed that ARIA may play a role in the formation of the neuromuscular junction. To determine whether ARIA increases the expression of other proteins concentrated at the neuromuscular junction, we have analyzed the effect of ARIA on voltage-sensitive Na⁺ channels (which *in vivo* are concentrated at the endplate) in cultured myotubes. ARIA treatments that increased the total number of AChRs (as measured by [¹²⁵I]- α -bungarotoxin (BTX)) by a factor of 2.4 in multinucleated myotubes, also increased [³H]-saxitoxin binding by a factor of 2. The increase in saxitoxin binding was not accompanied by changes in the single channel properties (mean open-time, conductance and voltage-dependence of activation) as measured in cell-attached patches. The number of channels/patch was low and variable, so differences in the number of Na⁺ channels were not obvious. However, changes in the number of Na⁺ channels could be measured reliably by voltage-clamp in whole-cell recordings of mononucleated myoblasts. Therefore, we first documented that ARIA did increase the rate of insertion (synthesis) of AChRs in myoblasts. Increases in [¹²⁵I]-BTX binding of 1.5 - 2 fold were reliably detected after 48hrs of exposure to ARIA by γ counting and autoradiography. The effect could not be explained by changes in cell size. Whole-cell Na⁺ currents were also increased by 1.5 fold after 48hrs of ARIA treatment. No change in voltage dependence of I_{Na} was evident. We conclude that ARIA increases the number of Na⁺ channels in myotubes and myoblasts, and that the increase is comparable to the increase in the number of AChRs.

93.6

AGRIN BINDING TO NEURONS OF THE EMBRYONIC CHICK SPINAL CORD. M.A. Nastuk and J.R. Fallon. Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545.

Aggrin plays a well-established role in the clustering of AChRs on cultured myotubes, and is thought to direct postsynaptic differentiation at neuromuscular junctions. Recent evidence indicates that the muscle cell surface agrin receptor is distinct from the AChR, and co-aggregates with it during agrin-induced clustering. It is not known whether agrin also serves to direct the differentiation of neuronal synapses. As a first step toward investigating this question, we have asked whether neurons express agrin binding sites. Dissociated embryonic (ED 9-10) spinal cord cells were incubated briefly with *Torpedo* agrin. The distribution of bound agrin was assessed with immunofluorescence microscopy. Neurons were identified based on their morphology and positive staining for synaptic vesicle protein. A subpopulation of the neurons were found to display agrin binding sites on their surfaces. The distribution of agrin binding sites is punctate, resembling that seen on myotubes. The majority of agrin binding is calcium dependent: staining is markedly reduced when extracellular calcium is chelated from the incubation solutions with EGTA. To learn whether the neuronal agrin binding sites can redistribute in response to prolonged agrin exposure, we incubated cultures with agrin for 14-16hr at 37°C. A subset of the stimulated neurons exhibit ligand-induced aggregation of agrin binding sites. These results suggest that a population of spinal cord neurons expresses an agrin receptor, and raise the possibility that agrin participates in directing synaptic differentiation in the central nervous system. Activity Dependent Changes In Neurotrophin Expression In Rat Hippocampal Slices. S.L. Patterson¹, L.M. Grover^{1,2}, M. Bothwell¹, and P.A. Schwartzkroin^{1,3}. Dept. Physiology & Biophysics¹, Dept. Psychology² and Dept. Neurological Surgery³, University of Washington, Seattle, WA 98195.

Hippocampal neurons are known to be a major CNS site of expression for the neurotrophins - nerve growth factor (NGF), brain derived neurotrophic factor (BDNF), and neurotrophin 3 (NT3). However, relatively little is known about the factors modulating their expression. The expression of NGF mRNA in hippocampal neurons is dramatically enhanced by experimentally induced seizure in rats (Gall and Isackson, 1989) and it is reasonable to suppose that neurotrophin expression may also be modulated by other, more "physiological" activity. The hippocampal slice preparation offers unique advantages for studying the role of specific neuronal activity and neuromodulatory substances in the regulation of neurotrophin expression. We have established that appropriate patterns of neurotrophin expression are observed when *in situ* hybridization is performed upon hippocampal slices after several hours in the slice chamber. Experiments are currently in progress to determine if the induction of long term potentiation (LTP) in the CA1 pyramidal cell layer results in changes in neurotrophin levels. Preliminary results suggest that there are activity dependent changes in levels of neurotrophin expression in rat hippocampal slices.

SEIZURES DECREASE NT3 mRNA LEVELS IN HIPPOCAMPAL AND CORTICAL NEURONS. C.M. Gall, R.T. Bonk, and P.J. Isackson. Dept. of Anatomy and Neurobiology, Univ. of Calif., Irvine, CA 92717.

Seizure activity stimulates rapid increases in the expression of mRNAs for NGF and BDNF in hippocampal and cortical neurons suggesting that activity-dependent regulation is an intrinsic property of the NGF-family of neurotrophic factors. In the present study, the influence of recurrent limbic seizures on neurotrophin 3 (NT3) mRNA expression in rat forebrain was examined using *in situ* hybridization and S1 nuclease protection analyses and compared to the effects on the NGF and BDNF mRNAs.

Experimental rats received a unilateral electrolytic lesion in dentate gyrus hilus. This treatment induces recurrent, bilateral EEG seizures in hippocampus and behavioral seizures from 2 to 12 hrs postlesion. Perfusion fixed tissue sections through forebrain of hilus lesion (HL) and paired control rats were processed for *in situ* hybridization with ³⁵S-labeled rat NT3 cRNA. In control rats, hybridization labeled neurons of hippocampal stratum granulosum and CA2 stratum pyramidale, caudal olfactory cortex, amygdala, and caudolateral neocortex. In HL rats, hybridization was slightly increased in stratum granulosum by 3 hrs postlesion but by 12-48 hrs post-HL had declined to ~10% control values in the granule cells and was markedly reduced in neocortex and amygdala. By 6 days post-HL, hybridization had increased in str. granulosum but remained below control values. In contrast to these effects, hybridization within CA2 stratum pyramidale was only slightly reduced at 12 and 24 hrs postlesion. S1 nuclease protection assays corroborate these findings. These data demonstrate that in contrast to NGF and BDNF, NT3 mRNA expression is reduced by seizure activity. Moreover, the marked differences in the pattern and direction of change in levels of mRNAs for NGF, BDNF, and NT3 in the dentate gyrus granule cells of HL rats provide evidence that these 3 mRNAs are differentially regulated by activity within individual forebrain neurons. THE INCREASE OF HIPPOCAMPAL NGF mRNA ASSOCIATED WITH BICUCULLINE CONVULSION, IS ABOLISHED IN ADRENALECTOMIZED RATS. F.Y. Sun, E. Costa, M. Fabrizio, and L. Mocchetti. FGIN and ¹Dept. of Anatomy and Cell Biology, Georgetown Univ., Sch. of Med., Washington, DC 20007.

It has been reported that NGF gene expression in the brain can be enhanced after seizure, a condition postulated to be associated with impaired GABAergic function, suggesting that GABA might regulate NGF gene expression. NGF biosynthesis also can be increased by adrenal steroids. We tested whether increase of NGF gene expression that follows behavioral seizure could be the result of high blood steroid levels. Bicuculline (0.4 mg/kg, i.v.), a selective GABA_A receptor antagonist, was used to induce seizure in sham-operated and adrenalectomized rats. Northern Blot hybridization analysis was used to measure the contents of NGF mRNA in the hippocampus. In sham-operated rats, bicuculline induced a two-three fold increase in NGF mRNA content one hour after the injection. This effect was time dependent since it was still present 6 hr but not 9 hr after the injection. Since bicuculline increases plasma corticosterone levels, we tested whether bicuculline could increase NGF mRNA in adrenalectomized rats. In these animals, although bicuculline could still induce seizures, it failed to change NGF mRNA content. These results suggest that steroids, released from the adrenal medulla during seizures, might be the stimulus responsible for the increase of hippocampal NGF mRNA content. It remains to be established whether the increase of NGF mRNA is due to an induction of gene transcription.

94.2

LIMBIC SEIZURES INDUCE BIPHASIC INCREASES IN HIPPOCAMPAL NGF mRNA EXPRESSION. J.C. Lauterborn, P.J. Isackson, and C.M. Gall. Department of Anatomy & Neurobiology, University of California, Irvine, CA 92717.

Work in our laboratories has established that physiological activity can induce an increase in nerve growth factor (NGF) mRNA in rat hippocampal and neocortical neurons. In particular, following seizures NGF mRNA levels increase rapidly in hippocampus, and several hours later in neocortex. In the present study, *in situ* hybridization and S1 nuclease protection assays were used to provide a detailed time course of seizure-induced changes in hippocampal NGF mRNA expression.

Adult male Sprague-Dawley rats received a unilateral electrolytic lesion of the dentate gyrus hilus. Such hilus lesions (HLs) induce EEG seizure discharges in hippocampus and behavioral seizures which recur from 2 to 12 hrs post-HL. Rats used exhibited at least 2 stage 4 seizures. Perfusion-fixed tissue sections from HL and paired control rats were processed for *in situ* hybridization with a ³⁵S-cRNA to the sequence coding for rat NGF. Levels of NGF mRNA were found to increase in two distinct phases in the dentate gyrus granule cells. Hybridization to NGF mRNA increased rapidly to maximal levels, at 600-1300% control values, by 3-6 hrs post-HL. By 12 hrs post-HL, the density of NGF cRNA hybridization dropped to 58% of control levels. This was followed by a second increase which reached 500% of control values by 24 hrs. Thus, the second increase in NGF mRNA develops after the termination of seizures and coincides with NGF mRNA increases in neocortex. By 48-96 hrs post-HL, hybridization declined to control levels. S1 nuclease protection assays corroborated these findings. These data demonstrate that recurrent HL-seizures cause a biphasic increase in hippocampal NGF mRNA content. Moreover, the temporal relationship of these increases to seizure activity suggests the first phase is directly induced by epileptiform activity whereas the second may be indirectly induced by processes set in motion during the seizure episode. Supported by NS26748 & AG00538.

NGF, bFGF and IGFs PROTECT RAT HIPPOCAMPAL AND HUMAN CORTICAL NEURONS AGAINST CALCIUM-MEDIATED HYPOGLYCEMIC DAMAGE. B. Cheng and M. P. Mattson. Sanders-Brown Center on Aging and Dept. of Anatomy & Neurobiology, Univ. of Kentucky, Lexington, KY 40536.

Neuronal growth factors have received considerable attention because of their potential for preventing or repairing brain injury, but the kinds of insults they might normally protect against and their cellular mechanisms of action are unclear. Central neurons are particularly vulnerable to hypoglycemia that occurs in ischemia or with insulin overdose. Glucose deprivation caused neuronal damage and death in human cerebral cortical and rat hippocampal cell cultures. The hypoglycemic damage was dependent upon calcium influx. Nerve growth factor (NGF) and basic fibroblast growth factor (bFGF) (10 ng/ml) each prevented hypoglycemia-induced neuronal damage when administered before or immediately after glucose deprivation. NGF also afforded protection when administered up to 12 hours following the onset of hypoglycemia. Similar protective effects were afforded by insulin-like growth factors (IGF-1 and IGF-2; 100 ng/ml), while epidermal growth factor was ineffective. NGF and bFGF prevented the elevation in intraneuronal calcium levels that mediated hypoglycemic damage. The glutamate receptor antagonists APV and DGG reduced hypoglycemic neuronal damage, while the calcium channel blockers nifedipine and nimodipine were ineffective. We conclude that growth factors can stabilize neuronal calcium homeostasis and thereby protect against environmental insults. The data also indicate that NGF acts on a broad array of central neurons including non-cholinergic neurons. (Alzheimer's Association and ILSI support).

94.6

EPILEPTOGENIC KAINATE LESIONS OF HIPPOCAMPUS INDUCE THE EXPRESSION OF NERVE GROWTH FACTOR RECEPTOR (NGFR). J.E. Franck, D.L. Roberts*, S. Patterson and M. Bothwell. Depts. of Neurological Surgery (J.E.F) and Physiology & Biophysics, Univ. of WA, Seattle, WA 98195.

Intraventricular kainic acid (KA) lesions hippocampal subfield CA3. Granule cells are not damaged and their mossy fibers remain in place in CA3 despite the loss of their targets; they do not form a substantial recurrent pathway into the dentate molecular layer. This lesion induces limbic seizures and is considered a model of temporal lobe epileptogenesis.

Hippocampal cell damage and seizures are associated with aberrant plasticity in remaining neurons. Trophic factors and their receptors may play a role in such plasticity. While NGFR is not expressed in intrinsic elements of normal adult hippocampus, seizures induce NGF in dentate granule cells. The present study examined whether NGFR is also induced following epileptogenic cell damage.

Subfield CA3 was lesioned bilaterally in adult rats by intraventricular KA (5µg/µl saline/side) and the hippocampus was immunocytochemically stained for NGFR (monoclonal IgG 192) three days to one month later. Intense NGFR immunoreactivity was present in the region of lesioned CA3 normally innervated by dentate mossy fibers at all post-lesion latencies. Much staining appeared to be associated with glial processes. While granule cells were not immunoreactive, fibers with mossy terminal-like expansions also stained for NGFR.

Seizures induce the expression of NGF in dentate granule cells. The present finding - that NGFR is expressed in the lesioned terminal field of dentate mossy fibers - suggests that NGF-containing granule cells interact with elements in the neuropil which make NGFR. This interaction may maintain mossy fibers in place despite target loss or, in other models, may assist in redirecting mossy fiber axons to form recurrent collaterals.

NEUROTROPHIC FACTOR FAMILY IMMUNOREACTIVITY IS PRESENT IN DEVELOPING MAMMALIAN CEREBRAL CORTEX. K.L. Allendoerfer and C.J. Shatz. Dept. of Neurobiology, Stanford University, Stanford CA 94305

Messenger RNA for nerve growth factor (NGF), and for the related neurotrophins brain-derived neurotrophic factor (BDNF) and neurotrophin-3 (NT-3), is known to be present in the developing cerebral cortex of mammals. Recent work indicates that unique cell types within the developing cortex may be responsive to this family of molecules. The early-generated and transient subplate (SP) neurons, for example, express the low-affinity NGF receptor (L-NGFR), and may require NGF or a related molecule for their survival and differentiation. We have used a polyclonal antibody which recognizes NGF, BDNF, and NT-3 (kindly provided by Dr. K. Nikolic, Genentech, Inc.; Knusel et al. 1991, PNAS 88, p. 961) to determine localization of this family of molecules within the cerebral cortex of ferrets between P1, when L-NGFR expression in the SP is high, and P10, by which time it has disappeared. At P1, the SP neurons stain darkly with the anti-neurotrophin antibody; the underlying white matter, ventricular zone (VZ), and cortical plate (CP) do not stain. At P10, the SP neurons retain their staining, and in addition, the VZ and the pyramidal neurons of cortical layer 5 are intensely immunoreactive. Outside the cerebral wall, the septal neurons of the basal forebrain also stain at both these ages. Injections of [125I]-NGF into the cortex or ventricle label the septal neurons as early as P1, indicating that the antibody recognizes cells which retrogradely transport NGF. However, the SP, VZ, and layer 5 neurons do not take up or retrogradely transport [125I]-NGF, suggesting that they may be responsive to a different member of the family. All of the cortical and septal immunoreactivity can be blocked by incubating the sections with primary antibody plus excess NGF, indicating the specificity of the antibody for the NGF family. Thus, the pattern of staining suggests that diverse cell types within the developing cerebral cortex synthesize or respond to members of the neurotrophin family, and is consistent with the idea that these molecules may play an important role in the development of CNS structures. ESTROGEN (ER) AND NERVE GROWTH FACTOR (NGFR) RECEPTOR mRNA REGULATION IN PERIPHERAL NEURONAL TARGETS OF NGF. F. Sohrabji¹, R. C. Miranda¹, L.A. Greene² and C. D. Toran-Allerand¹. Depts Anat. & Cell Biol.¹ and Path², Columbia Univ, P&S, New York, NY 10032.

Recent work in this laboratory has shown that ER and NGFR co-localize in several regions of the developing and adult rodent brain. We hypothesized that estrogen sensitivity may be a universal feature of neural NGF targets. The present experiments studied dorsal root ganglion (DRG) neurons and PC12 cells, prototypical peripheral targets of NGF not previously known to respond to estrogen. DRGs were obtained from proestrous and ovariectomized (ovx) adult female rats and hybridized with digoxigenin-labeled oligodeoxynucleotides for ER and NGFR mRNAs. NGFR and ER mRNAs appeared restricted to neurons. Although both large and small DRG neurons expressed high levels of ER mRNA, there were striking differences in the pattern of hybridization between the proestrous and ovx conditions. While hybridization intensity was heterogeneous during proestrous (high estrogen), estrogen deficiency (ovariectomy) resulted in a uniformly intense staining. In striking contrast, NGFR mRNA expression appeared upregulated by estrogen, with a dramatic reduction in staining intensity in the ovx female. PC12 cells cultured with/without NGF were also studied for ER mRNA expression. While a small proportion of NGF-deprived (undifferentiated) PC12 cells expressed ER mRNA, virtually all PC12 cells exposed to NGF exhibited intense ER mRNA hybridization signal. These findings suggest that estrogen sensitivity may be a property of central and peripheral NGF target neurons. Additionally, while co-localization of NGF and estrogen receptor systems suggest a possible interactive role for these substances, the present data suggest one mechanism for this interaction: that estrogen (DRG) or NGF (PC12) may influence neuronal responsiveness to the other ligand by regulating receptor expression for that ligand. LONG TERM SURVIVAL OF SEPTAL CHOLINERGIC NEURONS AFTER LESIONS THAT DEplete THE HIPPOCAMPUS OF CELLS PRODUCING NGF OR BDNF mRNA. M.V. Sofroniew, J.D. Cooper, C.N. Svendsen, P. Crossman, N.Y. Ip, R.M. Lindsay, F. Zafra, E. Castrén, H. Thoenen, D. Lindholm. Dept. of Anatomy, University of Cambridge, UK; Regeneron Pharmaceuticals, Tarrytown, NY, USA; Dept. of Neurochem., Max-Planck for Psychiatry, Martinsried, FRG

Most medial septal cholinergic neurons die following proximal axotomy of their projection to the hippocampus (Hp) in adult rats; in contrast, these neurons do not die for up to 120 days after excitotoxic ablation of nearly all Hp neurons (Science 247:338). We have now studied growth factor mRNA production in the Hp remnant, and the viability of septal cholinergic neurons in rats with long survival times after unilateral ablation of Hp neurons with NMDA (9-15 injection sites). By 28 days after complete Hp lesions, mRNA for NGF and BDNF and NT-3 were reduced to virtually undetectable levels in the Hp remnant, and did not recover for over 365 days, the longest times studied. In the ipsilateral septum of animals with equivalent lesions, cholinergic neurons detected by ChAT or NGFR immunohistochemistry did not decline appreciably in number for up to 500 days, but atrophied in the form of shrinkage and loss of staining intensity. These findings indicate that long term production of NGF and BDNF is not maintained by non-neuronal cells after neuronal cell death in the Hp. The findings suggest that 1) NGF and BDNF are not required for long term survival of septal cholinergic neurons in adult animals but are involved in the maintenance of structural and chemical phenotype; and 2) retrograde cell death after axotomy may not be due solely to loss of target-derived neurotrophic support.

A BASIS FOR POSSIBLE AUTOCRINE AND SYNERGISTIC MECHANISMS UNDERLYING ESTROGEN AND NEUROTROPHIC FACTOR EFFECTS ON NEURONAL DEVELOPMENT AND SURVIVAL. R. C. Miranda¹, F. Sohrabji¹, R. B. Hochberg^{2*}, N. J. MacLusky³, and C. D. Toran-Allerand¹. Dept. Anat. & Cell Biol.¹, Columbia Univ. P&S, NY, NY 10032, Dept. Ob.&Gyn.², Yale Univ. Sch. of Med., New Haven, CT 06510 and Div. Reprod. Sci.³, Univ Toronto, Toronto, Canada, M6L1A.

Development and survival of CNS neurons are dependent on the expression of a variety of endogenous neurotrophic factors. In the developing rodent brain, several distinct groups of cells such as the neurons of the cortical subplate, septum, nuclei of the diagonal band, hippocampus and the large cholinergic neurons of the striatum and substantia innominata express the mRNAs and proteins for estrogen and nerve growth factor (NGF) receptors. Using non-isotopic *in situ* hybridization histochemistry, we have found that these same neuronal subsets also co-express the mRNAs for NGF and brain-derived neurotrophic factor (BDNF), suggesting the potential for developmentally-critical autocrine and synergistic mechanisms that may insure survival of these neurons prior to and concurrent with neural differentiation and innervation. In contrast, NGF and BDNF appeared differentially expressed in many other regions such as the developing hypothalamus and cortical layers II-V. These findings suggest a basis for a putative autocrine mechanism which may be critical not only for neuronal development and survival, but also for aging and neurodegenerative disorders such as Alzheimer's and Parkinson's diseases. [Supported by NIH grants HD08364 and AG08099 (DT-A); and CA3799 (RBH); and grants from AHAF; NSF BNS 87-00400 and Research Scientist Award MH00192 (DT-A)]

94.10

INTERACTIONS OF ESTROGEN AND NERVE GROWTH FACTOR (NGF) ON ESTROGEN RECEPTOR mRNA EXPRESSION IN EXPLANTS OF THE SEPTUM/DIAGONAL BAND. C. D. Toran-Allerand, R. C. Miranda and F. Sohrabji. Dept. Anat. & Cell Biol., Columbia Univ. P&S, New York, NY 10032.

We have shown that estrogen binding sites co-localize with NGF receptor mRNA and/or protein in developing and adult rodent brain regions such as the septum, nuclei of the diagonal band, cerebral cortex, striatum and nucleus basalis. In order to determine whether or not NGF and estrogen may interact in neurons where their receptors co-localize, we studied their effects in septal explants of the newborn mouse, an important target of these ligands during development and in the adult. Preliminary studies with non-isotopic *in situ* hybridization, using digoxigenin-labelled oligodeoxynucleotides, demonstrated that both estrogen and NGF receptor mRNAs were expressed in cultured septal neurons after 21 days *in vitro*. Concurrent exposure to estrogen and NGF appeared to increase the number of cells expressing estrogen receptor mRNA and to enhance the intensity of the hybridization signal, as compared to either ligand added alone or not at all. Whether or not the observed response results from an enhancement of neuronal survival and/or an increase in gene expression is unclear at this time. However, this interaction may represent synergism of estrogen and peptide growth factors, as has been shown extra-neurally in estrogen target regions or, perhaps, "permissive" effects of NGF on estrogen action, a mechanism that may also underlie growth factor effects. [Supported by grants HD08364 and AG08099 (NIH); AHAF; NSF BNS 87-00400 and Research Scientist Award MH00192 (DT-A)].

94.12

AGED RATS DOWN-REGULATE IMMUNOREACTIVE ChAT BUT NOT NGFR IN SEPTAL CHOLINERGIC NEURONS AFTER LOSS OF HIPPOCAMPAL TARGET NEURONS J.D. Cooper, C.N. Svendsen, S. J. Stevens, K.J. Baker and M.V. Sofroniew. SPON: Brain Research Association. Department of Anatomy, University of Cambridge, England.

In young adult rats, unilateral excitotoxic lesions that ablate the hippocampus (Hp) of nearly all neurons, and reduce both NGF and BDNF mRNAs to undetectable levels, lead to the atrophy but not death of afferent septal cholinergic neurons (Sofroniew et al. this volume). To investigate the effect of Hp ablation in aged animals, NMDA or vehicle was injected unilaterally into the Hp in 9 sites in rats either 4-6 or 24-30 months of age. After survival times of 50-110 days, NMDA lesions reduced the cross-sectional area of the Hp by 60-90%. In aged rats with Hp lesions, a significant decline of $30.6 \pm 2.9\%$ occurred in the number of ChAT neurons in the septum ipsilateral to the Hp lesion as compared with the unlesioned side, and sham operated control animals. In contrast, the number of NGFR neurons in neighboring sections from the same portions of the septum showed no significant decline. In young adult rats with Hp lesions, no reduction in the number of ChAT or NGFR septal neurons was observed. Since nearly all NGFR-positive neurons in the normal septum are cholinergic, these findings suggest that the loss of ChAT staining observed in aged rats represents a down regulation of enzyme expression rather than cell death. We conclude that septal cholinergic neurons also do not die in response to loss of target neurons in aged rats, but that these neurons do respond with a down-regulation of chemical phenotype, and thus appear to react more severely to loss of trophic support than their counterparts in young adult animals.

94.13

NGF WITHDRAWAL RESULTS IN ATROPHY BUT NOT CELL DEATH OF MATURE CHOLINERGIC NEURONS IN LONG TERM CULTURES UNDER INVERTED COVERSLEIPS C.N. Svendsen¹, K. Staley¹, E. D. Bird and M.V. Sofroniew, Dept. of Anatomy, University of Cambridge, U.K.

The effects of inverting coverslips after plating (Brewer and Cotman; Brain Res. 494: 65), in the presence or absence of nerve growth factor (NGF) were studied in dissociated basal forebrain septal or dorsal root ganglion (DRG) neurons in cell culture. Cultures of the septal region at medium cell density showed significantly enhanced neuronal survival, reduced glial proliferation and increased long term neuronal survival under inverted coverslips, independent of the presence or absence of NGF. In contrast, DRG neurons were unaffected by inversion of coverslips and did not survive in the absence of NGF. We also studied the effects of NGF and NGF-withdrawal on cholinergic neurons identified by staining for AChE or ChAT in septal cultures grown under inverted coverslips. NGF (100 ng/ml) given at the time of plating or at 7, 9 or 14 days *in vitro* (div) increased the number of cholinergic neurons seen at 28 div. NGF antibodies (1%, kindly donated by Dr. E. Johnson) added to cultures at 14 div which had been exposed to NGF since plating caused, by 28 div, a significant 42% reduction in cholinergic cell size and a reduction in fiber staining, but no reduction in cholinergic cell number, as compared with sister wells not exposed to NGF antibodies. These findings suggest that protection against cell death provided by inverting the coverslips is independent of NGF and that NGF may regulate cholinergic and structural phenotype without being required for the survival of mature cholinergic neurons.

192-IgG-SAPORIN IMMUNOTOXIN: PRELIMINARY BIOCHEMICAL CHARACTERIZATIONS. A.A. Book¹, R.G. Wiley³, and J.B. Schweitzer^{1,2}. Department of Anatomy and Neurobiology¹ & Department of Pathology², University of Tennessee, Memphis 38163 & Lab of Experimental Neurology³, DVAMC, Nashville, TN 37212.

A monoclonal antibody directed against the rat nerve growth factor receptor, 192-IgG, is specifically and bilaterally accumulated by the cholinergic basal forebrain (CBF) system following intraventricular injection. We have synthesized an immunotoxin composed of 192-IgG chemically linked to the ribosome inactivating protein saporin and then administered it intraventricularly to rats in an effort to produce a model of CBF deficit. 192-IgG was disulfide coupled to saporin (Inland) using SPDP. The 192-IgG-saporin conjugate was purified by ion exchange and affinity column chromatography using CM-52 (Whatman) and MAPS-II (Bio-Rad). 192-IgG-saporin was injected into the right lateral ventricles (8 µg total dose) of 8 adult rats, whereas normal saline was injected into 3 control rats. At two weeks survival, immunohistochemistry (IHC) showed a modest decrease in choline acetyltransferase (ChAT)-positive neurons in the medial septal nucleus and a major loss of ChAT-positive neurons in the nucleus of the diagonal band of Broca and in the nucleus basalis magnocellularis. The breakdown of 192-IgG-saporin over time, as shown by SDS-PAGE, may explain the sparing of some CBF neurons. Radioenzymatic ChAT assays of brain homogenates showed significant decreases in ChAT activity in the terminal fields of CBF neurons that correlated with the IHC impression of neuronal loss in animals given 192-IgG-saporin. ChAT activity in CBF terminal fields of experimental animals (expressed as percentages of the average control values) was as follows: cortex (32% ± 12%); hippocampus (48.3% ± 16.5%); olfactory bulbs (42.7% ± 16.6%). This immunotoxin appears to be quite effective *in vivo* against CBF neurons as judged by both biochemical and IHC methods. (Supported by NINDS NS01230.)

CHRONIC RECOMBINANT HUMAN NGF TREATMENT INCREASES HIPPOCAMPAL CHOLINERGIC FUNCTION FOLLOWING FIMBRIAL LESIONS: COMPARISON BETWEEN ENDOGENOUS ACETYLCHOLINE AND NEWLY-SYNTHESIZED [³H]ACETYLCHOLINE POOLS. E. O. Junard, F. Hefti, D. J. Jenden, and P.A. Lapchak, Andrus Gerontology Center, USC & Dept. Pharmacol., UCLA, Los Angeles, CA.

Recent studies have shown that chronic NGF treatment attenuates lesion-induced measures of hippocampal cholinergic function when measuring labeled pools of acetylcholine (ACh). The present study determined the effects of chronic recombinant human NGF (rhNGF) treatment (1 µg every second day for 3 weeks) on hippocampal ACh synthesis and release *in vitro* following unilateral partial fimbrial lesions. In this study we compared the effects of rhNGF treatment on both endogenous and labeled pools of ACh. Partial fimbrial transections reduced the hippocampal content of endogenous ACh by 47% and basal and evoked release of endogenous ACh by 32% and 46%, respectively. These lesions also reduced the synthesis of [³H]ACh from [³H]choline by 56%, and basal and evoked release of [³H]ACh by 41% and 63%, respectively. Chronic rhNGF treatment elevated the hippocampal content of endogenous ACh in tissue slices of the lesioned side to 111% of control levels and the synthesis of [³H]ACh to 119% of control levels. Chronic rhNGF treatment also increased basal and evoked release of endogenous ACh by 21% and 31%, respectively, and [³H]ACh release by 29% and 51%, respectively. This study shows that rhNGF treatment effectively increases presynaptic hippocampal cholinergic function and that the effects of rhNGF treatment are reflected by endogenous and newly-synthesized ACh pools (supported by HFSP).

Multiple signals mediate hypoglossal motoneuron response to axonal injury. R.C. Hayes, R.G. Wiley, D. Greeson^{*}, L. Moix^{*}, R. Brady and D.M. Armstrong Fidia Georgetown Institute for the Neurosciences, Georgetown University, Washington, D.C. 20007, DVAMC, Nashville, TN, 37212.

Unilateral transection or crushing of the rat hypoglossal (XII) nerve results in an increase in NGF receptor (NGFr) mRNA levels in hypoglossal motoneurons ipsilateral to the lesion in a manner that paralleled the appearance of the protein as assayed by immunocytochemical techniques. Although the duration of the response following nerve crush was shorter lasting than that observed following transection of the nerve, the intensity of the response was greater in the crush paradigm versus that observed following transection. This robust response was most obvious four days following crushing of the nerve and appeared to be the result of an increased recruitment of motoneurons expressing NGFr mRNA. These data indicate that nerve crush is more effective in eliciting NGFr mRNA expression than transection of the nerve.

In a second study, we sought to determine if these motoneuron responses were due to loss of a factor supplied to perikarya by axonal transport. Axonal transport was blocked by local application of vincristine (VCR) to one hypoglossal nerve. After seven days, VCR produced ipsilateral loss of immunohistochemical staining for choline acetyltransferase (ChAT) without inducing NGFr staining. Tongue injections of WGA prior to sacrifice confirmed ipsilateral block of axonal transport. Combining VCR with nerve transection gave the same results. Mild trauma to the nerve without drug application elicited NGFr staining with little effect on ChAT and WGA transport. We interpret these findings to indicate that there are two separate signals responsible for the changes seen after axotomy. Failure of axonal transport causes loss of ChAT but not induction of NGFr. Whereas, local nerve damage results in the induction of NGFr.

94.16

IMMUNOLESIONING: SELECTIVE DESTRUCTION OF CENTRAL AND PERIPHERAL NEURONS *IN VIVO* USING AN IMMUNOTOXIN TO THE RAT NGF RECEPTOR. R.G. Wiley, T.N. Oeltmann^{*} & D.A. Lappi^{*}. Lab of Experimental Neurology, DVAMC, Nashville, TN 37212 & The Whittier Institute, La Jolla, CA.

In the present study, we sought to determine if an immunotoxin to the nerve growth factor receptor (NGFr), could selectively destroy neurons bearing that receptor *in vivo*. 192 IgG, a mouse monoclonal antibody to the rat NGFr, was disulfide coupled to one of 3 ribosome inactivating proteins (saporin, ricin A chain, barley RIP) using SPDP. 192 IgG-saporin was far more active *in vivo* than either of the other constructs. Systemic injection of 4 µg of 192 IgG-saporin destroyed > 1/3 of neurons in the superior cervical ganglia (SCG), and 20 µg destroyed > 95%. 350-fold larger doses of 192 IgG-ricin A or 192 IgG-barley RIP only destroyed scattered SCG neurons after systemic injections. Intraventricular injection of 4 µg of 192 IgG-saporin destroyed all of the neurons in the medial septum and nucleus of the diagonal band that stain for choline acetyltransferase (ChAT) and NGFr. Scattered ChAT- and NGFr-positive neurons survived in the nucleus basalis and numerous cerebellar Purkinje cells were destroyed after these doses of 192 IgG-saporin. Intraventricular injections of 40-fold larger doses of 192 IgG-ricin A or 192 IgG-barley RIP produced no detectable loss of ChAT+/NGFr+ cells. We conclude that 192 IgG-saporin has extraordinary potential as a selective lesioning tool. (Supported by DVAMC, Nashville, TN.)

CHRONIC NGF PRETREATMENT POTENTIATES KAINIC ACID-INDUCED INCREASES OF c-fos mRNA IN THE HIPPOCAMPAL FORMATION OF THE ADULT RAT. F. Hefti, G. Tocco, G. Pasinetti, M. Dugich-Djordjevic and P.A. Lapchak, Andrus Gerontology Center and Dept. Biol. Sci., USC, Los Angeles, CA, 90089.

Recent studies have shown that systemic administration of kainic acid (KA) results in increased levels of growth factor mRNA (BDNF, NGF) and immediate early genes (c-fos mRNA) in the hippocampal formation. Furthermore, the KA-induced elevation of c-fos mRNA appears to precede the loss of hippocampal cells. The present study determined whether pretreatment with recombinant human NGF (rhNGF) affects KA-induced elevations of c-fos mRNA in brain. Adult rats were administered either rhNGF (1 µg, every second day for 3 weeks) or cytochrome c (cc) prior to treatment with KA (10 mg/kg, s.c.) or saline. Animals were sacrificed 4 hours following KA-induced seizure activity or saline injections. *In situ* hybridization was carried out on brain sections using a riboprobe specific for c-fos mRNA. In cc-treated control animals, KA administration increased the levels of c-fos mRNA hybridization in the hippocampal formation compared to saline-injected controls. However, in animals chronically pretreated with rhNGF, the KA-induced increase of c-fos mRNA hybridization was significantly potentiated (by 40-50%) compared to that observed in KA injected cc-treated animals. In the absence of KA treatment, rhNGF treatment did not affect the expression of c-fos mRNA in the hippocampal formation. The present study shows that NGF pretreatment modulates excitatory amino acid responses in the hippocampal formation (supported by HFSP).

RECOMBINANT HUMAN NGF AMELIORATE MEMORY IMPAIRMENT IN RATS WITH BASAL FOREBRAIN LESIONS. K. Kato, E. Fujiwara*, M. Iwane* and M. Suno. Biol. and Biotech. Res. Lab., R & D Div. Takeda Chem. Ind. Ltd., Yodogawa-ku, Osaka 532, Japan.

Bilateral lesions of basal forebrain (BF) neurons in rats were produced by heating at 70°C for 60 sec with a radiofrequency lesion generator. Two weeks after the operation, learning and/or memory was examined in a one-trial passive avoidance task and Morris' water maze task done for 3 consecutive days. The rat with BF lesions showed severe learning and/or memory impairment in both tasks, and the activity of choline acetyltransferase (CAT) was reduced by 10% in the frontal region of the cerebral cortex. When recombinant human nerve growth factor (rhNGF; 5 µg/2.5 µl) was injected into the right lateral ventricle of the rat with BF lesions every 3-4 days for 2 weeks, it was found that the learning impairment was ameliorated in Morris' water maze task: on the 2nd day of training the median escape latency in NGF-treated rats was 60 sec which was significantly shorter than that (120 sec) in control rats with BF lesions. In animals receiving NGF injections, CAT activity in the frontal cortex was 30% higher than that in control animals with BF lesions, and similar increases in CAT activity were observed in the parietal, occipital and temporal cortex in which CAT activity had not been affected by BF lesions. These results suggest that rhNGF activates the cholinergic system in the cerebral cortex in rats with BF lesions, and this may result in the improvement of the learning behavior which is impaired in these animals.

94.20

THE ROLE OF NGF AND INSULAR CORTEX GRAFTS IN THE RECOVERY OF INHIBITORY AVOIDANCE LEARNING. M. Escobar, M. Hiriart, A.L. Piña and F. Bermúdez-Rattoni. Instituto de Fisiología Celular, UNAM, P.O. Box 70-600, México, D.F.

We recently showed that fetal brain grafts produced a significant recovery in the ability of insular cortex (IC) lesioned rats to learn a conditioned taste aversion (CTA) task. The expression of AChE and the acetylcholine release are correlated with the recovery in the ability to learn CTA. In the present work we evaluate the role of NGF in the recovery of learning induced by IC grafts in the inhibitory avoidance task. Four groups of male rats received bilateral lesions in the IC and one group remained as unoperated control. Ten days later two of the lesioned groups received homotopic fetal IC grafts combined with gelfoam implants impregnated with NGF (IC-NGF grafts) (20 µg/ml) or vehicle, respectively. Another group, received only homotopic fetal IC grafts, and the last group remained as a lesioned control. All groups were trained 15 days later in the IA paradigm. We found that IC-NGF grafts promoted recovery in the ability to learn the IA task assessed by the response latency. The remaining groups did not show any recovery. The histochemical analysis showed the presence of NGF receptors and many AChE labeled fibres and somas in the IC-NGF grafts. These results support that IC-NGF grafts play an important role in the behavioral recovery of IC lesioned rats.

GROWTH FACTORS AND TROPHIC AGENTS II

95.1

RAT BRAIN CONTAINS MESSENGER RNAs FOR EGF-RECEPTOR AND TGF-ALPHA BUT NOT FOR EGF. M. Kaser*, J. Lakshmanan, K. Huff and D.A. Fisher*. Harbor-UCLA Medical Center, Perinatal Research Laboratories, Torrance, CA 90509.

Evidence for the existence of EGF-receptor immunoreactivity (Neurosci. 22:5279, 1987), TGF-alpha immunoreactivity (Soc. Neurosci. 413.25, 1990) and preproTGF-alpha mRNA (J. Neurosci. 8:1901, 1988) in rat brain have been previously reported. However, evidence for the presence of EGF immunoreactivity in rat brain remains controversial (Neurosci. Lett. 63:290, 1986 and J. Biol. Chem. 264:10447, 1989). In the present investigation, we examined brain tissue for the presence of mRNAs for EGF-receptor, TGF-alpha and EGF using specific probes for rat. Poly (A)+ RNA isolated from adult rat whole brain and brain regions (cortex, cerebellum, midbrain and brain stem) were examined by Northern blot analysis. Whole brain contained 10, 5.6 and 4.8 kb bands when probed with the EGF-receptor probe and TGF-alpha mRNA was characterized by a 4.5 kb. No band was visible on the autoradiogram when probed with EGF cDNA. Both EGF-receptor and TGF-alpha mRNAs also were detectable in cerebral cortex, cerebellum and brain stem. Our results indicate that the TGF-alpha precursor or processed TGF-alpha could be the ligand for the EGF-receptor in brain.

IDENTIFICATION OF A COLLAGEN POTENTIATED NEURITE PROMOTING FACTORS. D.E. Coyne. Department of Anesthesia, University of Cincinnati, College of Medicine, Cincinnati, Ohio 45267-0531.

Non-neural cells have been shown to release factors that influence the morphology, survival and neurite outgrowth of peripheral and central neural cells. From this work, various neurotrophic factors (NPFs) and neurite promoting factors (NPFs) have been reported. This laboratory has initially identified two NPFs isolated from the C6 glial cell line. The C6 cells are capable of producing NPF activity under growth conditions in the presence and absence of serum. The NPFs appear to be distinct from nerve growth factor, since their activities are not blocked by the presence of anti-NGF antibodies sufficient to inhibit neurite outgrowth caused by 50 µg/ml NGF. These factors are capable of inducing neurite outgrowth from PC12 cells on various substratum (plastic, laminin, collagen), but are potentiated only by the presence of collagen. Neurite promoting activity is found in the molecular weight (MW) ranges of 30-50 kDa and 454-1,000 kDa. The low MW NPF is more resistant to acid and basic pHs and is only produced when C6 cells are grown in the presence of serum. The high MW NPF is produced under both growth conditions, however, serum-free growth conditions result in a 3.5 fold increased production of this factor. Experiments, using dissociative and denaturation conditions, results in the loss of neurite promoting activity of the high MW NPF. The high MW NPF is not bound by Q-Sepharose (pH 8.0), but, does exhibit heparin binding. Based on MW, the low NPF appears to be similar to glial derived nexin reported to be produced by C6 cells, however, the high MW NPF appears to be a novel NPF whose neurite promoting activity is potentiated by collagen and is distinct from NGF and nexin.

FURTHER CHARACTERIZATION OF A MUSCLE-DERIVED NEURITE-PROMOTING FACTOR. T.H. Oh, G.J. Markelonis, S.L. Hobbs* and S.J. Jeong. Dept Anatomy, Univ Maryland Sch Med., Baltimore, MD 21201

Survival of spinal motor neurons during embryonic development requires muscle-derived trophic factors. We have isolated a non-laminin protein from muscle which stimulates neurite outgrowth from embryonic neurons in culture. The protein also promotes the survival and growth of embryonic spinal motor neurons in culture. This trophic protein has been purified by gel-filtration chromatography followed by ion-exchange chromatography and analytical gel electrophoresis. The biologically active protein migrates as a doublet with molecular weights of 53 and 57 kDa on sodium dodecyl sulfate-gel electrophoresis. Both gel bands were excised, electro-eluted and tested for their biological activity on cultured DRG neurons. The 53 kDa protein showed virtually all of the trophic effects as compared to all other electroeluted proteins. The 53 kDa protein was digested with trypsin and the resulting peptides were fractionated by size using reverse-phase HPLC. Five peptides, ranging in length from 7 to 21 amino acid residues, were sequenced. Comparison of these peptide sequences to those stored in Gen Bank indicated no direct sequence identity to any other sequenced growth factor or muscle protein. Thus, the 53 kDa protein appears to be an undescribed neurite-promoting factor. (Supported by NIH grant NS 15013).

MDF, A MUSCLE FACTOR, PRODUCES PARTIAL MOTOR RECOVERY IN 6-HYDROXYDOPAMINE LESIONED RATS BY INCREASING TYROSINE HYDROXYLASE ACTIVITY AND CATECHOL LEVELS. B. K. Jin, J. S. Schneider, X.Y. Du and L. Jacyviti. Dept. of Neurology, Hahnemann University, Philadelphia, Pa. 19102

We have previously demonstrated that treatment with a 10,000-fold purified muscle-derived factor termed MDF will partially restore motor symmetry in rats with a 6-hydroxydopamine (6-OHDA) lesion of the nigrostriatal system. Concomitantly, the number of fibers immunoreactive for the catecholamine enzyme, tyrosine hydroxylase (TH) is dramatically elevated in the MDF-treated striatum. In the present study, we examined whether these changes 1) are accompanied by biochemical changes in TH and its catechol products and 2) are long-lasting effects of MDF. 6-OHDA was unilaterally injected into the rat substantia nigra, producing partial denervation of the ipsilateral striatum. Lesions were verified by monitoring rotational behavior after amphetamine challenge (5mg/kg). Four weeks after the lesion, either partially-purified MDF or PBS+BSA (control) was infused into the damaged striatum via an indwelling canula connected to a miniosmotic pump. Test solutions were delivered 1ul/hr for 6-14 days. At sacrifice, residual pump solutions were removed and bioassayed in culture to verify their biological activity. Following MDF treatment, rats showed a significant reduction in rotational asymmetry (48%-93%) and TH activity in the damaged striatum was 5-fold higher than in PBS controls. Moreover, endogenous dopa, undetectable in intact or PBS-treated striatum, reached 13.6 µg/gm protein in the lesioned, MDF-treated striatum. Similarly, when dopamine was measured in the lesioned striatum and expressed as a % of the intact striatum, levels were increased from 5% in PBS controls to 21% in MDF-treated rats. In some rats, MDF treatment was terminated after partial motor recovery. In this case, improved motor function gradually declined, but did not fully revert to pre-treatment levels for 60 days. These findings suggest that MDF increases the biochemical function of lesion spared dopamine neurons by inducing TH activity. It is likely that the consequent increase in endogenous dopa and dopamine levels contributes to the long-lasting motor recovery of lesioned rats treated with MDF. Supported by NIH NS2404-04 and the Ben Franklin Foundation.

TAURINE SYNTHESIS IN DEVELOPING CAT AND MOUSE CEREBELLUM *IN VIVO* AND *IN VITRO*. E. Trenkner, A. Gargano, P. Scala and J.A. Sturman, Inst. for Basic Research in Developmental Disabilities, Staten Island, NY 10314.

Taurine is essential for the development and survival of mammalian cells, in particular the cerebellum of the cat and weaver mutant mouse. Taurine biosynthesis is high in rodents but low in cats and primates which need taurine in their diet. Cysteinylsulfonic acid decarboxylase (CSAD) is the rate limiting step. This study measured CSAD activity in the developing cerebellum of normal and weaver mice *in vivo* and *in vitro* as well as from kittens raised on taurine controlled diets. We found that in mouse CSAD activity is developmentally regulated. Activity declines until P14, the time when the blood brain barrier is established, and then increases to mature levels. There were no significant differences in activity between normal and weaver cerebellum indicating that the taurine deficiency in weaver cerebellum is not due to reduced CSAD activity. CSAD activity was higher *in vitro* than in tissue and activity did not increase during the culture period. In P5 and P7 cat cerebellum, on the other hand, CSAD activity was low under normal and taurine deficient conditions. However, when cultured for 3 days, there was a significant induction of activity, the amount depending on developmental stage and diet. After 3 days in culture, activity induced was greater in cerebellum from normal kittens than from taurine-deficient kittens. These results suggest that taurine-synthesis in cat is suppressed *in vivo*, or might be regulated in a yet unknown way.

REGULATION OF ENKEPHALIN EXPRESSION IN DEVELOPING CHROMAFFIN CELLS AND MATURE SYMPATHETIC NEURONS BY NEURAL AND HORMONAL FACTORS. P. D. Henion and S. C. Landis, Dept of Neurosciences, Case Western Reserve Univ. Cleveland OH. 44106.

Most adrenergic cells derived from the sympathoadrenal lineage of the neural crest contain one or more neuropeptides. Although a great deal is known about the development and regulation of adrenergic properties in these cells, the regulation of peptidergic properties is poorly understood. We have examined the possible role of environmental cues in the regulation of leucine enkephalin (L-Enk) expression in developing chromaffin cells and mature sympathetic neurons. Highly enriched cultures of embryonic and neonatal chromaffin cells exposed to glucocorticoids (GLC) exhibited significantly increased L-Enk levels over controls. Cultures of neonatal chromaffin cells were exposed to high potassium to mimic the depolarizing effect of acetylcholine and to a L-Enk analog, DADLE, to mimic the effects of L-Enk which is present in a majority of cholinergic preganglionic fibers in the adrenal medulla. Depolarization stimulated L-Enk expression to levels over 4 times greater than control cultures while addition of DADLE completely blocked the depolarization-induced increase in L-Enk levels. These results, taken together with the developmental time course and pattern of L-Enk expression in chromaffin cells *in vivo* and the initiation of GLC synthesis and onset of impulse activity, suggest that GLC and preganglionic innervation regulate L-Enk expression in chromaffin cells during development. We then examined the effects of altered GLC levels and denervation on L-Enk expression in sympathetic neurons *in vivo*. Lowered GLC levels in adrenalectomized rats resulted in a dramatic decrease in ganglionic L-Enk content. Conversely, denervation of the superior cervical ganglion, like denervation of the adrenal gland, resulted in a large increase in the number of L-Enk immunoreactive cells. These results demonstrate that similar mechanisms regulate L-Enk expression in different sympathoadrenal derivatives and implicate these mechanisms in the autonomic response to stress.

REGULATION OF THE EXPRESSION OF RECEPTORS FOR NEUROTRANSMITTERS IN CULTURED SYMPATHETIC NEURONS. W.H. Ludlam, A.B. Johnson and J.A. Kessler. Depts. of Neuroscience and Neurology, Albert Einstein College of Medicine, Bronx, NY 10461.

Regulation of muscarinic and peptidergic receptor expression was studied in cultured sympathetic neurons of the neonatal rat superior cervical ganglion (SCG). Leukemia Inhibitory Factor (LIF), previously shown to stimulate levels of choline acetyltransferase activity and of substance P, was used to effect regulation of receptor expression. Exposure of SCG cultures to LIF (5 ng/ml) for 10-12 days resulted in a 75% reduction in muscarinic receptors as measured by whole cell binding of N-methyl-³H-scopolamine. This effect, as shown by Scatchard analysis, was due to a reduction in total receptor number (B_{max}) rather than a decrease in receptor affinity (K_d). Concentrations as low as 1 ng/ml reduced receptor expression with a dose of 10 ng/ml having near maximal effectiveness. Reduction in receptor binding could be detected after four days of treatment with an 85% reduction after 16 days. In contrast to the decrease in muscarinic binding, Substance P receptor expression was up-regulated 75-100% in sister cultures as measured by whole cell binding of ¹²⁵I-labeled Tyr⁸ Substance P (5 ng LIF/ml, 14-16 days tx). LIF, previously shown to be released by some populations of non-neuronal cells, could therefore play a role in the coordination of transmitter and receptor expression in the developing nervous system.

THE MECHANISMS UNDERLYING TAURINE'S CAPACITY TO ENHANCE AXONAL FORMATION AND POLYAMINE SYNTHESIS IN VITRO. C.L. Lu, G. Yorke and F.J. Roisen. Dept. of Anatomical Sciences and Neurobiology, Univ. of Louisville, Sch. of Med., Louisville, KY 40292.

The amino acid taurine is distributed widely in mammalian tissues and functions as a neurotransmitter. We and others have reported taurine's neurotrophic action *in vitro*. Although its underlying mechanism is unknown, studies suggest that it may be calcium dependent. To examine this possibility, we employed the Neuro-2a neuroblastoma cell model. With this cell line, we have shown previously that taurine increased neurite formation and ornithine decarboxylase (ODC) activity in a dose dependent manner. We now report a plateau of maximal neurogenesis after 24 hr exposure to 4.0 mM taurine. In contrast, a 3-fold increase in ODC activities was obtained after 5 hr exposure to 1.0 mM taurine. Media supplemented with a minimum of 3.0 mM extracellular calcium prevented taurine's capacity to enhance neurite formation; whereas, increased calcium did not block taurine-induced ODC activity. Since gangliosides enhance neurogenesis in a variety of cell culture models in a species specific, Ca²⁺-dependent fashion, we examined the interaction of taurine and gangliosides. The capacity of the 4 major gangliosides (GM1, GD1a, GD1b and GT1b) found in bovine brain to potentiate taurine was examined morphologically and biochemically. GD1a, GD1b and GT1b (150 ug/ml) enhanced taurine-mediated (1.0 mM) neurite development. These gangliosides also potentiated the effect of a subthreshold level of taurine (0.1 mM) on ODC activity. In Neuro-2a cells, it appears that neurite formation and polyamine synthesis are parallel but uncoupled events. These studies suggest that taurine potentiates neurite formation through a calcium dependent mechanism. In contrast, taurine's action on ODC activity appears calcium independent. Studies are in progress to demonstrate further the relationship between calcium and taurine's neurotogenic activity. Supported by NIH NS24524.

EFFECTS OF D-FACTOR ON SUBSTANCE P EXPRESSION IN SYMPATHETIC NEURONS. J.A. Kessler & M. Freidin. Depts. Neurology and Neuroscience, Albert Einstein Col. Med., Bronx, NY 10461

Cytokines, a class of immunoregulators, have been shown to alter the behavior of a variety of cell types. A link between the immune and nervous systems has been demonstrated by the localization and effects of these molecules on nervous tissue. For example the cytokine, D-factor (also known as leukemia inhibitory factor), has been shown to increase cholinergic traits in cultures of rat sympathetic superior cervical ganglion (SCG) neurons (Science, 1989). We have found that D-factor also regulates the expression of the neuropeptide substance P (SP) in SCG neurons. Pure neuronal cultures of the SCG do not express detectable SP peptide or preprotachykinin (PPT) mRNA. However, treatment with recombinant human D-factor (rhDF) stimulates SP expression dramatically. Further, SCG neurons grown in the presence of ganglion nonneuronal cells show a 25-fold increase in SP peptide over basal levels in response to rhDF treatment. This modulation of SP levels was also found under serum-free culture conditions in both pure neuronal and cocultures. Treatment with the glucocorticoid dexamethasone, which blocks the SP-stimulating activity of another cytokine (IL-1 β) in cocultures, failed to inhibit the effects of rhDF in neuronal cultures grown with or without ganglion nonneuronal cells. By contrast, potassium-induced depolarization decreased the increase in PPT mRNA seen after rhDF exposure. In addition, rhDF decreases the levels of norepinephrine and neuropeptide Y slightly. In conclusion, the roles of the cytokine, D-factor, must be expanded to include neuronal differentiating properties as well as an immune system modulation.

ACTH/MSH PEPTIDES ACCELERATE MUSCLE MATURATION AND FUNCTIONAL RECOVERY FOLLOWING TRAUMA OF THE DEVELOPING NERVOUS SYSTEM. L.A. Zuccarelli and F.L. Strand. Department of Biology, Center for Neural Science, New York University, New York, New York 10003.

ACTH 4-10 and α -MSH positively affect development and regeneration of nerve¹. Here we investigate their effects on muscle maturation and motor function. 2 d old rats are subjected to sciatic nerve crush and peptide treatment (10 μ g/kg/48h/10d). Walking, climbing and placing tests are performed on d 15 & 21. Pups climb a vertical mesh wall; foot failures compared to total steps are determined. Walking ability is rated on a 3 to 0 scale. In placing tests, pups are suspended by forelimbs on a platform; using their hindlimbs, they mount the platform. The time to place both hindlimbs is recorded. On d 7, 15, & 21, the extensor digitorum longus muscle is removed and incubated in 1% tetrazolium chloride solution; formazan is extracted from the muscle with acetone and analyzed at 435 nm to determine absorbance. Absorbance/dry muscle weight, as a measure of oxidation, is calculated. Total protein content is determined by the BCA method. ANOVA was used for statistical purposes.

Results show oxidation for the peptide-treated groups is significantly lower ($p < .05$) than the saline groups at d 7 & 15 indicating a change of muscle fiber type from slow oxidative to fast glycolytic. By d 21, no differences are observed. Preliminary results from protein content and behavioral tests show a trend toward peptide-prevention of protein loss and acceleration of functional recovery.¹ Strand et al., *Prog. in Neurobio*: 33, 1989.

95.11

NEUROTROPHIC ACTIVITY OF THE AMINO TERMINAL REGION OF ALBUMIN. S. Dostaler*, †P.M. Richardson, T.G. Flynn* and R.J. Riopelle. Queen's University, Kingston, Canada K7L 3N6 and †McGill University, Montreal, Canada H3G 1A4.

Neurite-promoting activity for embryonic sensory neurons has been detected in explants of tumours of patients with Von Recklinghausen Neurofibromatosis (NF-1). A small peptide factor (E-2) was purified from neurofibrosarcomas of three patients with NF-1 by extraction in the presence of protease inhibitors followed by reverse phase HPLC.

The addition of E-2 to cultures of isolated embryonic chick DRG neurons in defined medium promoted neurite outgrowth twice that of controls and 25-30% of the response observed with saturating concentrations of NGF.

Amino acid and peptide sequence analyses of the factor revealed strict homology with the amino terminal region of human serum albumin.

Synthetic derivatives reproduced the trophic effect of the tumour-derived material with the response by sensory neurons saturating at 50 pM.

Extraction and RPHPLC on C-18 and C-1 of normal human serum did not yield UV (214 nm) absorbing material with chromatographic behaviour resembling E-2.

Albumin exerts a trophic effect on neurons in culture that is mediated by a fragment of its primary sequence.

Supported by MRC Canada and the NCE Program in Neural Regeneration and Functional Recovery.

QUINUCLIDINYL BENZILATE INDUCES ACETYLCHOLINESTERASE POSITIVE FIBER INCREASES WITHIN ADULT RAT HIPPOCAMPUS. V. R. Heale and C. W. Harley. Dept. of Psychology and Basic Sciences, Memorial University of Newfoundland, St. John's, Newfoundland A1B 3X9.

Prolonged blockade of nicotine receptors induces sprouting of axon collaterals at the neuromuscular junction (Holland, R.L. and Brown, M.C. *Science*, 207, 649-651, 1980). The present study looked at the role of muscarinic receptors in the control of collateral sprouting in the adult hippocampus. Quinuclidinyl benzilate (QNB; 40 µg/2µl), an irreversible muscarinic antagonist was injected unilaterally into the hippocampus of female Sprague Dawley rats. Beta hydroxy cyclodextrin (36%) served as a vehicle. Vehicle injections were made in the opposite hemisphere. Subjects were sacrificed 1, 4, 14 or 21 days after treatment. Brain sections (40 µm) were reacted for acetylcholinesterase (AChE). Increased AChE staining in the area of the injection site was visible at the 4 day interval in the QNB treated hippocampi. No increase in AChE staining was seen at the 4 day interval in vehicle treated hippocampi. Brains examined after a 1 day interval showed increased staining limited to the needle track in both vehicle and drug injected hemispheres which appeared to be a function of blood accumulation. At the 14 day interval staining increases were still present at the QNB injection site but were reduced compared to the 4 day interval. An increase in AChE staining was no longer evident at the QNB injection site at the 21 day interval.

These data suggest that irreversible blockade of muscarinic receptors can induce collateral sprouting of AChE reactive fibers in the hippocampus. We hypothesize that sprouting is rapidly induced and retraction occurs following renewed receptor activation.

95.15

NEUROTROPHIC PROPERTIES OF ORG 2766 IN NERVE CRUSH MODEL MAY DEPEND ON THE TYPE OF NEURAL INJURY AND SPECIFIC SENSORIMOTOR FUNCTIONS TESTED. I.A.D.M. Tonnaer, G.J.P.T. Schuijers*, H.A. Van Diepen* and A.M.L. Van Delft*. CNS Pharmacology R&D Labs, Organon Intl. B.V., 5340 BH Oss, The Netherlands.

The neurotrophic properties of the ACTH(4-9) analog Org 2766 were studied in rats after sciatic nerve crush. Org 2766 increased the density of myelinated axons reinnervating the denervated nerve, and facilitated recovery of sensorimotor function as measured by foot withdrawal after thermal stimulation of the footsole. These facilitating effects were only seen if the nerve was lesioned using forceps with grooved jaws and not with cross-hatched jaws, suggesting that the type of neural injury influences the trophic response to Org 2766. Functional recovery of the nerve was found to be dependent on the particular variable assessed. Different recovery rates were found when foot withdrawal was tested after thermal or electric-al stimulation. Recovery of toe spreading did not correlate with recovery of sensorimotor functioning. The possibility that Org 2766 preferentially affects specific sensorimotor aspects of nerve regeneration is being studied.

EPENDYMIN PROMOTES NEURITE GROWTH IN NEUROBLASTOMA CELL CULTURES. V.E. Shashoua, P. Nolan and B. Milinazzo. Ralph Lowell Labs, McLean Hospital, Harvard Medical School, Belmont, MA 02178

Ependymin is a brain extracellular glycoprotein that has been implicated in synaptic changes associated with the consolidation step of long term memory formation and neuronal regeneration. [*Cell Molec. Neurobiol.* 5:183-207 (1985); *J. Physiol. Paris* 83:232-239 (1989)]. Neuroblastoma (NB2a/d1) cells in culture were found to express ependymin mRNA and synthesize and release the protein into the media. Increased ependymin synthesis and its mRNA expression occurred after stimulation of neurite growth by dibutyryl cAMP (dbcAMP).

Ependymin appears to act as a trophic factor in the absence of dbcAMP. Additions of 1-10nM levels of ependymin to growth media containing fetal calf serum were found to enhance neurite "sprouting" and "extension" in culture. Dose-response and time-course studies were carried out. Enhanced sprouting (80%) and neurite extension (95%) occurred after 24 hrs in culture. The results suggest that one of the possible functions of ependymin may be as a trophic factor. Investigations of primary CNS cultures are in progress. This research was supported by an NIH grant No. NS25748 from NINCDS.

THE ACTH (4-9) ANALOG, ORG 2766, BINDS PREFERENTIALLY TO NEURONS OF DORSAL ROOT GANGLION (DRG) AND SPINAL CORD (SC) CULTURES. F. Van Huizen, H.L.A. Philipsen* and I.A.D.M. Tonnaer. CNS Pharmacology R&D Labs, Organon Intl. BV., PO Box 20, 5340 BH Oss, The Netherlands.

Functional recovery after sciatic nerve crush is accelerated in ORG2766 treated rats. Furthermore, in a clinical study, ORG2766 has been shown to prevent the neurotoxic side-effects of the anti-tumour agent cisplatin.

In order to elucidate its neurotrophic mechanism of action, we studied the presence of binding sites for ORG2766 on in vitro cultured DRG and SC cells with biotinylated ORG2766 (b-ORG2766). The avidin-peroxidase-DAB technique revealed displaceable b-ORG2766 binding especially on neuron-like cells with round somata and fine processes. Labeling with neurofilament (NF) antibody indicated that such b-ORG2766 binding cells were NF positive.

In primary cultures of DRG cells, we started to look for functional consequences of ORG2766 stimulation. The effect of ORG2766 on neurite outgrowth parameters in 1-day-old DRG cultures was compared with those of NGF. With NGF (100 ng/ml) a marked effect was seen on the number of neurite bearing neurons, neurite length and branching. With ORG2766 such clear effects were not found, although preliminary data indicated that some parameters, e.g. branching, might be responsive to ORG2766.

These data suggest that binding sites for ORG2766 are present on neurons in dorsal root ganglion and spinal cord cultures; these sites might be involved in mediating a neurotrophic effect on these cells.

95.16

THE EFFECT OF INSULIN-LIKE GROWTH FACTOR-I ON THE NEUROMUSCULAR JUNCTION IN ADULT RAT SKELETAL MUSCLE. E. Yu*, K. Callison, J.M. Roberts-Lewis, and P. Grebow*. Cephalon, Inc., West Chester, PA 19380

Insulin-like growth factor-I (IGF-I) is considered to be a potential therapeutic agent that would stimulate peripheral nerve regeneration and sprouting. The goal of this study was to determine the ability of IGF-I to increase two indices of motor nerve terminal sprouting and function. Two groups of six normal adult female Sprague-Dawley rats were given daily subcutaneous injections of IGF-I (50 µg/kg) or vehicle for 14 days. The injections were applied directly over the gluteus muscle of the right leg, carefully avoiding the underlying tissue. The contralateral gluteus muscles were not treated. The day following the last dose, gluteus muscles from both legs were prepared for histochemical evaluation of neuromuscular endplate size or autoradiographic analysis of I-125 alpha-bungarotoxin binding to nicotinic acetylcholine receptors. The endplate size of the IGF-I treated gluteus muscle was found to be significantly greater than in vehicle-treated muscle. In addition, the endplate size in the IGF-I treated contralateral gluteus muscle was significantly greater than in the vehicle treated contralateral muscle. Acetylcholine receptor binding was also significantly increased in the IGF-I treated muscle. These results indicate that administration of IGF-I to normal adult rats increases both the size of the endplate and density of acetylcholine receptor binding at the neuromuscular junction, responses which are consistent with previous reports of enhanced sprouting in response to IGF-I treatment. Taken together, these results indicate that IGF-I may have therapeutic benefits in certain neuromuscular disease states.

95.17

EFFECTS OF TESTOSTERONE ON LEVELS OF RIBOSOMAL RNA (rRNA), IN HYPOGLOSSAL NEURONS FOLLOWING NERVE INJURY. W.H.A. Yu¹, R.B. Gibbs² and D.W. Pfaff². ¹Dept. of Cell Biol. & Anat. Sci., City Univ. of NY Med. Sch., NY, NY 10031, and ²Lab. of Neurobiol. & Behavior, Rockefeller Univ., NY, NY 10021.

Testosterone (T) has been shown to accelerate axonal regeneration and reduce neuronal cell loss in motor nuclei of cranial nerves following nerve injury. Mechanisms by which T exerts neurotrophic effects are not yet known. In the present study, effects of T on relative levels of rRNA in axotomized (AX) hypoglossal neurons (HNs) were examined. Young adult female rats underwent unilateral transection of the hypoglossal nerve under anesthesia. Following axotomy, one-half of the animals received s.c. implants of T while remaining animals received sham implants as controls. At 1h, 1d, 7d and 14d after surgery, animals were perfused with 4% paraformaldehyde in PBS. In situ hybridization and radioautographic procedures were performed on Paraplast embedded sections using a ³H-rRNA probe. Somal area, number of grains/cell (G/C) and grains/unit area (G/A) were measured for all HNs in which nucleoli could be identified. T produced a significant increase in cell size and in relative levels of rRNA as measured by G/C and G/A. T also produced a greater increase in rRNA in AX HNs within 1h after axotomy than was observed in controls. These data are consistent with the hypothesis that the ability for T to accelerate axonal regeneration is related to an acceleration and amplification of rRNA accumulation following injury.

95.19

A THIOL COMPOUND, 2-MERCAPTOETHANOL, PROMOTES SURVIVAL OF CULTURED CORTICAL, HIPPOCAMPAL AND OLFACTORY EPITHELIAL NEURONS. R.J. Grill and S.K. Pixley. Dept. of Anat. and Cell Biol., Univ. of Cincinnati, Cincinnati, OH 45267.

Olfactory receptor neurons (ORNs), dissociated from newborn, Sprague-Dawley rat olfactory mucosal tissues, were maintained in primary monolayer cultures for 4 days. The survival-promoting effect of 2-mercaptoethanol (2-ME) was seen previously in both serum-containing and serum-free medium. A role for thiol compounds in this neuroprotective phenomenon was confirmed when another thiol, 2-mercaptoethylamine (2-MEA) exerted a similar survival-enhancing effect.

The olfactory neurons are not unique in showing enhancement of survival in response to a thiol compound. Cortical neurons in both serum-containing and serum-free medium showed greater survival with 2-ME. Hippocampal neurons in serum-free medium were also dependent on 2-ME. These data show that several types of neurons respond to a novel class of neuron survival-enhancing factors, thiol compounds. (Supported by Amer. Paralysis Assoc. Grant P01-8803-1, and NIH P01-DC00347-06).

ESTABLISHMENT OF MESENCEPHALIC GLIAL CELL LINES USING AN INDUCIBLE EXPRESSION SYSTEM: NEUROTROPHIC EFFECTS ON DOPAMINERGIC NEURONS. J. Engele and M.C. Bohn. Department of Neurobiology and Anatomy, University of Rochester Medical Center, Rochester, NY 14642.

Our previous studies have shown that medium conditioned (CM) by mixed embryonic mesencephalic glia contains a factor that supports the survival and differentiation of dopaminergic (DA) neurons. To obtain sufficient material for identifying this factor(s), clonal cell lines were established using an inducible expression system. E14.5 rat mesencephalic glia were replated following mitogenic stimulation with aFGF. These were cotransfected with two DNA constructs: the SV40 T-antigen under control of the lac operon and a lac repressor/VP16 herpes activator fusion protein under control of the actin promoter¹.

As expected, addition of the galactose derivative, IPTG, results in a dose-dependent inhibition of cell proliferation. Several lines resemble type II astrocytes morphologically and are immunoreactive for A2B5, a marker for Q2A progenitors, as well as the astrocytic marker, GFAP. Moreover, adding CM from these cell lines to serum-free low-density cultures of E14.5 mesencephalic neurons increases the number of tyrosine hydroxylase-immunoreactive neurons 2-4 fold.

This study has established immortalized mesencephalic astroglial cell lines using an inducible oncogene. These lines produce neurotrophic activity for DA neurons and, thus, provide a useful source for purification of this factor.

(Supported by the American Parkinson's Disease Association and the Deutsche Forschungsgemeinschaft).

95.18

EXPRESSION OF IGF BINDING PROTEIN 5 IN SPECIFIC REGIONS OF THE RAT. FETAL AND ADULT NEURAL AND NEUROENDOCRINE SYSTEMS. B. Green, R. Streck, T. Wood, P. Rotwein, and J.E. Pintar. Dept. Anat and Cell Biol, Columbia P&S, NY, NY 10032 and Dept. Metabolism, Washington U., St. Louis, MO. 63110.

Insulin-like growth factors (IGFs) are mitogenic peptides that circulate throughout the body in the adult and are synthesized during early stages of mammalian embryogenesis. A variety of indirect evidence has suggested that members of the IGF system, especially IGF-1, function as trophic molecules in the brain. The activity of IGFs is, in part, mediated by members of a family of at least six IGF binding proteins (IGFBPs). One newly cloned IGFBP, provisionally termed here IGFBP-5, was initially identified as an IGFBP that dramatically increases in abundance during muscle differentiation *in vitro* (JBC 264:13810). We have here used *in situ* hybridization to demonstrate that IGFBP5 is expressed not only in the fetal rat muscle progenitors but also in discrete locations of the developing and adult nervous and neuroendocrine systems. Further, the expression pattern is distinct from that of IGFBP2. For example, in the adult animal, BP5, but not BP2, is expressed in the anterior lobe of the pituitary gland. Further, the first demonstration of biochemical heterogeneity of posterior lobe pituitary cells is shown by the distinct expression patterns for BP2 and BP5 in this tissue. In the embryo, BP5 expression in the notochord and floor plate of the neural tube is present at least as early as E11; at this stage, expression is also noted in at least some muscle progenitors located in the dermomyotome. BP5 continues to be expressed in the neural tube through E18 in regions related to the ependymal zone including the basal plate and possibly in distinct neuronal clusters that are presently being evaluated in detail. Further, the olfactory bulb at E18 expresses high levels of BP5, which suggests that BP5 may modulate effects of IGF-1 locally produced in this region. Taken together, these data are consistent with distinct roles for IGFBP-5 in different regions of the nervous system. Supported by NS21970.

THIOL-DEPENDENT SURVIVAL AND NEURITE OUTGROWTH OF SEPTAL NEURONS IN CULTURE. Y. Arakawa, K. Isahara and S. Tachibana. Tsukuba Res. Labs., Eisai Co., Tsukuba-shi 300-26, Japan.

Neurons in the CNS are highly susceptible to peroxide radicals generated, e.g., after ischemia, and which cause peroxidation of membrane phospholipids and perturbation of Ca²⁺ homeostasis, finally leading to cell death. A question arose as to whether these mechanisms are also involved in cell death in culture. To test this, we estimated the protective effects of thiol compounds. Fetal rat septal neurons cultured in Dulbecco's Modified Eagle Medium (D-MEM) which does not contain cysteine died rapidly within 24 h, while the addition of cysteine to the medium remarkably improved the survival (EC₅₀, 40µM). This result agrees with our previous observation that Leibovitz L-15 medium which contains 1mM cysteine is superior to other culture media such as D-MEM. We have also discovered previously the neurite-promoting activity of phospholipids for septal neurons (Y. Arakawa et al., *J. Neurochem.*, *in press*). Now we have found that this activity is also dependent on cysteine, but requires higher concentrations (more than 0.25mM). Other thiol compounds, such as glutathione and coenzyme A, also showed these survival and neurite-promoting effects. These results suggest that thiol compounds are essential for survival, probably protecting cells from toxic peroxides, and may activate the enzymes involved in neurite outgrowth.

95.22

PHARMACOLOGICAL MANIPULATION OF A N. ACCUMBENS (NAcc) DERIVED TROPHIC FACTOR AND IT'S EFFECT ON MESENCEPHALIC CULTURE GROWTH. L.R. Ptak, E.S. Lo, D.H. Lin, C.M. Buhriend, and P.M. Carvey. Dept. Neurology, Rush U. Chicago, IL

We have previously shown that a striatal-derived neurotrophic factor is present in the brain and that its production can be manipulated both pharmacologically and by selective lesioning. Using rostral mesencephalic tegmentum (RMT) cultures, we examined whether or not a similar factor was present in the NAcc of rats chronically treated with haloperidol (HAL), levodopa (LD), or amphetamine (AMP). Extracts from these animals were incubated with E-13.5 RMT cultures and number of viable cells and neurite extension was scored after 40 hours. HAL treated NAcc extracts increased while LD and AMP extracts decreased the number of viable cells as well as process length relative to cultures incubated with saline treated NAcc extracts. These data suggest that a NAcc derived trophic factor is present in the adult rat and that pharmacological manipulations may either increase (DA antagonists) or decrease (DA agonists) the expression of this soluble trophic substance. This factor may be involved in the treatment of schizophrenia or its etiology.

95.23

EFFECTS OF CNS DRUGS ON THE PRODUCTION OF A STRIATAL-DERIVED NEUROTROPHIC FACTOR (SdNTF).

E.S. Lo, L.R. Ptak*, C.M. Buhriend, D.H. Lin*, H.L. Klawans*, D.K. Sierens†, and P.M. Carvey. Dept. Neurology, Rush U., Chicago, IL.

We have demonstrated that striatal, but not cerebellar extracts, exert trophic effects on cultured rostral mesencephalic tegmentum (RMT) cells. We have demonstrated that 6-OHDA lesions, Parkinsons disease (PD), as well as chronic haloperidol (HAL) treatment increases the production of SdNTF whereas chronic treatment with the DA agonists levodopa or amphetamine, reduces the production of the SdNTF. Kainic acid lesions of the striatum as well as normal aging reduce the production of the SdNTF. Chronic HAL treatment has also been shown to increase synaptic density in the striatum suggesting that the alterations in DA neuron growth seen in culture may occur *in vivo* as well. These data suggest that the SdNTF exists in the normal adult striatum and participates in the maintenance of the structural integrity of the nigro-striatal pathway. The inverse relationship between DA and SdNTF production suggests a homeostatic regulatory mechanism involving compensatory structural changes in response to alterations in DA following chronic drug treatment.

95.25

DEVELOPMENTALLY PROGRAMMED CHANGES IN ENDOGENOUS GANGLIOSIDE LEVELS REGULATE NERVE GROWTH FACTOR-MEDIATED RESPONSES. D.F. Chen and F.J. Roisen. Dept. of Anatomical Sciences and Neurobiology, Univ. of Louisville, Sch. of Med., Louisville, KY 40292.

Gangliosides are membrane bound glycosphingolipids, whose expression is under strict control during neuronal development. We and others have shown that affinity purified antibodies against the ganglioside GM1 block the actions of NGF. Our previous experiments have demonstrated that NGF-mediated neurogenesis was enhanced when chick embryonic dorsal root ganglia (DRG) were exposed to exogenous GM1. The potentiation by GM1 occurred only during periods when NGF function was submaximal. To probe the effects of GM1 during *in vivo* neuronal development, two channel flow cytometry was employed to label GM1 and other ganglioside species. Cholera toxin-B-FITC was used to label GM1 and anti-A2B5 conjugated with phycoerythrin for other gangliosides. NGF-mandatory and permissive neurons were separated partially by 3 hr differential adhesion. We demonstrated that fluorescent intensity of GM1 but not other complex gangliosides mirrored neuronal responsiveness to NGF in DRG. NGF-mandatory neurons exhibited 2x greater fluorescent intensity of GM1 labeling than NGF-permissive neurons. A small subpopulation of GM1-positive neurons also were labeled with anti-A2B5. Moreover, two neuronal populations could be distinguished on the basis of cell size. Large neurons were more differentiated, while small neurons were, perhaps, progenitor cells. The large neurons exhibited higher GM1 reactivity than small neurons. The GM1 levels in large but not small neurons mirrored NGF responsiveness. Our results strongly suggest that changes in endogenous GM1 levels modulate neuronal responsiveness to NGF. Furthermore, endogenous levels of gangliosides may also regulate developmentally programmed changes in sensitivity to neurotrophic factors. Supported by NIH NS24524.

95.24

THE TOPOGRAPHICAL DISTRIBUTION OF GM1 ON NEURO-2A NEUROBLASTOMA CELLS USING CHOLERA TOXIN-B-COLLOIDAL GOLD. I.H. Fentle and F.J. Roisen. Dept. of Anatomical Sciences and Neurobiology, Sch. of Med., Univ. of Louisville, Louisville, KY 40292.

Exposure of murine Neuro-2a neuroblastoma cells to exogenous ganglioside GM1 increases neurogenesis *in vitro*. Our previous studies of the surface distribution of GM1 on these cells employed FITC-labeled cholera toxin-B. The label appeared uniformly distributed along the perikaryal and neuritic surfaces. The present ultrastructural study employed cholera toxin-B bound to colloidal gold and examined the GM1 distribution in living cells. The rate of internalization was examined with cells grown in media for 24 hr prior to exposure to cholera toxin-B-gold for 2, 5, 15 or 60 min and fixation. Substantial quantities of GM1 were internalized rapidly; within 2 min gold label was observed in vesicles. Internalized label increased with the duration of cholera toxin exposure, while the surface labelling remained fairly uniform. To determine the possible microtubule (MT) involvement in regulating the distribution of GM1, MT altering agents (Taxol for stabilization and Colcemid for disassembly) were employed. Quantitative analyses of label on the perikaryal and neuritic surfaces, as well as internally, were performed with computer-assisted measurement of perikaryal and neuritic perimeters. In all cases, more label was found on neuritic surfaces than on the perikarya. Greater amounts of label were found after Taxol treatment compared to untreated controls. The controls were more heavily labeled than cells treated with Colcemid. These studies demonstrate that during neurogenesis the surface distribution of GM1 undergoes specific changes. Furthermore, microtubules appear to play a key role in anchoring and regulating the distribution of GM1. Supported by NIH grant NS24524.

NEURONAL DEATH I

96.1

TRANSPLANTED SYMPATHETIC NEURONS FROM OLD RAT AND MOUSE SURVIVE WELL AND OUTLIVE THE ORIGINAL DONOR. J. Suhonen*, J. Koistinaho and A. Hervo. Lab. of Gerontology, University of Tampere Medical School, PO Box 607, SF-33101 Tampere, Finland.

Sympathetic neurons (SN) have been widely used as model for neuronal aging. Young and adult adrenergic neurons are also viable as transplants in different locations. Transplantation technique provides a means for studying the effects of different milieu on neuronal degeneration and survival. Here we report on the survival of aged SN as autotransplants and allotransplants in the submandibular gland, adrenal cortex and in oculo. The survival of transplants from young and old donors was compared using catecholamine histochemistry, immunohistochemistry of tyrosine hydroxylase and electronmicroscopical techniques.

The survival of the old SN is site-dependent. Best survival was observed after allotransplantation in the mouse submandibular gland known to contain high concentration of NGF. A majority of the SN of both young and old transplant survived up to three months, while most neurons degenerated in control sites (other salivary glands, kidney, muscle). Adrenal cortex also provided a favourable microenvironment which maintained a large population of the old SN.

To study, whether SN can outlive the original host, transplants from 36 months old rats were placed in the submandibular gland and in oculo of three months old recipient. In both locations, a population of SN survived additional 12 months and eventually also longer. The histochemical parameters and electron microscopy suggest that these neurons were functionally active.

We conclude that a population of aged SN maintain enough plasticity and regenerative potential to survive as transplants, even longer than the maximum life span of the strain.

EVIDENCE FOR A TROPHIC INTERACTION BETWEEN ENTORHINAL CORTEX AFFERENTS AND CELLS OF THE HIPPOCAMPUS. D.C. Snyder, J. Cronin, and C.F. Ide. Dept. of Cell and Molecular Biology, Tulane University, New Orleans, LA 70118.

Using *ex vivo* surgery techniques, we have previously identified the primordium of the developing entorhinal cortex, and shown that prenatal lesioning of this primordium causes a loss of innervation to the CA1 region of the hippocampus in the mouse at birth. No other morphological changes were evident at this time. In this study, we have again lesioned the entorhinal cortex primordium at embryonic day (E) 16. At birth, the animals were fostered and allowed to develop to postnatal day (P) 21-34. Histologically, the animals showed a loss of granule cells in the superior blade of the dentate gyrus, as well as a loss of mossy cells from the hilus and pyramidal cells in CA3. Cell death was seen only in hippocampal regions adjacent to the lesioned cortex. In areas away from the lesion, no damage was seen among these cell types. In addition, no sprouting of granule cell axon collaterals occurred along the entire length of the hippocampus. *In vitro* intracellular and extracellular recordings were done on hippocampal slices prepared from experimental and naive control animals. Responses to hilar stimulation were comparable, but experimental animals showed diminished responses to perforant path stimulation. Thus, entorhinal cortex afferent innervation of the hippocampus provides a trans-synaptic trophic influence on developing hippocampal cell types during postnatal development.

96.3

INTRARETINAL NEUROTROPHIC FACTORS PREVENT GANGLION CELL DEATH *IN VITRO*. R.Linden, R.G.de Araujo^{*1} & R.A.Pires^{*}, Instituto de Biofísica da UFRJ, Rio de Janeiro and ¹Instituto de Biologia da UFF, Niterói, Brazil.

Developmental neuron death among retinal ganglion cells (RGC) depends on competitive interactions within the retina. The present experiments were designed to test for the release of intraretinal trophic factors. RGC were backfilled with HRP injected into the superior colliculus of newborn rats. Then monolayers of the dissociated retinae were cultured in medium previously conditioned during 4-7 days by aggregates or explants of retinal cells from either rat pups or chick embryos. The conditioned media significantly increased the survival of RGC at 2-3 days after plating, when compared with control medium. The effect was dose-dependent. Medium conditioned by explants of rat cerebral cortex had no effect. The activity was not dialysable and was abolished by heating at 56°C for 30 minutes. Survival of RGC within the explants was negligible after 4 days *in vitro*. The results indicate that retinal cells, either intrinsic neurons or glia, release one or more proteinaceous trophic factors with an effect on the survival of developing ganglion cells. These molecules may underlie dendritic competition for survival during embryogenesis.

CHEMOTACTIC FACTORS ATTRACTING MACROPHAGES ARE PRODUCED BY DEGENERATING NEURONS IN THE DEVELOPING BRAIN. C.E. Milligan, T.J. Cunningham and P. Levitt. Department of Anatomy and Neurobiology, Medical College of Pennsylvania, Philadelphia, PA 19129.

The specific mechanisms involved in the targeting of macrophages to the sites of neuronal cell death in the central nervous system following injury are unknown. We have previously shown that lesions to the rat visual cortex at birth result in a rapid and transient invasion of peripherally derived macrophages to the degenerating dorsal lateral geniculate nucleus (dLGN) within days. We hypothesized that a chemotactic factor originating from the degenerating neurons of the dLGN aids in the targeting of these macrophages after cortex lesions. To investigate this hypothesis, we used a blindwell chemotactic chamber system that consists of a lower well into which tissue slices containing putative chemoattractant agents are placed, and an upper well into which the macrophages are placed. The two wells are separated by a filter through which macrophages migrate in response to chemotactic signals. The migratory response of a peripherally derived population, the resident peritoneal macrophages, was assayed with tissue slices containing the dLGNs from animals with and without cortex lesions and the chemotactic peptide, n-formyl MET-LEU-PHE. The maximal response, assessed by percent macrophage migration, was to chemotactic factors produced by tissue slices containing the dLGNs from animals which received visual cortex lesions at birth. This activity appears to be concentration dependent. The results suggest that neurons, upon being injured, actively produce a diffusible factor that attracts specific groups of phagocytic cells to a precise location for subsequent resolution of cell death. This work was supported by NINDS Grant NS 16487.

96.7

ENDONUCLEASE ACTIVITY IMPLICATED IN DEATH OF PC12 CELLS AND SYMPATHETIC NEURONS AFTER NGF DEPRIVATION. A. Batsistatou, L.A. Greene^{*}. Department of Pathology and Center for Neurobiology and Behavior, College of Physicians and Surgeons, Columbia University, New York, N.Y. 10032.

The purpose of this study has been to explore the mechanisms by which neurotrophic factors promote survival/prevent death of their responsive neurons. Primarily, we have used serum-free cultures of PC12 cells as a model system for studying the neuronal cell death which occurs after neurotrophic factor deprivation. In this experimental paradigm, NGF rescues the cells from death. We report that serum-deprived PC12 cells manifest an endonuclease activity that leads to internucleosomal cleavage of their cellular DNA. This activity is detected several hours before any morphological sign of cell degeneration or death. NGF and serum, which promote survival of the cells, inhibit the DNA-fragmentation. Aurintricarboxylic acid (ATA), a general inhibitor of nucleases *in vitro*, also suppresses the endonuclease activity and promotes long-term survival of PC12 cells in serum-free cultures. This effect appears to be independent of macromolecular synthesis. In addition, ATA promotes long-term survival of cultured sympathetic neurons after NGF-withdrawal. It is hypothesized that the activation of an endogenous endonuclease could be responsible for neuronal cell death after neurotrophic factor deprivation.

96.4

MULTIPLE PATHWAYS FOR DEGENERATION OF DIFFERENTIATING PC12 CELLS CAUSED BY ACUTE WITHDRAWAL OF NERVE GROWTH FACTOR. S.Tanaka^{*}, T.Koike, K.Kaji^{*} and A.Takashima. Department of Natural Science, Saga Medical School, Nabeshima, Saga 84001, Tokyo Metropolitan Institute for Gerontology, Tokyo 113, Mitsubishi-Kasei Institute of Life Sciences, Tokyo 194, JAPAN.

Degenerative processes of PC12 cells caused by nerve growth factor (NGF) deprivation were characterized by morphological and biochemical criteria including measurements of cellular ATP content and release of the cytoplasmic enzyme, lactate dehydrogenase (LDH), into medium. PC12 cells treated with NGF (50ng/ml) for 10-14 days underwent massive degeneration characterized by disintegration of neurites, decrease in the ATP content to less than 50%, which occurred in conjunction with increased release of LDH into medium (25-35% of the total activity by 25h after deprivation). About 40% of the LDH release was suppressed by treating the cells with cycloheximide (0.3µM) or cordycepin (1-10µM), indicating that active cell death occurs only partially. Neurite dilation was largely prevented by treating the cells with the protease inhibitor leupeptin (100µM) or other inhibitors. In the presence of leupeptin, about 60-70% of the LDH release was blocked by cycloheximide. These degenerative processes were completely prevented by chronic depolarization with high potassium (>35mM), CPT-cAMP (>0.1mM), acidic and basic FGF (10ng/ml), but other growth factors including EGF, PDGF, TGF or cholinergic agonists were ineffective. These results demonstrate the presence of transcription-dependent and -independent mechanisms for degeneration of differentiating PC12 cells caused by acute withdrawal of NGF.

96.6

BIOCHEMICAL CHARACTERIZATION OF DEGENERATION AND DEATH OF SYMPATHETIC NEURONS INDUCED BY NEUROTROPHIC FACTOR DEPRIVATION. T.L. Deckwerth and E.M. Johnson, Jr. Department of Pharmacology, Washington University School of Medicine, St. Louis, MO 63110.

Sympathetic neurons depend upon NGF for survival during embryonic and postnatal development. Dissociated superior cervical ganglion neurons of embryonic rats cultured for 5-7 days in the presence of NGF respond to NGF withdrawal by atrophy, lysis and death within 4 days as measured by altered morphology, release of cellular protein, and loss of refractility, respectively. In order to elucidate the molecular mechanism which irreversibly commits the neurons to die after NGF deprivation, we measured several biochemical parameters in dying neurons as function of time after NGF deprivation relative to undeprived control neurons. Among the parameters examined are amino acid uptake, incorporation of amino acids into protein, cytochrome oxidase activity, and mitochondrial function assessed by reduction of the tetrazolium dye MTT. We find that different parameters change with different timecourses, suggesting a temporal sequence of degenerative events triggered by NGF deprivation. The temporal correlation of the change of these and other parameters with the timecourse of commitment to die as measured by the ability of NGF to rescue dying neurons after different times of NGF-deprivation is under investigation.

TWO DISTINCT MOLECULAR MECHANISMS MEDIATE PROGRAMMED CELL DEATH.

L.M. Schwartz, S. Smith^{**}, M.E. Jones^{*}, B.A. Osborne^{**}. Depts of Zool. & Vet. Animal. Sci., U. Mass. Amherst, Mass. 01003.

Large numbers of cells die by a non-pathological process known as Programmed Cell Death (PCD). Relying on published data and our own results, we identified two distinct PCD pathways: apoptosis and autophagy. Apoptosis involves a nucleolytic mechanism which is expressed primarily in non-neuronal vertebrate cells. It is characterized by rapid degradation of chromosomal DNA, chromatin deposition along the nuclear membrane, and constitutive expression of the polyubiquitin gene. In contrast, autophagy appears to represent a proteolytic cell death pathway. It is observed in the majority of naturally dying vertebrate neurons and most if not all invertebrate cells undergoing PCD. Autophagic PCD is characterized by the retention of high molecular weight chromosomal DNA, nuclear pyknosis and dramatic increases in the levels of polyubiquitin mRNA. It is speculated that apoptosis arose late in phylogeny to rapidly destroy potentially dangerous mitotic cells. Supported by R01 grants (LMS and BAO) and an RCDA (LMS).

96.9

MOLECULAR REQUIREMENTS FOR NEURONAL DEGENERATION INDUCED BY DOMINANT MUTATIONS OF THE *MEC-4* GENE OF *CAENORHABDITIS ELEGANS*.

M. Driscoll and M. Chalfie, Dept. of Biological Sciences, Columbia University, New York, NY 10027

Rare dominant alleles of two genes, *mec-4* and *deg-1*, produce abnormal gene products that result in the vacuolar degeneration of specific neurons in the nematode, *C. elegans*. Molecular characterization of these two genes has established that *mec-4* and *deg-1* are members of a gene family that appear to encode membrane-spanning proteins. The sequences of the dominant *mec-4* alleles revealed that all degeneration-inducing mutations occur at the same position, normally an Ala residue thought to be situated adjacent to the cell membrane. *In vitro* mutagenesis has demonstrated that any large amino acid substitution at this position can induce neuronal degeneration. The region surrounding this site has been further altered using site-directed mutagenesis and the influence of neighboring amino acids on the degeneration mechanism will be discussed.

By comparing genomic sequences of the *mec-4* genes of *C. elegans* and *C. briggsiae*, a closely related nematode, several additional exons upstream of the start of our partial *mec-4* cDNA clone have been tentatively identified. Gene fusions and antibody staining experiments designed to determine when and where the *mec-4* protein is expressed are in progress.

96.11

CYCLOHEXIMIDE BLOCKS THE STEROID-MEDIATED DEATH OF PROLEG MOTONEURONS DURING THE METAMORPHOSIS OF *MANDUCA SEXTA*. J.C. Weeks, B.H.G. Debu and S.K. Davidson. Institute of Neuroscience, University of Oregon, Eugene, OR 97403

The abdominal prolegs, which are locomotory appendages of the caterpillar, are lost during the larval-pupal molt of *Manduca*. This transformation involves the degeneration of proleg muscles, regression of the dendrites of proleg motoneurons (MNs), and the programmed death of a subset of the MNs. The regression and death of the MNs are triggered by the prepupal peak of ecdysteroids in the hemolymph. To investigate whether protein synthesis is involved in the death of proleg MNs, we injected developing insects with the protein synthesis inhibitor, cycloheximide. Cycloheximide was injected into intact insects during the prepupal peak of ecdysteroids (1 injection every 12 hr), or into abdomens that were ligated before the prepupal peak and infused with 20-hydroxyecdysone to replace the missing steroids (1 injection of cycloheximide at the start of the infusion). In both cases, cycloheximide blocked the death of proleg MNs in a dose-dependent fashion, suggesting that protein synthesis is required for their death. Higher doses of cycloheximide were required to prevent dendritic regression than were required to block MN death.

RAPID RIBOSOMAL DEGRADATION ASSOCIATED WITH TRANSNEURONAL CELL DEATH: EFFECTS OF PROTEIN SYNTHESIS INHIBITION. Gwenn Garden, Mark Bothwell and Edwin W. Rubel, Dept. of Physiology-Biophysics and Hearing Development Laboratory, University of Washington, Seattle, WA 98195.

Neuronal death during development, after target deprivation or growth factor deprivation, is inhibited by protein synthesis inhibitors. Deafferented neurons of the chicken primary auditory brain stem nucleus, n. magnocellularis, undergo cell death characterized by early dissociation of ribosomes from polysomes and endoplasmic reticulum, followed by marked ribosomal degradation. Ribosomal degradation, seen by electron microscopy is also an early degenerative change in many other cell types undergoing developmental or physiologically induced cell death. Changes in ribosome integrity can be detected immunocytochemically using a monoclonal antibody, Y10B, which immunoprecipitates ribosomal RNA. At early time points after cochlea removal, n. magnocellularis neurons show a marked decrease in Y10B immunoreactivity.

To determine if neuronal death in activity deprived n. magnocellularis neurons is dependent on new gene expression, we treated chicks with 250 µg of cyclohexamide intracranially just prior to activity deprivation by cochlea removal. This treatment inhibited protein synthesis by 95% for at least 3 hours. At several time points after cochlea removal, cyclohexamide treated and control animals were perfused with 4% paraformaldehyde. Brain stems were embedded in paraffin and serially sectioned. Sections were labeled with Y10B anti-ribosomal antibodies or stained with thionin. Activity deprived neurons in both control and cyclohexamide treated animals showed decreased immunoreactivity for Y10B when compared to neurons in the contralateral n. magnocellularis. Cyclohexamide treatment for the first 3 hours after cochlea removal did not decrease loss of Y10B immunoreactivity. We conclude that cochlea removal effects on ribosome structure, as reflected by loss of Y10B immunoreactivity, occur in the absence of new gene expression.

Y10B antibody was a gift from M. Lerner and J. Steitz. Support: Hartford Foundation Fellowship and NIH grants NS23343 and DC00393.

THE PREVENTION OF EARLY CELL DEATH IN THE DEVELOPING NEURAL TUBE OF THE CHICK EMBRYO BY JANUS GREEN B. S. Homma and B. W. Oppenheim, Dept. of Neurobiol. and Anatomy., Bowman Gray Sch. of Med., Winston-Salem, NC 27103

Degenerating cells occur in the neural tube and floor plate of the chick embryo at stages (st. 17-20) when commissural neurons extend their axons ventrally and then across the ventral midline. Embryos were treated with Janus Green B (a dye which has been reported to prevent the programmed death in interdigital region of developing chick limb) for 6 hours during the peak period of cell death (st.18) in the brachial neural tube. The number of pyknotic cells was significantly reduced following treatment with Janus Green B. A number of growth and trophic factors are also being examined for their effect on this early form of cell death in the neural tube. Preliminary observations of axonal projections in the floor plate indicate that following treatment with Janus Green B the growth cones of commissural axons in this region (ventral midline) exhibit an altered morphology. By contrast, growth cones in the other regions along the commissural pathway, or growth cones of non-commissural neurons, appear normal. These initial results suggest that the death of cells in the pathway of elongating axons may play a role in axonal guidance.

96.12

ACTIVITY-DEPENDENT REGULATION OF RIBOSOMAL RNA K. S. Canady and E. W. Rubel, Hearing Development Laboratories, Univ. of Washington, Seattle, WA 98195

Ultrastructural studies investigating the cellular mechanisms underlying trans-neuronal degeneration in the chick auditory system have described a rapid dissociation of ribosomes in postsynaptic neurons following cochlea removal. Dissociation of ribosomes begins by 1 hr after cochlea removal and is predictive of subsequent cell death. Reduced protein synthesis in these neurons, presumably due to the ribosomal changes, has been observed as soon as 30 min after cochlea removal. By 6 hrs after cochlea removal, deafferented neurons segregate into 2 populations: one population shows a 20% reduction in protein synthesis, while the other (~25%) shows a complete cessation of protein synthesis and complete dissociation of cytoplasmic ribosomes. These responses to cochlea removal are due to the loss of 8th nerve action potentials since they can be duplicated by blocking afferent 8th nerve activity with TTX.

We examined immunoreactivity for a ribosomal antigen in neurons of the chick cochlear nucleus following elimination of afferent activity. Posthatch (1-2 wks) and adult (68 wks) chickens were sacrificed 1-6 hrs following unilateral cochlea removal or intralabyrinthine TTX injection. Brain stem sections were immunostained using the Y10B monoclonal antibody, which has been shown to immunoprecipitate ribosomal RNA. Other posthatch chicks received an intracardiac injection of 3H-leucine and were sacrificed 6 hrs after cochlea removal. Sections from the latter animals were processed for autoradiography in addition to Y10B immunoreactivity (Y10B-IR).

Posthatch chicks show a dramatic reduction in Y10B-IR in the ipsilateral cochlear nucleus as early as 1 hr following cochlea removal. Y10B-IR is also reduced, though to a lesser extent, in adult chickens following cochlea removal. Double-labeling for 3H-leucine and Y10B revealed a positive correlation between protein synthetic activity and Y10B-IR. These results suggest that the regulation of neuronal protein synthesis by afferent activity is mediated by rapid changes in ribosomal RNA.

The Y10B antibody was a gift from J. Steitz and M. Lerner. Supported by PHS grant DC00393.

96.14

NEURONAL DEATH FOLLOWING DEAFFERENTATION IS BLOCKED BY DELAYED INHIBITION OF MITOCHONDRIAL PROTEIN SYNTHESIS. G. E. Hyde and D. Durham, Departments of Otolaryngology and Biological Structure, RL-30, University of Washington, Seattle, WA 98195.

Removal of excitatory input to second-order auditory neurons (n. magnocellularis, NM) in the chick brain stem results in the eventual death of ~20% of these neurons. We have previously reported a rapid, dramatic proliferation of mitochondria in deafferented NM neurons (Hyde & Durham, Soc. Neurosci. Abstr. 15:290, 1989). To determine whether mitochondrial proliferation is necessary for neuronal survival following cochlea removal, we used chloramphenicol, a mitochondrial protein synthesis inhibitor, to block mitochondrial proliferation after cochlea removal in 10-day-old chicks. When chloramphenicol is administered at the rate of 1000 mg/kg/day for the first 12 hours following cochlea removal, up to 80% of the deafferented neurons will die (Hyde & Durham, Soc. Neurosci. Abstr. 16:984, 1990). To determine whether this effect was due to the timing of the treatment, the 12 hour chloramphenicol treatment was delayed for 6 hours after cochlea removal. After 5 days survival, these animals were deeply anesthetized and sacrificed. NM neuron counts, made in 10µm Nissl-stained paraffin sections, revealed no significant loss of deafferented neurons (p>.40). An additional set of animals surviving to 14 days following cochlea removal showed no significant neuronal loss (p>.90), indicating that neuronal death had been blocked rather than delayed. Vehicle-treated animals showed the expected degree of deafferentation-induced neuronal loss (p<.05).

Thus, mitochondrial protein synthesis appears to have opposing effects on neuronal survival following deafferentation. During the first 12 hours following deafferentation, mitochondrial protein synthesis is required for the survival of the majority of neurons. However, mitochondrial protein synthesis between 6 and 18 hours after deafferentation is necessary for the death of some deafferented neurons. (Supported by PHS grants DC00018 and DC00520 and the Deafness Research Foundation.)

97.1

MICROGLIA AND THE DEVELOPING OLFACTORY BULB. A. Q. Caggiano and P. C. Brunjes. Univ. of Virginia, Charlottesville, VA 22903.

Microglia have been implicated as markers of cell death in the developing nervous system (e.g., *J. Comp. Neurol.* **287**, 286). While it has been demonstrated that there are large increases in cell number within the rat olfactory bulb in the first 30 postnatal days, little is known about rates and patterns of cell death in this primary sensory relay. The fact that normal cell death does occur is suggested by a report indicating that blocking airflow through one half of the nasal cavity decreases cell survival rates in the bulb (*J. Comp. Neurol.* **289** 481). In addition, observations of both continuous olfactory receptor cell replacement and lifelong bulb neurogenesis suggest that the region might have unique needs for a stable population of the phagocytes. The present study investigated patterns of microglial staining in the maturing rat olfactory bulb. Microglia were visualized with the peroxidase labeled Isolectin B4 from *Bandeiraea simplicifolia* BS-1 (*J. Neurosci. Meth.* **38**, 1683). Initial data indicate that by postnatal Day 10 there is a large, uniform population of glia resident in all bulb layers. By Day 30 many more glia are found in the bulb and a deep-to-superficial gradient of staining emerges, with highest numbers of cells found in the subependymal layer. Supported by grant DC-00338.

MITRAL/TUFTED CELL AND OLFACTORY AXON NUMBERS ARE CORRELATED IN NORMAL AND PARTIALLY DEAFFERENTED XENOPUS TADPOLES. C.A. Byrd and G.D. Burd. Depts. of Anatomy and Molecular & Cellular Biology, University of Arizona, Tucson, AZ 85721.

Previous studies in several amphibian species reported that removal of the olfactory placode (OP) prevents the formation of the olfactory bulb (OB) (Piatt, 1951; Clairambault, 1971; and Stout & Graziadei, 1980). We have previously shown that throughout *Xenopus* larval development the total number of olfactory receptor cell (ORC) axons is correlated with the total number of cells in the mitral cell/plexiform layer (MC/PL) (Byrd & Burd, 1990, *Neurosci. Abstr.*). The present study examined tadpoles with one or both OPs removed before the ORC axons had reached the neural tube (NT). Quantitative analyses were performed on animals in which the OP did not regenerate or was significantly reduced. Animals with unilateral OP removal had one nasal capsule, one ON, and one OB; the other side of the telencephalon had no OB, did not fuse with the remaining OB, and appeared to contain only cells of the cortex. Both the number of ORC axons and the number of cells in the MC/PL were smaller than the total number of axons or cells in control animals, but these numbers were slightly larger than in one nerve or one OB of control animals. In a scatter plot of ORC axon number versus cell number in the MC/PL, these experimental animals fit on the same regression line that was generated in a normal development study (Byrd & Burd, 1990). Since it is possible that we removed some of the underlying NT with the OP, we also analyzed animals in which we removed part of the NT without disturbing the OP. The NT regenerated, and the ORC axon and MC/PL cell numbers were within the normal range. In conclusion, regardless of surgical treatment or larval stage, the number of cells in the MC/PL is correlated with the number of ORC axons. Supported by NIDCD #DC00446.

97.5

STEROID REGULATED DEVELOPMENT IN MOTH OLFACTION. R.G. Vogt and M.R. Lerner, Yale Med. Sch., New Haven, CT 06510.

The olfactory system is constructed in a spatially and temporally specific manner, with specific gene products (e.g. receptors) expressed in the "correct" cells at the "correct" times. The antenna of the moth *Manduca sexta* provides a model for studying the molecular signals which regulate spatial and temporal specificity of olfactory gene expression during development. Three classes of odorant binding proteins (OBP) are expressed in distinctly different and identifiable sensilla: the pheromone binding protein, PBP, and the general odorant binding proteins GOBP1 and GOBP2 (1991, *J. Neurobiol.* **22**:74). Development of the adult antenna occurs over about 18 days (Hildebrand & colleagues). Birth of sensory neurons occurs at about 10% of dev., axonal and dendritic outgrowth is complete by about 50%, and the neurons respond to odorants by 90%. Ecdysteroids, steroid hormones, are known to coordinate many events in insect development, and Schwartz & Truman (1983, *Dev. Biol.* **99**:103) had shown that preventing a normal decline of ecdysteroid late in adult development prevented the programmed death of certain muscles and neurons. Because PBP expression occurred at this same time, we cultured antennal fragments of staged animals for 20 hrs in the presence or absence of the active hormone 20-hydroxy ecdysone, followed by a 2 hr incubation in ³⁵S-methionine. PBP, GOBP1 and GOBP2, normally appearing 36 hrs before adult emergence, could be expressed at least 2 days early by prematurely lowering the ecdysteroid levels, suggesting that normal OBP expression is induced by the decline in steroid. This study supports a model in which olfactory development is temporally coordinated by external signals.

97.2

CELL PROLIFERATION IN THE DEVELOPING OLFACTORY NEUROEPITHELIUM OF THE CHICK. H. Martin. Northwestern Univ., Dep. of Neurobiology & Physiology, Evanston, IL 60201.

During the period in which the olfactory organ of the chick develops, nuclei of proliferating cells were labeled with 1-hr. pulses of [³H]-thymidine. Quantitative analysis of autoradiograms suggests that there are two populations of proliferating cells in the olfactory neuroepithelium. Each population is distinguished by the location of its progenitor cells and the temporal dynamics of its proliferation. One population has progenitor cells located in the basal cell layer. Proliferation of these cells remain relatively constant. Regional variability in nuclei labeling is related to cell density and the thickness of the columnar epithelium. On the other hand, progenitor cells from the second population is located in the intermediate layer of the epithelium. Proliferation in this population varies with the age of the embryo. It is highest during an early stage of development and declines to zero at the stage when olfactory neurites are known to reach the telencephalon. Other studies have suggested that this second population represents the cell line of olfactory receptor neurons. This study provides additional evidence to suggest that, during development, the regulation of neurogenesis in the olfactory neuroepithelium of the chick is independent of the regulation of proliferation of basal cells.

97.4

OLFACTORY RECEPTOR CELLS EXPRESS A UNIQUE ANTIGEN THROUGHOUT DEVELOPMENT AND INTO ADULTHOOD IN THE CLAWED FROG, XENOPUS LAEVIS. S.F. Matheson and G.D. Burd. Program in Neuroscience and Depts. of Anatomy and Molecular & Cellular Biology, University of Arizona, Tucson, AZ 85721.

We have characterized the distribution of the antigen recognized by a monoclonal antibody (E7) generated in our laboratory. Olfactory epithelia (OE) from *Xenopus laevis* larvae (stages 40-58) and young adults were examined using a combination of immunofluorescence and neuroanatomical techniques. In stage 58 larvae, cytoplasmic labelling was observed in dendrites, cell bodies and axons of olfactory receptor cells (ORCs) as well as in the olfactory nerve (ON), and extending into the OB. Unilateral ON transection resulted in total loss of specific labelling in the ipsilateral OE after 16 days. Furthermore, E7 immunofluorescence combined with retrograde labelling of ORCs by injection of Fluorogold into larval OB led to significant overlap in fluorescent regions of the larval OE. These results suggest that E7 recognizes an antigen expressed by ORCs in larvae. E7 immunofluorescence was observed as early as stage 40, two stages after ORC axons form synapses in the developing olfactory bulb (OB). Metamorphosis led to dramatic changes in E7 labelling; in young adult OE, E7 labelled the three different olfactory cavities in distinct patterns. Intense labelling occurred on the apical surface, presumably in the mucous layer, of the principal cavity, which may participate in air breathing. Cytoplasmic fluorescence, which was prominent in this cavity in larvae, was absent. The putative vomeronasal epithelium was diffusely labelled, while the third (presumably aqueous) region displayed a pattern similar to that seen in larvae. Further studies are examining the developmental time of appearance of the antigen and testing for its expression in other species. Supported by NIDCD DC00446 and ADCRC 82-1678.

VOLTAGE-DEPENDENT CURRENTS IN DEVELOPING AND MATURE TASTE CELLS IN MUDPUPPY (*Necturus maculosus*). Alan Mackay-Sim, Sue Kinnaman, and S.D. Roper. Dept of Anat and Neurobiol, Colo St Univ, Ft Collins, CO 80523, and the Rocky Mt Taste & Smell Cntr, Denver, CO 80262.

Underlying taste perception is a remarkable plasticity in which the receptor cells are continually replaced by division and differentiation of basal stem cells. Thus, in the taste bud, there is a variety of cell types including stem cells, developing cells and mature receptor cells. In many species there is an additional basal cell type which resembles a Merkel cell. In the mudpuppy this Merkel-like cell possesses synaptic contacts with taste receptor cells and with sensory axons (Delay et al., 1988). The aim of the present study was to identify the whole-cell currents associated with the different taste cell types. In order to label only those cells whose apical process had reached the taste pore, WGA-RITC conjugate was applied to the tongue surface prior to cell isolation. Whole-cell currents were recorded in physiological saline and in the presence of TEA, TTX and Ba²⁺. Cells were then classified according to their fluorescent label and their size. Mature receptor cells (those labelled with WGA-RITC) had voltage-dependent Na⁺, K⁺ and Ca²⁺ currents whereas most developing taste cells (elongate cells of similar size but without label) had only voltage-dependent K⁺ currents. Some developing cells (5/14) had all 3 currents. Basal cells (small, round, unlabelled cells) were of two classes: those with voltage-dependent Na⁺, K⁺ and Ca²⁺ currents; and those with K⁺ currents only. Preliminary experiments indicate that cells of the former class contain serotonin and are therefore probably a Merkel-like cell. The other basal cells may be stem cells or early-stage developing taste cells. These results provide evidence for a developmental sequence in which voltage-dependent K⁺ channels are expressed earlier in development than Na⁺ and Ca²⁺ channels. Na⁺ and Ca²⁺ channels appear to be expressed at about the same time, apparently when the cell extends its apical process into the taste pore. Supported by NIH grants DC00244, DC00766(SCK), DC00374(SDR), and AG06557(SDR).

BIRTH TIMES OF LABELLAR GUSTATORY NEURONS IN THE BLOWFLY *PHORMIA REGINA*. G.S. Pollack. Dept. of Biology, McGill University, Montreal, Quebec, Canada H3A 1B1.

Each labellar lobe contains two types of taste sensilla: ca. 65 interpsuedotracheal papillae, each innervated by 3-4 neurons, and ca. 125 taste hairs, each with 5 neurons. The neurons of a sensillum, all of which are believed to derive from a common precursor, differ in sensory specificity and behavioral import. An unanswered question is how these differences are specified. I measured the birth times of neurons to determine whether their phenotypes might be correlated with, and thus perhaps determined by, birth order. This initial study focuses on the interpsuedotracheal papillae.

Pupae of different ages were injected with the thymidine analog 5-bromo-2'-deoxyuridine (BRDU). Double-label immunocytochemistry, using antibodies specific for neuronal surfaces and for BRDU, made it possible to determine which neurons had incorporated BRDU and therefore had been born after the time of injection.

The papillae appear within the first day following pupation, with lateral ones born earlier than medial ones. In almost all cases, either all or none of the neurons of a single papilla were labeled with BRDU. This suggests that the neurons of a sensillum are born nearly simultaneously, and argues against birth order as a mechanism for specifying phenotype.

AUDITORY INVASION OF THE VISUAL CORTEX IN NEONATALLY ENUCLEATED SYRIAN HAMSTERS (*MESOCRICETUS AURATUS*). Z. Wollberg and A. Heicklen-Klein*. Dep. of Zoology, George S. Wise Faculty of Life Sciences, Tel-Aviv University, Tel Aviv 69978, Israel.

The visual cortex (VC) of neonatally enucleated hamsters was studied to determine if its function or connections had changed. Structurally, the blind hamster's VC was similar to the normal hamster's VC and as expected did not respond to flashes of light. However, auditory evoked responses were recorded on the surface of the remnant primary VC suggesting that parts of the visually deprived VC received auditory input. In order to disclose the origin of this input, WGA-HRP was applied into the area that responded to auditory stimuli and that topographically corresponded to the VC of normal hamsters. This revealed that the reciprocal connection between the dorsal lateral geniculate nucleus (dLGN) and the VC was intact. In addition, both in normal and enucleated hamsters the VC received projections from layer VI of the auditory cortex, yet, the number of these projections was significantly larger in the blind animal. WGA-HRP injection into the dLGN disclosed also retrogradely labeled neurons in the inferior colliculus. It is concluded that the deprivation of the VC from its original input facilitates the "invasion" of a new sensory modality into this area.

THE CRITICAL PERIOD FOR CHORDA TYMPANI TERMINAL FIELDS IN THE NTS OF SODIUM CHLORIDE DEPRIVED RATS. R. F. Krimm* and D. L. Hill. Department of Psychology, University of Virginia, Charlottesville, VA 22903.

Sodium restriction on or before postconception day 8 produces a suppression in the response of the chorda tympani nerve to sodium salts, while responses to nonsodium salts remain unaffected. Placement on a sodium replete diet after postnatal-day 28 results in complete recovery of the peripheral nerve response; however, alterations in the size and distribution of the chorda tympani terminal field are permanent. Therefore, there must be a critical period, during which placement on the sodium replete diet after sodium deprivation is effective in reversing the alterations in chorda tympani terminal field. The present study was designed to determine whether this critical period occurs prenatally or postnatally. The terminal field size and distribution was measured in deprived rats placed on the sodium replete diet on the day of birth (birth-repleted) or on postnatal day 28 (28-day repleted) and control rats. For visualization of the terminal field, HRP was placed on the cut nerve and the tissue was processed with a modified TMB technique after 24-hour survival. Preliminary results indicate that the terminal field size of birth-repleted rats is intermediate in size between control and 28-day repleted rats. The distribution of the terminal field for birth-repleted rats was similar to that of 28-day repleted animals. These results indicate that the critical period for the effects of sodium deprivation on the chorda tympani terminal field is before birth. Experiments are in progress to precisely define the boundaries of the critical period. Supported by NIH grants DC00025 and DC00407.

POSSIBLE CHEMOTOPIC ORGANIZATION OF THE CENTRAL GUSTATORY SYSTEM IN RATS DEPRIVED OF SODIUM CHLORIDE THROUGHOUT EARLY DEVELOPMENT.

C.T. King and D.L. Hill. Department of Psychology, University of Virginia, Charlottesville, VA 22903.

Dramatic alterations in the physiology and anatomy of both the peripheral and central components of the gustatory system have been reported in rats who have been raised on a low (0.03%) sodium chloride (NaCl) diet throughout very early development. Neurophysiological alterations include suppression of NaCl-elicited activity in the chorda tympani nerve (CT) and in cells located in the rostral NTS. Interestingly, recovery of peripheral CT activity results once rats are fed a NaCl replete (1%) diet; however, this replete diet does not induce normal function of central NTS cells. Instead, these cells show a "hyper-responsivity" to sodium stimuli. The present investigation was designed to determine whether metabolic changes in the NTS are also associated with the "hyper-responsivity" of these cells to sodium stimuli. Since the dorsal portion of the CT terminal field has been shown anatomically to be most affected by the dietary manipulations, it was hypothesized that NaCl repletion would result in increased metabolic activity of cells in the dorsalmost portion of the terminal field area. Indeed, compared to NaCl deprived rats (N=10), deprived rats fed the NaCl replete diet and 0.154M NaCl for 24 hours (N=9) show significant ($p < .05$) increases in succinate dehydrogenase (SDH) activity at the level of the NTS where the dorsal portion of the CT terminal field is typically located. Such results are suggestive of chemotopically segregated CT afferents and/or NTS cells in NaCl deprived rats. We are currently examining the effect of a 24 hour sucrose exposure to NaCl deprived rats to investigate the stimulus-specificity of this localized increase in SDH activity. Supported by NIH grants DC00025 and DC00407.

DOPAMINERGIC MODULATION OF PREPULSE INHIBITION OF ACOUSTIC STARTLE: CONTROL VERSUS NEONATALLY DOPAMINE DEPLETED ANIMALS. S.B. Schwarzkopf, T. Mitra*, J.F. Bruno. Departments of Psychiatry and Psychology, Ohio State University, Columbus, Ohio 43210

The magnitude of the acoustic startle response (ASR) is reduced significantly when the startle stimulus (Pulse) is preceded by a much weaker signal (Prepulse). This phenomenon, termed "prepulse inhibition" (PPI), is disrupted by dopamine (DA) agonists systemically administered and focally applied to ventral striatum. Previous studies suggest a greater D2 versus D1 receptor involvement in the disruption of PPI. In this study, we examined DA modulation of PPI in control and neonatally DA depleted animals (tested as adults).

Seventy four Sprague-Dawley rats (250-450 gm) were tested. At 3 days of age, DA depleted animals (N=38) received intraventricular 6-hydroxy-DA (6OHDA) while controls (N=36) received intraventricular vehicle (ascorbic acid/NaCl). PPI was assessed twice (1 week between sessions, T1/T2). One group of animals (N=20) underwent startle testing without injection. Fifty four animals were tested after subcutaneous injections of apomorphine (APO, doses: .05, .1, .5 mg/kg) or saline (SAL) in a counterbalanced design. PPI was computed as the percentage decrease in startle amplitude caused by prepulses of 75, 80, and 85 db.

Results in control (sham operated) animals agree with previous studies showing significant dose related disruption of PPI by APO. Although DA depleted animals exhibited "typical" PPI in non-injected and SAL conditions, they demonstrated significantly greater sensitivity to the PPI disrupting effects of APO compared to control animals ($P < .05$ at APO doses of 0.1 and 0.5). Significant group differences were also noted for baseline startle measures at these APO doses. Findings indicate increased sensitivity of neonatally DA depleted animals to APO's effect on PPI and baseline startle. (supported by NIMH grant MH00859)

97.12

MATURATION OF THE MAP OF AUDITORY SPACE IN THE SUPERIOR COLLICULUS OF THE FERRET. A.J. King and S. Carlile*. Lab. of Physiology, Parks Road, Oxford OX1 3PT, U.K.

The postnatal development of the map of auditory space in the superior colliculus (SC) is influenced by both auditory and visual experience. We have studied the time course over which neural responses in this nucleus become spatially tuned and topographically organized, by examining multi-unit responses from the SC of normal ferrets at various postnatal ages. The animals were anaesthetized and placed in an anechoic room, where recordings were made throughout the rostro-caudal extent of the SC. Between postnatal day 33 (P33), the earliest age examined, and the mid-P40s, most auditory responses were very broadly tuned, often responding to azimuthal locations throughout both hemifields. The proportion of spatially-tuned responses then increased at all sound levels tested, so that by P50-51 average spatial tuning had reached adult levels. The number of responses tuned to appropriate positions in space, according to their locations in the SC and their proximity to visual receptive fields recorded in the same electrode track, also increased in the mid-P40s, and a topographic progression of auditory best positions was apparent at P48. However, some responses were still spatially ambiguous or broadly tuned at this age, and an adult-like map was not present until after P50. The developmental emergence of the this map coincides with the maturation of sound localization cues in the ferret.

97.13

POSTNATAL DEVELOPMENT OF THE SPECTRAL TRANSFER FUNCTIONS AND INTERAURAL LEVEL DIFFERENCES OF THE AUDITORY PERIPHERY OF THE FERRET. S. Carille*. University Laboratory of Physiology, Parks Rd., Oxford OX1 3PT, U.K. SPON: Brain Research Association.

The transformations of sound by the auditory periphery provide important monaural and binaural cues to sound location. The pattern and time-course of the development of these cues have important consequences for the emergence of auditory localization mechanisms. The spectral transfer functions (STFs) of the auditory periphery of the ferret were examined using an impulse response technique (bandwidth 0.1kHz to 30kHz) for sound locations on the auditory-visual horizon (Carille, 1990 *J. Acoust. Soc. Am.* 88:2196-2204). By interpolating between the STFs determined for a number of azimuthal locations the horizon transfer function (HTF) is obtained. The HTF for the ipsilateral space of the adult ferret has a number of characteristic features. HTFs were obtained from ferrets at various postnatal ages from 32 days (P32) to P54. HTFs obtained around the onset of hearing were well outside the normal adult range. After P50 the HTFs were found to be adult-like. The changes in the patterns of interaural level differences, calculated over the same frequency range, also indicated the development of adult-like binaural cues by this time. This suggests that in the ferret, the normal pattern of sound localization cues develops rapidly over the three weeks from the onset of hearing.

HEARING IN FERRETS WITH UNILATERAL COCHLEAR REMOVAL. R.L. Martin*, J.E. Hine* and D.R. Moore. Univ. Lab. of Physiology, Oxford OX1 3PT, U.K. (SPON: Brain Research Association).

Unilateral cochlear removal in infancy has been shown to produce anatomical and physiological changes in auditory brainstem structures in a variety of species. Thresholds of single units in the inferior colliculi of adult ferrets subjected to unilateral cochlear removal at P5, for instance, are significantly lower than those of single units in the inferior colliculi of acutely deafened adult controls. We are currently examining the possibility that these changes are paralleled by changes at the behavioural level. Absolute intensity thresholds have been obtained for five pure tones ranging in frequency from 1 to 16 kHz using positive conditioning procedures and a descending method of limits technique. Thresholds for control animals with both cochleae intact are within the range previously reported for this species. To date, we have found no evidence of altered sensitivity in animals subjected to unilateral cochlear removal at P5. We are, however, yet to compare the sensitivity of P5 cochlear removed animals with that of animals subjected to unilateral cochlear removal in adulthood.

97.17

RESPONSES IN INFERIOR COLLICULUS UNITS OF NEONATALLY DEAFENED CATS AFTER CHRONIC INTRACOCHLEAR ELECTRICAL STIMULATION (ICES) R.L. SNYDER*, P.A. LEAKE, S.J. REBSCHER*. Coleman-Epstein Laboratories, Univ. of California, San Francisco, CA 94143

Examination of effects of neonatal deafening and chronic ICES on single unit responses can provide a context for interpreting the consequences of auditory deprivation and the application of cochlear prostheses in very young deaf children.

Implanted electrodes consisted of two pairs of contacts positioned at about the 8 kHz and 15 kHz locations within the cochlea. Chronic stimulation of one pair was initiated at approximately 2 months of age. Stimuli were charge-balanced, biphasic pulses 200 μ sec per phase delivered continuously at 30 pps for periods of 2-6 hrs/day for 4 to 20 weeks. Responses to acute ICES of each electrode pair were recorded in acutely deafened adults; in neonatally deafened, unstimulated adults; and in chronically stimulated, neonatally deafened adults. In all three groups neurons showed responses to ICES which were comparable to those evoked acoustically. Most responded with either onset or sustained increases in discharge rates. Like acoustic responses, ICES responses showed either monotonic or nonmonotonic increases in activity. Latencies ranged from 5 to over 40 msec. Response thresholds varied systematically across the IC depending upon the cochlear region stimulated and reflecting its tonotopic organization. Responses in deafened/unstimulated and normal animals were not statistically different. However, responses in chronically stimulated animals showed systematic differences from those in the other groups: The spatial resolution of the IC central nucleus was degraded, the perstimulus response latencies were significantly shorter, the late response latencies were significantly longer, and the frequency of occurrence of inhibitory and late responses was significantly higher.

These results suggest 1) that development of the cochleotopic organization and some basic response properties in IC neurons were not affected by the absence of normal postnatal acoustic input and 2) that the limited regime of ICES employed in these studies produced significant quantitative distortions in the perstimulus response patterns of IC neurons. (Supported by NINCDS Contract NS-7-2391)

97.14

REMOVAL OF THE RIGHT COCHLEA IN INFANT FERRETS CHANGES UNIT RESPONSE PROPERTIES IN THE LEFT INFERIOR COLLICULUS TO STIMULATION OF THE LEFT EAR. D.R. Moore, D. McAlpine and R.L. Martin*. Univ. Lab. of Physiology, Oxford OX1 3PT, U.K.

Unilateral hearing loss in infancy produces a variety of changes in the central auditory system, including an enhancement of single neuron excitatory responses to acoustic stimulation of the normal ear. We studied the inferior colliculus (IC) of year-old ferrets that had one cochlea removed at P5, P25 or P39. Rate-level functions were obtained using best frequency tone stimulation of the intact ear and single-unit recording on the side of that ear. Relative to acutely deafened adult controls, units in all groups of experimental ferrets had lower thresholds, and more units with sustained, excitatory responses were found. Ferrets in the P5 group showed the greatest change; response properties were intermediate between control responses ipsi- and contralateral to the intact ear. Ferrets in the older experimental groups showed progressively reduced changes. No changes were found in the IC contralateral to the intact ear of one P25 deafened ferret, or between control and unlesioned adults. The sensitive period suggested by these results is coincident with that for known anatomical changes.

97.16

THE ONTOGENY OF AUDITORY THRESHOLDS DETERMINED WITH REFLEX MODIFICATION AUDIOMETRY. K.M. Crofton, X. Zhao* and M. E. Stanton. Neurotoxicology Division, U.S. EPA, RTP, NC 27711

The ontogeny of the acoustic startle response and reflex modification are known to arise prior to weaning in the rat at times that correlate with anatomical development of the auditory system. The present study examined the ontogeny of auditory thresholds using reflex modification of the auditory startle response. Reflex modification thresholds were determined using male and female Long Evans rats. Auditory thresholds were determined at various postnatal ages (independent age groups on postnatal days (PND) 20, 30, 40, 70, and 120) using 5- and 40-kHz tones (6-90 dB SPL, 40-msec) presented 90-msec prior to the onset of the eliciting stimulus (a 40-msec burst of white noise with 2.5 msec rise/decay). The results indicate mature threshold levels (approximately 35 and 19 dB for 5 and 40 kHz, respectively) from PND 30 through PND 120. At PND 20 the high frequency threshold is at the adult level, but the low frequency threshold is still very high (~65 dB). These findings confirm longer ontogeny of low-frequency thresholds, and suggest that auditory thresholds derived using reflex modification may mature later compared to thresholds defined with other procedures.

IMMUNOCYTOCHEMICAL LOCALIZATION OF THE GLUCOSE TRANSPORTER IN NEURAL TRANSPLANTS AND IMPLANTED GLIOMA. J.M. Rosenstein and T.W. Moody. Depts. of Anat. Neurosurg. and Biochem. The George Washington University Med. Ctr., Wash. D.C. 20037.

The erythroid or brain-type glucose transporter (GT) is an independent and highly reliable marker for cerebral microvessels with blood-brain barrier function or cells linked by tight junctions. It is also present in varying amounts throughout the neuropil exclusive of neurons. Tissues from animals bearing fetal neocortical grafts or implants of C₆ glioma cells were examined for the expression of GT following aldehyde perfusion. In fetal rat brain the antigen is localized to microvessels as early as 17 days prenatally. However, immuno-gold staining showed that many microvessels in CNS grafts as late as 3 weeks postoperative either expressed GT very weakly or not at all. At later times most graft vessels were immunostained comparably to host vessels but neuropil staining remained reduced. Extensive angiogenesis followed glioma implantation; at 3 days vascular sprouts were positive for GT. Subsequently, the neovasculature was composed about equally of positively and negatively stained vessels. Biopsy specimens of human glioma showed a similar pattern. These results indicate that the glucose transporter within CNS transplants can be reduced below the fetal state. In C₆ tumor implants over time many microvessels lack GT expression. (NS-17468).

REINNERVATION OF ADULT RAT SKELETAL MUSCLE USING EMBRYONIC SPINAL CORD CELLS GRAFTED INTO THE AXOTOMIZED TIBIAL NERVE. D.E. Erb, J.H. Kim, W.H. Lee and R.P. Bunge. Dept. of Neurol. Surg., The Miami Project to Cure Paralysis, Univ. of Miami Sch. of Med., Miami, FL 33136.

Denervated skeletal muscle cannot effectively contract without connection to the brain stem or spinal cord and undergoes progressive atrophy and functional decline. Efforts to elicit muscle contraction or significantly retard muscle atrophy by direct electrical stimulation of the muscle are relatively ineffective without a nerve supply. We have employed a novel approach to re-establish innervation of the denervated gastrocnemius muscle in the adult rat. A heterogeneous neuronal population dissociated from ventral spinal cord regions of E14 rat embryos, was grafted as 10-70 μ l aliquots (20,000-300,000 cells) into the distal stump of an axotomized tibial nerve. Within 3 weeks, 15 μ m frozen serial sections of the injection site contained viable cells including many multipolar motor neuron-like cells with nuclei up to 48 μ m in diameter. The injection site also contained neuronal processes immunoreactive with antibodies against neurofilaments. These processes coursed from the injection site through the axotomized distal nerve stump into the muscle. In some animals, reinnervation of denervated muscle by grafted cells was electrophysiologically confirmed by extracellular recordings from single muscle fibers. Stimulation of the neuronal injection site produced single muscle fiber action potentials with stimulus intensities from 100 μ A to 400 μ A and latencies ranging from approximately 4 to 5 msec. Compound action potentials evoked by stimulation of the injection site remained intact following injection of pancuronium bromide, whereas single motor unit activity was completely abolished. Supported by The Hollfelder Foundation.

PERIPHERAL NERVE GRAFT REPAIR CHANGES SIZE AND HISTOCHEMICAL PROFILE OF AFFECTED MUSCLE FIBRES. H.Hashimoto*, A.Mautes* and A.C.Nacimientto. Neurosurgical Research Laboratory, Saarland University Medical School, 6650 Homburg/Saar, F.R.G.

A 10 mm gap created by excision in the peroneal nerve of the rat was microsurgically repaired by autologous grafting of an appropriate segment of radial nerve. After 14, 30 and 90 days size and histochemical profile of all extensor digitorum longus (EDL) fibers were assessed by computer-assisted quantification. Size increased significantly in the oxidative groups type I (SO) and type IIa (FOG), whereas the glycolytic type IIb (FG) decreased within 30 days and regained preoperative levels at 90 days. Type IIc, an intermediate group between IIa and IIb normally few in number, appeared at 30 days, and its size increased steadily over 90 days. Histochemical profiles showed a relative increase of type I, and decrease of type IIa and IIb fibers. Type IIc relative contribution increased proportionally with the latter decrease. This reinnervation pattern after nerve graft repair signals considerable functional remodelling of the affected motor units, and suggests a strong motoneuronal role in its determination.

98.2

MUSCLE ISOGRAFT AS A SITE OF ENTRY FOR CIRCULATING CELLS INTO BRAIN. S. Ishihara*, M. Sawada*, J. Kim*, L. Chang* and M. Brightman. Lab. of Neurobiology, NINDS, National Institutes of Health, Bethesda, MD 20892

An isograft of skeletal muscle on rat dorsal medulla is a permanent opening in the blood-brain barrier. Is the graft site also an entry for circulating monocytes that can bring virus or enzymes into brain? A bolus of 2X10⁶ peritoneal macrophages (M ϕ) activated with phorbol ester and labeled with a fluorescent dye, was infused into the vertebral artery via the axillary artery. The brains, with their 5 week old grafts, were fixed, frozen and cut at 15 - 30 μ m.

In rats without grafts, very few activated M ϕ lined vessels and none entered choroid plexus or brain. In rats with muscle grafts, non-activated M ϕ invaded grafts but very few entered the medulla at 2 h. Activated M ϕ entered both graft and medulla. The extent of M ϕ migration was the same at 2 and 24 h. In control rats with gel foam as a graft, a few activated M ϕ invaded gel and brain. Non-activated and activated M ϕ lined blood vessels near muscle and gel grafts. Thus, the entry route into brain from graft sites may be more from perturbed brain vessels than from muscle or gel grafts. Analysis is being made for major histocompatibility and LFA1 antigens in M ϕ and for induction in vessels, of I-CAM 1 antigen, involved in leukocyte adhesion.

FLUORESCENT LABELING WITH PKH-26 TO CHARACTERIZE THE INCORPORATION OF NERVE ISOGRAFTS AND ALLOGRAFTS. D. Parvin*, T.E. Trumble, & E. Cohen*. Department of Orthopaedics RK-10, University of Washington School of Medicine, Seattle, WA 98195.

Objective: To evaluate the role of host and graft cells and the physiology of graft incorporation in nerve transplantation in order to optimize nerve repair and regeneration.

Methods and Materials: 1.2 cm sciatic nerve isograft and allograft transplantation was performed using Lewis and Brown-Norway rats. In some, the grafts were labeled with PKH-26 (Zynaxis Cell Sciences, Malvern, PA), in others the host was labeled. Repaired nerves were harvested post-transplantation, and analyzed in cross-section with the Bioquant software system (R&M Biometrics Inc., Nashville, TN) as to the percent of area labeled with PKH-26 fluorescent dye.

Results: 1) Fluorescent labeled host cells were detected only in the epineurium of the nerve graft at day 3, in epineurium and perineurium by day 14 and not until day 25 in endoneurium. 2) Host cells migrated distally into the graft (95% fluorescence) from the dyed proximal host limb (85% fluorescence). 3) PKH-26 labeled graft cells migrated distally, with a 96% distribution of fluorescence in the distal host limb (unstained at transplant) compared to 76% in the proximal limb. 4) Allograft cells were destroyed both within the graft and after migrating distally into the host limb, resulting in loss of the vital dye demonstrated by a 40% difference between the peak fluorescence and the nadir in allograft compared to 20% in isografts.

Conclusions: Nerve graft incorporation occurs in 3 phases, with contributions from both host and graft elements. Optimal nerve repair and regeneration requires viable and histocompatible grafted tissue.

98.6

ABERRENT CYTOARCHITECTURE OF GRAFTED SUPRACHIASMATIC NUCLEUS STILL CAN RESTORE CIRCADIAN RHYTHMICITY INDUCED BY AN IN SITU LESION G.J. Boer, H.A. Griffioen, H. Duindam and W.J. Rietveld (spon: ENA), Neth. Inst. for Brain Res., Amsterdam, NL; Lab. of Physiology, University of Leiden, NL.

Grafting of the fetal SCN has been shown to restore circadian rhythmicity in rodents subjected to lesions of this 'biological clock' nucleus. The characteristics of the surviving SCN needed to explain recovery are poorly understood. A study was initiated to correlate VP, VIP, SOM and NPY immunocytochemical staining of an E17 solid block graft with the course of recovery of drinking rhythm.

Recovery was seen in 30% of the animals and is usually visible after 2-3 weeks. Cells of the implanted fetal SCN are then still immature. VP and VIP graft/host efferents cannot be seen yet but become visible 2 weeks later. The existence of SOM efferents could not be established. The cytoarchitecture of the implanted SCN shows contiguously located clusters of VP and VIP neurons, but in contrast to in situ, SOM cells nestle outside this field. Afferent NPY fibers preferentially ramify on SOM cells. After 5 weeks maximal outgrowth is reached. All recovery animals revealed a surviving SCN of partially aberrant configuration together with efferent connections. However, these outcomes were also seen in some of the animals that did not recover.

In conclusion, grafted fetal SCN rearranged its cytoarchitectural development but it could still be functional. The results have so far not been conclusive on what aspect of the 'new' SCN is needed for recovery.

98.7

A NEW MODEL TO STUDY INTERACTION BETWEEN TRANSPLANTED FOETAL NEURONS AND THE MATURE CENTRAL NERVOUS SYSTEM: OPTHOTOPIC DORSAL ROOT GANGLION ALLOGRAFTS. C.M. Rosario*, H. Aldskogius, T. Carlstedt and R.L. Sidman. Dept. of Anatomy, Karolinska Institutet, Stockholm and Dept. of Neuropathology, Harvard Medical School, Southborough, MA 01772-9102.

Transplanted, foetal neurons are able to survive and form functional contacts in the central nervous system of mature host animals. Neuronal transplants, including dorsal root ganglia can survive and differentiate following heterotopic transplantation. However, no attempts appear to have been made to determine if foetal DRGs can survive and differentiate in an orthotopic location. In the present study we transplanted E-15 DRGs to replace excised lumbar DRGs in adult rats and analyzed survivability, phenotypic differentiation and process outgrowth from the transplants. These analyses have been made with conventional light microscopy, immunocytochemistry for CGRP, and neuroanatomical tracing methods, including retrograde tracing with single or double labels and with transganglionic tracing from the peripheral nerve to the spinal cord. The results show that transplanted DRG cells survive, differentiate and send axons peripherally into sciatic nerve and centrally through the dorsal root. Suggestive evidence for axonal ingrowth into the spinal cord has been obtained, but this is under further study with additional methods.

98.9

ANOMALOUS CHOLINERGIC REINNERVATION OF THE INTERPEDUNCULAR NUCLEUS (IPN) BY THALAMUS TRANSPLANTS. T.C. Eckenrode*, M. Murray and F. Haun. Dept. of Anatomy & Neurobiology, Medical College of Pennsylvania, Philadelphia, PA 19129

We showed previously that cell suspension transplants of embryonic habenula cells placed in neonatal or adult rats contain both Substance P (SP) and ChAT immunoreactive cells. However only peptidergic reinnervation of deafferented habenular target sub-nuclei of the IPN was seen in adult-transplanted hosts. To test specificity, we transplanted ventral thalamus cells (which do not normally project to the IPN) into adult hosts after IPN denervation. At 2 mos. post-implantation, thalamus transplants contain no SP-staining cells and the host IPN shows no peptidergic reinnervation. However the transplants do contain numerous well-differentiated ChAT-positive neurons, an unexpected result in that the cholinergic phenotype is normally seen in the thalamus only transiently, at mid-to-late gestation. Moreover ChAT staining is seen in the IPN of animals with thalamus transplants, in contrast to complete absence of ChAT staining in the IPN of lesion-only controls as well as animals with habenula transplants. These results show the adult-deafferented IPN is able to support cholinergic reinnervation from an anomalous source, but not from its normal afferents. Supported by NIH grants NS28856 (FH) and NS 16556 (MM).

The Pineal Gland: Effects of Grafting Sites on Functional Recovery. Wutian Wu and David E. Scott Dept. of Anatomy & Neurobiology, Eastern Virginia Medical School, Norfolk, VA 23501.

Nighttime serum melatonin concentration increases significantly in pinealectomized rats in which pineal glands were grafted into the third cerebral ventricle. Recent studies demonstrated that there was no day-night variation in serum melatonin concentration in these animals. In the present investigation, pineal glands were grafted into several sites in pinealectomized rats, including the third cerebral ventricle, the renal capsule, the anterior chamber of the eye, and in situ (where the gland is normally found). Ten weeks after grafting, blood samples were collected twice from each rat and serum melatonin concentration was measured by RIA. Results demonstrate that nighttime serum melatonin concentration increased significantly in animals with pineal transplants in the third cerebral ventricle and the anterior chamber of the eye as compared with nongrafted pinealectomized host rats. Day-night variation in serum melatonin concentration was observed only in animals with pineal grafts in the anterior chamber of the eye. More neurites were found within the grafts in the latter site than any other graft location. These results indicate that only certain locations in the host can foster recovery of function after transplantation. Supported by National Science Foundation Grant No. BNS8709687.

BIOCHEMICAL COMPARISON AND CHARACTERIZATION OF CULTURED BOVINE CHROMAFFIN CELLS AND RAT BRAIN SLICES CONTAINING BOVINE CHROMAFFIN CELL TRANSPLANTS. J. Ortega and J. Sagen. Dept. of Anat. and Cell Biol. Univ. of Ill at Chicago.

Initial biochemical studies on rat brain slices containing bovine chromaffin cell transplants in the periaqueductal gray (PAG) revealed that 2-4 week old xenografts released significantly higher basal and nicotine stimulated levels of catecholamines (CA) and met-enkephalin (ME) than control brain slices. The purpose of the present study was to compare and characterize the biochemical and pharmacologic activity of isolated bovine chromaffin cells *in vitro* to that of transplanted bovine chromaffin cells. Bovine chromaffin cells were isolated using standard primary culturing techniques, and either transplanted into the rat PAG or plated for *in vitro* studies. Following a 2, 4, or 8 week period, brain slices (350 μ m) containing the transplant and PAG were sectioned, placed in a chamber and superfused continuously (2.0 ml/min.) with oxygenated artificial CSF (37°C). Following a one hour stabilization period, perfusion samples before and after nicotine stimulation (60 μ M) were collected and analyzed for ME and CA content, using RIA and HPLC, respectively. Studies on cultured bovine chromaffin cells consisted of the collection of basal and nicotine stimulated samples from chromaffin cells 2, 7, 14, and 21 days in culture. The results of this study reveal that cultured bovine chromaffin cells release basal and stimulated levels of both ME and CA up to 21 days in culture. Over the 21 day period the epinephrine:norepinephrine (E:NE) ratio declined from 4:1 to 2:1. This decline in epinephrine content can be attributed to the lack of steroidal influence from adrenal cortical cells. In contrast, samples collected from brain slices containing bovine chromaffin cell transplants showed no significant decrease in the E:NE ratio over an 8 week period. The results of this study indicate that the host environment can play an important role in modulating the activity of transplanted bovine chromaffin cells. The reasons for this are not completely clear, but endogenous steroidal activity could impart some influence on the biochemical activity of these xenografts. Supported in part by NIH grants NS25054 and NS28931.

HYPOTHALAMIC TRANSPLANTS CONTAINING HISTAMINERGIC NEURONS: II. ELECTROPHYSIOLOGY. Hanna Bergman*, George D. Prell¹ and Ann-Charlotte Granholm. Dept. Cell Biol., Univ. Linköping, S-581 85 Linköping, Sweden, ¹Dept. Pharmacol., Mount Sinai School of Medicine, New York, NY 10029. Histamine is a monoamine transmitter produced by neurons in the hypothalamic tuberomammillary nucleus. Extracellular electrophysiological recordings of histamine-type neurons in hypothalamic transplants in the anterior eye chamber of albino rats were performed. We found numerous spontaneously firing neurons with a mean firing rate of 2.8 ± 0.4 Hz (n=27) and a mean spike duration of 1.0 ± 0.1 ms (n=16). Furthermore, 10 of 14 neurons responded to local application of the selective histamine autoreceptor agonist α -methyl-histamine (0.1-10 μ M) with inhibitions of neuronal firing rate, and 5 of 6 cells responded to 5-200 μ M histamine with inhibitions. The auto-receptor antagonist thioperamide caused excitations in 4 of 5 cells tested, at doses of 1-4 μ M. The respective H₁ and H₂ antagonists dexchloropheniramine and ranitidine had no effects in any of the 3 cells tested. At present, levels of histamine and its metabolites, as well as the optimal fetal donor stage for histaminergic transplants are being examined. Taken together, these data indicate that histaminergic neurons in intraocular transplants of hypo-thalamic tissue will survive and develop many of the physiological features seen *in situ*. The project was supported by the Swedish MRC, grant #8650 and NINDS-28012. The autoreceptor compounds were generously provided by Dr. J.M. Arrang.

INTERPRETING THE ABSENCE OF A BLOOD-BRAIN BARRIER (BBB) IN BRAIN GRAFTS. R.D. Broadwell, B.J. Baker, and W.F. Hickey*. Univ. MD Sch. Med., Baltimore, MD 21201, and Washington Univ. Sch. Med., St. Louis, MO 63110.

Although BBB vessels indigenous to CNS grafts are sustained, breakdown of the BBB in CNS grafts is attributable to: 1) rupture of interendothelial tight junctions in graft vessels by perfusion-fixation of the host; 2) damage to host vessels during graft delivery; 3) graft placement in proximity to normally permeable host vessels supplying the pial surface and circumventricular organs; 4) graft rejection *vis-a-vis* the host immune response. The latter is prevalent in xenogenic grafts and in allografts associated with donor/host mismatch in major/minor histocompatibility complexes. Donor cells stained immunohistochemically for its MHC class I appear within the host spleen, suggesting a triggering of the host immune response. These cells most likely enter the general circulation through host cerebral vessels damaged during graft placement. Allografts between *outbred* donor and host of the same strain (e.g., Sprague Dawley or Wistar rats) likewise will reject; by 10 days post-grafting, the CNS grafts exhibit populations of immunohistochemically identifiable MHC classes I+ and II+ cells (microglia, macrophages, lymphocytes, and CD4+ (T-helper) and CD8+ (cytotoxic) lymphocytes. PC12 cell suspension grafts placed in the CNS of *outbred* hosts (Sprague Dawley rats) are rejected similarly. NIH Grant #NS18030.

PAIN REDUCTION BY ADRENAL MEDULLARY TRANSPLANTS IN THE SPINAL SUBARACHNOID SPACE OF TERMINAL CANCER PATIENTS. J. Sagen, A.P. Winnie*, H. Wang, T.J. Krolick*, and G.D. Pappas. Dept. of Anat and Cell Bio. and Pain Control Center, Univ. of Illinois at Chicago, Chicago, IL 60612.

Work in our laboratory over the past several years has demonstrated that the transplantation of adrenal medullary chromaffin cells into the spinal subarachnoid space can markedly reduce pain in rodents. This analgesia most likely results from the release of opioid peptides and catecholamines from the transplanted cells. The current study is an initial attempt to assess the potential for this approach to alleviate chronic pain in man. Approval for this preliminary study was obtained from the IRB of the University of Illinois. Consenting patients selected for the study were suffering from terminal cancer pain with reduced responsiveness to narcotic analgesics. Pain levels were determined using a Visual Analog pain scale prior to and at weekly intervals following the procedure. In addition, records of daily narcotic intake and activity were kept. When possible, CSF samples were collected via lumbar puncture for biochemical and cytological analysis before and at several intervals following transplantation. Of the first four patients selected for the study, three suffered from metastatic CA of the colon and one from metastatic CA of the breast. Human adrenal glands were obtained from the Regional Organ Bank of Illinois and adrenal medullary tissue was prepared for transplantation in our laboratory. Tissue was transplanted via lumbar puncture using a 14 ga Tuohy needle. Cyclosporine A was administered for two weeks beginning one day prior to the procedure. All four of the patients demonstrated progressive decreases in their pain scores over time, with a concomitant decrease in narcotic intake. Three of the patients remained pain free for over four months, with no recurrence of pain. One patient, who developed spinal cord compression secondary to metastasis was initially pain free, but the pain returned after 10 weeks. Spinal CSF samples revealed increased levels of both met-enkephalin and catecholamines for at least 4 months following the transplantation. Results of this study suggest that adrenal medullary transplants in the spinal subarachnoid space may be a promising approach for the management of chronic pain in humans. Supported in part by NIH grants NS25054 and NS28931.

INCREASED VASCULARITY AND CYTOCHROME OXIDASE LEVELS IN FETAL SUSPENSION GRAFTS OF THE ADULT RAT SPINAL CORD. P.J. Horner*, Dept. Physiology, The Ohio State Univ., B.T. Stokes Dept. Physiology, The Ohio State Univ., P.J. Reier Dept. Neurosci., Univ. Florida and F.R. Sharp Dept. Neurology, VA Med Ctr, San Francisco, CA.

Anatomical and behavioral studies of graft-mediated repair in an experimental spinal cord contusion injury have indicated that fetal grafts can alter post-transplantation behavior (Stokes and Reier, 1990). Physiological factors that influence the graft microenvironment (Stokes and Reier, 1991) may play a vital role in this repair process. The present experiments examined the relationship between two such factors in 3 month transplants: metabolic capacity as assessed by cytochrome oxidase histochemistry and graft vascularity. Cytochrome oxidase experiments were conducted according to the technique of Wong-Riley (1979) and diaminobenzidine reacted horizontal spinal cord sections (20um) were analyzed via densitometry. To quantitate vascularity, cords were fixed in 4% paraformaldehyde, 3.5% glutaraldehyde in 0.1M Sorensen's PBS overnight, sectioned, treated with 2X osmium tetroxide, dehydrated and embedded in epon. Computer assisted morphometry was used to determine blood vessel number, surface fraction, area and orientation distribution. Transplants show levels of cytochrome oxidase significantly above host gray matter. Although the number of very small (<10um) vascular profiles is decreased in graft and adjacent graft/host regions, average vessel area and surface fraction are markedly increased in comparison to host gray matter. These data provide evidence of a metabolically-active transplant with a well established vascular network, characteristics which may be important in graft mediated repair.

99.5

PAIN REDUCTION BY TRANSPLANTS OF POLYMER ENCAPSULATED BOVINE CHROMAFFIN CELLS IN THE RAT SPINAL SUBARACHNOID SPACE. H. Wang, P.A. Tresco, P. Aebischer, and J. Sagen. Dept. Anat. and Cell Biol., Univ. of Illinois at Chicago, Chicago, IL 60612 and Artificial Organs, Biomaterials and Cellular Technology, Brown Univ., Providence RI.

Studies over the past several years have indicated that the transplantation of adrenal medullary chromaffin cells into CNS pain modulatory regions may provide a renewable source of opioid peptides and catecholamines for the continued alleviation of pain. Donors for these studies have included both allogeneic and xenogeneic sources. Bovine adrenal glands may be an ideal donor source since chromaffin cells can be readily isolated in large amounts and the cells continue to produce high levels of opioid peptides and catecholamines. Previous findings in our laboratory have indicated that bovine chromaffin cells transplanted to the rat CNS can reduce pain. However, the survival of xenografts is limited by host immunologic responses. In order to circumvent this problem, bovine chromaffin cells were immunologically isolated by polymer encapsulation. Bovine chromaffin cell suspensions were encapsulated with an acrylic copolymer, and basal and nicotine stimulated release of catecholamines and met-enkephalin were determined. Either chromaffin cell-loaded or empty control capsules were transplanted in the rat subarachnoid space at the level of the lumbar enlargement. Baseline pain sensitivity and response to nicotine were determined using the tail flick, paw pinch, and hot plate tests. Results indicated that transplants of encapsulated chromaffin cells, but not control capsules, significantly reduced pain sensitivity following nicotinic stimulation. This analgesic response could be observed for at least 3 months following transplantation. Chromaffin cells could be identified immunocytochemically in the transplanted capsules after termination of behavioral testing. These results suggest that transplantation of encapsulated bovine chromaffin cells may be a means of alleviating pain without the complications of potential immunologic rejection. Supported in part by NIH grants NS25254 and NS28931.

99.2

DYNAMIC ASSESSMENT OF NEURAL GRAFT SURVIVAL IN THE INJURED CAT SPINAL CORD USING MAGNETIC RESONANCE IMAGING. E.D. Wirth III, D.P. Theele*, T.H. Mareci*, D.K. Anderson and P.J. Reier. Depts. of Neuroscience, Neurosurgery and Radiology, Univ. of Florida College of Medicine, Gainesville, FL 32610 and VA Medical Center, Cincinnati, Ohio.

Although previous work has demonstrated the usefulness of magnetic resonance imaging (MRI) for visualizing intraspinal transplants *in vivo*, the degree to which MRI can differentiate developing fetal neural tissue from evolving spinal cord pathology has not been investigated. Eight adult female cats received a hemisection injury at the L1 level, followed immediately by implantation of either embryonic cat spinal cord (SC) or neocortex (NCx) into the cavity. The spinal cords of two control animals were hemisectioned, but received no transplant. At each specified imaging interval (1, 2, 4, 8, 12, 16, 20 weeks post-grafting or post-lesion) multislice T₂-weighted (TR/TE = 2000/90 msec) and intermediate-weighted (TR/TE = 1000/30 msec) spin-echo images were obtained in the transverse and sagittal planes. Following sacrifice, low-power light microscopy was used for determination of transplant survival and correlation with MR images.

All control animals and graft recipients exhibited medium to high signal intensity on both intermediate and T₂-weighted images during the first four weeks following surgery. After 4-8 wks., the transplant site in three recipients remained slightly hyperintense on intermediate images, but became isointense with the host spinal cord on T₂ images. Histological analysis established that this appearance was indicative of graft survival. The transplant/lesion site in the controls and remaining recipients presented high signal for both sets of imaging parameters. Post-mortem specimens from this group revealed cavitation at the transplant/lesion site. We conclude that determination of transplant survival may be observed as early as four weeks post-grafting by a decrease in signal on T₂-weighted images. ENHANCED ANTINOCICEPTION BY ADENOSINERGIC AGONISTS IN RATS WITH ADRENAL MEDULLARY TRANSPLANTS IN THE SPINAL SUBARACHNOID SPACE. J.L. Stark*, H. Wang, W.F. Silverman, and J. Sagen. Dept. Anat. and Cell Bio., Univ. of Illinois at Chicago, Chicago, IL 60612 and Dept. Morphol., Ben-Gurion Univ. Fac. Health Sciences, Beer-Sheva, Israel.

Our laboratory has demonstrated that the transplantation of adrenal medullary tissue into the spinal subarachnoid space of rats can induce potent analgesia. Neurochemical assays have revealed increased levels of norepinephrine and epinephrine in the spinal CSF for at least 6 months following transplantation of adrenal medullary tissue. Recent work in other laboratories has shown that there is a potent synergism between adrenergic and adenosinergic systems in the production of antinociception in the spinal cord. This may be important since spinal release of adenosine has been implicated as a neural basis for the analgesic effects of vibration in humans, and is a potential physiological means to increase antinociception following transplantation. Since the transplanted chromaffin cells release catecholamines, it should be possible to induce antinociception with subthreshold doses of adenosinergic agonists in animals with adrenal medullary transplants. To assess this, antinociceptive responses to intrathecal injections of several doses of A1/A2 adenosine agonist 5'-N-ethylcarboxamide adenosine (NECA) or A1 adenosine agonist R-phenylisopropyladenosine (R-PIA) were compared in animals with adrenal medullary and control striated muscle transplants. Results revealed a potentiation in the dose-responsiveness to NECA in adrenal medullary, but not control transplanted animals. Doses of NECA as low as 0.065 µg produced significant antinociception. This potentiation could be blocked by pretreatment with α-adrenergic antagonist, phentolamine, suggesting that catecholamines released from the transplants may mediate this effect. In contrast to NECA, adrenal medullary transplants did not alter responsiveness to R-PIA. Results of this study indicate that adrenal medullary transplants may potentiate antinociception to adenosinergic agonists via co-activation of α-adrenergic and A2 adenosine receptors, and suggest a possible means of increasing antinociception following adrenal medullary transplantation. Supported in part by NIH grants NS25054 and NS28931.

ADRENAL MEDULLARY TRANSPLANTS REDUCE PAIN IN RATS WITH EXPERIMENTAL PAINFUL PERIPHERAL NEUROPATHY. A.T. Hama, W.J. Miller, H. Wang and J. Sagen. Dept. of Anat. and Cell Biol., Univ. of IL at Chicago, Chicago, IL 60612.

Recent work in our laboratory has demonstrated the effectiveness of adrenal medullary tissue in attenuating nociceptive responses to various noxious stimuli. Endogenous neuroactive substances such as catecholamines and opioid peptides, found abundantly in adrenal chromaffin cells, are thought to reduce nociception at the spinal level. Until recently, no satisfactory model of chronic neuropathic pain was available that would allow the examination of the effects of these compounds. Using a recently developed model of a painful peripheral neuropathy, we evaluated the effects of adrenal medullary chromaffin cells transplanted into the subarachnoid space. A peripheral neuropathy was induced by loosely tying 4 ligatures (4-0 chromic) around the right sciatic nerve. This procedure produces various pain syndromes including: allodynia, hyperesthesia and spontaneous pain. After baseline behavioral evaluation using innocuous and noxious stimuli, rats were given either adrenal medullary tissue or control striated muscle transplants. Animals were tested weekly for 12 weeks. Animals with adrenal medullary tissue transplants showed decreased allodynia to both cold plate and innocuous tactile stimuli. In addition the weight loss in control transplanted animals was attenuated by adrenal medullary transplants. Following termination of behavioral studies, the transplants, host spinal cord and sciatic nerve were analyzed morphologically using immunocytochemistry and electron microscopy. The sciatic nerve on the ligated side showed a marked decrease in large diameter primary afferents, with smaller axons relatively spared. Immunohistochemical analysis of spinal cord dorsal horn showed reduced levels of substance P and calcitonin gene-related peptide ipsilaterally to the ligation at 2 weeks. The increased incidence of chromatophilic cell bodies ("dark neurons") in the dorsal horn ipsilateral to the ligation was reduced in animals with adrenal medullary transplants but not control transplants. These findings indicate that adrenal medullary transplants may be effective in reducing neuropathic pain. Aided by a grant from the Paralyzed Veterans of America Spinal Cord Research Foundation.

ANATOMICAL AND BEHAVIORAL EFFECTS OF TRANSPLANTS IN SPINAL KITTENS. D.R. Howland, B.S. Bregman, A. Tessler, and M.E. Goldberger. Department of Anatomy and Neurobiology, The Medical College of Pennsylvania, Philadelphia, PA 19129.

Spinal cord transplants (E21-E26) survive in the transected thoracic spinal cords of newborn kittens and alter the behavioral and anatomical development of the animals. Behavior of normal kittens, of spinal kittens and of spinal + transplant kittens was studied from birth to 5 mos. In spinal kittens, a transplant accelerates the development of overground locomotion by about 6 wks. Although spinal kittens achieve quadrupedal locomotion (overground and treadmill) the performance of transplant animals is always superior in weight support, postural stability and coordination between fore and hindlimbs. HRP and immunocytochemistry (ICC) demonstrate that no descending systems grow past the lesion in spinal animals. ICC identified several host fiber systems characterized by fine axons bearing varicosities in the transplant. Descending serotonergic and noradrenergic systems grow extensively in the transplant. These systems also re-enter the host caudal to the transplant and the serotonergic system grows as far caudally as L6. The multiorigin Substance P and dorsal root origin Calcitonin Gene Related Peptide are found throughout the transplant and accumulate densely in many Substantia Gelatinosa-like regions in the transplant. These results indicate that embryonic spinal cord transplants support the growth of host systems and affect the locomotor development of neonatal kittens with complete spinal cord transections. (Supported by Grant NS24707).

INTRASPINAL TRANSPLANTS OF FETAL RAPHE NEURONS INHIBIT SPROUTING OF CGRP-IMMUNOREACTIVE PRIMARY AFFERENTS IN THE RAT INTERMEDIOLATERAL CELL COLUMN. V.R. Holets, R. Melinek and S.M. Onifer. The Miami Project and Department of Neurological Surgery, University of Miami, Miami, FL 33136.

Collateral sprouting and reactive synaptogenesis are responses of the CNS to injury that are well documented in the hippocampus and spinal cord. The response of spinal afferents to injury has been studied with an emphasis on changes in the dorsal horn. The present study focuses on changes in the afferent input to the intermediolateral cell column (IML) of the rat following a serotonin-depleting lesion, and the effect of transplantation of fetal raphe neurons into the thoracic spinal cord at varying times post-lesion.

Adult rats received an intrathecal injection of 5,7-DHT to lesion the raphe-spinal 5-HT fibers. An increase in the density of calcitonin gene-related peptide (CGRP)-immunoreactive (IR) fibers was observed in IML at 1 and 3 mo post-lesion. One wk post-lesion some animals received an intraspinal transplant of E14 raphe neurons in cell suspension into T8-T10 segments. The fetal neurons survived and reinnervated IML at early time points post-transplant (1 mo), and spread to reinnervate the dorsal and ventral horns at later times (3, 6, and 9 mo). There was no increase in the density of CGRP-IR fibers in IML at any level of the spinal cord as compared to lesion controls. These findings suggest that the ingrowth of the 5-HT-IR fibers from the transplant inhibits the sprouting of the CGRP-IR afferents to IML. Experiments are underway to determine the pattern of outgrowth of fetal raphe neurons transplanted into the spinal cord at later time points (3 mo) post-lesion when the CGRP-IR fibers have already increased in density in IML. Supported by The Miami Project, The Daniel Heumann Fund for Spinal Cord Research, and the American Heart Association.

PARAPLEGIA IN EXPERIMENTAL ANIMALS: IT'S ANATOMY UNDER DIFFERENT CONDITIONS OF LESION AND TRANSPLANTATION. P. Rai and G.D. Das. Dept. of Biol. Sci., Purdue Univ., West Lafayette, IN 47907.

The role of neural transplantation in the injured spinal cord was investigated in adult rats. Central hemorrhagic lesions were made at Thoracic (T-10/T-11) and Lumbar (L-2/L-3) levels of the spinal cords, and embryonic neocortex, brainstem or spinal cord tissue was transplanted. Control animals did not receive transplants. The ventral funiculi (VF) in thoracic lesion and motor neurons (MN's) in lumbar lesion animals were either spared or damaged in both experimental and control groups. After 2-3 months, the animals were sacrificed and their spinal cords were examined. Behavioral and histological data showed that animals with VF damage at T10/T-11, irrespective of the presence or type of neural transplant, were paraplegic. Similarly, animals with L-2/L-3 lesions showed paraplegia when there was MN damage, irrespective of the presence or type of neural transplant. The animals in both groups with VF or MN sparing did not show paraplegia. These results support earlier reports, emphasizing the role of spared VF in thoracic spinal lesions in spontaneous recovery from paraplegia. Sparing of MN's in lumbar spinal lesions is also essential to prevent paraplegia. Finally, embryonic neural transplants did not possess any ameliorative properties under these conditions of spinal cord trauma.

AXON GROWTH INTO SCHWANN CELL GRAFTS PLACED IN LESIONED ADULT RAT SPINAL CORD. C.L. Paino, C. Fernandez-Valle, and M.B. Bunge. The Miami Project, Univ. of Miami Sch. of Med., Miami, FL 33136

Schwann cell (SC) grafts placed in lesioned adult rat spinal cord elicits axonal ingrowth (Paino and Bunge, Soc. Neurosci. Abst. 16:1282 '90). SC-only implants were prepared in vitro on collagen with either dissociated SCs (dSC) or SCs associated with basal lamina they assembled (bISC). The collagen was rolled, enclosing the SCs, and placed in spinal cord cystic cavities that were induced photochemically (Cameron et al., Exp. Neurol. 109:214-23 '90) at the T9 level in adult female Sprague-Dawley rats either 5 or 28 days earlier. No immunosuppression was used. At 14 and 28 days and 3 and 6 months after grafting, animals were perfused and analyzed histologically with silver and toluidine blue stains and electron microscopy (EM). By 14 days bundles of unmyelinated and occasional thinly myelinated axons populated dSC and bISC implants. By 28 days and thereafter, great numbers of unmyelinated and myelinated axons were present in all preparations. By contrast, acellular collagen grafts were devoid of axons. EM of bISC implants at 28 days and 3 and 6 months showed that unmyelinated axons were at least 5X more numerous than myelinated axons; myelin thickness was greater by 3 months. Longitudinal sections of the host/implant junction revealed isolated or small bundles of axons associated with elongated (SC-like) cells extending at least 1mm caudal to the graft into degenerating corticospinal tract areas. These findings indicate that SCs induce profuse axon growth and suggest that, in long term grafts, axons may leave the SC implant and extend for some distance in degenerating white matter tracts if accompanied by SCs. (Supported by The Miami Project, NIH 09923, and The Spanish Ministry of Education).

INFLUENCE OF FETAL SPINAL CORD TRANSPLANTS ON RECOVERY OF MOTOR FUNCTION AFTER SPINAL CORD INJURY. Ellen Kunkel-Bagden, Paul J. Reier, Hai-Ning Dai* and Barbara S. Bregman, Dept. of Anatomy and Cell Biology, Georgetown Univ., Washington, DC 20007.

Fetal spinal cord transplants placed into the damaged spinal cord of a neonate promote the recovery of locomotor function. We wished to determine whether transplants would also influence the recovery of motor function after spinal cord injury in the adult. Transplant-mediated recovery of function was assessed after spinal cord hemisection with a series of quantitative tests of reflex responses and locomotion. Adult male rats (14) were tested for reflex responses and trained to cross runways and walk on a treadmill. The rats then received a mid-thoracic "over-hemisection" (HX, N=5) followed immediately by the placement of embryonic (E14) spinal cord transplants into the lesion site (HX+TP, N=6). Three normal animals served as controls (CON). After 4 weeks the animals were again trained and tested for reflex responses and locomotor function. Footprint analysis revealed that animals with a HX had an increased base of support, but the presence of the transplant (HX+TP) decreased this toward normal (CON) values. Animals with transplants were also able to cross the runways faster and with fewer errors than the hemisected animals. Analysis of the lesion sites revealed that the transplant-mediated alterations in recovery were dependent upon good apposition of the transplant with the host spinal cord. Although the ingrowth of axons from the host CNS into the transplant in the adult is less extensive than after similar lesions at birth, this anatomical plasticity is sufficient to promote recovery of function. Supported by NIH NS27054, NS19259, NS01356 (to BSB) and NS27511 (to PJR).

CHARACTERIZATION OF PROTEIN KINASE C ACTIVITY IN CEREBRAL MICROVESSELS OF AGED RATS. K. Morgenstern¹, P. Grammas and O. Hanson-Painton². University of Oklahoma Health Sciences Center, Oklahoma City, OK 73190.

The phospholipid and Ca²⁺ dependent protein kinase, PKC, is a critical component of receptor-mediated signalling pathways. Previous studies in brain demonstrate that PKC regulation is altered in aging and dementia. In this study, we examined microvascular PKC in isolated cerebral microvessels (MVs). Partial purification of PKC from MVs, using Q-Sepharose batch adsorption and single step salt elution into microfuge tubes, resulted in an enrichment of PKC specific activity in both the cytosolic and particulate fractions by 52- and 41-fold, respectively. In addition, single step fractionation of PKC resulted in greater than 100% yields, suggesting that a PKC inhibitor was present in crude homogenates. This was supported by the finding that purified rat brain PKC activity was inhibited in a dose-dependent manner by the Q-Sepharose effluent (50% at 10 µg/ml). MV crude cytosol from aged rats showed a 56% decrease in PKC specific activity compared to control while minor differences in PKC levels were observed after fractionation on Q-Sepharose. These results demonstrate the utility of batch adsorption to Q-Sepharose for the study of PKC and PKC inhibitory activities in MVs. Furthermore, results from aged MVs suggest that alterations in PKC inhibitor levels could underlie altered PKC activity and cell responsiveness in aging. Supported by American Health Assistance Foundation and OCAST HSO-008.

VASCULAR REMODELING ADJACENT TO BRAIN IMPLANTS OF EMPTY AND PC12 CELL-LOADED POLYMER CAPSULES. C.B. Jaeger¹, P. Aebischer², S.R. Winn², P.A. Tresco², L.A. Greene³. ¹CPR, Purdue Univ.SVM, W. Lafayette, IN 47907; ²Artificial Organ Lab., Brown Univ., Providence, RI 02912; ³Dept. of Pathol. Columbia Univ., New York, NY 10032.

Previous work indicated that repair of the blood-brain barrier (BBB) occurs following implantation of polymer capsules. Here we studied the fine structure of brain capillaries at the interface of polymer capsules and host brain. Capsules were prepared from polyvinyl-acrylic copolymer tubing with a molecular cut-off of 50KDa. Suspended PC12 cells were loaded into tube segments of 3- to 5 mm and the ends were closed with liquid polymer. Empty and cell-filled capsules were implanted in the brains of rats or guinea pigs. At 1/2, 1 and 2 months animals were euthanized and the ultrastructure of capillaries and host brain tissue near implants was examined. Structural changes were related to BBB function as indicated by Evans blue marker. In short-term implants, endothelial cell junctions near the capsule surfaces were leaky to serum proteins. This correlated with gaps in the junctions, and non-overlapping and open junctions. Double layered endothelial cells with interdigitating, multilayered cytoplasm was seen in newly formed vessels. Macrophages, processes of reactive astroglia, fibroblasts and collagen bundles were noted in the capsule membrane and near capillaries. Integrity of the BBB was observed at two months following implantation of empty and cell-filled capsules. Changes in capillary structures could reflect transient alterations of the CNS microenvironment. The data are relevant for evaluating the usefulness of PC12 cell-filled capsules as alternatives to neural tissue implants. Supported by grant No. NS27694 from NINDS.

Changes in the blood-brain barrier to macromolecules after an excitotoxic lesion in the CNS, by S. Marty¹, I. Dusart and M. Peschanski, Groupe de Recherche Ce Médecine Nucléaire, CHU Henri-Mondor, 94010 Créteil cédex, France

In situ injection of an excitotoxin induces a rapid neuronal death and profound changes of glial and vascular cell populations. Among these, we have described a massive leakage of the blood-brain barrier (BBB) to macromolecules, at the same time GFAP immunostaining disappears. After a few weeks, however, GFAP⁺ hypertrophied astrocytes reappear and send processes that surround blood vessels. This observation led us to hypothesize that these reactive astrocytes may tend to reform a *glia limitans* eventually limiting the functional alteration of the BBB. To check this hypothesis, we have studied, in parallel, the leakage of the BBB to peroxidase and the astroglial environment of blood vessels.

Two groups of rats were sacrificed one day to one year after KA: (i) in the first group HRP was allowed to circulate for 45 minutes after iv injection. Rats were perfused with mixed aldehyde, the brain was cut on a cryostat and peroxidase was revealed histochemically using TMB. (ii) a second group was directly perfused and brain sections were processed using standard electron microscopy techniques.

Two periods were defined: (i) As soon as twenty-four hours, and up to two months after KA, leakage of the blood-brain barrier was visible. During the same period, there was a swelling then a disappearance of astrocytic endfeet in apposition to the vascular walls. Swollen astrocytes, characterized by a pale cytoplasm and few intermediate filaments were observed during the first two weeks, sometimes exhibiting signs of cell suffering. (ii) After this period, up to one year after KA, a leakage of the BBB was no longer observed. In parallel, astrocytic processes making a basal lamina were systematically observed around endothelial cells, in most cases totally surrounding them although without apposition to the vascular wall.

The present results indicate that the evolution of the BBB for peroxidase is closely paralleled in the KA lesion by astroglial changes. The leakage of BBB occurs during retraction of endfeet and recovery during rebuilding of an abnormal *glia limitans* by reactive astrocytes. (supported by MRT grant 106728).

100.2

BLOCKING OF IL-1 INDUCED INFLAMMATION BY MONOCLONAL ANTIBODIES TO ADHESION MOLECULES James A. Martiney, Tina M. Calderon^{*}, Joan W. Berman^{*}, and Celia E. Brosnan^{*}, Albert Einstein College of Medicine, Bronx, NY 10461.

Previous results from this laboratory have shown that intraocular injection of interleukin-1b (IL-1b) in the rabbit retina induces an acute and chronic inflammatory response associated with the epi-retinal vessels. Analysis of this reaction have defined the following series of events associated with the acute inflammatory episode: a mononuclear (MN) and polymorphonuclear (PMN) exudate accompanied by an increase in vascular permeability and hemorrhage that peaks between 6 and 24 hours post-intraocular challenge (PIC). No further migration of PMN or hemorrhagic events occurred after 24h PIC. A more persistent MN cellular inflammation followed this acute episode. To test the role of specific adhesion molecules in these events, monoclonal antibodies (MAbs) directed against CD18, the common beta chain of the integrin LFA-1 (R15.7, provided by R.Rothlein) and against a novel endothelial cell adhesion molecule specific for monocytes (IG9, Calderon, et al., Circulation V82, p.III-94, 1990) were employed. The results show that significant inhibition of all parameters of inflammation was achieved with both MAbs, including a reduction of the IL-1-induced increase in vascular permeability and hemorrhage. However, the pattern of reduction of cellular inflammation was different between the two MAbs. With the MAb R15.7, the most striking change was a decrease in PMN and MN extravasation whereas with MAb IG9 both intravascular and extravascular PMN and MN cell numbers were decreased. Interestingly, contralateral eye involvement due to systemic effects was also inhibited in these animals. Supported by NS11920 and 07089.

EXTRACELLULAR SPACE VOLUME FRACTION IN THE REGION OF A BACTERIAL CEREBRITIS. W. Lo and D. McNeely^{*}. Dept. of Pediatrics, Ohio State Univ. Columbus, OH 43205.

As a first step in studies which seek to modify the development of inflammatory brain edema, we sought to measure the brain extracellular space volume fraction (VFecs) in the brain surrounding a bacterial cerebritis. The VFecs was measured with an ion-selective microelectrode sensitive to tetramethylammonium chloride (TMA-ISM). Sprague-Dawley rats were intracerebrally inoculated with S. aureus; the VFecs was measured 4 days later when the blood-brain barrier is known to be permeable. The VFecs in bacterially inoculated animals was 49% +/- 7% (n=3), and in controls was 24.5% +/- 8.5% (n=4) (p<0.01). The VFecs could be reliably measured down to 1000 microns below the cortical surface, and the regional increase in the VFecs could be mapped in a band surrounding the bacterial inoculation site.

This two-fold increase in the VFecs occurs in the cortex and demonstrates that a pronounced expansion of the VFecs can occur in gray as well as white matter in an acute inflammatory lesion.

IMPROVED BRAIN UPTAKE OF A CHEMOTHERAPEUTIC AMINO ACID WITH HIGH AFFINITY FOR THE CEREBROVASCULAR LARGE NEUTRAL AMINO ACID TRANSPORTER. Y. Takada, D. Vistica^{*}, N. Greig^{*}, S.I. Rapoport and O.R. Smith. Laboratory of Neurosciences, NIA, NIH, Bethesda, MD 20892.

The blood-brain barrier restricts the brain uptake of many hydrophilic drugs and limits their usefulness in the treatment of brain diseases (e.g., brain tumors, AIDS, Alzheimer's disease). In an attempt to improve brain delivery through facilitated transport, agents were sought with high affinity for the cerebrovascular nutrient carriers of the blood-brain barrier. One such agent that was found was D,L-2-amino-7-bis(2-chloroethyl)amino]-1,2,3,4-tetrahydro-2-naphthoic acid (NAM), an analog of the poorly penetrating anticancer drug L-melphalan. NAM, because of its increased hydrocarbon mass on the amino acid side chain, was predicted to have improved affinity for the large neutral amino acid carrier (L-system) of the blood-brain barrier. Following tritium labelling and examination of cerebral uptake in rats, NAM was shown to be taken up into brain at a ~10-30-fold greater rate than L-melphalan at tracer concentrations. Transport was BCH sensitive (>95%) and saturable with a V_{max} of ~1 nmol/min/g and a K_m of <1 µM. For comparison, the K_m of L-melphalan is ~150 µM, whereas the K_m of L-phenylalanine, the highest affinity endogenous amino acid, is ~10 µM. The primary degradation product of NAM (dechlorinated NAM) was also shown to be transported into brain by the L carrier, though with less affinity (K_m ~6 µM). The results demonstrate that rational drug modification can be used to improve drug delivery to brain via the saturable blood-brain barrier nutrient carriers.

EFFECT OF ACUTE AND CHRONIC HYPERTENSION ON THE BRAIN UPTAKE OF LIBENZAPRIL IN RATS. I-P Tang^{1,*}, S. Melethil¹, F. Douglas^{2,*}, A. Rakhit^{2,*} and G. Kochak^{3,*}. ¹Schools of Pharm. & Med., Univ. of Missouri, Kansas City, MO, and Ciba-Geigy Corp., ²Summit, NJ, and ³Ardley, NY.

Brain uptake of libenzapril (LZP) in Sprague-Dawley (SD) rats was essentially similar at MAP values (\pm SD) of 96 ± 4 (normal, $n=6$) and 148 ± 2 mmHg (phenylephrine induced acute hypertension, $n=6$). However, at a MAP of $171 (\pm 2)$ mmHg ($n=8$), uptake of LZP by all the 7 regions examined (medulla, olfactory lobe, colliculus, pons, diencephalon, cortex and cerebellum) was significantly higher compared to the 2 groups with lower MAPs. These results show that the effect of acute hypertension on brain permeability of LZP is observed only above a certain threshold pressure and are consistent with pressure-mediated autoregulation of cerebral blood flow.

Brain uptake in spontaneously hypertensive (SH) rats (chronic case) with a MAP of 149 ± 10 ($n=8$) mmHg was higher than the corresponding values in the SD group with the MAP of 148 mmHg in 6 out of the 7 regions. Since it was shown that the brain uptake of LZP was similar in SD and Wistar-Kyoto (normotensive controls for SH rats), these results show that the blood-brain barrier is more permeable to LZP in chronic hypertension. This enhancement in permeability may be related to morphological differences in the vascular endothelium. (Supported in part by Ciba-Geigy Corp.).

EXPERIMENTAL EVIDENCE OF ENZYMATIC BARRIER PROTECTING BLOOD-BRAIN BARRIER FROM LEUKOTRIENE C₄. T. Baba, K. L. Black, T. Inamura* and D. P. Becker. Division of Neurosurgery and Brain Research Institute, Univ. of California, Los Angeles, CA 90024.

We previously reported that intracarotid infusion of leukotriene C₄ (LTC₄) selectively increases blood-brain barrier (BBB) permeability within ischemic tissue in the brains of middle cerebral artery (MCA)-occluded rats. To reveal the mechanism how LTC₄ selectively opens the BBB in brain ischemia, and not to normal brain, BBB permeability in the MCA-occluded rats was determined by quantitative autoradiography using ¹⁴C-aminobutyric acid, with/without pretreatment of acivicin, an inhibitor of gamma glutamyl transpeptidase (γ -GTP). 72 hours after MCA occlusion, γ -GTP activity had disappeared in ischemic areas, LTC₄ (4 μ g total dose) infused into the carotid artery ipsilateral to the MCA occlusion after 72 hrs selectively increased unidirectional transfer constant for permeability, K_i, approximately two fold within ischemic tissue. No effect on BBB permeability was seen within non-ischemic brain tissue or in ischemic tissue after only 24 hours post MCA occlusion, when γ -GTP activity still remains moderately in histochemistry. 24 hours after MCA occlusion, however, LTC₄ could increase K_i with pretreatment of acivicin. We also examined the effects of acivicin on γ -GTP histochemistry and HPLC. Acivicin almost completely blocked both the activity of γ -GTP in brain capillaries and the metabolism of LTC₄ in isolated bovine brain capillaries. We further examined binding of LTC₄ to isolated bovine brain capillaries with/without acivicin. After 10 minutes of incubation, LTC₄ binding markedly decreased in the samples without acivicin, while it remained high in those with acivicin. These findings indicate that there is "enzymatic barrier" which protects normal brain capillaries from the vasogenic effects of LTC₄.

MECHANISMS OF BLOOD-BRAIN BARRIER BREAKDOWN IN MULTIPLE SCLEROSIS. L. Claudio, C. S. Raine, C.F. Brosnan* Department of Pathology, Albert Einstein College of Medicine, 1300 Morris Park Avenue, Bronx, New York 10461.

The blood-brain barrier (BBB) is characterized by interendothelial tight junctions, few pinocytotic vesicles and high mitochondrial content in CNS capillary endothelium. We have analyzed ultrastructural and morphometric features of capillaries from brain biopsies of 8 cases of multiple sclerosis (MS). The data were expressed as the percentage of endothelial cell area occupied by the respective organelles. The values for vesicular content ranged from 0.53% in endothelium located within normal-appearing CNS parenchyma to 1.1% in endothelium located within a lesion. Mitochondrial content ranged from 10.87% in normal areas to 4.72% in lesions. Thus, these results showed an inverse correlation between transcytotic vesicles and mitochondrial content in endothelial cells. The endothelium also showed a high number of cytoplasmic projections protruding into the lumen, a feature commonly associated with active inflammation. In acute inflammatory lesions there was evidence of gaps between endothelial cells in venules. Interendothelial tight junctions in capillaries appeared normal. There were no significant changes in coated vesicle area or the thickness of capillary basal laminae. Our previous studies on experimental autoimmune encephalomyelitis (EAE), a laboratory model of MS, have shown that clinical signs correlate with increased vesicular transport and decreased mitochondrial content in capillary endothelium. Taken together, these data suggest that vesicular transport is an important mechanism of edema formation in CNS inflammation and that a high mitochondrial content may play a major role in the maintenance of BBB function. PROSTAGLANDIN D₂ PRODUCTION IN HUMAN CEREBROMICROVASCULAR ENDOTHELIUM. F. Bacic, S. Uematsu, R.M. McCarron and M. Spatz. LNNS, NINDS, NIH, Bethesda, MD 20892.

Prostaglandin D₂ (PGD₂), a cyclooxygenase product of arachidonic acid metabolism was detected in various tissues including brain in many animal species and man. The cellular origin of PGD₂ in human brain is still uncertain although its synthesis and metabolism are well documented. Recently we demonstrated the presence of PGD₂ among other prostaglandins in the medium obtained from cultured endothelium (EC) derived from cerebral capillaries, and small and large microvessels. Here we show that PGD₂ release from the EC can be augmented by vasoactive peptides. Endothelial cultures were established from isolated capillaries and microvessels of human brain by a modified technique of Gerhard et al. (*Brain Res. Bull.*, 1988). Confluent propagated EC were washed and preincubated with 1 ml serum-free medium (Gibco 199) for 30 min at 37°C. PGD₂ release was evaluated after 1-4 hrs of incubation with angiotensin II [Ang II (10⁻⁸M-10⁻⁶M)], arginine-vasopressin [AVP (10⁻⁸M-10⁻⁶M)] in the presence or absence of [Sar¹, Ala⁸]-Ang II (10⁻⁵M) or [1- β -mercapto- β ,8-cyclopentamethylene propionic acid] POMT, 10⁻⁶M], respectively; by immunoassay with the use of specific PGD₂ antibodies. Ang II and AVP greatly increased PGD₂ release from the EC into the medium. AVP was a more potent inducer than Ang II. The stimulatory effect of Ang II and AVP was almost completely inhibited by their specific receptor antagonists [(Sar¹, Ala⁸)-Ang II and POMT-AVP, respectively]. The inducible increase of PGD₂ was also inhibited by pretreatment with cyclooxygenase blockers (ASA, indomethacin). These findings represent the first demonstration of receptor-mediated release of PGD₂ from EC of human cerebral capillaries and microvessels induced by well known vasoconstrictive peptides.

100.10

SELECTIVE OPENING OF THE BLOOD-TUMOR BARRIER BY INTRACAROTID INFUSION OF LEUKOTRIENE C₄-- DOSE RESPONSE STUDY. C.C.Chio*, K.L.Black, T.Baba. Div. of Neurosurgery, Univ. of Calif., Los Angeles, Sch. of Med., Los Angeles, CA 90024

Leukotriene C₄ (LTC₄) has been shown to selectively increase the blood-tumor barrier permeability after intracarotid infusion in RG-2 tumors in rats. In this study, four doses of LTC₄ (Vehicle, 0.5 μ g, 5 μ g and 50 μ g) were infused into right internal carotid artery for 15 minutes in female Wistar rats ($n=7$ in each group). Rats were implanted with RG-2 tumors in the right basal ganglion 10 to 11 days before. Blood-tumor permeability was determined by quantitative autoradiography using ¹⁴C aminoisobutyric acid.

The unidirectional transfer constant for permeability (K_i) within the tumor was increased two-fold in the 5 μ g and 50 μ g groups. No significant increase was observed after 0.5 μ g infusion. B.P., Hct, body temperature, and arterial blood gas all remained within physiological range. Maximal opening of tumor-blood barrier by LTC₄ in tumors may be achieved in rats with a total dose of 5 μ g infusion.

INCREASED PERMEABILITY ACROSS THE BLOOD-NERVE BARRIER OF ALBUMIN GLYCATED *IN VITRO* AND *IN VIVO* FROM PATIENTS WITH DIABETIC POLYNEUROPATHY. J.F. Poduslo and G. L. Curran*. Molec Neurobiol Lab, Depts of Neuro & Biochem/Molec Biol, Mayo Clinic, Rochester, MN 55905 USA

The blood-nerve transfer of human plasma albumin (ALB) glycosylated with D-glucose was investigated by measuring the permeability coefficient-surface area (PS) product of the BNB to radiiodinated ALB in normal rat sciatic nerve. ALB, isolated by CM-Affi-Gel Blue chromatography, was glycosylated *in vitro* for 1, 3, 10, 19 and 30 weeks. Glycosylated ALB (gALB) was separated from ALB by boronate-affinity chromatography. The efficiency of this separation was assessed by chromatography of ALB glycosylated with [¹⁴C]-glucose and by rechromatography of isolated ALB and gALB after radioiodination. The gALB was also shown to have a higher M_r and be completely separated from ALB after SDS-PAGE in a TRIS-Borate-EDTA buffer. After 1 week of glycation, the gALB-PS was 2.2 fold greater than the ALB-PS (0.724 ± 0.063 S.D. $\times 10^{-6}$ vs. 0.328 ± 0.053 S.D. $\times 10^{-6}$ ml/g/s; $P < 0.0001$) and increased with the time of glycation to a maximum value of 16.2 fold at 30 weeks (4.656 ± 1.117 S.D. $\times 10^{-6}$ vs. 0.288 ± 0.042 S.D. $\times 10^{-6}$ ml/g/s; $P < 0.0001$). The PS of gALB isolated from patients with diabetic neuropathy was significantly increased ($P < 0.0001$) compared to the PS for ALB isolated from the same patients. It is hypothesized that the increased permeability of gALB across the BNB, as well as the observed quantitative increase in ALB, IgG, and IgM in patient sural nerve biopsies (Poduslo et al, PNAS 85:4879-4883, 1988), contributes to osmotic changes in the nerve microenvironment which may play a role in the development of the neuropathy over a prolonged period of time. (NS14304-P4)

DISCORDANT MATURATION OF THE PERINEURIAL-NERVE AND BLOOD-NERVE PERMEABILITY BARRIERS IN RATS.

N. A. Azzam, A. A. Zalewski, and R. N. Azzam*. Lab. of Neural Control, NINDS, NIH, Bethesda, MD 20892.

Minifascicles of nerve fibers are present in cables formed in silicone tubes and in the healed anastomosis site between cut nerve ends. Because blood vessels are excluded from the endoneurium of these fascicles, the axons are protected only by a perineurial permeability barrier. This situation is different from normal where the passage of agents into the endoneurial environment of the nerve fibers is regulated by two barriers, the perineurial-nerve barrier (PNB) and the endoneurial blood-nerve barrier (BNB). We have begun a series of experiments to determine how and why barriers develop. We report here the results of a developmental study of the PNB and BNB, examined with the permeability tracer horseradish peroxidase (HRP). The tracer was administered intravenously (IV) or topically and localized in sciatic nerve of rats by a histochemical reaction seen by electron microscopy (EM). No barriers were present 1-9 days postnatally, and IV or topically applied HRP flooded the endoneurium. At 15 days, IV HRP leaked into the nerve from most endoneurial vessels whereas topically applied HRP was retained outside the nerve. Some vessels continued to leak HRP at 30 days, but all were impermeable at 100 days. EM revealed that intercellular junctions were present between endothelial cells of the BNB, but not the perineurial cells of the PNB, at 3 days. Despite this difference, perineurial cells formed impermeable junctions before endothelial cells. Our results demonstrated that the PNB developed before the BNB. Further studies are needed to determine whether the same or different factors govern barrier formation in nerve.

EFFECT OF SELECTIVE ASTROGLIAL DAMAGE ON BLOOD-BRAIN BARRIER DEVELOPMENT IN VIVO. J.M. Krum. Dept. of Anatomy, George Washington University Medical Center, Washington, D.C. 20037.

Recent studies have suggested that astrocytes can induce certain endothelial blood-brain barrier (BBB) characteristics in vitro. In order to determine if intact perivascular astroglia are necessary for development of BBB properties in vivo, neonatal rats aged 6-21 days received systemic injections of 6-aminocaproic acid (6-ACA), an antimetabolite of nicotinamide which specifically affects glial cells. Several BBB functions were examined, including the BBB to endogenous (serum albumin) and exogenous (intravascularly administered HRP) protein and endothelial expression of the glucose transporter antigen (GTA). Ultrastructural examination revealed no damage to endothelial cells or neurons, although massive perivascular astroglial degeneration occurred as a result of cytotoxic edema. Endothelial GTA expression remained at normal levels for each age examined. In animals younger than two weeks postnatal, even though astroglia were significantly diminished, no defect in the BBB was observed. Protein extravasation occurred only in animals older than two weeks, and leakage progressively increased with age. The destruction of astroglial endfeet does not appear to influence the expression of endothelial GTA, but does compromise the BBB to protein with increasing age. Studies are now in progress to determine how the defect in the BBB to protein occurs and to examine the effects of astroglial destruction on other BBB characteristics in vivo. (NIH-NS-17468).

IMMUNOCYTOCHEMICAL IDENTIFICATION OF TIGHT JUNCTIONS BETWEEN ASTROCYTES IN VITRO AND IN VIVO. George M. Smith and H. David Shine. Department of Neurosurgery, Baylor College of Medicine, Houston, Texas 77030.

An integral aspect of the blood-brain barrier is the development of tight junctions between specific non-neuronal cells of the central nervous system (CNS). To identify tight junctions in vitro or in vivo, we used a monoclonal antibody (ZO-1) that recognizes a 225 kd cytoplasmic protein associated with tight junctions (Stevenson et al., 1986 J. Cell Biol. 103:755). This protein displayed a continuous staining pattern around the perimeter of 80-90% of GFAP-positive astrocytes in confluent cultures. Expression of ZO-1 by astrocytes was contact dependent and only occurred in confluent monolayers. To determine if astrocyte morphology affected tight junction formation, astrocytes were grown in the presence of di-butyl cAMP or serum-free medium. Under these conditions astrocyte morphology changed from polygonal to stellate and the number of cells that stained with anti-ZO-1 dramatically decreased. In these stellate astrocytes staining localized exclusively to the cell bodies of clustered astrocytes. To determine if astrocytes in the rat CNS possess tight junctions, frozen brain sections were double labeled with ZO-1 and GFAP antibodies. The majority of stellate astrocytes were not ZO-1-positive; however GFAP-positive ependymal cells that have a cuboidal shape and line the ventricles were ZO-1-positive. Cells previously shown to have tight junctions, such as pial fibroblasts, endothelial cells, and cells of the choroid plexus also stained positive for ZO-1. These data indicate that the formation of tight junctions between astrocytes depends on cell contact and morphology. Supported by Navy-N60014-89-J-3003 and the Kleberg Foundation.

SATURABLE TRANSPORT OF NEUTRAL AND BASIC AMINO ACIDS AT THE BLOOD-NERVE BARRIER OF THE RAT PERIPHERAL NERVE. K.C. Wadhvani, Q.R. Smith and S.I. Rapoport. Lab of Neurosciences, NIA, NIH, Bethesda, MD 20892.

Unidirectional transport of L-leucine, L-arginine, and L-glutamic acid from blood into rat sciatic nerve were quantitatively determined, using an in-situ perfusion technique (Wadhvani et al. Am. J. Physiol. 258: R1436, 1990). The mean permeability-surface area products (PA) of ^{14}C -L-leucine for the blood-nerve barrier (BNB) was $61 \pm 5 \times 10^{-5}$ ml/s.g wet wt (n = 4), and decreased by >90 % when 10 mM [L-leucine] or 10 mM [BCH] was added to the perfusion medium. Transport appeared stereospecific as 10 mM [D-leucine] produced less inhibition than 10 mM [L-leucine]. Mean PA of ^{14}C -L-arginine was $20 \pm 2 \times 10^{-5}$ ml/s.g (n = 5), and fell by 50 % when perfusion medium contained 10 mM [L-arginine]. At 20 or 50 mM [L-arginine], mean PA of ^{14}C -L-arginine was $4 \pm 1 \times 10^{-5}$ ml/s.g wet wt (n = 5). No significant change was produced in BNB PA of ^{14}C -L-arginine when perfusion media contained either 50 mM [BCH], 50 mM [MeAIB], or Na-free 165 mM [Tris]-buffer. Mean BNB PA of ^{14}C -L-glutamic acid was $2 \pm 1 \times 10^{-5}$ ml/s.g (n = 5), and did not differ when perfusion medium contained either 10 or 50 mM [L-glutamic acid]. Our results demonstrate the presence of a carrier mediated transport system for L-leucine, and a different system for L-arginine, at the blood-nerve barrier of the rat peripheral nerve.

100.16

PROTEIN KINASE C MODULATES NEURAL MICROVESSEL MORPHOGENESIS.

John Laterra*, Ravi R. Indurti*, Joseph Bressler, Gary W. Goldstein*. The Kennedy Research Inst., Baltimore, MD 21205

Astrocytes ensheath central nervous system (CNS) capillaries, regulate endothelial differentiation and induce CNS microvessel endothelial cells to organize into capillary-like tubes in vitro (Laterra et al., J. Cell. Physiol. 144:204, 1990). We examined the effect of phorbol 12-myristate 13-acetate (PMA), a protein kinase C activator, on astroglial-induced capillary-like tube formation in vitro. PMA had no effect on the proliferation of either C6 cells, a cell line of astroglial origin, or bovine retinal microvessel endothelial (BRE) cells. PMA at concentrations of 0.1, 1.0, 10.0 and 100.0 nM inhibited C6-induced capillary-like tube formation by 50, 75, 95, and 100% respectively. 4 α -phorbol 12,13-di-decanoate, a PMA analogue that does not activate PKC, was without effect. These results suggest that PKC activation modulates morphogenic astroglial endothelial interaction within the central nervous system.

100.18

KINETICS OF FATTY ACID DISSOCIATION FROM ALBUMIN AND TRANSPORT INTO BRAIN. Q.R. Smith, H. Nagura*, K. Washizaki, J. DeGeorge*, P.J. Robinson, and S.I. Rapoport. Laboratory of Neurosciences, NIA, NIH, Bethesda, MD 20892.

Brain uptake of unesterified fatty acid from blood far exceeds that predicted by the free ("non protein bound") fraction, indicating that some fatty acid may be stripped off albumin as blood passes through the cerebral circulation. To examine this further, the brain uptake of unesterified [^{14}C]palmitate was studied in the presence and absence of albumin in anesthetized rats using an in situ brain perfusion technique (Takasato et al., 1984). Results were analyzed using a model that incorporates rates of palmitate binding and release from albumin, as well as blood flow and transport across the blood-brain barrier (Robinson and Rapoport, 1986). [^{14}C]Palmitate was found to be taken up into brain from whole rat blood or artificial plasma (2-3% albumin with ~100 $\mu\text{g/ml}$ palmitate) with a blood-to-brain transfer coefficient (K_{in}) of $2-3 \times 10^{-4}$ ml/s.g. The measured free (nonprotein-bound) fraction of palmitate in plasma equaled 0.005-0.01%, and the k_{off} from albumin was obtained from the literature (Svenson et al., 1974). To explain the observed uptake, it was calculated that a blood-brain barrier permeability-surface area product (PA) to free palmitate of at least 1 ml/s.g would be required. Evaluation of free palmitate uptake in the absence of protein, and with and without preperfusion, indicated that free palmitate was essentially completely extracted ($E > 0.9$) from perfusion fluid up to a flow rate of 0.5 ml/s.g (the highest flow rate examined). The calculated lower limit of PA for free palmitate was thus 1.2 ml/s.g. The results indicate that unesterified fatty acid uptake into brain can be explained with a simple model that incorporates dissociation from protein and transport into brain.

VOLUME REGULATION IN ISOLATED TURTLE CEREBELLUM UNDER HYPER- AND HYPOOSMOTIC CONDITIONS. D. Krizai, M.E. Rice & C. Nicholson. Dept. Physiology & Biophysics, New York University Medical Center, New York, NY 10016

Does isolated brain tissue behave as an osmoregulator or an osmoconformer? Turtle (*Pseudemys scripta*) cerebella were incubated (30 min.) in Ringer solutions whose osmolarity was adjusted by addition or subtraction of NaCl. The volume of the extracellular space (as the volume fraction, α) and its geometry (as tortuosity, λ) were measured with ion selective microelectrodes using the diffusion of a probe ion (TMA⁺) as described previously (*J. Physiol.* 321:225, 1981). Synaptic potentials evoked by peduncular stimulation were monitored continuously.

The cerebellar tissue behaved as a perfect osmometer up to about 586 mosmoles, where $\alpha = 0.53 \pm 0.06$, an increase from its value of 0.22 ± 0.06 in the control Ringer (326 mosmoles) solution; decreasing control NaCl by half (to 256 mosmoles) decreased α to 0.12 ± 0.02 . In addition, λ showed a small but consistent decrease from 1.70 ± 0.13 in controls to 1.54 ± 0.08 at 706 mosmoles. These data conformed to Archie's Law ($\lambda^2 = \alpha^B$), with $\beta = 0.2$. Field potentials gradually diminished with increasing osmolarity and disappeared around 600 mosmoles. This effect was always reversible upon return to normal Ringer.

This study suggests that isolated cerebellar tissue does not exhibit significant short-term regulation of its extracellular volume. A possible relation between a physical parameter (α) and the geometry of the space was also demonstrated by the conformation of the data to Archie's Law. Supported by NINDS NS-13742 and NS-28642 to CN.

EXTRACELLULAR PATHWAYS FOR ENTRY OF SERUM PROTEINS TO THE CNS. P. Fishman, R. Broadwell and M. Sofroniew. Univ. MD, Sch. Med., Balto., 21201, and Cambridge Univ., Cambridge, U.K.

Extracellular pathways circumventing the blood-brain barrier (BBB) were identified in rats by immunohistochemical localization of endogenous serum proteins albumin, IgG, complement C9, and IgM and by HRP delivered intravenously. Each of the proteins enters the CNS thru fenestrated vessels in circumventricular organs (e.g., median eminence, subfornical organ, etc.); the proteins gain extracellular access to adjacent brain parenchyma and ependymal lining of the ventricular system. Blood-borne proteins entering the subfornical organ are distributed within the white matter of the corpus callosum. An extracellular pathway also exists at the level of pial surface vessels; immunoreaction product for the serum proteins and HRP appear on the pial surface, within subarachnoid macrophages, the Virchow-Robin spaces and associated perivascular cells, and in the subpial parenchyma. Immunoreaction product for IgG is localized within punctate granules in cell bodies of hypothalamic neurosecretory neurons and motor neurons, the axons of which project outside the BBB. The findings suggest that blood-borne immune and complement macromolecules have unrestricted extracellular access to the CNS. Widespread distribution of serum proteins within the CNS may have important implications in experimental and pathologic autoimmune dysfunction within the CNS. Supported by NIH/NINDS Grant #NS18030.

BLOOD-TO-BRAIN TRANSPORT AND METABOLISM OF CIRCULATING VASOPRESSIN. B.V. Zlokovic, W.A. Banks^{1,2}, H. El Kadji, J. Ercegyi^{1,2}, J.G. McComb² and A.J. Kastin¹. Department of Neurological Surgery and Division of Neurosurgery Childrens Hospital Los Angeles, University of Southern California, Los Angeles, California and Veterans Affairs Medical Center and Tulane University School of Medicine, New Orleans, Louisiana¹

Recent *in vivo* experiments suggested that arginine-vasopressin (AVP) is taken up at the luminal side of the blood-brain barrier (BBB) by peptide-specific carrier and/or receptor mediated process [*Biochim. Biophys. Acta* (1990) 1025: 191-198]. In this study, a capillary depletion step [*J. Neurochem.* (1990) 54: 1882-1888] was coupled to the vascular brain perfusion (VBP) method to examine whether a significant brain distribution of circulating [³H]-AVP represents either sequestration to cerebral microvessels or its transport across the BBB. Cerebrovascular permeability of [³H]-AVP determined in the forebrain was almost ten times higher than for the vascular space marker [¹⁴C]-sucrose. The [³H]-radioactivity determined in the vascular pellet after a dextran density centrifugation of the forebrain homogenate was barely above the background level, and after 10 min of the VBP experiment was indistinguishable from [¹⁴C]-sucrose. HPLC analysis of radioactivity of the postcapillary supernatant revealed time-dependent fragmentation of blood-borne neuropeptide. The percentage of intact [³H]-AVP during brain perfusion progressively declined from 49% at 1 min to 11.9% at 10 min. The major detectable labeled metabolite was [³H]-phenylalanine (labeled amino acid residue of [³H]-AVP), while the percentage of radioactive peptide fragments increased to about 11% at 10 min. The results indicate transport of intact AVP across the BBB and its rapid *in vivo* metabolism in the brain with no evidence of capillary sequestration (Supported by Childrens Hospital Los Angeles and the VA).

CISTERNAL MICRODIALYSIS TO EVALUATE EFFECTS OF FUROSEMIDE AND ETHACRYNIC ACID ON BLOOD-TO-CSF TRANSPORT OF CHLORIDE. C. Johanson, D. Palm*, M. Dyas* and N. Knuckey. Program in Neurosurgery, Dept. of Clin. Neurosciences, Brown Univ./R.I. Hospital, Providence, RI 02902.

Microprobe dialysis in the cisterna magna (CM) can be used to assess CSF ion transport and fluid formation rate. Male Sprague-Dawley rats (200-300g) were anesthetized with ketamine/xylazine and secured in a head frame. A 2-mm BAS microprobe was inserted through a burr hole in the occipital bone, angled parallel to the occipital squama, and directed into the CM. Cl-36, injected IV after nephrectomy, was allowed to penetrate into CSF for eventual dialysis from CM. Average steady-state control values for volume of distribution (Vd, i.e., dpm/g CSF ÷ dpm/g plasma) of Cl-36 in cisternal dialysate were $111 \pm 11\%$ (n=4). The potent loop diuretics furosemide or ethacrynic acid, 50 mg/kg, significantly decreased the level of Cl-36 in CM dialysate by 34% and 32%, respectively. Acetazolamide (50 mg/kg), an inhibitor of carbonic anhydrase but not a loop diuretic, reduced the steady-state Vd of Cl-36 by 55%. In all experiments the arterial pressure was between 80 and 130 mm Hg. Because Cl transport from blood to CSF is proportional to CSF formation rate, we conclude that loop diuretics are able to substantially alter CSF flow in the rat CNS, presumably by inhibition of Na-K-Cl cotransport in the choroid plexus. Supported by funds from R.I. Hospital and by NIH grant NS 27601.

100.22

IN VIVO TRANSLOCATION AND SELECTIVE REMOVAL OF ¹²⁵I-TYR-MIF-1 FROM THE RAT BRAIN AFTER ICV INJECTION. L.M. Maness, A.J. Kastin, W.A. Banks, and J.E. Zadina. Dept of Medicine and Neuroscience Training Prog, Tulane U Sch of Med, New Orleans, LA 70112; VA Med Ctr, New Orleans, LA 70146.

The endogenous peptide Tyr-MIF-1 (Tyr-Pro-Leu-Gly-NH₂) is known to be transported out of the CNS (*Am J Physiol* 259:E1, 1990). Here, we further defined this process by injecting ¹²⁵I-Tyr-MIF-1 or ¹²⁵I-albumin icv and contrasting their distributions over time in brain slices by autoradiography. At 20 min, albumin could not be detected outside the ventricles (VENT), but Tyr-MIF-1 had nearly completely cleared the space and was localized in the periventricular tissue (PVT). At 120 min, albumin had moved almost completely into the PVT, but Tyr-MIF-1 was barely evident in the sections.

		ALBUMIN	TYR-MIF-1	
20 min	VENT	+++	0/+	0 = No Labeling
20 min	PVT	0	+/+++	
120 min	VENT	0/+	0	+++ = Max Labeling
120 min	PVT	++	0/+	

These results suggest that while albumin is not readily removed from brain within the tested time period, Tyr-MIF-1 moves rapidly into the PVT with subsequent removal from the CNS. (Supported by NIMH/APA P32 MH18882 and VA).

ENDOTHELIAL CELLS EXPRESS BRAIN-TYPE GLUCOSE TRANSPORTER IN A TISSUE CULTURE MODEL OF THE HUMAN BLOOD-BRAIN BARRIER. A.A. Hurwitz, W.T. Norton, J.W. Berman, and W.D. Lyman. Dept. of Pathology, Albert Einstein Coll. of Med., Bronx, NY 10461.

Endothelial cells of the Blood-Brain Barrier (BBB) have been shown to have unique morphologic and functional characteristics. In addition, BBB endothelium expresses specific cell surface molecules. Studies have indicated that brain-type glucose transporter (GLUT-1) can be solely localized to the microvessels of the CNS. Here, we describe the expression of GLUT-1 on human fetal endothelial cells in co-culture with autologous astrocytes. Astrocytes were seeded on one side of a permeable tissue culture insert. Early passage human fetal umbilical vein endothelial cells were added to the gelatin coated, opposite side of the insert. The two cell types were cultured for up to two weeks when they were tested for glial fibrillary acidic protein (GFAP), Factor VIII, and GLUT-1 immunoreactivity. Our results show that astrocytes maintained GFAP expression and endothelial cells were factor VIII positive. In addition, only endothelial cells grown in co-culture expressed GLUT-1 and this expression appears to be contact-dependent. These findings support the use of this model as a system to examine the development of the BBB as well as to characterize BBB-specific molecules. In addition, this model may permit examination of neuropathological processes involving the BBB. Supported by USPHS grants NIH NS 07098-14, MH 47667, MH 46815.

DECREASED CHLORIDE TRANSPORT IN CHOROID PLEXUS ASSOCIATED WITH CHRONICALLY ELEVATED INTRACRANIAL PRESSURE. N. Knuckey, J. Preston*, M. Dyas*, R. Jenkins*, M. Epstein, D. Palm*, and C. Johanson. Program in Neurosurgery, Dept. of Clin. Neurosciences, Brown Univer./RI Hosp., Providence, RI 02902.

Choroid plexus (ChPl) ion transport, and CSF formation secondarily, may be down-regulated when intracranial pressure (ICP) is chronically elevated. To test this hypothesis we analyzed the transport of Cl by ChPl excised from rats subjected to ICP elevation by kaolin hydrocephalus. Adult male rats (6-8 wk), anesthetized with ketamine, underwent injection of kaolin (375 mg) into cisterna magna. Three weeks later, the ICP and ventricular volume were assessed prior to removing the lateral ChPl for transport studies. We analyzed the ability of ChPl isolated in artificial CSF to transport Cl outward from epithelial cells. The experimental findings allowed categorization into 4 groups, i.e., either controls or those with mild, moderate or severe hydrocephalus. With maximally dilated ventricles and ICP 15 cm water or greater in severe hydrocephalus, the Cl-36 efflux constant (per sec) was reduced 35% from the control value of 0.029. Moderately hydrocephalic rats with less extensive increases in ICP (5-15 cm water) showed smaller decreases in ability to transport Cl outward into CSF. Electron micrographical analysis revealed no apparent alteration in ChPl epithelial ultrastructure. The findings fit the idea of down-regulated transport, possibly as a homeostatic response to ICP rise. Supported by NIH NS 27601.

PURIFICATION OF A CALCIUM BINDING PROTEIN FROM CARP CEREBROSPINAL FLUID. G.D. Chang, C.C. Chen* and F.L. Huang*. Inst. of Biochem. Sci. and Dept. Zool., Natl Taiwan Univ., PO Box 23-106, Taipei 10098, Taiwan.

A calcium binding protein was purified from carp cerebrospinal fluid to apparent homogeneity. Using ammonium sulfate precipitation, Sephacryl-S200 column, Phenyl-Sepharose hydrophobic interaction column, Hydrophase HP-PEI HPLC protein column chromatography, the protein was purified with high yields. Under reduced and non-reduced SDS PAGE, it behaved as a molecule of 60 kDa. Calcium binding assay was conducted after electrophoretic transfer of the proteins from SDS polyacrylamide gel onto nitrocellulose paper (J. Biochem., 95:511-519, 1984).

Tissue distribution of this calcium binding protein was examined by a homologous radioimmunoassay, western blotting and immunocytochemical methods. It has been found that this protein is also present in serum and brain extract in much higher concentrations than in other tissue fluids (semen, ovarian fluid) or other tissue extracts.

RAPID BRAIN TRANSPORT OF MANGANESE(II)-54 AT THE RAT BLOOD-BRAIN BARRIER. Q. Rabin, S.I. Rapoport, and O.R. Smith. Laboratory of Neurosciences, National Institute on Aging, NIH, Bethesda, MD 20892.

Manganese (Mn) is essential for brain function, yet is neurotoxic at elevated concentrations. To evaluate the factors that regulate Mn uptake into the central nervous system, the blood-brain barrier transport of Mn was studied in rats using an in situ brain perfusion technique (Takasato et al., 1984). Both cerebral hemispheres of the pentobarbital-anesthetized rat were perfused by direct infusion of physiologic saline or artificial blood containing Mn(II)-54 and [¹⁴C]sucrose into the carotid artery. At the end of perfusion, the rat was killed and tracer concentrations were determined in perfusate and brain. Mn(II)-54 was found to be taken up into brain at a very rapid rate during perfusion with physiologic saline that did not contain plasma proteins. The blood-brain barrier transfer coefficient (K_{in}) for Mn-54 in rat parietal cerebral cortex equaled $1.02 \pm 0.14 \times 10^{-3}$ ml/s/g (6.12 ml/min/100g)(n=18) and was not appreciably affected by pre- or post-perfusion with tracer-free fluid to wash-out the cerebral vasculature. The K_{in} for brain Mn-54 uptake agreed well with previous in vivo estimates in rats, after correction for the protein-bound fraction (Murphy et al., 1991), suggesting that "free" Mn is the form that crosses the blood-brain barrier. Addition of 5 mM EDTA to the perfusate essentially abolished uptake, whereas addition of transferrin (3 mg/ml) had no effect. The results demonstrate that Mn(II)-54 is rapidly taken up into brain with a K_{in} 50-100 times that of calcium, and that it is likely the "free", nonprotein bound form of Mn that crosses the blood-brain barrier.

DIFFERENTIAL EXPRESSION OF Na,K-ATPase ISOFORMS IN THE CHOROID PLEXUS AND CEREBRAL MICROVESSELS OF THE GUINEA-PIG BRAIN. A.J. Sarai, A.A. McDonough¹, J.G. McComb² and B.V. Zlokovic. Departments of Neurological Surgery, Physiology and Biophysics¹, and Division of Neurosurgery, Childrens Hospital Los Angeles, University of Southern California School of Medicine, Los Angeles, California

The choroid plexus (CP) and the blood-brain barrier (BBB) play major roles in maintaining Na⁺ and K⁺ concentrations in the cerebrospinal fluid (CSF) and brain extracellular fluid (ECF). Na,K-ATPase is a key enzyme responsible for active transport of Na⁺ and K⁺ between blood, ECF and CSF. Three isoforms of Na,K-ATPase α subunit have been characterized, all found in brain. Previous cytochemical and ouabain-binding studies have demonstrated localization and relative enrichment of Na,K-ATPase in the choroid epithelium and cerebrovascular endothelium. In this study we utilized isoform specific antibodies to detect Na,K-ATPase subunits α_1 and α_2 in the choroid plexus and cerebral microvessels of the guinea-pig. Vascular brain perfusion technique (J. Neurochem. (1988) 46: 1444-51) was used to eliminate any protein source from regions other than the brain. Different brain regions (e.g., cortex, cerebellum, caudate, hippocampus, midbrain), microvessels from cerebral cortical mantles and choroid plexi from lateral ventricles were pooled from 3 to 19 guinea-pigs and prepared for immunoblotting procedure as described (Am.J.Physiol. (1985) 248: C247-C251). α_1 and α_2 were detected in all brain regions studied. Only α_2 was detected in cerebral microvessels with undetectable α_1 form, while choroid plexus showed the presence of α_1 form and a much lower signal of α_2 . The data support the hypothesis that blood-CSF barrier and BBB regulate brain CSF and ECF ionic composition by different mechanisms. (Supported by Childrens Hospital Los Angeles. Antibodies to rat Na,K-ATPase subunits are provided by Dr. K. Sweadner).

REGULATION OF GENE EXPRESSION I

101.1

TISSUE SPECIFIC EXPRESSION OF THE MYELIN P2 PROTEIN GENE.

Vinodh Narayanan and Benedetta Ripepi, Departments of Pediatrics, University of Pittsburgh, and The Children's Hospital of Pittsburgh, Pittsburgh, PA.

The myelin P2 protein, a member of a family of fatty acid binding proteins, is expressed only in Schwann cells and oligodendrocytes. It is more abundant in peripheral nerves and nerve roots, than in the spinal cord and brain. What are the segments of the P2 gene that limit its expression to oligodendrocytes and Schwann cells, and account for this gradient of expression within the nervous system?

We have previously isolated and analyzed the structure of the mouse myelin P2 gene (V. Narayanan, et al, J. N.chem, in press). By removing the first exon of the P2 gene, and replacing it with the E. coli β -galactosidase gene, *lac Z* (derived from pNlacF, a gift of Dr. R. Palmiter), we have constructed two mini-genes that express the *lac Z* protein. The first, MP2PrLacZ, contains 2 kbp of 5'-flanking sequence fused with the *lac Z* gene, and the second, MP2lacZ, contains the rest of the gene as well. These mini-genes will be used to generate lines of transgenic mice, and the expression of *lac Z* assayed by histochemical staining with X-gal. This will allow us to localize the part(s) of the P2 gene responsible for tissue specific expression.

101.2

ASTROCYTE-SPECIFIC TRANSCRIPTION OF THE HUMAN GENE FOR GLIAL FIBRILLARY ACIDIC PROTEIN (GFAP). F. Besnard*, K. Masood*, Y. Su* and M. Brenner. Lab. of Molec. Biol., NINDS-NIH, Bethesda, MD 20892

The *gfa* gene encodes glial fibrillary acidic protein (GFAP), an intermediate filament protein found almost exclusively in astrocytes. To identify regions of the human *gfa* gene that regulate its transcription, we have conducted cell transfection studies with reporter gene constructs. A 2.2 kb 5'-flanking fragment has been found to confer astrocyte-specific expression. Analysis of this fragment has revealed three regions critical for activity; a basal promoter extending from -40 to +40 (RNA startpoint = +1), a promoter proximal element between -132 and -70, and a promoter distal element between -1660 and -1489. Chimeric constructs indicate that cell specificity is largely controlled by the distal element. In addition, when the region between the distal and proximal elements is deleted, reporter gene activity increases about 10-fold, and the proximal element is no longer essential. These effects appear to be due to proximity of the distal element to the basal promoter, rather than to removal of a silencer region.

Both the proximal and the distal elements contain previously identified regulatory motifs as well as a novel 10 bp sequence. The functionality of several of these elements is indicated by their presence in regions showing strong DNase I footprints, and by the results of site-directed mutagenesis.

101.3

TRANSCRIPTIONAL REGULATION OF β -CGRP IN C6 GLIOMA CELLS.

Marc A. Kirschner and Susan G. Amara, Section of Molecular Neurobiology, Howard Hughes Medical Institute, 333 Cedar St. Yale University School of Medicine, New Haven, CT, 06510.

α -CGRP and β -CGRP genes show distinct patterns of expression within the nervous system and are differentially regulated by a variety of second messengers. 5'-flanking region sequences of both neuropeptides are highly divergent, suggesting distinct mechanisms of transcriptional regulation. Vector constructs containing serial exonuclease III deletions of the β -CGRP promoter upstream of a luciferase reporter gene have been used in transfection experiments in C6 glioma cells to identify *cis* elements important for the high levels of endogenous β -CGRP expression seen in this cell line. Extracts of cells transfected with the full length construct containing 2.3 kb of the 5'-flanking region contain luciferase activity of the same order of magnitude as seen with an SV40 promoter. Several activator and repressor elements have been identified within the 2.3 kb upstream of the β -CGRP cap site and will be discussed. The identification of such *cis*-acting elements is an initial step towards the characterization of neuronal *trans*-acting factors important in the transcriptional regulation of β -CGRP.

101.5

RETINAL DNA-BINDING PROTEINS THAT INTERACT WITH THE OPSIN PROMOTER. X. Yu* and C. J. Barnstable, Dept. of Ophthalmology and Visual Science, Yale University School of Medicine, 330 Cedar St., New Haven, CT 06510.

Opsin is one of the earliest genes expressed in differentiated photoreceptor cells. Its expression is regulated primarily at the transcription level. Transgenic mice studies and sequence homology between species imply two regions in its promoter to be important in opsin gene regulation. One is within 300 bp to the transcription start site, the other is about 1.5 kb upstream. Protein binding sites within these regions have been identified (Morabito, M and Barnstable C. J. (1989) Soc. Neurosci. Abstr. 15,1269.) Our results indicate that at least two proteins bind to the proximal region. One of them, Ret1, a developmentally regulated retina specific binding factor, has an apparent molecular weight of 40 kd on SDS-PAGE. However, the binding activity is eluted at about 100 kd by a gel filtration chromatography column. Another protein of 105 kd binds to a retina specific binding site 5' to the Ret1 site. The protein that binds to the distal region which is highly homologous between species also has an apparent molecular weight of 105 kd. Its binding activity is restricted to retina and some other tissues and appears not to be developmentally regulated based on gel retardation assay. Further study of these DNA-binding factors will shed light on opsin gene regulation and photoreceptor differentiation.

COLD-INDUCED ALTERATIONS IN THE BINDING OF ADRENOMEDULLARY NUCLEAR PROTEINS TO THE PROMOTER REGION OF THE TYROSINE HYDROXYLASE (TH) GENE. L.L. Miner, S.P. Pandalai, and B. Kaplan, Department of Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, PA 15213.

Previously, we have demonstrated that cold exposure induces a rapid trans-synaptically mediated increase in rat adrenomedullary TH gene expression. To explore the molecular genetic mechanisms mediating this adaptive response, adrenomedullary nuclear protein extracts were prepared from control and cold-stressed (5°C) rats and were incubated with fragments obtained from the 5' flanking region of the bovine TH gene. Radiolabelled DNA-protein complexes were resolved from unbound DNA using a mobility shift assay. Two of these fragments (0 to -82 bp and -213 to -268 bp) showed cold-specific alterations in gel migration patterns. These shifts were observed within 1 hr of cold exposure and were abolished by sympathetic denervation of the gland. The -213 to -268 bp fragment contains a highly conserved AP1 consensus sequence, and the mobility shift could be eliminated by competition with synthetic AP1 sequences, but not by the SP1 consensus sequence. Combined, these data suggest that cold-induced alteration in TH gene expression are mediated by alterations in the interaction of *trans*-acting factors with regulatory elements present in the 5' flanking region of the gene and implicate the AP1 transcription complex in the trans-synaptic modulation of TH gene expression *in vivo*.

101.4

DETERMINATION OF TRANSCRIPTION STARTS AND PROMOTER ACTIVITY OF THE RAT B-50 (GAP-43) GENE. L.H. Schrama, B.J.L. Eggen*, H.B. Nielander*, A.J. van Rozen*, P. Schotman, and W.H. Gispen*, Div. Mol. Neurobiol., Rudolf Magnus Inst., Lab. Physiol. Chem., Inst. Molec. Biol. & Med. Biotechnol., Univ. of Utrecht, Padualaan 8, 3584 CH Utrecht, The Netherlands.

The neuron-specific phosphoprotein B-50 (GAP-43) gene is encoded by a single copy gene. The B-50 gene includes 3 exons (Nedivi et al., *Soc. Neurosci. Abstr.*, 15:503.15, 1989; Grabczyk et al., *Eur. J. Neurosci.*, 2: 822, 1990).

Comparison of the primary structure of the B-50 gene upstream of the translation start with the published sequence by Grabczyk et al., 1990, showed that two out of four genomic exon 1 clones contained a deletion varying between 2 and 58 bp of alternating A and G residues. The apparent instability of this region in *E. coli* may be related to the potential of homopurine residues to form unusual DNA conformations (H-DNA). Data obtained by rapid amplification of cDNA ends (RACE) suggest the presence of multiple transcriptional initiation sites upstream of -81. The most 5' ends are located upstream of -235. Some of the RACE products showed a deletion upstream of -81, in a homopurine rich area. This deletion was the result of an artifact of the used reverse transcriptase (AMV-RT).

Primer extension of poly(A)⁺ RNA from 8 day old rat brains, using an upstream primer in exon 2 with AMV-RT and MMLV-RT, showed that AMV-RT gives rise to several shorter products than MMLV-RT, since AMV-RT stops specifically in purine rich sequences. Data from both RTs indicate two major transcription starts at -133 and -342. These transcription starts for cDNA synthesized with MMLV-RT were supported by PCR using nested primers.

Promoter analysis of the -1012 to -114 bp fragment upstream of the translation start, with or without the 56 bp AG deletion, in NGF differentiated PC12 cells, using luciferase as reporter gene, showed that this deletion caused a 4-fold decrease in the B-50 promoter activity compared to the intact fragment.

101.6

ISOLATION AND CHARACTERIZATION OF THE PROMOTER REGION OF RAT TRYPTOPHAN HYDROXYLASE (TPH) GENE

S.O. Huh*, K.S. Kim, D.M. Stone, T.H. Joh, and J.H. Son*, Lab. of Molec. Neurobiol., Cornell Univ. Med. Coll., The Burke Med. Res. Inst., White Plains, NY 10605.

TPH is the rate-limiting enzyme in the biosynthesis of a monoamine neurotransmitter, serotonin. Since the regulation of serotonin levels in the brain is directly related to TPH activity, understanding TPH regulation at the molecular level is an essential step toward elucidating the function of serotonin in the central nervous system. With this aim in mind, we isolated the rat TPH gene from a Charon 4A rat (Sprague-Dawley, female) genomic library. Seven TPH positive clones were isolated with a rat dorsal raphe nucleus-derived TPH cDNA probe. Southern blot analyses of the recombinant phage DNA using several different portions of the cDNA probes identified two independent clones, each containing about 14.5 kb of TPH genomic DNA insert. Further detailed restriction enzyme mapping and DNA sequence analysis of the clones revealed the 5' promoter region. In addition, a mouse genomic TPH clone was isolated from an EMBL3 mouse (C57BL, male) genomic library using the rat cDNA as probe. This 15.1 kb mouse genomic clone containing the 5' flanking region is currently being characterized to identify the upstream consensus sequences among rodents, which may be functionally important for the regulation of TPH gene expression.

To further delineate the sequence elements that are responsible for directing cell type specific and developmentally regulated transcription of the TPH gene, we are carrying out deletion analysis of the 5' flanking region of the rat TPH gene and assaying its expression in a mouse mastocytoma cell line and transgenic animals.

101.8

3' ELEMENTS RESPONSIBLE FOR NEUROENDOCRINE TISSUE-SPECIFICITY IN THE HUMAN TYROSINE HYDROXYLASE GENE. S.C. Wong*, M. Moffat*, and K.L. O'Malley, Department of Anatomy and Neurobiology, Washington University School of Medicine, St. Louis, MO 63110.

Tyrosine hydroxylase is the rate limiting enzyme in the synthesis of catecholamines. The expression of tyrosine hydroxylase gene is restricted to dopaminergic, noradrenergic, and adrenergic cells in the central nervous system as well as sympathetic ganglia and adrenal medullary cells in the periphery. Our laboratory has previously demonstrated that the region responsible for the cell-type specific expression of the human tyrosine hydroxylase gene may be located in a 760 base pair region immediately 3' of the exon 13 (Gandelman K.-Y. et al., 1990). Nucleotide sequence analysis of the 760 base pair region reveals the presence of two consensus sequences (CAXXTG) recognizable to the helix-loop-helix family of transcriptional factors. The two CAXXTG motifs are separated by 140 bases. Using transient expression assays, we showed that the up-stream CAXXTG exhibits tissue-specific enhancement irrespective of the presence of the down-stream CAXXTG and that the 100 base pair region immediately 3' of the exon 13 may contain additional elements essential for the tissue-specific expression of the human tyrosine hydroxylase gene. The involvement of the up-stream CAXXTG motif in tissue-specific expression was further demonstrated with the double stranded oligonucleotides containing the same CAXXTG sequence. These new findings support our previous report that the elements responsible for neuroendocrine tissue-specificity expression in the human tyrosine hydroxylase gene is located at the 3' end of the gene.

101.9

ANALYSIS OF E BOXES IN THE CHICK MUSCLE ACETYLCHOLINE RECEPTOR δ -SUBUNIT GENE. Xin-Min Wang*, Ying-Shuan Lee*, and Jakob Schmidt. Dept. of Biochem. & Cell Biol., State Univ. of New York at Stony Brook, Stony Brook NY 11794.

The chick muscle δ -subunit promoter contains several copies of the MyoD recognition motif CANNTG or 'E box': at -110 from the translation start site (1); at -156 (2) and -204 (3) where they are embedded in a subunit enhancer similarities; and at -238 (4) and further upstream in the silencer region 5' of -207 (Wang et al., EMBO J. 9, 783, 1990). DNase I footprinting shows that proteins from fibroblast and myotube nuclei bind to E boxes 2 and 3. Base substitutions in these elements and at sites in close proximity (at -193/-191 and -164/-162) abolish factor binding and reduce transcriptional activity in all cells. Corruption of E box 1, on the other hand, does not impair promoter activity in muscle cells and doubles activity in fibroblasts. The MyoD family member myogenin footprints to 1 and 3, but not to 2. In cotransfection experiments myogenin overrides the silencer effect in 3T3 and 10T1/2 cells, probably by activation of the myogenetic program, and not as a consequence of direct binding to the promoter, because appropriate constructs remain inactive in cotransfected HeLa and Cos-1 cells. Nevertheless, competition experiments suggest that E boxes in the silencer region interact with factors present in fibroblasts; perhaps such interactions play a role in the suppression of the δ -subunit gene in non-muscle cells.

101.11

REGULATION OF OXYTOCIN GENE TRANSCRIPTION BY ESTROGEN AND THYROID HORMONE R.A.H. Adan* H. Rigter J.P.H. Burbach* Rudolf Magnus Institute, University of Utrecht, the Netherlands; Gezondheidsraad, the Hague.

This study is focussed on endocrine factors involved in the regulation of oxytocin (OT) gene transcription. Plasmids having a 5'-flanking region of the rat OT gene (-363/+16) cloned in front of the firefly luciferase gene were co-transfected with expression vectors for the human estrogen receptor or the rat thyroid hormone receptor in P19 EC Cells. Estrogen strongly stimulated rat OT promoter activity. Two regions of the promoter were located each conferring approximately 15-fold stimulation, between nucleotides -172 and -149 and between -148 and +16. Thyroid Hormone also stimulated OT promoter activity, but less strongly than estrogen. Responsiveness accounting for about 5-fold stimulation was located between nucleotides -172 and -148. There was no cooperativity between estrogen and thyroid hormone stimulation. The sequences of the OT promoter mediating these responses are characterized by site directed mutagenesis and by footprints with purified receptor-proteins. Thyroid hormone and estrogen regulate the OT gene.

101.13

PROMOTER ACTIVITY OF THE 5' FLANKING SEQUENCE OF THE MOUSE SEROTONIN 1C RECEPTOR GENE ASSAYED IN XENOPUS OOCYTES. L.J. Bloem, Y. Chen, J. Liu, J. Harts, and L. Yu. Dept. of Med. & Mol. Genetics, Indiana Univ. Sch. of Med., Indianapolis, IN 46202.

The serotonin 1c (5-HT_{1c}) receptor is found in many brain regions, but is particularly enriched on the epithelial cells of the choroid plexus where it couples to phosphatidylinositol turnover. To understand more about the molecular processes that regulate the regional expression pattern of the receptor, we have isolated the 5' flanking sequence of the mouse 5-HT_{1c} receptor gene and cloned it into a vector containing the 5-HT_{1c} receptor cDNA. The plasmid DNA was injected into the nucleus of *Xenopus* oocytes. After two days of incubation, individual oocytes were tested for the presence of the 5-HT_{1c} receptor by voltage-clamp recording. Upon superfusion of serotonin-containing Ringer's solution, depolarizing membrane currents were detected in injected oocytes, suggesting that the 5-HT_{1c} receptor is functionally expressed under the promoter activity of the 5' flanking sequence. This assay system provides the sensitivity of electrophysiology recording and will be used to analyze the cis-acting elements in the promoter region of the receptor gene and the trans-acting factors that regulate the region-specific expression of the receptor gene.

101.10

A Negative Retinoic Acid Response Element in the Rat Oxytocin Promoter Restricts Transcriptional Stimulation By Constitutive Transactivation Domains. By Steven M. Lipkin, Ronald B. Emeson and Michael G. Rosenfeld. GMM 239, UC San Diego, La Jolla 92093

We have identified a high-affinity binding site in the rat Oxytocin promoter that mediates negative transcriptional regulation by the retinoic acid receptor. To determine whether strong, constitutive transactivation domains could stimulate gene transcription when bound to a DNA binding site that mediates transcriptional repression, we fused the Herpes Simplex Virus Protein 16 (VP16) transactivation domain to the retinoic acid receptor amino-terminus. This chimeric receptor demonstrated an enhanced ability to increase mRNA transcription when bound to promoters containing palindromic thyroid hormone/retinoic acid response elements, but surprisingly still repressed gene transcription when bound to promoters containing the negative retinoic acid response element. These results suggest that the activity of even constitutive transactivation domains can be constrained by the DNA binding sites to which they are bound.

101.12

CIS ACTING ELEMENTS INVOLVED IN THE REGULATION OF VASOPRESSIN GENE EXPRESSION. K. Parody*, R.A.H. Adan*, D.A. Carter, J.P.H. Burbach* and D. Murphy. Neuropeptide lab, Institute of Molecular and Cell Biology, National University of Singapore, Singapore 0511 and #Rudolf Magnus Institute, University of Utrecht, 3521 GD Utrecht, The Netherlands.

Cyclic adenosine 3',5'-monophosphate (cAMP) has been implicated as a mediator of the physiological regulation of vasopressin (VP) gene expression (1). As no appropriate VP synthesising cell lines exist, we have investigated the effect of cAMP on VP gene expression using transfection into two heterologous cell lines (CV1 and P19EC). 5' upstream regions of the bovine, human and rat VP genes were linked to the reporter genes chloramphenicol acetyl transferase and luciferase and the response of reporter enzyme activity to cAMP activation was analysed for each construct following transfection into each cell line. The bovine VP promoter was found to give highest basal expression of reporter enzyme activity and also the greatest response to cAMP (2.5 fold increase). Further analysis of the sequences involved in mediating the response to cAMP was performed using 5' deletion mutants of the bovine VP gene. A cAMP responsive element has been mapped to within 179bp 5' to the start of transcription and DNase I footprint analysis has been performed on this region to identify interactions between DNA binding proteins and VP promoter sequence.

CHARACTERIZATION AND EXPRESSION OF RAT RETINAL cGMP-GATED CHANNEL AND GUANYLATE CYCLASE GENES. Iqbal Ahmad and Colin J. Barnstable. Dept. of Ophthalmology and Visual Science, Yale University School of Medicine, New Haven, CT 06510.

cGMP plays a pivotal role in visual transduction in rod photoreceptors. A light dependent decrease in cGMP concentration leads to closure of cation channel and restoration of cGMP levels by guanylate cyclase in the dark opens the channel. We have cloned and characterized rat rod photoreceptor cGMP-gated channel gene. The deduced aa sequence shows a strong homology to both the bovine rod channel and the rat olfactory channel. In situ hybridization studies using antisense probe have shown that cGMP-channel mRNA to be expressed in rod photoreceptors. In addition, cGMP-channel mRNA are also localized in the inner retina. This has been confirmed by PCR analyses performed on cDNA from microdissected retinal sections. The presence of cGMP-channel mRNA in medullary layers of kidney as revealed by in situ hybridization and PCR analyses confirms our earlier report of a 3.2 kb cGMP-channel mRNA in kidney. We have obtained a partial cDNA clone of guanylate cyclase from retina by PCR amplification using primers flanking a conserved region in carboxyl portion of intracellular domain of brain guanylate cyclase. Results regarding the temporal and tissue specific expression of this gene will be presented. The cGMP gated channel and guanylate cyclase may be members of family distributed throughout the nervous system or even throughout the body. (Supported by EY00785, EY05206 RPB Inc., ARVO/ALCON Fellowship).

102.1

Interactions between sigma ligands and NMDA in rat cortex and hippocampus
 J.H. Connick², J.I. Addae¹, C.D. Nicholson² & T.W. Stone¹, Department of Pharmacology¹, University of Glasgow, Glasgow, G12 8QQ, and Department of Pharmacology, Organon Laboratories Ltd.², Newhouse, U.K.
 Many compounds possess high affinity for the sigma binding site. Much effort has been put into attempts to differentiate agonist from antagonist actions of these compounds. Several lines of evidence have suggested an interaction between the sigma site and the NMDA receptor. We have therefore investigated these interactions by microiontophoresis both *in vitro* using slices of rat hippocampus (500 μ m) and *in vivo* using cells in the neocortex and hippocampus of urethane-anaesthetised animals. A majority of the neurones tested were depressed by ditolylguanidine (DTG) or 3-PPP administered by microiontophoresis. Responses to amino acids (NMDA, quisqualate) and carbachol were also inhibited reversibly on most cells. There was little evidence for any selectivity in these actions of sigma ligands. These inhibitory effects were not prevented by the iontophoresis or intraperitoneal administration of haloperidol (0.1 mg/kg). Spike height remained unaffected during application of sigma ligands, indicating that the depressant effects were not due to local anaesthetic activity.

102.3

ZINC BLOCKS POST- BUT NOT PRESYNAPTIC ACTIONS OF BACLOFEN IN AREA CA1 OF RAT HIPPOCAMPUS.

M. Levitin, N.A. Lambert¹ and N.L. Harrison²
 Committee on Neurobiology, and ²Dept. of Anesthesia, Univ. of Chicago, and ¹Dept. of Neurobiology, NEUCOM, Rootstown, OH.

Zinc is present in high concentration in the hippocampus, especially in the mossy fiber terminals. Zinc application to hippocampal slices elicits giant depolarizing potentials in CA3 pyramidal neurons (GDPs; Xie and Smart, Nature, 349: 521). It was suggested that this action of zinc results from the blockade of pre- and/or postsynaptic GABA_B receptors; we have tested this hypothesis in the CA1 subfield of rat hippocampal slices (where there is little endogenous zinc) using intracellular and extracellular recording. Population excitatory postsynaptic potentials (pEPSPs) were evoked by stimulation of the Schaffer collateral/commissural fibers and monosynaptic inhibitory postsynaptic potentials (mIPSPs) were evoked in the presence of the excitatory amino acid antagonists, 25 μ M 6,7-dinitroquinoxaline 2, 3-dione and 50 μ M D,L-2-amino 5-phosphonovalerate.

Baclofen hyperpolarizes CA1 neurons (postsynaptic action) and depresses pEPSPs and mIPSPs (presynaptic action). All actions of baclofen are antagonized by CGP 35348 or 2-hydroxy-saclofen. In the presence of zinc (0.2mM), GABA_A receptor-mediated GDPs occurred spontaneously or in response to stimulation; pEPSP slope and fast IPSP amplitude were unaltered. Zinc prevented baclofen-induced hyperpolarization but not the depression of pEPSP slope or mIPSP amplitude. These effects of zinc show significant overlap with those of barium, which blocks post- but not presynaptic actions of baclofen (Lambert et al., Soc. Neurosci. Abstr., 16: 1041) and 4-aminopyridine, which induces GDPs (Perreault and Avoli, J. Neurophysiol., 61: 953). We suspect that the actions of zinc are mediated by blockade of potassium channels on pyramidal neurons and interneurons.

EFFECTS OF ADENOSINE ON SYNAPTIC ACTIVITY RECORDED IN THE PERFORANT PATHWAY TERMINAL ZONE OF THE DENTATE GYRUS OF THE RAT AFTER ENTORHINAL LESIONS. L.S. Kahle and C.W. Cotman, Department of Psychobiology, University of California, Irvine, CA 92717.

Adenosine acts at presynaptic receptors to inhibit the release of transmitter in many pathways in the brain. Binding to adenosine receptors has been shown to decrease dramatically in the molecular layer of the dentate gyrus after entorhinal lesions as perforant path fibers degenerate.

We studied the effects of adenosine on evoked synaptic activity recorded in the perforant path terminal zone in the dentate gyrus after partial lesions of the entorhinal cortex. Male rats were given electrolytic lesions in the full extent of the left entorhinal cortex and a vertical strip in the middle third of the right entorhinal cortex. After two weeks recovery period, slices were prepared from the right hippocampus, the remaining perforant path fibers were stimulated, and responses were recorded extracellularly from the middle third of the molecular layer of the dentate gyrus maintained *in vitro*. Additions of adenosine (50 μ M) reduced low frequency (0.05Hz) field potentials in a manner similar in control slices, but by ~55% as compared to ~25% in control slices. Also similar in control slices, additions of adenosine (50 μ M) blocked paired-pulse depression recorded with pairs of stimuli given 40 or 100msec apart. In contrast to control slices, paired-pulse depression was not blocked by adenosine when pairs of stimuli were given 400msec apart.

These results suggest that the physiological effect of adenosine receptor activation is not generally reduced, but may be enhanced two weeks following entorhinal lesions, despite an apparent decrease in adenosine binding. Paired-pulse depression recorded at short interpulse intervals remained sensitive to adenosine modulation, only paired-pulse depression recorded at long interpulse intervals was no longer sensitive to adenosine two weeks after lesions. Reactive synaptogenesis of another fiber system and/or adenosine receptor supersensitivity during the two week recovery period may allow for some recovery of function in the adenosine system.

COMPLEX ALTERATIONS IN THE KINETICS OF INHIBITORY POSTSYNAPTIC CURRENTS BY THREE VOLATILE ANESTHETICS IN CULTURED RAT HIPPOCAMPAL NEURONS. M.V. Jones*, L.A. Homberger, H.K. Radke and N.L. Harrison, Dept. of Anesthesia and Critical Care and *Dept. of Pharmacological and Physiological Sciences, Univ. of Chicago, Chicago, IL 60637

We have studied the effects of the volatile anesthetics (VAs) enflurane (ENF), halothane (HAL), and isoflurane (ISO) on inhibitory postsynaptic currents (IPSCs) in cultured rat hippocampal neurons. Whole-cell recordings were made from pairs of neurons at 25°C, using K gluconate based intracellular solutions, under conditions that prevent polysynaptic events. Single action potentials were evoked in one neuron, and elicited transient outward IPSCs in the 'postsynaptic' neuron voltage-clamped at -40mV. IPSCs were blocked by bicuculline, and reversed between -70 and -80mV. VAs were applied via the perfusion line, and concentrations were determined by gas chromatography of samples withdrawn from the bath during each experiment. Data were filtered at 2kHz and digitized at 4kHz. IPSC decay kinetics were fit using a version of the simplex algorithm. Time constants (τ) are expressed as mean \pm SEM.

IPSC decay phases were usually better fitted by two exponentials (τ_{fast} (75%) = 20 \pm 1 ms; τ_{slow} (25%) = 73 \pm 7 ms) than by one. In the presence of VAs, the relative contribution of the slow component was increased, and the time-course of this component was prolonged. The time-course of the fast component was either not affected, or shortened. In addition, the peak amplitude of the IPSC was reduced, especially at higher concentrations of VA. VAs produced all these effects at concentrations within the clinically effective range (\leq 0.69 mM ENF; \leq 0.2 mM HAL; \leq 0.7 mM ISO). We have shown previously that clinically relevant concentrations of these VAs cause increases in both the duration and amplitude of currents activated by exogenously applied GABA, and we therefore suspect that their depressant effects on the peak amplitude of IPSCs are presynaptic in origin, while the effects on IPSC decay kinetics reflect modulation of postsynaptic GABA_A receptors.

102.4

DOES ETHANOL ENHANCE GABA_A-MEDIATED SYNAPTIC TRANSMISSION IN HIPPOCAMPAL CA1 CELLS?

I. Weiner, L. Zhang, P.L. Carlen, Playfair Neuroscience Unit; Addiction Research Foundation; Toronto Western Hospital and the Dept. of Pharmacology, University of Toronto, Ontario, Canada.

The effects of low concentrations of ethanol on synaptic transmission in rat hippocampal CA1 cells were investigated using the whole cell patch clamp configuration in an *in vitro* brain slice preparation. Experiments were performed at 35°C, using a pH and calcium buffered internal recording solution containing ATP and GTP. Under these conditions, ethanol (20-100 mM) significantly increased the amplitude of orthodromically evoked IPSP's but had minimal effects on EPSP's evoked in the same cells. In subsequent experiments, CNQX + APV (glutamate receptor blockers) were used to suppress EPSP's, leaving pharmacologically-isolated evoked IPSP's. These inhibitory responses were fully blocked by bicuculline and were presumably GABA_A-mediated potentials. In the presence of these blockers, no potentiation of the IPSP's was observed over the same concentration range that enhanced inhibitory potentials under normal conditions.

These initial results suggest that the potentiation of the evoked IPSP's observed under standard conditions may not be due to a direct action of ethanol on GABAergic synaptic transmission. (Supported by MRC and a Connaught Scholarship)

MU OPIOID RECEPTOR-MEDIATED DISINHIBITION IN RAT DENTATE GYRUS. C.W. Xie, R.A. Morrisett and D.V. Lewis, Pediatric Neurology, Duke Univ. Med. Ctr., Durham, NC 27710.

The effect of opioids on synaptic inhibition was examined in rat dentate gyrus. Whole-cell voltage-clamp recordings were undertaken in granule cells of hippocampal slices. In the presence of D-APV (NMDA antagonist, 40 μ M) and DNQX (AMPA antagonist, 20 μ M), monosynaptic inhibitory postsynaptic currents (IPSCs) were evoked in granule cells by stimulating in the outer molecular layer near to recorded granule cells. The IPSC was found to consist of 2 distinct components, an early component sensitive to the GABA_A antagonist bicuculline or picrotoxin, and a late component blocked by GABA_B antagonists. Bath application of the mu agonist PL017 (0.3-3 μ M) significantly reduced the amplitude of the early IPSC by 21-56%, and the late IPSC by 43-81%. This effect could be antagonized by naloxone (1 μ M) or by the selective mu antagonist β -FNA (10 μ M).

These results suggest that the activation of mu receptors suppresses both GABA_A and GABA_B-mediated IPSCs in the dentate, and the resulting disinhibition may be responsible for previously reported opioid enhancement of LTP at the lateral perforant path- dentate granule cell synapses. Supported by NS27488.

REDOX MODULATION OF SYNAPTIC FIELD POTENTIALS IN THE HIPPOCAMPUS. D.L. Tauck and J.E. Tullis*, Laboratory of Neurophysiology, Department of Biology, Santa Clara University, Santa Clara, CA, 95053.

Sulfhydryl redox reagents reversibly modulate currents evoked by N-methyl-D-aspartate (NMDA) [Aizenman, et al., 1989, *Neuron* 2:1257]. Similarly, chemical reduction increases the magnitude of long-term potentiation but has no effect on field potentials evoked by low frequency stimulation [Tauck, et al., 1990, *Brain Res.* 519:129]. The present study shows that the sulfhydryl reducing agent dithiothreitol (DTT) and the oxidizing agent 5,5-dithio-bis-2-nitrobenzoic acid (DTNB) reversibly antagonize each other's effects on the NMDA channel mediated component of synaptic field potentials in area CA1 of the hippocampal slice. To reveal the component of synaptic responses mediated by NMDA channels, field potentials evoked by single stimuli were compared to the responses generated after 5 stimuli at 10 Hz [Poolos et al., 1990, *Brain Res.* 508:7]. The NMDA antagonist D,L-2-amino-5-phosphonovaleic acid (APV), 100 μ M, blocked the potentiation induced by conditioning stimuli. DTT (1 mM) and DTNB (1 mM) were added to the perfusate repeatedly. DTT reversibly potentiated the NMDA component of the synaptic potentials while DTNB had the opposite effect.

THE MONOSYNAPTIC PERFORANT PATH TO CA1 RESPONSE IS MEDIATED BY EXCITATORY GLUTAMINERGIC SYNAPSES. C.M. Colbert and W.B. Levy, Dept. of Neurosurgery, Univ of Virginia, Charlottesville VA, 22908.

When stimulated under experimental conditions, the perforant path (PP) monosynaptically fires CA1 pyramids rather poorly compared to the Schaffer collaterals, although it maps as expected for a distally located excitatory response and is occasionally seen to fire individual cells when recording from s. pyramidal. In light of this fact, and because binding studies imply the presence of modulatory neurotransmitters in s. lacunosum-moleculare, it has been proposed that the PP input to CA1 is predominantly modulatory. Here, to the contrary, we report that 1) it is a glutaminergic system and 2) that it mediates the monosynaptic response in s. moleculare evoked by stimulation of the perforant path.

Transverse slices from 8 rats were maintained in an interface chamber. We stimulated the perforant path (PP) in the subiculum along its ventricular edge, and recorded postsynaptic potentials extracellularly in s. moleculare of CA1. To exclude any confounding DG responses, we gently dissected the DG from CA1 along the obliterated fissure in some slices. DNQX (20 μ M) added to the bath greatly reduced the magnitude of the initial negativity (>1mV) evoked by PP stimulation in s. moleculare leaving a small positivity (<150 μ V). Subsequent application of picrotoxin (45 μ M) resulted in a small negativity (<100 μ V) to PP stimulation. Finally, addition of APV (100 μ M) resulted in no observable extracellular response to PP stimulation. At this same concentration, addition of APV alone did not alter the response.

These findings indicate that glutaminergic receptors of the NMDA and AMPA subtypes mediate the excitatory evoked synaptic potential recorded in s. moleculare, and suggest that this pathway may serve as a primary information-carrying input to the CA1 pyramids. RESPONSES TO EXTRACELLULAR ATP IN CULTURED RAT HIPPOCAMPAL NEURONS. K.Inoue, K.Nakazawa, T.Watano, K.Fujimori* and A.Takanaka*, Div.Pharmacology, Biological Safety Research Center, NIHS, Tokyo158

We have already reported that extracellular ATP stimulates P2-purinoceptors and activates Ca-permeable cation channels causing Ca^{2+} influx which evokes catecholamine release from PC12 cells (Neurosci.Let.106,294,1989; J.Physiol. 428,257, 1990; J.Physiol. 434,647,1991; Br.J.Pharmacol.102,581,1991 & 102, 851,1991). We show here the effects of ATP on cultured rat hippocampal neurons.

ATP (100 μ M) evoked a rapid depolarization and transient inward currents (100 to 300 pA at -60 mV) in most cells (24 of 36 cells tested). The currents were reversed near 0 mV and abolished in the presence of 3 μ M tetrodotoxin (TTX). The transient currents were inhibited not by 2-amino-5-phosphonovaleic acid (AP5, 100 to 200 μ M), an NMDA receptor antagonist, but by CNQX (30 μ M), a non-NMDA receptor antagonist. In a part of cells (6 of 36 cells tested), ATP evoked small (20 to 40 pA at -60mV) and sustained inward currents which resisted TTX. In almost all neurons, ATP induced an increase of intracellular Ca^{2+} which was dependent on extracellular Ca^{2+} and blocked by P2-purinoceptor blocker Suramin. These data suggest that ATP stimulates the hippocampal neurons directly via P2-receptor and trans-synaptically through a mechanism coupling to non-NMDA glutamate receptors.

PUTRESCINE, α -METHYLORNITHINE AND α -DIFLUOROMETHYL ORNITHINE INCREASE NEURONAL EXCITABILITY IN HIPPOCAMPAL SLICES. P.A. Ferchmin*, P. Di Scenna*, M. Morales**, N.A. Lambert*, E.M. Rivera**, V.A. Eterovic* and T. Teyler*, *Dept. Biochem. Univ. Central del Caribe, Bayamon, Puerto Rico 00621 and **Dept. Neurobiol. Northeastern Ohio Univ. Col. Med. Rootstown, OH 44272.

Polyamines regulate neuronal activity. To study this we tested the effect of two inhibitors of ornithine decarboxylase (ODC), α -difluoromethyl ornithine (DFMO) and α -methylornithine (MO), and putrescine (PUT), on extracellular recordings in hippocampal slices. Cumulative dose-response curves were obtained by perfusing the slices with increasing drug concentrations. PUT (100 nM to 2 mM) increased neuronal excitability in a dose dependent manner. DFMO (2.5 to 5 mM) increased neuronal excitability, blocked paired-pulse (PP) inhibition and caused PP facilitation. The effects of DFMO were not mediated by ODC inhibition since they were also observed in the presence of PUT. MO increased neuronal excitability but did not affect PP inhibition. The effects were reversible but became irreversible after longer incubations. Ornithine seemed to be inactive. These results suggest that PUT and inhibitors of ODC have a complex effect on the nervous system.

PHARMACOLOGICAL CHARACTERIZATION OF EXCITATORY SYNAPTIC POTENTIALS IN RAT BASOLATERAL AMYGDALOID NEURONS. P.W. Gean and F.C.Chang*, Dept. of Pharmacology, College of Medicine, National Cheng-Kung University, Taiwan, R.O.C.

The pharmacological properties of synaptic responses in rat basolateral amygdaloid (BLA) neurons were studied using intracellular recording techniques. Three distinct types of synaptic potential were evoked by stimulation of adjacent ventral endopyriform nucleus: (1) a fast excitatory postsynaptic potential (f-EPSP); (2) a late EPSP (l-EPSP) following the f-EPSP; and (3) a multiphasic hyperpolarization following the initial depolarizing potential. Superfusion of 6-cyano-7-nitroquinoxaline-2,3-dione (CNQX), a selective non-N-methyl-D-aspartate (non-NMDA) receptor antagonist, produced a concentration-dependent reduction of the f-EPSP with a shift of the input-output relationship downward and to the right. The ED50 for this effect was around 4 μ M. In the presence of CNQX, however, a small depolarizing potential remained. This residual depolarizing component was markedly enhanced on removing Mg^{++} from the perfusing medium and could subsequently be abolished by DL-2-amino-5-phosphonovaleate (DL-APV, 50 μ M) indicating its mediation via NMDA receptor-coupled ionophore. The l-EPSP was reversibly blocked by DL-APV. These results suggest that the pyriform cortex-amygdala pathway is mediated through excitatory amino acids acting on non-NMDA as well as NMDA receptors located on the BLA neurons.

PRE-ANESTHETIC CONCENTRATIONS OF HALOTHANE ALTER THE CARBACHOL-INDUCED FIELD ACTIVITY OF IN VITRO HIPPOCAMPAL NEURONS. S.H.Roth and J.Kohli*, Dept. of Pharmacology, Faculty of Medicine, University of Calgary, Calgary, Alberta T2N 4N1.

We have demonstrated that carbachol can induce rhythmic field activity in the hippocampal slice preparation that is similar to in vivo hippocampal 'theta' rhythm. This activity has been shown to be associated with memory and sensory processing, features that are relevant to the state of anesthesia. The effects of halothane were examined on the field activity recorded from rat dentate granule neurons in vitro. It was observed that low concentrations, 0.2 to 0.4 vol%, of halothane significantly altered this activity; the MAC (minimum alveolar concentration) for halothane anesthesia in the rat is 1.0 vol%. Using power spectral analysis, it was shown that halothane shifted the relative power of the field activity to lower frequency ranges and also decreased total power. These data demonstrate that this activity is very sensitive to the effects of halothane at pre-anesthetic levels, and may be a useful model to study the state of anesthesia and the mode of action of anaesthetic agents on the central nervous system. AMINO ACID COMPOSITION, IMMUNOREACTIVITY, AND SEQUENCE ANALYSIS OF BOVINE HIPPOCAMPAL METALLOTHIONEIN ISOFORMS. M. Ebadi*, F. Perini**, R.F. Pfeiffer**, V.K. Paliwal**, J.S. Garvey††, and K. Mountjoy*, Depts. of Pharmacol.* & Neurol.†, Univ. Nebr. Coll. Med., Eppley Inst., Univ. Nebr. Med. Ctr.*; Dept. of Int. Med., Yale Univ. Sch. of Med.**; & Dept. Biol., Syracuse Univ.††.

The mammalian hippocampi not only contain high concentration of zinc, but also exhibit subregional variation in this essential element, with concentration being highest in the hilar region and lowest in the fimbria. Studies from our laboratory first described the biochemical properties of metallothionein (MT) in the hippocampus (Paliwal & Ebadi, Exp. Brain Res. 75, 477, 1989) and explored its involvement in the synthesis of GABA (Ebadi, et al. Annals New York Acad. Sci. 189, 1990). The amino acid composition of bovine hippocampal MT isoforms I and II consists of high concentration of cysteine, lysine, serine, alanine, being devoid of aromatic amino acids. Antibodies formed against both the sheep- and rat-hepatic MTs cross reacted completely with the hippocampal MT. These data along with sequence analysis of 60 residues of MT isoform I reveal that the immunologically dominant region of the NH₂-terminal domain (residues 1-29) of hippocampal MT is conserved. The continuous synthesis of MT in the hippocampus of zinc untreated animals, its involvement in the synthesis of GABA and in the NMDA receptor-mediated channel currents are interpreted to indicate that MT isoforms appear to be involved in hippocampal neurotransmission. (Supported by a grant from USPHS ES 03949).

PHARMACOLOGY OF SYNAPTIC TRANSMISSION: NEUROTRANSMITTERS

103.1

EXCITATORY AMINO ACIDS (EAAs) MEDIATE FAST SYNAPTIC TRANSMISSION IN RAT LATERAL PARABRACHIAL NUCLEUS: DIRECT EVIDENCE FROM WHOLE-CELL SLICE PATCH RECORDING. J.A. Zidichouski and J.H. Jhamandas, Dept. of Medicine (Neurology & Div. of Neuroscience), University of Alberta, Edmonton, Alberta, Canada, T6G 2B7.

The brainstem lateral parabrachial nucleus (LPBN) is increasingly viewed as an important site for the integration of autonomic signals. Although glutamate-like immunoreactivity is present, the role of EAAs in neurotransmission in the LPBN is unknown. We have recently reported excitatory effects of exogenously-applied EAAs on LPBN neurons *in vitro*. We therefore directly assessed the role of EAAs in synaptic transmission in the LPBN by testing the effects EAA antagonists on fast excitatory post-synaptic potentials (fEPSPs) and currents (fEPSCs) recorded from pontine slices *in vitro* by means of whole-cell patch recordings. Stimulus-evoked fEPSPs or fEPSCs (fEPs) were recorded from 39 neurons. The fEPSC reversed at ≈ 0 mV and was reduced in low Ca²⁺ and high Mg²⁺ solution. All fEPs had a rapid onset followed by a slow decline to baseline. The non-selective EAA antagonist kynurenic acid (10 μ M) attenuated fEPs. Non-N-methyl-D-aspartate (NMDA) antagonists 6-Cyano-7-nitroquinoxaline-2,3-dione (CNQX; 1-60 μ M, dose-dependent) and 6,7-Dinitroquinoxaline-2,3-dione (DNQX, 10 μ M) markedly reduced fEPs. In addition, a few cells displayed a slow Mg²⁺-dependent component of the fEP that was sensitive to the NMDA-selective antagonist DL-2-amino-5-phosphonovaleate (APV, 10 μ M). These results suggest that endogenously-released EAAs act predominantly at non-NMDA receptors within the LPBN to mediate rapid excitatory synaptic transmission. The role of the NMDA-mediated responses is less clear but may facilitate neurotransmission at this site. These data reflect an increasingly important role for EAAs in central autonomic regulation. DO SOME M-CELL GLYCINE RECEPTORS INTERACT WITH GABA? D.S. Faber and H. Korn, Dept. of Physiology, SUNY, Buffalo, NY, 14214, and INSERM, Institut Pasteur, Paris.

Activation of the Mauthner (M-) cell's recurrent collateral network produces a somatic IPSC considered to be glycinergic and a later, longer lasting dendritic one, for which the transmitter(s) is (are) unknown. Both produce Cl⁻-dependent conductance changes which can be easily quantified. A contribution of GABA to the latter is suggested by reports of GABAergic terminals and receptors, particularly on the main dendrites. In confirmation, we found in current- and voltage-clamp experiments that GABA-A antagonists (Bicuculline, BIC, 40 μ M and Picrotoxin, PTX, 100 μ M) can completely abolish the dendritic IPSC. This response is often followed in current clamp by a late hyperpolarization due to an outward current, which can be produced by iontophoretic applications of GABA but not of glycine. Yet BIC and PTX could also suppress, or completely block, the glycinergic M-cell inhibition, and strychnine ($\leq 1\mu$ M) reduced both somatic and dendritic IPSCs and their associated conductance changes by 80% or more. When one class of antagonist produced only a partial block, the other eliminated the remaining IPSC. These overlapping effects suggested that the blockers and/or a fraction of the receptors linked to Cl⁻ channels are non-specific. This prospect was tested with iontophoresis of glycine; in 5 of 6 preparations superfused with BIC, the somatic glycine response was reduced by 63 \pm 12% (mean \pm SD) but never was blocked completely. In 4 cases this effect was associated with an increase in the apparent Hill coefficient. It can be concluded that, in addition to the glycinergic component of collateral inhibition, there is a dendritic GABAergic IPSC. In addition, at least some "glycinergic" receptors may be sensitive to GABA, particularly in cases where the two transmitters are colocalized in presynaptic terminals.

CHARACTERISTICS OF EXCITATORY AMINO ACID RECEPTORS IN SENSORY SYNAPSE. G. N. Akozov*, S. A. Dambinova*, A. J. Gorodinski*, G. N. Andrianov*, V. Ryzova*, & R. Stiles. I. P. Pavlov Institute of Physiology, Institute of the Human Brain, Academy of Sciences of the USSR, Leningrad, USSR.

The synaptic neurotransmission in electroreceptors ampullae of Lorenzini of scates *Raja clavata* was investigated by means of electrophysiological and ligand-binding techniques. Exogenous glutamate and aspartate and their agonists, N-methyl-D-aspartate, kainate and quisqualate, dose-dependently activated the receptors. This effect as well as the responses to electrical stimulation were suppressed by the selective excitatory amino acids antagonists 2-amino-5-phosphonovaleic acid, glutamic acid diethylester, kinurenat, glutamyl-glycine, piperidine carboxylate, and L-serine-O-phosphate. The synthetic analogue of enkephalin, dalargin, diminished the glutamate-evoked responses. Ligand binding analysis revealed one type of ³H-L-glutamate binding sites with K_D 286 nM and B_{max} 2.1 pmol/mg of protein. These experiments confirm the electrophysiological data about the existence of excitatory amino acid receptors in the synaptic membranes of ampullae of Lorenzini.

103.4

DIFFERENTIAL ACTIONS OF ANABASEINE AND ITS 3-DMAB ADDUCT UPON BRAIN AND NEUROMUSCULAR NICOTINIC RECEPTORS. W. R. Kem, L. Abraham and B. Lin, Department of Pharmacology and Therapeutics, University of Florida College of Medicine, Gainesville, FL 32610.

Anabaseine, (2-(3-pyridyl)-3,4,5,6-tetrahydropyridine), an alkaloid occurring in certain marine worm venoms, possesses pharmacological actions similar to (-)-nicotine. We have investigated the abilities of anabaseine, its dimethylaminobenzaldehyde (DMAB) adduct, and nicotine to displace specific [³H]methylcarbachol binding to rat cerebral cortex synaptosomes, to cause a characteristic nicotinic prostration behavior when injected i.c.v., to relax the contractile response of the innervated rat colon longitudinal muscle to oxotremorine, and to stimulate frog neuromuscular nicotinic receptors. Relative to nicotine, anabaseine is 5 times more potent upon frog neuromuscular nicotinic receptors, but displays about 15-fold lower affinity (K_D 60 nM) for brain receptors, and is 5 times less potent in causing rat prostration. At physiological pH, anabaseine exists in three different forms: unionized cyclic imine, monocationic cyclic iminium and open-chain ammonium-ketone (Zoltevicz, Bloom and Kem 1989). We found that nicotinic activity of anabaseine resides in its cyclic iminium form. Comparing the cyclic iminium form of anabaseine with the nicotine monocationic species, anabaseine is 10 times more active on skeletal muscle, possesses 7.5 times lower affinity for rat brain nicotinic receptors, and is about 2.5 times less potent than nicotine in causing rat prostration. Relative to nicotine, anabaseine displays greater selectivity for muscle nicotinic receptors. DMAB-anabaseine acts as an agonist upon neuronal nicotinic receptors, but lacks nicotinic agonist activity at the neuromuscular junction. Addition of a benzylidene group at the 3 position of anabaseine reduces the coplanarity of the pyridyl and tetrahydropyridyl rings of anabaseine, and this apparently results in a preferential decrease in neuromuscular potency. 103.5

EFFECT OF PMSF IN THE PRESENCE OF TACRINE ON MEMBRANE-BOUND AChE. C.G. Triplett* and K.A. Skau, Div. of Pharmacology/Medicinal Chemistry, College of Pharmacy, University of Cincinnati, Cincinnati, OH 45267-0004.

Tacrine has been shown to be a noncompetitive inhibitor of AChE. Its site of action on AChE has not been fully determined but has been suggested to be at a hydrophobic site. The inhibition of AChE by Tacrine has shown a possible use in treatment of memory loss associated with Alzheimer's Disease (AD) in its early stages and determination of how Tacrine inhibits AChE may provide information in developing better drugs for treatment of AD. We have studied the effect of Tacrine interacting with PMSF in solubilized AChE, membrane-bound AChE, and in vivo. Rat brain was homogenized and soluble forms of AChE removed. The membrane-bound AChE was pretreated with Tacrine followed by PMSF with samples taken at timed intervals, homogenized with Triton and assayed by the method of Ellman. Our results show an acceleration of inhibition by PMSF with pretreatment of Tacrine on solubilized AChE. Fifteen min. pretreatment with Tacrine (10 mg/Kg) in vivo, followed by PMSF (85 mg/Kg) showed no increase or acceleration of inhibition by PMSF. Studies with pretreatment of Tacrine followed by PMSF on membrane-bound AChE showed no acceleration of inhibition by PMSF. These studies show a difference in effect of Tacrine on soluble and membrane-bound AChE. Membrane-bound AChE may have a change in conformation altering the ability of Tacrine to bind to AChE.

24-DITHIOBIURET DECREASES OPEN-TIME OF AChR-CHANNELS IN CLONAL CELLS AND INTACT NEUROMUSCULAR PREPARATIONS. J.M. Spitsbergen and W.D. Atchison, Department of Pharmacology and Toxicology and Neuroscience Program, Michigan State University, E. Lansing, MI 48824

2,4-dithiobiuret (DTB) a thiourea derivative with moderate reducing properties, causes a delayed onset neuromuscular weakness when given chronically to rats. Previous two microelectrode voltage-clamp experiments demonstrated that the decay time constant (τ) for miniature end-plate currents (MEPCs), recorded in muscles taken from rats exhibiting muscle weakness following treatment with DTB, was decreased compared to τ_{MEPC} for control muscles. Agents known to decrease channel open-time for the nicotinic AChR-channel also cause a decrease in MEPC decay. Thus, the purpose of the present study was to determine whether DTB exposure alters the open-time for nicotinic AChR-channels present in muscle. Effects of bath application of DTB on single-channel currents were examined using patch voltage-clamp techniques in a clonal cell line and fluctuation analysis in intact neuromuscular preparations. Exposure of cultured G8 myotubes to 1 μ M DTB caused a decrease in mean channel open-time, measured at a holding potential of -100 mV, from 1.82 ± 0.28 ms in control cells to 0.98 ± 0.28 ms in treated cells. Mean channel open-time, measured at -50 mV, was also decreased from 12.4 ± 5.2 ms in hemidiaphragms taken from control rats to 3.93 ± 1.06 ms following exposure to 1 μ M DTB in the bathing medium. Thus, exposure, of both cultured myotubes and intact hemidiaphragm preparations, to DTB appears to decrease mean channel open-time of nicotinic AChR-channels. This DTB induced decrease in channel open-time may underlie the decrease in τ_{MEPC} observed in muscles taken from rats treated with DTB.

DOPAMINE-INDUCED GANGLIONIC BLOCKADE: ANTAGONISM BY DRUGS THAT INCREASE cAMP. C. A. Davis* and K. A. Alkadhi, Department of Pharmacology, University of Houston, Houston, TX 77204-5515.

Dopamine acting through DA₁ receptors is known to increase cAMP levels in a variety of tissues. However, measurement in sympathetic ganglia showed either a decrease or no change in cAMP levels on treatment with dopamine or fenoldopam both of which inhibited postganglionic spike (Alkadhi et al. *JPET* 238:547, 1986; Sabouni et al. *JPET* 240:93, 1987). The involvement of cAMP in the inhibition of the ganglionic spike was investigated in the isolated superior cervical ganglion (SCG) of rat. Suction electrodes were used to stimulate preganglionic nerve and record evoked compound postganglionic spike. Dopamine (1-566 μ M) produced concentration-dependent inhibition of the spike. This effect was readily reversed after 30 min of wash. When the ganglia were pretreated with isoproterenol (1 μ M) the dopamine-induced inhibition was markedly attenuated and there was a dextral shift of the dopamine concentration-inhibition curve. Similar results were obtained on pretreatment of ganglia with the adenylate cyclase activator arginine-vasopressin (10 nM). Isoproterenol or vasopressin alone had no significant effect on the spike (1 hr incubation). Preliminary results with adenylate cyclase inhibitors (e.g. SQ 22,536) and phosphodiesterase activators (e.g. imidazole) suggest that these compounds could enhance the inhibitory action of dopamine and antagonize the effects of isoproterenol or vasopressin on the dopamine-induced inhibition of the spike. The results indirectly suggest that the inhibitory action of dopamine may be due to a decrease in cAMP level.

MUSCARINIC RECEPTOR-MEDIATED EVENTS IN OPOSSUM LUMBAR PARAVERTEBRAL GANGLIA. W.H. Percy, Division of Gastroenterology, Winthrop-University Hospital, Mineola, New York 11501 & SUNY at Stony Brook.

In rabbit lumbar paravertebral ganglia a percentage of cells exhibit a slow excitatory postsynaptic potential (s-EPSP) mediated via muscarinic m1 receptors. This phenomenon is related to the number of preganglionic fibers impinging on the cell (Percy & Krier, *JANS* 18: 195-205, 1987). The aim of the present study was to investigate whether a similar phenomenon is found in the paravertebral ganglia of the North American opossum. The lumbar sympathetic chains from above the L3 ganglion to below the L5 ganglion with attached inferior lumbar splanchnic nerves and rami communicantes were removed *en bloc* from opossums euthanized with pentobarbital (75mg/kg i.p.). Intracellular recordings were made from the largest ganglion in the L4 region. All fast excitatory postsynaptic potentials and action potentials were hexamethonium-sensitive. No cells of 9 tested exhibited either a s-EPSP or s-IPSP in response to stimulation of preganglionic fibers at frequencies ranging from 0.5-20Hz. In 7 of 7 cells McNeil-A-343 (10^{-4} - 10^{-3} M) caused no change in transmembrane potential or membrane input conductance but fast excitatory synaptic events were reversibly abolished. This was blocked by an equimolar concentration of atropine but not pirenzepine. In a further 4 of 4 cells oxotremorine (10^{-4} M) caused a membrane depolarization and continuous discharge of action potentials. These data suggest that preganglionic fibers in the paravertebral chains possess inhibitory presynaptic muscarinic receptors whereas excitatory muscarinic receptors are located postsynaptically. The lack of a muscarinic s-EPSP may reflect a sparse preganglionic cholinergic input to these cells.

SIGMA LIGANDS MODIFY CHOLINERGIC AGONIST-INDUCED Ca²⁺-ACTIVATED K⁺-EFFLUX IN DIFFERENTIATED PC-12 CELLS. H.Yamamoto¹, T.Yamamoto¹, N.Saqui¹, T.Hori¹, T.Moroi¹, T.Yamaguchi², ¹Dept. of Psychopharmacology, Psychiatric Res. Inst. of Tokyo, Tokyo156, ²Medical Res.Lab. I, Central Res. Lab., Yamanouchi Pharmaceutical Co., Ibaraki 305, Japan.

PC-12 cells has been shown to express sigma-2 site as well as many properties of neurons, including neurite formation by NGF. Using differentiated PC-12 cells, the interaction between cholinergic receptors and sigma compounds was investigated. The cells treated with NGF(50ng/ml) were washed twice, preincubated for 20min at 37°C in the modified Locke medium(K⁺ replaced by Na⁺), finally incubated with drugs for 20min. The amount of K⁺-efflux was measured using K⁺-selective microelectrode. The response to carbachol application shows a dose-dependent increase of K⁺-efflux. (Maximal response at 10^{-4} M- 10^{-3} M conc. of carbachol; 2.6-fold of control). The stimulated K⁺-efflux was markedly inhibited by phencyclidine(PCP), and moderately antagonized with 1,3-di-o-tolylguanidine(DTG) or haloperidol (35.0, 48.8 or 50.1 % of control, respectively). Antidepressants (desipramine or iprindole) also inhibited the carbachol-induced K⁺-efflux (43.2 or 71.8% at the 10^{-4} M conc.) These results indicate that sigma-2 site modulates cholinergic receptor-coupled K⁺-efflux in the differentiated PC-12 cells.

103.10

DOPAMINE (DA) RELEASE IN INTERMEDIATE PITUITARY: REAL TIME MEASUREMENTS & PHARMACOLOGY. P.J.WILLIAMS, T.V.DUNWIDDIE, G.A.GERHARDT, Depts Pharmacology & Psychiatry, Univ Colorado Health Sciences, 4200 E 9th Ave, Denver, Colorado, U.S.A. 80220

We investigated the synaptic release of DA in intact intermediate pituitary (IL) maintained *in vitro*. This system is ideal for the study of DA neurotransmission since it contains only a single type of DA receptor (D2), & consists of only the axon terminals of the DA neurons & postsynaptic cells (melanotrophs). Electrochemical measurements were made using single 30 μ carbon fiber electrodes coated with Nafion to enhance their sensitivity & selectivity to DA. When rats were pretreated with pargyline (100mg/kg) DA release was routinely detected in response to electrical stimulation of the pituitary stalk (0.5ms, 10Hz, 10V, 30 sec). In control conditions peak DA concentration following stalk stimulation was between 100 & 300nM. Release was abolished by the Ca²⁺-channel blocker Cd²⁺ (1 μ M) & by 100nM tetrodotoxin. Release was modulated by presynaptic autoreceptors since the D2 antagonist sulpiride (1 μ M) increased DA release by 97 \pm 30% (mean \pm S.D.). Quinpirole (10 μ M), a DA D2 agonist, however, had no effect on DA release, so released DA may be already maximally inhibiting these receptors. DA reuptake inhibitors markedly increased peak DA concentrations (20 μ M Nomifensine - 100 \pm 12%, 20 μ M Mazindol - 108 \pm 20%, 20 μ M Cocaine - 70 \pm 22%) thus confirming the importance of reuptake in removing released DA. The IL provides an excellent system for real time study of synaptic DA release. Supported by USPHS Grants NS09199 & DA02702 & Veterans Administration

RAT VENTRAL PALLIDAL NEURONS RECORDED *IN VITRO*: MEMBRANE PROPERTIES AND RESPONSES TO DOPAMINE. R.J. Maslowski, T.C. Napier and S.G. Beck. Department of Pharmacology, Loyola University Chicago, Stritch School of Medicine, Maywood, Illinois 60153.

The ventral pallidum (VP) is comprised of a heterogeneous cell population which includes cholinergic neurons. Extracellularly recorded VP neurons demonstrate both rate increases and decreases to microiontophoretic applications of dopamine¹. The present study was conducted to examine membrane properties of rat VP slices recorded *in vitro* and to determine the effects of bath-applied dopamine (100µM). In contrast to the adjacent striatal region, viable VP neurons were obtained only after utilizing tissue preparation methods of Aghajanian and Rasmussen². VP neurons (N=18) were segregated into three categories based on the post-spike afterpotentials: fast (39%) or slow (50%) hyperpolarizing (AHPs), or depolarizing after-potentials (11%). Neurons with slow AHPs were similar to those described as AChE-positive by Griffith and Matthews³. All three groups had a comparable resting membrane potential (68 ± 1.4 mV) and input resistance (146 ± 9.5 MΩ). Eleven neurons tested with dopamine demonstrated an average depolarization of $+6 \pm 1.5$ mV. In addition, dopamine often augmented spontaneous synaptic activity (9 of 11 cells). The response to the agonist did not distinguish among cell types. Thus, dopamine-induced increases in firing rate that are observed for these neurons with *in vivo* extracellular recording techniques may be attributed to the above *in vitro* effects. Supported by MH45180 to TCN; MH41917 and KO2-MH00880 to SGB.

α₂-ADRENOCEPTOR AGONISTS (AAA) MODULATE GANGLIONIC TRANSMISSION IN THE PERIPHERAL SYMPATHETIC NERVOUS SYSTEM (SNS). H.K. Schedewic*, N. Boban* and Z.J. Bosnjak. Dept. of Anesthesiology, The Medical College of Wisconsin, Milwaukee, Wisconsin 53226.

The inhibitory effects of AAA on central sympathetic outflow at the spinal and cranial CNS level have been well established. However, AAA effects on the peripheral SNS remain to be elucidated. Therefore, we have studied the effect of dexmedetomidine (D), a selective AAA, and its antagonist yohimbine (Y) on synaptic transmission in the canine stellate ganglion (SG) *in vitro*.

Ten SG were desheathed and superfused with modified Krebs' solution (Ca⁺⁺ 0.85 mM), equilibrated with 97% O₂ - 3% CO₂ (37°C, pH 7.4). The preganglionic T₃ ramus and the postganglionic ventral ansa subclaviae were used for stimulating and recording purposes, respectively. The percent compound action potential (CAP) change from control was measured following 15-min periods of SG superfusion with log step increments of D 5.5×10^{-9} to 10^{-6} M or equimolar concentrations of Y. Hexamethonium (10^{-4} M) was used at the conclusion of the experiment to verify the synaptic nature of CAP. D caused a dose-dependent CAP depression (fig) which was

specifically and consistently reversed by Y. These findings suggest that AAA have potent inhibitory effects on the peripheral SNS in addition to their well known central effects. Peripheral AAA action may have important physiological and potential therapeutic implications for the control mechanism that regulates cardiopulmonary and nociceptive function.

SYNAPTIC TRANSMISSION

104.1

L-TYPE VOLTAGE SENSITIVE CALCIUM CHANNELS MEDIATE SYNAPTIC ACTIVATION OF IMMEDIATE EARLY GENES. T.H. Murphy, P.F. Worley, and J.M. Baraban. Dept. of Neuroscience, Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205.

Although L-type voltage sensitive Ca⁺⁺ channels (VSCC) have been well characterized, their role in neuronal function remains unclear. Recent studies demonstrating localization of these channels to the soma suggest they may be involved in coupling synaptic activity to transcriptional regulation. Previously, we found that spontaneous synaptic activity present in cultured cortical neurons leads to the expression of immediate early genes (IEG), as TTX and Glu receptor antagonists reduce basal expression. We now report that treatment of these cultures with L-type VSCC blockers PN 200-110 or nitrendipine decrease basal c-Fos immunostaining and *zif268*, *jun-B*, and *fos-B*, mRNA. Conversely, (-)BayK-8644, a VSCC agonist, augments basal expression. These agents do not appear to be acting in a non-specific fashion as they do not reduce gene induction by phorbol esters. Furthermore, these agents do not suppress synaptic Ca⁺⁺ transients, although they reduce kainate induced rises in intracellular Ca⁺⁺ and c-Fos expression. Measurement of Ca⁺⁺ during synaptic stimulation indicates contributions of both NMDA and kainate receptors. Our findings indicate that even though L-type VSCCs appear to contribute only a small fraction of synaptically-induced Ca⁺⁺ transients, they play a key role in coupling synaptic activity to regulation of gene expression.

NOREPINEPHRINE INHIBITS MITRAL CELL EVOKED EPSPS IN MAMMALIAN OLFACTORY BULB GRANULE CELLS IN CULTURE. Paul O. Trombley & Gordon M. Shepherd. Section of Neurobiology, Yale University School of Medicine, 333 Cedar Street, New Haven, CT 06510.

We are interested in plastic changes in the olfactory bulb that may underlie olfactory learning. Recent evidence suggests that alterations in the efficacy of excitatory and inhibitory synapses between mitral (M) and granule (GR) cells may be the bases of these changes (Brennan et al. 1990). Norepinephrine (NE) has been implicated in olfactory learning, and although the mechanism is not well understood it has been proposed that NE may act by reducing GR cell inhibition of M cells (Jahr & Nicoll, 1982). We examined the action of NE on synaptic potentials between pairs of monosynaptically coupled M and GR cells to reveal modulatory effects of NE that might be related to synaptic plasticity.

Dissociated olfactory bulb neurons from neonatal rat pups were grown in primary culture. Using simultaneous whole-cell recording from monosynaptically coupled M-GR cell pairs, an EPSP mediated by glutamate was evoked in the GR cell by intracellular stimulation of the M cell. These EPSPs invariably consisted of both CNQX and AP5 sensitive components. Flow pipe application of 30 µM NE reduced these EPSPs to 52 ± 14 % of control in 6 out of 6 pairs. Under voltage clamp, however, 30 µM NE had no effect on glutamate evoked currents in 5 out of 5 GR cells. In both M and GR cells NE did not affect currents evoked by voltage ramps from -60 to +40 mV nor currents evoked by discrete 10 mV steps between -60 and +40 mV.

Concurrent results (Trombley & Westbrook, in preparation) demonstrate that NE acts presynaptically to inhibit high threshold calcium currents. These results suggest that NE may disinhibit M cells not by a direct action on GR cells but rather by reducing M cell excitation of GR cells. This effect would reduce GR cell inhibition of M cells at reciprocal dendrodendritic synapses. This suggests a mechanism in which arousal, mediated through NE, could affect synaptic plasticity associated with learning. Supported by NIH 5-T32-NS07224-07 to PQT and NIH DC-00086 to GMS.

104.2

EXCITATORY POSTSYNAPTIC POTENTIALS EVOKED BY VENTRAL ROOT STIMULATION IN NEONATE RAT SYMPATHETIC PREGANGLIONIC NEURONS IN VITRO. E. Shen, S. Y. Wu*, C. Ren*, S. L. Dun* and N. J. Dun. Dept. of Anatomy, Medical College of Ohio, Toledo, OH 43699.

Intracellular recordings were made from sympathetic preganglionic neurons (SPNs) in neonate rat transverse spinal cord slices. Stimulation of ventral rootlets evoked in the majority of SPNs a depolarizing response and in a few SPNs a hyperpolarizing response. We have shown that the hyperpolarization was a di-synaptically mediated inhibitory postsynaptic potential (IPSP). The depolarizing response was eliminated in a low Ca (0.25 mM) solution and was reduced by the excitatory amino acid receptor antagonist CNQX, indicating it was an excitatory postsynaptic potential (EPSP). The amplitude of EPSPs increased with membrane hyperpolarization; the extrapolated reversal potential was between -10 to 0 mV; the responses were not significantly increased in Mg²⁺-free solution. The estimated conduction velocity of the fibers transmitting the EPSPs was about 1 m/s. Dense fiber tracts and labelled cells were observed in the lateral horn and ventral horn following *in vivo* injection of Dil into the dorsal root ganglia. Our results indicate that SPNs receive glutamergic inputs from ventral root afferents which may have their origin in the dorsal root ganglia. (Supported by NS18710).

Spatial and Temporal Studies of Electrochemical Oscillations of The Brain Extracellular Space. C. C. Turbes. Creighton University School of Medicine, Omaha, Nebraska 68178

In these studies, recordings from the brain extracellular space of cats are considered. Macro and microelectrodes are utilized. Special studies using visual, auditory stimuli and certain drugs are done. Drug studies involved amphetamine, ketamine and lidocaine with recordings from cerebral cortex, hippocampus, amygdala and thalamus. Coherence power and partial coherence spectra of wave field potentials and unit potentials are investigated.

There are several reasonable mechanisms whereby natural ac electrical oscillations arise in cells from cooperative dipolar oscillations fed by metabolic energy. This mechanism accounts for oscillations at very high frequencies in the multigigahertz range. We are interested in electrical fields present in the extracellular space of the brain. Our interest is in the relationship of the intrinsic electrochemical oscillations in the pericellular space of the brain as they change during induced chemical and electrical changes. We are interested in the frequency and coherence of these electrical fields. In these studies microelectrode recordings are compared with macroelectrode recordings in the extracellular space.

G_s AND GAP-43 ARE CONCENTRATED WITHIN AXON TERMINALS OF ADULT RAT VISUAL CORTEX THAT FORM ASYMMETRIC SYNAPSES. C. Aoki, L.I. Benowitz, K. Wu & P. Siekevitz, Center for Neural Science, New York Univ., NYC, 10003.

Visual cortex (area 17) of aldehyde-fixed adult rat brains were immunolabeled either for GAP-43 or for G_s, a GTP-binding protein, by the pre-embed avidin-biotin peroxidase complex method using previously characterized antisera (Benowitz et al., J. Neurosci. 8:339; Worley et al., PNAS 83: 4561). Light microscopic labeling for GAP-43 and G_s revealed most neuronal perikarya, including pyramidal cells, as unlabeled profiles within a rather homogeneously immunoreactive grey matter. In addition, intense immunoreactivity for G_s was evident within perikarya and dendrites of a few bipolar neurons. Electron microscopy showed that the antigenic sites for GAP-43 were almost exclusively within axons and terminals forming asymmetric synapses, many of which were perforated. G_s-immunoreactivity also occurred within axons and terminals forming asymmetric perforated synapses. These synapses resembled those associated with glutamate-immunoreactive terminals in previous studies. The results support the following ideas: (1) both G_s and GAP-43 are localized to axon terminals of adult cortex forming excitatory synapses; (2) these are sites where GAP-43 may stimulate GTP binding to G_s (Strittmatter et al., Nature 344: 836), perhaps in relation to the modulation of glutamatergic transmission. Future work are needed to determine whether single axons contain both G_s and GAP-43. (Supported by EY08055 to CA; NS25830 to LB)

ACETYLCHOLINE RECEPTORS: NEURONAL NICOTINIC I

105.1

PHARMACOLOGICAL PROPERTIES OF THE HOMO-OLIGOMERIC NEURONAL NICOTINIC ACETYLCHOLINE RECEPTOR $\alpha 7$. M. Ballivet, S. Bertrand* and D. Bertrand Dpt of Physiology Medical School, 1, Rue Michel Servet, 1211 Geneva 4, Switzerland.

Two laboratories have recently isolated from chicken brain a cDNA encoding an α -bungarotoxin (α -Bgt) sensitive protein ($\alpha 7$). Functional neuronal nicotinic acetylcholine receptors (nAChR) can be expressed by nuclear injection of this cDNA alone, indicating that the protein forms homo-oligomeric nAChR. Physiological and pharmacological properties of $\alpha 7$ differ from those of other known neuronal nAChRs. While ACh sensitivity of $\alpha 7$ is rather low ($EC_{50} = 115 \mu M$), its sensitivity to nicotine and cytosine is about ten fold higher. Curare (TC) is a potent antagonist of $\alpha 7$, but the block induced by TC is not competitive whereas TC is a competitive blocker of the major brain nAChR $\alpha 4/\alpha 1$. Receptors formed by $\alpha 7$ resemble those of the neuromuscular junction in their sensitivity to α -Bgt and insensitivity to hexamethonium. However, the larger methonium salt decamethonium decreases the amplitude of ACh-evoked currents, suggesting that channels formed by $\alpha 7$ present a slightly larger apparent pore diameter than that of other neuronal nAChRs.

105.3

DISTRIBUTION OF ALPHA 7 NEURONAL NICOTINIC RECEPTOR mRNA IN THE RAT CNS. D.S. Johnson, H.M. Strossner-Johnson, J. Boulter, D.G. Amaral, and S. Heinemann. The Salk Institute For Biological Sciences, La Jolla, CA 92037; Department of Neuroscience, UCSD, San Diego, CA 92122.

Alpha-bungarotoxin has proven a useful tool in the elucidation of the structure, distribution, and function of the nicotinic acetylcholine receptor at the neuromuscular junction. Specific binding sites for α -bungarotoxin also exist within the CNS. The recently cloned chicken nicotinic acetylcholine receptor $\alpha 7$ subunit has been shown to code for a functional receptor which is blocked by α -bungarotoxin. We have used a full length cRNA probe to the rat $\alpha 7$ subunit gene to carry out *in situ* hybridization studies in rat brain sections. The distribution of $\alpha 7$ RNA in rat CNS correlates strongly with total α -bungarotoxin binding, suggesting that this subunit accounts for most of the toxin binding sites. Many limbic areas are labeled, including: hippocampus (CA3 > CA2 > CA1); dentate gyrus; medial, cortical, and basal amygdaloid nuclei; and entorhinal, pyriform, and cingulate cortices. All layers in cerebral cortex are labeled, with the heaviest label occurring in the deepest layers. Many hypothalamic nuclei are intensely labeled, including: supra-, medial, and lateral mammillary nuclei; lateral and anterior hypothalamic areas; supraoptic, arcuate, and ventromedial hypothalamic nuclei. The superior colliculus is labeled, as are many reticular and cranial nerve nuclei. One notable exception to the correlation between toxin binding and the distribution of $\alpha 7$ message is the absence of signal in the suprachiasmatic nuclei which exhibit high toxin binding.

105.2

SINGLE CHANNEL CURRENTS THROUGH α -BUNGAROTOXIN-SENSITIVE NEURONAL NICOTINIC ACETYLCHOLINE RECEPTORS. N. Hussy and D. Bertrand. Dpt de Physiologie, CMU, Univ. de Genève, 9 Av. de Champel, 1211 Geneva 4, Switzerland.

A gene encoding a neuronal nicotinic acetylcholine receptor α subunit ($\alpha 7$) sensitive to the snake toxin α -bungarotoxin has been recently cloned from chicken brain. Expression of this single gene into *Xenopus* oocytes yields functional nicotinic receptors indicating that $\alpha 7$ can form homo-oligomeric channels. We investigated the single channel properties of $\alpha 7$ receptors reconstituted into oocytes. *Xenopus* oocytes were injected intranuclearly with a vector containing the $\alpha 7$ cDNA under the control of a SV40 promoter. Oocytes presenting large responses to acetylcholine ($> 1 \mu A$) two days after injection were selected for patch-clamp recordings, in the cell-attached configuration. Receptors appeared highly clustered in the oocyte membrane, and presented a single slope conductance of 45 pS in physiological solution in the presence of $10 \mu M$ ACh. These channels were never observed in the absence of ACh in the pipet. No activity was observed at depolarized potentials, suggesting that the strong rectification exhibited by whole-cell recordings of $\alpha 7$ receptors may be due to a decreased channel open probability. The kinetics of the channel openings are currently investigated.

105.4

IMMUNOHISTOCHEMICAL STUDIES OF THE DISTRIBUTION OF ALPHA-BUNGAROTOXIN BINDING PROTEINS AND NICOTINIC RECEPTORS IN THE CHICK VISUAL SYSTEM. L.R.G. Britto, K.T. Keyser, H.J. Karten, R. Schoepfer*, P.J. Whiting*, W.G. Conroy*, & J.M. Lindstrom*. Dept. Neurosci., Univ. California, San Diego, La Jolla CA 92093 and *Inst. Neurol. Sci., Univ. Pennsylvania, Philadelphia PA 19104.

Two subtypes of brain alpha-bungarotoxin binding proteins (BGTBPs) have been recently identified in the chick brain (Schoepfer et al., *Neuron* 5:35-48, 1990). One BGTBP subtype contains only $\alpha 1$ subunits, whereas the other includes both $\alpha 1$ and $\alpha 2$ subunits. We have used monoclonal antibodies to study the localization of both $\alpha 1$ and $\alpha 2$ BGTBP subunits in the chick visual system. Their distribution was compared to that of nicotinic receptor-like immunoreactivity (nAChR-LI). All retinorecipient areas of the chick brain were observed to contain nAChR-LI, $\alpha 1$ BGTBP-LI and $\alpha 2$ BGTBP-LI. In some structures, both the somata and the neuropil staining for all three kinds of immunoreactivity was similar (e.g., ventral lateral geniculate nucleus, pretectal nuclei and the intergeniculate leaflet). In some other structures, however, we observed marked differences in the distribution of labeled somata and the intensity of neuropil staining with the different antibodies. For example, neuropil staining within the suprachiasmatic nucleus was more intense for nAChR-LI than for $\alpha 1$ BGTBP-LI and $\alpha 2$ BGTBP-LI, whereas staining for $\alpha 2$ BGTBP-LI was by far most evident in the visual nuclei of the dorsal thalamus. In the isthmio-optic nucleus, the origin of the centrifugal system, no staining was observed for nAChR-LI or $\alpha 2$ BGTBP-LI, but there was intense labeling for $\alpha 1$ BGTBP-LI. Retinal lesions produced a marked reduction of nAChR-LI neuropil staining in retinorecipient structures. Neuropil staining for $\alpha 1$ BGTBP-LI and $\alpha 2$ BGTBP-LI was also reduced after retinal lesions, but to a lesser degree. These results reveal clear differences in the localization of nAChR-LI, $\alpha 1$ BGTBP-LI and $\alpha 2$ BGTBP-LI in the chick brain and suggest that both nAChRs and BGTBPs are transported from the retina to the brain.

Supported by EY07845 (KTK), EY06890 and NS24560 (HJK), Contract USP/BID and FAPESP (LRGB) and grants from NIH, MDA & CTR (JML).

105.5

ASSEMBLY AND FUNCTION OF α -BUNGAROTOXIN BINDING PROTEIN SUBUNITS EXPRESSED IN *XENOPUS* OOCYTES.

R. Anand, M. White and J. Lindstrom. Institute of Neurological Sciences and Department of Pharmacology, School of Medicine, University of Pennsylvania, Philadelphia PA 19104.

cDNA clones for two subunits of the chick brain α -bungarotoxin binding proteins (α BgtBP $\alpha 1$ and $\alpha 2$) have been recently identified (Schoepfer et al., *Neuron* 5:35-48, 1990). There are two subtypes: >75% of all α BgtBPs contain the $\alpha 1$ subunit, while ~15% contain both the $\alpha 1$ and $\alpha 2$ subunits, plus an undefined complement of structural subunits. Binding studies with synthetic peptides reveal that both $\alpha 1$ and $\alpha 2$ bind 125 I α Bgt (McLane et al., 1991, *JBC*, in press). We find major differences in the ability of these subunits to assemble and function in the *Xenopus* oocytes. We confirm that the $\alpha 1$ subunit when expressed alone in oocytes forms acetylcholine-gated cation channels (Couturier et al., *Neuron* 5:847-856, 1990), but we find that the $\alpha 2$ subunit fails to do so. The expressed $\alpha 1$ subunits produce currents in response to bath application of acetylcholine (EC_{50} =90 μ M) which can be blocked by 10nM α Bgt. The $\alpha 2$ subunit expressed alone gives no response to acetylcholine. The $\alpha 1$ subunit expressed by itself and in conjunction with the $\alpha 2$ is efficiently transported to the oocyte outer membrane where it binds 125 I α Bgt with high affinity, whereas the $\alpha 2$ subunit by itself fails to do so. In addition, Triton X-100 solubilized α BgtBP formed from $\alpha 1$ subunits alone or from $\alpha 1$ co-expressed with $\alpha 2$, but not by $\alpha 2$ alone, cosediment on sucrose gradients with solubilized chicken brain α BgtBPs, and thus appear to form homo- or hetero-oligomers of the same size as native α BgtBP.

105.7

SYNTHESIS, PURIFICATION, AND CHARACTERIZATION OF A PUTATIVE ENDOGENOUS LIGAND FOR THE α -BUNGAROTOXIN BINDING PROTEIN: THYMOPOIETIN. D.D. Smith*, J. Petzel*, and B.J. Morley. Dept. of Biomedical Sciences, Creighton University Medical School Omaha, NE 68178, and Research Division, Boys Town National Research Hospital, Omaha, NE 68131.

Several laboratories have reported that thymopietin (TPO), a polypeptide isolated from thymus, will alter muscle function, block α -bungarotoxin binding to neural and muscle-like cells in culture, and induce neurite formation in PC12 cells. TPO-like immunoreactivity is found in mammalian brain, and it has been hypothesized that TPO may be the endogenous ligand for the brain α -bungarotoxin binding protein.

Thymopietin II was made using Merrifield's solid phase polypeptide synthesis methodology. Butyloxycarbonyl-amino acid derivatives were double coupled as their hydroxybenzotriazole-active esters to the phenylacetamidomethyl polystyrene resin in the solvent, N-methylpyrrolidone. Unreacted amine groups were capped with acetic anhydride. The peptide was cleaved from the resin employing the low-high trifluoromethanesulphonic acid method and purified by gel filtration, ion-exchange and RP-HPLC techniques. Correct amino acid compositions and mass determinations were obtained. Further confirmation of the peptide's structure was gained after digestion of the peptide with *S. aureus*, V8 and identification of the resulting fragments by amino acid analysis and mass spectrometry.

The biological activity of synthetic thymopietin and peptide fragments was tested using bioassays and *in vitro* receptor binding assays.

This research was supported in part by DA06482 to B.J.M.

REGULATION OF NEURONAL NICOTINIC ACH RECEPTOR GENE EXPRESSION. M. Hu¹, N.L. Whiting¹, J. Boulter², E. Deneris², R. Duvoisin², S. Heinemann², and P.D. Gardner¹.

¹Department of Biochemistry, Dartmouth Medical School, Hanover, NH 03756 and ²Molecular Neurobiology Laboratory, The Salk Institute, San Diego, CA 92138.

In situ hybridization studies utilizing recombinant DNA probes for neuronal nACh receptor subunit genes indicate differences in the cell-specific patterns of expression of the various members of this gene family. As part of a long term goal to understand the molecular events controlling nACh receptor expression, we have begun to identify the regulatory mechanisms involved in the cell-specific expression of these genes. Our initial studies have focussed on the gene encoding the $\beta 4$ subunit of neuronal nACh receptors. The $\beta 4$ subunit gene exhibits a very restricted pattern of expression in the nervous system. It is likely that this limited expression is due, at least in part, to transcriptional regulation of the $\beta 4$ subunit gene. Consequently, we have begun to identify transcriptional regulatory elements in the $\beta 4$ subunit gene. Initial studies indicated that 2.3 kb of 5' flanking DNA of the $\beta 4$ subunit gene are sufficient to confer cell-type-specific expression of a reporter gene (luciferase) in transfected mammalian cells. Deletional analysis of this DNA indicated that a 391-bp region of the $\beta 4$ subunit gene contains the sequence information necessary for the cell-type-specific expression. In addition, the deletional analysis revealed the existence of both positive and negative transcriptional regulatory elements in the 5' flanking DNA.

THYMOPOIETIN INTERACTS WITH AND REGULATES α -BUNGAROTOXIN BINDING SITES IN HIPPOCAMPAL CELLS IN CULTURE. R. Afar, G. Goldstein and M. Quik. Dept. Pharmacol., McGill U., Montreal, Can. and Immunobiol. Res. Inst., NJ, USA.

Previous studies in our lab have shown that the thymic polypeptide thymopietin (TPO) bound in a specific manner to the α -BGT binding site in brain, but did not interact with the high affinity nicotinic receptors. The present studies were done to investigate the regulation of the former sites by TPO in hippocampal neurons in culture, which provide a rich source of α -BGT binding sites. Hippocampal neurons in culture were obtained from day 18-19 old rat embryonic hippocampi. Inhibition curves with increasing concentrations of TPO showed that TPO inhibited [125 I] α -BGT binding with an IC_{50} of 19 nM, compared to an IC_{50} of 550 nM for nicotine. The effect of TPO did not appear to be readily reversible, even though binding of TPO to whole brain homogenates is reversible within 30 minutes. In addition, long term exposure to TPO affected the α -BGT binding sites; a three day exposure to TPO resulted in a 73% decrease in B_{max} with no change in K_d . TPO can therefore interact with and regulate α -BGT binding sites in rat brain implying that this polypeptide may act as a ligand for this receptor.

IDENTIFICATION OF CIS-ACTING ELEMENTS REGULATING THE $\alpha 3$ AND $\alpha 7$ NEURONAL NICOTINIC AChR GENES. L.Matter-Sadzinski*, M.C.Hernandez*, S.Couturier*, M.Ballivet and J.-M.Matter. Département de Biochimie, Université de Genève, 30, quai Ernest-Ansermet, 1211 Genève 4, Switzerland.

Ten neuronal chicken nAChR genes have been cloned and each of them exhibits a distinct pattern of expression in the developing central or peripheral nervous system. We have begun to define the cis-acting regulatory elements which govern the spatio-temporal expression of $\alpha 3$ and $\alpha 7$ nAChR genes during development of the chick nervous system. 5' flanking regions of both genes have been cloned and sequenced, and restriction and deletion fragments were fused to the reporter genes encoding CAT or SV40 T-antigen. Activity of these fragments was determined in transient transfection assays on cells freshly dissociated from different regions of the CNS (e.g., retina and optic tectum) at various stages of embryonic development. For both $\alpha 3$ and $\alpha 7$ we have delimited control elements which are active in neurons but inactive in glial cells. Furthermore, the control element of $\alpha 7$ was found to be active in identified retinal ganglion cells, i.e., in the cell population where $\alpha 7$ transcripts have been localized.

105.10

$\alpha 3$, $\beta 4$, AND $\alpha 5$ HUMAN NICOTINIC RECEPTOR SUBUNITS GENES: GENETIC LINKAGE, CHROMOSOMAL LOCALIZATION AND DIFFERENTIAL EXPRESSION IN NEURONAL AND NON-NEURONAL CELLS. B.Chini¹, F.Rubboli¹, P.Taroni¹, D.Fornasari¹, E.Raimondi², F.Clementi². CNR Center of Cytopharmacology, Univ. of Milano, Milano, Italy; ²Dept. of Genetics and Microbiology, Univ. of Pavia, Pavia, Italy

The cDNAs coding for the human $\alpha 3$, $\beta 4$ and $\alpha 5$ human nicotinic receptor subunits were cloned from a neuroblastoma cell line. Using these clones as probes, several genomic clones were isolated for studying the organization of the $\alpha 3$, $\beta 4$ and $\alpha 5$ genes in the human genome. By Southern blot and restriction mapping analysis of two overlapping genomic clones, we could demonstrate that the $\alpha 3$, $\beta 4$ and $\alpha 5$ human genes are organized in a cluster, as already described in rat and chicken. Furthermore, by *in situ* hybridization on metaphase chromosomes using both cDNA and genomic probes, we localized the $\alpha 3$, $\beta 4$ and $\alpha 5$ human genes in the same locus on chromosome 15.

We have also studied the expression of the $\alpha 3$ and $\alpha 5$ subunit genes in several human cell lines in culture. The expression of the $\alpha 3$ subunit was restricted to neuroblastoma and small-cell lung carcinoma cell lines; the latter have several neuro-endocrine properties. Transcripts corresponding to the $\alpha 5$ subunit were also found in several non neuronal cells of different embryological origin, a finding which opens a new perspective on the role of this subunit in non-excitatory cells.

105.11

CHARACTERIZATION OF VARIANT THYMIC cDNA CLONES ENCODING FOR THE ALPHA-3 NEURONAL ACETYLCHOLINE RECEPTOR SUBUNIT: NOVEL EXON AND MULTIPLE 3' END NON-CODING ALTERNATES. M. Mihovilovic, A. Vaughan*, C. Austin* and A.D. Roses. Depts. of Medicine & Neurobiology, Div. of Neurology, Duke University Medical Center, Durham, N.C.

We have isolated 13 cDNA clones encoding for the α -3 subunit of a thymic neuronal AChR (M. Mihovilovic and A.D. Roses; Exp. Neurol. 111:175-180, 1991). Sequencing and PCR analysis have identified 2 clones that carry a 122bp insert downstream from exon 5. The insert not only shifts the reading frame of the normal α -3 transcript but also carries an in-frame stop codon. Translation of this variant transcript will result in a truncated peptide lacking the complete 4th membrane spanning domain. The domain is needed for the production of a functional AChR gated ion channel. PCR analysis of genomic DNA suggests that the 122bp fragment represents a novel exon. RNase protection assays utilizing thymic poly (A)+RNA indicates that both the variant and normal transcripts of α -3 are expressed in thymus.

In addition to the 122bp variant, 3 alternative 3' end sequences are represented in the isolated thymic α -3 cDNA clones. The existence of multiple α -3 variant cDNA clones suggests that transcriptional regulatory mechanisms play an important role on the expression of thymic neuronal AChR(s).

The roles played by the normal and the variant α -3 transcripts and their translation products in thymus are unknown. It is likely that the α -3 subunit associates with 1 or more subunits of the AChR family to produce a thymic AChR. A thymic AChR may play a role in the transduction of signals originating in the CNS and transmitted to the thymus through autonomic innervation; and/or could represent a poorly understood cholinergic autoimmunogen in human acquired Myasthenia gravis(MG).

β -NERVE GROWTH FACTOR ENHANCES 3 H-NICOTINE BINDING TO NICOTINIC CHOLINERGIC RECEPTORS ON PC 12 CELLS. T.C. Madhok and B.M. Sharp.* Endocrine-Neuroscience Laboratory, Minneapolis Medical Research Foundation, and Dept. of Medicine, Hennepin County Medical Center and University of Minnesota, Minneapolis, MN 55455.

Although nicotinic cholinergic agonists affect PC 12 cells, radioligand binding sites have not been described. We, therefore, studied PC 12 cells incubated in the presence of β -nerve growth factor (β -NGF). Specific 3 H-nicotine binding sites were induced approximately 3-fold above baseline in the presence of β -NGF (50 or 100 ng/ml); specific binding was maximal by the second to fourth day and these levels were detected for two weeks. By equilibrium analysis, K_d of 356.5 ± 6.9 nM, mean \pm S.E., $N=3$ and B_{max} of 65×10^{-21} mole/cell were obtained using intact cells. Association and dissociation rate constants were $0.0023 \text{ min}^{-1} \text{ nM}^{-1}$ and 0.0709 min^{-1} at 22°C or $0.0012 \text{ min}^{-1} \text{ nM}^{-1}$ and 0.0101 min^{-1} , respectively, at 40°C , yielding an apparent K_d of 38.7 ± 12.8 nM, $N=4$. Intact cells and cell membrane yielded similar K_d values. 3 H-nicotine binding was inhibited on an equimolar basis by L(-)nicotine and N-methylcarbamylcholine. D(+) nicotine was 10-fold less potent while, α -bungarotoxin, mecamylamine and atropine show little or no inhibition. 3 H-nicotine binding was also inhibited quantitatively by monospecific polyclonal antibodies raised against the predicted α -3 subunit sequence (amino acids 130-139) of the rat neuronal nicotinic receptor. Sedimentation rate analysis showed that the NGF-sensitive 3 H-nicotine binding sites were macromolecules with MW ranging from $>240\text{K}$ to approximately 60K . This study represents the first biochemical characterization of β -NGF stimulated-nicotine binding sites on PC 12 cells and confirms previous observations of the presence of functional nicotinic cholinergic receptors on these cells. (Supported by P.H.S. grants DA-04446 [T.C.M.] and DA-03977 [B.M.S.].)

105.15

CNS NICOTINIC AChR CLUSTERING: HOT SPOTS AT NASCENT SYNAPSES. M. Martinic and W.L. Klein. Neuroscience Institute, Northwestern University, Evanston, IL 60208. The developmental distribution of nAChR in the avian retina *in vivo* was examined by confocal microscopy. Labelling with monoclonal antibody 210 (generously provided by Dr. J. Lindstrom) showed that immunoreactivity appeared in the inner plexiform layer and on ganglion cell bodies after E7. The signal was highest at E18, but decreased by P0. The *in situ* receptor distribution was punctate, as determined by confocal analysis. For comparison, the distribution of nAChR was studied in cultures from dissociated E9 chicken retina. Immunoreactivity was present on cells with retinal ganglion cell morphology. Examination of permeabilized cells showed that retinal neurons contained an intracellular nAChR pool. The distribution of receptor within cell bodies was punctate, as if associated with intracellular vesicles. Confocal analysis of immunoreactive cells showed that cell surface receptor distribution also was punctate. Extracellular receptors were distributed on cell bodies, as well as on processes. Preliminary EM analysis of receptor distribution showed association of label with growth cones and filopodia, as well as with membrane which had been shed from the cells. Receptor clustering into "hot-spots" also was observed at points of contact between processes in culture. Confocal microscopy revealed that the distribution of immunoreactivity at points of contact also was punctate. The punctate nature of the label both in culture and *in vivo* suggests a one punctum, one synapse correlation, and that neuronal nAChR may cluster at focal points similar to those observed at the neuromuscular junction during synaptogenesis.

105.12

NICOTINIC RECEPTOR SUBUNIT mRNAs IN RAT PERIPHERAL GANGLIA. A. Mandelzys, E. Deneris*, and E. Cooper. Dept. of Physiol., McGill Univ., Montreal, Quebec, H3G 1Y6 and *Dept. of Neurosciences, Case Western Reserve Univ., Cleveland, Ohio, 44106-4975

Recently, we have characterized functional nicotinic receptor (nAChR) current densities on neurons from both the sympathetic superior cervical ganglion (SCG) and the sensory nodose ganglion using whole-cell patch clamp techniques. All SCG neurons were sensitive to ACh and over 75% of the neurons had ACh current densities greater than 30 pA/pF. In contrast, most nodose neurons do not express functional nAChRs, and of those that were sensitive to ACh, the majority had ACh current densities below 8 pA/pF. However, we have shown that when nodose neurons develop in culture without other cell types, most nodose neurons express nAChRs and their ACh current densities can be up-regulated by NGF. We have now determined which nAChR subunit mRNAs are present in the two ganglia. Using the RNase protection assay, we examined total cellular RNA isolated from newborn rat SCG and nodose ganglia with antisense RNA probes to the mRNA for the α -2, α -3 and β -2, β -4 subunits. The results indicate that the major nAChR subunit mRNAs present in both ganglia are α -3 and β -4, with a lesser, although significant amount of β -2. This finding presents the possibility that the majority of nAChRs expressed by these neurons may be α -3/ β -2, α -3/ β -4, or a hybrid receptor incorporating α -3 and both β -2 and β -4. We are currently investigating whether the satellite cell influence and/or NGF are acting at the pre- or post-translational level on nodose neurons to specifically increase nAChR subunit mRNAs or to cause the appearance of novel nAChR subunit mRNAs. (Supported by the MRC of Canada, FRSQ, and FCAR).

SYNAPSE FORMATION IN CHICK LUMBAR SYMPATHETIC GANGLIA IN VIVO: TIMING OF PRESYNAPTIC INPUT AND PROJECTIONS TO TARGET. P. Devay, M. D. Listerud and L. W. Role. Dept. of Anatomy and Cell Biology in the Center for Neurobiology and Behavior, Columbia Univ., P & S, New York, NY 10032

To study potential developmental influences on the expression of acetylcholine receptors in sympathetic neurons, we need to know the time when these neurons establish connections with their pre- and postsynaptic partners.

Fibers growing out from the sympathetic neurons toward their targets as well as the arrival of preganglionic axons within the sympathetic ganglia were visualized by injecting Dil into the lumbar sympathetic chain of chicken embryos. By ED8 a number of fibers could be detected growing out of the chain towards peripheral targets. At this stage, examination of AChR subunit gene expression by Northern blot analysis and PCR indicates that the neurons express α -3, α -4, α -5, α -7, β -2 and β -4. By ED10 some lumbar sympathetic axons have reached the skin and blood vessels. At about the same time, the preganglionic fibers have entered the lumbar sympathetic ganglia, as indicated by retrograde labeling of the preganglionic neurons. Expression of synapse specific proteins is being examined to extend this analysis and determine the time-interval between axon ingrowth and formation of synapses. This work was founded by grants from the NIH (PS22061, NS29071) and the Council for Tobacco Research.

DENERVATION DOES NOT ALTER THE NUMBER OF NICOTINIC ACETYLCHOLINE RECEPTORS ON AUTONOMIC NEURONS IN THE FROG CARDIAC GANGLION. P.B. Sargent, G.K. Bryan, L.C. Streichert, and E.N. Garrett*. Depts. of Stomatology and Physiology, University of California, San Francisco, CA 94143

The binding of neuronal bungarotoxin (n-BuTX) was analyzed in normal and denervated parasympathetic cardiac ganglia of the frog, *Rana pipiens*. n-BuTX at 5-20 nM blocked both EPSPs and acetylcholine (ACh) potentials. Scatchard analysis of homogenates indicated that cardiac ganglia have two classes of binding sites for ^{125}I -n-BuTX -- a high-affinity site with an apparent K_d of 1.7 nM and a B_{max} of 3.8 fmol/ganglion and a low-affinity site with an apparent K_d of 12 μM and a B_{max} of 14 pmol/ganglion. α -Bungarotoxin does not appear to interfere with the binding of ^{125}I -n-BuTX to either site. The high-affinity binding site is likely to be the nicotinic acetylcholine receptor (AChR), given the similarity between its affinity for ^{125}I -n-BuTX and the concentration of n-BuTX required to block AChR function.

Light microscopic autoradiographic analysis of ^{125}I -n-BuTX binding to intact ganglia demonstrated that ^{125}I -n-BuTX bound selectively to synaptic sites. Scatchard analysis of the autoradiographic data revealed that ^{125}I -n-BuTX binding to synaptic sites has a K_d of about 1.5 nM.

Denervation of the heart increased the acetylcholine sensitivity of cardiac ganglion cells but did not change the number of high-affinity binding sites for ^{125}I -n-BuTX in tissue homogenates or the number of ^{125}I -n-BuTX binding sites on the ganglion cell surface. These results suggest that denervation alters neither the total number of nicotinic AChRs in the cardiac ganglion nor the number found on the surface of ganglion cells. The increase in acetylcholine sensitivity displayed by cardiac ganglion cells upon denervation cannot be explained by an increase in AChR number. (Supported by NIH NS24207)

105.17

DECREASED EFFECTIVENESS OF ACETYLCHOLINESTERASE UNDERLIES DENERVATION SUPERSENSITIVITY TO ACETYLCHOLINE IN THE FROG CARDIAC GANGLION. L.C. Streichert^{1,2} and P.B. Sargent². ¹Neurosciences Program, Stanford University, Stanford, CA 94305, and Depts. of Stomatology and Physiology, University of California, San Francisco, CA 94143-0512.

Sensitivity of the parasympathetic neurons in the cardiac ganglion of the frog, *Rana pipiens*, was assessed by measuring the peak depolarization elicited in response to the application of ligand emitted from a pipette positioned 10 μ m from the neuronal surface. Denervation produced an increase in acetylcholine (ACh) sensitivity, but had no effect upon sensitivity to carbachol, a nonhydrolyzable cholinergic agonist. The inhibition of extracellular acetylcholinesterase (AChE) by echothiophate, a poorly-lipid soluble AChE inhibitor, resulted in similar responses to ACh in normal and denervated ganglion cells. These results suggest that denervation supersensitivity in the cardiac ganglion is caused by a reduction in ACh hydrolysis by AChE.

In normal ganglia, both AChE and ACh receptors (AChRs) are concentrated at the base of the cell, and the effectiveness of AChE is thereby maximized. Following denervation, AChR clusters disperse and are found over the entire cell surface, but the distribution and amount of extracellular AChE is apparently unchanged. Thus, denervation supersensitivity in the cardiac ganglion may be due to changes in the distribution of AChE relative to AChRs and not to an actual decrease in AChE. In skeletal muscle, increased ACh sensitivity is the result of a denervation-induced increase in AChR number. Therefore, the mechanisms underlying denervation supersensitivity may be fundamentally different at neuromuscular and at interneuronal cholinergic synapses. (Supported by NIH NS24207).

EFFECTS OF AGING AND NUCLEUS BASALIS LESIONS ON THE DENSITY OF NICOTINE BINDING SITES IN CEREBRAL CORTEX. N. Zawia, G. Arendash, and L. Wecker. Departments of Pharmacology and Biology, University of South Florida, Tampa, Florida 33612.

The main objective of these studies was to determine whether the density of nicotine binding sites, and activities of cholineacetyltransferase (CHAT) and acetylcholinesterase (AChE) in frontal-parietal cortex (fpc) are altered during normal aging, as well as in response to lesions of the nucleus basalis magnocellularis (nbm). To accomplish this, male Sprague-Dawley rats aged 2-3 and 23-24 months old were chosen for study. Unilateral lesions of the nbm were produced by injections of ibotenic acid. Two weeks later, the activities of CHAT and AChE were measured radioisotopically and spectrophotometrically, respectively, and the density of nicotine binding sites was determined by measures of the binding of L-(-)-[N-methyl-³H-nicotine] at concentrations of 5 and 25 nM. Neither enzyme activities nor nicotine binding site density were altered as a function of age. The loss of CHAT and AChE activities 2 weeks following unilateral lesions of the nbm was significantly greater in fpc from aged rats (71-74% decrease) as compared to young adult rats (55-57% decrease). Nicotine binding site density in fpc from young adult rats decreased by 23-25% following the lesion, whereas the density in fpc from aged animals decreased by 31-34%. Results indicate that although the activities of CHAT and AChE and the density of nicotine binding sites are not altered as a function of normal aging, basal forebrain cholinergic neurons in the aged brain are more severely affected by nbm lesions than neurons in the young adult brain, perhaps due to an age-related decrease in neuronal plasticity. Furthermore, a sizeable number of neocortical nicotine binding sites appear to be located presynaptically on the terminals of nbm cholinergic neurons (Supported by NIMH 33443 and STRC 0245).

EXCITATORY AMINO ACIDS: ANATOMY AND PHYSIOLOGY I

106.1

EVIDENCE FOR DISRUPTION OF NEURON-ASTROCYTE METABOLIC INTERACTIONS IN HEPATIC ENCEPHALOPATHY. J. Lavoie and R.F. Butterworth. Lab. of Neurochemistry, André-Viallet Clin. Res. Centre, Hôpital Saint-Luc (University of Montreal), Montreal, Quebec, Canada H2X 3J4.

Chronic liver disease and portal-systemic shunting result in astrocytic changes characterized by mitochondrial swelling and, ultimately, Alzheimer type II astrocytosis. Studies of autopsied brain tissue from 9 cirrhotic patients who died in hepatic coma revealed severe astrocytosis in cerebral cortex and caudate nuclei, decreased activities of glutamine synthetase (GS) in caudate nuclei and increased densities of astrocytic ("peripheral-type") benzodiazepine receptors (PTBR's) in cerebral cortex and caudate nuclei. Similarly, brain tissue from rats following portacaval anastomosis (PCA) contains decreased activities of GS in cerebral cortex and hippocampus and a generalized 2 to 4-fold increase of PTBR's throughout brain. Ca²⁺-dependent release of glutamate from hippocampal slices of rats following PCA is increased 2-fold and high affinity glutamate receptor densities are concomitantly decreased. Such changes probably result from decreased reuptake of glutamate into damaged perineuronal astrocytes. Thus, selective alterations of glutamatergic synaptic regulation resulting from disruption of neuron-astrocytic metabolic interactions appear to play a major role in the pathogenesis of hepatic encephalopathy in chronic liver disease. [supported by MRC Canada].

CAPSAICIN SELECTIVELY RELEASES AMINO ACIDS FROM CULTURED SENSORY NEURONS IN A TTX-RESISTANT MANNER.

B. Manwiller, K. Jettinija*, F. Liu, and S. Jettinija. Department of Vet. Anatomy and Neuroscience Program, Iowa State University, Ames, IA 50011, USA.

Capsaicin has been shown to selectively stimulate C-type sensory neurons which are involved in nociception. The specific objective of this study was to study the mechanism by which capsaicin releases amino acids (AA) from cultured dorsal root ganglion (DRG) neurons. DRG from 1 to 8-day-old rats were dissected and cultured on chicken plasma-coated slides for 6 to 8 days. Cultures were mounted in a perfusion chamber and perfused at a rate of 100 μ l/min, with aerated Ringer solution at 36 \pm 1 $^{\circ}$ C. Quantification of amino acids was performed by high performance liquid chromatography utilizing fluorescence detection and pre-column OPA-derivatization. Following a period of culture equilibration 2 min, 200 μ l samples were collected. Perfusion application of capsaicin in concentration of 0.1 to 10 μ M for 1 to 2 min resulted in an increase of aspartate, glutamate, asparagin, serin, glutamin, and glycin release from cultured sensory neurons. This release of AA evoked by capsaicin was not abolished by pretreating the cultures with tetrodotoxin (TTX) or in zero Ca-EGTA solution. Pretreatment of the cultures with 1 μ M ruthenium red (RR) failed to antagonize capsaicin-evoked increase in the release of AA from cultured sensory neurons. However, cultures that were allowed to grow in media containing capsaicin in concentration of 1 μ M failed to respond with an increase of release of AA in response to perfusion of up to 10 μ M capsaicin. The same cultures, however, responded by increase in the release of AA in response to 50 mM K applied by perfusion. Our results show that capsaicin evokes the release of AA including aspartate and glutamate in TTX-resistant Ca-independent manner. This effect was selectively abolished in cultures grown in presence of capsaicin and was not blocked by RR. Work was supported by NIH Grant NS27751 and USDA Grant PL95-113.

INFLUENCE OF N-METHYL-D,L-ASPARTATE (NMA) ON PROLACTIN (PRL) AND GROWTH HORMONE (GH) SECRETION IN THE PIG.

C.R. Barb¹, G.M. Derochers², B. Johnson¹, R.V. Utley², W.J. Chang², G.B. Rampacek², R.R. Kraeling¹, USDA-ARS¹, Athens, GA, and Animal and Dairy Science Dept., University of Georgia², Athens

Mature female pigs were ovariectomized and assigned to one of four treatments administered i.m.: corn oil vehicle (V; n=6); 10 μ g estradiol-17 β /kg BW given 26 h before NMA (ES; n=6); 10 μ g estradiol-17 β /kg BW given 33 h before NMA (EL; n=6); 0.85 mg progesterone/kg BW given for 6 days prior to NMA (P₄; n=6). Blood was collected every 15 min for 6 h. Pigs received 10 mg NMA/kg BW i.v. 2 h after blood collection began and a GRF analog challenge (1 μ g/kg BW) given i.v. 3 h after NMA. Treatment x period (P<0.01) interaction was detected for PRL and GH. NMA did not alter PRL secretion in P₄ pigs, while PRL increased (P<0.0001) from 2.9 \pm 0.2, 4.7 \pm 0.2 and 5.0 \pm 0.2 ng/ml to 5.1 \pm 0.3, 8.0 \pm 0.3 and 7.5 \pm 0.3 ng/ml for V, ES and EL pigs, respectively. NMA increased (P<0.0001) GH from 0.4 \pm 0.3, 0.5 \pm 0.3, 0.8 \pm 0.3 and 0.5 \pm 0.3 ng/ml to 8.9 \pm 0.5, 10.4 \pm 0.5, 7.1 \pm 0.5 and 9.5 \pm 0.5 ng/ml for V, ES, EL and P₄ pigs, respectively. GH response to NMA was greater (P<0.001) in ES and lower in EL pigs compared to V pigs. NMA is a potent secretagogue of PRL and GH secretion and ovarian steroids modulate this response.

106.4

ETHANOL ALTERS EXCITATORY AMINO ACID-INDUCED LUTEINIZING HORMONE RELEASING HORMONE SECRETION IN VITRO.

W. Las Deas and J. K. Hiney*. Department of Veterinary Anatomy & Public Health, Texas A&M University, College Station, TX 77843.

In the present study, we evaluated the *in vitro* effects of ethanol (ETOH) on basal and excitatory amino acid (EAA) stimulated luteinizing hormone releasing hormone (LHRH) secretion from arcuate nucleus-medial eminence (AN-ME) fragments removed from prepubertal female rats. Fragments were preincubated for 15 min in Krebs-Ringer bicarbonate glucose buffer in an atmosphere of 95% O₂-5% CO₂. These media were discarded and all AN-MEs were incubated for 30 min in media only. This media was collected to establish basal LHRH release, and replaced with media only (controls) or with media containing ETOH (30, 50, 70 mM). After a 60 min incubation, these media were collected to establish ETOH's effects on basal LHRH release by RIA. New media containing 20 mM N-methyl-DL-Aspartic Acid (NMDA) or NMDA plus each dose of ETOH was added, vials were incubated 30 min, and media collected. Another experiment was conducted as above, except that 1 mM kaicnic acid (KA) was used in place of NMDA and the amount of LHRH released was measured. Results indicate that both NMDA and KA stimulate LHRH 3-fold (p < 0.01) over basal secretion. ETOH did not alter basal LHRH release at any of the doses used, but compared with controls, blunted both the NMDA (p < 0.01) and KA (p < 0.01)-induced release of LHRH in a dose-related manner. Our results indicate that ETOH is capable of altering EAA-induced LHRH release from the AN-ME region of the prepubertal female rat *in vitro*, and suggest that this mechanism, at least in part, contributes to ETOH's inhibitory effect on LH secretion.

106.5

MUSCARINIC RECEPTOR ACTIVATION ENHANCES NMDA-STIMULATED DOPAMINE RELEASE FROM MESENCEPHALIC CELL CULTURES.

H. Alloua, J. Chaudieu, R. Ouiron and P. Boksa. Douglas Hosp. Res. Ctr., Dept. of Psychiatry, McGill University, Montreal, Quebec, Canada H4H 1R3

Recent *in situ* hybridization histochemistry studies localizing muscarinic receptor mRNA indicate the presence of high levels of m5 mRNA in the ventral tegmentum and substantia nigra within dopaminergic neurons, while mRNA for m1, m2 and m4 receptors has been detected in the striatum (Vilario et al., 1990; Weiner et al., 1990). In light of this, the present study examined some of the mechanisms involved in the functional modulation of dopamine (DA) release by cholinergic agents, using cell cultures of fetal rat mesencephalon as a model system. Both oxotremorine (OXO), a muscarinic agonist, and carbachol, a mixed muscarinic-nicotinic agonist, potentiated NMDA-stimulated DA release. The EC50 for OXO enhancement of the NMDA response was 2 μ M. This effect of OXO was antagonized by 1 μ M QNB, a muscarinic antagonist, while DMPP, a nicotinic agonist had no effect on NMDA-stimulated DA release, indicating that muscarinic receptor activation is responsible for enhancement of the NMDA response. OXO alone had no effect on DA release and OXO also had no effect on DA release evoked by kainate or quisqualate. Reversal of the OXO enhancement of NMDA-stimulated DA release by additional muscarinic antagonists was tested to examine muscarinic receptor sub-type involvement; pirenzepine (selectivity: M1> or =M3>M2) was the most potent antagonist tested, followed by 4-DAMP (M1=M3>M2) and AFDX 384 (M2>M4>M3>M1). This profile indicates that M2 and M4 receptor sub-types are not likely to be involved in muscarinic enhancement of NMDA-evoked DA release. Preliminary studies indicate that OXO enhancement of the NMDA response is reversed by a protein kinase inhibitor, staurosporine, suggesting that muscarinic enhancement of NMDA-stimulated DA release may be mediated by protein kinase activation. Supported by Fonds de la Recherche en Sante du Quebec.

106.7

INDUCTION OF PRECOCIOUS PUBERTY IN FEMALE RATS BY N-METHYL-D-ASPARTIC ACID (NMDA). C. Smyth*, M.C. MacDonald* and M. Wilkinson. Depts. of Obst. Gynecol. and Physiol. Biophys., Dalhousie University, Halifax, N.S. Canada B3H 4H7.

We have previously reported (Neuroendocr. 52: 143, 1990) that a single daily injection of NMDA (15 mg/kg; from d27 of life) synchronizes and slightly accelerates first ovulation (VO) in female Sprague-Dawley rats. Further investigation of this phenomenon reveals that a higher dose of NMDA (20 mg/kg), given from postnatal day 24, significantly advances the day of VO (CON: 34.1 \pm 0.7 days vs. NMDA: 31.5 \pm 0.3; n=10; p<0.01). Most rats ovulated coincident with VO, or were in proestrus, and cycled normally. NMDA was effective regardless of the time of injection (11.00 h, 14.00 h or 18.00 h). In an additional model of precocious puberty (i.e. MSG (2 mg/kg) given on postnatal day 2) the combination of NMDA (20 mg/kg; from day 24) and neonatal MSG causes a greater precocity than MSG alone (CON: 36.1 \pm 0.6 (7) vs. MSG: 34.0 \pm 0.5 (11) vs. NMDA/MSG: 31.3 \pm 0.6 (12)). This suggests that neonatal MSG treatment may induce some degree of NMDA receptor supersensitivity. As a prelude to a study of LH secretion in these models we have fully characterized the LH response to NMDA in prepubertal female rats. For example, maximal responses are seen at 8 mins. post-injection (s.c.) and are dependent on dose (ED50: 3.8 mg/kg) and age (zero response at 10 days, max. at 20 days). The non-competitive antagonist MK-801 (0.1 mg/kg) prevented the stimulatory effect of NMDA (15 mg/kg). The present data, together with a previous study on c-fos induction (Dev. Brain Res. 56: 294, 1990), implicate MBH NMDA receptors in the regulation of sexual maturation. Supported by Canadian MRC and Atlee Endowment.

EFFECT OF DEVELOPMENT AND CHRONIC NEUROLEPTIC TREATMENT ON KYNURENIC ACID SYNTHESIS IN THE RAT BRAIN. M. Susol*, H. Baran, H.-O. Wu and R. Schwarcz. Maryland Psychiatric Research Center, Baltimore, MD 21228.

Kynurenic acid (KYNA) production has been shown to be reduced in the striatum of patients dying from Huntington's disease (HD), a movement disorder with early to mid-adult onset of clinical symptoms (J. Neurochem., 55:1327, 1990). We have therefore studied the ontogenetic profile of KYNA's biosynthetic enzyme, kynurenine aminotransferase (KAT), in rat brain. In all six regions examined, KAT activity increased consistently from postnatal days 3, 7, 14, 21 and 28 to young adulthood (3 months). However, cortical KAT, which was lowest at 3 days (0.17 pmoles/mg prot/h), rose 34-fold during the age range studied, whereas KAT in the substantia nigra and cerebellum (0.40 and 0.54 pmoles/mg prot/h at 3 days) increased much more slowly so that these regions contained only approx. one third of cortical KAT at 3 months. Hippocampus, olfactory bulb and striatum presented intermediate developmental curves. In order to evaluate drugs which are in current or possible future use as therapeutic agents in HD, rats were treated for 30 days with haloperidol (1.5 mg/kg/day), raclopride (10 mg/kg/day), clozapine (25 mg/kg/day) and SCH 23390 (0.5 mg/kg/day). None of the drugs influenced KAT in the cerebral cortex, striatum and substantia nigra. They also did not affect the extracellular levels of endogenous KYNA, assessed by striatal microdialysis *in vivo* (N = 7 per group). Supported by grant MH 44211.

RELEASE OF SEGMENTAL AMINO ACID NEUROTRANSMITTERS IN RESPONSE TO PRIMARY AFFERENT AND MOTOR CORTEX STIMULATION. B.K. Simson Jr., C.S. Robertson, and J.C. Goodman. Dept. Neurosurg., Baylor Col. of Med., Houston, TX, 77081

The role of amino acid (AA) neurotransmitters in the spinal cord has been primarily studied using *in vitro* preparations. The technology required for *in vivo* study has only recently become available. Such an investigation could yield valuable information regarding the segmental neurochemistry. We measured the release of AAs into the rabbit lumbar spinal cord in response to sciatic nerve and transcranial stimulation with stereotactically placed microdialysis catheters. Samples were obtained periodically during 90 minutes of continuous stimulation of either the left or right sciatic nerve, or motor cortex. Quantification of γ -amino butyric acid (GABA), aspartate, glutamate, glycine, and taurine was performed using high pressure liquid chromatography. Adequate neural excitation was verified by recording somatosensory evoked potentials (SSEPs) or corticomotor evoked potentials (CMEPs). Sensory activation, at intensities sufficient to activate small and large diameter peripheral fibers, of the ipsilateral sciatic nerve produced a significant increase only in segmental glycine levels. Contralateral sciatic nerve stimulation failed to evoke significant changes in AA levels. A significant increase in the release of glycine and taurine, but not aspartate or glutamate, was measured after 90 minutes of transcranial stimulation. Although GABA was detected during sensory or motor stimulation, the levels remained consistently very low. SSEP and CMEP components repeatedly showed adequate activation of primary afferent, descending motor fiber pathways, and segmental interneuron pools during dialysis sampling. Glycine, and taurine, have been shown to inhibit motor neuron activity and both are closely associated with segmental interneuron pools. Furthermore, these AAs have been shown to modulate segmental afferent activity. Our data are consistent with the hypothesis that supra-segmental influence over peripheral afferent and motor activity may be, in part, through these inhibitory AA neurotransmitters in the rabbit lumbar spinal cord.

106.8

GLIAL LOCALIZATION OF THE EXCITATORY AMINO ACID HOMOCYSTEATE. P. Grandes*¹, Ph. Tschopp*², F. Ortega*¹, C. Decavel*², K.Q. Do*², P. Morino*², M. Cuénot*² and P. Streit*². ¹Dept. of Neurosci., Basque Country Univ., Bilbao, Spain; ²Brain Res. Inst., Univ. of Zürich, CH-8029 Zürich, Switzerland.

L-Homocysteate (HCA) is an NMDA receptor preferring excitant, is released by K⁺-induced stimulation in a Ca²⁺-dependent manner from rat brain slices and, thus, has been proposed as transmitter candidate. In cerebellar slices, the HCA release depends on the presence of climbing fibers. To localize HCA, postembedding immunohistochemistry was performed using poly- and monoclonal antibodies. Surprisingly, HCA-like immunoreactivity (HCA-LI) was found predominantly in glial elements of several rat brain areas. In cerebellum, HCA-LI was most impressive in Bergmann glia. Furthermore, it was dramatically increased in the rat dorsolateral geniculate undergoing gliosis following cortical or combined retinal and cortical ablations. Astrocytes prepared from rat cerebral cortex showed strong HCA-LI; moreover, they contained high levels of HCA as determined by HPLC analysis in extracts. Since HCA fulfills certain transmitter criteria, but is localized predominantly in glia, it might be considered as 'gliotransmitter'. Supported by Proyecto del Gobierno Vasco and Swiss National Foundation.

106.10

IMMUNOHISTOCHEMICAL LOCALIZATION OF KYNURENINE AMINOTRANSFERASE IN THE RAT STRIATUM. R.C. Roberts, F. Du, E. Okuno and R. Schwarcz. Maryland Psychiatric Research Center, Baltimore, MD 21228.

Kynurenine aminotransferase (KAT) is the biosynthetic enzyme for kynurenic acid, an antagonist of excitatory amino acid receptors. The distribution of KAT-immunoreactivity (-i) was examined in the adult rat striatum at the light and electron microscopic levels. KAT-i was abundant in glia where the label was robust and homogeneous in both the nucleus and cytoplasm. The majority of neurons, both medium and large, exhibited granular KAT-i located in the cytoplasm of somata and proximal dendrites. The preadsorption control vastly reduced or eliminated specific staining at both the light and electron microscopic levels. At the ultra-structural level, KAT-i astrocytic processes dominated the neuropil. In neurons, label occurred in round membrane-bound organelles distributed throughout the cytoplasm. Cisternae and vesicles were identifiable in some of the labeled spheres. These data provide an anatomical basis for biochemical studies which have suggested the presence of striatal KAT in both astrocytes and neurons (Turski et al., J. Neurochem., 52:1629, 1989). Supported by USPHS grants NS28236 & MH44211 and a HDSA fellowship (to F.D.).

EXTRACELLULAR CONTENT OF POLYAMINES IN THE STRIATUM: A MICRODIALYSIS STUDY IN AWAKE RATS. C. Speciale, M. Marconi*, L. Raimondi* and R.G. Fariello. Farmitalia Carlo Erba-Erbamont Group, R&D CNS Dept., 20014 Nerviano, Milano, Italy.

On the basis of biochemical and electrophysiological data, it has been suggested that endogenous polyamines (PA), putrescine (PUT), spermidine (SPD) and spermine (SPM), may play a modulatory role on the N-methyl-D-aspartate (NMDA) receptor. Several studies are available on PA in brain tissue, yet little is known on the extracellular content. Using the microdialysis technique in awake rats, we have studied the extracellular PA content in the rat striatum. Wistar rats (200-220 g) were implanted and perfused as described in Speciale et al., *Neurosci. Lett.* 104:345, 1989. PA were measured according to Yun and Zhong (*Biomed. Chrom.* 2:173,1987) with slight modifications. Under these experimental conditions, extracellular striatal PA were estimated 147 ± 3 , 301 ± 32 and 73 ± 12 nM for PUT, SPD and SPM, respectively (n=6). Upon perfusion with isotonic Krebs buffer containing 100 mM K⁺, we observed $74 \pm 25\%$, $179 \pm 62\%$ and $1432 \pm 236\%$ of increase above basal levels for PUT, SPD and SPM, respectively (n=6). Data represent, to our knowledge, the first attempt to study the physiology of extracellular PA in the central nervous system and are relevant for investigating the modulatory role that endogenous PA may play on the NMDA receptor function.

FUNCTIONAL MAPPING IN THE BASAL FOREBRAIN USING EXCITATORY AMINO ACID-INDUCED PROTO-ONCOGENE EXPRESSION. K.J. Page, A. Saha, B.J. Everitt. (Spon: Brain Research Assn) Dept. of Anatomy, University of Cambridge, Cambridge CB2 3DY, U.K.

The effects of infusing excitatory amino acids (EAAs) into the ventral striatum (VS) or substantia innominata (SI) on direct and transynaptic immediate early gene (IEG) induction in ventral pallidal (VP) and cholinergic nucleus basalis (nbm) neurons was studied in rats.

Bilateral infusions into VS of AMPA (15mM) induced, 3h later, the *c-fos* protein, FOS, both within the VS and the sub-commissural VP/SI. The products of *c-jun* and *egr-1* were unchanged. Approximately 10% of the FOS-immunoreactive (IR) VP/SI neurons also contained choline acetyltransferase (ChAT)-IR. Thus, excitation of the VS leads to a change in state of both VP neurons and cholinergic neurons of the nbm.

Unilateral infusion into the nbm region of AMPA (1.5-15mM), Quisqualic acid (QUIS. 12-120mM), or NMDA (6-60mM) resulted, 1hr later in differential basal forebrain patterns of FOS-IR. AMPA induced a highly restricted, discontinuous pattern, while NMDA and QUIS resulted in a more widespread appearance of FOS-IR in pallidal and other structures. Double-staining revealed that the majority of ChAT-IR nbm neurons also contained FOS-IR following AMPA, but not NMDA or QUIS, infusions. Thus nbm ChAT-IR neurons appear preferentially to possess the AMPA sub-type of EAA receptor.

The results indicate that *c-fos* induction, in response to direct or indirect neuronal excitation, can be used to map aspects of the connective and chemical characteristics of basal forebrain systems.

ACTIVATION OF GLUTAMATE METABOTROPIC, MUSCARINIC, AND α_1 -RECEPTORS CONTROLS FIRING MODE IN NEOCORTICAL BURSTING NEURONS. Zhong Wang and David A. McCormick. Section of Neurobiology Yale Univ. Sch. Med. New Haven, CT 06510.

A subpopulation of layer V neocortical pyramidal cells generate action potentials in two distinct patterns characterized by burst firing and single spike activity. Here we investigated, using standard *in vitro* electrophysiological slice techniques, the possibility that activation of glu metabotropic, muscarinic, or α_1 -noradrenergic receptors may determine which of these two firing modes is exhibited. Picodrop application of either the metabotropic receptor agonist 1S,3R-ACPD (400 μ M in micropipette), the muscarinic agonist MCh (1-5 mM), or noradrenaline (400 μ M) to layer V burst generating neurons in the guinea pig or rat sensorimotor or primary visual cortex resulted in membrane depolarization and a switch in firing mode from burst firing to single spike activity. The noradrenergic (NA) depolarization was blocked by the α_1 -selective antagonist prazosin (1 μ M) and mimicked by the α -agonist phenylephrine (400 μ M), indicating that the NA effect is mediated by α_1 -adrenoceptors. The shift in firing mode by these agonists appeared to result from the suppression of various potassium currents including I_M, I_{AHP} and a leak potassium current. All these effects were derived from the direct excitation of the neurons since they persisted after block of synaptic transmission with TTX. Furthermore, we found that brief trains of electrical stimuli to the white matter beneath the neuron were effective in switching the cell from the burst to single spike firing mode, suggesting that endogenous release of ACh, glu and/or NA may be capable of having this effect. We suggest that the firing mode of neocortical bursting neurons *in vivo* is controlled by glu, ACh and/or NA releasing neurons.

HEAT SHOCK PROTEIN (HSP 72) RESPONSE TO NMDA ANTAGONISTS IS BLOCKED BY ANTICHOLINERGICS OR GABAMIMETICS. M.A. Sesma, M.T. Price and J.W. Olney. University of Missouri-St. Louis, MO 63121 & Washington University, St. Louis, MO 63110.

NMDA antagonists, including PCP, ketamine and MK-801, induce transient pathomorphological changes in cingulate and retrosplenial (C/RS) cerebrocortical neurons (Olney et al., *Science*, 244:1360, '89) in rats, mice and tree shrews. Associated with these changes is an abnormal expression of 72KD heat shock protein (HSP) (Sharp et al., *NS Abst.* 15:761, '90). The HSP response may be a sensitive indicator of this type of injury as Sharp et al. detected it not only in C/RS but in at least some other neocortical neurons and found it to be a long lasting reaction (up to 2 wks). The question arises whether these histological changes and the psychotomimetic effects of NMDA antagonists could be manifestations of the same toxic process, especially since the psychotic effects sometimes recur over a period of weeks (similar to the time course of the HSP response). We have found (Olney et al. *NS Abst* 1991) that the pathomorphological effects of NMDA antagonists can be prevented by co-administration of drugs having either anti-cholinergic (e.g. scopolamine) or GABA-mimetic (e.g. diazepam or pentobarbital) actions, and here we report that these same drugs also prevent the HSP response. This strengthens the assumption that the pathomorphological and HSP responses have a common triggering mechanism and also supports the postulated link between the psychotomimetic and neurotoxic changes, since it is known from human anesthesia that the psychotomimetic effects of ketamine can be prevented by benzodiazepines, including diazepam. We propose that the pathomorphological changes induced by NMDA antagonists constitute a form of neuronal injury which induces synthesis of HSP, perhaps as a reparative response, and psychotic symptoms as a reflection of the dysfunctional status of neural networks integrally associated with the injured C/RS neurons. Supported by grants to M.A.S. (NSF 861 8448 & Univ. MO Weldon Spring Fund and Research Leave Award) and to J.W.O. (RSA MH38894, DA05072, DA53568, AG05681).

GLUTAMATE METABOTROPIC RECEPTOR ACTIVATION MODULATES THALAMIC NEURONAL ACTIVITY. M. von Krosigk and D. A. McCormick. Sec. Neurobiology, Yale Univ. Sch. Med., New Haven, CT 06510.

The dorsal lateral geniculate nucleus (LGNd) and reticular nucleus of the thalamus (nRt) receive presumed glutamatergic input from both cortical and subcortical afferents and contain mRNA for the glutamate (glu) metabotropic receptor (Masu et al., *Nature* 349, 760-765, 1991). Here we examined the consequences of activation of glu metabotropic receptors on neurons in the LGNd and nRt using standard *in vitro* slice techniques. Application of the glutamate metabotropic receptor agonist 1S,3R-ACPD resulted in prolonged membrane depolarization and a decrease in apparent input conductance. These effects were direct (not blocked by TTX) and due to a decrease of a "leak" current which reversed at E_K (-105 mV in 2.5 mM [K⁺]_o). This K⁺ current varied in a relatively linear manner with membrane potential and was not blocked by extracellular application of Cs⁺, indicating that this current is distinct from I_M and I_h. The slow depolarizing effect of 1S,3R-ACPD persisted in solutions containing NMDA and non-NMDA antagonists (kynurenic acid, APV, CNQX). The response to 1S,3R-ACPD was occluded by a maximal activation of α_1 -adrenoceptors by NA, and vice-versa, suggesting that these transmitters converge onto the same effector mechanism. Functionally, the 1S,3R-ACPD induced depolarization was able to shift neuronal firing from rhythmic bursting to single spike-tonic activity, similar to that seen *in vivo* in association with increases in arousal and alertness. Local electrical stimulation resulted in a slow excitatory postsynaptic potential which was similar to that seen with the application of 1S,3R-ACPD. We are currently investigating the possibility that endogenous release of glutamate may control the firing mode of thalamic neurons.

106.16

EFFECTS OF t-ACPD IN SIMULTANEOUS PATCH/SLICE, FURA-2 RECORDINGS OF THE NUCLEUS TRACTUS SOLITARIUS (NTS). S.R. Glaum, S.N. Murphy and R.J. Miller. Dept. of Pharmacological and Physiological Sciences, University of Chicago, Chicago IL 60637.

The NTS is the primary central nucleus coordinating respiratory, cardiovascular and gastrointestinal reflexes (Champagnat et al., 1986, *J. Phys.* 381, 551). The effects of glutamate (GLU) microinjected into the NTS on deglutative and baroreceptor reflexes are only partially blocked by the AMPA/KA antagonist kynurenic acid (KYN) or the NMDA antagonist AP5 (Leone & Gordon, 1989, *JPET* 250, 953; Hashim & Bieger, 1989, *Neuropharm.* 28, 913). We therefore examined the effects of the metabotropic EAA receptor agonist *trans*-1-aminocyclopentane-1,3-dicarboxylic acid (ACPD) on synaptic transmission and [Ca²⁺]_i in these cells.

Neurons in coronal slices of 3-6wk rat NTS were recorded at 25°C with K-gluconate filled patch electrodes containing (in mM): K-gluconate, 145; MgCl₂, 2; HEPES, 5; K₂ATP, 5 and the Ca²⁺ indicator fura-2 pentapotassium salt, 0.1. ACPD (10-25 μ M) produced a depolarizing response (11 ± 3 mV, $\bar{x} \pm$ SD) and an increase in somatic [Ca²⁺]_i that paralleled V_m. Under voltage clamp (-60mV), ACPD produced an inward current with a reversal potential = -96mV and a decrease in slope conductance. ACPD reduced the peak amplitude of CNQX (10 μ M)-sensitive EPSPs and EPSCs (V_{hold} = -80mV) evoked by stimulation of the tractus solitarius by 38%. Bicuculline (10 μ M)-sensitive evoked IPSPs or IPSCs (V_{hold} = -50mV) were completely blocked by ACPD. ACPD effects were mimicked by GLU (50 μ M), preserved in the presence of the AMPA/KA antagonist CNQX (10 μ M) and D-AP5 (50 μ M), but occluded by 1-5mM BaCl₂. ACPD effects were not blocked by L-AP3 (50-100 μ M). These data suggest that the excitatory, KYN/AP5-insensitive effects of GLU in the NTS may be the result of direct depolarizing and indirect disinhibitory actions of metabotropic receptor activation.

SECOND MESSENGER CASCADE TRIGGERED BY GLUTAMATE RECEPTORS IN MESENCEPHALIC NEURONS. A. Ambrosini*, N. Brunello and G. Racagni. Center of Neuropharmacology, Inst. Pharmacol. Sci., Univ. of Milan, Italy.

Glutamatergic agonists act on dopamine neurons in midbrain by activating synaptic currents (Mereu et al, J. Neurosci. 4, 1991) and releasing dopamine (Mount et al., Soc. Neurosci. Abstr., 1988, 198.14). These effects seem to be mediated by glutamate receptors of both NMDA and non-NMDA ionotropic subtypes. However, the intracellular events triggered by glutamate stimulation have not been characterized yet.

We present here evidence that quisqualate metabotropic receptors are also present in midbrain neurons obtained from rostral mesencephalic tegmentum of 13 day-old mouse embryos. Indeed, 10 μ M quisqualate (QUIS) induced inositol phosphate accumulation, reaching values about 170 % above basal after 10 min stimulation. This effect could be prevented (more than 90 % inhibition) by pretreating cells acutely with 80 nM phorbol dibutyrate, a protein kinase C activator. Further, we analysed cGMP production after neuronal stimulation with several glutamate receptor agonists, namely glutamate, NMDA, kainate and QUIS (100 μ M). Kainate was the most potent stimulant (40 % above basal after 1 minute incubation), while no significant increase was observed with QUIS. The cross-talk between glutamate receptor subtypes and their different metabolic pathways is at present under investigation.

106.19

METABOTROPIC GLUTAMATE RECEPTOR ACTIVATES THE POTASSIUM CONDUCTANCE IN FRESHLY DISSOCIATED HIPPOCAMPAL CA1 NEURONS. N. Akaike, T. Shirasaki and N. Harata. Dep. of Neurophysiol., Tohoku Univ. Sch. of Med., Sendai, 980 JAPAN.

The presence of new type glutamate receptor coupled to inositol phosphate/ Ca^{2+} signal transduction has been demonstrated in *Xenopus* oocytes injected the rat brain mRNA. Recently, the sequence of metabotropic glutamate receptor (mGluR) has also characterized. However, the functional role of mGluR has not been investigated in native mammalian CNS neurons. Hence, we studied the metabotropic Glu response with perforated patch clamp technique. Hippocampal pyramidal neurones were isolated from 1 to 4 week-old Wistar rats by mechanical dissociation following enzyme treatment. Drugs were applied by the "Y-tube" technique, which enables to rapid exchange of external solutions. Application of Glu and quisqualate (QA) induced inward current which was superimposed by an outward current. The outward current was 1) resistant to APV, CNQX and DNQX, and 2) disappeared once switched to the whole cell configuration. These results suggest that the outward current is mediated by the mGluR. Since this outward current was 1) abolished by pretreatment of caffeine, ryanodine and acetylcholine, 2) activated in Ca^{2+} free external solution, and 3) its reversal potential was close to E_{K^+} , it was concluded that mGluR in native rat hippocampal CA1 neurons activates Ca-dependent K channel via second messenger (probably IP_3) system. The concentration-response relationship of QA-induced I_K was characterized by followings. The threshold, K_a (apparent association constant) and Hill coefficient were 10^{-8} M, 1.1×10^{-7} M and 2.28, respectively. This K_a was 100 fold lower than that of inward current induced by QA. This suggest that mGluR may play important roles in physiological condition such as synaptic plasticity.

106.18

EXCITATORY SYNAPTIC TRANSMISSION IN NEOSTRIATUM AND ACTIVATION OF A GLUTAMATE AUTORECEPTOR BY t-ACPD. D.M. Lovinger, Dept. of Molecular Physiol. and Biophys., Vanderbilt Univ. School of Medicine, Nashville, TN 37232.

Glutamatergic afferents provide excitatory input to the neostriatum. The patch/slice technique was used to examine these glutamatergic synapses. Electrical stimulation in 400 μ m thick striatal slices produced excitatory postsynaptic potentials (EPSPs) and currents (EPSCs) in current- and voltage-clamp recordings respectively. Transmission was mediated primarily by AMPA-type glutamate receptors, but NMDA receptor-mediated responses could be observed in CNQX and 0.5 mM $[Mg^{2+}]_o$. The amplitude of EPSPs and EPSCs was reduced by t-ACPD (a metabotropic glutamate receptor agonist). The reduction in transmission increased in a concentration-dependent manner at 5-100 μ M t-ACPD ($IC_{50}=22.6 \mu$ M). t-ACPD appeared to act presynaptically as indicated by the findings that: 1) t-ACPD decreased AMPA and NMDA receptor-mediated transmission, but did not block current activated by agonist application; indicating that t-ACPD is not a glutamate receptor antagonist; 2) t-ACPD decreased transmission without altering postsynaptic cell properties. This t-ACPD-activated receptor differs from previously described amino acid autoreceptors as APB was without effect, and the action of t-ACPD was not reduced by the GABA_B receptor antagonist 2-OH-saclofen. In sum, glutamatergic transmission in neostriatum is modulated by a t-ACPD-activated glutamate autoreceptor.

EXCITATORY AMINO ACIDS: ANATOMY AND PHYSIOLOGY II

107.1

SEROTONIN DEPRESSES EXCITATORY AMINO ACID-MEDIATED EXCITATION OF RAT CEREBELLAR PURKINJE CELLS IN VIVO. J.G. Netzeband, J.C. Strahlendorf and H.K. Strahlendorf. Departments of Physiology and Medical and Surgical Neurology, Texas Tech University Health Sciences Center, School of Medicine, Lubbock, TX 79430.

Serotonin (5-HT) can facilitate or depress neurotransmission mediated by excitatory amino acids (EAA), depending on the area of the nervous system under study. In the cerebellar slice, 5-HT was shown to depress glutamate- and quisqualate-induced excitation of Purkinje cells to a greater extent than that of N-methyl-D-aspartate (NMDA; Hicks et al., 1989, *Brain Research*, 492:371). More recently, however, it has been shown that quisqualate can activate both ionotropic and metabotropic receptors, which are activated by α -amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA) and trans-1-aminocyclopentyl-1,3-dicarboxylic acid (ACPD), respectively. Thus, we have extended these findings by including kainate, AMPA and ACPD in our studies. Extracellular activity of Purkinje cells was recorded from urethane-anesthetized adult male rats. EAA and 5-HT were applied by iontophoresis. We found that 5-HT (40 nA) was equally effective in depressing the magnitude of excitation produced by glutamate (70% decrease), kainate (62%), quisqualate (57%) and NMDA (56%), but that it had much less effect on AMPA (20%). 5-HT facilitated and depressed ACPD-mediated excitation, but these actions could be attributed to changes in cellular firing rates and were not significant when compared to the other agents studied. These results indicate that 5-HT preferentially modulates ionotropic EAA receptors, but that this modulation may require co-activation of intracellular second messengers, e.g. via metabotropic EAA receptors. NIH grant NS19296.

107.2

INDUCTION OF COBALT ACCUMULATION BY EXCITATORY AMINO ACIDS (EAA) IN THE HIPPOCAMPAL SLICE. J.F. Pregenzer*, E. Dunn, J.A. Ostvee, and L.R. Williams, CNS Diseases Res., The Upjohn Co., Kalamazoo, MI

Computer-assisted image analysis was used to establish the dose response of EAA analogs on the induction of cobalt accumulation within pyramidal and granule cell neurons in 400 μ m slices of gerbil hippocampus. Slices were incubated 20 min at 22°C according to Pruss et al., (1990), in a solution containing 5 mM $CoCl_2$ and 0 to 1000 μ M EAA analog. The cobalt was visualized by development in $(NH_4)_2S_8$ and the slices were digitized for quantitative densitometry. Kainic acid (KA) had the largest effect ($ED_{50} = 30 \mu$ M), inducing cobalt accumulation in the dentate gyrus and CA1, 180% and 150% above control, respectively. Quisqualate (QA) induced accumulations in CA1 and hilar neurons, but had no effect on dentate granule cells. The accumulations induced by KA and QA were blocked by CNQX, but not by AP5. NMDA induced accumulation in the dentate and CA1 150% above control. The accumulation was blocked by both AP5 and CNQX. These data indicate that cobalt-permeable, ligand-activated ion channels are differentially distributed within the gerbil hippocampus, and have differential sensitivities to non-NMDA agonists. The NMDA effect is probably mediated through a secondary synapse acting on KA receptors.

107.3

NMDA INDUCES RHYTHMIC BURSTING ACTIVITY IN RAT MAGNOCELLULAR NEUROSECRETORY CELLS (MNCs) IN VITRO. Charles W. Bourque and Bin Hu. *Centre for Research in Neuroscience, McGill University, Montreal, Québec, Canada H3G 1A4*

Phasic bursting activity is known to facilitate peptide release from the neurohypophysial terminals of hypothalamic MNCs. In this study we report a novel mode of burst firing which MNCs evolve when exposed to NMDA receptor agonists. Intracellular recordings were obtained from 48 MNCs impaled in the supraoptic nucleus of superfused hypothalamic explants. Bath application of NMDA (10-100 μ M) from subthreshold membrane potentials induced intense (\approx 30 Hz) bursts of action potentials lasting 300-800 ms which recurred periodically every 1-2 seconds and which were associated with 10-20 mV oscillations in membrane potential. These effects could be mimicked by glutamate (n=3) or quinolinate (n=4), but not by quisqualate, kainate or AMPA (n=12). NMDA-evoked bursts were abolished in the presence of 10 μ M APV (n=2), but persisted in the presence of CNQX (10 μ M; n=2). Application of NMDA in the presence of TTX (300 nM; n=4) resulted in voltage-sensitive subthreshold oscillations (5-15 mV) recurring every 1-2 seconds. These results indicate that sustained activation of postsynaptic NMDA receptors can induce rhythmic bursting activity in rat supraoptic MNCs. *Supported by MRC and FCAR*

107.5

CALCIUM ENTRY EVOKED IN DORSAL HORN NEURONS BY GLUTAMATE: DOSE-DEPENDENT RELIEF OF MAGNESIUM ION BLOCK. D.B. Reichling and A.B. MacDermott. Department of Physiology and Cellular Biophysics and Center for Neurobiology and Behavior, Columbia University, New York, NY 10032.

Calcium ion (Ca^{2+}) entry into neurons through NMDA-gated channels has been implicated in mechanisms of synaptic plasticity. Blockade of this route of calcium entry by physiological concentrations of magnesium ions (Mg^{2+}) is relieved by depolarization of the membrane, for example when the endogenous transmitter L-glutamate co-activates NMDA and non-NMDA receptors. To quantify the effect of this unblocking action on the dose-response curve for Ca^{2+} entry evoked by glutamate, the intracellular concentration of calcium ions ($[Ca^{2+}]_i$) was measured using indo-1 in single cultured neurons isolated from the dorsal horn of embryonic rat spinal cord while glutamate was rapidly applied for a period of 3 sec. In all experiments the bath contained 5 μ M glycine. At concentrations of glutamate that activate NMDA receptors alone (1 μ M or less), 1 mM Mg^{2+} completely blocked Ca^{2+} entry in most neurons, while in the remaining neurons Ca^{2+} elevation was only partly blocked. As the concentration of glutamate was increased above 1 μ M, and non-NMDA receptors were activated, the Mg^{2+} block was progressively relieved until, at 30 μ M glutamate little block was evident. On the other hand, antagonism of the $[Ca^{2+}]_i$ response by 0.1 mM Mg^{2+} was much less potent, and was dramatically decreased by increasing concentrations of glutamate even below the level at which non-NMDA receptors are activated. Thus, 0.1 mM Mg^{2+} reduced the mean response to 0.3 μ M glutamate by 75%, and to 1 μ M glutamate by only 24%. These results demonstrate that, in physiological concentrations of Mg^{2+} , non-NMDA receptor activation is sufficient but not always necessary to relieve the Mg^{2+} block of NMDA receptors sufficiently to produce elevations of $[Ca^{2+}]_i$. We are now using co-cultures of dorsal root ganglion and dorsal horn neurons to determine if these conclusions also apply to the action of synaptically released excitatory amino acid transmitters upon postsynaptic receptors.

THE TIME COURSE OF GLUTAMATE IN THE SYNAPTIC CLEFT. J.D. Clements*, R.A.J. Lester*, C.E. Jahr & G.L. Westbrook. Vollum Institute, Oregon Health Sciences University, Portland, OR. 97201.

The concentration time course of free transmitter in the synaptic cleft for synapses in the vertebrate CNS is not known. We have estimated this time course for released glutamate by measuring the block of excitatory synaptic transmission produced by a rapidly dissociating competitive antagonist, D-amino acidipate (DAA). If free transmitter is present for only a brief period, agonist and antagonist binding will not reach equilibrium. Thus the synaptic response will be proportional to the number of receptors which are not initially occupied by a competitive antagonist such as DAA. Longer durations of free transmitter will increase the response as glutamate replaces DAA on the receptors.

To obtain the antagonist dissociation rate, pulses (1-40 ms) of glutamate (2 mM) were applied to outside-out patches of cultured hippocampal neurons in the continuous presence of saturating concentrations of DAA (200 μ M). Control experiments revealed that solution exchange at the membrane patch was < 1 ms. As expected, increases in glutamate pulse length reduced the effectiveness of DAA in blocking NMDA channels. The response amplitude plotted as a function of pulse length followed a single exponential time course ($\tau = 8$ ms), implying a dissociation rate for DAA of 125 sec^{-1} . These results predict that in 200 μ M DAA, a 2 ms pulse of 2 mM glutamate will reach only 10% of the response amplitude seen in the absence of DAA. In whole cell recordings from pairs of hippocampal neurons, synaptic activation of NMDA receptors was inhibited to 10% of control in 200 μ M DAA. Therefore, assuming similar association rates for DAA and glutamate, free transmitter is present in the cleft at >200 μ M for less than 2 ms. Using a kinetic model of NMDA receptor activation, the results predict that the transmitter concentration peaks at a value near 2 mM, then decays with a 1 ms time constant. Supported by grants from USPHS and the McKnight Foundation (CEJ & GLW).

IONIC BASIS OF NMDA-INDUCED RHYTHMIC BURSTING ACTIVITY IN RAT MAGNOCELLULAR NEUROSECRETORY CELLS (MNCs) IN VITRO. Bin Hu and Charles W. Bourque. *Centre for Research in Neuroscience, MGH, McGill University, Montreal, Québec, Canada H3G 1A4*

NMDA receptor activation in hypothalamic MNCs results in the appearance of high frequency (\approx 30 Hz) bursts of action potentials lasting 300-800 ms, recurring every 1-2 seconds. We have obtained intracellular recordings from 20 supraoptic MNCs in superfused explants of rat hypothalamus to examine the ionic basis of this response. In the presence of TTX, NMDA (10-100 μ M) induced rhythmic subthreshold oscillations. Application of a voltage clamp within the same voltage range revealed no oscillations of membrane current, suggesting that voltage-dependent interactions are required for the genesis of the response. NMDA induced bursting was abolished by (i) removal of external Mg^{2+} (n=7), (ii) removal of external Ca^{2+} (n=4), (iii) intracellular Ca^{2+} chelation with BAPTA (n=2), or (iv) bath-application of apamin (100 nM; n=4). In each case, NMDA-induced oscillations and rhythmic bursts were replaced by steady depolarizing plateaus. We conclude that NMDA-induced bursting activity requires the intrinsic voltage-dependency of NMDA channels, Ca^{2+} influx, and the activation of apamin-sensitive Ca^{2+} -activated K^+ channels. *Supported by MRC and FCAR*

GLUTAMATE AND NMDA ACTIONS ON MESOPONTINE CHOLINERGIC NEURONS IN VITRO. R. Sanchez, A. Kahteb, M. Mühlethaler and C.S. Leonard. Center for Neural Science, NYU 6 Wash. Pl. NY, NY 10003 and Geneva Sch Med, CMU 1 rue Michel Servet, 1206 Geneva, Switzerland.

The actions of glutamate (Glu) and NMDA on pedunculopontine (PPT) and laterodorsal tegmental (LDT) neurons were studied with intracellular recording methods in a guinea pig brain slice preparation. Cholinergic neurons were identified by combined intracellular injection of biocytin and histochemical staining for NADPH-diaphorase. Focal application of Glu or NMDA produced a dose-dependent increase in firing rate and membrane depolarization in type II cells. Glu and NMDA depolarizations were of similar magnitude but had different time courses. Glu produced short latency depolarizations (50-200ms) which peaked rapidly and lasted for less than 15 seconds while comparable NMDA depolarizations had long latencies (800-1600 ms) and long durations (40-80S). The NMDA mediated depolarization was completely blocked by AP-5 (50 μ M) while the Glu responses were only marginally reduced by AP-5 (50 μ M) but were strongly antagonized by both DNQX (10-50 μ M) and CNQX (10 μ M) suggesting that a major part of the Glu response was mediated by non-NMDA receptors. It appears that Glu acts directly since neither TTX (1 μ M) nor low Ca^{2+} /mMCo Ringer, which blocks synaptic transmission, altered the response. NMDA may also act directly since its depolarization was unaltered by TTX (1 μ M) although possible indirect actions must be further considered. These findings imply that excitatory amino acid inputs may have both short and long-lasting effects on the integrative properties of mesopontine cholinergic neurons.

NBQX REVEALS AN NMDA MEDIATED SYNAPTIC CURRENT.

Paul A. Coleman, Weifeng Yu, Tage Honoré, and Robert F. Miller. Dept of Physiology, Univ of Minnesota, MN 55455; Novo Nordisk A/S, Søborg, Denmark.

The effects of NBQX (2-3 Dihydroxy-6-nitro-7-sulfamoylbenzo (F) quinoxaline) were tested on amphibian inner retinal neurons. Whole cell currents were measured from these cells in the intact retinal eyecup or slice preparations. NBQX acted as a potent non-NMDA antagonist but like the other quinoxalines, its selectivity is concentration dependent. Nevertheless, NBQX (0.7-25 μ M) preferentially attenuated the depolarizing effects of non-NMDA over NMDA receptor agonists, in a manner superior to DNQX or CNQX.

In current clamp recordings, NBQX didn't reduce the amplitude of light-evoked EPSPs nor made their time course systematically slower. Likewise, blocking NMDA receptors (with D-AP7) resulted only in minor alterations of the EPSP. The changes seen with either of the selective antagonists were restricted to subtle alterations of the EPSP/IPSP complex. A substantial reduction in synaptic response amplitude was only observed when NMDA and non-NMDA antagonists were combined. Additionally, NBQX had no apparent effect on the response of the ON bipolar cell, indicating no antagonism of the L-AP4 receptor.

Under voltage-clamp conditions, NBQX revealed a voltage-dependent EPSC similar to classical NMDA-mediated responses, in that negative holding potentials reduced the inward current when compared to more depolarized holding potentials. In contrast, EPSCs recorded in the presence of D-AP7 varied linearly with holding potential.

NBQX permits the study of NMDA mediated EPSCs in relative isolation from non-NMDA contributions due to its improved selectivity of non-NMDA over NMDA receptors. This has provided new insight on the role of these receptors in retinal ganglion cell function. Our results suggest that normal synaptic activation depends on the interactions between NMDA and non-NMDA receptor mediated currents. This research was supported by EY03014 and EY07376 to RFM.

QUISQUALATE INDUCES LONG-TERM CHANGES IN EPILEPTIFORM ACTIVITY IN HIPPOCAMPAL SLICES. W.W. Anderson and R.J. DeLorenzo, Dept. of Neurology, Medical College of Virginia, Richmond, VA 23298.

One goal of epilepsy research is to reverse the process of seizure development or epileptogenesis. Recent studies have shown that activation of a metabotropic glutamate receptor is necessary to produce long-term depression (LTD) of EPSPs (Chattarji et al., *Neurosci. Abst.* 16:660, 1990). Because seizure development is thought to be partially due to potentiation of EPSPs, we have begun to investigate the ability of metabotropic glutamate receptor agonists to depress epileptiform activity induced by electrical stimulation in rat hippocampal slices.

Interictal bursts (IIBs) and electrographic seizures (EGSs) were induced in physiological medium by repetitive tetanic stimulation of CA3 s. radiatum. To prevent further induction of epileptiform activity by NMDA receptor activation, 100 μ M of the NMDA antagonist 2-amino-5-phosphonovalerate (APV) was applied. Then 10 μ M (\pm) or 5 μ M (+) quisqualate (QUIS), a metabotropic and AMPA receptor agonist, was added to the APV solution for 2 min. Following the washout of QUIS, a complex alteration of epileptiform activity occurred that continued for the remainder of APV application (30-60 min). Spontaneous IIBs increased in frequency and spikes/burst, but EGS activity was substantially reduced or blocked. The antidromic population spike (APS) amplitude was also reduced by one-third. When APV was washed out, IIBs decreased and EGSs increased to pre-APV levels.

The results show that QUIS produces long-term changes in epileptiform activity during NMDA receptor blockade. These changes are not simply decreases in all types of activity, but include an increase in IIBs and a decrease in EGSs. The mechanisms of EGS decrease are not known, but could include inhibition by stronger IIBs, EPSP depression, and APS decrease. The reversal of QUIS activation after washout of APV is reminiscent of biochemical studies showing that activating NMDA receptors decreases the effects of metabotropic receptor agonists.

A SLOW NMDA RECEPTOR-MEDIATED EPSP EVOKED BY REPETITIVE MOSSY FIBER STIMULATION IN TURTLE CEREBELLAR PURKINJE CELLS.

L.J. Larson-Prior, P.D. Morrison, and N.T. Slater, Department of Physiology, Northwestern University Medical School, Chicago, IL 60611 U.S.A.

A contemporary view of the neurotransmitter receptors involved in the mossy fiber-granule cell-Purkinje cell pathway in adult cerebellum indicates a predominate role for NMDA receptors at the mossy fiber-granule cell synapse, and for Quisqualate receptors at the granule cell-Purkinje cell synapse. We have examined this hypothesis by studying the actions of excitatory amino acid (EAA) receptor antagonists on synaptic potentials in cerebellar Purkinje cells activated by stimulation of the trigeminal nerve (Vn) or the ascending spinal lemniscus (SL).

Intracellular recordings were obtained in turtle Purkinje cells in an *in vitro* brainstem-cerebellum preparation with sharp microelectrodes. Single or repetitive (10-50 Hz) stimuli were applied to the Vn or SL with suction or tungsten electrodes, respectively. Single stimuli produced fast EPSPs (latency: 10-20 ms) only in response to SL stimulation; repetitive stimulation at either stimulus site evoked slow EPSPs (time-to-peak: 100-150 ms) which could drive 'pacemaker' discharges. The EPSPs differed in their sensitivity to EAA antagonists: the fast SL-activated EPSP was blocked by CNQX (10 μ M), reduced by L-AP4 (100 μ M), and was unaffected by D,L-AP5 (100 μ M). In contrast, the slow Vn- and SL-evoked EPSP was not affected by CNQX, potentiated by L-AP4, and blocked by D,L-AP5. Both EPSPs were potentiated by bicuculline (10 μ M). The pharmacologic profile for the slow mossy fiber-evoked EPSP also differs from a slow EPSP previously demonstrated in response to direct, repetitive parallel fiber stimulation (*J. Neurophysiol.* 63:637,1990). The parallel fiber-evoked slow EPSP was blocked by L-AP4 and CNQX, but not by D,L-AP5.

These data further indicate that while both NMDA and non-NMDA EAA receptors are required for the activation of Purkinje cells by mossy afferents, the selective effects of the EAA antagonists rule out the *exclusive* involvement of either receptor type at each synapse. Supported by NS 17489 and NS 25682.

ROLE OF EXCITATORY AND INHIBITORY AMINO ACIDS IN A PRIMARY SENSORY PROCESSING AREA, THE ELECTROSENSORY LATERAL LINE LOBE OF WEAKLY ELECTRIC FISH. J. Bastian, Dept. of Zoology, Univ. of Oklahoma, Norman, OK 73019.

The electrosensory lateral line lobe (ELL) receives the electroreceptor afferent projection as well as descending inputs from higher centers. The descending inputs terminate in a cerebellar-like molecular layer, the fibers of which make synaptic contacts with apical dendrites of the ELL interneurons and output (pyramidal) cells.

Pressure injection of Kainic acid, AMPA, or NMDA near a pyramidal cell's apical dendrite causes short latency excitatory responses as is expected given the prior autoradiographic demonstration of receptors for these substances (Maler and Monaghan, *J. Chem. Neuroanat.*, 4, 1991). These responses are antagonized by application of DNQX in the case of KA or AMPA, or APV in the case of NMDA. Injection of GABA or Baclofen causes short latency inhibition of pyramidal cells which are antagonized by Bicuculline and 2-Hydroxyisaclofen respectively.

Responses to a given substance were sensitive to the position of the injection pipette. Changes in position of from 20 to 40 μ m reversed glutamate mediated excitation of pyramidal cells to inhibition. Inhibitory responses to GABA also reversed to excitation with small changes in pressure injection pipette position. The reversal of a cell's response to a given transmitter agonist with movement of the injection pipette away from the neuron's apical dendrite tree is thought to reflect excitation or inhibition of nearby ELL inhibitory interneurons.

The normally rapidly adapting pyramidal cell responses to electrosensory stimulation were rendered more tonic after application of Bicuculline or DNQX but not APV. The phasic nature of pyramidal cell responses may be explained in part as due to activation of GABAergic interneurons via descending glutaminergic inputs to the ELL molecular layers. GLUTAMATE SYNAPSES ON RETROGRADELY-LABELLED SYMPATHETIC PREGANGLIONIC NEURONS IN THE RAT. P.M. Pilowsky¹, I.J. Llewellyn-Smith^{1,2}, K.D. Phend², J.B. Minson¹ and J.P. Chalmers¹*. ¹Department of Medicine, Flinders University, Bedford Park, Australia and ²Department of Anatomy and Cell Biology, University of North Carolina, Chapel Hill NC 27599.

Physiological and anatomical evidence has suggested that L-glutamate (GLU) is involved in regulating the activity of sympathetic preganglionic neurons (SPN). In this study, we investigated whether or not GLU-immunoreactive synapses occurred on retrogradely-labelled SPN. Cholera toxin B subunit (CTB) was injected into the superior cervical ganglion or adrenal medulla of the rat. After fixation with 2.5% glutaraldehyde, CTB-labelled SPN were revealed by immunocytochemistry with avidin-biotin-peroxidase. GLU-immunoreactive axon terminals that directly contacted or synapsed on retrogradely-labelled neurons were visualized by post-embedding immunogold staining. GLU synapses were found on the cell bodies and dendrites of SPN projecting to the adrenal medulla or to the superior cervical ganglion. Close to two-thirds of the terminals that contacted or synapsed on sympathoadrenal SPN were positive for GLU. Double immunogold labelling for GABA and GLU indicated that GLU-immunoreactive profiles on SPN did not contain GABA and vice versa. These results suggest that GLU may be the major excitatory neurotransmitter regulating sympathetic outflow. This work was supported by the Australian National Health and Medical Research Council and National Heart Foundation.

EXTRACELLULAR AMINO ACID CONCENTRATIONS IN THE VENTROCAUDAL PAG OF FREELY MOVING RATS FOLLOWING VERATRIDINE AND/OR Ω -CONOTOXIN STIMULATION. W. M. Renno*, M. A. Mullett*, and A. J. Beitz. Dept. of Veterinary Biology, Univ. of Minnesota, St. Paul, MN 55108.

Glutamate, aspartate and GABA have been proposed as important neurotransmitters in the periaqueductal gray (PAG). The baseline concentrations and release of these amino acids in response to PAG neuronal depolarization were examined in the present study using *in vivo* microdialysis coupled to high-performance liquid chromatography (HPLC). A chronic guide cannula was implanted into the PAG of male Sprague-Dawley rats using stereotaxic coordinates. Seven to ten days later a microdialysis probe was inserted through the chronic guide cannula into the caudal ventrolateral PAG. The dialysis system was attached to a peristaltic pump and perfused with Ringer's solution (147 mM NaCl, 4.0 mM KCl, and 2.2 mM CaCl₂) at a flow rate of 2-5 μ l/min. Samples were collected at 12 min intervals in polypropylene tubes and analyzed for amino acids, within 12 hours, by HPLC. PAG depolarization with 75 μ M veratridine (ver, a Na channel activator) resulted in a 2,204% increase in aspartate, 2,006% increase in glutamate, 327% increase in glycine, 1,358% increase in taurine and 14,012% increase in GABA. Surprisingly, when 800 nM Ω -conotoxin (con, a calcium channel blocker) was co-administered with 75 μ M ver through the dialysis probe, it potentiated the release of these amino acids (3,670%, 3,108%, 238%, 352%, 1,252%, and 21,417%, respectively). On the other hand 800 nM con by itself produced no significant increase in any of the amino acids under investigation. This study indicates that glutamate and aspartate are released by ver depolarization and these may serve as important excitatory amino acids in the PAG, while GABA appears to play an important inhibitory role in this region. The potentiation of ver induced release of these 3 amino acids by con may reflect a stimulatory effect of con on PAG neurons. Supported by DA06687, DE06682, and NS1920

GABAERGIC AND GLUTAMATERGIC-MEDIATED SYNAPTIC INHIBITION AND EXCITATION IN RAT SUPRAOPTIC NEURONES FROM ACTIVATION OF ORGANUM VASculosum LAMINA TERMINALIS (OVLt). C.R. Yang and L.P. Renaud, Neuroscience Unit, Loeb Research Institute, Ottawa Civic Hosp., Ottawa, Canada, K1Y 4E9.

Neuroanatomical studies have demonstrated that the rat OVLt, a circumventricular structure involved in body fluid homeostasis, projects to the supraoptic nucleus (SON). The present study evaluated the synaptic inputs from the OVLt to SON neurones recorded intracellularly (3M KAc-filled electrode) in superfused rat hypothalamic explants.

Both IPSPs and EPSPs were evoked by electrical stimulation of the OVLt. IPSPs evoked by single-pulse stimulation (50-200 μ A, 0.02ms duration pulses) displayed a mean latency of 9.3 ± 0.4 ms, a mean reversal potential (V_r) of -65 ± 2 mV, and were reversibly blocked by bath-applied bicuculline (10-25 μ M), implying mediation by GABA_A receptors. EPSPs and spikes elicited by single-pulse or repetitive stimulations displayed a mean latency of 8 ± 0.4 ms, a mean V_r of -26 ± 9 mV. The EPSP amplitudes were enhanced in Mg²⁺-free media, were partially blocked by APV (60 μ M), an NMDA receptor antagonist, and were completely and reversibly blocked upon addition of CNQX (10 μ M), an AMPA receptor antagonist, suggesting that both glutamate receptor subtypes mediate these EPSPs. Microinjection of glutamate (50 μ M) onto OVLt, to circumvent activation of fibres-of-passage, induced 3 - 7 mV depolarizations in SON neurones, thus supporting an excitatory OVLt input to the SON.

These results suggest the presence of a glutamatergic pathway linking OVLt neurones with neurosecretory neurones in the SON. This pathway may permit circulating substances acting through this circumventricular structure to influence the secretion of neurohypophysial hormones. (Supported by FRSQ & MRC).

SHORT-LATENCY SENSORY TRANSMISSION THROUGH NMDA RECEPTORS IN RAT SI BARRELFIELD CORTEX. *M. Armstrong-James, **E. Welker, and *C.A. Callahan *Physiology Dept, Queen Mary College, London E1 4NS, and **Institut d'Anatomie, Rue du Bugnon 9, Lausanne, Switzerland.

In adult rat neocortex *in vitro* NMDA-EPSPs play a minor and solely "late" role in transmission, neither of which appears to be so for sensory transmission *in vivo*. Using rats lightly anaesthetized with urethane, post-stimulus time histograms (PSTHs) for SI cortical cells were generated in reply to 50 small abrupt deflections of principal whiskers both with or without iontophoresis of the NMDA antagonist APV. Spikes within successive epochs of PSTHs were counted at 0-9, 10-20, 20-50 and 50-100 ms post-stimulus. Relative to controls, APV reduced counts in the 0-9 ms epoch by a mean of 39% for layer IV cells and 83% for layer III cells, and by 80-100% (layer I-IV) for subsequent epochs (10-100 ms). Since the earliest evoked spikes occurred at 6-8 ms post-stimulus, (4-6 ms in the thalamic relay nucleus), these results suggest that in lightly anaesthetized rats monosynaptic thalamocortical fast EPSPs with a rise-time of <3ms to natural stimuli are about equally expressed through a mixture of NMDA and non-NMDA channels, with later (10-100 ms latency) intracortical relay largely being expressed through NMDA channels. Support: Swiss NSF 3100.009468.

EXCITATORY AMINO ACID (EAA) ACCUMULATING NEURONS WITHIN BRAINSTEM RESPIRATORY CIRCUITRY OF THE RAT. H.H. Ellenberger & J.L. Feldman. Systems Neurobiology Lab., Dept. of Kinesiology, UCLA, Los Angeles, CA 90024-1527.

Respiratory neurons that utilize EAAs for neurotransmission were selectively labeled in rats by retrograde transport of D-[³H]aspartate (D-[³H]Asp). D-[³H]Asp is selectively internalized and accumulated within the parent cell body of neurons that possess a high-affinity uptake system for glutamate or aspartate along the synaptic region of their terminal bouton membranes. Injections of D-[³H]Asp (~30 nl; 10-20 μCi) were made into the inspiratory portion of the rostral ventral respiratory group (rVRG) to identify the source(s) of presumptive EAA inputs to rVRG. Retrogradely labeled neuron somata were visualized by autoradiographic methods in Thionin counterstained tissue.

D-[³H]Asp labeled neurons were distributed within several subnuclei of the ipsilateral nucleus of the solitary tract and bilaterally within the VRG. D-[³H]Asp injections into rVRG labeled fewer neurons than we have previously observed utilizing non-selective retrograde tracers (e.g., rhodamine beads [Ellenberger & Feldman, Brain Res., 513:35-42, 1990]). We propose that these presumptive EAA neurons represent medullary sources of excitatory inputs to bulbospinal and propriobulbar inspiratory neurons of rVRG. The remaining neurons labeled by non-selective tracers but not by D-[³H]Asp within medullary respiratory groups may represent inhibitory or non-EAA modulatory neurons that project to rVRG. Supported by NIH grant NS 24742 and American Lung Association grant J900701.

LOCALIZATION OF NMDA AND AMPA RECEPTORS IN RAT BARREL FIELD. D. Jaarsma, J.B. Sebens, G.J. ter Horst* and J. Korff, Depts. Biol. Psychiatry and Neurobiology*, University Groningen, P.O.Box 30.001, 9700 RB Groningen, The Netherlands.

In layer IV of the face portion of the rat primary sensory cortex (barrel field) the pattern of termination of excitatory afferents is highly organized, the thalamic and the cortical afferents ending in the barrel hollow and in the septa between the barrels, respectively. In an attempt to correlate the origin of excitatory input with a specific subtype of excitatory amino acid receptor, we studied the distribution of N-Methyl-D-aspartate (NMDA) and α-Amino-3-hydroxy-S-methyl-4-isoxazole propionic acid (AMPA) receptors in rat somatosensory cortex using *in vitro* receptor autoradiography. Freshly frozen brains from 8 male Wistar rats were used. Sections were cut in the transversal, horizontal or tangential plane, thaw-mounted, and incubated with the competitive NMDA antagonist [³H]CGP39653 (20 nM), or [³H]glycine (150 nM) in the presence of 1 mM strychnine to label NMDA receptors, or with [³H]AMPA (100 nM) to label AMPA receptors. Autoradiograms were generated by apposing the sections against emulsion coated coverslips. NMDA, but not AMPA receptors were heterogeneously distributed throughout the barrel field with high density levels in the hollows and low levels in the barrel sides and septa. The table shows the densities of silver grains as a percentage of grain density in layer II/III of the SI cortex.

barrel subfield:	anterolateral hollow side	posteromedial hollow side
[³ H]CGP39653	87 44	82 55
[³ H]glycine	75 49	84 57
[³ H]AMPA	82 76	78 79

These results suggest that in rat barrel field the NMDA receptors are mainly present in the thalamo-cortical synapses, whereas AMPA receptors are present in both the corticocortical and the thalamocortical synapses. (Supported by NWO/MW, grant 552.076)

SYNAPTICALLY MEDIATED COMPONENT OF THE NEOSTRIATAL FIELD POTENTIAL IS HIGHLY SENSITIVE TO DNQX AND CNQX. J.A. Wilson. Division of Physiology, Creighton Univ. Sch. of Medicine, Omaha, NE 68178

The neostriatum receives major inputs from the cortex, thalamus, and substantia nigra. There has been much interest in the nigral dopaminergic inputs due to their association with Parkinson's disease; however, the transmitters used in the other pathways have been more difficult to establish. Cordingley & Weight (Br. J. Pharmacol. 88 (1986) 847-856) tested many agents thought to act at a variety of synapses and suggested that a glutamate like neurotransmitter mediated cortico-striate synaptic transmission. Though they were unable to differentiate between classes of glutamate receptors, their findings are consistent with the hypothesis that the cortico-striate field potential is mediated by a kainate/quisqualate type receptor. To test this hypothesis, the newer antagonists CNQX and DNQX were applied to mouse nigrostriatal brain slices. ED₅₀s were estimated to be 1.25 μM for CNQX and 1.6 μM for DNQX. This finding is interpreted as strong support for Cordingley and Weight's suggestion that a glutamate like transmitter mediates cortico-striate synaptic transmission.

IMMUNOLABELING OF TERMINALS OF CORTICAL DESCENDING FIBERS I. Valtchanoff, R.J. Weinberg, A. Rustioni. Depts. of Cell Biology & Anatomy and of Physiology, University of North Carolina, Chapel Hill, NC 27599.

Previous work from our lab has found that a large fraction of cortical neurons with descending projections immunostain with an anti-glutamate antibody. While this suggests that these neurons may use glutamate as neurotransmitter, immunostaining of terminals, as reported here, provides more direct evidence. To identify these terminals, pressure injections of WGA-HRP were made in the sensorimotor cortex of anesthetized Sprague-Dawley rats. After 48 h survival, the animal was anesthetized and perfused with glutaraldehyde/formaldehyde/picric acid fixative. Fifty μm Vibratome sections of medulla and cervical spinal cord were cut, reacted for TMB with tungstate stabilizer (Weinberg & Van Eyck, J. Histochem. Cytochem. in press), and processed for light and electron microscopy.

Terminal labeling in the caudal medulla was concentrated in the dorsal column nuclei; in the spinal cord, labeling was concentrated in laminae 3, 4, and 5. Ultrastructurally, labeling in the form of electron-dense crystals and amorphous deposits was inside small dome-shaped terminals. In some cases, labeling could also be seen in postsynaptic elements, including dendrites, somata, and glia and in the extracellular space outside cortical terminals. Postembedding ICC (using methods described in Phend et al., Soc. Neurosci. Abstr. 18) revealed that the large majority of the labeled terminals were positive for glutamate, and did not stain above background for GABA.

This research was supported by NINDS award #NS-16264.

CNOX INCREASES SPONTANEOUS INHIBITORY INPUT TO CA3 PYRAMIDAL NEURONS OF THE NEONATE RAT HIPPOCAMPAL SLICE. I.V. EATON[†], C.J. McBAIN, T.A. BROWN, & R. DINGLEDDINE. Dept. Pharmacology & Curr. Neurobiology, Univ. of North Carolina, Chapel Hill, NC 27599-7365.

6-Nitro-7-cyano-quinoxaline-2,3-dione (CNOX) acts at non-NMDA receptors to block polysynaptic inhibitory input in the hippocampal slice (Davies and Collingridge, Proc. R. Soc. Z36:373,1989). We investigated the effects of CNOX on spontaneous inhibitory input to CA3 pyramidal neurons in neonate rat hippocampal slices (4-10 days; 300 μ m) using the whole-cell patch clamp technique. Instead of blocking spontaneous inhibitory input to CA3 pyramids, CNOX (3 μ M) increased the frequency of inhibitory post-synaptic currents (IPSCs). IPSC frequency was increased from a control of 2.24 ± 0.6 Hz to 4.37 ± 1.1 Hz (n=16 neurons) without affecting the holding current. CNOX did not significantly affect the amplitude (control = 12.7 ± 0.8 pA and 13.9 ± 0.8 pA after CNOX) or the decay time constant (τ) (control = 23.9 ± 2.2 ms and 23.0 ± 1.3 ms in CNOX) of the IPSCs. Other structurally related quinoxalines varied in effect as IPSC frequency was increased by DNQX but decreased by NBQX. The majority of IPSCs observed, both in control and following addition of CNOX, were eliminated by 1 μ M tetrodotoxin (TTX), suggesting that the majority of IPSCs in CA3 are driven by action potential firing in inhibitory interneurons. Recordings made from interneurons of *st. radiatum* revealed that CNOX blocked spontaneous EPSCs in the interneurons while leaving the IPSCs intact. CNOX also induced an inward current and concomitant burst firing in the interneurons, presumably the mechanism responsible for the increased frequency of IPSCs in CA3 pyramids. These results suggest that CNOX, while acting as a non-NMDA receptor antagonist, has an additional direct excitatory action on some hippocampal interneurons.

NBQX BLOCKS SYNAPTIC TRANSMISSION IN RAT HIPPOCAMPAL SLICES. J.M. GOLDSTEIN, L.C. LITWIN* and A.J. SALAMA. ICI Pharmaceuticals Group, ICI Americas Inc., Wilmington, DE 19897 USA

NBQX (2,3-dihydroxy-6-nitro-7-sulfamoyl-benzo(F)quinoxaline) is a potent and selective inhibitor of binding to the quisqualate subtype of the glutamate receptor, with essentially no binding affinity at the N-methyl-D-aspartate (NMDA) or glycine sites. We examined the effects of NBQX on both NMDA and non-NMDA-mediated excitatory postsynaptic potentials (EPSPs) in area CA1 of the rat hippocampus, and compared its activity to the nonselective NMDA antagonist DNQX (6,7-dinitroquinoxaline-2,3-dione). In the presence of Mg⁺⁺ (non-NMDA mediated synaptic transmission), bath application of NBQX caused potent and reversible antagonism (IC₅₀=0.66 μ M) of EPSPs evoked by stimulation of the CA3 Schaffer collateral-commissural fiber system. When the studies were conducted in Mg⁺⁺-free medium (NMDA and non-NMDA transmission) concentrations of NBQX up to 30 μ M reduced by 50% but did not abolish the EPSPs. These residual EPSPs could, however, be completely abolished by the addition of the competitive NMDA antagonist CPP (10 μ M). When similar studies in zero Mg⁺⁺ were conducted with DNQX (10 μ M), this agent was also found to reduce but not abolish the synaptic response to CA3 stimulation. In addition, bath application of CPP (10 μ M) with DNQX again resulted in a further reduction of the EPSPs. However, in marked contrast to the inhibitory actions of NBQX, the inhibitory actions of DNQX could be reversed by bath application of D-serine (200 μ M). The results of these studies suggest that NBQX is a selective antagonist of non-NMDA mediated synaptic transmission in the rat hippocampus. These data further support the hypothesis that DNQX is a non-NMDA antagonist with additional actions at the glycine modulatory site of the NMDA receptor complex.

Regulation of Kainate/AMPA Currents in Cultured Hippocampal Neurons. E.J. Fletcher, Lu Wang and J.E. MacDonald. Depts. of Physiology and Pharmacology, University of Toronto, Toronto, Ont. M5S 2A8.

We have examined the possible regulation of kainate/AMPA receptors by cAMP-dependent kinase (PKA). Whole cell or perforated patch recordings were made from cultured hippocampal neurons. Kainate was applied by pressure from pipettes or individual neurons were constantly perfused and agonist applied using a motorized system. Kainate currents declined or "ran down" during whole cell patch recordings when conventional pipette solutions were employed. This rundown could be retarded by including an ATP regenerating system (ATP, creatine, creatine phosphokinase) within the patch electrode. Even more effective was the inclusion of cAMP and/or the catalytic subunit of PKA. Kainate currents recorded using the perforated patch technique were potentiated by the phosphatase inhibitor okadaic acid as well as by cAMP activators. In order to determine which pharmacological parameters were altered during rundown dose-response relations were determined relatively soon after break through and then again after 20 to 30 mins of whole cell recording. The rundown of kainate currents was associated with an average increase in the K_d value of approximately 60% (from 33 to 55 μ M) as well as a 20% decrease in R_{max} values. In a separate group of neurons the patch pipette also included the ATP regenerating solution and no significant shift in the dose-response relationship was observed. In contrast to whole cell recordings kainate and AMPA currents did not demonstrate any time-dependent decline in amplitude. This evidence suggests that phosphorylation by endogenous PKA may be an important step in maintaining kainate/AMPA currents in these neurons. Supported by a grant to the MRC "Nerve Cell & Synapses" Group.

PATCH CLAMP RECORDINGS FROM INTERNEURONES OF HIPPOCAMPAL SUBFIELD CA3; RESPONSES TO EXCITATORY AMINO ACIDS. C. J. McBAIN and R. DINGLEDDINE. Dept. of Pharmacology, Univ. of North Carolina, Chapel Hill, NC 27599-7365.

Using the whole cell patch clamp technique we have made recordings from interneurons of CA3 stratum radiatum located in the neonate (3-15 days) rat hippocampal slice (300 μ m thick). Interneurons possessed a mean input resistance of 380 ± 52.2 megohm at a mean resting potential of -59 ± 2.6 mV (n=10 neurons). In the presence of 5 μ M bicuculline, spontaneous excitatory events were small in amplitude (mean = 8.5 ± 1.4 pA) and had a frequency of 1.43 ± 0.47 Hz. At a holding potential of -70 mV the decay time constant of spontaneous EPSCs was described by a single exponential of 15.9 ± 3.2 msec (n=8). This was significantly faster than the decay time constant observed in CA3 pyramidal neurons (mean = 21.9 ± 2.4 msec; n=11 neurons).

The I-V relationship of the glutamate receptor agonists, kainate (100 μ M) and AMPA (30 μ M) are linear in CA3 pyramidal neurons and reverse polarity at ~ 0 mV. The I-V relationships of these agonist responses in interneurons however were highly variable. The response to kainate was either linear or possessed marked inward rectification. The I-V responses to AMPA were more complex. Interneurons displayed either linear responses, inward rectification or outward rectification. These currents reversed polarity at ~ 10 mV. These data suggest that the glutamate receptors present on inhibitory interneurons differ from those in CA3 pyramidal neurons in their responses to both exogenous and endogenous excitatory amino acids.

QUINOXALINE DERIVATIVES (QD): INHIBITION OF EXCITATORY AMINO ACID (EAA) RECEPTOR CURRENTS AND SYNAPTIC POTENTIALS. J.C.R. Randle*, I. Guet**, C. Bobichon**, C. Moreau**, P. Curutchet**, B. Lamboloz**, L. Prado da Carvalho**, A. Cordi** and J. Lepagnol**. *FONDAX - Groupe Servier, 92800 Puteaux, **Inst. de Recherche Servier 92210 Suresnes, **Labo. Physiol. Nerveuse, CNRS, 91190 Gif/Yvette, FRANCE.

The relative EAA receptor inhibitory potencies of 11 QDs were evaluated. Kainate, AMPA and NMDA/glycine currents in voltage-clamped rat cortex mRNA-injected *Xenopus* oocytes were inhibited by all the QDs. Apparent K_i values for inhibition of kainate and AMPA currents were closely correlated over a >1000-fold range of potencies (CNOX = 0.16 μ M --> QX = 300 μ M) indicating that the two EAA agonists act at a single site. The QDs all potently inhibited NMDA/glycine current; K_i values varied only 20-fold (MNQX = 0.28 μ M --> 5NQX = 6 μ M). Excitatory postsynaptic field potentials were recorded in the CA1 region of hippocampal slices following electrical stimulation in the stratum radiatum in 1 mM Mg⁺⁺ or Mg⁺⁺-free medium. QD IC₅₀ values in 1 mM Mg⁺⁺ correlated with K_i values against kainate and AMPA in oocyte experiments, but were 10-fold higher. QD IC₅₀ values in Mg⁺⁺-free medium correlated with K_i values vs. NMDA/glycine in oocytes, but were 50-fold higher. Comparison of these two sets of results suggests that hippocampal synaptic transmission is mediated by near-saturating local concentrations of the endogenous ligands acting on kainate/AMPA and NMDA-type receptors.

SYNTHESIS AND EXCITATORY AMINO ACID PHARMACOLOGY OF A SERIES OF HETEROCYCLIC FUSED QUINOXALINONES AND QUINAZOLINONES. E.C.R. Smith, L.A. McQuaid, A.J. Williams*, C.H. Mitch, P.L. Ornstein, K.K. South*, P.J. O'Malley*, D.O. Calligaro, D. Lodge, R.A. True*, and D.D. Schoepp. Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, IN 46285 and Royal Veterinary College, London, NW10TU, UK.

As a part of our program aimed at identifying novel, potent antagonists of the AMPA excitatory amino acid receptor we have prepared a series of triazolo-, tetrazolo-, imidazo-, and pyrazolo-fused quinoxalinones and quinazolinones related to dichloroquinoxalinedione and dinitroquinoxalinedione. Among the derivatives evaluated, appropriately substituted triazolo[4,3-a]quinoxalin-4(5H)-ones exhibited the greatest affinity for the both the AMPA receptor and for the glycine site on the NMDA receptor. In fact, LY133578, represents a more potent antagonist of the glycine site (K_i = 0.63 μ M) than of the AMPA receptor (IC₅₀ = 7.0 μ M). Additionally, 7,8-dichloroimidazo[1,2-a]quinoxalin-4(5H)-one, LY282261, was found to possess good affinity for the glycine site (K_i = 1.3 μ M.) Antagonist activity at the glycine site was substantiated by a corresponding inhibition of [³H]-MK801 binding. Compounds such as these which act by functionally inhibiting both NMDA and AMPA receptors may offer a distinct advantage in the treatment of ischemic episodes.

108.7

DISCRIMINATIVE EFFECTS OF NBQX, (2,3-DIHYDROXY-6-NITRO-7-SULFAMOYL-BENZO(F)QUINOXALINE).

M. D. B. Swedberg, P. Jacobsen * and T. Honoré *. Novo Nordisk, CNS Division, Sydmarken 5, DK-2860 Soeborg, Denmark.

NBQX, a potent and selective inhibitor of AMPA receptor binding, has anticonvulsant (1) as well as antiischemic properties (2). The present studies examined NBQX for substitution in rats discriminating phencyclidine (PCP; 3.0 mg/kg, i.p., 15 min) from no drug, morphine (3.0 mg/kg, i.p., 30 min) from no drug, or for antagonism in rats discriminating pentyletetrazole (PTZ; 17.5 mg/kg, i.p., 15') from no drug. NBQX (3.0 - 30.0 mg/kg) produced no PCP-like effects (< 1%); there was a dose dependent depression of rate of responding with a max effect of 0.5 % of vehicle rates at 30.0 mg/kg. NBQX (1.0 - 30.0 mg/kg) also did not produce morphine-like effects up to doses that totally eliminated responding (30.0 mg/kg). NBQX (1.0 - 30.0 mg/kg) only slightly and non dose dependently attenuated PTZ with a max of 25% at 1.0 mg/kg of NBQX. These data indicate that NBQX is only marginally effective as an anxiolytic, and does not possess abuse liability of PCP or opiate type.

IN VIVO ELECTROPHYSIOLOGICAL AND BEHAVIORAL EFFECTS OF THE SELECTIVE AMPA ANTAGONIST, 2,3-DIHYDROXY-6-NITRO-7-SULFAMOYL-BENZO(F)QUINOXALINE (NBQX). L.T. Meltzer, K.A. Serpa, A. Corbin, J. Wiley*, T.G. Heffner. Parke-Davis Pharm. Res. Div., Warner-Lambert Co., Ann Arbor, MI 48105.

NBQX is a selective antagonist of AMPA-type glutamate receptors *in vitro*. In the present studies, the *in vivo* CNS consequences of systemic administration of NBQX were evaluated. In electrophysiological experiments, the effects of NBQX were determined on the dentate gyrus e.p.s.p. and population spike evoked by electrical stimulation of the perforant path in urethane anesthetized rats. A current-response curve was generated every 15 min for 30 min preinjection and 1 h postinjection. NBQX (30 mg/kg i.v.) increased the latency to and reduced the amplitude of the evoked dentate gyrus population spike. The NBQX induced effects were present for the duration of the postinjection period. No effects were observed on the slope of the e.p.s.p. In behavioral experiments in rats, NBQX (30 mg/kg i.v.) inhibited spontaneous locomotion, produced catalepsy and produced analgesia (tail pressure assay). All these effects were determined 15 - 30 min postinjection. In the electrophysiological and behavioral studies lower doses of NBQX (3 - 10 mg/kg i.v.) had very little or no effect. These data indicate that systemically administered NBQX can block a CNS glutamate-mediated response and begin to characterize some of the behavioral consequences of this action.

108.11

ANTICONVULSANT PROPERTIES OF THE NONNMDA RECEPTOR ANTAGONIST, 2,3-DIHYDROXY 6-NITRO-7-SULFAMOYL-BENZO(F)QUINOXALINE (NBQX). S. Hoshino, D.W. Bonhaus and J.O. McNamara, Duke and V.A. Med. Ctrs., Durham, N.C. 27710

Antagonists of nonNMDA subtypes of excitatory amino acid receptors exhibit anticonvulsant properties *in vitro*. In certain of these models nonNMDA antagonists have greater efficacy than NMDA receptor antagonists. However, little is known about the properties of nonNMDA receptor antagonists *in vivo*. In this study, we examined the effects of NBQX, a potent antagonist of nonNMDA excitatory amino acid receptors, in two seizure models, electroshock (ES) and electrically-induced hippocampal afterdischarge (AD). Injection of NBQX (3 to 30 µg) into the lateral ventricle (ICV) failed to reduce the duration of ES-induced tonic hindlimb extension or the duration of the primary AD evoked by hippocampal stimulation. NBQX (10 µg) did reduce the number of wet-dog-shakes (from 22.0 ± 1.9 to 0.3 ± 0.2; p < 0.003) and the recurrent discharge (from 21.3 ± 3.1 to 3.0 ± 3.0 seconds; p < 0.02) evoked by hippocampal stimulation. NBQX (10 and 30 µg) also produced a behavioral toxicity (loss of muscle tone, ataxia and sedation) which resembled that produced by NMDA receptor antagonists. The inhibitory effects of NBQX on behavior, wet-dog-shakes and recurrent discharge were partially reversed by co-administration of D-serine. These findings demonstrate that NBQX has some anticonvulsant activity *in vivo*. However, since the behavioral and anticonvulsant profile of NBQX was found to be identical to that of 7-chloro-kynurenic acid (an antagonist of the glycine recognition site on the NMDA receptor) and since the actions of NBQX were partially reversed by D-serine (a selective agonist at the glycine site) these findings raise the possibility that at least some of the *in vivo* actions of NBQX are mediated by inhibiting glycine binding to the NMDA receptor.

108.8

IN VIVO NEUROPROTECTIVE, AND ANTICONVULSANT ACTIONS OF 2,3-DIHYDROXY-6-NITRO-7-SULFAMOYL-BENZO(F)QUINOXALINE (NBQX). M.G. Vartanian, J.W. McDonald¹, and C.P. Taylor. Parke-Davis Pharm. Res. Div., Warner-Lambert Co., Ann Arbor, MI. 48105, and ¹University of Michigan, Ann Arbor, MI.

NBQX is a selective AMPA-type glutamate receptor antagonist, which has been shown to reduce global ischemic injury. The neuroprotective effects of NBQX were assessed in postnatal day (PND) 7 rats that received a unilateral intrastratial injection of 10 nmol/0.5 µl AMPA ((RS)-α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid) by comparison of cerebral hemisphere weights on PND 12. Post-treatment (15 min) with single doses of NBQX (3, 10, 30 mg/kg, i.p.) did not reduce brain injury and higher doses increased mortality. Repeated post-treatment dosing reduced the severity of injury (20 mg/kg, i.p., 15, 60, 105 min; 35.5 ± 9.8% protection, p < 0.05). Co-intrastratial injection of NBQX with 10 nmol AMPA was most effective (40 nmol, 70.1 ± 7.9% protection, p < 0.001).

NBQX produced rapid and short lasting (15-180 sec) suppression of tonic extensor seizures induced by low-intensity (ED₅₀ = 6.0 mg/kg IV) and maximal (ED₅₀ = 13.1 mg/kg IV) electroshock in mice. Pronounced behavioral side-effects were not noticed until doses of at least 30 mg/kg IV had been attained. These effects included ataxia, reduction of skeletal muscle tone, and decreases of spontaneous locomotor activity. The data show that NBQX is a short acting effective blocker of AMPA induced neurodegeneration in perinatal rat pups, and prevents electroshock induced tonic extensor seizures in mice.

DIAZEPAM WITHDRAWAL PREVENTED BY AMPA ANTAGONIST NBQX.

K.G. Steppuhn and L. Turski, Res. Labs of Schering AG, 1000 Berlin 65, Germany.

The benzodiazepines (BDZs) are most commonly prescribed psychoactive drugs for the therapy of modern society disorders such as anxiety and sleep disturbances. Long term treatment leads to tolerance and dependence on BDZs. Abrupt termination of BDZs administration gives rise to unpleasant withdrawal syndromes. Adult NMRI mice withdrawn from chronic administration of diazepam (15 mg/kg/day) showed a time related evolution of anxiety, muscle rigidity and seizures between days 4 and 21 after discontinuation of the treatment. The peak intensity of withdrawal symptoms was detected at days 5 and 7. A period between withdrawal days 1 and 3 was symptom-free. This "silent phase" was characterized by lowering of the threshold for ATPA (α-amino-3-hydroxy-5-tert-butyl-4-isoxazolepropionate; an AMPA agonist) and kainate seizures, and an increased magnitude of monosynaptic reflexes [mediated by non-N-methyl-D-aspartate (NMDA) mechanisms]. The "active phase" of withdrawal, between days 4 and 21, was characterized by a lowering of the threshold for NMDA seizures and enhanced magnitude of polysynaptic reflexes (which are NMDA dependent). Treatment of mice with the AMPA antagonist NBQX (2,3-dihydroxy-6-nitro-7-sulfamoyl-benzo(F)quinoxaline; 10 mg/kg/h), but not with the NMDA antagonist CPP (3-([(2S)-carboxypiperazin-4-yl]-propyl)-1-phosphonate; 10 mg/kg/h) during the "silent phase" of withdrawal prevented or reduced the evolution of withdrawal symptoms. No muscle rigidity and seizures, and little anxiety were observed up to withdrawal day 21 in mice subjected to NBQX treatment during first three withdrawal days. These data indicate that excitatory neurotransmission mediated by L-glutamate may be differentially involved in withdrawal observed after abrupt termination of BDZ treatment. The non-NMDA phase of withdrawal is short and symptom-free, but essential for triggering clinical symptoms of withdrawal. Interference with non-NMDA mediated mechanisms during the "silent phase" of withdrawal by using AMPA antagonists such as NBQX may offer a therapeutic approach for preventing the evolution of withdrawal symptoms after BDZs, and perhaps other sedative drugs such as barbiturates and alcohol.

108.12

ARCAINE NEGATIVELY MODULATES RESPONSES OF NMDA RECEPTORS EXPRESSED IN XENOPUS OOCYTES. C. Maciver, D. Bednar, J. Ferkany and W. Karbon, Nova Pharmaceutical Corporation, Baltimore, MD 21224-2788.

In addition to containing recognition sites for the coagonists NMDA and glycine (Gly), the NMDA receptor complex also harbors a polyamine modulatory site through which compounds such as spermine augment NMDA/Gly-induced cation flux. In the present study we tested the effects of several polyamines on NMDA receptor function using rat brain mRNA-injected *Xenopus* oocytes with particular emphasis on arcaine (1,4-diguandinobutane), a putative polyamine antagonist. Spermine enhanced the response to the combined application of NMDA (100 µM) and Gly (3 µM), and increased the functional potency of Gly, but not NMDA. In contrast, both arcaine and 1,10-diaminodecane inhibited NMDA/Gly-induced currents. The inhibitory potency of arcaine was comparable in the absence (60.1 µM) and presence (52.8 µM) of spermine and, similarly, the potency of spermine to enhance NMDA/Gly-induced currents was unaffected by arcaine (49.8 µM and 43.5 µM in the absence and presence of arcaine, respectively). However, the maximal response to spermine was substantially reduced in the presence of arcaine. Putrescine and diethylenetriamine, reported polyamine antagonists, also inhibited NMDA/Gly-induced currents in the absence of spermine, and did not attenuate the inhibitory response to arcaine. These findings suggest that spermine and arcaine act at distinct, non-interacting sites on the NMDA receptor complex and that arcaine functions as a negative allosteric modulator or inverse agonist.

108.13

DUAL EFFECT OF SPERMINE ON THE N-METHYL-D-ASPARTATE-EVOKED [³H]-NOREPINEPHRINE RELEASE. L. Facheris*, C. Speciale and R.G. Fariello. Farmitalia Carlo Erba-Erbamont Group, R&D CNS Dept., 20014 Nerviano, Milano, Italy.

A modulatory role for endogenous polyamines on the N-methyl-D-aspartate (NMDA) receptor has been suggested. Recently, the effect of spermidine on the NMDA-evoked release of [³H]-Norepinephrine (³HNE) in rat hippocampal slices has been studied. We now present experiments using 1 mM spermine (SPM) and extending data analysis to the post-NMDA fractions (tail). Hippocampi obtained from Wistar rats (200-220 g) were used and experiments performed according to Vezzani et al., J. Neurochem. 49:1438, 1987. Five minutes fractions were collected and fractional release (FR) expressed as per cent of ³HNE present in the tissues at correspondent times. Under these conditions, SPM decreased ³HNE release to 60±7% of control (100% FR= 3.37±0.49, 100 μM NMDA). In the tail FR, measured up to 25 min, a prolongation of the NMDA effect was found (20'-25' FR= 0.33±0.02% and 1.00±0.08% without and with SPM, respectively). SPM was totally inactive on the ³HNE release evoked by 200 μM kainate in the absence of Mg⁺⁺. In the presence of 50 mM K⁺ and 1.2 mM Mg⁺⁺ (100% FR= 12.38±1.51), SPM decreased ³HNE release to 62±7%, but no effect was observed in the tail FR. Data suggest a dual component in the pharmacological action of SPM on the NMDA receptor function.

108.15

POLYAMINES MODULATE NMDA-INDUCED NEUROTOXICITY M. Munir, S. Subramaniam and P. McGonigle, Dept. of Pharmacology, Univ. of Pennsylvania, Philadelphia, PA 19104.

The presence of high concentrations of polyamines in the brain and their ability to modulate activation of the NMDA receptor-channel has led to the suggestion that they may have a role as endogenous modulators of NMDA receptor function. We have studied the ability of polyamines to modulate NMDA-induced neurotoxicity in the rat. Unilateral injections of NMDA in the presence or absence of polyamines were made into the striatum of 7 day old rat pups using the following coordinates: 2 mm lateral and 0.2 mm anterior to the bregma and 4 mm deep from the dura. After 5 days, the brains were removed and 20 μm thick sections were cut at the plane of injection and stained with cresyl violet. A computer-based image analysis system was used to densitometrically measure regions of necrosis and neuronal loss in the stained sections. These measurements were normalized with respect to the unlesioned contralateral side. Different doses of NMDA (5-35 nmol) were injected to determine the dose response relationship in this paradigm. A dose of 15 nmol produced a lesion of intermediate size and was chosen to determine the effects of co-injected polyamines. The polyamine agonist, spermine (10-200 nmol), offered marginal protection against neurotoxicity at lower doses whereas higher doses exacerbated the toxicity of NMDA in a dose-dependent fashion. The inverse agonist DA-10 produced only a small increase in the toxicity of NMDA at the highest doses tested. The divergence in the dose-response relationship between spermine and DA-10 suggests that the effect of spermine is a specific action mediated through the NMDA receptor. (Supported by USPHS GM 34781 and the Pew Charitable Trusts)

108.17

EVIDENCE OF DISSOCIATION BETWEEN THE MECHANISMS OF DOMOIC ACID AND KAINIC ACID TOXICITY IN VIVO. S.M. Strain and R.A.R. Tasker. Dept. of Anatomy & Physiology, Atl. Vet. College, U.P.E.I., Charlottetown, P.E.I., Canada, C1A 4P3

Based largely on *in vitro* evidence the neurotoxins domoic acid (DOM) and kainic acid (KA) have been presumed to produce toxicity by an identical mechanism. *In vivo*, however, these compounds produce some recognizably different behaviours. We have investigated the actions of drugs known to interact with excitatory amino acid (EAA) systems on DOM and KA toxicity. Drugs were administered 15 minutes prior to TD50s of KA and DOM in groups of female CD-1 mice. Measures of overall toxicity and latency to onset of toxic behaviours were recorded. With most EAA antagonists tested the response to DOM and KA was similar, however CPP (15mg/kg), a competitive NMDA antagonist produced a significantly greater reduction in the toxicity of KA than DOM. Injection of the EAA agonists NMDA and Quisqualic acid significantly altered DOM toxicity while having no effect on KA toxicity. Low doses of morphine (2 & 4 mg/kg) produced the greatest reduction in DOM toxicity of all drugs tested but had minimal effects on the toxicity produced by KA. Finally, toxicity following co-administration of DOM and KA was not additive. We conclude that the mechanisms responsible for DOM and KA toxicity *in vivo* are pharmacologically similar but not identical.

108.14

ONTOGENETIC PROFILE OF REGIONAL POLYAMINE EFFECTS ON THE NMDA RECEPTOR S. Subramaniam and P. McGonigle, Dept. of Pharmacology, University of Pennsylvania, Philadelphia, PA 19104.

Polyamines are thought to modulate the activation of NMDA receptors through a unique allosteric regulatory site. We have characterized the regional effects of polyamines on the NMDA receptor during development using a quantitative autoradiographic assay for [³H]MK-801. The binding of [³H]MK-801 in discrete brain regions was measured in the presence and absence of polyamines in 3, 7, 15, 25 and 60 day old Sprague-Dawley rats. In the absence of added polyamines, [³H]MK-801 binding in different brain regions increased during development, peaking at 15 days and then gradually declining to adult levels. The effect of the polyamine agonist spermidine (75 μM) was greatest during early development, enhancing binding by 300% at 3 days. This effect declined between 5 and 25 days and then increased to 40% at 60 days. The pattern of regional variability observed in the effects of spermidine was similar to that in the adult except at 3 days when [³H]MK-801 binding was extremely low. The weak partial agonist DET (1 mM) stimulated binding at 3 and 7 days and had a progressively greater inhibitory effect at later developmental stages. Spermidine and DET produced a complementary pattern of regional effects at 7, 15, 25 and 60 days, spermidine tending to enhance binding to a greater extent in the ventromedial striatum and DET producing a greater inhibitory effect in the dorsolateral striatum. In contrast, no regional heterogeneity was observed for the inhibitory effects of the inverse agonist DA-10. The varied profile of polyamine effects observed in this study suggests that the role of these endogenous substances may change during development. (Supported by USPHS GM 34781 and the Pew Charitable Trusts)

108.16

POLYAMINE EFFECTS ON THE NMDA RECEPTOR IN HUMAN BRAIN P. McGonigle, A. Dai, M.L. O'Connor and S. Subramaniam, Dept. of Pharmacology, University of Pennsylvania and Dept. of Neurosurgery, Graduate Hospital, Philadelphia, PA 19104.

Polyamines are thought to modulate the activation of NMDA receptors through a unique allosteric regulatory site. The effects of polyamines on the binding of [³H]MK-801 were measured in cortical and hippocampal tissue that was surgically removed to relieve intractable seizures. The polyamine agonist spermidine increased the binding of [³H]MK-801 in the cortex in a dose-dependent manner and this effect could be blocked by the weak partial agonist diethylenetriamine (DET). Spermidine (75 μM) decreased the K_d of [³H]MK-801 for the NMDA receptor from 4.3 ± 0.5 nM to 1.6 ± 0.3 nM but did not alter the density of receptors. Spermidine had essentially the same effect on the K_d and B_{max} for [³H]MK-801 measured in the dentate gyrus. The binding of [³H]MK-801 in human cortex was decreased by 30% by incubation with DET (1 mM). Pre-washing the tissue sections at room temperature for 1 hr also decreased binding by 30%, suggesting that the tissue contains an endogenous agonist that is removed by washing. In contrast, DET alone does not alter the binding of [³H]MK-801 in rat cortex. Moreover, pre-washing sections of rat brain produces an increase rather than a decrease in binding suggesting that there are different endogenous modulators for the polyamine site in rat than in human tissue. The inverse agonist 1,10-diaminododecane decreased the binding of [³H]MK-801 in a dose-dependent manner and this effect could also be blocked by DET. These results suggest that the fundamental modulatory properties of polyamines in rat and human tissues are essentially the same and that endogenous polyamines may regulate human NMDA receptors (Supported by GM 34781 and the Pew Charitable Trusts)

108.18

ARCAINE BLOCKS OPEN N-METHYL-D-ASPARTATE (NMDA) CHANNELS. S.D. Donevan, S.M. Jones and M.A. Rogawski, Medical Neurology Branch, Neuronal Excitability Section, NINDS, NIH, Bethesda, MD 20892.

Recent studies have suggested that arcaïne is an antagonist at the NMDA receptor complex (Reynolds, *Eur. J. Pharmacol.* 177:215, 1990; Sacaan & Johnson, *Mol. Pharmacol.* 38:705, 1990). Arcaïne blocks polyamine-stimulated increases in NMDA-evoked [³H]MK-801 binding in a competitive manner. In addition, arcaïne inhibits NMDA-induced [³H]MK-801 binding in the absence of added polyamines. In the present study, we examined the interaction of arcaïne with the NMDA receptor using whole cell and single channel recordings from cultured rat hippocampal neurons. In whole cell recordings, arcaïne caused a concentration-dependent block (IC₅₀=57 μM) of currents evoked by NMDA applied by flow pipe (V_h = -60 mV). Arcaïne did not act directly at the NMDA or glycine binding site as the block could not be overcome by increasing the concentration of NMDA (3-50 μM) or glycine (0.1-10 μM). In addition, the block was not reduced by spermine (1-50 μM). The block by arcaïne was, however, use dependent and could be prevented by prior application of Mg²⁺. Like the open channel block of NMDA currents by Mg²⁺, the block by arcaïne was voltage dependent, and was almost completely relieved at positive holding potentials. In outside-out patches, arcaïne caused a concentration-dependent decrease in apparent channel amplitude at negative holding potentials, which may, like the block seen with Zn²⁺ and Mn²⁺, reflect unresolvable flickering. The reduction in channel amplitude was not observed at positive holding potentials as is consistent with the failure of arcaïne to block outward currents in the whole cell recording experiments. These observations indicate that arcaïne antagonizes NMDA responses by blocking the open NMDA channel and provide a likely mechanism by which arcaïne reduces NMDA-evoked [³H]MK-801 binding in the absence of exogenous polyamines.

108.19

ARCAINE AND Mg^{2+} INHIBIT NMDA RESPONSES BY DISTINCT VOLTAGE-DEPENDENT MECHANISMS. J. Wang* and K.M. Johnson. Dept. of Pharmacology, Univ. of Texas Medical Branch, Galveston, TX. 77550.

In the nominal absence of glutamate and glycine, both polyamines (e.g. spermidine, SPD) and divalent cations (e.g. Mg^{2+}) affect [3H] TCP binding to the rat brain NMDA receptor ionophore complex in a biphasic manner. The ascending, but not descending, limb of the concentration-response curve for SPD and Mg^{2+} is competitively inhibited by arcaine. This study further characterizes arcaine's mechanism of inhibition. NMDA-induced release of [3H] NE from hippocampal slices in either 3 mM or 7.5 mM KCl was used to assess the potential voltage dependence of arcaine's inhibition. The higher KCl concentration significantly diminished the inhibition produced by Mg^{2+} and arcaine, but had no effect on the inhibition by a competitive antagonist, CGS 19755. A multiple NMDA stimulus paradigm was used to examine possible use-dependency of the arcaine block. MK-801, used as a positive control, produced a stimulus dependent onset of blockade that showed only a slight recovery after washout over the subsequent NMDA pulses. In contrast, the block produced by both arcaine and CGS 19755 was very fast in onset and washout, with neither parameter being effected by the number of NMDA pulses. Thus, like Mg^{2+} , arcaine inhibition showed voltage-dependence, but not use-dependence. However, in washed rat cortical membranes the inhibition of [3H] TCP binding by Mg^{2+} and arcaine was differentially affected by SPD, glutamate and glycine. Under non-equilibrium conditions, 100 μM SPD shifted the Mg^{2+} IC_{50} from 6.3 mM to 2.0 mM, but shifted the arcaine IC_{50} from 5.2 μM to 25 μM . Further, the addition of 10 μM L-glutamate and 10 μM glycine had no significant effect on the arcaine IC_{50} value, but shifted the Mg^{2+} IC_{50} leftward, from 6.3 mM to 1.0 mM. Thus, these data suggest that the inhibitory mechanisms for arcaine and Mg^{2+} involve binding to different voltage-sensitive sites, perhaps close to the mouth of the channel, rather than deep within the channel. Supported by DA-02073.

GABA RECEPTORS: FUNCTION I

109.1

GABA_A-RECEPTOR ANTIBODIES RAISED AGAINST A β_2 SUBUNIT-SPECIFIC SYNTHETIC PEPTIDE OF THE RECEPTOR. T.K. Machu¹, R.W. Olsen² and M.D. Browning¹. ¹Dept. of Pharmacology, University of Colorado Health Sciences Center, Denver, CO. ²Dept. of Pharmacology, University of California at Los Angeles Medical School, Los Angeles, CA.

The GABA_A receptor is a multimeric subunit complex consisting of α , β , γ , and δ subunits. To date 3 β subunits have been identified as a result of cDNA library screening. The β_2 subunit has wide distribution in rat brain based on *in situ* hybridization studies measuring β_2 mRNA. We have raised polyclonal antibodies to the β_2 subunit peptide KKAEEKAANNEKMRDLVN conjugated to thyroglobulin. This sequence is specific for the β_2 subunit and is contained in the large intracellular loop between the third and fourth membrane spanning regions of the receptor. The antibody which had been affinity purified recognized the β_2 -subunit specific peptide in an immunoblot, whereas preimmune serum did not. Immunoblots with this purified antibody labeled two polypeptides of the purified GABA_A receptor. One component had an M_r of ~56 kD whereas a second component, presumably a breakdown product, had an M_r of ~35 kD. In cortex homogenate immunoblots this antibody labeled three polypeptides. Two of these migrated similarly to those seen in the purified receptor. The third polypeptide had an M_r of ~68 kD. The 68 kD band may represent a glycosylated form of the β_2 subunit or an aggregate of the multiple subunits. The peptide which we had injected blocked, in a concentration dependent manner, the binding of the antibody to all three bands in cortex immunoblots. Moreover, a peptide representing another part of the large intracellular loop and not contiguous with the sequence we injected, failed to block the binding of antibody to cortex immunoblots. CAMP-DEPENDENT PROTEIN KINASE REDUCES SYNAPTICALLY ACTIVATED GABA_A-RECEPTOR CONDUCTANCES IN RAT HIPPOCAMPAL CA1 PYRAMIDAL NEURONS *IN VITRO* MEASURED USING WHOLE-CELL RECORDING. B.L. Soldo, M.D. Browning, W.R. Proctor and T.V. Dunwiddie. Department of Pharmacology, University of Colorado Health Sciences Center, Denver, CO 80262.

Recent studies indicate that purified GABA_A-receptors from rat brain can be phosphorylated by the catalytic subunit of cAMP-dependent protein kinase (PKA) (Browning et al, 1990, *PNAS* 87: 1315). Furthermore, it has been shown that PKA can decrease GABA-induced currents in mouse spinal cord neurons (Porter et al, 1990, *Neuron* 5:789). We were interested in whether PKA could also regulate GABAergic function in the hippocampal slice. The bicuculline-sensitive GABA_A-mediated IPSP evoked by local stimulation was pharmacologically isolated by using the specific glutamate receptor antagonists, DNQX (10 μM) and APV (40 μM). Whole-cell voltage-clamp recordings were made from CA1 pyramidal neurons to measure GABA_A-receptor responses to synaptically released GABA. When the catalytic subunit of PKA was included in the recording pipette, GABA_A-receptor conductances were significantly reduced within 30-50 minutes as compared to initial conductances measured following patch rupture. On average, PKA-treated cells had an approximately ten-fold lower GABA_A conductance than control cells after 30 minutes. These data suggest that GABA_A-receptor function in hippocampal CA1 pyramidal neurons may be regulated by PKA phosphorylation.

DIFFERENTIAL STIMULATION OF NMDA RECEPTOR ACTIVATION BY GLYCINE AND POLYAMINES: A KINETIC ANALYSIS. S.R. Zukin, D.C. Javitt, R. Sircar, M. Frusciante, J. Manheim* and T. Porzeline*, Depts. of Psychiatry and Neuroscience, Albert Einstein College of Medicine and Bronx Psychiatric Center, Bronx, NY 10461.

Activation of *N*-methyl-D-aspartate (NMDA) receptors is regulated at separate sites by the allosteric potentiators glycine and polyamines. In order to determine the differential effects of glycine and polyamines on NMDA receptor activation, specific binding of [3H]MK-801, serving as a probe of NMDA receptor activation, was measured at 12 time points between 5 min and 24 hr in the absence and presence of L-glutamate, glycine and the polyamine spermidine. We have previously demonstrated that association of [3H]MK-801 to the PCP receptor is biexponential, the fast component representing binding to the activated conformation of the NMDA channel. In the present study, two components of association were again found. Under control conditions (absence of L-glutamate, glycine and spermidine), virtually all binding manifested slow kinetics. Addition of L-glutamate (0.3 - 100 μM) alone led to a dose-dependent 3-fold increase in total [3H]MK-801 binding but did not significantly increase binding manifesting fast kinetics. Neither glycine nor spermidine alone led to significant increases in either fast or total [3H]MK-801 binding. Both agents potentiated the degree to which L-glutamate increased binding manifesting fast kinetics of association. However, spermidine but not glycine increased total [3H]MK-801 binding in the presence of L-glutamate. Both glycine and spermidine act primarily by increasing the interconversion of agonist-associated NMDA channels from the closed to the open state. Spermidine increases the total number of NMDA receptors that are accessible to binding of PCP-site ligands more effectively than does glycine, possibly implying a greater inhibition of NMDA receptor desensitization.

CYCLIC AMP-DEPENDENT PROTEIN KINASE DECREASES GABA_A RECEPTOR-MEDIATED ^{36}Cl UPTAKE BY BRAIN MICROSACS. N.J. Leidenheimer¹, T.K. Machu¹, S. Endo², R.W. Olsen², R.A. Harris³ and M.D. Browning¹. ¹Dept. of Pharmacology, Univ. of Colorado HSC., Denver, CO 80262; ²Dept. of Pharmacology, UCLA School of Medicine, Los Angeles, CA 90024; ³Denver VA Medical Center, Denver, CO 80220;

The effect of CAMP-dependent protein kinase (PKA) on GABA_A receptor-mediated ^{36}Cl uptake was examined using mouse brain membrane vesicles (microsacs). Microsacs were transiently permeabilized by hypoosmotic shock to introduce the catalytic subunit of PKA. At a low concentration of muscimol (2 μM), muscimol-stimulated ^{36}Cl uptake (nmoles ^{36}Cl /mg protein/3 sec \pm SEM) in control (8.1 \pm 1) and PKA (6.3 \pm 1) treated microsacs was significantly different, $p < 0.05$. Muscimol-stimulated ^{36}Cl uptake in control (12.2 \pm 0.7) and PKA (9.4 \pm 0.9) treated microsacs was also significantly different, $p < 0.01$ at a maximally effective concentration of muscimol (50 μM). No effects were observed with heat-inactivated PKA. To determine whether PKA treatment resulted in GABA_A receptor phosphorylation, microsacs were loaded with PKA and [γ - ^{32}P]-ATP and immunoprecipitation experiments were performed with a GABA_A receptor anti- α subunit antibody (under non-denaturing conditions to precipitate the entire complex). PKA-loaded microsacs showed an increase in the phosphorylation of a variety of microsome proteins, including a 66 kDa polypeptide specifically precipitated by the anti-peptide sera. Phosphopeptide mapping of this 66 kDa polypeptide yielded a 14 kDa fragment similar to that obtained with the purified, PKA-phosphorylated GABA_A receptor. These results show that the catalytic subunit of PKA inhibits brain GABA_A receptor function concomitant with an increased phosphorylation of several proteins including a 66 kDa polypeptide believed to be a GABA_A receptor subunit. 109.4

EFFECTS OF CPT-cAMP ON GABA_A RECEPTOR BINDING AND FUNCTION. Patricia P. Edgar and Rochelle D. Schwartz. Dept. of Pharmacology, Duke University Medical Center, Durham, NC. Our recent studies indicate that membrane-permeant cAMP analogs inhibit GABA_A mediated ^{36}Cl flux and activate protein kinase A in synaptoneuroosomes (Heuschneider and Schwartz, 1989; Schwartz et al, 1991). We have investigated the effect of 8-chlorophenylthio (CPT) cAMP, the most potent analog, on the binding of several GABA_A receptor-associated ligands (3H -muscimol, 3H -diazepam, and ^{35}S -TBPS) and on the modulation of GABA_A receptor function. Binding assays were performed in synaptoneuroosomes under conditions identical to those used for ion flux. For 3H -muscimol, this resulted in the identification of a low affinity site with a K_d (2 μM) comparable to the EC_{50} for muscimol-induced ^{36}Cl uptake (11 μM). CPT-cAMP did not alter the number or affinity of these binding sites, indicating that inhibition of ^{36}Cl uptake by CPT-cAMP is not the result of a decrease in GABA_A agonist binding. Under identical conditions CPT-cAMP decreased the affinity of benzodiazepine (BZ) sites labeled with 3H -diazepam by 30%. This was apparently due to the inhibition of endogenous GABA's ability to enhance BZ receptor affinity, since CPT-cAMP had no effect on BZ receptor affinity in the presence of bicuculline (BIC). In contrast, diazepam produced a greater enhancement of muscimol-induced (10 or 50 μM) ^{36}Cl uptake in the presence of CPT-cAMP. Finally, CPT-cAMP decreased the affinity of the chloride channel for ^{35}S -TBPS by 20% in both the presence and absence of BIC. We suggest that cAMP can cause allosteric changes in sites other than the functional GABA agonist recognition site. These results do not distinguish between a direct effect of cAMP on the chloride channel or an indirect effect via PKA-mediated phosphorylation. SUSTAINED COMPONENT OF GABA-ACTIVATED Cl⁻ FLUX: SELECTIVE MODULATION BY PROTEIN KINASE C. R.A. Harris, S.J. McQuilkin* and L. Hahner*. V.A. Medical Center and Dept. of Pharmacology, Univ. of Colo. Sch. Med., Denver, CO 80262.

Phosphorylation of GABA_A receptor subunits by protein kinase C (PKC) occurs *in vitro*, but the functional significance is unknown (TPS 12:84, 1991). We used the initial (3 sec) and sustained (30 sec) phases of GABA-stimulated uptake of ³⁶Cl⁻ (G-Cl) by mouse brain cortical microsacs (FASEB J., in press) to study effects of activation and inhibition of PKC. PMA (10-100 nM), a phorbol ester that activates PKC, inhibited G-Cl at 30 sec, but not at 3 sec. The inactive analog, PMM, did not alter G-Cl. The kinase inhibitors staurosporine (10 nM) and sphingosine (3 μM) blocked the action of PMA. G-Cl of microsacs lysed and resealed in the absence of Ca⁺⁺ and Mg⁺⁺ (to abolish phosphorylation, *Mol. Pharmacol.* 38:823, 1990) was not affected by PMA. The protein phosphatase inhibitor okadaic acid (100 nM) mimicked the action of PMA and the actions of PMA and okadaic acid were not additive. Okadaic acid did not alter the rapid phase of G-Cl. We conclude that activation of PKC inhibits the sustained GABA_A current without affecting the rapidly desensitizing current. PKC may selectively inhibit a non-desensitizing subtype of GABA_A receptor or may slow receptor resensitization.

ONTOGENY OF GABA_A RECEPTOR ION CHANNELS: REVEALED BY ZINC INHIBITION. T.G. Smart. School of Pharmacy, Department of Pharmacology, University of London, UK.

The sensitivity of GABA_A receptors to inhibition by zinc declines with neuronal age. This aspect and the mode of zinc antagonism on single GABA ion channel currents were studied in cultured rat neurones using patch clamp techniques. Whole-cell GABA currents recorded from acutely cultured sympathetic neurones (<5 days *in vitro*) using embryonic (E21 days), postnatal (P3) and adult (P>90) rats to monitor development *in vivo*, were antagonised by zinc with mean inhibitions of 78, 43 and 16% respectively. A single exponential component described the reduction in zinc inhibition, with a $t_{1/2}$ of 48.2 days. Chronic culture (>4 months) of embryonic neurones (E21) also revealed a decline in zinc inhibition *in vitro*, proceeding at a slow rate of 0.45% per day. Single GABA channel currents recorded from large cerebellar neurones, exhibited multiple current levels with conductances of 8, 18, 23, 29 and 34pS. Zinc (10-50 μM) did not affect the main conductance state (29pS), but reduced the opening frequency. The mean open time was unaffected by zinc, but the mean closed time increased. A small reduction in the mean burst duration and proportion of long duration bursts was also observed and correlated with noise analysis. The underlying developmental process rendering GABA_A receptors insensitive to zinc apparently proceeds *in vivo* and *in vitro*. The major inhibitory effect of zinc is to reduce the GABA channel opening frequency.

CHRONIC ETHANOL ADMINISTRATION INDUCES CHANGES IN GABA_A RECEPTOR GENE EXPRESSION. M.K. Ticku and M. Mhatre. Univ. TX Hlth. Sci. Ctr., Dept. of Pharmacology, San Antonio, TX 78284-7764

In order to evaluate the mechanism underlying the structural and functional changes in GABA_A receptor following chronic ethanol (alcohol) administration, we measured the steady state levels of the mRNAs for the α_1 , α_2 , α_3 , α_4 and α_6 subunits of GABA_A receptor following chronic ethanol administration to rats and the ethanol withdrawal for 24 h. A marked decrease (40-60%) in the level of the GABA_A receptor α_1 subunit mRNAs (3.8 and 4.3 kb), α_2 subunit mRNA (6 kb) and α_4 subunit mRNA (2.8 kb) was observed in the cerebral cortex in rats, while there was no change in the level of α_3 subunit mRNA (3 kb). On the other hand α_6 mRNA levels in cerebellum remained unchanged. The level of α_6 mRNA which selectively encodes Ro15-4513 binding sites was found to be increased by 263% in the cerebellum. Also, the photoaffinity labeling studies using [³H]Ro15-4513 indicate a significant increase in the levels of various protein components of GABA_A receptor in the cerebellum and the cerebral cortex (e.g. 50 and 56 kDa in the cerebellum and 41, 50 and 59 kDa in the cortex), following chronic ethanol treatment. These data indicate chronic ethanol induced alteration in the regulation of the expression of GABA_A receptor subunit-encoding mRNAs. Supported by NIAAA grant AA04090.

THE ROLE OF N-LINKED GLYCOSYLATION IN EXPRESSION OF THE RAT GABA_A RECEPTOR IN XENOPUS OOCYTES

A.L. Buller*, G.A. Hastings*, E.F. Kirkness and C.M. Fraser, Section on Molecular Neurobiology, LPPS, NIAAA, Rockville, MD 20852.

The GABA_A receptor, a ligand-gated chloride channel, represents the major inhibitory neurotransmitter receptor in vertebrates. The receptor is an oligomeric transmembrane glycoprotein complex. We have expressed functional GABA_A receptors in *Xenopus* oocytes microinjected with RNA coding for the α_1 , β_1 and γ_2 subunits. Bath application of GABA elicits inward chloride currents in voltage clamped microinjected oocytes with an EC50 of approximately 10 μM and a Hill coefficient of 1.25. GABA currents are potentiated by phenobarbital (200% of control) and by flunitrazepam (35% of control). Benzodiazepine potentiation is blocked by the benzodiazepine antagonist, RO15-1788.

Sequence analysis has revealed that the α_1 subunit contains two consensus sequences for N-linked glycosylation (Asn-X-Ser/Thr). Tunicamycin (TM) was used to investigate the role of N-linked glycosylation in expression of the GABA receptor in *Xenopus* oocytes. TM inhibits the transfer of the oligosaccharide precursor to the growing polypeptide chain and thus prevents the formation of all forms of N-linked glycosylation. Oocytes were injected with GABA receptor subunit-specific RNAs (α_1 , β_1 , γ_2 mixed in equimolar stoichiometry) alone or in combination with TM (25 mg/ml) and incubated for 48 hr. TM completely abolished functional expression of GABA receptor. To further investigate the role of glycosylation in expression of the GABA receptor, glycosylation-deficient mutants have been generated. We have constructed mutant α_1 subunits containing only one of the two sites for glycosylation (changing residues Asn¹⁰ and Asn¹¹⁰ to Gln) or missing both sites. We are currently investigating the effects of these mutations on expression of the GABA receptor in *Xenopus* oocytes.

CENTRAL BENZODIAZEPINE RECEPTORS ARE SEQUESTERED IN BRAIN MEMBRANE VESICLES. E.M. Barnes, Jr. and M.H. Jalilian Tehrani. Dept. of Biochemistry, Baylor Col. of Med., Houston, TX 77030.

In order to study the intracellular trafficking of GABA_A/benzodiazepine receptors, we have synthesized an impermeant benzodiazepine, N-(4-sulfophenyl)thio-carbamoyl-1012S [SPTC-1012S]. The receptors which are sequestered within brain membrane vesicles were detected by displacement of specific [³H]flunitrazepam binding by SPTC-1012S and the permeant homolog, 1012-S. The fraction of sequestered receptors was estimated by difference, using the ³H which remained bound in the presence of SPTC-1012S and 1012-S. Sequestered benzodiazepine receptors represented 20-30% of the total in microsomal (P₃) membranes from rat brain, while a 1-2% level of internal receptors was observed for crude nuclear (P₁) and mitochondrial-synaptic (P₂) membranes. Similar findings were obtained with goat brain membranes. Exposure of P₃ vesicles to Triton X-100 reduced the level of sequestered receptors to <1%. Microsomal fractions enriched in clathrin-coated vesicles were isolated on discontinuous sucrose or ficoll-²H₂O gradients. Of the receptors on crude coated vesicles, 17-26% were internalized. This approach may prove useful for the study of receptor down-regulation following exposure of animals to GABA and benzodiazepine agonists. Supported by DK 17436 and NS 11535 from NIH.

109.10

AGE-RELATED ALTERATION IN THE BINDING AND SUBUNIT mRNA LEVELS IN GABA_A RECEPTOR. M. Mhatre, G. Fernandes* and M.K. Ticku. Univ. TX Hlth. Sci. Ctr., Depts. of Pharmacology and Medicines, San Antonio, TX 78284-7764

The effect of aging on the binding of ligands to the GABA_A benzodiazepine and picrotoxin binding sites as well as steady state mRNA levels of α subunit genes of γ -aminobutyric acid (GABA) receptor complex, was investigated in cerebral cortex and cerebellum of male Fischer F-344 rats. In aged (730-780 day-old) rats, the binding of [³⁵S]t-butyl-bicyclophosphorothionate (TBPS) was significantly reduced, whereas [³H]muscimol and [³H]flunitrazepam binding did not change compared with adult (6-mo-old) values. This decrease of TBPS binding derived from a reduced density of binding sites, rather than from affinity changes. In contrast, there was no alteration in the binding pattern of various ligands in the cerebellum in old animals. The allosteric interaction of GABA with the benzodiazepine and picrotoxin (TBPS) sites of the oligomeric GABA_A receptor was not altered in aged animals. Also, α_1 mRNA level was markedly decreased in the cerebral cortex of old animals (86% suppression). In contrast, α_1 mRNA remained unchanged in cerebellum. These findings indicate a selective age-related structural change in GABA_A receptor chloride ionophore complex in rat cerebral cortex.

109.11

IDENTIFICATION OF GABA_A RECEPTOR ABNORMALITIES IN THE CEREBRAL CORTEX OF THE TOTTERING MOUSE. M.H. Jalilian Tehrani and E.M. Barnes, Jr., Biochemistry Dept., Baylor Col. of Med., Houston, TX 77030.

Previous electrophysiological studies of tottering mice (tg/tg) have suggested that reduced inhibition may contribute to their characteristic seizure activity. We have compared the properties of GABA_A receptors in cortical membranes from tg/tg mice and co-isogenic controls (+/+). In +/+ microsacs, the rate of GABA-gated ³⁶Cl flux was nearly constant during the initial 5 sec of uptake and declined thereafter, while Cl entry into tg/tg microsacs faded more rapidly. Kinetic analysis of the muscimol dose response shows a higher affinity for tg/tg receptors (tg/tg: K_{0.5} = 0.2 μM; +/+ : K_{0.5} = 1.3 μM) and a lower maximum rate of ³⁶Cl flux (tg/tg: V_{max} = 6.1 nmol/mg·3s; +/+ : V_{max} = 12.1 nmol/mg·3s). Scatchard analysis of specific [³H]muscimol binding suggests that affinities of both classes of tg/tg sites were higher than those for +/+ (tg/tg: K_{d1} = 3.8 nM, K_{d2} = 225 nM; +/+ : K_{d1} = 5.4 nM, K_{d2} = 534 nM), while the densities of tg/tg sites were lower (tg/tg: B_{max1} = 0.85 pmol/mg, B_{max2} = 5.9 pmol/mg; +/+ : B_{max1} = 1.70 pmol/mg, B_{max2} = 10.1 pmol/mg). The data suggest that the tg mutation leads to functional alterations in GABA_A receptors which could produce dysinhibition. Supported by NS1535 from NIH and by the American Epilepsy Society.

CHRONIC GABA EXPOSURE INDUCES DOWN-REGULATION OF THE GABA/BENZODIAZEPINE (BZ) RECEPTOR COMPLEX IN CULTURED CORTICAL NEURONS. A.K. Mehta and M.K. Ticku, Univ. TX Hlth. Sci. Ctr., Dept. of Pharmacology, San Antonio, TX 78284-7764.

The effect of chronic exposure (1-5 days) of GABA (500 μM) to cultured cortical neurons was investigated using [³H]flunitrazepam, [³H]Ro15-1788 and [³H]Ro15-4513 binding, and GABA-induced ³⁶Cl-influx as paradigms for GABA-BZ binding sites and function, respectively. Treatment of cultures with GABA (500 μM) caused a decrease in [³H]flunitrazepam, [³H]Ro15-1788 and [³H]Ro15-4513 binding. The decline in the specific binding was maximal (-40%) on the fifth day of GABA exposure, and was reversed by concomitant exposure of the neurons to RU5135 (1 μM), a GABA_A-receptor antagonist. GABA-induced downregulation was due to a decrease in the B_{max} of [³H]flunitrazepam binding, without any effect on the K_d value. GABA induced ³⁶Cl-influx in control cultured cortical neurons, and the effect declined on prior exposure of the neurons to GABA. This effect was also susceptible to reversal by GABA_A-receptor antagonist, RU5135. These findings indicate that chronic GABA exposure induces down regulation of GABA/BZ receptor complex through GABA_A receptors in cultured cortical neurons. Supported by NINDS grant #15339.

109.15

HORMONAL INFLUENCES ON SN RETICULATA RESPONSES TO GABA AND BENZODIAZEPINES IN RATS. Marlene A. Wilson, Dept. Pharmacology, Univ South Carolina Sch of Medicine, Columbia, SC 29208.

Prior studies have shown that administration of gonadal steroids can modify GABA and benzodiazepine (BZ) receptor sites in several brain areas. Progesterone metabolites can also directly modulate the GABA/BZ/chloride ionophore complex and physiological responses to GABA.

Extracellular single unit recording of substantia nigra pars reticulata (SNr) neurons was used to assess the influences of gender and gonadectomy on GABA effects and BZ responses. Groups of male, cycling female, ovariectomized (OVX) and orchidectomized (ORCH) rats were compared. Sensitivity to iontophoretically applied GABA (GABA IT₅₀) and the ability of iontophoretically (locally) applied BZ to enhance GABA responses (% BZ INCREASE) were comparable in all hormone groups. GABA effects on ³⁶Cl-influx into cortical synaptosomes were also similar in male, female, and OVX groups. Basal SNr firing rates were nonsignificantly elevated in MALES compared with other groups. The ability of systemic diazepam (DZ; 0.03-1.5 mg/kg, iv) to decrease SNr firing differed significantly between hormone groups. DZ-induced inhibition was greater in MALE rats than in other groups (see 1.0mg/kg effect below). Thus, neither gender nor castration modified local SNr responses to GABA or BZs. Since systemic BZ effects involve enhancement of GABA inputs, group differences in DZ responses suggest hormonal factors may be modulating endogenous GABAergic control of SNr neurons.

	N	GABA IT ₅₀	% BZ INCREASE	FIRING RATE	% DECREASE SYSTEMIC DZ
	cells/rats	(nA, sec)			
MALE	19/9	196 ± 23	40 ± 6%	243 ± 18	45 ± 7%
FEMALE	16/8	164 ± 31	38 ± 4%	181 ± 21	38 ± 6%
OVX	22/10	161 ± 17	37 ± 3%	204 ± 18	34 ± 7%
ORCH	14/7	165 ± 44	28 ± 7%	183 ± 21	23 ± 6%

EFFECTS OF CHRONIC MILD STRESS ON IN VIVO BINDING OF BENZODIAZEPINE RECEPTOR ANTAGONIST, [³H]RO 15-1788, TO MOUSE BRAIN. M. MOSADDEHGI*, P.D. FELDMAN, AND J.M. MOERSCHBAECHER, 1901 Perdido St., LSUMC, Dept. of Pharmacology and Experimental Therapeutics, New Orleans, LA. 70112

This study examined the effect of a brief mild stress on *in vivo* benzodiazepine (BZD) receptor binding in mouse brain. Mice in one group received daily single injection (i.p.) of saline (5 ml/kg) for 7 days (N=7). Mice in the second group were restrained for 5-6 sec by grabbing the back skin and holding the subject upside-down at 45° as if to be injected (sham control, N=7) for 7 days. Mice in the third group were neither restrained nor injected (acute control, N=7). On the 8th day BZD receptors were labeled *in vivo* by administering (i.p.) 3 μCi of [³H] Ro 15-1788. The levels of *in vivo* binding of the radioligand to cortex (CX), cerebellum (CB), striatum (ST), hippocampus (HP), hypothalamus (Hy) and brain stem (BS) were determined. Results indicated that the level of binding was significantly (p<0.01) lower by (30 - 50% depending on the brain region) in saline injected or sham control groups as compared to acute control animals. The levels of binding in CX, CB, BS, ST, HP, and HY for acute control were 34.6 ± 2.6, 18.8 ± 0.5, 8.5 ± 0.5, 21.3 ± 2.4, 52.2 ± 4.0 and 41.4 ± 5.0 cpm/mg tissue, respectively. Whereas, the values in CX, CB, BS, ST, HP, and HY for saline injected mice were 15.2 ± 1.4, 10.0 ± 1.1, 5.9 ± 0.5, 11.6 ± 1.2, 31.9 ± 2.5, and 23.1 ± 1.9 cpm/mg tissue, respectively. The values for sham control were similar to the saline treated group. Our data suggest that exposure to chronic mild stress produces a decrease in *in vivo* binding of [³H] Ro 15-1788 in mouse brain. Thus, these results support the hypothesis that chronic stress produces a decrease in BZD receptor binding sites. Supported by DA 03573 and DA 04775.

CHRONIC BENZODIAZEPINE (BZ) TREATMENT REDUCES GABA AND BZ AGONIST ACTIONS *IN VITRO* HIPPOCAMPUS. X-H. Xie and E.L. Tietz, Dept. of Pharmacology, Med. Coll. of Ohio, Toledo, OH 43699

Previous studies showed a significant reduction in GABA-mediated paired-pulse inhibition and subsensitivity to the GABA_A agonist, isoguvacine (ISO) in hippocampal slices from chronic BZ treated rats. Behavioral studies had indicated differential subsensitivity to GABA agonists after chronic BZ treatment. Therefore, the potency and efficacy of other GABA_A agonists (muscimol (MUS) and GABA) were examined 48 hr after 1 week flurazepam (FZP) treatment in *in vitro* superfused slices. The effect of diazepam (DZP) to potentiate ISO actions was also examined. Male rats (200-280 gm) were offered FZP in their drinking water (100 mg/kg X 3 dy; 150 mg/kg X 4 dy). Population spikes elicited by Schaffer collateral stimulation (1 ms monophasic pulse) were recorded (2 M NaCl filled glass pipette, 2-5 mΩ) from CA1 pyramidal cells. MUS and GABA (in presence of 200 μM nipeptic acid) were delivered for 5 min via syringe pump (10-50 μl/min) to the superfusate (2 ml/min) in increasing concentrations. Responses, averaged over the last 2 min, were compared to the pre-drug baseline. MUS and GABA showed a significant decrease in potency to reduce CA1 evoked responses in treated (EC₅₀:MUS, 6.7 μM/n=5; EC₅₀:GABA, 195 μM/n=6) vs. control slices (EC₅₀:MUS, 2.4 μM/n=5; EC₅₀:GABA, 115 μM/n=6). DZP was tested in slices 48 hr after 1 week FZP treatment by its ability to shift the ISO dose-response curve. After superfusion of ISO (2.5-20 μM), DZP (300 nM, 20 μl/min) was superfused 20 min before a 2nd ISO curve was determined in the presence of DZP. DZP produced a significant parallel shift of the ISO dose-response curve in control (p < .05, n=6) but not treated (n=6) slices, indicating BZ tolerance. Supported by grants R01-DA04075 and S07-RR05700.

EFFECT OF OVARECTOMY OR STAGE OF ESTROUS CYCLE ON BENZODIAZEPINE BINDING IN FEMALE MOUSE BRAIN. J. V. Martin, N. Agrawal and H. Lee, Biology Dept., Rutgers Univ., Camden, NJ 08102.

To assess the effect of physiological fluctuations in ovarian hormones on benzodiazepine receptor availability, we measured the equilibrium binding of ³H-diazepam to membranes from brains of 15 mice killed after ovariectomy or at different stages of the estrous cycle. Vaginal smears prepared daily from adult female CD-1 mice were classified by stage of the estrous cycle, until at least two complete cycles were recorded. The ovariectomized mice were used at two weeks after surgery. Separate binding analyses were performed in homogenates from the cerebral cortex and hypothalamus isolated from each mouse. As expected, uterine weight showed significant fluctuations by stage of estrous cycle and after ovariectomy. Both brain areas showed significant differences in both apparent K_d and B_{max} according to phase of the estrous cycle and ovariectomy (p < 0.02 for each ANOVA). The patterns of differences were very similar for cortex and hypothalamus. (All data given are for cortex, presented as means ± S.E.M.) The apparent K_d (in nM) was significantly higher in the estrus phase (2.8 ± 0.4) as separately compared to other phases of the cycle (metestrus: 1.4 ± 0.4; diestrus: 1.3 ± 0.3; proestrus: 1.0 ± 0.2) using a post-hoc least-significant difference test (p < 0.05). After ovariectomy, the K_d was significantly lower (0.6 ± 0.3 nM) than in intact mice. The B_{max} (in fmoles/mg protein) was significantly higher in cortex from mice in estrus (564 ± 71) than in the other phases (metestrus: 310 ± 56; diestrus: 316 ± 129; proestrus: 282 ± 56). The B_{max} after ovariectomy was significantly lower (26 ± 3) than in any of the intact groups. These data suggest the influence of an endogenous ovarian factor on the binding characteristics of the benzodiazepine receptor. Supported by the Busch Fund and NIH (NS23200).

CHARACTERIZATION OF ANTAGONISTIC ACTIVITY AND BINDING PROPERTY OF SR 95531 IN RAT BRAIN. Y.Ito, T.Koshiba*, M.Doi* and H.Fukuda*. Dept. of Pharmacology, Coll. of Pharmacy, Nihon Univ., Funabashi-shi, Chiba 274, Japan.

Experiments were performed to characterize antagonistic activity and binding properties of ^3H -SR 95531, a synthetic GABA_A antagonist, in rat brain. SR 95531 and bicuculline methiodide (BMI) inhibited the muscimol-stimulated $^{36}\text{Cl}^-$ uptake into cortical synaptosomes. Inhibitory potency of SR 95531 for the muscimol-stimulated $^{36}\text{Cl}^-$ uptake was 15 times higher than that of BMI. The IC₅₀ value of SR 95531 for the muscimol-stimulated $^{36}\text{Cl}^-$ uptake was in close agreement with the K_d value for low-affinity [^3H]SR 95531 binding sites. Pretreatment of the frontal cortical and cerebellar membranes with phospholipase A₂ (PLase A₂) invariably decreased [^3H]SR 95531 binding in a concentration-dependent manner. On the other hand, the treatment significantly increased [^3H]GABA binding in these regions. The products generated by the catalytic activity of PLase A₂ such as arachidonic acid and lysophosphatidylcholine mimicked the effects of PLase A₂. These results suggest that SR 95531 exerts GABA antagonistic action through the low-affinity binding sites of SR 95531. It is also suggested that GABA_A agonist and antagonist bind differentially to GABA_A receptors and that exogenously added PLase A₂ causes opposite modulation of antagonist binding to agonist binding.

UNCOUPLING OF GABA-BENZODIAZEPINE RECEPTORS IN CHICK CEREBRAL CORTICAL NEURONS REQUIRES CO-ACTIVATION OF BOTH RECEPTOR SITES. A. Prasad and J.N. Reynolds, Faculty of Medicine, Memorial University of Newfoundland, St. John's, Nfld., Canada A1B 3V6.

Primary cultures of cerebral cortical neurons were prepared from seven day old chick embryos. After 5 days *in vitro*, culture dishes were exposed to one of four conditions: 1) control; 2) 1 μM Flurazepam; 3) 1 μM GABA; 4) 1 μM Flurazepam + 1 μM GABA. GABA-activated chloride currents and the interaction between flurazepam and GABA were examined using whole-cell voltage-clamp recordings. Cells were continuously perfused (1-2 ml/min) with a physiological saline containing (in mM) 140 NaCl, 5 KCl, 2 CaCl₂, 1 MgCl₂, 10 HEPES, 10 glucose, pH 7.3. Flurazepam HCl was dissolved in extracellular solution (0.1-10 μM) and applied by bath perfusion. Recording pipettes (3-5 M Ω) contained (in mM) 140 KCl, 2 MgCl₂, 10 HEPES, 4 ATP, pH 7.3. GABA (10-50 μM) was applied by brief (20-100 msec) pressure pulses directly to the soma. Cells grown under all four experimental conditions responded equally well to GABA, with no apparent differences in sensitivity. In control cultures perfusion with 0.5 μM flurazepam resulted in a strong potentiation of GABA-activated membrane currents. Cells exposed to 1 μM flurazepam for 5 days also had GABA-activated currents which were strongly potentiated by 0.5 μM flurazepam. Similarly, exposure of chick cortical neurons to 1 μM GABA did not alter the ability of flurazepam to potentiate GABA-activated membrane currents. In contrast, in cells exposed to flurazepam + GABA for 18 hours, no effect of flurazepam on GABA-activated membrane currents could be detected. These results suggest that co-activation of both GABA and benzodiazepine receptors is required in order to elicit changes in the functional coupling between these two sites.

OPIOIDS: ANATOMY AND PHYSIOLOGY I

110.1

ALTERATIONS IN N. ACCUMBENS EXTRACELLULAR DA AND BEHAVIOR FOLLOWING INTRA-VTA OPIOIDS. M.E. Hamilton and A. Pert. BPB/NIMH, Bethesda, MD. 20892.

Microinjection of opioids into the ventral tegmental area (VTA) has been shown to produce a variety of responses consistent with goal-directed behavior and intrinsic reward. The most dramatic goal-oriented responses have been observed following low pmole doses of the endogenous κ agonist, Dynorphin A (DYN). Indeed, other opioids produce similar effects only at those doses consistent with their relative binding affinities at the κ receptor. It was of interest to examine the relative effects of three naturally occurring opioids on both behavior and DA overflow in the n. accumbens. Male, Long-Evans rats were implanted with guide cannulae directed toward the medial n. accumbens and the VTA. At least one week following surgery, a microdialysis probe was inserted into the n. accumbens and each rat was placed in a sound-attenuated locomotor activity chamber. At 20 min intervals, dialysate was collected and photocoil counts were recorded. When stable DA levels were achieved, rats received one of the Met-Enkephalin analog, DALA, the Leu-Enkephalin analog, DADLE, or DYN, at doses previously shown to elicit feeding in food-satiated rats (3 nmoles for the enkephalins; 3 pmoles DYN). Behaviors were recorded during the 20 min immediately following injection, and dialysate samples were further collected for two hours. Feeding durations following opioid injection were similar in all three groups; however locomotor activity was both more pronounced and more sustained following DALA and DADLE than after DYN. DADLE treatment was also characterized by a tight circling not observed in either of the other groups. DA overflow in the n. accumbens was also more pronounced and sustained following DALA or DADLE. A small, transient increase in DA following DYN accompanied the behavioral activation. It would appear that μ and/or δ receptor activation in the VTA probably contributes to a net disinhibition of DA cells, and that κ activation either is independent of mesolimbic DA or affects only a small subpopulation of DA cells.

110.3

ALFENTANIL-INDUCED HYPERMETABOLISM, SEIZURE, AND NEUROPATHOLOGY IN RATS; W.A.Kofke, R.H.Garman*, W.C.Tom*, M.E.Rose*, and R.A.Hawkins. Dept. of Anes/CCM and Dept. of Pathology, Univ. of Pittsburgh; Dept. of Physiology & Biophysics, Chicago Med. Sch.

Three experiments were performed on paralyzed ventilated rats to determine whether alfentanil (ALF) caused local seizures and neuronal damage. First, rats (n=15, 5/grp) were assigned to: 1) control (1h N₂O/O₂ 70/30); 2) low dose ALF (150ug/kg/min followed by 15ug/kg/m); 3) high-dose ALF (1000ug/kg iv followed by 100ug/kg/min). Glucose consumption was measured by quantitative autoradiography with $^6\text{-}^{14}\text{C}$ glucose as a tracer. Second, hippocampal electrodes were placed in 12 rats. They were assigned to control, low-dose and high-dose ALF grps. Depth and scalp EEG were recorded. Third, rats (n=15) were assigned to either a control grp (n=5) or an extra high dose grp (ALF 2000ug/kg iv followed by 33.3ug/kg/min). They were allowed to recover for 24hr before cerebral perfusion-fixation the next day. With high-dose ALF there was increased glucose consumption in the ventral hippocampus and lateral septal nuclei. Both the scalp and hippocampal electrodes showed epileptiform EEG patterns. Light microscopy showed neuronal damage in 6 of 10 high-dose ALF rats with amygdala most affected. No control rats had lesions. We conclude that high-dose ALF produces limbic seizures with hypermetabolism and brain damage.

110.2

EFFECT OF μ - AND δ -OPIOID AGONISTS ON SCHAFFER COLLATERAL AND MOSSY FIBER EVOKED RESPONSES IN CA1 AND CA3 OF HIPPOCAMPAL SLICE. L.S.Jones*, S.Grooms*, S.Salvadori** and L.H.Lazarus*. *Dept. of Anat., U. So. Carolina, Columbia, SC 29208; **Dipt. Sci. Farm., Univ. di Ferrara, Ferrara, I-44100, Italy; *NIEHS, RTP, NC 27709.

Hippocampal slices from young rats were used to test physiological CNS responses to a μ - (dermorphin=DM) and a δ - (deltorphin A=DEL) agonist, which exhibit high affinity and selectivity. DM potentiated responses at 5 and 50 nM, while 100 nM caused evoked responses to become epileptiform, and 500 nM lead to low amplitude spontaneous epileptiform events more apparent in CA1 than CA3. The epileptogenic effects of DM were partially reversible with washing in ACSF. 5 μM Naloxone, a nonspecific opioid antagonist, markedly reduced the excitatory effects of 100 nM DM. The inactive enantiomer (L-Ala²)-DM had no effect. DEL had little effect on responses; potentiation was observed only at the highest concentrations (0.5-1 μM) tested. These data provide evidence that epileptogenic effects in rat hippocampal slices are triggered in part through μ receptors. Work supported by NS27903 and Minis. Publica Instruzione and C.N.R.+

EFFECTS OF OPIOIDS ON EVOKED AND SPONTANEOUS CELLULAR EVENTS IN THE DENTATE GYRUS. JH Mayer, SC Steffensen*, SJ Henriksen. Dept. Neuropharmacology, Research Institute of Scripps Clinic, La Jolla, CA 92037

In order to better understand the effects of opioids on hippocampal function, we studied the changes in dentate neuronal activity occurring spontaneously (unit activity) and after stimulation of the perforant path (population spikes) following systemic or local (iontophoretic) administration of opioids. Cells were differentiated as probable dentate granule cells (DGCs) or as probable dentate interneurons (INTs). Both DGCs and INTs were located from 50 to 200 μm below reversal of the population EPSP. Cells were considered to be probable INTs when perforant path stimulation produced multiple cell firings extending beyond the envelope of the population spike and EPSP. The responsiveness of the dentate to stimulation of the perforant path was assessed via input/output curves (I/O) and paired-pulse (PP) paradigms. In each test we used either the iontophoretic administration of the mu-selective opioid agonist [D-Ala², NMe-Phe⁴, Gly-ol]-Enkephalin (DAGO) or the systemic administration (IV or IP) of morphine sulfate (MS), 2.5 mg/kg.

DAGO and MS had similar effects on unit cell activity. There was a tendency for the spontaneous activity of DGCs to decrease or remain unchanged and for the spontaneous activity of INTs to increase or remain unchanged. However, DAGO and MS had differing effects on population spikes (PS) produced by stimulation of the perforant path. DAGO enhanced the response to stimulation with a shift to the left of the I/O curve and disinhibition in the PP paradigm. MS produced a very small decrease in primary PS amplitude as compared to baseline levels and no change in the PP paradigm. These results are consistent with previous work from our lab showing application of enkephalin produced decreased spontaneous activity of DGCs with increased responsiveness to perforant path stimulation. The current results suggest that opiates produce their effects on the dentate through multiple actions, and that INTs may be important in this expression. Furthermore, the difference in responses to stimulation between DAGO and MS is most likely due to effects of systemic MS on other inputs to the dentate. (Supported by DA 00143 to JHM)

MU-OPIOID RECEPTORS MODULATE CARDIOVASCULAR AND SYMPATHOADRENAL FUNCTION AT REST AND DURING STRESS.

A.A. Houdi, L. Marson, K. Davenport* and G.R. Van Loon. Department of Medicine, University of Kentucky and VAMC, Lexington, Kentucky.

The role of brain μ -opioid receptors in modulating cardiovascular and sympathoadrenal function was examined by studying the effect of μ -receptor antagonist, B-funaltrexamine (BFNA), administered icv, on plasma catecholamines, blood pressure and heart rate under basal conditions and during restraint stress. Rats were prepared with chronic carotid and icv cannulae for blood pressure recording, blood sampling and drug injection. Two days later, rats were injected with either saline or BFNA, 2.5 μ g icv. After a further 48 hrs, rats were treated with μ -opioid receptor agonist, D-Ala²,Me-Phe⁴,Gly-ol⁵-enkephalin (DAMPGO), 1 nmole icv. Blood pressure and heart rate were recorded throughout the experimental period, and blood samples were taken 5 min prior and 20 min after DAMPGO treatment. Restraint stress was imposed 20 min after DAMPGO. DAMPGO produced analgesia that was completely blocked by pretreatment with BFNA. DAMPGO increased blood pressure and plasma catecholamines and evoked a small bradycardia. Pretreatment with BFNA reversed the DAMPGO-induced bradycardia and exposed a tachycardia and significantly blunted the increase in plasma epinephrine with only a small attenuation of pressor response. However, BFNA did not alter the pressor response to restraint in DAMPGO-treated rats. Thus, stimulation of μ -opioid receptors activates both sympathetic and parasympathetic outflow. μ -Opioid receptors tonically activate parasympathetic outflow to the heart at rest and mediate partially the parasympathetic cardiac response to restraint stress. These data further support roles for μ -opioid receptors in modulating heart rate and sympathoadrenal responses under basal conditions and in response to stress.

ENHANCED SEROTONERGIC TRANSMISSION MAY ATTENUATE ACTIVATION OF LOCUS COERULEUS (LC) BY OPIATE WITHDRAWAL

Hideo Akaoka and Gary Aston-Jones. Div. Behav. Neurobiol., Dept. Mental Health Sci., Hahnemann University, Philadelphia

Noradrenergic neurons of the nucleus LC in morphine-dependent rats are strongly activated by opiate withdrawal (OW). We have recently shown that such activation of LC neurons may be mediated by direct excitatory amino acid (EAA) input to LC (Akaoka et al., 1990). On the other hand, we have also shown that the excitation of LC neurons induced by iontophoretic application of glutamate is strongly attenuated by co-iontophoresis of 5HT (Aston-Jones et al., 1991). Here, LC neurons were recorded extracellularly to examine the effects of direct and indirect agonists of 5HT on the OW-induced activation of LC neurons in halothane anesthetized, morphine-dependent rats. These 5HT drugs were injected intravenously (IV) about 2 min following the induction of OW precipitated by IV injection of naloxone (NLX, 0.1 mg/kg).

Intravenous administration of the 5HT releaser, d-fenfluramine (2mg/kg), substantially reversed the LC hyperactivity induced by OW (n=2, 50 and 70% blockade). The same dose of d-fenfluramine only slightly decreased the spontaneous activity of LC neurons in naive rats (mean decrease -0.3 \pm 0.3 Hz, n=3). Sertraline, a 5HT reuptake-blocker (3 mg/kg IV), also attenuated the LC hyperactivity, but with a slower time course. The mean firing rate of LC neurons sampled during the 10-30 min period following the induction of OW was significantly lower in sertraline treated than in non-treated rats (1.7 \pm 0.2 Hz, n=4, and 3.4 \pm 0.5 Hz, n=9, respectively; p<0.04). Fluoxetine, another 5HT uptake blocker, (4 mg/kg IV) yielded qualitatively similar results (2 \pm 0.3 Hz during the 10-30 min post-OW period, n=3). The effects of the 3 indirect 5HT agonists tested may not be mediated by 5HT_{1A} receptors as buspirone (1 and 4 mg/kg IV) and 8OHDPAT (3 mg/kg IV) did not attenuate the LC hyperactivity (n=3). Supported by US PHS grant DA 06214.

110.9

ACTIVATION OF EAA PATHWAYS IN THE RAT LOCUS COERULEUS DURING ACUTE MORPHINE WITHDRAWAL: AN *IN VIVO* VOLTAMMETRIC STUDY. M. Hong, D. Anderson*, B. Milne* and K. Jhamandas.

Departments of Pharmacology and Toxicology, and Anaesthesiology, Queen's University, Kingston, Ontario, Canada, K7L 3N6.

The increase in neuronal firing in the locus coeruleus (LC) which occurs during morphine withdrawal may involve activation of excitatory amino acid (EAA) inputs to this area. To examine this during acute morphine withdrawal, LC neuronal activity was measured using differential normal pulse voltammetry (DNPV). In all groups, morphine (10 μ g icv) significantly reduced LC activity ranging from 50.6 \pm 1.3 % to 54.3 \pm 3.1% of baseline 45 min following morphine. A subsequent injection of naloxone (1 mg/kg iv) resulted in a significant increase in LC activity: peak increase of 145.4 \pm 10.1% of baseline. This naloxone-induced increase above baseline was completely attenuated by pretreatment with the EAA antagonists, gamma-D-glutamylglycine (DGG) (2.0-200 μ g icv) or (-)-2-amino-7-phosphonoheptanoic acid (D-APH) (25 μ g icv). In the presence of these agents, the naloxone-induced change in LC activity ranged from 88.3 \pm 6.0% to 104.9 \pm 2.5% of baseline. These data suggest that activation of LC activity during naloxone-precipitated acute morphine withdrawal is mediated at least in part by activation of EAA pathways to the LC.

VENTRAL PALLIDAL AND SUBSTANTIA INNOMINATA NEURONS RESPOND TO SYSTEMIC AND MICRO-IONTOPHORETIC MORPHINE TREATMENT.

J.J. Chrobak & T.C. Napier. Department of Pharmacology, Loyola University Chicago, Maywood, IL 60153.

The ventral pallidum (VP) and substantia innominata (SI) receive an extensive enkephalineric projection from ventral striatal regions. The present study examined the response of spontaneous or glutamate-activated VP and SI neurons to systemic or microiontophoretic morphine treatment. Neurons were monitored *in vivo* using extracellular recording techniques in chloral hydrate anesthetized Sprague-Dawley rats. A dose-dependent (1-30mg/kg) suppression of firing rate was observed in 89% of VP/SI neurons tested with intravenous administration of morphine (ED₅₀ = 7.3 \pm 1.2mg/kg) which was antagonized by naloxone (1mg/kg). Iontophoretic application of morphine (75mM;20-80nA) resulted in current-related suppressions (40% of cells tested) and excitations (30% of cells tested) which were attenuated by naloxone (75mM;10-40nA). The prominence of responding cells corroborates the density of enkephalineric input to the VP and SI. The present findings demonstrate the sensitivity of VP and SI neurons to morphine treatment and provide evidence of the physiological function of opiates in the region. (Supported by DA05255 to TCN).

EFFECTS OF MU AND DELTA OPIOID RECEPTOR AGONISTS ON SYNAPTIC RESPONSES IN HIPPOCAMPAL CA1 PYRAMIDAL CELLS USING CONVENTIONAL AND WHOLE-CELL INTRACELLULAR RECORDINGS. C.R. Lupica, W.R. Proctor and T.V. Dunwiddie. Dept. Pharmacology, Univ. Colorado Hlth. Sci. Ctr., Denver, CO 80262.

Opioid agonists are thought to produce excitation in the hippocampus by reducing inhibitory GABAergic influences on pyramidal cells. However, in previous reports we demonstrated that while selective μ (DAGO) and δ (DPDPE) opioid agonists increased population spikes recorded in CA1 in a similar manner, the δ agonist DPDPE seemed to do so without reductions in recurrent or feed-forward GABAergic inhibition (Lupica et al., 1990, *Soc. Neurosci. Abst.* # 448.1; Lupica & Dunwiddie, *Synapse*, in press). In a further effort to elucidate the mechanism(s) of opioid-induced excitation in the hippocampus the effects of DPDPE and DAGO on intracellularly recorded EPSPs and IPSPs were characterized. DPDPE, DAGO and the GABA_A receptor antagonist bicuculline all increased EPSPs, while only DAGO and bicuculline reduced evoked IPSPs. It was, thus, hypothesized that μ and δ opioids reduce a "fast" GABA-mediated inhibition that occurs concurrently with the EPSP. Further evidence that the enhanced excitation produced by these opioids was related to a reduction in GABAergic input to pyramidal cells came from the observation that DPDPE, DAGO and bicuculline all reduced the frequency of spontaneously occurring IPSPs, recorded using high intracellular Cl⁻ concentrations and whole-cell electrodes. These findings indicate that opioids may enhance pyramidal cell excitability by reducing a fast GABA_A receptor-mediated conductance that is not observed using standard evoked intracellular potentials. Supported by NIDA grant DA 02702 and the V.A. Medical Research Service.

110.10

ENHANCED cAMP RESPONSIVENESS OF LOCUS COERULEUS (LC) NEURONS IN OPIATE DEPENDENCE: SINGLE-UNIT RECORDINGS IN RAT BRAIN SLICES

L.H. Kogan, E.J. Nestler, and G.K. Aghajanian. Depts. of Cellular and Molecular Physiology, Psychiatry, and Pharmacology, Yale University School of Medicine, New Haven, CT 06508.

Both extrinsic and intrinsic mechanisms have been proposed to play a role in opiate tolerance and dependence in the LC. To investigate the involvement of intrinsic factors, extracellular, single-unit activity was recorded in noradrenergic neurons of the LC in brain slices prepared from rats chronically treated with morphine. In contrast to previous reports, the basal rates of firing were two-fold higher in LC neurons from dependent animals compared to controls and they remained elevated for at least 7 hours (n=350, p<0.01). The maximal excitatory response of LC neurons from dependent animals to 8-Br-cAMP was found to be substantially greater than the response of controls with no change in the EC₅₀ (n=354, p<0.01). This result parallels biochemical evidence of an up-regulation of the cAMP pathway in the LC of dependent animals. Since an excitatory amino acid (EAA) input appears involved in withdrawal activation of LC neurons *in vivo*, the response to glutamate was tested. However, no change in the responsiveness to EAAs was observed (n=150). These results show that an intrinsic increase in basal firing rate may contribute to the activation of the LC during opiate withdrawal *in vivo* and that this increase in firing rate may be mediated by an up-regulation of the cAMP pathway.

THE DIRECT EFFECTS OF DYNORPHIN A ON ISOLATED RAT CEREBRAL ARTERIES. J. Chen*, S.H. Graham, and A.I. Faden, Department of Neurology, University of California, San Francisco, CA 94121

Opioid peptides have been shown to constrict pial arteries *in vivo*, but whether this represents a direct effect upon cerebral arteries is not known. The purpose of this study was to determine the direct effects of dynorphin A (DynA) related peptides on rat cerebral arteries. In 16 rats, the first branch of middle cerebral artery was isolated and mounted in a wire myograph perfused with oxygenated artificial CSF. ED50 of the peptides was defined as the dose required to produce half of the tension produced by 10⁻⁴M phenylephrine. DynA(1-17), a proposed endogenous κ -receptor agonist, directly constricted the isolated vessels (ED50=0.45 \pm 0.07 μ M). The DynA(1-8) fragment had less vasoconstrictive activity (80 \pm 40 μ M). The selective κ agonist U50,488H (3.2 \pm 0.7 μ M) and the selective μ agonist (D-Ala², N-Me-Phe⁴, Gly⁵-OL)-enkephalin (4.2 \pm 1.7 μ M), were less potent vasoconstrictors than DynA(1-17). DynA(2-17), which does not bind to opioid receptors, produced vasoconstriction but was less potent than DynA(1-17) (2.8 \pm 1.2 μ M). Furthermore, nalmeferine (10⁻⁵M), an opioid antagonist, inhibited the effect of U50,488H, but not that of DynA(1-17). These results demonstrate that DynA directly constricts cerebral vessels and suggest that DynA's actions on cerebral arteries are not predominantly mediated by κ -opioid receptors.

110.13

OPIOIDS ACT AT PRE- AND POSTSYNAPTIC SITES IN THE SUBSTANTIA GELATINOSA OF THE SPINAL TRIGEMINAL NUCLEUS IN RAT. T.J. Grudt and J.T. Williams, Vollum Institute, Oregon Health Sciences University, Portland, OR 97201.

Intracellular recordings were made from neurons in slices of brainstem cut in the horizontal plane containing the substantia gelatinosa of the spinal trigeminal nucleus pars caudalis (Sp5c). [Met⁵]enkephalin (ME) (3 μ M) hyperpolarized 32 of 36 cells. Under voltage clamp ME caused an outward current at -60 mV that reversed polarity at the potassium equilibrium potential. Increasing the external potassium concentration shifted the reversal potential as predicted by the Nernst equation for an increase in conductance to potassium. The μ -opioid receptor agonist [D-Ala², MePhe⁴, Gly⁵-ol⁵]enkephalin (DAMGO) (30 nM to 3 μ M) hyperpolarized 12 of 12 cells with an EC₅₀ of 69 nM. Focal electrical stimulation of the spinal trigeminal tract rostral to the Sp5c evoked a fast excitatory post-synaptic potential (epsp) that was sensitive to CNQX (10 μ M). ME (3 μ M) (5 of 8 cells) and DAMGO (1 μ M) (2 of 3 cells) reduced the amplitude of the epsp by 40-90%. These results suggest that opioids acting at μ -opioid receptors are inhibitory at both pre- and postsynaptic sites in the substantia gelatinosa. Supported by NIH grants DA04523 and MH45003.

ENDOGENOUS OPIOID REGULATION OF NOREPINEPHRINE RELEASE IN GUINEA PIG HIPPOCAMPUS. M.L. Simmons, J.J. Wagner*, R.M. Caudle, and C. Chavkin, Dept. of Pharmacology, University of Washington, Seattle, WA 98195.

Previous studies have shown that exogenously applied opioids regulate norepinephrine release in the hippocampus. In this report, a radioligand displacement assay method was used to investigate the regulation of norepinephrine release by endogenous opioids. Guinea pig hippocampal slices were incubated with [³H]-propranolol and depolarized by focal electrical stimulation of the dentate gyrus molecular layer to release both endogenous norepinephrine and endogenous opioids. Endogenous norepinephrine release was detected by a decrease in specific [³H]-propranolol binding, due to the displacement of radioligand from β -adrenergic receptors. Stimulation of adrenergic fibers caused a decrease in specific [³H]-propranolol binding to 38% of the unstimulated control, and this effect was calcium dependent. In the presence of 1 μ M PLO17, a μ opioid agonist, the stimulus-induced reduction in specific [³H]-propranolol binding was attenuated, suggesting that PLO17 inhibited the release of endogenous norepinephrine. Additionally, stimulation-induced norepinephrine release was attenuated by endogenously released opioid peptides in the presence of peptidase inhibitors. The effects of both PLO17 and endogenously released opioids were blocked by naloxone. These results indicate that endogenous opioids can act to inhibit the release of endogenous norepinephrine in guinea pig hippocampus. Supported by DA 04123 and GM07266

FREQUENCY-DEPENDENT EFFECTS OF MU OPIOID RECEPTOR ANTAGONISTS ON HIPPOCAMPAL MOSSY FIBER-CA3 RESPONSES. B.E. Derrick and J.L. Martinez, Jr., Dept. of Psychology, University of California, Berkeley, CA 94720.

Mossy fiber long-term potentiation (MF LTP) requires both high frequency stimulation (J. Neurophys., 64:948, 1990) and mu opioid receptor activation (Soc. Neurosci. Abstr., 16:980, 1990). In the present study we found that the μ opioid receptor selective antagonist CTOP (Cys¹-Tyr²-Orn³-Pen⁴ amide; 3 nmol) has no effect on mossy fiber-CA3 responses evoked in the rat *in vivo* at 0.033 Hz. However, CTOP produces a dose-dependent attenuation of both MF LTP and short-term potentiation (STP) measured 5 sec following high frequency stimulation (100 Hz). The delta receptor selective antagonist naltrindole (3 or 10 nmol) has no effect on either STP or MF LTP. These findings indicate that the effects of mu opioid receptor activation by endogenous opioid peptides are expressed only following high frequency stimulation. That this stimulation is essential for MF LTP induction may reflect a requirement for frequency-dependent activation of mu opioid receptors. Because STP involves primarily presynaptic mechanisms (J. Neurophys., 63:491, 1990), and because treatments that augment presynaptic calcium influx enhance STP (Brain Res., 459:192, 1988), mu opioid receptors may participate in MF LTP induction via actions that enhance calcium influx presynaptically.

KAPPA OPIOIDS DECREASE EXCITATORY TRANSMISSION IN THE DENTATE GYRUS OF THE GUINEA PIG. J.J. Wagner*, R.M. Caudle, and C. Chavkin, Dept. of Pharmacology, University of Washington, Seattle, WA 98195.

Kappa opioid binding sites were localized in the molecular layer of the dentate gyrus in the guinea pig hippocampus using the kappa₁ selective radioligand [³H]-U69,593. The effects of kappa₁ receptor activation in this region of the hippocampus were identified using extracellular and intracellular recordings of dentate granule cell responses in the hippocampal slice preparation. U69,593 reduced the amplitude of the stimulation-evoked population spike with an EC₅₀ of 23nM. Schild analysis was used to determine the affinity of the kappa₁ selective antagonist, nor-binaltorphimine. The K_i obtained (0.2nM), agreed with the apparent dissociation constant of nor-binaltorphimine (0.2nM), as measured by binding displacement curves. As with U69,593, dynorphin B, an endogenous opioid peptide that is present in the dentate gyrus, also inhibited the population spike response. Mu and delta selective opioid agonists had no effect on the evoked response. Intracellular recordings of dentate granule cells showed no direct effects of U69,593 on the granule cells themselves. However, analysis of synaptic potentials revealed that U69,593 significantly reduced the amplitude of EPSP's evoked by afferent stimulation without affecting IPSP amplitudes. The specific effect of U69,593 application on granule cell EPSP's indicates that presynaptic kappa₁ receptor activation inhibits glutamate release from perforant path terminals in the molecular layer of the dentate gyrus. These results suggest that endogenous dynorphins present in the granule cells may act as feedback inhibitors of the major excitatory input to the dentate gyrus. SEXUAL DIFFERENCES IN KAPPA OPIOID RECEPTOR-MEDIATED REGULATION OF TUBEROINFUNDIBULAR DOPAMINERGIC NEURONS. E.J. Wagner, J. Manzanares, S.D. LaVigne*, K.J. Lookingland and K.E. Moore, Dept. of Pharm. & Tox., Michigan State Univ., East Lansing, MI 48824.

The effects of kappa receptor blockade and antagonism on the activity of tuberoinfundibular dopaminergic (TIDA) neurons were examined. The basal activity of TIDA neurons (accumulation of 3,4-dihydroxyphenylalanine [DOPA] in the median eminence) was 2-3 times higher in female rats than in males. Following administration of the kappa antagonist nor-binaltorphimine (NOR-BNI), male rats exhibited a dose-related increase in TIDA neuronal activity. NOR-BNI had no effect on TIDA neuronal activity in intact diestrous female rats, but increased TIDA neuronal activity in ovariectomized females. In diestrous female rats, administration of the kappa agonist U-50,488 caused a dose-related decrease in TIDA neuronal activity. U-50,488 had no effect on TIDA neuronal activity in intact male rats, but decreased TIDA neuronal activity in orchidectomized males. These results suggest that gonadal steroids influence TIDA neuronal activity by altering tonic inhibition of these neurons by endogenous kappa opioids (supported by ADAMHA grant MH 42802).

SUCROSE DRINKING REDUCES DORSAL HYPOTHALAMIC β -ENDORPHIN LEVELS IN SHR BUT NOT IN WKY. T. Zhang and R. W. Rockhold, Dept. of Pharmacol. and Toxicol., Univ. of Miss. Med. Ctr., Jackson, MS.

The present study was performed to test whether drinking of a sucrose solution (S; 10%) would preferentially alter cardiovascular function in the spontaneously hypertensive rat (SHR) and if this effect correlated with changes in hypothalamic β -endorphin, a putative mediator of diet-induced changes in cardiovascular sympathetic nervous tone. Male SHR and Wistar-Kyoto (WKY) rats (12 wks of age) were trained to drink total 24 hr water consumption between 9-11 a.m. Catheters were implanted to record arterial blood pressure (BP) and heart rate (HR). Rats consumed 8 ml of either S or deionized (DI) water during a 10 min test period. Blood was removed for plasma glucose analysis 10 min before and at the end of test period. Rats were sacrificed and hypothalamus removed for analysis of β -endorphin content (BE). Comparable increases in BP were noted in SHR and WKY during either S or DI drinking. Drinking-induced tachycardia was blunted in SHR-S. Plasma glucose levels were significantly elevated ($p < 0.05$) following S, but not DI. Dorsal, but not ventral, hypothalamic β E was reduced ($p < 0.05$) following S in SHR only. The S-induced changes in β E do not appear to correlate with altered BP in SHR or WKY. The results are consistent with exaggerated stimulation of β E release in the dorsal hypothalamus following S in SHR. (Supported by HL 39387 and the AHA-Mississippi Affiliate.)

OPPOSITE EFFECTS OF OPIATE-RELATED AND NON-OPIATE-RELATED SIGMA LIGANDS ON BURST FIRING IN RUBRAL NEURONS. B.B. Matsumoto, L.N. Eisenman, W.D. Bowen* and J.C. Houk, Northwestern Univ. Med. Sch., Chicago, IL 60611 and *Brown Univ., Providence, RI 02912.

Bursts of red nucleus (RN) activity are associated with limb movements in behaving monkeys, cats, and turtles. Stimulation of the spinal cord or cerebellar cortex of the *in vitro* turtle brain also elicits bursts of RN activity, which can be used as a neurophysiological correlate of movement. The effects of sigma ligands on these burst responses were tested by bath-applying various concentrations (0.1 to 100 μ M) of opiate-related [dextralorphan (DEX), (+)-pentazocine (PENT)] and non-opiate-related [DTG, haloperidol (HAL)] sigma ligands while recording extracellularly (N=73) from the RN of the *in vitro* turtle brain. DTG and HAL increased the duration of RN bursts whereas PENT and DEX decreased the duration of the bursts. All of the effects were dose-dependent and a Student's t-test showed that the effects of the opiate-related sigma ligands differed significantly from those of the non-opiate-related compounds ($P < 0.001$). Although the compounds affected the burst response in RN neurons, they had no consistent effect on spontaneous firing rate, suggesting a neuromodulatory role for the ligands. Scatchard and competition studies confirmed that sigma receptors labelled with 3H-DTG were present in the turtle brain and that all of the compounds used in this study displaced 3H-DTG binding. These data suggest that opiate-related and non-opiate-related sigma ligands affect brainstem motor circuits through different populations of sites and that activation of these sites may have different functional ramifications.

CATECHOLAMINES: HORMONAL REGULATION

111.1

SEXUAL DIFFERENCES IN THE RESPONSIVENESS OF TUBEROINFUNDIBULAR DOPAMINERGIC NEURONS TO CENTRAL ADMINISTRATION OF BOMBESIN. J. Manzanares, T.W. Toney, K.J. Lookingland and K.E. Moore, Dept. Pharmacology & Toxicology, Michigan State University, East Lansing, MI 48824.

The purpose of the present study was to examine the effects of bombesin on the activity of tuberoinfundibular (TIDA) and tuberohypophysial dopaminergic (THDA) neurons, and the secretion of prolactin (PRL) and α -melanocyte stimulating hormone (α MSH) in gonadally-intact and castrated male and female rats. TIDA and THDA neuronal activity was estimated by measuring the concentrations of 3,4-dihydroxyphenylacetic acid (DOPAC) in the median eminence and intermediate lobe of the pituitary, respectively. Bombesin (10 ng/rat; i.c.v.; 30 min) decreased pituitary secretion of PRL in both male and female rats, and this was accompanied by an increase in the activity of TIDA neurons in male, but not female rats. Orchidectomy increased TIDA neuronal activity in male rats, but failed to alter the ability of bombesin to increase in the activity of these neurons. On the other hand, ovariectomy decreased the activity of TIDA neurons in female rats and rendered these neurons responsive to the stimulatory actions of bombesin. Taken together, these results suggest that sexual differences in the responsiveness of TIDA neurons to central administration of bombesin are due to the presence of ovarian hormones. In contrast, bombesin increased the activity of THDA neurons and decreased α MSH secretion in both gonadally-intact and castrated male and female rats, indicating that gonadal steroids have no effect on the responsiveness of THDA neurons to bombesin. (Supported by NIH grant NS 15911 and ADAMHA grant MH 42802).

110.18

THE ACTIVATION OF FUNCTIONAL AND STRUCTURAL HOMEOSTATIC PROCESSES BY SELECTIVE UNINVASIVE TRANSCRANIAL ELECTROSTIMULATION (TES) OF BRAIN STEM OPIOID STRUCTURES (BSOS). V.P. Lebedev, Ya.S. Katzmelson, A.V. Krasjukov, O.B. Illyinski, A.V. Lebedeva, Pavlov Inst. of Physiol., Leningrad, 199034, USSR, Neuro Systems, Inc., Dallas, TX, 75238, USA

In screening experiments on different species of mammals the optimal regime of TES of BSOS was determined. TES with these parameters as demonstrated by ¹³H-³H-2-Deoxyglucose uptake selectively activated the BSOS. TES produced several central effects, namely deep analgesia and stabilization of bulbar vasomotor control. Emotional pain reactions, motor and autonomic nociceptive reflexes were inhibited or abolished by TES. The peripheral effects included the acceleration of repair processes in epithelium connective tissue and in damaged peripheral nerve fibers. The obvious increase of immunity and some antitumor effect of TES were demonstrated in connection with activation of NK-cells and other phagocytic lymphocytes. The following data on the opioid nature of TES effects were obtained: the reversibility by naloxone, considerable increase of opioid neuropeptides level in plasma and cerebrospinal fluid, the potentiation by enkephalinase inhibitor, cross-tolerance with morphine analgesic effect. Clinical efficacy of our method of TES in anesthesiology, neurology and internal medicine coincided with experimental results obtained.

111.2

SEX DIFFERENCES IN STRIATAL DOPAMINE UPTAKE AND BASAL EXTRACELLULAR DOPAMINE CONCENTRATIONS? S. A. Castner and J. B. Becker, Reproductive Sciences Program & Department of Psychology, The University of Michigan, Ann Arbor, Michigan 48104-1687.

The nigrostriatal dopamine (DA) system is sexually dimorphic. There are sex differences in both DA-mediated behaviors and the neurochemistry of the striatum. For example, there are sex-related and estrous cycle-dependent differences in amphetamine (AMPH)-induced rotational behavior and AMPH-stimulated striatal DA release. In addition, last year we reported a sex difference, independent of concurrent gonadal hormones, in basal extracellular striatal DA concentrations as assessed by *in vivo* microdialysis. Castrated (CAST) male rats had significantly higher basal extracellular striatal DA concentrations than ovariectomized (OVX) female rats. The present experiments were designed to determine if the sex difference in basal extracellular DA concentrations is due to a difference in striatal DA uptake.

Adult male and female rats were CAST or OVX for at least 1 month prior to experimental use. In the first experiment, the time course of (3H) DA uptake in striatal synaptosomes from CAST male and OVX female rats was determined. In the second experiment, dialysis probes were inserted through chronic guide cannulae aimed at the striatum. On the day of dialysis, 12 to 18 hours after dialysis probe insertion, striatal dialysate samples were collected at 15 min. intervals following the sequential administration of increasing (1-100) nM concentrations of DA through the dialysis probe. Percent DA recovered in dialysate was determined by high performance liquid chromatography with electrochemical detection. Results from these studies will be presented at the meeting. SEX DIFFERENCES IN STRIATAL DOPAMINE RECEPTOR BINDING. J.B. Becker¹, T. Bazzett¹, & R. L. Albin².

¹Psychology Dept, Neuroscience Prgm, and Reproductive Sciences Prgm, ²Neurology Dept and Neuroscience Prgm, Univ. Michigan, Ann Arbor, MI 48104.

In female rats the ovarian hormones estrogen and progesterone modulate striatal dopamine (DA) release, striatal DA receptor binding, and DA-mediated behaviors. By contrast, in males estrogen does not affect striatal DA release and effects of estrogen on striatal DA receptor binding have been reported only after very high doses. This experiment was conducted to determine if there are sex differences in the effects of physiological doses of ovarian hormones on striatal DA receptor binding.

Adult male and female rats were castrated (CAST) or ovariectomized (OVX). Two weeks later animals received injections (s.c.) of: 1) peanut oil X 4 days; 2) 2 µg estradiol benzoate (EB)/100 g X 3 days, then 0.48 mg progesterone (P)/100 g 4 hr prior to use; or 3) peanut oil X 3 days, then 2 µg EB/100 g 30 min prior to use. Specific binding to [³H]SCH23390 and [³H]spiperone were determined in fresh frozen horizontal sections using quantitative autoradiography for D1 and D2 DA receptors.

Striatal binding (pmole/mg protein) to the D1 DA receptor antagonist [³H]SCH23390 was decreased by approximately 12% 30 min after EB in striatum of OVX (p<0.01). There was no effect of EB in CAST, nor was there an effect of EB + P in either sex. OVX and CAST animals receiving oil were not different, but D1 binding in the lateral striatum was lower in OVX than in CAST 30 min after EB (p<0.04). Experiments are in progress to determine whether these effects are due to changes in D1 DA receptor density or affinity. Results of binding to the D2 DA receptor antagonist will also be reported. These results demonstrate that the rapid down-regulation of striatal D1 DA receptor binding by EB is sexually dimorphic.

PUBERTAL-RELATED NOREPINEPHRINE UTILIZATION IN THE RAT HYPOTHALAMUS Su-Jean Choi and Carol K. Kellogg, Dept. of Psychology, University of Rochester, Rochester, N.Y. 14627.

Previous studies have indicated that at 28 days of age hypothalamic (HYP) norepinephrine (NE) turnover in rats is one third the adult rate, while in the cortex the NE turnover rate is at adult levels. To investigate this age related influence on NE utilization, catecholamine turnover was measured in male Long Evans rats at 28, 42, and 70 days of age. NE levels were measured at 15, 30, 45, 60, 120, and 240 min after inhibition of synthesis using alpha-methyl-tyrosine (MT; 250 mg/kg). NE levels decreased linearly over time in 28 and 70 day-old animals, with a greater rate of NE utilization in 70 day-olds. The pattern of NE utilization was markedly different at 42 days of age (midpuberty). NE levels decreased slightly over the first 45 min after inhibition (14% decrease). At 60 min, however, NE levels were 50% of basal levels, after which there was no further decrease. To estimate the degree of inhibition of tyrosine hydroxylase (TH) achieved by MT, DOPA accumulation was measured 30 min following inhibition of the decarboxylase enzyme with NSD-1015 (100 mg/kg). At both 28 and 42 days of age, DOPA accumulation decreased 70% 45 min after treatment with MT. Hence, the limited decrease in NE levels at 45 min in 42 day old rats treated with MT does not appear to be due to reduced inhibition of TH. Studies measuring the *in vitro* conversion of ³H-tyrosine to ³H-NE are underway to investigate the differential contributions of newly synthesized vs. stored NE to NE utilization at 28, 42, and 70 days of age. In summary, NE utilization is marked by a unique pattern in 42 day olds as compared to 28 and 70 day old animals. Grant No DA07080

CATECHOLAMINERGIC INNERVATION OF AROMATASE AND ESTROGEN RECEPTOR-IMMUNOREACTIVE CELLS IN THE QUAIL BRAIN. T. Bailhache*, A. Foidart, C. Surlemont*, N. Harada*, J. Balthazart, Lab. Biochemistry, Univ. Liège, B-4020 Liège, Belgium and Molec. Genetics, Fujita Health Univ., Toyoake, Aichi 470-11, Japan.

Steroids, in particular estrogens modulate the activity of catecholaminergic systems in the brain. It has also been shown that catecholamines have direct effects on steroid-sensitive systems and namely modify the concentration of estrogen receptors (ER) and the activity of aromatase (ARO), the enzyme catalyzing estrogen synthesis in the brain. In quail, we recently showed that a noradrenergic denervation produced by the specific neurotoxin, DSP4 increases preoptic aromatase activity, suggesting that the noradrenergic system exerts a tonic inhibition on this enzyme activity (Brain Res. 1989, 492:163-175). We have now analyzed the morphological relationships between catecholaminergic innervation and estrogen-sensitive and aromatase containing cells using double label immunocytochemical procedures (see J. Neurobiol. 1991, 22:143-157 for the general procedure). The dopamine β-hydroxylase (DBH) and tyrosine hydroxylase (TH) fibers were labelled using commercial antibodies (Inctar), ER were identified by the monoclonal antibody H222 (Abbott) and finally ARO-immunoreactive (ARO-ir) cells were stained with a polyclonal antibody raised against human placental ARO and purified by affinity chromatography (J. Biochem. 1988, 103:106-113; J. Comp. Neurol. 1990, 301:276-288). TH and DBH punctate structures were found in close association with ARO-ir cell bodies in all brain regions where these are present namely the medial preoptic nucleus, the ventral septum, the bed nucleus of the striae terminalis and the ventro-medial and tuberal hypothalamus. DBH fibers and punctate structures were also found in association with ER-containing cells throughout the hypothalamus, in the nucleus intercollicularis, the nucleus taniae and the septum. Many cell bodies in the hypothalamus and septum were in addition completely surrounded by TH and/or DBH punctate structures but were not immunoreactive for ER or ARO. The punctate structures suggesting direct innervation of ARO-ir and ER-ir cells might represent the anatomical substrate for the regulation by catecholamines of aromatase activity and/or ER concentration. Supported by NIH HD22064, FRFC (2.9003.91, 9.4601.90) and EEC (SCI-0230-CIT).

111.4

THE EFFECT OF CASTRATION UPON NOREPINEPHRINE RELEASE FROM SUPERFUSED OLFACTORY BULB OF MALE RAT. X.-B. Guan and D.E. Dluzen, Department of Anatomy, Northeastern Ohio Universities College of Medicine, Rootstown, OH 44272.

In order to investigate the possible relationship among the olfactory bulb (OB), norepinephrine (NE) and gonadal steroids, we measured basal and potassium stimulated (K⁺-30mM) NE release from superfused anterior and posterior OB in intact and castrated male rats (Experiment I) as well as in castrated male rats implanted with either empty or testosterone filled silastic capsules (Experiment II). Both basal (pg/mg/min) and K⁺-stimulated (area under curves-pg/50 min) release of NE was greater in posterior OB compared to anterior OB in Exp. I. (mean±SEM, basal release: anterior OB = 0.21±0.03, posterior OB = 0.29±0.04; K⁺-stimulated release: anterior OB = 1.45±0.16, posterior OB = 2.34±0.27, n=18, p<0.05). All groups were responsive to the 30 mM KCl stimuli showing increases in NE release. The degree of K⁺-stimulated release was significantly greater in intact (mean±SEM = 2.31±0.22, n=20) compared to that of castrated rats (mean±SEM = 1.38±0.21, n=16, P<0.01). No differences in K⁺-stimulated release were observed between castrated and castrated plus testosterone treated groups. These results demonstrate that castration of male rats significantly reduces OB noradrenergic responsiveness of K⁺ stimulation, an effect which was not restored following administration of silastic capsules containing testosterone.

111.6

NEUROENDOCRINE EFFECTS ON ADAPTATION OF NA-K ATPASE TO NOREPINEPHRINE DEPLETION. A.C. Swann, Dept. of Psychiatry, Univ. of Texas Med. Sch., Houston TX 77225.

Depletion of norepinephrine (NE) reduces brain Na,K-ATPase, but the enzyme recovers over time. We have investigated neuroendocrine effects on this adaptation. NE depletion was produced by injection of DSP4 (50 mg/kg ip) and verified by assay of NE in cerebral cortex. Most of the experiments described were also duplicated in rats receiving lesions of the dorsal noradrenergic bundle. The number of Na,K-ATPase sites in cerebral cortex was reduced 25% by 2 wk after DSP4 but had returned to normal, or was even slightly increased, by six weeks. Thyroid hormone increases Na,K-ATPase in non-CNS tissues and is involved in the development of brain Na,K-ATPase, but neither thyroid hormone nor experimental hypothyroidism altered the adaptation of Na,K-ATPase to depletion of NE. Dexamethasone prevented the reduction in Na,K-ATPase 2 wk after DSP4 but had no effect on the late recovery of enzyme activity. Adrenalectomy had no effect on Na,K-ATPase two weeks after DSP4, but adrenalectomized rats had a marked increase (40%) in Na,K-ATPase 8 weeks after DSP4. Intraventricular infusion of corticotropin releasing factor (CRF) also increased Na,K-ATPase after DSP4, but the effect was less than that of adrenalectomy. These results suggest that the hypothalamic-pituitary axis, particularly CRF, may be involved in the adaptation of Na,K-ATPase to depletion of NE.

111.8

STRESS AND β-CARBOLINES STIMULATE CATECHOLAMINE RELEASE IN RAT MEDIAL PREFRONTAL CORTEX, ASSESSED BY MICRODIALYSIS.

Deidra S. Atkins*, Jan Lavicky*, Xiao-Min Yang, R. Don Brown, and Adrian J. Dunn, Department of Pharmacology, Louisiana State University Medical Center, Shreveport, LA 71130-3932.

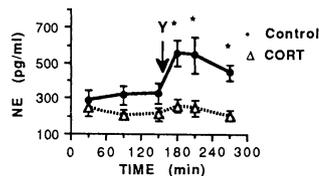

Various stressful treatments increase the metabolism of catecholamines and serotonin (5-HT) in many brain regions. Norepinephrine (NE), and perhaps also dopamine (DA) and 5-HT appears to play an important role in the etiology of anxiety. Benzodiazepines (BZD) are the prototypical anxiolytic drugs. By contrast, inverse BZD agonists are anxiogenic. We have studied the effects of stress and benzodiazepines on extracellular concentrations of catecholamines, serotonin and catabolites in the prefrontal medial cortex (PFM) of freely moving rats using microdialysis. The inverse BZD agonist, FG 7142 (15 mg/kg i.p.) increased concentrations of NE and DA in the dialysate, as well as those of the catabolites 3-methoxy,4-hydroxyphenylglycol (MHPG) and dihydroxyphenylacetic acid (DOPAC). These effects were prevented by pretreatment with the BZD antagonist, Ro 15-1788 (20 mg/kg i.p.). Rats preconditioned to electric footshock, also showed increased dialysate concentrations of catecholamines and catabolites. The responses to stress were also studied in BZD-pretreated rats. The results suggest some interactions of benzodiazepines with cerebral catecholaminergic systems during stress.

GLUCOCORTICOID INHIBITS YOHIMBINE-INDUCED RELEASE OF CATECHOLS IN POSTEROLATERAL HYPOTHALAMUS. K. Pacak*, J. Armando*, S. Komoly*, J. J. Kopin, D. S. Goldstein*. Clinical Neuroscience Branch and Laboratory of Experimental Neuropathology, NINDS, NIH, Bethesda, MD 20892.

Systemically administered yohimbine (YOH) increases sympathetic outflow and plasma levels of norepinephrine (NE); chronic hypercortisolemia markedly attenuates plasma NE responses to YOH. The present study assessed whether hypercortisolemia affects YOH-induced release of catechols in the brain—in particular, in the posterolateral hypothalamus (PLH), a region that participates in the regulation of the sympathetic outflow. Cortisol (CORT, 25 mg/kg/day) was infused s.c. for 7 days via osmotic minipumps, and release of endogenous catechols in the PLH was assessed in conscious, freely moving rats by *in vivo* microdialysis. Extracellular fluid concentrations of NE, its metabolites dihydroxyphenylglycol (DHPG) and methoxydihydroxyphenylglycol (MHPG), and the dopamine metabolite dihydroxyphenylacetic acid (DOPAC) were measured before and during YOH administration (1 mg/kg i.v.). Microdialysate collection (30-minute periods, 1 μ l/min) began 24 hours after probe implantation. YOH markedly increased NE (Figure), DHPG, MHPG, and DOPAC levels in controls, whereas in CORT-treated animals the responses were significantly reduced. These results are consistent with the view that CORT treatment suppresses central noradrenergic mechanisms that contribute to sympathetic outflow.

111.10

NERVE GROWTH FACTOR ALTERS DOPAMINE UPTAKE KINETICS IN PC12 CELLS: RELATIONSHIP TO 2'-ET-MPTP-INDUCED TOXICITY.

H.M. Geller*, A.N. Basma*, M.S. Saporito, R.E. Heikkila and W.J. Nicklas, Dept. of Neurology and *Pharmacology, UMDNJ-RWJ Med. School, Piscataway, NJ 08854.

The oxidative metabolite of MPTP, MPP⁺, is a potent dopaminergic neurotoxin. MPP⁺ and analogs such as 2'-Et-MPP⁺, are actively accumulated in mitochondria and inhibit NADH dehydrogenase of complex I, ultimately resulting in cell death. PC12 cells are a catecholamine-containing cell line which are neoplastic in nature and have a high rate of glycolysis accompanied by a large production of lactate and a low utilization of glucose carbon through the Krebs cycle. It has been reported that NGF-treated PC12 cells exhibited a marked increase in glucose utilization/energy consumption via the Krebs cycle to support the changes in morphology caused by the growth factor. If inhibition of mitochondrial respiration is indeed the mechanism of toxicity of 2'-Et-MPP⁺, then NGF treatment would be expected to enhance the toxicity of 2'-Et-MPTP in PC12 cells. However, toxicity, measured by counting live cells following exposure to the neurotoxin was similar in both untreated and NGF-treated cells. Other parameters, such as uptake of the pyridinium were assessed. NGF treatment decreased the uptake capability of the cells significantly. For example, the V_{max} measured for uptake of dopamine in either the untreated or NGF-treated cells were 1409 ± 399 or 552 ± 94 fmol/mg protein/min, respectively. These results suggest that the change in morphology induced by NGF is accompanied by alterations in the dynamics of the DA uptake system which may make NGF-treated PC12 cells less susceptible to the neurotoxic actions of 2'-Et-MPP⁺. Supported by NIH NS 21469.

CATECHOLAMINES: ASCORBIC ACID

112.1

ASCORBIC ACID AS AN ADJUNCT TO NEUROLEPTIC THERAPY IN TREATMENT RESISTANT SCHIZOPHRENICS. L. K. White, J. Chiles* and G. V. Rebec, Dept. of Psychology, Indiana University, Bloomington, IN 47405.

Several distinct lines of evidence indicate that ascorbate (AA) serves as a modulator of dopamine transmission in the mammalian brain (White et al., *Pharm. Biochem. & Behav.* 36:485, 1990). In animals, AA, when administered peripherally or infused directly into the neostriatum attenuates the behavioral response to amphetamine and potentiates the anti-amphetamine effects of haloperidol, a widely used neuroleptic drug. To the extent that these data are relevant for the treatment of schizophrenia, AA may potentiate the therapeutic effects of neuroleptics in a clinical population. To test this hypothesis, 30 schizophrenic inpatients maintained on standard neuroleptic therapy received 4-gram supplements of AA for 4 weeks followed by 4 weeks of placebo, with an intervening 3-week washout period. Psychiatric symptoms and extrapyramidal side effects were monitored weekly, along with daily patient behaviors. Although AA produced no consistent effects on positive psychotic symptoms, AA was associated with a decrease in irritability and agitation in a subgroup of patients.

112.3

INTRANEOSTRIATAL ACETYLCHOLINE AND GLUTAMATE, BUT NOT AMPHETAMINE OR DOPAMINE, INCREASE NEOSTRIATAL ASCORBATE LEVELS. R. C. Pierce, P.E. Langley* and G.V. Rebec, Prog. Neural Science, Dept. Psychology, Indiana Univ., Bloomington, IN 47405.

Ascorbate (AA), an important modulator of neostriatal function, increases markedly in the extracellular fluid of the neostriatum following systemic injection of compounds known to enhance acetylcholine, dopamine, or glutamate transmission. To assess the central mechanisms underlying this effect, we infused (0.33 μ l/min) acetylcholine (50 μ g/ μ l), dopamine (2 μ g/ μ l) or glutamate (30 μ g/ μ l) directly into the neostriatum of freely moving rats and simultaneously monitored AA release in this site via voltammetry. Relative to control infusions, both acetylcholine and glutamate significantly elevated neostriatal AA, but dopamine was without effect. In fact, intraneostriatal amphetamine (30 μ g/ μ l) also failed to alter AA, though systemic injections of this drug nearly double AA levels in the neostriatum (Pierce & Rebec, *Eur. J. Pharmacol.* 191:295, 1990). Thus, neostriatal AA is not regulated by intrinsic dopaminergic mechanisms but may be controlled instead by cholinergic and glutaminergic neuronal systems.

Supported by NSF grant BNS 87-11240.

112.2

IN VIVO VOLTAMMETRY IN FREELY MOVING RATS: DOPAMINE AGONISTS DECREASE EXTRACELLULAR ASCORBATE IN MEDIAL PREFRONTAL CORTEX. M.E. Taylor, R.C. Pierce, G.V. Rebec, Prog. Neural Science, Dept. Psychol., Indiana Univ., Bloomington, IN 47405.

Ascorbate (AA), which appears to modulate dopamine (DA)-mediated behaviors, increases markedly in neostriatum but not in nucleus accumbens in response to amphetamine or other DA agonists (Pierce & Rebec, *Eur. J. Pharmacol.* 191:295, 1990; Rebec et al., *Soc. Neurosci. Abstr.* 16:131, 1990). These results suggest that AA release mechanisms are not uniform in DA-rich forebrain areas. We extended this research to medial prefrontal cortex (mPFC), which like nucleus accumbens receives DA input from the ventral tegmental area. Electrochemically modified carbon-fiber electrodes were positioned in mPFC of awake, behaving rats that subsequently received either d-amphetamine (1.0-2.5 mg/kg) or the combination of SKF-38393 (10.0 mg/kg) and quinpirole (1.0 mg/kg), selective D1 and D2 agonists, respectively. Relative to saline controls, both amphetamine and the D1-D2 combination significantly lowered extracellular AA in mPFC. The drug-induced decline in AA typically ranged between 20-40% of the pre-injection baseline level. These results contrast with data obtained from neostriatum and nucleus accumbens and suggest that dopaminergic mechanisms do not exert uniform effects on AA release in different forebrain regions.

UNILATERAL NEOSTRIATAL KAINATE, BUT NOT 6-OHDA LESIONS BLOCK DOPAMINE AGONIST-INDUCED ASCORBATE RELEASE IN THE NEOSTRIATUM OF FREELY-MOVING RATS. D. W. Miller, R. C. Pierce, D. B. Reising, and G. V. Rebec, Prog. in Neural Science, Dept. Psychology, Indiana Univ., Bloomington, IN 47405.

Neostriatal ascorbate (AA), which is known to modulate dopamine-mediated behavior, increases following dopamine (DA) agonist treatment (Pierce & Rebec, *Eur. J. Pharmacol.*, 1990, 191:295). In the present study, unilateral neostriatal kainate (KA) and 6-hydroxydopamine (6-OHDA) lesions were used to assess the role of the striatonigral and nigrostriatal pathways, respectively, on DA agonist-induced neostriatal AA release. Following a post-surgery recovery period (7-10 days), the subjects were challenged with either direct (a combination of 10.0 mg/kg SKF-38393 and 1.0 mg/kg quinpirole) or one of two indirect (2.5 mg/kg d-amphetamine or 20.0 mg/kg GBR-12909) DA agonists. Voltammetric recordings with electrochemically modified, carbon-fiber electrodes revealed that, relative to controls, unilateral neostriatal KA lesions abolished the ability of direct and indirect DA agonists to induce neostriatal AA release. In KA lesioned rats, AA levels decreased 20-60% following systemic drug administration. Histological analysis of the KA lesions indicated substantial gliosis in approximately 60-80% of the striatum. Conversely, 6-OHDA lesions (>95% depletion) of the nigrostriatal pathway had no effect on DA agonist-induced neostriatal AA release. These results suggest that the striatonigral, but not the nigrostriatal pathway is necessary for DA agonist-induced AA release.

Supported by NSF BNS 87-11240.

112.5

NEUROTOXIC EFFECTS OF ASCORBIC ACID ON HIPPOCAMPAL NEURONS IN CULTURE. M. B. Ghasemzadeh and M. A. Dichter. Depts. of Pharmacology and Neurology, U. of Pennsylvania School of Medicine, Philadelphia PA 19104.

Ascorbic acid (AA) is present at high concentrations (1-3 mM) in mammalian brain (ECF = 200-500 uM in rat brain); however, its significance in CNS functioning is still poorly understood. In rat fetal brain AA content almost doubles during the last week of gestation and thereafter is gradually reduced to adult levels. AA is an important biological antioxidant and free radical scavenger; although, it also possesses a paradoxical ability to act as a pro-oxidant. It has been proposed that lipid peroxidation and free radicals play a role in ischemic brain damage. Recently, it was shown that brain trauma and focal ischemia lead to a dramatic increase of extracellular AA. Given the results of the above studies, we decided to examine the effect of ascorbic acid on rat hippocampal neurons grown in primary dissociated cell culture.

A concentration dependent toxicity of AA was observed. Ascorbate at ≤ 200 uM did not exhibit any toxicity. Higher concentrations of AA produced cell death within 24 hours, with complete cell loss at ≥ 1 mM. The neurotoxic effect could be prevented by addition of catalase, a hydrogen peroxide scavenger. Inhibition of lipid peroxidation was also able to counteract the AA effect. Surprisingly, AA at the highest concentration tested (6 mM) was not cytotoxic to glial cells. These results indicate that AA produces profound neurotoxic effects on hippocampal neurons in culture which are mediated through production of hydrogen peroxide and membrane lipid peroxidation. Therefore, release of AA during trauma and ischemic episodes may contribute to neuronal degeneration and brain damage.

112.7

CHOLINERGIC AND GLUTAMATERGIC MODULATION OF AMPHETAMINE-INDUCED INCREASES IN ASCORBIC ACID IN RAT CAUDATE NUCLEUS. P. Kunko, K. Mueller and R. Saponic. Dept. of Psych., Texas Christian Univ., Ft. Worth, TX 76129.

Ascorbic acid (AA) levels in the rat caudate nucleus are increased by low-dose amphetamine. However, AA levels may not be directly related to DAergic neurotransmission. Amphetamine also increases cholinergic and glutamatergic activity in the caudate. Therefore we tested the ability of scopolamine and MK-801 to block amphetamine-induced increases in AA in the rat caudate.

AA levels were measured in adult male albino rats by semidifferential linear sweep voltammetry. Locomotion was defined as line crossovers in the testing cage. One group of rats received scopolamine (0.6mg/kg, ip) and amphetamine (1.5mg/kg, sc). Three other groups received MK-801 (0.05, 0.1, or 0.5mg/kg, ip) and amphetamine (1.5mg/kg, sc). Scopolamine reduced the amphetamine-induced AA increase by 50% while increasing crossovers. MK-801 reduced amphetamine-induced AA increases but did not alter crossovers.

AA levels and locomotor behavior appear to be mediated by different amphetamine-sensitive substrates.

112.9

ANOXIA-RESISTANT TURTLE BRAIN MAINTAINS ASCORBIC ACID CONTENT *IN VITRO*. M.E. Rice & J. Cammack. Dept. Physiology & Biophysics, New York University Medical Center, New York, NY 10016; Dept. Pharmacology, University of Kansas, Lawrence, KS 66045.

Tissue content of ascorbate in mammalian brain is 2-3 mM with an extracellular concentration of 200-400 uM. Total tissue ascorbate is rapidly lost, however, when incubated in ascorbate-free media *in vitro* (*Brain. Res.* 253: 353, 1982). We have previously reported that tissue and extracellular ascorbate concentrations in turtle brain (*J. Neurochem.* 49: 1096, 1987) are similar to those in mammals. Here we report that, in contrast to mammalian brain, isolated turtle brain tissue maintains intra- and extracellular ascorbate levels when incubated in ascorbate-free media for as long as 24 hours. After incubation for one hour, total tissue content of ascorbate in the turtle (*Pseudemys scripta* or *Chrysemys picta*) cerebellum was the same as in uninoculated controls. After 20-24 hours, tissue ascorbate content remained at 65% of control levels, while extracellular ascorbate concentration, measured with carbon fiber voltammetric microelectrodes, was 56% of the initial value. For an intermediate incubation period of 6 hours, reduced ascorbate content was maintained at about 80% of control levels, regardless of whether incubation was under normal conditions or in the absence of glucose or oxygen. By contrast, only 4% of the ascorbate content of guinea pig brain slices remained after a 6 hour incubation. Maintenance of ascorbate concentration by the anoxia-resistant turtle brain suggests that this antioxidant is important in ameliorating anoxic injury. Inclusion of ascorbate in media used for *in vitro* studies of mammalian brain tissue is recommended. Supported by USPHS Grants NS-13742 and NS-28480 and NS-08740, BRSG S07 RR05399-29 and PHS Training Grant GM-07775.

112.6

ASCORBIC ACID REGULATES TYROSINE HYDROXYLASE AND DOPAMINE LEVELS IN MESENCEPHALIC CULTURES. H.H. Kalir and C. Mytilineou. Dept. of Neurology, Mt. Sinai Sch. of Med., New York, N.Y. 10029.

Embryonic brain cells rapidly lose their ascorbic acid (AA) content when placed in culture, unless AA is supplied with the feeding medium (Kalir and Mytilineou, 1991). We have investigated the acute and long term effects of AA on the levels of dopamine (DA) and tyrosine hydroxylase (TH) immunocytochemistry in mesencephalic cultures prepared from E14 rat embryos and maintained in serum containing medium in the presence or absence of 200uM AA. After 12 days *in vitro* AA-treated cultures had DA levels 5-fold higher than controls and 10 times the number of TH+ neurons. The TH+ neurons in the AA-treated cultures were also more darkly stained and had more prominent processes than in the controls. When control cultures were treated with AA for 24 hrs, the levels of DA increased by 34% and the number of neurons that could be visualized by TH immunocytochemistry increased more than 3-fold. The intensity of the staining was also increased. Conversely, when AA was removed from AA-treated cultures, both DA levels and the number of TH+ neurons were reduced by about 50%. The staining intensity of individual neurons was also reduced after AA removal. The changes in the number of TH+ neurons and staining intensity after 24 hr exposure or removal of AA suggest a change in the amount of enzyme molecules rather than a change in the number of DA neurons. Taken together our results indicate that the levels of TH in the DA neurons are regulated by AA and that the increased levels of DA in the AA-treated cultures could result from increased enzyme levels. Supported by NIH grant NS-23017 and by the United Parkinson Foundation.

112.8

RESTRAINT INCREASES RELEASE OF ASCORBIC AND URIC ACID IN CINGULATE CORTEX OF RAT. K. Mueller, Dept. Psych. TX Chrst. Univ., Ft. Worth TX 76129

Ascorbic acid (vitamin C) is plentiful in brain and is released into the extracellular space in response to a variety of stimuli. Ascorbic acid (AA) also modulates neuronal functions; thus AA may play an important role in brain. Uric acid (UA) is also plentiful in brain. Although UA is less likely to have any function in brain it may provide important information. Whether release of AA and/or UA are associated with particular neuronal events or behaviors is still unclear. Previous research suggested that increased release of AA in anterior cingulate cortex is an indirect result of stress. Therefore, the effects of restraint on release of AA and UA from anterior cingulate cortex (limbic) was compared to the effects in caudate (sensorimotor). Voltammetry *in vivo* was used to monitor release of AA and UA in conscious behaving rats. Restraint (40 min) increased both AA and UA in both brain areas, although the increase was greatest in cingulate cortex. Repeated restraint produced a gradually increasing AA response. The anxiolytic diazepam reduced resting AA and UA levels but failed to block the restraint-induced increase in AA.

112.10

INHIBITION OF CATECHOLAMINE AUTOXIDATION BY ASCORBIC ACID AND URIC ACID. W.H. Church, V. Ward*. Dept. of Chemistry, East Carolina Univ., Greenville, NC 27858-4353.

The inhibition of catecholamine autoxidation by ascorbic acid and uric acid is evaluated with regard to the production of cytotoxic agents. Previous work from this lab has shown that uric acid and ascorbic acid have a synergistic effect on the inhibition of dopamine autoxidation. The present work extends these findings to other catecholamine neurotransmitters, as well as other oxidizable biomolecules. UV photo-diode array and electrochemical detection are used to establish the kinetics and reaction mechanisms associated with these reactions *in vitro*. Relevance of *in vitro* results to *in vivo* processes is discussed. The ability of these antioxidants to inhibit aerobic oxidation of the catecholamines and, as a result, the generation of cytotoxic quinones and free radicals is interpreted in relation to the neuronal cell death associated with aging and Parkinson's disease.

112.11

PHYSIOLOGICAL AND CLINICAL EFFECTS OF ASCORBIC ACID ADMINISTRATION. L.C. Tolbert, J. Spollen*, and L.D. Middaugh¹. Dept. of Psychiatry and Behavioral Neurobiology, Univ. of Alabama at Birmingham, Birmingham, Al 35294 and ¹Dept. of Psychiatry Medical University of South Carolina, Charleston, SC.

A variety of experiments conducted over the last decade or so have produced results consistent with the hypothesis that one of the roles of this vitamin in the CNS might be that of a dopamine neuromodulator. These experiments have demonstrated, for example, effects on ligand binding and second messenger system *in vitro* as well as effects on neuronal firing rates, neurotransmitter turnover, and modulation of the effects of concomitantly administered dopaminergic pharmacologic agents, *in vivo*. Additionally, a series of these experiments have demonstrated that extracellular ascorbate levels in the CNS are dynamic and change in response to a variety of manipulators. Although alternative explanations for the results of individual experiments can be offered, but the recurrent conclusion, and most parsimonious explanation is that ascorbic acid can have pharmacologic effects consistent with the hypothesized role as a dopamine neuromodulator.

We have conducted two experiments to further evaluate this possibility. In one experiment we evaluated the ability of pharmacologic doses of ascorbate to impact the neuroendocrine system in rats; specifically the ability to modulate the L-Dopa-induced changes in prolactin and LH. Ascorbate significantly attenuated those L-Dopa-induced changes. In the second experiment we conducted a double-blind, placebo-controlled, cross-over design clinical trial of the ability of ascorbic acid to attenuate symptoms in a group of autistic subjects. Ascorbate significantly reduced total symptom scores and motor symptom scores. It had no effect on affectual symptom scores.

SEROTONIN RECEPTORS: 5HT_{1A} II

113.1

MONOCLONAL ANTIBODIES FOR THE VISUALIZATION OF BMY 7378-SENSITIVE 5HT_{1A} RECEPTOR SITES. G.P. Martinelli¹, G.R. Holstein^{2,3}, D.W. Smith⁵, F. D. Yocca⁵, and S. Maayani⁴. Depts. of Surgery¹, Neurology², Anatomy³ & Anesthesia⁴ Mount Sinai Sch Med., NY, NY 10029; Preclinical CNS Res., Pharm. R&D Div., Bristol-Meyers Comp⁵, Wallingford, Conn. 06492.

The goal of this work was the localization of BMY 7378 [(8-[2-[4-(2-methoxyphenyl)-1-piperazinyl] ethyl]-8-azaspiro[4,5]-decane-7,9-dione) as a marker for 5HT_{1A} receptor sites in the rat CNS. To obtain antibodies which might not interfere with the binding of BMY 7378 to an acceptor site, the compound 8-(4-aminobutyl)-8-azaspiro [4,5] decane-7,9-dione-HCl (BMY-Hpt) was synthesized and conjugated to keyhole limpet hemocyanin using 1-ethyl-3-(3-dimethylamino-propyl) carbodiimide (ECD). Such conjugate was used to immunize mice to raise monoclonal antibodies. Six stable clones producing antibodies with specificity against BMY-Hpt were thrice cloned. None of these showed cross-reactivity with ECD conjugates of various neuroactive substances to bovine serum albumin. The specificity of such antibodies for BMY 7378 was confirmed by immunoprecipitation with [³H]BMY 7378. Subsequently, immunocytochemical studies of BMY 7378 localization were conducted in rats. Experimental animals received subcutaneous injections of BMY 7378 (10 mg/kg); controls received saline. Rats were sacrificed 40 min post-injection. Sections were exposed to the primary antibody for 16 hr, followed by the PAP procedure. Ultrastructural observations revealed immunoreactive elements in discrete brain regions of the BMY-injected rats. In the hippocampal CA1 region, most of the immunostain is present in unmyelinated axons, usually in apposition to long thin dendritic shafts, but without synaptic specializations. Many axon cylinders of myelinated profiles are also immunolabeled. Identically processed sections from saline-injected animals showed no specific immunostaining. Aided by Grants NS-24656, GM-34852.

113.3

Phosphorylation may be involved in agonist-mediated desensitization of 5-HT_{1A} receptors. M.A. Harrington and R.D. Ciaranello. Nancy Pritzker Laboratory, Stanford University School of Medicine, Stanford, CA 94305.

Preincubation of rat cortical membranes in 1 nM 8-OH-DPAT, but not 1 nM (-)pindolol results in a significant decrease in the density (B_{max}) of ³H-8-OH-DPAT binding to 5-HT_{1A} receptors without affecting the affinity (K_D). Preincubation in 100 uM cAMP or 10 uM forskolin has a similar effect on ³H-8-OH-DPAT binding, decreasing the B_{max} while having no effect on the K_D. In addition, 8-OH-DPAT inhibition of forskolin-stimulated adenylate cyclase in rat hippocampal membranes is desensitized by preincubation in DPAT, cAMP or forskolin. Preincubation of HA7 cells (HeLa cells expressing 5-HT_{1A} receptors) with 5 pM 8-OH-DPAT results in a significant decrease in the B_{max} of ³H-8-OH-DPAT binding without affecting the K_D, while preincubation with 5 pM (-)pindolol has no effect on the binding. Preincubation in either forskolin or cAMP also significantly decreases the B_{max} of ³H-8-OH-DPAT binding. In HA7 cells, 8-OH-DPAT inhibition of forskolin-stimulated adenylate cyclase is desensitized by preincubation with either DPAT or forskolin. In addition preincubation with the catalytic subunit of protein kinase A results in a desensitization of DPAT-mediated inhibition of adenylate cyclase similar to preincubation with agonist. These results suggest that phosphorylation may play a role in regulation of the 5-HT_{1A} receptor.

113.2

CHARACTERIZATION OF ANTIBODY-BMY-7378 IMMUNE COMPLEX BINDING TO THE 5-HT_{1A} RECEPTOR IN RAT BRAIN. W.P. Clarke¹, G.P. Martinelli², G.R. Holstein^{3,4}, and S. Maayani^{1,5}. Departments of Pharmacol¹, Surgery², Neurology³, Cell Biology/Anatomy⁴ and Anesthesiology⁵, Mount Sinai School of Medicine, CUNY, New York, NY 10029.

Ultrastructural localization of 5-HT_{1A} receptor sites with electron microscopy requires new methods to label the receptor. Martinelli *et al.*, (this volume) have developed a monoclonal antibody that binds to BMY-7378, a potent, selective and low efficacious 5-HT_{1A} agonist. The characteristics of binding to the 5-HT_{1A} receptor of an immune complex between this antibody and BMY-7378 were examined in rat hippocampal membranes. Immune complexes were formed by incubating the antibody (100 µg; 2-15 mg/ml) with BMY-7378 (20 µg; 1 mM) for 30 minutes at 37 °C. The immune complex was separated from free BMY-7378 by filtration with a Sephadex G-25 column and the void volume collected. Immune complexes labelled with ¹²⁵I were made by prelabelling the antibody with ¹²⁵I prior to incubation with BMY-7378. In homogenates of rat hippocampus, unlabelled immune complex (0.1-100 µg/ml) competed for [³H]-8-hydroxy-2-(di-*n*-propylamine)tetralin (8-OH-DPAT; 1-2 nM) binding. Antibody alone (not complexed with BMY-7378) did not reduce [³H]-8-OH-DPAT binding. The void volume collected when BMY-7378 alone (not complexed with antibody) was eluted from the G-25 column did not compete for [³H]-8-OH-DPAT binding. Although non-specific binding (determined in the presence of 1 µM 5-carboxamido-tryptamine) was high, incubation of hippocampal membranes with 100 µg/ml of the ¹²⁵I-immune complex appeared to label 5-HT_{1A} receptor sites. These data suggest that the immune complex between antibody and BMY-7378 binds to the 5-HT_{1A} receptor. The high specific activity and selectivity of iodinated immune complexes and Fab fragment complexes should be useful for binding and autoradiographic studies of the 5-HT_{1A} receptor in brain. In addition, the complex will allow for ultrastructural localization of 5-HT_{1A} in brain. (Supported by grants USPHS GM-34852, MH-48125, NS-24656)

113.4

ELEVATED BRAIN 5-HT LEVELS OR 5-HT_{1A} RECEPTOR AGONISM INDUCE C-FOS PROTEIN WITH SIMILAR PATTERNS IN NUCLEI OF RAT BRAIN. R.A. Leslie, T.P. Flanigan*, J.M. Harvey* and D. G. Grahame-Smith*. Oxford University - SmithKline Beecham Centre, Dept. of Clinical Pharmacology, Radcliffe Infirmary, Oxford OX2 6HE, U.K.

Many functions are mediated by CNS 5-HT, and most 5-HT cell bodies are in raphé nuclei of the brainstem. Little is known about the localization of 5-HT terminals which mediate specific functions. Immunocytochemistry has been used to localize c-fos protein to map brain activity associated with 5-HT functions. Increased 5-HT function produced by MAO inhibition and L-tryptophan results in the 5-HT hyperactivity syndrome and specific Fos-like immunoreactivity (FLI) in many limbic nuclei and in certain subdivisions of striatum, parasympathetic nuclei, paraventricular hypothalamus, dorsomedial thalamus and inferior olive. A similar pattern of FLI was seen in animals experiencing the 5-HT syndrome after being given 8-OH-DPAT, a specific 5-HT_{1A} receptor agonist. Anaesthesia with sodium pentobarbital to prevent locomotor effects of the syndrome resulted in a loss of FLI in striatal but not other brain regions. We conclude that Fos immunocytochemistry is a valuable technique for localizing 5-HT activity in rat brain.

113.5

EXPRESSION OF RAT 5-HYDROXYTRYPTAMINE_{1A} RECEPTOR GENE IN CULTURED CELLS: CHARACTERIZATION BY [³H]DPAT BINDING. Y. Fujiwara, I. Sorai, H. Tomita*, S. Otsuki*, H. I. Yamamura#, T. Ohnuki##, Y. Hamagishi*## and T. Oki##, Dept. of Neuropsychiat. Okayama Univ. Medical Sch., Shikata-cho 2-5-1 Okayama 700, Japan, #Dept. of Pharmacol., Sch. of Med., Univ. of Arizona, Tucson, AZ85724, USA, ##Bristol-Myers Squibb Research Institute, Tokyo 153, Japan.

We report the expression of the rat 5-HT_{1A} receptor gene cloned by us (Fujiwara et al. 1990) and the characterization of this receptor by [³H]DPAT binding. BamHI-XbaI fragment of this gene was cloned into Rc/RSV and transfected into HeLa cells by calcium phosphate method. The cells were scraped, centrifuged and resuspended in TEM buffer. For [³H]DPAT binding, ligand (1nM for inhibition study) and 7.5ug protein of cell membrane in 500ul of buffer (50mM Tris-HCl pH=7.4, 2.5mM MgCl₂) were incubated at 30°C for 30 min. 5-HT (10uM) was used to define nonspecific binding, which was less than 10% of total binding at 1nM of [³H]DPAT. Cells expressed specific and saturable binding of [³H]DPAT with a K_D value of 0.6nM and a Bmax value of 2 p mol/mg protein. Specific binding was inhibited by partial agonists, which were expected to have anxiolytic effect. Ipsapirone, buspirone, SM3997 and gepirone displaced [³H]DPAT binding at 10-100nM concentration, whereas spiperone and mianserin were effective only at 1 uM concentration. The displacement potencies of these compounds by [³H]DPAT binding are similar to affinities obtained in rat hippocampus.

113.7

SEROTONIN INHIBITION OF CYCLIC AMP FORMATION IN XENOPUS OOCYTES INJECTED WITH RAT STOMACH FUNDUS RNA. J. Harts, J. Liu*, J.D. Kursar¹, M. Baez¹, D.L. Nelson¹, M.L. Cohen¹ and L. Yu Dept. of Med. and Mol. Genetics, Indiana Univ. School of Medicine, Indpls, IN 46202; ¹Lilly Research Laboratories, Lilly Corp. Center, Indpls, IN 46285.

Serotonin-elicited contractions in rat stomach fundus are mediated by a serotonin (5HT) receptor pharmacologically distinct from the known subtypes. Oocytes injected with fundus RNA, 5HT_{1A} receptor RNA or tRNA were treated with either 100 μM forskolin or 100 μM forskolin and 1 μM 5HT. cAMP content was analyzed using a radioimmunoassay. Basal cAMP levels are 1.05, 1.41 and 1.78 pmoles for tRNA, fundus RNA and 5HT_{1A} RNA-injected oocytes. Forskolin treatment gave significant increases in cAMP content in all groups. 5HT treatment decreased cAMP content by 85% and 28% in fundus RNA or 5HT_{1A} receptor RNA-injected oocytes, but did not change cAMP levels in tRNA-injected oocytes. To determine the feasibility of studying receptors linked to inhibition of adenylyl cyclase by voltage-clamp methods, 5HT_{1A} receptor RNA was injected into follicle oocytes. Membrane potential was held at -20 mV and currents were measured during application of either 1 μM forskolin or 1 μM forskolin and 1 μM 5HT. Forskolin elicited a weak, outward current which was reversed by 5HT. These methods will be useful in further studies of the fundus serotonin receptor and other receptors linked to inhibition of adenylyl cyclase.

113.9

CONSERVED ASPARTATE AND SERINE RESIDUES INVOLVED IN LIGAND BINDING OF THE SEROTONIN 1A (5-HT_{1A}) RECEPTOR. B. Y. Ho*, A. Karschin, N. Davidson and H. A. Lester Division of Biology, California Institute of Technology, Pasadena CA 91125.

Aspartate¹¹⁶ in the 2nd transmembrane region and serine¹⁹⁸ in the 5th transmembrane region of the human 5-HT_{1A} receptor were mutated to asparagine¹¹⁶ (D116N) and alanine¹⁹⁸ (S198A), respectively, to study their effects on ligand binding. The wild type and mutant receptors were expressed in COS-7 cells using vaccinia virus vectors and membranes were prepared for radioligand binding assays. Saturation binding experiments showed that the wild-type and mutant receptors were expressed in comparable levels (2-4 pmol/mg protein). Both mutants showed major decreases in affinity for serotonin but smaller changes in affinity for the antagonist pindolol. The K_i values for serotonin increased from 1 nM in the wild type to 148 nM in D116N and 246 nM in S198A. Those for pindolol changed from 18 nM to 28 nM in D116N and 32 nM in S198A. These findings suggest that aspartate¹¹⁶, which is conserved among monoamine receptors, may form electrostatic interaction with the protonated amino group of serotonin, while serine¹⁹⁸, which is conserved among various serotonin receptors, may form hydrogen bond with the 5-OH group on the indole ring of serotonin. (supported by American Heart Association, Humboldt Foundation, NIH GM-29836, GM-10991).

113.6

EXPRESSION AND FUNCTIONAL COUPLING OF THE SEROTONIN-1A (5-HT_{1A}) RECEPTOR IN HUMAN EMBRYONIC KIDNEY (293) CELLS. I.G. Hensler, D.B. Pritchett, A. Frazer and P.B. Molinoff. Depts. of Psychiatry, Pharmacology, and Pediatrics, Univ. of Penna. School of Medicine, and Dept. of Veterans Affairs Medical Center, Phila., PA 19104.

Human embryonic kidney (293) cells were transiently transfected by the method of Chen and Okayama (Mol Cell Biol 7:2745, 1987) with the BamHI-XbaI fragment of the human 5-HT_{1A} receptor gene using a eukaryotic expression vector containing a cytomegalovirus promoter. Expression of receptor was detected 48 hr after transfection by the binding of the agonist ligand [³H]8-OH-DPAT. Saturable binding of [³H]8-OH-DPAT was measured with a K_D value of 2.5 nM, and Bmax values of 200 to 1000 fmol/mg protein. No specific binding was measured in untransfected cells. Specific binding of [³H]8-OH-DPAT in transfected cells was inhibited by guanine nucleotides. Inhibition of forskolin-stimulated adenylyl cyclase by 5-HT, as determined by prelabeling cells with [³H]adenosine and measuring the conversion of [³H]ATP to [³H]cAMP, was present in transfected but not in untransfected cells. 5-HT inhibited forskolin (1 μM)-stimulated adenylyl cyclase in a concentration-dependent manner (IC₅₀=20 nM) with a maximal inhibition of approximately 50%. The expression and coupling of the 5-HT_{1A} receptor to G proteins, and the functional coupling of this receptor to the inhibition of the adenylyl cyclase system, suggest that this expression system may be useful for studying the structural requirements of the receptor protein and the regulation of this receptor. (Supported by research funds from the Dept. of Veterans Affairs, USPHS grants MH 48125, and MH 29094).

113.8

MOLECULAR STRUCTURE AND FUNCTIONAL EXPRESSION OF α2-ADRENERGIC AND SEROTONERGIC RECEPTORS.

N.J. Stam, R. Dijkema*, F. Van Huizen, J.A.D.M. Tonnaer. Microbiology and CNS Pharmacology R & D Labs, Organon Int. bv, PO Box 20, 5340 BH Oss, The Netherlands

In order to isolate individual α2-adrenergic and 5-HT receptor subtypes, a human genomic DNA library was screened under low stringency conditions with a set of degenerated oligonucleotide probes derived from consensus sequences (TMR segments) of known α2-AR and 5HT receptor genes. Three α2-AR subtypes were cloned and expressed in CHO cells. All three genes encoded a single high affinity receptor site with clearly different pharmacological characteristics. Exposure of α2-AR transfectants to the agonist clonidine attenuated forskolin induced cAMP levels by more than 40%, suggesting a functional coupling of the human receptors in the rodent cells to the intracellular second messenger system. Northern blot analysis with subtype specific probes indicated a differential expression of the receptor subtypes in various tissues. The complete coding sequence of the human 5-HT_{1A} receptor was isolated. Rodent fibroblasts transfected with this 5-HT_{1A} gene expressed a single receptor site for 8-OH DPAT with a K_d of 2-3 nM. Functional studies suggested a negative coupling of the 5-HT_{1A} receptor to the enzyme adenylyl cyclase. A panel of independent transformants was generated that expressed the receptor at different densities. These clones are used to investigate the relationship between receptor densities and affinity state and coupling efficacy of the receptor. Preliminary results suggest that high affinity binding of 8-OH DPAT is independent of receptor density per cell.

113.10

EXPRESSION OF THE HUMAN 5-HT_{1A} RECEPTOR GENE (G21) IN A NEURONAL CELL LINE.

F. Yocca^{1,2}, E. Baetge¹, M. Bachinsky¹, G. Gaughan¹, J. Torrente¹, and S. Maayani², ¹CNS Drug Discovery, Bristol-Myers Squibb Co., Wallingford, CT, and ²Dept. Anesthesiology, Mt. Sinai School of Medicine, N.Y., N.Y.

The 5-HT_{1A} receptor subtype has been described to date only in the CNS, but the human gene for this receptor (G21) has been expressed solely in non-neuronal cell lines. We have transfected the gene for the human 5-HT_{1A} receptor into HT4 cells, a line derived from a mouse neuronal cell line and immortalized with temperature sensitive SV40 T-antigen (Whittemore, et al., *J. Neurosci. Res.* 28, 156-170, 1991). Using the published gene sequence, we employed the polymerase chain reaction of human genomic DNA to isolate an incomplete 5-HT_{1A} coding sequence (Kobilka, et al., *Nature*, 329, 75-79. Complete restriction and partial DNA sequence analysis confirmed the identity of the 5-HT_{1A} gene, which was subsequently subcloned into a plasmid expression/selection vector. The HT4 cells were transfected with the 5-HT_{1A} receptor gene by use of calcium phosphate with osmotic shock by 25% glycerol (Schweitzer and Kelly, 1985).

Preliminary saturation studies indicate [³H]-8-OH-DPAT, a selective 5-HT_{1A} agonist, labelled with high affinity an apparently homogenous population of binding sites (K_D=1.6 nM). This value is comparable to that obtained utilizing rat hippocampal tissue and to the G21 expressed in non-neuronal cell lines. In competition experiments, 5-HT_{1A} agents displayed monophasic displacement curves with nanomolar affinities. Further, when [³H]-8-OH-DPAT binding to the 5-HT_{1A} receptor binding site was performed in the presence of 5'-guanylylimidodi-phosphate (GppNHp), a concentration-dependent decrease in [³H]-8-OH-DPAT binding was observed suggesting the site is coupled to a G-protein. This system offers the first cell line derived from neuronal tissue for studying the signal transduction mechanism initiated by activation of the 5-HT_{1A} receptor (supported in part by USPHS6M-24852).

IDENTIFICATION AND LOCALIZATION OF 5-HT_{1A} RECEPTORS IN THE RAT BOWEL AND PANCREAS. A.L. KIRCHGESSNER, M. LIU* and M.D. GERSHON, Dept. of Anat. & Cell Biol., Columbia University, New York, NY 10032.

We tested the hypothesis that the rat enteric nervous system (ENS) contains 5-HT_{1A} receptors. [³H]8-OH-2-(di-n-propylamino)tetralin ([³H]8-OH-DPAT) was used as a radioligand. Binding of [³H]8-OH-DPAT to membranes derived from the myenteric plexus and the pancreas was investigated by rapid filtration. Alternatively, radioautography was employed to locate [³H]8-OH-DPAT binding sites in frozen sections of unfixed bowel or pancreas. An excess of 5-HT (10 μM) was used to define nonspecific binding. Saturable, high affinity binding of [³H]8-OH-DPAT to enteric ($K_D = 2.8 \pm 1.1$ nM; $B_{max} = 39.9 \pm 4.3$ fmol/mg protein) and pancreatic ($K_D = 6.6 \pm 1.3$ nM; $B_{max} = 44 \pm 2.2$ fmol/mg protein) membranes was found. As is true of [³H]8-OH-DPAT binding to 5-HT_{1A} receptors of the CNS, the binding of [³H]8-OH-DPAT to enteric and pancreatic membranes was inhibited by 8-OH-DPAT, NAN-190, spiperone, and metergoline. In contrast, the binding of [³H]8-OH-DPAT to enteric and pancreatic membranes was not inhibited by 5-carboxyamidotryptamine, or by a variety of compounds known to bind to other subtypes of 5-HT receptor. Radioautography revealed that the highest density of [³H]8-OH-DPAT binding sites was found in the stomach and the colon. These sites were concentrated in the muscularis mucosa and myenteric ganglia. Fewer binding sites were observed in the muscularis mucosa and myenteric plexus of the esophagus, small intestine, and cecum. Pancreatic 5-HT_{1A} receptors were located on nerves, lymphoid tissue (especially the capsule of nodes), and on the tissue adjacent to ducts and some islets. It is concluded that the rat ENS and its extension in the pancreas contains 5-HT_{1A} receptors. The function of these receptors in the physiology of the entero-pancreatic innervation remains to be determined. Supported by American Diabetes Association & NS27645.

ALLOSTERIC INTERACTION BETWEEN BINDING OF HORMONES AND BINDING OF GUANYLNUCLEOTIDES TO G-LINKED RECEPTORS IS AFFECTED BY ISOFLURANE; A QUANTITATIVE AUTORADIOGRAPHIC STUDY.

J.H. Silverstein, C.D. Mahle and S. Maayani, Dept. of Anesthesiology and Pharmacology, Mount Sinai Medical Center, CUNY, New York NY 10029.

The initial steps of signal transduction mediated in neurons by hormone receptors may be perturbed by inhaled anesthetics. The binding of hormone to the receptor stabilizes a high affinity ternary complex between hormone, receptor and guanyl nucleotide regulatory proteins (G-proteins)(H-R-G). An early event is the destabilization of H-R-G by guanyl nucleotides. This perturbation may be receptor and brain region dependent. We have measured the destabilization of H-R-G by quantitative receptor autoradiography in 15 μ coronal sections from cow hippocampus. Guanosine 5'-(β,γ-imido)triphosphate (Gpp(NH)p), a non-hydrolyzable analogue of GTP, destabilized H-R-G in a concentration dependent and saturable manner. Two Gi-linked receptors were labeled with their respective ³H agonists: 8-hydroxy-2-(di-n-propylamino)tetralin ([³H]-8-OH-DPAT) and R-phenylisopropyladenosine ([³H]-R-PIA). Concentration-response curves to Gpp(NH)p were evaluated by a four parameter logistic equation to yield basal level of agonist binding, EC₅₀, E_{max}, and slope index. The first three parameters were not affected by 1.5% isoflurane while the value of the slope index was significantly decreased for ³H-DPAT (0.98 to 0.72). Increased sensitivity of the H-R-G complex to lower concentrations of Gpp(NH)p was observed in the presence of isoflurane. Changes in attenuation of binding of ³H-PIA by Gpp(NH)p were biphasic in the presence of isoflurane. The regional nature of these changes are evaluated. This study should enhance the delineation of the region and the receptor dependency of inhaled anesthetic action.

113.15

ALLOSTERIC INTERACTIONS BETWEEN BINDING SITES OF RECEPTOR AGONISTS AND GUANINE NUCLEOTIDES: A COMPARATIVE STUDY OF THE 5-HYDROXYTRYPTAMINE_{1A} AND ADENOSINE A₁ RECEPTORS. C.D. Mahle¹, D.P. Healy¹, D.P. Perli², & S. Maayani^{1,3}. ¹Pharmacol., ²Pathol. & ³Anesthesiol., Mt. Sinai Sch. Med., CUNY, NY, NY, 10029.

The high affinity ternary complex HRG (hormone/receptor/G-protein) is rapidly destabilized by guanine nucleotides (GN), e.g., guanosine 5'-(β,γ-imido)triphosphate (Gpp(NH)p), that convert R into a low affinity state. These allosteric interactions were characterized in membranes from rat hippocampus (HIP) and 15 μ sections of rat and human HIP (8-13 subregions) prepared for quantitative receptor autoradiography (QRA). Gpp(NH)p attenuated [³H]-8-hydroxy-2-(di-n-propylamino)tetralin and [³H]-R-phenylisopropyladenosine binding to the 5-hydroxytryptamine_{1A} (5-HT_{1A}) and adenosine (AD) A₁ and receptor sites, respectively, in a concentration-dependent and saturable manner, described by three parameters: E_{max}, EC₅₀, and slope index. In rat HIP, for both receptors, the E_{max} was consistently greater in the tested subregions (80-90%) than in membrane preparations (50%). EC₅₀ values were independent of subregion in both species, but were receptor system dependent in human HIP (CA1), with 5-HT_{1A} values consistently less (0.1-0.2 μM) than AD (0.3-0.4 μM). Virtually complete attenuation of binding (90-95%) was observed when sections were incubated for 60 min with either [³H]-agonist in the presence of 100 μM Gpp(NH)p. In contrast, when 100 μM Gpp(NH)p was added to sections pre-incubated for 60 min with either [³H]-agonist, the binding after an additional 60 min was attenuated only 70-80%. In addition, 100 μM Gpp(NH)p at the earliest time point (1 min) produced a substantially greater decrease in binding of either [³H]-agonist, compared to displacement with agonist or antagonist. Steady-state and kinetic analyses of destabilization of HRG by GN can be discretely localized by QRA and used to measure the allosterism existing between binding of hormone and GN to RG. This technique may be useful in identification of the effect of perturbations such as aging, disease, and chronic drug treatment on specific events in receptor signalling. (USPHS GM 34852, HL 42585, DA 06620, and MH 48125)

113.12

CHARACTERISATION OF THE GTP-SENSITIVE AND GTP-INSENSITIVE STATES OF THE 5HT_{1A} RECEPTOR. J. M. Elliott* & S. Phipps*. (SPON: Brain Research Association). Oxford University-SmithKline Beecham Centre for Applied Neuropsychobiology, Radcliffe Infirmary, Oxford OX2 6HE, U.K.

Binding of the agonist radioligand ³H-DPAT to the 5HT_{1A} receptor is partially but not completely inhibited in the presence of GTP (Harrington & Peroutka, 1990; J. Neurochem. 54, 294-299). We have further investigated this phenomenon using ³H-DPAT to label 5HT_{1A} receptors in rat cerebral cortex.

Specific binding to the GTP-sensitive state of the receptor was defined by the presence of 100 μM GppNHP whereas specific binding to the GTP-insensitive state was defined by 10 μM 5HT in the presence of 100 μM GppNHP. Binding capacity of the two sites was similar but affinity was consistently higher at the GTP-insensitive site ($K_D = 0.90 \pm 0.04$ nM; n=6) compared to the GTP-sensitive site ($K_D = 1.23 \pm 0.13$ nM). Competitive binding affinity of other agonists and antagonists showed no significant difference at the two sites. However addition of monovalent cations reduced binding affinity of ³H-DPAT at the GTP-insensitive site ($K_D = 2.13 \pm 0.28$ nM) whilst not affecting affinity at the GTP-sensitive site.

We conclude that the GTP-sensitive and GTP-insensitive states of the 5HT_{1A} receptor are similar in ligand binding profile but differ in their sensitivity to guanine nucleotides and monovalent cations.

113.14

BIOCHEMICAL PARAMETERS ASSOCIATED WITH DRUG EFFICACY: A QUANTITATIVE AUTORADIOGRAPHIC STUDY OF THE 5-HYDROXYTRYPTAMINE_{1A} RECEPTOR IN RAT AND HUMAN HIPPOCAMPUS. S. Maayani^{1,2}, K.A. Hogan¹, D.P. Perli³, F.D. Yocca⁴, and C.D. Mahle². Depts ¹Anesthesiology, ²Pharmacology and ³Pathology, Mt. Sinai Sch. Med., CUNY, NY, NY 10029, and ⁴CNS Neuropharmacology, Bristol-Myers Squibb Co., Wallingford, CT 06492.

The density of the ternary complex (hormone/receptor/G-protein; HRG) appears to be associated with the relative efficacy of β-adrenoceptor agonists (Kent et al., Mol. Pharmacol. 17: 14, 1980). We have previously reported a similar finding in rat hippocampal (HIP) homogenates using full ([³H]-8-hydroxy-2-(di-n-propyl-amino)tetralin; PAT) and partial ([³H]-BMY-7378) 5-hydroxytryptamine_{1A} (5-HT_{1A}) agonists (Mahle et al., Soc. Neurosci. Abstr. 16: 1036, 1990). Binding of the two 5-HT_{1A} agonists to 15 μ sections of rat and human HIP (8-13 subregions), was analyzed using quantitative receptor autoradiography (QRA). The current study was done in an attempt to discretely localize HRG to subregions of HIP, as well as test in human HIP the previously formulated hypothesis. Binding of the [³H]-agonists in both species was saturable and high affinity. [³H]-PAT and [³H]-BMY-7378 displayed similar affinity (0.3-0.5 nM) for the 5-HT_{1A} receptor in both preparations and species. In subregions analyzed in both rat and human HIP, [³H]-PAT displayed a 20-40% greater B_{max} than [³H]-BMY-7378. Thus using QRA, we have demonstrated that, similar to findings in rat HIP membrane homogenates, [³H]-PAT stabilizes a greater density of HRG in both rat and human HIP than does [³H]-BMY-7378. Similar to the β-adrenoceptor, the density of the high affinity ternary complex measured with a higher efficacy agonist is greater than that measured with a lower efficacy agonist. We propose that the greater density of HRG results in a greater amount of complex available for destabilization by guanine nucleotides, thus generating a greater functional response. (USPHS GM 34852, DA 06620, and MH 48125)

113.16

DIFFERENCES IN THE CHARACTERISTICS OF ALLOSTERIC INHIBITION OF [³H]AGONIST BINDING BY GppNHP AT PRE- AND POSTSYNAPTIC 5-HT_{1A} RECEPTORS IN COW BRAIN.

L. Iben*, J. Torrente, and F. Yocca, CNS Neuropharmacology, Bristol-Myers Squibb Co., Pharmaceutical Research Institute, Wallingford, CT.

Observed region-dependent variations of drug efficacy on the 5-HT_{1A} receptor subtype (Sprouse and Aghajanian, 1987) may reflect differences in the receptor system and not necessarily different receptor subtypes. Previously, we demonstrated region-dependent heterogeneity of the 5-HT_{1A} receptor in rat and cow brain (Yocca, et al, 1989), suggesting that a difference in regional receptor coupling to G proteins may explain variations in drug efficacy. To test this hypothesis, the allosteric inhibition of [³H]8-OH-DPAT (agonist) and [³H]BMY 7378 (partial agonist) by GppNHP was examined utilizing saturation binding studies at the presynaptic, dorsal raphe (DR), and postsynaptic, hippocampus (HIP), 5-HT_{1A} receptor binding sites. Pharmacological profiles generated for the displacement of both radioligands by selected 5-HT_{1A} agonists and antagonists reveal no differences in the recognition component of the pre- and postsynaptic 5-HT_{1A} receptor binding sites. Displacement curves for GppNHP in DR and HIP of [³H]8-OH-DPAT and [³H]BMY 7378 showed a distinct regional difference in potency. In HIP, they appear to be monophasic, while in DR the curves appear to be biphasic and are best fit by a two site model. Saturation studies indicate that GppNHP caused a greater reduction in B_{max} in DR, as compared to HIP, with the percent decrease being equal for both radioligands in DR. However, in HIP, GppNHP appeared to more potently inhibit the binding of [³H]8-OH-DPAT than [³H]BMY 7378. These results demonstrate that allosteric inhibition of agonist binding at 5-HT_{1A} receptors in DR vs. HIP occurs with lower concentrations of GppNHP, suggesting differences in regional receptor-G protein interactions. This phenomenon, as it relates to the concept of receptor reserve, will be discussed.

113.17

AFFINITY OF DRUGS FOR THE LOW AFFINITY STATE OF THE 5-HT_{1A} RECEPTOR OF RAT HIPPOCAMPUS. J. Chamberlain, B.B. Wolfe and A. Frazer, Dept. of Psychiat., Univ. of Pa. Sch. of Med. and Dept. of Vet. Affairs Med. Ctr., Phila. PA 19104 and Dept. of Pharmacol., Georgetown Univ. Sch. of Med., Wash. D.C., 20007.

Previously (Soc. Neurosci. Abstr. 13:343, 1987), we reported that the affinity of serotonergic agonists for the high affinity state of ³H-DPAT binding was 15-100 fold greater than the EC₅₀ values of the same agonists for inhibiting forskolin-stimulated adenylyl cyclase. Potency in functional systems may reflect the affinity of these drugs for the low affinity state of the 5-HT_{1A} receptor. To test this, we developed a binding assay for the low affinity state. Saturation isotherms of ³H-DPAT binding done in the absence of Gpp(NH)p and EDTA indicated two components of binding, one with a K_D of 0.82±0.05nM and the other with a K_D of 20±7nM. In the presence of Gpp(NH)p (100µM) and EDTA (1mM), the binding was fit by a single-site model (K_D = 12±1nM). Low affinity state binding was measured using 15nM ³H-DPAT in the presence of Gpp(NH)p and EDTA. The affinity of drugs for the low affinity state were (K_i, nM): DPAT, 16±3; RU24969, 205±49; mCPP, 607±87. Their K_i values for the high affinity state were 1.4±0.2, 5±1 and 114±6, respectively. Previously calculated EC₅₀ values (nM) for these drugs in the adenylyl cyclase assay were: DPAT, 16; RU24969, 71; mCPP, 9000. Thus, the potency of agonists to elicit 5-HT_{1A}-mediated responses may be quantitatively better related to their affinity for the low affinity state of ³H-DPAT binding than for the high affinity state. 113.19

DELAYED EFFECT OF SPIPERONE ON 5-HT_{1A} RECEPTORS IN THE CA₃ REGION OF THE RAT DORSAL HIPPOCAMPUS. T. Dennis, G. Rizkalla, P. Blier and C. de Montigny, Neurobiological Psychiatry Unit, Department of Psychiatry, McGill University, Montreal, Quebec, Canada H3A 1A1.

Acute administration of BMY 7378 readily blocks the effect of microiontophoretically-applied 5-HT and 8-OH-DPAT on CA₃ pyramidal neurons (JPET, 246:359, 1988) in contrast to spiperone (SPIP) which blocks their effects on dorsal raphe 5-HT neurons, but not on CA₃ pyramidal neurons. In the latter region, antagonism of 5-HT becomes apparent only 24 h after a single dose of SPIP (Neurosci. Abstr. 16:462.4, 1990). To elucidate the mechanism of this delayed effect of SPIP on postsynaptic hippocampal 5-HT_{1A} receptors, we investigated *in vitro* and *ex vivo* its effects on [³H]8-OH-DPAT binding characteristics in rat hippocampal CA₃ membrane preparations and tissue sections.

In *in vitro* membrane binding studies, saturation analysis of [³H]8-OH-DPAT binding yielded an apparent K_d of 1.48 ± 0.28 nM and a B_{max} of 223 ± 17 fmol/mg protein. Saturation isotherms in the presence of 200 and 500 nM SPIP showed 2- and 3-fold increases in K_d, accompanied in both cases by 55-60% reductions of B_{max}. In contrast, a 2-fold increase in K_d, with no change in B_{max}, was observed in the presence of 5 nM BMY 7378. Haloperidol, ritanserin and prazosin (500 nM) were without effect. Autoradiographic analysis showed significant increases in K_d in pyramidal and radiatum layers of the CA₃ region, but not in the dorsal raphe, 24 h after a single injection of SPIP (5 mg/kg i.p.).

The divergent *in vitro* effects of SPIP and BMY 7378 indicate a competitive antagonism of 5-HT_{1A} receptors by the latter, but not by the former. The delayed and regionally selective modification of the properties of 5-HT_{1A} receptors in the dorsal hippocampus by SPIP, detected by autoradiography, is consistent with our previous electrophysiological findings, although its nature remains to be elucidated.

TRANSMITTERS IN INVERTEBRATES: ARTHROPODS

114.1

PHYSIOLOGICAL AND PHARMACOLOGICAL PROPERTIES OF GABA RECEPTORS ON MOTOR NEURONS IN THE MOTH MANDUCA SEXTA. Brian Waldrop, Dept. Zoology, Univ. Oklahoma, Norman, OK, 73019.

Motor neurons which innervate intersegmental muscles of the abdomen in the moth are retained through the larval and pupal stages during metamorphosis to promote two analogous reflex movements. The larva responds to tactile stimulation of its abdomen by bending, bringing its head towards the site of stimulation. In the pupa, the same muscles contract to close the gin traps, cuticular pits where the mechanosensory hairs are located. The pupal gin trap closure reflex consists of coordinated bouts of excitation and inhibition of the motor neurons, not seen in the larva. I wish to determine if and how inhibitory, presumably GABAergic, synaptic inputs might change during the metamorphic transition.

The motor neurons have large dorsal somata which make them easily identifiable, and large dorsally-located dendritic arbors which are accessible to application of pharmacological agents. Responses of larval and pupal motor neurons to pressure-ejection of GABA, and to GABA plus bicuculline, are recorded in the isolated abdominal nerve cord. GABA hyperpolarizes larval and pupal motor neurons, and this response is partially blocked by co-ejection of bicuculline (as methiodide). Muscimol also potently hyperpolarizes the motor neurons, but baclofen is without effect. By varying the duration of the GABA pressure pulse, a form of dose-response curve can be obtained. Application of bicuculline, either by co-ejection or superfusion, will allow a quantification of its effect on the GABA dose-response function. The actions of bicuculline on synaptically-mediated inhibition during the reflex responses initiated by stimulation of axons of sensory neurons will also be examined.

113.18

REGULATION OF BRAINSTEM 5-HT_{1A} RECEPTORS IN THE RAT. J.N. Murthy and M.R. Exaristelli, Neurology, Pediatrics, and Pharmacology Depts., The George Washington University, Washington, D.C.

To study the regulation of 5-HT_{1A} receptors located on raphe nuclei in the brainstem, the region most relevant to serotonin-responsive human myoclonic disorders, we chronically treated rats with various 5-HT agonists and antagonists and labeled 5-HT_{1A} sites with [³H]8-OH-DPAT. Ipsipirone and buspirone (presynaptic 5-HT_{1A} agonists), 8-OH-DPAT (pre- and post-synaptic 5-HT_{1A} agonist), L-propranolol, (±) pindolol and spiperone (5-HT_{1A} and 5-HT₂ antagonists), methysergide (5-HT₁ and 5-HT₂ antagonist), RU 24969 (5-HT_{1B} agonist), DOI and m-CPP (5-HT_{1C/2} agonists) and MDL 7222 (5-HT₂ antagonist) or vehicle were injected once daily for 30 consecutive days at 10 mg/kg ip and the adult male Sprague-Dawley rats were sacrificed 24 hours after the last injection. There were no significant differences between vehicles (n=22): B_{max} = 4.7 ± 0.2 pmol/g, K_D = 2.5 ± 0.1, n_B = 1.0 ± 0.01, r_S = 0.98 ± 0.01. None of the drugs significantly altered B_{max} of [³H]8-OH-DPAT specific binding and there were only a few small differences in K_D. These data demonstrate absence of down-regulation of presynaptic 5-HT_{1A} sites at doses which we have previously shown induce behavioral tolerance of 5-HT_{1A}-mediated behaviors of the serotonin syndrome and suggest changes in the postsynaptic cell rather than the receptor recognition site as the mechanism of tolerance. This phenomenon contrasts the marked down-regulation of 5-HT₂ receptors after chronic treatment with appropriate 5-HT agonists and antagonists.

114.2

OCTOPAMINE BIOSYNTHESIS IN THE CNS OF MANDUCA SEXTA.

H.K. Lehman, C. Murgic*, and J.G. Hildebrand. ARL Div. of Neurobiology, Univ. of Arizona, Tucson, AZ 85721.

Octopamine is a widespread neurotransmitter/hormone in *M. sexta* and fluctuates in the brain and hemolymph on a daily basis (Lehman, H.K. Soc. Neurosci. Abstr. 16:1334, 1990). We have now characterized tyramine β-hydroxylase (the putative rate-limiting enzyme controlling octopamine synthesis) in CNS homogenates of *M. sexta* in order to examine the mechanisms responsible for altering octopamine titers during the diurnal cycle.

The assay for octopamine synthesis depends upon the hydroxylation of [³H]tyramine to form [³H]octopamine. Incubation of [ring-³H]tyramine with crude brain homogenates results in the formation of three radiolabeled products. [³H]octopamine was identified by comparison to octopamine standards in two HPLC systems. Octopamine synthesis is linear over time for at least 180 min and depends upon protein concentration and the presence of optimal levels of copper, ascorbate, and catalase. The optimum pH for the conversion of tyramine to octopamine is 7.0, and dopamine inhibits the formation of octopamine. The rate of tyramine hydroxylation as a function of the concentration of tyramine appears to follow Michaelis-Menten kinetics (K_m=0.5 µM, V_{max}=1.2 x 10⁻⁶ moles/min/mg protein). Levels of [³H]octopamine produced by scotophase homogenates are 4-fold greater than levels produced by photophase homogenates. No detectable differences in dopamine β-hydroxylase (DβH)-like immunoreactivity have been observed in scotophase and photophase homogenates, but phosphorylation of photophase homogenates with the catalytic subunit of A-kinase slightly enhanced enzyme activity. Experiments are under way to examine ³²P incorporation into purified tyramine β-hydroxylase. Our findings suggest that an enzyme related to the mammalian enzyme DβH exists in *M. sexta*, and its activity is controlled diurnally.

114.3

MECHANISM OF ECLOSION HORMONE-STIMULATED CYCLIC GMP INCREASES IN *MANDUCA SEXTA* CNS. D.B. Morton and M. Giunta*, ARL Division of Neurobiology, University of Arizona, Tucson, AZ 85721.

Eclosion hormone (EH) is a neuropeptide which triggers ecdysis behavior in insects. Previous work has shown that EH acts via the second messenger, cyclic GMP (cGMP). We have been investigating the mechanisms underlying EH-stimulated cGMP production.

EH will not stimulate guanylate cyclase activity in homogenates, suggesting that EH receptors are not directly coupled to guanylate cyclase. Some neurotransmitters elevate cGMP via the production of nitric oxide (NO). NO is generated by the conversion of arginine to citrulline which is blocked by arginine analogues. Incubation of *Manduca* nervous tissue with 0.5mM N-methyl arginine or nitro-arginine failed to prevent the EH-stimulated cGMP increase. Furthermore, no EH-stimulated production of 3-H-citrulline was observed when tissue was incubated in 3-H-arginine.

Another possible pathway is via the production of arachidonic acid from diacylglycerol which is generated from the hydrolysis of phosphatidylinositol bisphosphate (PIP₂). LiCl depletes cells of inositol and hence reduces the hydrolysis of PIP₂. Incubation of *Manduca* nervous tissue with 10mM LiCl for 30 minutes significantly reduced the EH-stimulated production of cGMP. This suggests that EH acts via the hydrolysis of PIP₂ to stimulate guanylate cyclase.

114.5

STEROID-DEPENDENT MODIFICATION OF PRE-SYNAPTIC PATHWAYS IS REQUIRED FOR TRANSMITTER SWITCH IN INSECT PEPTIDERGIC NEURONS. P.K. Loi and N.J. Tublitz, Inst. of Neurosci., U. Oregon, Eugene, OR 97403.

What are the mechanisms that enable a fully mature neuron to alter its transmitter phenotype post-embryonically? The CNS of the moth, *Manduca sexta*, contains four lateral neurosecretory cells (LNCs) that switch their neurotransmitter phenotype from Cardioacceleratory Peptide 2 (CAP₂) to bursicon. The LNC transmitter conversion occurs at metamorphosis and is regulated by the ecdysteroids, the insect steroid hormones, which appear in two discrete pulses during the last larval instar. These two pulses, the commitment (CP) and prepupal peaks (PP), are apparently required for the normal CAP₂-to-bursicon transition. We have previously demonstrated that the second pulse, the PP, acts directly on the LNCs to increase bursicon levels. Here we describe experiments testing the role of and identifying the target of the CP, which is temporally associated with the major reduction of CAP₂ in the LNCs.

To test the role of the CP, the entire CNS was removed from a Vth instar larva prior to the CP (Day 2) and implanted into a second, intact Day 2 animal. Two days later, after the endogenous CP, the LNCs were dissected from implants and hosts, and assayed for both CAP₂ and bursicon. Under these conditions, both host and implanted LNCs showed a normal decrease in CAP₂ levels without any change in bursicon. This CAP₂ drop was blocked by application of juvenile hormone. That the CP is involved in this transmitter switch was confirmed by directly applying 20-HE to a complete CNS implanted into an isolated Day 2 abdomen. In these experiments, CAP₂ declined only in the implanted LNCs; no CAP₂ change was measured in the host LNCs. These results, combined with those from experiments with implanted brainless CNS, suggest that the brain is the target for the CP, and that direct neuronal connections between the brain and the rest of the CNS is required for this switch to proceed normally. Thus, the LNC transmitter shift is controlled by two separate steroid pulses: the CP which acts via the brain to promote a reduction in CAP₂, and the PP which directly induces a rise in bursicon.

114.7

BIOGENIC AMINES MODULATE SYNAPTIC TRANSMISSION BETWEEN VENTRAL GIANT INTERNEURONS AND THORACIC INTERNEURONS IN THE ESCAPE SYSTEM OF THE COCKROACH. J.L. Casagrand and R.E. Ritzmann, Dept. of Biology, Case Western Reserve University, Cleveland, OH 44106.

In the escape system of the cockroach, *Periplaneta americana*, a population of uniquely identifiable thoracic interneurons (type A or TIAs) receive information about wind via short latency, functionally direct, and apparently cholinergic inputs from a population of ventral giant interneurons (vGIs). The TIAs are involved in the integration of sensory information necessary for orienting the animal during escape. It is likely that there are times in an animal's life (i.e. in the presence of alarm pheromone) when it is advantageous to modify the responses of some or all TIAs to vGI input, which would result in changes in the processing of the circuit, and thereby, its outputs. A great deal of evidence exists for the use of biogenic amines as neuromodulators in a variety of neural circuits, and the amines octopamine (OCT), serotonin (5-HT), and dopamine (DA) are present in cockroach nervous tissue. We, therefore, tested the ability of OCT, 5-HT, or DA to modulate synaptic transmission between vGIs and TIAs. We found that both OCT and DA significantly increased the amplitude of vGI-evoked excitatory postsynaptic potentials (EPSPs) in TIAs when bath-applied to a semi-intact animal at 10⁻⁴-10⁻²M and 10⁻³M, respectively. On the other hand, 5-HT significantly decreased the vGI-evoked EPSPs in TIAs at 10⁻⁴-10⁻³M. These results indicate that OCT, 5-HT, and DA are able to modulate the responses of at least some of the neural elements in this circuit.

MODULATING A MODULATOR: AMINERGIC POTENTIATION OF A PEPTIDERGIC RESPONSE IN A MOTHS. K.R. Prier and N.J. Tublitz, Inst. of Neuroscience, U. Oregon, Eugene, OR 97403.

The CNS of the moth, *Manduca sexta*, contains a myoregulatory neuropeptide, CAP₂ (Cardioacceleratory Peptide₂), that is released during wing inflation and flight in adult moths. This peptide induces a physiologically important, dose-dependent increase in heart rate. The heart responds in a similar fashion to both octopamine and serotonin (5-HT), known insect neuromodulators. We report here that the CAP₂ response of the adult heart is greatly facilitated in the presence of subthreshold (nanomolar) concentrations of either amine. The CAP₂ response of the adult heart is increased to 170% and 180% of normal in the chronic presence of subthreshold concentrations of octopamine and 5-HT, respectively. The presence of subthreshold CAP₂ does not alter the heart's response to either amine.

We have begun to investigate the molecular mechanisms underlying this facilitation. Previous work on the adult heart has shown that CAP₂ works via an inositol 1,4,5 trisphosphate (IP₃) second messenger system. IP₃ added to individual, FURA2-filled heart cells causes an immediate rise in Ca²⁺_i. This rise is partially blocked in the presence of 10mM Co²⁺_o, suggesting that the rise in Ca²⁺_i is due both to the opening of membrane channels and to release by internal stores. In contrast to CAP₂, the cardioexcitatory effects of the two amines are mediated by cAMP; application of either octopamine or 5-HT elicits a 3-fold increase in intracellular cAMP levels after pre-treatment with a phosphodiesterase inhibitor. CAP₂ has no effect on cAMP levels in the heart. The relationship between cAMP and Ca²⁺_i is not yet known.

These results illustrate a mechanism by which the efficiency of a neurohormone can be increased with minimal cost. In *Manduca*, subthreshold levels of octopamine are found in the haemolymph during wing inflation and flight, and thus it is likely that octopamine up-regulates the CAP₂ effects during these important activities via a cAMP-dependent mechanism.

CHARACTERIZATION OF A PIGMENT-DISPERSING FACTOR FROM THE AMERICAN COCKROACH. C. J. Mohrher*, K. R. Rao and J. P. Riehm*, Dept. of Biology, Univ. of West Florida, Pensacola, FL 32514.

The occurrence of a pigment-dispersing factor (PDF) in the cephalic nervous tissues of the American cockroach, *Periplaneta americana*, was indicated by previous studies involving bioassays (R. M. Dores and W. S. Herman, *Gen. Comp. Endocrinol.*, 43:76, 1981) and immunocytochemistry (U. Homberg *et al.*, in press). In the present study we have purified the PDF from lyophilized heads of the cockroach, *Periplaneta americana*, utilizing the method of Rao *et al.* (*J. Biol. Chem.*, 262:2672, 1987). The immunoreactivity of this peptide towards *Romalea* PDF antibody facilitated its detection by ELISA during purification. Automated sequencing established the primary structure of *Periplaneta* PDF as NSELINSLGLPKVLNDA. A synthetic peptide, prepared as the C-terminal amide, gave a HPLC profile identical to the native form. Based on net charge and sequence similarity, *Periplaneta* PDF is more closely related to crustacean β-PDH (NSELINSILGLPKVMNDA-NH₂) than to α-PDH (NSGMINSILGIPRMTEA-NH₂). *Periplaneta* PDF differs from *Acheta* PDF by a single residue (Leu for Ile at position 4). *Periplaneta* PDF is several-fold more potent than *Acheta* PDF in assays for melanophore pigment dispersion in the fiddler crab, *Uca pugilator*. (This work was supported by NSF Grant DCB-8711403.)

MODULATION OF A CALCIUM CURRENT BY MUSCARINIC RECEPTORS IN AN INSECT MOTONEURONE. J.A. David and R.M. Pitman, Dept. of Biology and Preclinical Medicine, Gatty Marine Laboratory, St. Andrews, Fife, Scotland, KY16 8LB.

At membrane potentials more negative than -40 mV, ACh externally applied to the cell body membrane of the cockroach fast coxal depressor motoneurone (D_f) induces an α-bungarotoxin-sensitive inward current which is carried by Na⁺, K⁺ and Ca²⁺. At membrane potentials more positive than -40 mV, externally-applied muscarinic agonists also induce an inward current which is insensitive to α-bungarotoxin but blocked by muscarinic antagonists. In the presence of TEA⁺ the response to muscarinic agonists is reversed in direction; this residual current is blocked by externally applied Ca²⁺ indicating that muscarinic agonists induce a reduction in Ca²⁺ conductance and a consequent reduction in Ca²⁺-activated K⁺ conductance. The response appears to involve an increase in intracellular concentrations of cAMP since the effects of muscarinic agonists are mimicked by externally-applied dibutyryl cAMP and modified by the phosphodiesterase inhibitor theophylline.

THE PRODUCTION AND USE OF PCR PROBES TO STUDY CONSERVED SEQUENCES IN THE *dsk* GENE.

R. Nichols. University of Michigan Medical School, Ann Arbor, MI 48109.

In order to identify functionally important regions of the *dsk* gene in *Drosophila melanogaster* and the corresponding *dsk* neuropeptides (DSK-0, DSK-I, and DSK-II), the presence of the *dsk* gene in related species has been studied. The method of polymerase chain reaction (PCR) was used to amplify the *dsk* gene from genomic DNA of related species. Two PCR primers were designed to sequences present in the *D. melanogaster dsk* gene. Sequences corresponding to *D. virilis*, *D. pseudoobscura*, and *C. erythrocephala* have been amplified and sequenced. The PCR-generated *dsk* probes were then used to screen genomic libraries and the corresponding *dsk* genes have been sequenced. Sequences corresponding to all three *dsk* peptides are present. Significant sequence conservation is found among the DSK precursors. These data will be presented and discussed relative to neuropeptide biosynthesis and gene expression.

114.11

SEROTONIN CAUSES THE RELEASE OF [³H]-SEROTONIN IN THE ABSENCE OF EXTRACELLULAR CALCIUM FROM THE ABDOMINAL NERVES OF *Rhodnius prolixus* H. Cook and I. Orchard, Dept. of Zoology, Univ. of Toronto, Toronto, Ontario, Canada M5S 1A1

In the blood-sucking bug, *Rhodnius prolixus*, there are extensive serotonergic neurohaemal areas, located on the abdominal nerves, whose stores of serotonin are released during feeding. The major contributors to these neurohaemal areas are 5 serotonergic, dorsal, unpaired, median neurons located in the terminal segment of the CNS, the mesothoracic ganglionic mass (MTGM).

We incubated an *in vitro* preparation, consisting of the MTGM and associated abdominal nerves, in 10⁻⁶M [³H]-serotonin for 3 h prior to experimentation. We have demonstrated that 10⁻⁶M serotonin elicits a significant release of previously accumulated [³H]-serotonin in the absence of Ca²⁺ in the bathing medium, during 5 min incubations. A significant release of [³H]-serotonin, by serotonin, is also seen in Ca²⁺-free saline which contains 10 mM CoCl₂. No significant release of [³H]-serotonin is elicited by the application of 10⁻⁶M octopamine, dopamine, acetylcholine or glutamate.

The second messenger cAMP does not appear to be involved in the mechanism of release. While 10⁻⁶M serotonin elicits a significant increase in cAMP levels, in the abdominal nerves during 5 min incubations, in normal saline, it does not do so in Ca²⁺-free saline. We are presently investigating the potential role of other second messengers in the mechanism of release and using serotonergic agonists and antagonists to characterize this putative serotonergic autoreceptor.

GALANIN-LIKE PEPTIDE IN THE BLOWFLY BRAIN: DISTRIBUTION, CHROMATOGRAPHIC CHARACTERIZATION AND ¹²⁵I-GALANIN BINDING. C.T. Lundquist¹, H. A. D. Johard¹*, Å. Rökæus² and D. R. Nässel¹. ¹Dept. Zoology, Stockholm University and ²Biochemistry I, Karolinska Institute, Stockholm, Sweden.

Galanin (GAL) is a 29 amino acid bioactive peptide originally isolated from upper small intestine of pigs (Tatemoto et al., *FEBS Lett.* 261: 397-401, 1983). GAL is present in several vertebrate species and GAL-immunoreactive (GAL-IR) neurons have been demonstrated in both mammalian and submammalian species such as amphibians and fish. This is the first report on the presence of GAL-immunoreactivity (GAL-LI) in an invertebrate, the blowfly *Phormia terraenovae*. Immunocytochemistry indicated that there are about 160 GAL-IR neurons in the brain and subesophageal ganglia. In the brain GAL-IR fibers innervate the central body, superior protocerebrum, medulla of the optic lobe and tritocerebral neuropil. Neurosecretory cells of the median neurosecretory group (MNC) also display GAL-LI. GAL-LI is present in acetic acid extracts of fly heads as measured in RIA. Gel filtration indicated that the GAL-LI material is heterogeneous with components of about the same molecular weight as porcine GAL. The hydrophobic properties GAL-LI differ from that of porcine GAL as demonstrated by rPHPLC. Several immunoreactive components from fly head extracts can be seen in the chromatogram indicating the presence of several forms of GAL-like peptides. Autoradiography experiments with ¹²⁵I-labeled porcine GAL on fresh frozen brain sections revealed GAL binding sites in the central body and in deutocerebrum. The binding was displaced by porcine GAL at a concentration of 10⁻⁷M. Our findings indicate the presence of GAL-like peptide(s) and putative binding sites in the fly central nervous system and suggest a role in neuromodulation in circuits of the brain as well as a neurosecretory role of the peptide(s).

114.10

CHARACTERISATION OF A LOCUST NEURONAL OCTOPAMINE RESPONSE. L. Kaufmann* and J.A. Benson. R & D Plant Protection, Agricultural Division, CIBA-GEIGY Ltd., CH-4002 Basel, Switzerland.

Octopamine evokes changes in membrane potential when applied to the somata of insect neurones *in vitro* (Usherwood, P.N.R. et al., In: *Insect Neurobiology and Pesticide Action*, p. 115, 1980; Suter, C., *Comp. Biochem. Physiol.* 84C:181, 1986). To investigate the voltage-dependence, ionic basis and pharmacology of the octopamine response, we voltage-clamped mechanically isolated neurones from the thoracic ganglia of *Locusta migratoria*. In unclamped somata at their normal resting potential of -50 to -60 mV, pressure micro-application of octopamine (10 mM, 100 - 200 ms) evoked a slow depolarisation accompanied by a small decrease in membrane resistance. In clamped somata, octopamine evoked a current that was inward over the membrane potential range -40 to -90 mV, with a peak amplitude at -70 mV. This current was blocked by 5 mM Cs and by Na-free saline. As an agonist, tyramine was ca. 100-fold less potent than octopamine, and the octopaminergic agonists clonidine and tolazoline were weak or inactive at 10 μM. The insecticidal compound desmethylchloridimeform was a highly potent and reversible agonist. Naphazoline reduced the octopamine response (EC50 value ca. 5 μM) but, in contrast to octopamine, it hyperpolarised somata at normal resting potential. Mianserin, an antagonist of octopamine, dopamine and serotonin receptors, blocked the response with an EC50 value in the nanomolar range. Maroxepine, another insecticidal compound, was antagonistic, with potency similar to that of mianserin. Phenolamine and promethazine were antagonists with micromolar EC50 values. Chlorpromazine, yohimbine and metoclopramide, which are antagonists of the locust muscle octopamine receptors (Evans, P., *J. Physiol.* 318:99, 1981), were without effect at concentrations of up to 0.1 mM. This neuronal pharmacological profile agrees well with findings from binding studies on membranes from the *Locusta* central nervous system (Roeder, T., *Eur. J. Pharmacol.* 191:221, 1990), but differs from the pharmacology of the three muscular octopamine receptor subtypes located in the locust (*Schistocerca*) hind leg extensor tibiae (Evans, P., *J. Physiol.* 318:99, 1981).

114.12

TACHYKININ-LIKE PEPTIDES IN THE CNS OF THE BLOWFLY: DISTRIBUTION AND PARTIAL CHARACTERIZATION.

D. R. Nässel¹, C. T. Lundquist¹ and E. Brodin*², ¹Dept. Zoology, Stockholm University, and ²Dept. Pharmacology, Karolinska Institutet, Stockholm, Sweden

Neuropeptides of the tachykinin family have been isolated from a wide range of organisms including mammals, lower vertebrates and invertebrates. In insects such peptides have been isolated from brain and corpora cardiaca extracts on basis of their myotropic activity in a cockroach hindgut bioassay (Holman et al., *Ann. Rev. Entomol.* 35: 201-217, 1990). The mapping of tachykinin-like peptide(s) in the insect nervous system, however, relies on immunocytochemistry with antisera against substance P and bombesin. To extend these studies we have tested a large number of antisera against tachykinins of various vertebrates and of one insect, the cockroach *Leucophaea maderae*. We found three distinct populations of tachykinin immunoreactive neurons in the blowfly *Phormia terraenovae*: (1) one recognized by antisera against substance P, (2) another by antisera against the frog peptide kassinin and (3) a third with antisera raised against the cockroach peptide Leucokinin I (LKI). Two of these populations constitute unique sets of interneurons that were not detected previously with other antisera. The third, recognized by antisera against substance P, is a subpopulation of the FMRFamide immunoreactive neurons. The kassinin immunoreactive material has been partly characterized from fly head extracts by chromatography (rPHPLC) and radioimmunoassay and it is clear that it represents material distinct from that recognized by the substance P and LKI antisera respectively. The results presented here indicate the presence of multiple forms of tachykinin-like peptides in the blowfly, present in at least three distinct populations of brain neurons. From the immunocytochemistry it appears that the insect tachykinins may be involved in a variety of modulatory functions in the CNS and in some cases they possibly act as neurohormones.

114.14

OCTOPAMINE-LIKE IMMUNOREACTIVITY IN THE FUSED SPIDER CNS. E.-A. Seyfarth¹, K. Hammer¹, U. Spörhase-Eichmann² and H.G.B. Vullings³. ¹Zoologisches Institut, Universität, D-6000 Frankfurt a. M. 11, FRG; ²I. Zoologisches Institut, Universität, D-3400 Göttingen, FRG; ³Dept. of Exp. Zoology, The University, Padualaan 8, NL-3584 CH Utrecht, The Netherlands

We used antiserum against octopamine (OA) to map the serially organized system of OA-like immunoreactive (OA-ir) neurons in the fused ganglion complex of the wandering spider *Cupiennius salei*.

In the subesophageal ganglion complex (SOG), the total number of OA-ir somata varies and ranges from 56 to 73; all lie ventromedially. Surprisingly, there is no strict bilateral symmetry in soma number and location. Neurites from somata in the SOG ascend dorsally. Some processes end near longitudinal and anterior septa. Other OA-ir arborizations merge into plurisegmental tracts connecting the various neuromeres; collaterals project into lateral neuropil.

In the supraesophageal ganglia ("brain"), we find OA-ir somata merely in the 2 cheliceral neuromeres. Neurites from 2 bilateral clusters of 4 to 5 large somata (ca. 25 μm in diameter) descend to the SOG where they continue into the opisthosomal neuromeres as 2 longitudinal tracts. Processes from smaller somata (<10 μm) project into the antero-dorsal brain. Profuse OA-ir projections end in the "central body" of the spider brain.

Except for fine varicosities at the roots of nerves, we find no OA-ir fibers leaving the CNS. Within the CNS, however, OA-ir terminals are concentrated near hemolymph spaces. Hence we suspect that OA acts directly at central synapses, while it reaches peripheral sites via the hemolymph system. [Supported by the DFG, SFB 45/A3]

PROCTOLIN AND OCTOPAMINE SYNERGISTICALLY ENHANCE cAMP LEVELS IN CRAYFISH TONIC FLEXOR MUSCLE. K. Obrietan*, C.A. Bishop and J.J. Wine. Dept. of Psychology, Stanford Univ., Stanford, CA 94305-2130.

Complex modulatory input can dramatically alter muscle function. For example, in the tonic flexor muscle of the crayfish, the cotransmitter proctolin and the hormone octopamine synergistically enhance both depolarization-induced tension and the activity of a large conductance plasma membrane Ca^{2+} channel (38 pS in 137 Ba²⁺). CPT-cAMP also enhances activity of the Ca^{2+} channel, suggesting that modulation might occur via a cAMP pathway. Therefore, we examined the effects of proctolin and octopamine alone and together on cAMP levels in the tonic flexor muscles.

cAMP levels were measured in the presence of 0.5 mM IBMX using radioimmunoassay. Proctolin's enhancement of tension and Ca^{2+} channel activity is seasonal, with the lowest effect seen in winter, during which its effect can be restored by addition of octopamine. All of our experiments were performed between December and March, when proctolin's effect is predicted to be small. Addition of a maximal concentration of proctolin (5×10^{-9} M, this concentration produces the greatest tension and channel responses) produced no significant increase in cAMP levels, whereas addition of a moderate concentration of octopamine (10^{-7} M) produced a 4-fold increase in cAMP levels. cAMP levels were measured as pmol/mg protein and are given as the mean \pm S.E.M). Results were:

control: 20.4 ± 2.2 (n=16); proctolin: 26.7 ± 5.0 (n=9), n.s.;

octopamine: 88.4 ± 7.8 (n=6), $p < 0.05$.

For proctolin + octopamine: cAMP levels rose to 193.2 ± 16.3 (n=4), $\sim 10 \times$ the control level and $2 \times$ the level for octopamine alone ($p < 0.01$ and 0.05 respectively). These results demonstrate a synergistic enhancement of cAMP levels by the two neuromodulators, which parallels and may explain the synergistic enhancement of Ca^{2+} channel activity and muscle tension.

114.17

PROCTOLIN DEGRADATION BY THE CRAB NERVOUS SYSTEM. M.J. Coleman*, M.P. Nusbaum* and B.S. Rothman*. ¹Neurobiology Research Center/Dept. of Physiol. & Biophys., Univ. of Alabama, Birmingham; Birmingham, AL 35294; ²Dept. of Biology; San Francisco State Univ.; San Francisco, CA 94132.

The pentapeptide proctolin (RYLPT; 10nM) excites the pyloric network in the stomatogastric ganglion of the crab, *Cancer borealis*. This proctolin effect is enhanced by co-application of amastatin (50uM), an aminopeptidase inhibitor (Nusbaum et al., Soc. Neurosci. Abstr. 15:366), suggesting that proctolin is enzymatically inactivated in the extracellular space. To test this hypothesis, we incubated this peptide with the larger, thoracic ganglion (TG) and used HPLC analysis to determine the fate of proctolin.

Over time (2-120 minutes at 13°C), the HPLC-detected proctolin peak diminished and three novel peaks appeared. Two of these peaks co-migrated with synthetic proctolin fragments YLPT and LPT. The third peak has yet not been identified. The YLPT fragment was produced in greatest abundance. Proctolin (10uM) degradation was reduced by co-applying amastatin (100uM). With amastatin present, the YLPT peak size was reduced to a greater extent than were those of the other two fragments. Conditioned saline (CS), which was incubated with the TG and then removed, was also effective in degrading proctolin. Incubating either the TG or CS with 10mM Co^{2+} reduced both the amount of proctolin degradation and the YLPT peak size. However, Co^{2+} increased the peak size of the other two proctolin fragments. These results suggest that proctolin is cleaved by at least two different peptidases in the crab CNS. These include an aminopeptidase that is suppressed by Co^{2+} and amastatin, and a second, Co^{2+} -insensitive peptidase.

Supported by BNS-8909613 (MPN) and NS24046 (BSR).

BOTH GABA AND HISTAMINE ACTIVATE A CHLORIDE CONDUCTANCE IN MOTONEURONS OF THE LOBSTER CARDIAC GANGLION. J. Freschi, H. Hashemzadeh-Gargari, and J. Kerrison. Neurology Dept., Emory University, Atlanta, GA 30322.

The cardiac ganglion of decapod crustaceans is innervated by a single pair of inhibitory axons from the central nervous system. From indirect evidence, it is thought that the neurotransmitter released by the inhibitory fibers is GABA. GABA mimics the IPSP, which has been shown to be a chloride-dependent potential, and picrotoxin blocks both the IPSP and the response to exogenously applied GABA. We found that GABA and histamine (neurotransmitters) have similar actions on motoneurons of the cardiac ganglion. Both neurotransmitters evoke a current that reverses at E_{Cl} under various conditions of altered internal and external $[Cl^-]$. The underlying Cl^- conductance in both cases is voltage-dependent. Both neurotransmitter-activated Cl^- conductances were inhibited by drugs known to interact at Cl^- channels, such as curare and picrotoxin. GABA responses were not inhibited by bicuculline. Histamine responses were best blocked by the H_2 -blocker cimetidine. One difference between the effects of the two neurotransmitters was that GABA strongly inhibited the burst potentials whereas histamine did not. This suggests that GABA but not histamine may inhibit small pacemaker cells. Since it is not known whether histamine is released by inhibitory synapses or released from near-by pericardial organs into the hemolymph as a neurohormone, the hypothesis that GABA is the inhibitory neurotransmitter released by the inhibitory fibers must be re-examined by cross-desensitization experiments and by using pharmacological agents specific to the receptor rather than the Cl^- channel (supported by NIH NS-22628).

114.16

DEVELOPMENTAL AND GENDER DIFFERENCES IN PROCTOLIN AND DOPAMINE-LIKE IMMUNOREACTIVITY IN THE BLUE CRAB. Debbie Wood, Charles Derby, Ted Simon. Georgia State Univ., Dept. of Biology, Atlanta

We are interested in the modulation of simple motor systems by peptides and biogenic amines. Exogenously applied proctolin and dopamine produce rhythmic and postural components, respectively, of a courtship behavior in male blue crabs, and produce limited effects on juveniles and female adults. We have examined proctolin- and dopamine-like immunoreactivity across developmental and gender groups to understand these behavioral differences. Juveniles and adults show differences in the locations of cell bodies and numbers of fibers showing dopamine-like IR in the protocerebrum, optic nerve and circumoesophageal connectives. We are investigating the potential that proctolin may be expressed seasonally in the adult male.

IMMUNOCYTOCHEMICAL IDENTIFICATION OF MULTIPLE CCK-RELATED PEPTIDES IN THE STOMATOAGASTRIC NERVOUS SYSTEM OF SEVERAL SPECIES OF DECAPOD CRUSTACEA. Andrew E. Christie*, G.G. Turrigiano, S. Retter*, Wendi S. Neckameyer, and Eve Marder.

Dept. of Biology, Brandeis Univ., Waltham, MA 02254

Turrigiano and Selverston showed that a CCK-related molecule plays a role in modulating the feeding behaviour of crustacea (1990, Nature 344:866-868). Using a polyclonal antibody generated against mammalian CCK8 designated 243, these authors determined the distribution of CCK-related immunoreactivity in the stomatogastric nervous system of several species of decapod crustacea (1991, J. Comp. Neurol. 305:164-176).

Here, we compare the results of staining with two monoclonal antibodies, C36-9H and C37-4E, generated against CCK8 (Stretton laboratory, University of Wisconsin-Madison) with the results of Turrigiano and Selverston. In *Panulirus interruptus*, *Cancer borealis*, and *Homarus americanus*, each monoclonal antibody recognizes a different set of immunoreactive structures of which only subpopulations also stain with 243. For example, in the oesophageal ganglion of *P. interruptus* 243 detects no immunoreactive structures while C36-9H recognizes a diffuse neuropil, and C37-4E a set of brightly staining somata. All of these antibodies recognize an intense neuropil within the stomatogastric ganglion. The staining seen with these antibodies suggests a differential distribution of several CCK-related peptides within the stomatogastric nervous system. Supported by NS 17813.

115.1

IDENTIFICATION AND LOCALIZATION OF DOPAMINE IN FRESHWATER HYDRA BY HPLC AND IMMUNOHISTOCHEMISTRY. M. Carlberg, University of Lund, Department of Zoology, Helgonavägen 3, S-223 62 Lund, Sweden.

Coelenterates are the most primitive animals known to have a nervous system. Different FMRFamide-like neuropeptides probably play an important role in chemical neurotransmission in these animals. The role of monoamines and other "classical" transmitters in coelenterate nervous systems is more uncertain. There is good chemical evidence for dopamine (DA) in coelenterate tissue, but its localization and function has not been established. In the present communication, quantitative determination of DA in single specimens of *Hydra* with HPLC is combined with immunohistochemical localization.

Single specimens of *Hydra attenuata* were analysed with HPLC for DOPA, catecholamines and 5-S-cysteinylDOPA (5-SC.D). DOPA generally occurred in minor amounts usually not exceeding 1 ng/specimen. The major metabolites of DOPA seemed to be DA (3.3 ± 4.0 ng/specimen, n=48) and 5-SC.D (3.2 ± 2.5 ng/specimen, n=24). A marked correlation between the amounts of DA and 5-SC.D indicated that the dopamine biosynthesis in *Hydra* is not protected from oxidative side-reactions.

To relate the DA content in single *Hydra* with immunohistochemical observations, living *Hydra* were cut in half - one half was analysed with HPLC and the other half was processed for immunohistochemistry. Occasional DA-immunoreactive neurites were found in specimens containing moderate to high amounts (>3 ng) of DA.

This investigation is the first evidence of a catecholamine in a coelenterate nervous system. Its sporadic occurrence suggests that it may have a function during certain physiological conditions rather than being a generally occurring neurotransmitter. Supported by the Swedish Natural Science Research Council.

115.3

ASCARIS FMRFAMIDE-LIKE PEPTIDES. C. Cowden and A.O.W. Stretton, Dept. of Zoology, University of Wisconsin-Madison 53706

We are interested in the role of neuropeptides in the control of locomotion in *Ascaris*. We have been isolating FMRFamide-like peptides (FLPs) from *Ascaris* heads using an RIA that detects -RFamide peptides. AF1 and AF2 have similar chemical structures and similar effects on muscle tension including relaxation, contraction, and rhythmic activity. Two more *Ascaris* FLPs have been isolated by reverse phase HPLC and confirmed by microsequencing and FAB-mass spectroscopy. The effects on muscle tension of one of these, AF4, are strong contraction and rhythmic activity; there is no relaxation effect.

In addition, there is sequence data for 9 other FLPs which are not related by proteolytic cleavage or post-translational modification. Even though peptides are extracted from 10,000 heads, the amount of purified peptide is often less than 100 pmoles making it necessary to repeat the purification in order to confirm the chemical structure. HPLC analysis has shown that *Ascaris* FLPs are differentially distributed between heads and tails, between females and males, and between acetone and acid methanol extracts. These findings will be useful in confirming the structures of the other *Ascaris* FLPs. NS07954(CC), AI20355(AOWS)

115.5

THE EFFECTS OF BIOGENIC AMINES ON ASCARIS LOCOMOTION. C.A. Buchanan and A.O.W. Stretton, Neuroscience Training Prog and Dept. Zoology, Univ. Wisconsin, Madison, WI 53706.

We have developed a behavioral assay to investigate the influence of biogenic amines on *Ascaris* locomotion. Ligating the head induces *Ascaris* to generate anteriorly propagating body waveforms. This is called the head restricted behavior (HRB). Initiation of waveform propagation occurs near the egg-laying pore (ELP). Generally there are 3 complete waveforms anterior to the ELP.

Previously, Stretton and Johnson (Soc. Neurosci. Abstr. 11: 184.8) showed that there are two serotonin (5-HT)-like immunoreactive neurons in the pharynx with a putative neurosecretory function. *Ascaris* with heads ligatured posterior to the pharynx, were injected posterior to the ligature with 0.1 ml test aliquots and the effects on HRB scored. Injections of dye showed that there was a ca. 10X dilution in pseudocoelomic fluid. 5-HT (10^{-2} M) caused a paralysis of forward movement, the disappearance of waveforms anterior to the ELP, and a 3% increase in body length. Dopamine (DA) and octopamine (OA) (both at 10^{-2} M) disrupt HRB, but produced decreases in body length. Tryptophan, 5-hydroxytryptophan, tryptamine, histamine (all at 10^{-2} M), and *Ascaris* saline had no detectable effects on HRB. These results suggest the presence of 5-HT, DA, and OA receptors which affect *Ascaris* locomotion.

115.2

POLYCHLORINATED BIPHENYL (PCB) EFFECTS ON BIOGENIC AMINES IN THE PLANARIAN, DUGESIA DOROTOCEPHALA. R.F. Seegal and L.G. Hansen*, Wadsworth Center, NYSDOH, Albany, NY 12201 and College of Veterinary Medicine, University of Illinois, Urbana, IL 61801.

Planarians have a well-developed nervous system with many biochemical similarities to the vertebrate nervous system. Because planarians are fresh water organisms they may provide a valuable bioassay for determining toxic effects from environmental chemicals and mixtures. We used sensitive HPLC methods to determine if Aroclor 1254 induces neurochemical deficits in *D. dorotocephala* similar to those we have seen in mammalian preparations.

Solutions of Aroclor 1254 in acetone (10, 25, 50 or 100 mg/beaker) were deposited on 600 ml beakers, the acetone evaporated and a standard culture medium (10 ml/planarian) added. After 1, 2, or 4 weeks planarians were weighed, frozen and homogenized in 0.2N perchloric acid containing 100 mg/l of EGTA. Only dopamine (DA) and serotonin (5-HT) were detected with their concentrations varying over the 4-week exposure period, due perhaps to changes in nutritional and developmental status. Aroclor 1254 reduced DA in a dose-dependent manner (resulting in a maximum 30% decrease) when control DA levels were less than 0.35 ng/mg wet weight. 5-HT levels, elevated at intermediate doses, were also reduced by 30% at the high-dose exposure.

Changes in biogenic amine concentrations after toxicant challenge indicate that *D. dorotocephala* can be used to monitor exposure to complex toxicants and elucidate their effects on basic neurochemical function.

DIFFERENTIAL DISTRIBUTION OF AF1, A FMRFAMIDE-LIKE NEUROPEPTIDE IN ASCARIS NERVOUS SYSTEM REVEALED BY SPECIFIC MONOCLONAL ANTIBODIES. Paisarn Sithigorngul* and Antony O.W. Stretton, Department of Zoology, University of Wisconsin-Madison, WI 53706.

Monoclonal antibodies were generated from mice immunized with peptide AF1 (KNEFIRFamide, Cowden et al., 1989) conjugated to BSA or ovalbumin with paraformaldehyde. Four monoclonal antibodies specific to AF1 peptide were obtained. ELISA and dot blot tests showed that none of these antibodies bound to BSA conjugates of either FMRFamide or AF2 (KHEYLRFamide; Cowden and Stretton, 1990). These antibodies recognize a small subset of the neurons that are recognized by other monoclonal antibodies that bind to FMRFamide as well as to AF1 and AF2. This evidence suggests that FMRFamide-like peptides are differentially localized in different subpopulations of neurons in the *Ascaris* nervous system. (Supported by AI 20355).

115.6

SEROTONIN AND MALE MATING IN THE NEMATODE *C. ELEGANS*. C. M. Loefer and C. J. Kenyon*, Dept. of Biochemistry and Biophysics, Box 0554, University of California, San Francisco, CA 94143.

We are seeking to identify genes required for specification of neurotransmitter phenotype in the nematode *C. elegans*. Mutations in genes that alter transmitter expression may be identifiable by specific behavioral defects in worms that carry such mutations. For example, mutants lacking immunocytochemically detectable serotonin entirely (*cat-4*) or from neuronal processes (*cat-1*) exhibit reduced male mating efficiency (Hodgkin, Genetics 103: 43, 1983; Desai et al., Nature 336: 638, 1988). Staining with serotonin antisera suggests that some CP and CA cells, male-specific motoneurons located along the ventral nerve cord, use serotonin (G. Garriga, pers. comm.). Preliminary observations suggest that these putative serotonergic neurons assist in one or more components of male mating behavior. Application of serotonin to adult males results in tight ventral curling of the tail, which contains the male-specific copulatory structures. This posture is reminiscent of a behavior exhibited by males during mating behavior: when an adult male moving its tail along the surface of a hermaphrodite reaches the end of its intended mate, it makes a tight ventral curl to place the tail in contact with the opposite surface. The male then continues moving its tail along that surface in search of the vulval opening. This behavior may be repeated many times before the vulva is located and copulation is initiated. Adult males in which precursors of CP and CA neurons were ablated appear to exhibit difficulty in executing the tight ventral curl; the defect is similar to that we have observed in *cat-1* mutant males. We are presently seeking to quantify the effects of mutations that alter serotonin expression and of ablation of CP and CA neurons on this aspect of male mating behavior. We also plan to identify additional mutations that alter serotonin expression or expression of genes required for serotonin synthesis.

115.7

IDENTIFICATION OF GLUTAMATE AND AVERMECTIN-SENSITIVE CHLORIDE CURRENTS IN *XENOPUS* OOCYTES INJECTED WITH mRNA FROM THE NEMATODE *CAENORHABDITIS ELEGANS*. D.F. Cully*, P.S. Paress*, K.K.S. Liu*, C.J. Cohen, and J.P. Arena*. Merck & Co. Biochemical Parasitology, Rahway, N.J. 07065.

The avermectins (AVM) are a family of naturally occurring macrocyclic lactones with anthelmintic and insecticidal activity. To investigate the mode of action of these compounds we have used as a model the free living nematode *Caenorhabditis elegans*. *C. elegans* is highly sensitive to the AVMs and contains a membrane associated high affinity AVM binding site ($K_D = 0.2$ nM). In this study we have used the *Xenopus* oocyte for expression of *C. elegans* mRNA and have identified an AVM-sensitive membrane current. Application of AVM to injected oocytes increased inward membrane current by 241 ± 50 nA, when measured at -80 mV using a two microelectrode voltage clamp. The AVM-sensitive current was unchanged in oocytes injected with EGTA and exhibited a reversal potential of -19 mV that shifted in low chloride solutions as predicted for a chloride current. Injected oocytes were insensitive to GABA, picrotoxin or bicuculline. Oocytes injected with *C. elegans* mRNA also responded to glutamate with an increase in inward membrane current exhibiting properties consistent with a chloride current. When maximal concentrations of AVM and glutamate were used the response was less than additive, suggesting they both activate the same current. Size fractionation of mRNA showed that the AVM and glutamate-sensitive current was enriched in the 1.1-2.5 Kb mRNA class. A cDNA library has been synthesized and is being used to screen for expression in oocytes.

BIOSYNTHESIS OF RFAMIDE PEPTIDES IN LEECH CNS NEURONS. B.D. Evans, J.L. Sperring and R.L. Calabrese. Dept. of Biology, Emory Univ., Atlanta, GA 30322.

Recently, five RFamide peptides (containing the carboxyl terminal sequence -Arg-Phe-amide) were isolated and identified from central nervous system extracts of the leech *Hirudo medicinalis* (Evans et al., 1991). Three of these peptides contain methionine (FMRFamide, YMRFamide, & GGKYMRFamide). Upon depolarization, some or all of these peptides are released from neural processes on heart tubes in a Ca^{2+} -dependent manner. Cropper et al. (1987) and Church & Lloyd (1990) have incorporated ^{35}S -methionine into newly synthesized peptides to demonstrate the biosynthesis of methionine-containing peptides by individually identified CNS neurons of the mollusc *Aplysia*.

Several CNS neurons in leech, including heart motor neurons, contain RFamide peptides as indicated by immunocytochemistry (Kuhlman et al., 1985). Whole nerve cords *in vitro* incorporate ^{35}S -methionine into a large number of peptides as indicated by rPHPLC elution profiles. Heart motor neurons also incorporate ^{35}S -methionine into peptides. A radioactive peak obtained from rPHPLC analysis of heart motor neuron extracts coelutes with synthetic FMRFamide, indicating that these neurons synthesize FMRFamide. We are presently analyzing extracts from large numbers of heart motor neurons (10 or more) to verify our results. Other identified neurons which contain RFamide peptides, such as heart modulatory neurons or anterior pagoda cells, will be analyzed in a similar manner. We suggest that heart motor neurons synthesize FMRFamide and possibly YMRFamide and GGKYMRFamide.

EFFECTS OF NEUROACTIVE ANTHELMINTICS AND METABOLIC INHIBITORS ON MUSCLE FUNCTION AND ATP LEVELS IN HAEMONCHUS CONTORTUS. J.P. Davis*, E.M. Thomas* and D.P. Thompson. Parasitology Research, The Upjohn Co., Kalamazoo, MI 49001.

To determine the relationship between muscle function and energy charge in the gastrointestinal nematode *Haemonchus contortus*, we measured the effects of several neuroactive anthelmintics and metabolic inhibitors on motility, axial muscle tension and ATP during *in vitro* incubations. Concentration-dependent effects of drugs on motility were measured using an automated recording system consisting of a 4-channel Micromotility Recorder (B&P Inst., East Lansing, MI) and a Zymark® robotics system. ATP levels were measured using a bioluminescence assay. Axial muscle tension in 2-3 mm neuromuscular strips were recorded using a modified suction electrode-balance beam system. Results of these tests showed that ATP levels were not affected by the neuroactive anthelmintics ivermectin, milbemycin D, levamisole or pyrantel; all of which caused rapid paralysis of the axial muscle at therapeutic concentrations. ATP and motility levels were reduced in a concentration- and time-dependent manner by closantel and carbonyl cyanide phenylhydrazone, agents which inhibit oxidative phosphorylation in nematodes, and by potassium antimony tartrate, which inhibits the enzyme phosphofructokinase in nematodes. Isotonic tension recordings showed that the metabolic inhibitors caused a flaccid paralysis of *H. contortus* segments, while the neuroactive agents cause a spastic paralysis (levamisole, pyrantel) or do not affect tension (ivermectin, milbemycin D). These results suggest that the anthelmintic actions of the neuroactive agents tested do not depend on ATP depletion.

115.10

IDENTIFICATION OF CATECHOLAMINES, INDOLEAMINES AND THEIR METABOLITES IN THE SEA PANSY, *RENILLA KOELLIKERI*. A.K. Pani*, D. Umbriaco and M. Anctil. Dépt. de sciences biologiques and CRSN, Univ. de Montréal, Montréal, Québec, Canada H3C 3J7.

Several monoamines were reported to activate or modulate light emission and/or muscular activities in this colonial cnidarian species. These studies prompted the present biochemical investigation of such amines in the sea pansy using HPLC with electrochemical detection and radioimmunoassays. Among the catecholamines, dopamine, norepinephrine and epinephrine were present in variable amounts, and there was a correlation between the detected levels of the latter two amines and the intensity of their immunohistochemical reactivity in the same colonies. Among the indoleamines, both serotonin and a melatonin-like substance were detected. In addition, metabolites such as DOPAC, normetanephrine, metanephrine, N-acetylserotonin and 5-HIAA were occasionally detected. In view of the key phylogenetic position of Cnidaria regarding the evolutionary emergence of nervous systems, these results suggest that all major vertebrate monoamines and their oxidation, methylation and acetylation pathways are evolutionarily ancient.

BEHAVIORAL PHARMACOLOGY II

116.1

REDUCED IMMOBILITY FOLLOWING ANTIDEPRESSANTS IN A GENETIC ANIMAL MODEL OF DEPRESSION. D.H. Overstreet, G.D. Schiller*, O. Pucilowski*. Center for Alcohol Studies, University of North Carolina, Chapel Hill, NC 27514.

The Flinders Sensitive Line (FSL) rats exhibit exaggerated immobility in the forced swim test, increased sensitivity to cholinergic agonists, & increased numbers of muscarinic receptors (Overstreet et al., *Experientia* 44:465-472, 1988). The present project assessed whether this immobility could be overcome by chronic treatment with classical antidepressants (imipramine, desmethylimipramine), a novel antidepressant (sertraline), or an anticholinesterase (DFP). Imipramine, a classical antidepressant with strong inhibiting effects on the uptake of both serotonin and norepinephrine, almost completely counteracted the exaggerated immobility in the FSL rats. Desmethylimipramine, with more selective inhibition of norepinephrine uptake, & sertraline, with more selective inhibition of serotonin uptake, had only partial counteracting effects. DFP was without any counteracting effect. None of these agents, at the dose regimens used, significantly altered the immobility of control, Flinders Resistant Line rats. The findings confirm the utility of the FSL rats as an animal model of depression, since the mixed spectrum antidepressant produced the greatest "therapeutic" effect, as is the case in human depressives. In addition, these findings call into question the postulated association between elevated muscarinic receptors and immobility. Rather, changes in serotonin and/or norepinephrine are more likely to underlie the exaggerated immobility of the FSL rats.

116.2

5-HT₁ MODULATION OF SENSORIMOTOR REACTIVITY AND SPONTANEOUS ACTIVITY IN MICE. M. Schmidt, D. Helton, D. Modlin*, and J. Tizzano. Lilly Research Laboratories, Eli Lilly and Company, Greenfield, Indiana 46140.

In rats, 5HT_{1A} agonists increase startle while 5-HT_{1B} agonists decrease startle amplitude, and both types of 5-HT₁ agonists decrease activity levels. In the present study, auditory startle and spontaneous activity in male CD-1 mice were evaluated after treatment with: 5-HT_{1A} receptor subtype agonists, LY228729 (0, 0.05, 0.5, 5.0 mg/kg, PO) or LY165163 (PAPP, 0, 0.05, 0.5, 5.0 mg/kg, PO); the partial 5-HT_{1A} agonist 8-OH-DPAT (0, 1.0, 3.0, 10.0 mg/kg, IP); or the preferential 5-HT_{1B} agonist, 1-(m-chlorophenyl) piperazine (MCPP, 0, 1.25, 2.5, 5.0 mg/kg, IP). Spontaneous activity was measured for 2 hours in a novel home-cage environment (Multi-Varimex). Auditory startle was measured in automated SDI chambers. Each startle test session involved a 5-minute acclimation period at a background noise level of 70 dBA prior to 50 presentations of 120 dBA noise bursts at 8-second intervals. LY228729 and LY165163 produced dose-related decreases in auditory startle amplitudes and decreased initial activity levels, at 5.0 mg/kg. 8-OH-DPAT decreased startle and produced a biphasic effect on activity levels. In contrast, at 5.0 mg/kg MCPP increased startle amplitude but produced a dose-related decrease in activity levels. These data indicate that the effects of 5-HT₁ agonists are dependent not only on the specific receptor subtype involved and the behavior measured, but also on the species tested.

116.3

POTENTIAL ANXIOLYTIC ACTIVITY OF 5-HT_{1A} PARTIAL AGONISTS MDL 102,181 AND MDL 73,005EF IN ANIMAL MODELS OF ANXIETY SENSITIVE TO BUSPIRONE. J.M. Hitchcock, T.C. McCloskey*, R.A. Padich*, D.R. McCarty*, M.W. Dudley, J.S. Sprouse, J. Freedman, and J.H. Kehne, Marion Merrell Dow Research Institute, 2110 E. Galbraith Rd., Cincinnati, OH 45215.

Compounds acting at the 5-HT_{1A} receptor represent a new class of anxiolytics devoid of the sedative and muscle relaxant effects seen with the benzodiazepines. The 5-HT_{1A} partial agonist buspirone is representative of this anxiolytic class. Although buspirone is a clinically effective anxiolytic, it does not show anxiolytic activity in all animal models of anxiety. Two models in which buspirone does show anxiolytic activity are the fear-potentiated startle paradigm, in which rats exhibit an enhanced acoustic startle reflex in the presence of a conditioned stimulus that has previously been paired with shock, and the separation-induced ultrasonic vocalization paradigm, in which rat pups emit ultrasonic vocalizations when separated from the litter. These paradigms were used to assess potential anxiolytic effects of novel compounds with activity at 5-HT_{1A} receptors.

MDL 102,181 (2-[1-(2-isopropoxyphenoxy)-2-phenylethylimidazole], an arylalkylimidazole chemically unrelated to any known anxiolytic drug, and MDL 73,005EF (8-[2-(2,3-dihydro-1,4-benzodioxin-2-yl-methylamino)ethyl]-8-azaspiro [4,5]decane-7,9-dione methyl sulphate), a 1,4-benzodioxan, displayed agonistic properties at dorsal raphe autoreceptors and higher potency than buspirone at the 5-HT_{1A} binding site. MDL 73,005EF has shown potential anxiolytic activity in other animal models (Moser et al., *Br. J. Pharm.*, 99, 1990). MDL 102,181, like MDL 73,005EF (Kehne et al., *Eur. J. Pharm.*, 193, 1991), suppressed separation-induced vocalizations and did not affect performance on an inclined plane test. Furthermore, both compounds decreased fear-potentiated startle without depressing baseline startle. Thus, these animal models appear to be sensitive to drugs acting at the 5-HT_{1A} site, even those in different chemical classes than buspirone. The data indicate that the 5-HT_{1A} partial agonists MDL 102,181 and MDL 73,005EF have profiles of selective potential anxiolytics lacking sedative or muscle relaxant activity.

116.5

LY53857 BLOCKS RESPONSE SUPPRESSION (RS) INDUCED WITH 5-HTP AND DOI BUT NOT WITH 8-OH-DPAT IN AN ANIMAL MODEL OF DEPRESSION. E.A. Engleman, J.N. Hingtgen, J.M. Murphy, F.C. Zhou, and M.H. Aprison. Depts. Psychiat; Biochem; Psychol; & Anat; Prog. Med. Neurobiol.; Inst. Psychiat. Res.; Indiana U. Sch. Med. & Purdue Sch. Sci. IUPUI, Indianapolis, IN 46202.

Studies from this laboratory have demonstrated that administration of the selective 5-HT_{2C} antagonist LY53857 can block 5-HTP induced RS (Hingtgen et al., *Biol. Psychiat.*, 20:592 1985). To further investigate the serotonergic mechanisms involved in this effect we tested the ability of LY53857 to block RS induced with DOI and 8-OH-DPAT (agonists selective for 5-HT_{2A/C} and 5-HT_{1A} receptors, respectively). Rats trained to press a lever for milk reinforcement on a VI 1' schedule were given 1.0 mg/kg IP injections of DOI or 8-OH-DPAT to induce RS after a 15 minute baseline period. IP injections of 1.0 mg/kg LY53857 1 hour before DOI or 8-OH-DPAT resulted in a 100% blockade of DOI induced RS but did not block RS induced with 8-OH-DPAT. These results indicate that RS can be induced with agonists selective for 5-HT_{2A/C} or 5-HT_{1A} receptors, but 5-HTP induced RS shows more pharmacological similarity to DOI induced RS and may be mediated primarily through 5-HT₂ and/or 5-HT_{1C} receptors. (Indiana Dept of Mental Health, IUPUI Research Investment Fund, and AA08553).

116.7

DIFFERENTIAL ANTAGONISM BY KETANSERIN OF BEHAVIORAL EFFECTS OF 5HT₂ VERSUS 5HT_{1B} AGONISTS ON A COUNTING PROCEDURE. M.A. Kautz, R. Preston*, G. Agritellis*, Z. Ritch*, and G. Galbicka*. Department of Medical Neurosciences, Walter Reed Army Institute of Research, Washington, DC 20307-5100.

The behavioral effects of the 5HT antagonist ketanserin were examined alone and in combination with the 5HT_{1B} and 5HT₂ agonists TFMPP and DOI, respectively, in a complex operant task designed to mimic control by response number, or "counting." Rats pressed the left of two response levers one or more times and then made one press on the right lever to end a trial. The probability of reinforcement increased systematically as the number of left lever responses (a "run") more closely approximated the target value of 12. Under one procedure the current run was reinforced if it was closer to the target than two-thirds of the most recent 24 runs. This maintained a constant reinforcement probability of 0.33. Under a second procedure, the reinforcement probability was fixed such that runs around the target would result in the same overall reinforcement probability, but any drug-induced disruption in run length decreased reinforcement probability.

The 5HT_{1B} and 5HT₂ agonists TFMPP and DOI both produced decreases in run length at a dose of 3.0 mg/kg. Ketanserin (0.3-30.0 mg/kg) administered in isolation only decreased run length when reinforcement probability was held constant. Administered in combination with the agonists, ketanserin substantially antagonized the effects of DOI, but not TFMPP. These behavioral results are consistent with differential sensitivity of ketanserin at the different 5HT receptor subtypes obtained in receptor binding studies. Antagonism of DOI's behavioral effects was obtained at doses that were ineffective administered alone. This suggests that ketanserin pretreatment may be useful therapeutically in blocking the behavioral side-effects of 5HT₂ compounds.

116.4

BEHAVIORAL PHARMACOLOGY OF THE 5-HT_{1A} RECEPTOR LIGANDS IPSAPIRONE AND 8-OH-DPAT IN RATS AFTER REPEATED ^{1A} ADMINISTRATION. J. De Vry*, R. Schreiber* and T. Glaser. Institute for Neurobiology, Troponwerke, Berliner Straße 156, 5000 Köln 80, FRG

Acute administration of the 5-HT_{1A} receptor ligands ipsapirone (1, partial agonist) and 8-OH-DPAT (D, full agonist) [8-hydroxy-2-(di-n-propylamino)tetralin] results in anxiolytic, anti-aggressive and antidepressive effects in several animal models [De Vry et al. (1991). In Briley M and File SE (Eds) *New Concepts in Anxiety*. MacMillan Press, London, chapter 7]. Rats treated for two weeks with low to moderate doses of I (0.5 - 10 mg/kg i.p.) and D (0.03 - 1 mg/kg i.p.) do not develop tolerance to the anxiolytic effects in a shock induced ultrasonic vocalization test. With regard to the antidepressive effects in a rat forced swimming test, repeated treatment with low doses either do not affect (D), or even produce sensitization (I), whereas repeated treatment with higher doses results in weak (I, ≥ 10 mg/kg i.p.) and strong tolerance (D, ≥ 0.3 mg/kg i.p.). Tolerance to the antidepressive effect of D (higher doses), as well as to its capacity to induce a 5-HT behavioral syndrome, develops already after 1 or 2 applications; a finding not observed in the case of its hyperthermia and hyperphagia effects. The data suggest that the behavioral effects of 5-HT_{1A} ligands after repeated treatment are the result of a complex interaction of tolerance and sensitization processes. It is hypothesized that the development of tolerance/sensitization depends on (a) the particular behavioral effect (reflecting the activation of a particular population of pre- and/or postsynaptic 5-HT_{1A} receptors), (b) the dose and (c) the intrinsic activity of the compound at these receptors.

116.6

SELECTIVE ATTENUATION OF THE DOI-INDUCED HEAD SHAKE RESPONSE IN RATS BY DEFECT IN TERRITORIAL AGGRESSION. D.J. Knapp, D. Benjamin, & L.A. Pohorecky, Rutgers University Center of Alcohol Studies, Piscataway, NJ 08855-0969.

Head shakes induced by DOI (1-(2,5-dimethoxy-4-iodophenyl)aminopropane)-2 reflect 5-HT₂ receptor function. Neurochemical changes induced by antidepressant drugs attenuate 5-HT₂ receptor function; an effect correlated with antidepressant efficacy. To characterize the effects of non-pharmacological manipulations, such as stress, on 5-HT₂ receptor function, the effects of four qualitatively different stressors on DOI-induced head shakes were investigated. Male Long Evans rats were exposed to one of the following conditions at least 24 hours prior to a 30 minute observation period which began with DOI injection (0.64 mg/kg, ip): 1) no manipulation, 2) repeated exposure to startle-inducing air puff, 3) 2 hour exposure of resident rats to intruder rats, 4) 2 hour exposure to a novel environment similar to the resident's cage, or 5) 2 hour exposure of intruder rats to resident rats. Head shake responses following these manipulations were 12.6±1.9, 10.6±1.6, 9.9±2.1, 8.7±2.4, 2.8±0.5, respectively. Analysis of variance of these data indicate a significant overall effect (p < .05), the variance of which was accounted for entirely by the intruder rat group (p < .0026). Pre-exposure to the novel environment alone, air puff stimuli, or status as a resident were not sufficient to reduce head shakes. It is concluded that exposure to a stressful encounter with an aggressive resident produces a decrement in the function of 5-HT₂ receptors which may reflect a specific adaptive response to stress induced by conspecific attack. (Supported by USPHS AA05306, AA08499, and a Smithers Foundation Grant)

116.8

EVALUATION OF 5-HT₃ ANTAGONISTS ON SCHEDULE-CONTROLLED PERFORMANCE IN RATS. P.C. Mele and J.H. McDonough. Behavioral Sciences Dept., Armed Forces Radiobiology Research Institute, Bethesda, MD 20814-5145.

5-HT₃ antagonists are effective antiemetic agents; they may have anti-anxiety, antipsychotic and nociceptive properties as well. The present study extended the behavioral evaluation of three 5-HT₃ antagonists to schedule-controlled performance in male Sprague-Dawley rats. Zacopride, GR38032F and ICS 205-930 did not alter responding under a multiple fixed-interval 2 min, fixed-ratio 20 (mult FI FR) schedule of milk presentation at 0.01-10 mg/kg IP. These doses inhibit emesis induced by ionizing radiation and chemotherapeutics, and are active in paradigms used to evaluate drugs for anti-anxiety and antipsychotic efficacy. A higher dose (32 mg/kg) of GR38032F and ICS 205-930 reduced both FI and FR response rates. Higher doses of zacopride (32 and 56 mg/kg) did not alter either FI or FR responding consistently. The effects of each of the 5-HT₃ antagonists differed from those of several reference compounds (metoclopramide, haloperidol, buspirone and chlordiazepoxide) that were examined because of their known antiemetic, anti-anxiety, and/or antipsychotic effects. ICS 205-930 was administered in combination with each of the reference compounds, caffeine, scopolamine, and morphine.

116.9

ALPHA-2 RECEPTOR ANTAGONIST POTENTIATES BARBITURATE ANESTHESIA IN RATS. D. Stenberg, T. Kauppila* and Z. Lelkes*. Department of Physiology, University of Helsinki, Siltavuorenpenger 20 J, 00170 Helsinki, Finland.

Alpha-2 receptor agonists are increasingly being used as adjuvants to anesthesia, and specific antagonists are developed to end the effect. Thus the highly specific alpha-2 receptor antagonist atipamezole (A) at 1 mg/kg reverses completely the sedative-anesthetic effect in rats of 0.3 mg/kg medetomidine (M), a highly specific alpha-2 receptor agonist. We found, however, that A greatly prolonged anesthesia induced by 40 mg/kg pentobarbital ip. in rats. When A was given 20 minutes after B, the duration of EEG spiking was prolonged from a mean of 35 min to 90 min, and the loss of righting reflex from 90 to 200 min. The combination of B+M induced loss of righting for a mean of 440 min, and was only partly antagonized by A given 20 minutes after the combination. We conclude that the pharmacological occupancy of alpha-2 receptors is highly potentiating to the depressing effect of barbiturates, as evidenced by the paradoxical action of the antagonist after barbiturate.

116.11

ANTAGONISM OF THE BEHAVIORAL EFFECTS OF MEDETOMIDINE BY ATIPAMEZOLE IN THE DOG. S.G. Kamerling, L. Berryhill*, C. Bagwell*, and W.R. Kilgore. Dept. of Vet. Physiol. Pharmacol. Toxicol., Sch. of Vet. Med., Louisiana St. Univ., Baton Rouge, LA 70803.

Atipamezole (ATI), a novel alpha-2 adrenoceptor antagonist, is currently being evaluated as a reversal agent for the sedative/analgesic, medetomidine (MED), in the dog. Vaha-Vahe (1990) reported that ATI (80-240 ug/kg i.m.) rapidly and effectively reversed medetomidine-induced sedation, analgesia, bradycardia, and recumbency in dogs. The purpose of the present study was to extend these observations using (1) a more extensive assessment of sedation and ambulation, (2) a broader range of doses of ATI, and (3) mixed breed hounds of similar weight and size.

Eight male and 8 female mixed breed hounds received a 1mg/m² dose of MED followed 30 minutes later by ATI (1, 5, and 10 mg/m² and saline) according to a latin square crossover design. All three doses of ATI significantly shortened time to arousal, standing, and ambulation. Significant differences between the 1 and 10 mg/m² doses of ATI were observed for standing and walking times. No differences were observed between the 5 and 10 mg/m² doses. All three doses of ATI significantly antagonized MED-induced sedation and reduction in walking ability. The 5 and 10 mg/m² doses produced greater antagonism than the 1 mg/m² dose. However, there were no statistical differences between the 5 and 10 mg/m² doses. ATI produced dose related antagonism of MED-induced bradycardia. Significant reversal was observed at the 5 and 10 mg/m² doses.

These data support the use of atipamezole as an effective antagonist for the sedative and bradycardic effects of medetomidine in the dog. (Supported by a grant from SmithKline Beecham Animal Health)

116.13

A DOSE-RESPONSE FOR D-AMPHETAMINE AND BEHAVIORAL THERMOREGULATION IN RATS. Cheryl Chancellor-Freeland and Harry J. Carlisle. University of California, Santa Barbara, CA 93106.

Past studies have shown that hyperthermic animals under the influence of amphetamine approach heat sources while hypothermic animals avoid heat. These paradoxical effects of amphetamine on behavioral thermoregulation have been attributed to changes in thermal set-point (Yehuda & Frommer, 1978). The present experiment reexamines this notion by allowing rats to select preferred ambient temperature in a thermal gradient. Eight female rats were administered 0, 1, 5, and 10 mg/kg d-amphetamine sulfate and tested for 60 minutes. Thermal preferences as well as core temperatures were used to assess the thermic effects of amphetamine. With doses of 1 and 5 mg/kg animals responded to the thermogenic properties of the drug by lowering temperature preference. However, in contrast to previous reports (Bushnell & Gordon, 1987; Yehuda & Wurtman, 1974), these dosages also produced dose-dependent decreases in core temperature. The high dose of amphetamine (10mg/kg) produced an inconsistent pattern of thermoregulation. Some animals preferred the cold and became hypothermic, while others preferred warmth and became hyperthermic. The present findings tend to support the view that amphetamine reduces the set-point, although this effect was observed at much lower doses than previously reported (Yehuda & Wurtman, 1974).

116.10

ATIPAMEZOLE, AN ALPHA-2-ADRENOCEPTOR ANTAGONIST, INCREASES SEXUAL BEHAVIOR IN MALE MONKEYS. I. Linnankoski*, M. Grönroos*, S. Carlson and A. Pertovaara. Dept. Physiol., Univ. Helsinki, 00170 Helsinki, Finland. (SPON: ENA)

Atipamezole is a novel imidazole-type alpha-2-adrenoceptor antagonist. The alpha-2/alpha-1 selectivity ratio of atipamezole is 200-300 X higher than that of either idazoxan or yohimbine. In the present study the effect of atipamezole on sexual behavior was studied in three male stump-tail macaques (*Macaca Arctoides*). Following i.m. administration of atipamezole (0.01-0.30 mg/kg) or saline control the male monkey was put together with a female monkey and the behavior observed for 30 min. Atipamezole produced a significant dose-dependent increase in the number of ejaculations in all three monkeys, including an old one with decreased sexual activity in control conditions. No side-effects, except increased alertness, were observed. It is concluded that atipamezole is highly effective in increasing sexual behavior in male monkeys.

Intracerebroventricular minocycline inhibits amphetamine-induced increases in rearing in rats. O. Kofman*¹, R.H. Belmaker*¹ and Y. Shavit*². Psychiatry Research Unit, Ben-Gurion University¹, Beer-Sheva & Dept. Psychology, Hebrew University², Jerusalem, ISRAEL.

The tetracycline derivative minocycline, like lithium, inhibits agonist-induced stimulation of cAMP in vitro and ex vivo and inhibits motor activity and amphetamine hyperactivity in rats. To verify that these behavioural effects are centrally mediated, baseline and amphetamine-induced activity were measured following injections of minocycline in the lateral ventricle. Rats were injected with minocycline HCl (50 µg) or vehicle (2µl) icv, and with either d-amphetamine (1 mg/kg) or saline ip. Amphetamine increased locomotor, total and rearing activity (p<.001). Minocycline significantly reduced rearing (p<.05), and there was a significant interaction between amphetamine and rearing (p<.05). Minocycline (100 µg) did not reverse hypokinesia induced by the cAMP phosphodiesterase inhibitor, rolipram. Thus, while minocycline has central effects on motor behaviour, it remains unclear whether these effects are due to its actions on cAMP.

TOLERANCE, WITHDRAWAL AND SUPERSENSITIVITY TO DOPAMINE MEDIATED CUES IN A DRUG-DRUG DISCRIMINATION PARADIGM. R.J. Barrett* & W.F. Cautl. Veterans Administration Medical Center and Dept. of Psychology, Vanderbilt University, Nashville, TN 37204

Rats were trained to discriminate between 0.25 mg/kg amphetamine (AM) and 0.03 mg/kg haloperidol (HD) in a two-lever drug discrimination task. In order to test for a drug-induced withdrawal state, Ss were assigned to one of three groups and given 10 consecutive, daily injections of 10 mg/kg AM, 1.0 mg/kg HD or distilled water (DW). Ss from each treatment condition were then tested either 24, 48 and 72 hrs after the final injection. Results showed that at the 24 hr retest interval Ss injected with AM responded as though administered an acute dose of HD (0.02 mg/kg) and Ss injected with chronic HD responded as though administered an acute dose of AM (0.15 mg/kg). By 72 hrs choice behavior had returned to pre-treatment values.

To determine whether the rebound observed after 10 daily injections was present after a single injection, independent groups of subjects were injected with single doses of either 10 mg/kg AM or 1.0 mg/kg HD and then retested either 4, 6, 12, 20, 24, 30, 36, or 42 hrs later. The data showed that single doses of both AM and HD produced significant rebounds that peaked between 20 hrs (AM) and 24 hrs (HD) following administration.

In a third experiment, Ss tested with acute doses of HD 24 hr after a single 1.0 mg/kg dose of HD demonstrated enhanced AM lever choice (supersensitivity), while Ss tested with acute doses of AM 20 hr after a single 10.0 mg/kg dose of AM showed diminished AM lever choice (tolerance). Taken together the data suggest a common mechanism of action for the observed phenomena.

AGE-RELATED CHANGES IN ATTENTIONAL ABILITIES IN FISCHER-344 RATS: EFFECTS OF BENZODIAZEPINE RECEPTOR LIGANDS AND AMPHETAMINE. K. Quigley, H. Moore, P. Dudchenko, J.P. Bruno, and M. Sarter. Dept. Psychology, The Ohio State University, Columbus, OH 43210.

While studies on the age-related changes in cognitive functions in animals have focused on impairments in learning and memory, the human data suggest that attentional processes are predominantly affected by age. Fischer-344 rats (4, 12, 18 months) were trained in a sustained attention task that partly resembles the continuous performance task frequently used in human studies. Animals were trained to report detection of an unpredictably and rarely occurring brief visual signal (0.1 sec) by pressing a lever which remained active for 3 sec after stimulus onset. The probability for a hit and a false alarm (an operation during the prestimulus 3 sec bin) were used for the calculation of indices of signal sensitivity (SI) and response bias (RI). In comparison to 4 and 12 month old rats, aged rats showed a decrease in vigilance (SI) but not in response bias (RI). Middle-aged and aged rats were slower in responding than 4 month old animals. While these data suggested that this task model age-related changes in sustained attention, drug testings did not support this hypothesis. In contrast to human data (Koelega, 1989), chlordiazepoxide (1,3,5 mg/kg) did not affect SI and RI. Likewise, neither the nootropic ZK 93426 (1,3,5 mg/kg) nor amphetamine (0.25 mg/kg) were effective. Thus, the animals' performance appeared insensitive to these pharmacological manipulations. The nature of the effects of age remains unclear as cognitive, locomotor, and motivational demands were not varied. Future attempts to model age-related changes in attention will have to be based on a more precise analysis of the factors that provoke age-related effects in humans, particularly on the integration of recently acquired information about changes in spatial and temporal stimulus characteristics. Furthermore, conclusions on the cognitive nature of age-related effects should be based on variations of task demands.

LOCALIZATION OF A BENZODIAZEPINE RECEPTOR MEDIATED, CONTROL-DEPENDENT INCREASE IN ANXIETY FOLLOWING STRESS IN THE RAT. K. R. Short and S. F. Maier, Dept. of Psychology, Univ. of Colorado, Boulder, CO 80309.

This laboratory has reported that an inescapable stressor but not an escapable stressor produces a decrease in social interaction, an animal model of anxiety, 24 hrs later. This control-dependent anxiety was blocked by the benzodiazepine receptor antagonist Ro15-1788 (flumazenil) when systemically administered prior to stress treatment but not when given prior to social interaction measurement. We now report that Ro15-1788 (200 ng in 1.0 µl) or an equal volume of vehicle microinjected into the third ventricle immediately prior to inescapable shock, via a chronically implanted cannula, reproduces the blockade of stress-induced anxiety observed following intraperitoneal injections. This result confirms that a central mechanism mediates the production of anxiety associated with inescapable stress. The search for the brain areas responsible was further narrowed to noradrenergic and serotonergic nuclei that would be capable of activating numerous cortical and diencephalic regions to produce anxiety. Cannulae were chronically implanted either on the midline into the dorsal raphe or bilaterally into the locus coeruleus. Ro15-1788 or vehicle was injected into each site (50 ng in 0.5 µl in each cannula) prior to inescapable or escapable shock exposure. Social interaction measured 24 hrs later revealed a blockade of anxiety only in inescapably-stressed rats that had received the benzodiazepine receptor antagonist in the dorsal raphe. This result suggests that neurons synapsing onto the dorsal raphe release an endogenous benzodiazepine receptor inverse agonist (anxiogenic) in response to inescapable stress but not in response to escapable stress. Incremental Shock in the Conflict Procedure Provides a Behavioral Baseline Sensitive to Bidirectional Changes in Anxiety. R.L. Smith, J.S. Shumsky, and I. Lucki, Departments of Psychiatry and Pharmacology, University of Pennsylvania, Philadelphia, PA 19104

Pollard and Howard's (1979) modification of the Geller-Seifter conflict procedure was used to create a baseline of operant responding sensitive to both increases and decreases in anxiety. Rats were trained under a multiple schedule using food reward. Sessions consisted of three, six-m periods under a RI 80-s schedule alternated with three, tone-signalled, two-m periods under a CRF schedule. In addition to reinforcement, each response during the tone period was punished using an incremental shock procedure whereby every other lever press incremented the shock intensity. Animals made an average of 12 responses/conflict period for a total of 36 punished responses/session; the twelfth response corresponded with the midpoint in the range of shock intensity. The benzodiazepine agonists diazepam, chlordiazepoxide (CDP) and lorazepam produced dose-related increases in punished responding. The antipunishment effect of CDP (10 mg/kg) was antagonized by flumazenil. The putative anxiogenic compound pentyleneetetrazol produced a selective suppression of punished responding while the inverse agonist FG 7142 suppressed responding under both schedules. Additional anxiogenic compounds are being tested, these include: βCCE, DMCM and picrotoxin. Experiments investigating the usefulness of this model for studying BZ withdrawal are underway. Supported by DA 05413 and DA 05186.

CHARACTERIZATION OF THE SEXUAL DIMORPHISM IN STRESS-INDUCED CHANGES IN RENAL PERIPHERAL BENZODIAZEPINE RECEPTORS IN RAT

R.C. Drugan, J. Chang*, R. Park* and P.V. Holmes. Schrier Research Laboratory, Department of Psychology, Brown University, Providence, R.I. 02912

Last year we reported a gender difference in inescapable shock-induced changes in [3H]Ro 5-4864 binding to renal peripheral benzodiazepine receptors (PBR) in rat. Subsequent scatchard analysis has indicated that both genders exhibit a reduction in PBR density in kidney following inescapable shock stress, with females showing an attenuated response in comparison to males.

We have begun to characterize the etiology of these gender differences by surgical gonadectomies in both groups. Castration of male rats does not appear to influence the magnitude of the stress-induced reduction in renal PBR density. However, preliminary evidence suggests that ovariectomy in females may potentiate the stress-induced change in this group in comparison to sham surgery controls. We have also recently observed a gender difference in stress-induced alterations in both behavior and renal PBR binding following the forced swim behavioral despair test. We are currently confirming and expanding our findings in an effort to characterize the etiology of this phenomenon as well. These differences in renal PBR changes in response to stress may shed light on the cause of certain behavioral and physiological gender differences in stress responsivity. Uncovering the mediators of these gender differences in PBR responsivity to stress may aid in the discovery of the functional significance of this receptor. This research was supported by an NIMH Grant # MH 44034 and an Alfred P. Sloan Research Fellowship to R.C.D.

A COMPARISON OF THE SCHEDULE-INDUCED EFFECTS OF BEHAVIORAL TOLERANCE IN TRIAZOLAM AND COCAINE. S.E. Bowen*, M.J. Kallman and M.R. Durnam*. Depts. of Psychol. & Pharmacol., Univ. of Mississippi, University, MS 38677.

This investigation explored the effects of repetitive oral exposure to triazolam (TZ) and cocaine (CO) on behavioral tolerance and withdrawal. Forty male rats were trained to respond on a multiple fixed ratio 30: differential reinforcement of low rate 20 sec. schedule during daily 20 min. sessions. An initial dose effect curve was obtained with 16 rats for TZ (0.05-1.0 mg/kg) or CO (2.0-24.0 mg/kg) and redetermined following 30 days of chronic exposure for each group. During the chronic exposure period half of the rats from both drug groups (N=8/drug) were gavaged pre-session (PRE) and the other half were gavaged post-session (POST). The remaining 8 rats were tested as saline treated controls. Disruptions in operant performance were assessed for 15 days following the termination of drug exposure. FR and DRL performance was assessed with measures of response rate (RR), response duration (RD), interresponse times (IRT), and reinforcements earned. Both TZ and CO produced greater tolerance when the rats were given the opportunity to practice under the drug state (PRE group). Repetitive exposure to CO was more susceptible to conditioned tolerance effects than repetitive TZ exposure. The severity of disruption following drug withdrawal was also enhanced for the PRE animals for both TZ and CO exposure. Supported by NIDA funds DA05253.

MORPHOLOGY OF BULLFROG SYMPATHETIC PREGANGLIONIC NEURONS. D. Peruzzi and C.J. Forehand, Dept. of Anatomy and Neurobiology, University of Vermont, Burlington, VT 05405.

Bullfrog sympathetic preganglionic neurons are segmentally segregated according to function (Horn and Stofer, *J. Comp. Neurol.* 268:71, '88). Preganglionic neurons that project to lumbar ganglion cells that innervate blood vessels are known as C cells; they are located in spinal segments seven and eight. Preganglionic neurons that project to lumbar ganglion cells that innervate non-vascular targets are known as B cells; they are located in spinal segments five and six. Whether these two classes of preganglionic neurons have similar dendritic arborizations within the spinal cord is unknown. To address this issue, we examined the morphology of these preganglionic neurons by intracellular injection with neurobiotin.

Of the five cells labeled thus far, two were C cells and three were B cells. In general, B and C cells were similar. They averaged 18 μ m in cell body diameter and had an average total dendritic length of 3253 μ m arising from three to four primary dendrites. However, differences were noted between B and C cells in both axonal and dendritic parameters. Axons of B cells had a larger diameter at their origin (three to four μ m) than axons of C cells (one μ m). Both C cell axons arose from a dendrite, while two of the B cell axons arose directly from the cell soma. One of the C cell axons branched extensively within the spinal grey. Both cell types had extensive dendritic projections into the lateral funiculus. In contrast to B cells, C cell dendrites also extended into the dorsal horn. This dorsal extension of C cell dendrites may be involved in specific central connections for vascular control.

117.3

CLASSIFICATION OF STELLATE GANGLIA (SG) NEURONS IN NEONATAL SWINE. A.L. Sica, J.A. Armour, N.A. Kaplan, F.M. Pisana* and P.M. Gootman, Albert Einstein Coll. Medicine, Long Island Jewish Med. Ctr., Schneider Children's Hosp., Dept. of Peds., New Hyde Park, NY 11042.

In anesthetized (pentobarbital or saffan), paralyzed, thoracotomized and artificially ventilated (100% O₂) neonatal swine, extracellular potentials of SG neurons were recorded along with phrenic nerve (monitor of central inspiratory activity), EKG, intratracheal and arterial blood pressure signals. While neurons with spontaneous discharges related to phrenic nerve activity were not observed, some neurons had discharges during the inflation or the deflation phases of the ventilator cycle. Surprisingly, few neurons had discharges related to the cardiac cycle. In contrast to the relatively smaller number of neurons with spontaneous discharges, many neurons were evoked by ipsilateral mechanical stimulation (i.e. probing, or stroking) of their receptive fields located on a) the ventricular surface; b) the lateral surface of the thorax; c) the hairy regions of the upper and lower arms. The finding of few cardiac-related SG neurons was unexpected and suggested that such activities may emerge in an age-dependent fashion.

117.5

ELECTRON MICROSCOPIC STUDY OF DOG CARDIAC GANGLIA AFTER CHRONIC DENERVATION. M.H. Mostafa, J.X. Thomas Jr., R.D. Wurster and E.J. Neafsey, Neuroscience Graduate Program and Department of Physiology, Loyola University Chicago, Maywood IL 60153.

Cardiac ganglia were dissected from the pulmonary vein fat pads of three groups of dogs: Intact, selective vagal denervation (VagX), and total sympathetic and vagal denervation (TotalX). After processing the ganglia for EM, the number of boutons and synaptic contacts per primary ganglionic neuron were counted. As seen from the table below, both types of denervation produced statistically significant (*, p < .05)

	boutons/cell (sem)	synapses/cell (sem)
Intact	2.53 (0.36)	1.26 (0.13)
VagX	0.10 (0.002)*	0.03 (0.01)*
TotalX	0.09 (0.03) *	0.02 (0.01)*

decreases in both bouton number and synapse number compared to Intact dogs. There was no significant difference between the two denervation groups, implying that there is little or no sympathetic innervation to these primary ganglionic neurons. In both denervation groups the ganglionic neurons also displayed an obviously high accumulation of intracellular glycogen, as well as a slight increase in lipofuscin granules. Their cell nuclei had normal ultrastructure, but the nuclear membrane did appear convoluted compared to cells in Intact dogs. However, only 3% of the cells showed signs of degeneration (large vacuoles and severely dilated cisternae). (NIH HL 27595)

117.2

GENE EXPRESSION OF TYROSINE HYDROXYLASE AND NPY IN PREVERTEBRAL GANGLIA OF RENAL HYPERTENSIVE RATS. T.L. Krukoff and Y. Zheng*, Dept. of Anatomy & Cell Biol., Fac. of Medicine, Univ. of Alberta, Edmonton, Canada T6G 2H7.

Gene expression of tyrosine hydroxylase (TH) and neuropeptide Y (NPY) was studied in prevertebral ganglia and adrenal glands of adult male rats during development of one kidney/one clip (1k/1c) Goldblatt hypertension. Tissues from 1k/1c rats with arterial pressures significantly elevated by day 3 were compared to those from sham controls. Four or 5 days after renal surgery, superior cervical ganglia, celiac-mesenteric plexus, adrenal glands, and stellate ganglia were surgically removed from non-fixed rats for Northern blot analysis or from perfusion-fixed rats for 'in situ' hybridization. In all tissues, levels of TH mRNA were decreased in hypertensive rats; cells with decreased levels were scattered throughout each tissue. In contrast, levels of NPY mRNA were unchanged in hypertensive rats compared to controls. Changes in TH mRNA levels suggest that the developing phase of renal hypertension is associated with a decrease in sympathetic outflow to the periphery. The failure of NPY mRNA levels to change suggests different regulatory mechanism for NPY expression or a different role for NPY in sympathetic neurotransmission.

ANATOMY OF CANINE INTRINSIC CARDIAC NEURONS. Yuan, Bing-Xiang*, D.A. Hopkins, J.A. Ardell*, J.A. Armour, Depts. of Physiology / Biophysics and Anatomy, Dalhousie University, Halifax, N.S., B3H 4H7, and Physiology, University of South Alabama, Mobile, Alabama, 36688.

Ganglionated plexi were identified on the ventral and lateral surfaces of the right and left atria, the dorsal surface of the two atria, as well as the dorsal surface of the atria adjacent to the origin of the inferior vena cava by means of microscopic analysis of methylene blue-stained fresh and fixed tissues. Ganglia were identified on the cranial surface of the ventricles surrounding the aortic root and extending ventrally and dorsally adjacent to the origins of the major coronary arteries. Ganglia were also identified near the origin of the right and left marginal coronary arteries. The somata of single neurons were identified along the course of nerves. Some of these, arising from nerves like a row of grapes, appeared to be similar to pseudounipolar neurons. The majority of neurons were multipolar. About 40% of histologically identified neurons contained multiple nucleoli. The canine intrinsic cardiac nervous system contains many more neurons than has been considered previously. These neurons are widely distributed and appear to include a number of different cell types. Supported by the MRC of Canada (MT-10122), as well as Nova Scotia and Alabama Heart Foundation grants.

117.6

DECREASED VAGAL SENSORY INNERVATION OF THE HEART IS ASSOCIATED WITH PROLONGED QT INTERVALS IN THE ELECTROCARDIOGRAM. M.J. Mulroy and I.H. Harrison, Dept. of Anatomy, School of Medicine, Medical College of Georgia, Augusta, GA 30912.

Longer than normal QT intervals in electrocardiograms are associated with cardiac arrhythmias which can be fatal. Chicks with long QT intervals can be experimentally produced by ablation of the nodose placode early in development (Christiansen et al., 1989; Mulroy et al., 1990). We will present morphometric evidence from experimental chicks with long QT intervals and control chicks with normal QT intervals indicating a reduction in the sensory innervation to the heart provided by the nodose ganglion in chicks with long QTs.

We speculate that in this animal model a decrease in vagal sensory innervation to the heart during development can induce the long QT syndrome. This could occur directly by interfering with the development of normal cardiac sensory pathways or indirectly by interfering with the development of normal cardiac motor innervation, that is, an appropriate balance between sympathetic and/or parasympathetic innervation. We are currently investigating these alternatives. (Supported by NIH P01HL36059).

117.7

CARDIAC MYOCYTE MET-ENKEPHALIN-IMMUNOREACTIVITY (ir). B.A. Barron, J.F. Gaugl*, J.L. Caffrey*. Dept. of Physiology, Texas College of Osteopathic Medicine, Ft Worth, TX 76107.

We find met-enkephalin-ir uniformly distributed in the canine heart. When combined with reports of concentrated enkephalin mRNA in rodent hearts, these observations suggest cardiac opioids are not confined to nerves and may originate in the myocytes. The myocytes and intact left ventricle (LV) were acid extracted for estimation of total opioids and met-enkephalin-ir by RRA and RIA, respectively.

Tissue Assayed (n=5)	Met-enkephalin-ir: fmol/mg protein	Total Opioids: fmol etorphine equivalents/mg protein
Left ventricle	3.11 ± 0.42	143.0 ± 33.60
LV myocytes	11.53 ± 4.07	34.3 ± 3.99

The enkephalin content of the isolated myocytes is 3-4 X that found in intact ventricle, despite a 75% decrease in total opioids. This suggests that enkephalin and the larger pool of total opioids may be functionally independent. The large enkephalin increase in isolated myocytes suggests that other influences in intact tissue suppress synthesis and/or processing of enkephalin. HPLC of extracts indicates approximately 12% of myocyte and 45% of LV met-enkephalin-ir chromatographed with authentic met-enkephalin. These results suggest that the myocytes will be useful in determining the characteristics of heart enkephalin synthesis, processing and release.

117.9

NEUROPEPTIDE Y PRODUCTION IN RAT MYOCYTE CULTURE IS REGULATED BY SYMPATHETIC NEURON CO-CULTURE. K.L. Marek AND T. Niven-Fairchild. Dept. of Neurology, Yale Univ. School of Medicine, New Haven CT 06510

The regulation of Neuropeptide Y (NPY) production and secretion was examined in primary cell cultures from rat atrium, ventricle, superior cervical ganglion (SCG) and in myocyte-SCG co-cultures. NPY mRNA levels were quantitated by Northern analysis, NPY synthesis was measured after incubation in medium containing [³H]tyrosine followed by immunoprecipitation and SDS-PAGE, and NPY content was measured by radioimmunoassay. NPY was stable in spent medium for at least 48 hours. Cultures were maintained in complete serum free medium for up to 21 days.

NPY production and secretion was reduced in SCG-atrial cultures by 3-fold and SCG-ventricular cultures by 7-fold as compared to atrial and ventricular cultures alone. The reduction in NPY secretion shows a dose-dependent response to the number of neurons added to the co-cultures. In previous studies we have shown that NPY is rapidly secreted from myocyte cultures, but minimally secreted from SCG cultures alone.

Thus innervation of myocyte culture dramatically alters myocyte peptide expression. Experiments are underway to further elucidate the mechanism of this neuronal-target interaction and to identify the developmental significance of cardiac NPY expression. Support NSO1168, AHA900834.

117.11

LOCATIONS AND PEPTIDE CONTENT OF POSTGANGLIONIC NEURONS INNERVATING HINDLIMB VEINS, ARTERIES AND FOOTPADS OF RATS. N.S. Dehal*, A. Kartseva* and L.C. Weaver. J.P. Roberts Res. Inst., London, Ont., Can. & Bogomoletz Inst., Kiev, U.S.S.R.

The ganglionic location and peptide content of sympathetic neurons innervating hindlimb arteries, veins or footpads have not been compared. The different responses of these targets to sympathetic activation may relate to differences in the peptides contained in specific hindlimb sympathetic neurons. Retrograde transport of fluorescent dyes was used to identify, separately, postganglionic neurons innervating femoral arteries or veins in 28 rats. Footpad neurons were studied in 6 additional rats without distinguishing sweat gland neurons from footpad vasomotor neurons. Proportions of dye-labelled neurons containing NPY -and VIP-like immunoreactivity (LI) were compared in 24 of these rats. Venous vasomotor neurons were found in the T13-L6 ganglia with 62% in L1 and L2. Few were in L4-L6. Arterial vasomotor neurons were also found in the T13-L6 ganglia with most (81%) located in L1-L3. Veins and arteries were not innervated by the same cells. Footpad neurons were mostly in L4-6. NPY-LI was identified in 8% of 143 venomotor neurons, 94% of 637 arterial neurons and 24% of 267 footpad neurons. VIP-LI was found in 4% of 130 venomotor neurons, 8% of 385 arterial neurons and 44% of 305 footpad neurons. In summary, hindlimb venous, arterial and footpad neurons are anatomically distinct and differ markedly in their content of NPY-LI. The high proportion of footpad neurons containing VIP-LI likely reflects innervation of sweat glands; those containing NPY-LI may innervate footpad arteries. (Support: MRC Canada)

EFFECT OF OPIOID RECEPTOR ANTAGONISTS ON VASODILATOR NERVE ACTIONS IN THE PERFUSED RAT MESENTERY. Y.J. Li* and S. P. Duckles. Dept. of Pharmacology, College of Medicine, University of California, Irvine, CA 92717.

We have previously shown that opioid peptides inhibit sensory nerve effects in the rat mesentery. To explore the possibility that endogenous opioids modulate sensory nerve function, we investigated the effects of opioid receptor antagonists. In the presence of 5×10^{-6} M guanethidine and 10^{-5} M methoxamine, transmural nerve stimulation (TNS) causes a vasodilator response. This response was significantly potentiated by 3×10^{-7} M naloxone. Naloxone did not alter vasodilator responses to exogenous calcitonin gene related peptide, suggesting that potentiation by naloxone is mediated by a prejunctional action. To further characterize the opioid receptors involved, selective antagonists were used. 3×10^{-7} M ICI 174,864, a selective δ antagonist, had no effect on vasodilator responses to TNS. In contrast 3×10^{-7} M CTOP, a selective μ receptor ligand, significantly inhibited vasodilator responses to TNS. However, this effect was reversed by naloxone, suggesting that CTOP is a partial agonist at μ receptors. In preparations pretreated with the irreversible μ antagonist β -funtaltrexamine (2×10^{-7} M, 30 min) naloxone did not further potentiate vasodilator responses to TNS. These results confirm that opioid receptors are involved in regulation of sensory nerves and suggest that potentiation of vasodilator responses to TNS by naloxone may be due to blockade of μ receptors, resulting in reduced inhibitory modulation by endogenous opioids.

117.10

MODULATION OF VASCULAR SMOOTH MUSCLE GROWTH BY A SYMPATHETIC NEUROTRANSMITTER, NEUROPEPTIDE Y. Z. Zukowska-Grojec*, C. Colton, J. Yao*, S. Abi-Younes*, A. K. Myers*, J. L. Koenig and C. Wahlestedt. Department of Physiology & Biophysics, Georgetown University Medical Center, Washington, D.C. 20007

Neuropeptide Y (NPY) is a 36 amino acid peptide present with norepinephrine (NE) in all sympathetic postganglionic nerves innervating the cardiovascular system, in the adrenal medulla and in platelets. NPY evokes direct vasoconstriction via Y1 receptors in many vessels (e.g. vena cava) and potentiates NE-induced vasoconstriction (e.g. aorta). Since sympathetic nerves are presumed to play a role in vascular smooth muscle (VSM) growth, we studied the effects of NPY (and NE) on proliferation of cultured VSM cells (C) from aorta and vena cava of female rats. Passaged cells (passage 5-8) were plated into 96-well dishes at a density of 2×10^4 cells/well in DMEM containing 0.5% fetal calf serum (FCS). Following 48 hrs of treatment of aortic VSMC with NPY in 0.5% FCS, [³H] thymidine uptake tended to decrease at 10^{-9} M of NPY, whereas at 10^{-7} and 10^{-6} M, it significantly increased ($+19 \pm 5$ and $35 \pm 1\%$); NE, at 10^{-5} M, stimulated proliferation by $42 \pm 9\%$. Similar results were found with venous VSMC. At 30 min of treatment with NPY, 80% of NPY-like immunoreactivity (NPY-LI) was taken up by the cells, but at 48 hrs, cell media still contained 25% of NPY-LI (RIA). NPY-specific, high affinity binding sites were present on cultured VSMC and corresponded to Y1 receptor type on aortic and Y1- and Y2-type on venous cells. NPY had no effects on basal but inhibited forskolin-stimulated cAMP accumulation in VSMC. We propose that NPY, a sympathetic and platelet-derived vasoconstrictor, has a novel action on VSM: stimulation of cell proliferation, probably mediated by specific NPY (Y1) receptors.

117.12

ENDOTHELIAL-DERIVED NITRIC OXIDE (NO) INFLUENCES BASAL CORONARY VASCULAR TONE IN ANESTHETIZED RATS. Leslie F. Jones and Michael J. Brody. Dept. Pharmacology & Cardiovascular Ctr., Univ. Iowa, Iowa City, IA 52242.

The present study evaluated the role of NO in determining basal coronary vascular tone. Sprague Dawley rats were anesthetized and instrumented for recording arterial pressure (AP), heart rate (HR) and coronary blood flow velocity (CBF; Doppler). In rats without ventricular pacing L-N-nitro arginine (LNA) and L-N-nitro arginine methyl ester (LNAME), inhibitors of NO synthase, produced a L-arginine reversible increase in AP and decrease in HR and CBF. Stellate ganglionectomy and adrenal medullectomy did not alter the decrease in CBF but attenuated the decrease in HR produced by LNAME. Sinoaortic denervation inhibited the LNAME-induced bradycardia. Dose-response curves were performed for LNA and LNAME (0.3-300 μ M/kg, iv) in rats with ventricular pacing. LNAME produced a more potent increase in AP and coronary vascular resistance ($EC_{50} = 4.7 \pm 0.2$; 6.3 ± 1.1 μ M/kg, iv, respectively) compared to LNA ($EC_{50} = 8.0 \pm 1.1$; 9.8 ± 1.1 μ M/kg, iv, respectively). However, LNAME and LNA produced similar maximal responses. These results indicate that NO has a tonic action on coronary vessels in vivo and that bradycardia produced by LNAME is due to baroreceptor mediated withdrawal of sympathetic tone. (Supported by HL-32295)

CARDIOVASCULAR REFLEXES IN PATIENTS WITH TENSION-TYPE HEADACHE. T. Pogačnik*, M. Perovič*, S. Šega* and T. Kiauta. Dept. of Neurology, University Medical Centre, YU-61105 Ljubljana, Slovenia.

The role of the autonomic nervous system in the etiopathogenesis of functional headaches has been investigated for a number of years, with equivocal results. The aim of this study was to apply a standardized battery of cardiovascular tests to a sizable group of functional headache patients and healthy controls.

The Valsalva manoeuvre, deep breathing test, sustained handgrip test and orthostatic test were performed in a group of 51 patients of both sexes aged 21 to 50 years (average age 35.6 years) and in an age-matched control group of healthy volunteers. Data were acquired and processed by an IBM PC/AT-compatible computer.

Diastolic blood pressure increase and particularly heart rate increase during sustained handgrip were significantly reduced in the headache group when compared to the control group, while the results of the remaining tests were not significantly different. No significant differences were found between the episodic (19 patients) and chronic (32 patients) tension-type headache subgroups.

It is concluded that sympathetic function is impaired in tension-type headache patients.

117.15

ALTERATIONS WITH AGE IN ADRENAL MEDULLARY TYROSINE HYDROXYLASE EXPRESSION IN RESPONSE TO COLD STRESS. N. Tümer*, P.J. Scarpace*, and G. Rajakumar. GRECC, VA Med. Center; Dept. of Pharmacology, University of Florida, Gainesville, FL 32608.

One of the most serious consequences of the aging process is an inability to respond to environmental stimuli. Cold exposure is known to increase tyrosine hydroxylase (TH) expression in the sympathetic nervous system. We have recently shown that exercise, another modulator of TH activity, reduces TH expression in young but not in old rats. We assessed TH activity with age in adrenal medullae of 3- and 24-month old F-344/BN rats ($n = 5-6$) following 48 h cold exposure at 5°C. TH activity was measured by a coupled decarboxylase assay. Concentration of L-tyrosine was 40 μM , 6-MHPH₄ was 3mM and pH was 6.5.

	TH Activity with Age and Cold Exposure (pmol/h/adrenal)	
	Room Temperature (26°C)	Cold (5°C)
Young	5171 \pm 490	5548 \pm 280
Old	8350 \pm 745	8939 \pm 626

There was an age-related increase in TH activity in control rats ($p < 0.01$). Surprisingly, TH activity did not increase following 48 h of cold exposure in either age group. However, there remained an age-related increase in TH activity in the cold exposed rats ($p < 0.001$). Cold exposure for a 48 h period normally increases the expression of TH activity in several rat strains. The present results indicate that the induction of TH activity in F-344/BN rats is not as sensitive to cold exposure as other rat strains. However, the increase with age in TH activity is much larger (72% vs 21%) compared with our previous study in F-344 rats. The F-344/BN strain has recently been made available by the NIA for aging research. Our results indicate there are differences between the F-344 and the F-344/BN cross in both the age-related increases in TH activity and the sensitivity to cold exposure. Supported by Med. Res. Service of Dept. of Veterans Affairs and Center for Neurobiology of Aging, UF.

SYMPATHETIC NERVOUS SYSTEM (SNS) INNERVATION OF WHITE ADIPOSE TISSUE (WAT): POTENTIAL ANATOMICAL BASIS FOR REGIONAL DIFFERENCES IN LIPOLYSIS. T. G. Youngstrom and T. L. Barness. Depts. of Psychology and of Biology, Georgia State Univ., Atlanta, GA 30303.

We previously demonstrated regional differences in lipid content and metabolism of WAT in Siberian hamsters during the short day-induced decreases in body weight (fat). We tested whether the innervation of two WAT pads that had differential lipid mass loss in response to short day exposure had unique SNS innervation. Male Siberian hamsters were injected with the retrograde tracers Fluoro-Gold (FG; 1% solution) or rhodamine-labeled microspheres (RLM; 1:4 dilution). The inguinal subcutaneous WAT (IWAT) and epididymal (EWAT) depots were injected (five, 1 μl injections) at the apparent site of entry of SNS fibers and killed 10-20 days later. RLM labeled few cells and no fibers; therefore the results pertain to FG injections only. Labeled cells were more readily apparent in hamsters killed 10 vs 20d postinjection. Fibers were intensely labeled bilaterally from both injection sites throughout the extent of the sympathetic chain (SC); however their origin and destination were not apparent. Although some overlap in labeled cells occurred for these pads, a distinct pattern of labeling was seen with tracer injected into IWAT labeling cells in the SC predominantly in the celiac ganglion and extending caudally to L3. In contrast, tracer injected into EWAT labeled cells in the SC predominately in L1 and extending caudally to L3. Labeled cells from both injection sites were frequently as large as 50 μm . These results form one possible neuroanatomical basis for differential control of lipid metabolism in these fat pads. Supported by grants NIMH RSDA MH-00841 and NIH DK-35254.

THE RELATIONSHIP OF CEREBRAL LATERALIZATION TO HEMIBODY AUTONOMIC FUNCTION AS EVIDENCED BY THE HISTAMINE WHEAL RESPONSE. S.S. Avery,* K.J. Meador, S.L. Wise,* D.L. Loring,* G.P. Lee,* N. Thrash,* R.E. Figueroa* and B.B. Wray*. Department of Neurology, Medical College of Georgia, Augusta, GA 30912.

In a prior study, we found differential left/right cerebral effects on heart rate following unilateral cerebral inactivation via intracarotid amobarbital (Neurology 1990;40:1408-1411). In order to further investigate possible differential left/right cerebral effects on autonomic function, two studies were performed. In the first study, the effects of cerebral lateralization on histamine skin test response were examined in 177 patients from the allergy clinic. Wheals were larger on the left than right forearm for dextrals with dextral family history ($p < .02$), equal in dextrals with primary sinistral relatives, and larger on the right in sinistral/ambidextrous patients ($p < .005$). In the second study, histamine skin testing was performed before and during Wada testing in 14 epilepsy surgery patients. Preliminary results reveal no differences in wheal size for left vs. right Wada test and for ipsilateral vs. contralateral arm to injection. However, intracarotid amobarbital appears to suppress right arm and enhance left arm responses ($p < .03$). Additional studies are needed to further delineate the relation of cerebral lateralization to autonomic function.

DIURETIC AND NATRIURETIC RESPONSES AFTER A WATER LOAD IN HUMANS UNDER DIFFERENT SODIUM BODY CONTENT CONDITIONS. EVIDENCES OF A SODIUM HOMEOSTATIC MECHANISM. M.P. Rosas-Arellano*, R. Guevara-Guzmán and L.P. Solano-Flores. Dept. Fisiología, Medicina-U.N.A.M. A.P. 70-250, 04510 México.

The present study was focused to observe the diuretic and natriuretic responses after a water load (2% body weight) in four groups of young volunteers submitted previously during three days to a hyper- (500 mEq Na/day), hypo- (35 mEq Na/day), and normosodic diet (200 mEq Na/day) or treated with furosemide (Lasix 40 mg/day). During the three days of treatment the urine of each day was collected. The fourth day in the morning the bladder was emptied, the water load was drunk and the urine was collected during ten periods of 20 minutes each. The urinary, sodium and chloride flows were determined. The four groups displayed diuretic curves following a similar pattern. In contrast, the natriuretic curves of the four groups were completely different one from the other: totally flat in low values for the furosemide group and a large initial natriuretic curve for the hypersodic group with a gradual decrease to maintain high values. The results indicate that the way the organism compensates the excess of water by means of urinary water loss is independent of the body sodium content, meanwhile, the way in which the sodium loss is accomplished is determined by the body sodium content and is independent of the way in which the water is lost. *Supported by CONACyT 47969.

MORPHOLOGY OF VAGAL AFFERENT NEURONS IN THE NODOSE GANGLION OF THE CAT. L. Kubin, R. Rogers* and R.O. Davies. Department of Animal Biology and Center for Sleep and Respiratory Neurobiology, University of Pennsylvania, Philadelphia, PA. 19104.

Although vagal afferent pathways have been well studied, a comprehensive description of the morphology of nodose ganglion cells in relation to their electrophysiological and functional properties is not available. To fill this gap, horseradish peroxidase was injected intracellularly into nodose ganglion cells after determining the conduction velocities of their peripheral axons and (where possible) their peripheral receptor modalities in decerebrate, paralysed and artificially ventilated cats. Cell bodies and up to 4 mm of their peripheral and 0.7 mm of their central axons were visualized. Of the 11 cells analyzed to date, 4 had conduction velocities over 19 m/s (3 pulmonary stretch receptors, one baroreceptor) while the remaining had conduction velocities below 1.4 m/s (receptor modality undetermined). The peripheral axonal diameters of the fast conducting, myelinated axons were $5.4 \mu\text{m} \pm 0.9(\text{SD})$, only about twice that of the slowly conducting axons. The central axons of the fast conducting cells were $0.7 \pm 0.15(\text{SD})$ that of their peripheral axons; the corresponding ratio was $0.3 \pm 0.2(\text{SD})$ for the slowly conducting cells. The latter cells had longer common portions of the axon (between the cell body and the bifurcation into the central and peripheral axons) than the former. We did not find anatomical evidence for bifurcations of the peripheral axons. However, the central axon of one slowly conducting cell branched within the ganglion. This study should provide useful morphological correlates for electrophysiological properties and developmental patterns of vagal afferent cells of different modalities. 118.3

PROJECTION OF NODOSE GANGLION CELLS TO THE UPPER CERVICAL SPINAL CORD IN THE RAT. M.J. Chandler, D.L. McNeill, Q.G. Fu and R.D. Foreman. Depts. of Physiology and Biophysics and Anatomical Sciences, University of Oklahoma, Oklahoma City, OK 73190.

Noxious input from myocardial ischemia classically is believed to enter the central nervous system via sympathetic afferent fibers. After sympathectomies, however, angina pectoris still may be referred to the neck and inferior jaw. These observations suggest that vagal afferent fibers may participate in transmitting information to upper-cervical spinal cord segments. The purpose of this study was to determine the density and pathway of vagal afferent nerve fibers to the upper cervical spinal cord. Male Sprague-Dawley rats were divided into 3 groups. Group 1 rats received a unilateral injection of 2 μl of 2% WGA-HRP into the cervical (C) 2, 3 or 4 dorsal spinal cord. Group 2 rats received a similar injection followed by an ipsilateral cervical vagotomy. For Group 3 rats, a spinal cord hemisection was performed cranial to the WGA-HRP injection site. Following a 2 day survival, the nodose ganglion was removed and processed for WGA-HRP reactivity. Approximately 5.8% of the nodose ganglion cells from Group 1 rats contained WGA-HRP reaction product. In the Group 2 rats, cervical vagotomy did not produce a diminution in the density of WGA-HRP-labeled cells in the nodose ganglion. However, no labeling was observed in nodose ganglia from Group 3 rats. These data suggest that a portion of vagal afferent neurons project from the nodose ganglion to the upper cervical spinal cord. In addition, vagal afferent fibers reach the spinal cord via a supraspinal pathway, rather than through peripheral nerves. (National Heart, Lung and Blood Institute, HL-22732.)

X-IRRADIATION-INDUCED EMESIS IN SUNCUS MURINUS. N.Matsuki¹, Y.Torii*¹, M.Shikita*² and H.Saito². 1)Dept. of Chem. Pharmacol., Fac. of Pharmaceut. Sci., The Univ. of Tokyo, Tokyo 113, 2)Nat'l. Inst. Radiol. Sci., Chiba 260, Japan.

We have shown previously that Suncus murinus (house musk shrew), a species of insectivore, vomits in response to emetic drugs and motion stimulation. Cisplatin-induced emesis was inhibited by surgical vagotomy or pre-treatment with 5-HT₃ antagonists. In the present study we investigated whether or not X-irradiation caused emesis in the suncus. Whole body X-irradiation (800 cGy) caused emesis in all animals studied with mean frequency 10.0 times/90 min, and mean latency was 20 min. The strength of X-ray which causes emesis in 50 % of animals was calculated to be 429 cGy. Abdominal X-irradiation caused vomiting in all animals whereas the same irradiation to the head had no emetogenic effect. The surgical vagotomy completely abolished the emesis. Subcutaneous injection of ICS205-930, a selective 5-HT₃ antagonist, prevented the emesis with ID₅₀ value of 29 $\mu\text{g}/\text{kg}$. These results indicate that 1) Suncus murinus can be a new animal model for X-irradiation-induced emesis, 2) peripheral 5-HT is involved in X-irradiation-induced emesis, which is very similar to that caused by cancer chemotherapeutic agents.

118.2

DEVELOPMENT AND ELECTRICAL MEMBRANE PROPERTIES OF NODOSE GANGLION CELLS GROWN IN CULTURE. L. Schmiedel-Jakob* and S.Tyc-Dumont. Unité de Neurocybernétique Cellulaire, CNRS UPR 418, 280, Bd Ste Marguerite, Marseille, France.

Dissociated nodose ganglion cells from adult rat were cultured for up to 5 weeks in DMEM/F12 medium supplemented with foetal calf serum and hormones. Neurite outgrowth started within 3 days in culture (DIC). Although the cells are always pseudounipolar in vivo, in culture they exhibit more anatomical diversity including bipolar or multipolar cells. Using whole-cell patch-clamp technique active and passive membrane properties of the ganglion cells were studied from 1 to 28 DIC. Prolonged depolarizing current steps evoked one or several action potentials (AP). At their maximal response some neurons gave only one AP while other increased frequency with increasing current intensities. APs had a mean threshold of -31 mV and a mean amplitude of 48 mV. They overshoot 0 mV with a mean of 32 mV. On their basis of spike duration there appeared to be 2 types a short <3 ms and a longer duration AP. Voltage-current relations revealed mild anomalous rectification for some neurons and input resistances in the range of 50-520 Mohm. In voltage-clamp step depolarizations elicited transient inward and sustained outward currents. The results suggest that following dissociation and culturing the neurons retain most of their electrical properties.

118.4

EXCITATORY VAGAL INPUT TO THE UPPER CERVICAL NEURONS IN THE RAT. Q.-G. Fu*, M. J. Chandler, D. L. McNeill, R. D. Foreman. Depts. of Physiology and Biophysics and Anatomical Sciences, University of Oklahoma HSC, P.O. Box 26901, Oklahoma City, Ok 73190

Our recent anatomical study showed a direct projection of nodose ganglion cells to the upper cervical cord. This result suggested that vagal afferents may activate upper cervical neurons. In this study, we tested this possibility. Effects of electrical stimulation of cervical vagus nerve on 80 cervical dorsal horn cells were examined in 27 rats anesthetized with pentobarbital. Sixty-three of 80 cervical cells were excited by ipsilateral cervical vagal stimulation (ICVS) and most of them (47/63) were located in C₁ segment. Twelve of 47 C₁ cells also were excited by contralateral cervical vagal stimulation (CCVS). The spontaneous activity of 8 cervical cells excited by ICVS was inhibited by CCVS. CCVS also inhibited the increased cell activity by ICVS in 6 cervical cells. Some properties of C₁ cells were summarized according to responses to ICVS and CCVS: the cells not affected by ICVS and CCVS were most often LT cells with lower spontaneous activity; cells activated by both ICVS and CCVS were most often located in deeper laminae in dorsal horn and had higher spontaneous activity, compared with the cells activated only by ICVS. Excitatory vagal input to the C₁ cells was not significantly affected by cutting C₂ and C₃ dorsal roots. These results demonstrate that a large group of cells located in the upper cervical cord were excited by vagal afferent input. This excitatory vagal input reaches the C₁ segment probably via a supraspinal route. (National Heart, Lung, and Blood Institute, HL-22732)

PUTATIVE NEUROTRANSMITTER AGENTS IN SENSORY NEURONS OF THE CAROTID SINUS NERVE (CSN) OF THE RAT. C.J. Helke, A. Rabchevsky and H. Ichikawa. Dept. of Pharmacol., Uniformed Services University of the Health Sciences, Bethesda, MD 20814.

The origin of calcitonin gene-related peptide (CGRP), substance P (SP), tyrosine hydroxylase (TH) and vasoactive intestinal polypeptide (VIP) in the rat carotid body and carotid sinus was examined by retrograde labelling of the CSN with Fluoro-gold (FG) and by immunohistochemistry. At 3 days after application of FG to the central cut end of the CSN, many petrosal and some jugular neurons were labelled with FG. The nodose ganglion contained few, if any, FG-labelled neurons. CGRP- and SP-immunoreactivities (-ir) were observed in many petrosal and in a few jugular neurons labelled with FG. In the petrosal ganglion, 25.0±6.5% of FG-labelled neurons showed CGRP-ir and 15.8±4.8% of FG-labelled neurons showed SP-ir. Only a few FG-labelled cells in the petrosal ganglion showed TH- or VIP-ir. No FG-labelled neurons in the jugular ganglion were immunoreactive for these substances. The present study indicates that subpopulations of petrosal neurons innervating the carotid sinus and carotid body contain CGRP or SP. The failure to see significant TH-ir in FG-labelled neurons at 3 days may result from an axotomy-induced reduction of TH-ir (Helke and Rabchevsky, 1991). [Supported by NIH grant NS20991]

CYTOCHROME OXIDASE ACTIVITY IN THE NODOSE AND PETROSAL SENSORY NEURONS OF THE RAT AFTER PERIPHERAL NERVE SECTION. H. Ichikawa and C.J. Helke, Dept. of Pharmacol., Uniformed Services University of the Health Sciences, Bethesda, MD 20814.

Axotomy of the peripheral axons of bipolar sensory neurons alters the synthesis and content of putative transmitter agents. Changes in cellular metabolism in response to injury or to loss of afferent inputs may be involved in these axotomy-induced transmitter effects. Using enzyme histochemistry for cytochrome oxidase, an endogenous metabolic marker, axotomy-induced changes in metabolic activity were investigated in visceral sensory neurons of the rat nodose and petrosal ganglia. Most neurons in control nodose and petrosal ganglia were stained darkly. By 3 days after section of all peripheral nerves from the nodose and petrosal ganglia, darkly-stained neurons decreased in number and lightly-stained neurons which were not observed in control ganglia began to appear in the nodose ganglion. At 7 days after peripheral nerve section, the average population of these lightly-stained neurons increased to 29% in the nodose ganglion. Subsequently, the population decreased so that at 14 days and at 21 days, 19% and 7% respectively of neurons were lightly stained. In the petrosal ganglion, no remarkable change was observed at any stages after peripheral nerve section. These results suggest that the metabolic activity decreases in some nodose neurons after peripheral nerve section.

SPINAL CAPSAICIN EXACERBATES 1K RENAL WRAP HYPERTENSION IN THE RAT. M. Burg*, D.S. Zahm, O. Gan*, and M.M. Knuepfer, Dept. of Pharmacol. and Physiol. Sciences and Dept. of Anatomy and Neurobiology, St. Louis University School of Medicine, St. Louis, MO 63104

Afferent renal nerves (ARN) in the rat contain substance P (SP) and calcitonin gene-related peptide (CGRP). We examined whether spinal depletion of SP and CGRP affects the development of renal hypertension. One week after intrathecal administration of capsaicin (70 µg) or vehicle at spinal level T12, right nephrectomy and left renal figure-8 wrap or sham wrap were performed. After 8-10 weeks, renal wrap induced an increase in arterial pressure that was greater in capsaicin-treated rats. Diamidino yellow was placed on the central cut renal nerve 3 days before processing spinal cord and dorsal root ganglia (DRG) at T9-L1 for immunocytochemistry. Two thirds of ARN cells in DRG contained CGRP-immunoreactivity (ir) and approximately half of these also contained SP-ir. The percentage of CGRP- and/or SP-ir ARN soma in DRG were not significantly affected by capsaicin treatment or renal wrap. In contrast, spinal CGRP- and SP-ir were substantially reduced in capsaicin-treated rats. These results suggest that spinal SP and/or CGRP may play a role in reducing renal hypertension. Furthermore, intrathecal capsaicin depletes SP- and CGRP-ir in spinal cord but not in DRG. (Supported by USPHS Grants HL38299 and NS23805).

118.11

EFFECTS OF SPINAL CORD TRANSECTION AND MK-801 ON CGRP-IMMUNOREACTIVE FIBERS IN THE URINARY BLADDER OF THE RAT. D.L. McNeill, R.L. Shew and R.E. Papka, Dept. of Anatomical Sciences, Univ. of Oklahoma, Oklahoma City, OK 73190.

If supraspinal control of bladder function is removed, micturition is often restored, at least partially, via spinal reflex mechanisms. In theory, increasing the density of sensory nerve fibers in the bladder wall may elicit a more effective reflex contraction. MK-801, an NMDA receptor antagonist, increases the density of CGRP-immunoreactive (I) primary afferent nerve fibers in the spinal cord, stomach and uterine cervix. In this study, the effect of MK-801 on CGRP-I bladder fibers following spinal cord transection was examined. Rats received either a spinal cord transection at the L2 level (n=8) or a transection plus a daily i.p. injection of MK-801 (1.0 mg/kg, n=6). Additional rats served as untreated controls (n=5). Twelve days post-surgery, bladders from all rats were processed for CGRP-I. In control rats, CGRP-I nerve fibers were present as perversular plexi and as a dense, non-vascular network of fibers throughout the detrusor muscle. In bladders from transected rats, the density, number of varicosities and the fluorescence intensity of CGRP-I fibers associated with vessels and the musculature were greatly reduced. Bladders from cord-transected rats receiving MK-801, showed a marked increase in the density of varicose, intensely fluorescent CGRP-I fibers throughout the detrusor muscle. However, the density of non-vascular CGRP-I nerve fibers remained less than that in bladders from control rats. These data suggest that MK-801 treatment following spinal cord transection increases the intensity of immunostaining, the density of CGRP-I fibers and the number of varicosities in the urinary bladder. ALTERATION OF CALCITONIN GENE-RELATED PEPTIDE (CGRP) EXPRESSION IN VISCERAL SENSORY NEURONS OF THE NODOSE AND PETROSAL GANGLIA OF THE ADULT RAT FOLLOWING PERIPHERAL AXOTOMY. E.K. Tavo, J.T. McCabe and C.J. Helke, Depts. of Pharmacol. & Anatomy, Uniformed Services Univ. of the Health Sci., Bethesda, MD 20814.

Visceral sensory neurons of the glossopharyngeal and vagus nerves are located in the petrosal and nodose ganglia respectively. Peripheral axotomy of visceral sensory neurons causes differential changes in the content of putative transmitters (Helke and Rachevsky, 1991).

In situ hybridization histochemistry with ³²P- or ³⁵S-labeled oligonucleotide probes was used to study CGRP mRNA in control and axotomized (7 d survival) ganglia. Transections of the cervical vagus and superior laryngeal nerves, or of the glossopharyngeal and carotid sinus nerves comprised peripheral axotomies of the nodose and petrosal ganglia, respectively. In control nodose ganglia, a few CGRP mRNA-containing cells were seen in the rostral and caudal poles. Axotomy caused little or no change in the numbers of these CGRP mRNA-containing cells. CGRP mRNA was observed in a large number of neurons distributed throughout the control petrosal ganglia. Axotomy caused a pronounced decrease in the number of these CGRP mRNA-containing cells. Reductions in CGRP mRNA were also seen in somatic sensory neurons of the jugular ganglion. These findings suggest that CGRP expression decreases in visceral sensory ganglia following peripheral nerve section and are consistent with previously reported axotomy-induced decreases of CGRP immunoreactivity in visceral sensory neurons.

118.10

REFLEX ACTIVITY OF THE RAT VAGINAL ORIFICE. M. Martínez-Gómez, R. Chirino*, P. Carrillo* and P. Pacheco. CIRA, Univ. Auton. Tlaxcala-CINVESTAV, Panotla, Tlax.; CIB, Univ. Veracruzana; IIB-UNAM, México, D.F.

As a part of a study on the reflex components involved in the vaginal orifice dilation (VOD), we analyzed on ovariectomized rats the effects of genital area denervation, adrenergic influence and temperature on VOD. In addition the effect of direct electrical stimulation of ischiocavernosus muscle (*icm*) was analyzed. RESULTS: Denervation: Bilateral transection of genitofemoral, pudendal or pelvic nerve does not block evoked perineal tapping VOD; however, pudendal nerve transection maintains longer VOD (10-20sec) as compared to controls (3-5sec). Adrenergic effects: Noradrenaline (NA: 25,50 or 75ug) intracerebroventricularly injected provokes a dose-related intermittent, spontaneous VOD during a 90 min period. NA (25ug) administered intrathecally provoked a continuous VOD for 2 h. Temperature: VO stimulation with a cold (15°C) wet cotton device induces sudden closing when the VO is open or an increment in closure if the VO is partially closed. Muscular stimulation: Unilateral or bilateral stimulation of *icm* induces the closure of VO with a velocity and intensity-pulse/frequency related fashion. The caudal third of vaginal internal wall presented contractions. CONCLUSIONS: a) Different innervation to that here studied and perhaps vascular related, determines VOD. b) Central adrenergic mechanisms regulate VOD. c) VO closure appears to be regulated via reflex muscular mechanisms. CONACT D111-903851; SEP C90-01-0439 (M.M.G.).

IN VITRO CHARACTERIZATION OF MESENTERIC MECHANORECEPTORS OF THE SMALL INTESTINE. J.Y. Wei, CURE/VA Wadsworth MC, Dept. of Medicine and BRI, UCLA, CA.

The purpose of the current study was to develop a splanchnic nerve - mesentery *in vitro* preparation to characterize the mechanosensitivity of the nerve endings under a controlled experimental environment. Urethane anesthetized rats were used. A segment of abdominal aorta, with superior mesenteric artery and the celiac-superior mesenteric ganglionic complex attached to it, the splanchnic nerves connecting suprarenal and celiac ganglia, the greater splanchnic nerve, and the attached mesentery were isolated and removed. The preparation was transferred into a perfusion bath flowing with oxygenated normal rat saline (2-3 ml/min). Unitary activity was recorded from a thin splanchnic nerve filament. The receptive field was searched and defined with a camel's hair brush and/or von Frey hairs. Of the 22 units studied 11 had irregular and one regular low frequency on-going discharge; 2 had rhythmic while 8 had no resting activities. Location of the receptive fields includes 11 units near the main vascular nerve bundle, 8 on the mesentery, 1 near the aorta and 2 unknown. Fourteen units were slowly adapting and 6 rapidly adapting; after-discharge occurred in 10 units. A short after-inhibition following termination of the stimulus was observed in 6 units. Conclusion: this preparation can be used to study afferent terminals in the mesenteric membrane and their interaction with the surrounding environment. (Supported by NIH grant NS28433)

IMPROVED TRACER LABELING: FAST BLUE IN DORSAL ROOT GANGLIA AFTER INJECTIONS INTO REPRESENTATIVE GUT SEGMENTS. M.-Q. Zhang, J.Y. Jew, Y.-F. Wang and T.H. Williams. Dept. of Anatomy, Univ. of Iowa, Coll. of Medicine, Iowa City, IA 52242.

Previous investigations have provided information about the sources of sensory nerve fibers servicing selected portions of the gastrointestinal system but have not systematically addressed comparative aspects of the sensory innervation between the different gut segments. This report represents preliminary findings for stomach, jejunum, ileum, cecum, ascending colon, and descending colon of the rat. The retrograde fluorescent tracer Fast Blue (FB) was injected into the wall of portions of the gut as listed above of male Sprague-Dawley rats (anesthetized with Nembutal, 40 mg/kg b.w.). Eight days later the animals were reanesthetized and sacrificed by perfusion fixation. Dorsal root ganglia (DRG) from levels T1-S4 were dissected out and serial sections were cut and processed for fluorescence microscopic examination. Labeled perikarya were counted and measured to establish differences between DRG neurons that innervate different parts of the gut. We also compared the effectiveness of retrograde labeling when a given amount of FB tracer was administered via numerous versus few multiple injection sites. The greatest number of FB labeled perikarya was found in T9 after injections into the wall of stomach; in T11 for jejunum; in T11 for ileum; in T12 for cecum; in T13 for ascending colon; and in L1 and S2 for descending colon where there was a double distribution peak. Preliminary results indicated that DRG neurons innervating stomach, cecum, and colon were larger than those innervating jejunum and ileum. When FB tracer was injected via numerous (200) sites into a specific gut segment, the number of labeled perikarya per DRG was greater than that following the use of few (20) injection sites. This information is intended to lead to transmitter correlation experiments utilizing combinations of retrograde tracers and immunohistochemical techniques. Supported by grant DK38123.

118.14

DEVELOPMENT OF A RETROGRADE DYE LABELING TECHNIQUE FOR THE IDENTIFICATION AND FUNCTIONAL STUDY OF LUNG-SPECIFIC VISCERAL C-FIBER NEURONS. K.E. Nager, E.P. Christian, G. Koschorke, G.E. Taylor, B.W. Forbush* and D. Weinreich. Dept. of Pharmacol., ICI Americas, Inc., Wilmington, DE 19878, and Dept. of Pharmacol., Univ. of Maryland Sch. of Med., Baltimore, MD, 21201.

The nodose ganglion contains cell bodies which give rise to visceral afferent C-fibers innervating the respiratory, cardiovascular and gastrointestinal systems. To study airways-specific C-fiber neurons, a 100 μ l volume of (w/v ratio) 10% rhodamine conjugated dextran, 1-2.5% fast blue, or 1% fluorogold is instilled into the trachea of anesthetized (mg/kg: 30 ketamine, 5 xylazine, 2 acepromazine) male guinea pigs (450-550g) by either intubation or catheterization below the cricoid cartilage. After allowing 5-10 days for retrograde transport, label can be visualized in viable 100 μ m ganglion sections, and is retained following acute dissociation of neurons. Equivalent dye administrations directly into the esophagus or carotid artery fail to label neurons; thus providing evidence that neurons extrinsic to the airways are not inadvertently labeled by tracheal instillations. Passive and active electrophysiological properties do not differ between unlabeled and rhodamine-labeled dissociated neurons, and are not altered in labeled neurons by 5-15 s illumination by the 530-560 nm excitation wavelength for rhodamine. This methodology should provide new information on the physiological, biochemical and pharmacological properties of airways-specific C-fiber neurons. (NIH NS22069 to D.W)

SUBCORTICAL SOMATOSENSORY PATHWAYS: BRAINSTEM

119.1

DIFFERENTIAL LABELLING OF CLASSES OF PRIMARY AFFERENT SYNAPTIC TERMINALS IN THE RAT NUCLEUS GRACILIS AFTER INJECTION OF EITHER WGA-HRP OR B-HRP INTO THE SAPHENOUS NERVE. S.E. Kapadia, C.M. Shapiro, and C.C. LaMotte. Section of Neurol. Surgery, Yale Univ. Sch. of Med., New Haven, CT. 06510.

The saphenous nerves of anesthetized rats were labelled by injection of either 0.5 mg of WGA-HRP or 0.05 mg of B-HRP. After 72 hours the animals were sacrificed by perfusion; the lumbar roots, lumbar cord and the medullary junction were removed, sectioned, and reacted with a combined TMB-DAB procedure for EM visualization of the label. Counts of labelled axons in the roots showed that 98% of the axons labelled by B-HRP and 16% of the axons labelled by WGA-HRP were myelinated. The two labels were differentially localized within some, but not all, afferent terminal types in the nucleus gracilis: 1. simple terminals with round vesicles and few mitochondria (B-HRP and WGA-HRP); 2. larger simple terminals with many mitochondria (B-HRP); 3. small terminals with few mitochondria, having 1-2 postsynaptic targets and often postsynaptic to other terminals (B-HRP); 4. large glomerular terminals with several central mitochondria and no neurofilaments (WGA-HRP); 5. large glomerular terminals with neurofilaments and many mitochondria (B-HRP and WGA-HRP); and 6. large glomerular terminals with no neurofilaments and many mitochondria (B-HRP and WGA-HRP). Some of these terminal types resemble the terminal classes associated with myelinated and nonmyelinated afferents in the spinal dorsal horn. (NIH NS 13335)

POST-SYNAPTIC DORSAL COLUMN TERMINALS IN THE CUNEATE NUCLEUS OF THE RAT: MORPHOLOGY AND PUTATIVE TRANSMITTER. S. De Biasi, L. Vitellaro-Zuccarello*, P. Bernardi* and A. Rustioni. Dip. Fisiol Biochim gen, Univ. Milano, Italy; Dept Cell Biol & Anat, Univ North Carolina, Chapel Hill, NC.

The dorsal column nuclei (DCN) receive two ascending inputs that may subserve different sensory modalities: 1) primary afferent terminals from dorsal root ganglion cells and 2) post-synaptic dorsal column (PSDC) terminals from neurons in the ipsilateral dorsal horn. Multiple injections of WGA-HRP were made in the cervical spinal cord of rats 6 days after unilateral cervical rhizotomy and lesion of the dorsal quadrant at T1. After 24-36h, rats were reanesthetized and perfused. Vibratome sections of brainstem, processed for HRP visualization, were embedded in plastic and blocks of cuneate nucleus (CN) from 3 rats were thin sectioned. At the EM, HRP reaction product is in numerous medium-size terminals (mean area 1.5 μ m²) containing many small clear vesicles. HRP+ terminals synapse on small- to medium-size dendrites and, at variance with the large-size primary afferent terminals, are not contacted by GABAergic endings of interneurons. In thin sections of CN processed with a post-embedding immunogold method using anti-glutamate (Glu) serum, about 2/3 of the HRP+ terminals are Glu+. Since most of the primary afferents to CN are Glu+ (DeBiasi and Rustioni, *J Histochem Cytochem* 38:1745, 1990) it is likely that Glu is the major transmitter for both ascending pathways to DCN. Supported by NIH grants NS27827 and 12440.

119.2

CALCITONIN GENE-RELATED PEPTIDE (CGRP) IMMUNOREACTIVE FIBERS ARE PRIMARILY RESTRICTED TO A "MIDDLE" REGION OF THE CUNEATE NUCLEUS IN THE RAT. D.P. Crockett, S.L. Harris*, S. Maslany, and M.D. Egger. Dept of Neuroscience and Cell Biology, UMDNJ-Robert Wood Johnson Med. Sch., Piscataway, NJ 08854-5635.

Contrary to earlier reports, the cuneate nucleus (CN) in the rat appears to have a functional "middle" region, extending from approximately 0.2 mm to 0.8 mm caudal to the obex. Within this middle region, there is maximal differentiation of cutaneous primary sensory afferent termination zones (particularly from the glabrous skin of the forepaw digits), corresponding topographically to dense patches of cytochrome oxidase staining. CGRP-like immunoreactivity (n = 5 rats) was largely confined to this "middle" region of the CN, with a few fibers being found more caudally. In contrast, substance P-like immunoreactive fibers (n = 6 rats) were located chiefly outside of this region, most abundantly in the caudal CN near the spinomedullary junction, extending caudally into the internal basilar nucleus. Our evidence that the CN in the rat has a distinct "middle" region indicates that it is organized more like that of other mammalian species than previously recognized.

CONNECTION RELATIONSHIP OF SPINAL NEURONS WITH BOTH THE POINT ZUSANLI AND THE SOLITARY TRACT NUCLEUS. G.W. Lu, and Z. Meng* Dept. of Neurobiol. Capital Institute of Medicine, Beijing 100054, China.

We have demonstrated that the point zusanli (tsu-san-li, St-36, ZSL) is innervated by the peroneal nerve (Amer J Physiol 245:606-612, 1983) and that spinal dorsal horn neurons project to the solitary tract nucleus (STN)-spinosolitary tract neurons (SST) (*Chin Sci Bull* 35: 1474-1479, 1990). The present study aims at studying the connection among the ZSL, SST and STN.

Experiments were performed on 27 Wistar rats anesthetized with sodium pentobarbital. Microelectrode recording was made from the lumbosacral dorsal horn of the spinal cord. Electro-stimulation was delivered to the STN and ZSL to antidromically and orthodromically activate the nucleus and the point, respectively. Natural stimulation of the receptive fields (RF) was used to identify the physiological category of the recorded neurons.

A total of 57 neurons was intracellularly recorded and identified as SST neurons in laminae III-V of the lumbosacral dorsal horn. Synaptic responses were also shown in 34/57 neurons. All these neurons orthodromically responded to electrical stimulation of the ZSL. An equal number of LTM and WDR neurons were categorized based on RF stimulation. Most LTM neurons responded to ZSL electrical stimulation to the similar degree at 10T and 50T and almost all the WDR neurons discharged greater at 50T than at 10T.

These results indicate that single spinal dorsal horn neurons receive somatic information and transmit it to the viscerosensory nucleus, STN, and that the somatic and visceral input may converge on common SST neurons as well as within the STN.

119.5

THE TOPOGRAPHIC ORGANIZATION OF THE RAT ZONA INCERTA. R.C.S. Lin, M. A. L. Nicoletis, J. McLean, and J. K. Chapin. Department of Physiology and Biophysics, Hahnemann University, Philadelphia, PA 19102-1192, USA.

Using the cytochrome oxidase (CO) staining method the rat zona incerta (ZI) can be subdivided, throughout its rostro-caudal extension, into two laminae: a distinctly dark ventral layer and a much lighter dorsal zone. This clear subdivision can be observed since the day of birth and is correlated with the topography of the main afferents to the ZI. Here, the connectivity and physiology of ZI neurons were investigated by combining the use of anterograde/retrograde fluorescent tracers with mapping and multi-single unit recording techniques. Injections of rhodamine dextran (RD) into the somatosensory (SI) and motor cortices, deep layers of the superior colliculus, trigeminal complex and dorsal column thalamus revealed the presence of anterogradely labeled terminals within the ZI. These terminals were mainly distributed around the ventral portion of the ZI, within the darkest CO-stained lamina. Less dense terminals were also found into the dorsal subdivision of the nucleus. Conversely, injections of RD in the deep cerebellar nuclei labeled terminals in the most dorsal, lighter CO zone whose cells project to the SI. Injections of (RD) into the ZI demonstrated that its cortical afferents derive mainly from layer V pyramidal neurons and that intercortical neurons may project to layer I. Mapping experiments revealed the existence of a crude somatotopic map of the rat body within the ZI. This map seems to parallel the somatotopic map of the ventral posterior thalamus, being mainly characterized by large contralateral facial RFs. Large contralateral, circular, and non-direction selective visual RFs were also observed in the ZI. These results suggest that the rat ZI may be involved in sensorimotor integration related to the control of gaze. Sponsored by grants NS29161, NS26722, and FAPESP 88/4044-9.

119.7

PARCELLATED ORGANIZATION IN THE TRIGEMINAL AND DORSAL COLUMN NUCLEI OF PRIMATES. A.L. Noriega* and J.T. Wall. Department of Anatomy, Medical College of Ohio, Toledo, OH 43699.

Previous studies have used cytochrome oxidase (CO) staining to describe patterns of parcellated organization in the trigeminal nuclei of rodents and cats. The present studies used CO histochemistry to test if parcellated organization patterns also occur in the brainstem of adult monkeys. The results demonstrate that a parcellated pattern of neural organization exists in the primate trigeminal nucleus principalis. In the more caudal spinal trigeminal nuclei, interruptions in CO staining are also seen, but the overall patterns are more uniform and do not reflect the parcellated pattern seen in the nucleus principalis. In contrast, the organization in nucleus principalis resembles the parcellated organization in nuclei of the dorsal column complex. Taken together with findings of previous studies in rodents and cats, these results suggest that aggregated or parcellated neural organization is a common characteristic of specific ascending somatosensory projections from the face and other body parts in many mammals including primates. ULTRASTRUCTURE OF PRIMARY DEAFFERENTATION IN THE NEONATAL FELINE TRIGEMINAL SYSTEM. 1,2,3 L.E. Westrum, 1,2,3 M.A. Henry, and 1 X.M. Dong*. Depts. 1Neurol. Surg., 2Biol. Struct., 3Restor. Dent. University of Washington, Seattle, WA 98195.

We are investigating the age-related, morphological effects of total retrogasserian rhizotomy on the synaptic organization and remodeling in the brainstem spinal trigeminal nuclei (STN) in felines. Other previous publications by ourselves and by F.W.L. Kerr have suggested that plasticity in the STN is greater in neonates than in older felines following primary deafferentation. Our several past publications have described time-dependent changes in the adult system and here we present preliminary findings on STN alterations in the immature system.

Felines of postnatal age (PN) 3 days, under deep anesthesia, received total unilateral retrogasserian rhizotomy. Following survival times varying from 16 hours to one week the subjects were reanesthetized, perfused and tissue from STN prepared for study by conventional electron microscopy. The preparations show striking alterations of the axons and synapses in STN. Even in the shortest (16 hours) survival, extensive degeneration occurs in the tract and disintegration of axon terminals and synapses can be seen in large numbers. Within 1-2 days postsurgery, deafferented postsynaptic specializations are frequently apposed by one or more profiles. The latter may be glia, dendrites or axons. Some of these profiles contain vesicles, vacuoles, and smooth endoplasmic reticulum suggestive of "growth processes". The observations demonstrate an exceedingly rapid post deafferentation degenerative process as compared to the adult system with even earlier evidence of competitive reoccupation of denervated postsynaptic sites, possibly by growth processes, than occurs in adults. These findings could explain the age-dependent plasticity occurring in the system. (Supported by NIH Grants DE04942 and DE00219. L.E.W. is a research affiliate of the CDMRC at the University of Washington).

119.6

CODING OF NOVELTY BY MULTISENSORY NEURONS IN THE SUPERIOR COLLICULUS OF THE HAMSTER. M. M. Nikolettseas. Dept. of Anatomy, Univ. of Puerto Rico, Sch. of Med., San Juan, PR 00936.

Although multisensory neurons in the tectum have been known for several decades, details of their fine morphology and physiology are still lacking. The problem of coding stimulus novelty presents more facets for these cells, since afferent input comes from more than one sensory systems. Hamsters were anesthetized and paralyzed. Stimulation parameters were programed in strict temporal sequence: interstimulus interval 30 ms and intertrial interval 1 s. Spikes were preamplified and fed into a computer for on-line acquisition and analysis. Spike activity was monitored for periods of 20 s or more. The main findings are: 1. A novel stimulus induces a decrease in interspike intervals in the baseline of spontaneous activity. 2. An increase in number of spikes is not a good predictor of novelty. 3. As novelty fades, the system lapses into longer interspike intervals. 4. This coding mechanism operates when a cell is processing either a stimulus of one sensory modality, or a compound stimulus consisting of stimuli from two sensory modalities.

119.8

DISTRIBUTION AND MORPHOLOGY OF EFFERENT PROJECTIONS FROM NEURONS IN DORSOMEDIAL SUBDIVISIONS OF RAT TRIGEMINAL NUCLEUS INTERPOLARIS. M. S. Cook* and W. M. Falls, Dept. Anat., Michigan State Univ., East Lansing, MI 48824.

Efferent projections from dorsomedial (DM) subdivisions of rat trigeminal nucleus interpolaris (Vi), were studied using the PHA-L method. Contralateral projections were to ventral posteromedial thalamic nucleus (VPM), zona incerta (ZI), parvocellular red nucleus (RPC) and anterior pretectal nucleus (APT). Projections to superior colliculus (SC), medial accessory oculomotor nucleus (MA3) and portions of inferior olivary nucleus (IO) were bilateral with contralateral predominance while those to facial motor nucleus (VII), sensory trigeminal complex (SVC), cervical spinal cord (CSC), as well as cerebellum (Cb) and deep cerebellar nuclei (DCN) were bilateral with ipsilateral predominance. No more than one type of efferent ended in APT, RPC, MA3, VII, SVC, IO or CSC, while more than one type was located in VPM, ZI, SC and DCN. Efferents to Cb were mossy fibers with some extending into Purkinje cell layer. These results suggest DM subdivisions play a major role in conveying orofacial tactile input to functionally diverse areas along the neuraxis and support Vi subdivisional organization by showing that major differences exist in DM efferent projections when compared to those originating from neurons in ventrolateral subdivision. EFFECTS OF 'LATE' INFRAORBITAL NERVE TRANSECTION UPON CYTOCHROME OXIDASE PATTERNS IN TRIGEMINAL NUCLEUS PRINCIPALIS AND SUBNUCLEUS INTERPOLARIS OF THE RAT. R.W. Rhoades, C.A. Bennett-Clarke and N.L. Chiaia. Dept. of Anatomy, Medical College of Ohio, Toledo, OH 43699.

The vibrissa-related cytochrome oxidase patterns in nucleus principalis (PrV) and subnucleus interpolaris (Spl) are both completely disrupted by neonatal transection of the infraorbital nerve (ION). This effect has been interpreted as being the result of a loss and/or disruption of the normal primary afferent innervation of these nuclei. Since the same primary afferent axons innervate both PrV and Spl, it follows that a peripheral lesion that disrupts the CO pattern in one nucleus should have the same effect in the other nucleus. ION lesions made between postnatal days (P) 3 and 8 have different effects upon the CO pattern in PrV and Spl. In rats that sustain ION lesions on these days and are killed 2-6 days later, the density and clarity of the CO pattern in Spl is significantly reduced while the pattern in PrV is essentially unaltered. Such differential effects are not observed in rats that sustain ION transection on P-0 to P-2, or on P-10 and later ages. The differential effects of ION damage in PrV and Spl are not likely to be the result of differential transganglionic degeneration in these two nuclei; transganglionic tracing with HRP in rats that sustained ION damage on P-4 and P-5 indicated essentially equivalent deafferentations of PrV and Spl. These results indicate that the CO patterns in PrV and Spl have different sensitive periods for ION damage. They also support the conclusion, at least for PrV, that normal primary afferent input, while necessary for the development of the vibrissa-related CO pattern, need not be maintained for that pattern to persist. NORMAL DEVELOPMENT AND EFFECTS OF INFRAORBITAL NERVE LESIONS UPON THE INNERVATION OF THE TRIGEMINAL BRAINSTEM COMPLEX BY CGRP-POSITIVE PRIMARY AFFERENTS. F.A. White, C.A. Bennett-Clarke and N.L. Chiaia. Dept. of Anatomy, Medical College of Ohio, Toledo, OH 43699.

Previous experiments have shown that neonatal infraorbital nerve (ION) transection results in the death of many trigeminal ganglion cells that contain substance P-like immunoreactivity (SPLI), but only a small and transient decrease in the density of SPLI in subnucleus caudalis (SpC) of the rat's brainstem trigeminal complex. In an effort to determine the extent to which the effects observed in the brainstem result from primary afferent reorganization or alterations in central SP projections to SpC, we evaluated the normal development and lesion induced alterations of CGRP-like immunoreactivity in SpC. This peptide co-localizes extensively with SP in primary afferents and has not been reported to exist in any central projections to SpC. In normal adults, CGRP-positive fibers form a dense plexus in lamina I and outer lamina II. A smaller number of fibers extend into layers III-V. Essentially the same pattern of CGRP immunoreactivity is present in newborn rats. Neonatal ION transection produces no substantial alteration in this pattern in rats killed between one and 60 days after the lesion. Densitometry indicated a slight (5%-11%), but non-significant reduction in the density of CGRP-like immunoreactivity ipsilateral to the ION lesion on postnatal days 4-6. Thus, neonatal ION transection has little effect upon the distribution and density of CGRP-positive fibers in SpC. Since this lesion is likely to kill numerous CGRP-positive trigeminal ganglion cells, our results further suggest that neurons surviving neonatal axotomy increase their innervation of SpC. DAMAGE TO VIBRISSAE FOLLICLES IN FETAL RATS INCREASES THE SIZE OF CYTOCHROME OXIDASE PATCHES CORRESPONDING TO INTACT FOLLICLES IN THE TRIGEMINAL BRAINSTEM COMPLEX. C.A. Bennett-Clarke, N.L. Chiaia, and R.W. Rhoades.

Dept. of Anatomy, Medical College of Ohio, Toledo, OH 43699.

Damage to vibrissa follicles in newborn rats and mice does not alter the brainstem representations of the remaining vibrissa as demonstrated by cytochrome oxidase (CO) staining. This study asked whether this lack of effect might be due to the fact that trigeminal primary afferents in rodents are already quite well developed at birth. We made partial lesions of the vibrissa pad on embryonic (E-) days 15-20 and on postnatal (P-) day 0 (at least 5 and an average of 11 animals for each age), killed pups on P-6 or P-7, and measured the size of the CO patches in trigeminal subnucleus interpolaris (SpI) on both sides of the brainstem. All vibrissa pad lesions were verified by silver staining sections through the face and the correspondence between CO patches and clusters of primary afferent terminal arbors was verified in some animals by combining transganglionic HRP tracing and CO staining in alternate sections. Vibrissa pad damage on E-15 through E-18 resulted in significant (20%-37%) increases in the average area of the remaining CO patches in SpI ipsilateral to the lesion. Furthermore, there was a significant inverse relationship between the average increase in patch size and the number of patches that remained in SpI. Vibrissa pad damage on E-19, E-20, and P-0 produced small (6%-9%), but non-significant, increases in patch size in SpI ipsilateral to the lesion. These data suggest the possibility that competitive interactions among the central arbors of trigeminal primary afferents in fetal life may influence the development of central vibrissa representations. DE 07734, NS 28888

119.15

PLASTICITY OCCURS IN THE SPINAL TRIGEMINAL NUCLEUS OF THE ADULT MOUSE UPON PARTIAL PERIPHERAL DEPRIVATION.

M.E. Corthésy*, S.B. Rao*, E. Welker*, J. Dórfi*, H. Van der Loos, J.P. Hornung. Institute of Anatomy, University of Lausanne, 1005 Lausanne, Switzerland.

After injection of ^{14}C -deoxyglucose (DG), vibrissae of rows B and D were stimulated. In 3 mice the nerve innervating the follicles of row C had been divided 60 days earlier; 4 mice served as controls. Autoradiograms of transverse brainstem sections showed stimulus-evoked DG uptake in nucleus principalis, and in subnuclei oralis, interpolaris (SI) and caudalis (SC). Representations of rows B and D were consistently observed along a major extent of Sc and SI only, except for their rostral and caudal poles. They were either separated (sections displayed as ) by an area of low uptake (row C) or fused () due to high uptake over row C. Unusable sections: . The left "keyboard" represents a control mouse; the right, a deprived one. Transition zone between SI and Sc (TZ) serves as reference point. Numbers refer to serial sections. Per animal we determined an "index" for each subnucleus by dividing the number of fused sections by the total number of usable sections. For controls, the mean index for Sc = .1 (range: .0 - .3) and for SI = .3 (.2 - .7); for the deprived mice, the mean index for Sc = .6 (.3 - .9) and for SI = .9 (.9 - 1). We conclude that the increase in the functional representations of the B and D whiskers occurs without preference for a rostrocaudal level. The effects in SI are more marked, with smaller interindividual variability. For similar signs of plasticity in the barrel cortex see Melzer et al., 1988. Does the functional enlargement occur in brainstem and cortex independently? Support: Swiss NSF 3100.009468.

INNERVATION OF SPARED FOLLICLES AFTER DAMAGE TO THE VIBRISSA PAD IN FETAL RATS. R.S. Crissman, N.L. Chiaia and F.A. White. Dept. of Anatomy, Medical College of Ohio, Toledo, OH 43699.

Partial damage to the vibrissa pad on embryonic (E-) days 15 through 18 increases the representations of undamaged follicles in the trigeminal brainstem complex (Bennett-Clarke et al., this meeting). This study used anatomical and electrophysiological methods to determine whether such lesions altered the trigeminal innervation of surviving vibrissa follicles in adult rats that sustained vibrissa pad lesions on E-17. We recorded single trigeminal ganglion cells from 12 rats with fetal vibrissa pad lesions verified by both direct examination of the face and by CO staining of flattened sections through the cerebral cortex contralateral to the lesion. As is the case in normal rats, all of the 49 vibrissa-sensitive ganglion cells recorded from the lesioned animals were responsive to deflection of one and only one vibrissa. We dissected 11 deep vibrissal nerves from intact follicles in rats that sustained fetal vibrissa pad damage and counted numbers of myelinated axons in 1 μm plastic sections using the light microscope. These counts were compared with counts from the corresponding follicle on the intact side of the face and with previous results from normal adult rats (R.S. Crissman et al., *Somatosensory and Motor Res.*, in press). The average number of myelinated axons from deep vibrissal nerves innervating intact follicles in the damaged vibrissa pad was 197 ± 28 and that for nerves on the intact side was 195 ± 26 . These results suggest that damage to vibrissa follicles on E-17 does not significantly affect the trigeminal innervation of undamaged follicles and that increases in the central representations of these follicles need not be correlated with changes in their peripheral innervation. NS 28888, DE 07734

ORGANIZATION AND RESPONSE PROPERTIES OF NEURONS IN THE CAUDAL TRIGEMINAL COMPLEX OF THE MUSKRAT. W.M. Panetonn and M.F. Jacquin. Dept. of Anatomy and Neurobiology, St. Louis University School of Medicine, St. Louis, MO 63104.

The caudal subnucleus interpolaris and rostral medullary dorsal horn of the muskrat were explored electrophysiologically to establish data on the response properties of neurons to orofacial and upper respiratory tract (URT) stimulation. Muskrats were anesthetized with chloralose-urethane, tracheotomized, paralyzed and artificially ventilated. Single units were recorded with glass micropipettes (DC resistances 35-60 megohms) filled with 6% HRP in 0.05M Tris-buffered KCl to mark recording sites. All units responded to electrical stimulation of the ipsilateral trigeminal ganglion and were tested with innocuous and noxious stimuli to orofacial areas, ammonia vapors to the nasal cavity, and electrical stimulation of the superior laryngeal nerve.

None of the 58 cells studied were activated antidromically from the thalamus or the dorsolateral pons. Their topographical organization was similar to that previously described for the cat and rat. 91% of the neurons responded to innocuous stimulation with a mean latency of 1.49 ms to ganglion shock. 9% responded to noxious or URT stimulation with a latency of 2.3 ms. 17% were spontaneously active; 30% of these were inhibited by stimulation of their receptive field surrounds. 57% gave phasic responses to tactile stimulation, while 43% had tonic responses. 34% responded to stimulation of mystacial vibrissae, 29% to guard hairs, 16% to hairy skin, 16% to nasal vestibule or nasal mucosa with ammonia, 9% to nasal glabrous skin, 7% to oral mucosa, and 2% to superior laryngeal nerve. These data establish baseline data for more concentrated efforts to characterize trigeminal neurons responsive to URT stimulation. NIH HL38471, DE07762.

COMPUTER SIMULATIONS OF SIGNAL PROCESSING IN THE RAT TRIGEMINAL BRAINSTEM AND THALAMUS. D.W. Doherty, R. Granger and H.P. Kilackey. Dept. of Psychology, University of California, Irvine, CA 92717.

A model of the trigeminal neuroaxis, from periphery to thalamus, has been developed. The model simulates a 3 by 3 array of 9 whiskers. Thirty primary afferents connect each whisker to a corresponding barrelet of 12 trigeminothalamic neurons in the trigeminal nucleus principalis (PrV). The bifurcating primary afferents also synapse with trigeminothalamic neurons of both the corresponding and the surrounding whiskers in the spinal trigeminal nucleus interpolaris (SpVi). There are 3 SpVi neurons for each whisker. Synapses from individual barrelets in PrV or SpVi are restricted to neurons in their corresponding barreloid in the thalamic ventral posterior medial nucleus (VPM). Each of the 30 VPM neurons in a barreloid receives input from both PrV and SpVi and sends collaterals to a restricted portion of the thalamic reticular nucleus (TRN). Six inhibitory neurons in TRN synapse with their VPM input neurons and neurons in adjacent barreloids.

An equivalent circuit model based on ion fluxes was implemented to mimic cellular voltage dynamics. The physiological characteristics of each neuron type were matched with available data. A mix of rapidly and slowly adapting primary afferent response types was simulated.

Stimulation of a single simulated whisker for 4 ms elicited responses in the thalamic barreloid of the principle whisker with latencies of between 3 to 6 ms and a mean of 1.0 spikes per stimulus. Neurons in the surrounding barreloids responded with latencies between 4 to 6 ms and a mean of 0.2 spikes per stimulus. When PrV was lesioned the high amplitude (center) response in the barreloid of the principle whisker disappeared and was replaced by the low amplitude (surround) response typically seen in the surrounding barreloids. When SpVi was lesioned the center response remained intact but the surround response disappeared. The model demonstrates that the parallel trigeminal pathways through PrV and SpVi that converge onto VPM are sufficient to account for the principle whisker (center) and non-principle whisker (surround) response characteristics recorded from thalamocortical neurons in vivo.

120.1

CHARACTERIZATION OF THE CARDIOVASCULAR AND VISCEROMOTOR RESPONSES TO ESOPHAGEAL DISTENTION IN THE RAT. S.T. Meller and G.F. Gebhart, Department of Pharmacology, University of Iowa, Iowa City, IA, 52242

The aim of this study was to characterize the cardiovascular (CV) and visceromotor (VM) responses to graded levels of esophageal distention (ED; 0.5-1.5 ml, 30 s) produced by a Swan-Ganz catheter inserted intra-orally into the middle third of the esophagus in the lightly-pentobarbital anesthetized male Sprague-Dawley rat (420-460 g).

The CV response during ED was consistently a robust, intensity-dependent pressor response (0-35 mmHg) and a tachycardia (0-50 bpm). Following distention, arterial blood pressure showed a small, but consistent decrease (5-15 mmHg). The VM response, which was measured from the EMG recorded in the masseter muscle, was a vigorous intensity-dependent contraction (2-5 s) followed by a smaller sustained contraction throughout ED (30 s). Peak magnitude of this response with graded levels of ED was 110 μ V. The VM response was completely abolished by bilateral transection of the cervical vagus or neonatal capsaicin treatment. The CV response was unaffected following bilateral vagotomy. In neonatal capsaicin-treated rats (50 mg/kg, s.c.), the pressor response to ED was unaffected, but the depressor response following distention was abolished. The VM response to esophageal distention was abolished in a dose-dependent manner by morphine (0.5-4 mg/kg, i.v.) and reversed by naloxone (1 mg/kg, i.v.). The CV responses were unaffected by 4 mg/kg morphine.

These results suggest that the nociceptive responses to graded levels of ED are mediated by capsaicin-sensitive vagal afferents.

120.3

CEREBRAL CORTICAL NEURONS RESPOND TO NOXIOUS VISCERAL STIMULATION. K.A. Follert, R. Hadley, and G.F. Gebhart, Depts. of Neurosurgery and Pharmacology, University of Iowa, Iowa City, IA 52242

The role of cerebral cortex in visceral nociception has not been well-studied. We have undertaken studies to determine whether cortical neurons respond to a physiologic noxious visceral stimulus (balloon distention of the colon) and have characterized the responses.

Sprague-Dawley rats were anesthetized with pentobarbital. Spontaneously active single neurons were isolated in somatosensory cortex using standard microelectrode recording techniques. Their responses to graded distention of the colon (20-100 mm Hg) and cutaneous stimuli were recorded.

Thirteen neurons responding to colon distention were identified. Ten units (77%) were excited upon distention (112-415% of control, mean 166%), 3 were inhibited (35-65% of control, mean 48%) with thresholds as low as 20 mm Hg. Contralateral cutaneous receptive fields were identified for 3 units.

We have demonstrated that cerebral cortical neurons respond to noxious visceral stimulation. Convergence of visceral and somatosensory input occurs in a subset of these neurons. The responses of these cells are similar to those observed in spinal cord and thalamus.

120.5

ASSESSMENT OF OROFACIAL PAIN FOLLOWING NEONATAL INFRAORBITAL NERVE TRANSECTION USING THE FORMALIN TEST. B.G. Klein and C.F. White*, Dept. of Biomedical Sciences, College of Veterinary Medicine, VA Tech, Blacksburg, VA 24061.

Much literature is devoted to the anatomical and physiological effects of neonatal infraorbital nerve (ION) transection in rat. Effects of such damage on sensation in conscious animals has received little attention. We therefore employed the formalin test for orofacial pain (Clavelou et al., 1989, *Neurosci. Let.*, 103:349-353) in normal adult rats and adults subjected to neonatal ION cut. Formalin (5% in saline, 0.05 ml) or saline vehicle was injected into the vicinity of the C4/D4 vibrissae. Rats were placed in an observation tank and videotaped for 45 min. Continuous records of whiskerpad rubbing were made from the tapes, which were examined blind. As previously described, normal rats (N=12) injected with formalin exhibited an early, short-lasting response (0-3 min) and a later, prolonged response (18-39 min), separated by a period of relative inactivity. No such pattern was observed for ION cut rats injected with formalin (N=11) or saline vehicle (N=11). Total duration of rubbing in formalin injected ION cut rats (\bar{x} =65, SEM=11 s) was significantly less than that in formalin injected normal rats (\bar{x} =205, SEM=29 s), and did not differ from that of ION cut rats injected with saline (\bar{x} =67, SEM=9 s). Thus, neonatal ION cut appears to render rats insensitive to the noxious stimulation of subcutaneous formalin. Support: NIDR DE08966 to BGK.

120.2

CHARACTERIZATION OF NOXIOUS VISCERAL INPUT TO MEDIAL THALAMIC NEURONS. R.M. Danzebrink, S.T. Meller and G.F. Gebhart, Dept. Pharmacology, Univ. Iowa, Iowa City, Iowa 52242.

Anatomical and physiological studies suggest that various nuclei of the medial thalamus are involved in nociceptive processing. This study characterized the location and responsiveness of neurons in the medial thalamus to a natural, noxious visceral stimulus, colorectal distention (CRD), in pentobarbital-anesthetized rats. The locations of 133 units responding to noxious CRD in the medial thalamus were histologically verified to be distributed throughout nuclei such as medialis dorsalis, medialis and lateralis centralis, lateralis medialis and ventralis, paracentralis, reunions and submedialis. The spontaneous activity of 55 units was inhibited by noxious CRD; 78 units were excited by CRD. About half of the units gave reproducible responses to repeated CRD for at least 90 minutes. These units also responded to CRD in an intensity-dependent manner. 61% of the 133 units exhibited large, bilateral convergent cutaneous receptive fields. Noxious distention of the esophagus also activated some (n=34/64) of the neurons which responded to noxious CRD. These results reveal that visceral nociceptive input to medial thalamic nuclei is widespread and that medial thalamic neurons receive convergent input from other visceral as well as somatic structures.

RAT LOW BACK DYSFUNCTION ASSOCIATED WITH AMBULATION IN AN ABNORMAL POSTURE. J Hulse Neufeld, VA Medical Center, San Diego, CA 92161.

An animal model of low back dysfunction was developed in order to study the mechanism of induction and maintenance of low back pain. Male Sprague-Dawley rats (2 mo) ambulated 1 hr/day for 4 - 6 weeks in motorized apparatus. Two groups of rats were compared: rats that ambulated on a flat surface (AF) and in a rotating cylinder (AC). While ambulating, the AF rats held their low back in the normal kyphosis and the AC rats in a relative extension. Using repeated measures design significant interactions were obtained in body weights, ambulation in an open field test, and surface temperatures at the base of the tail. The results of these significant findings and of trends in a tail flick assay of nociception were consistent with the hypothesis that the AC group had experienced increased levels of general stress (body weight results) and disability (ambulation) associated with hyperalgesia in the lower body (tail flick) and increased sympathetic output (tail temperature). Also, a significant inverse correlation between ambulation and concentration of calcitonin gene-related peptide in the dorsal part of the caudal spinal cord was observed. The correlation related sensory pathways to locomotion in rats.

ACTIVATION OF LOCUS COERULEUS NEURONS BY DORSAL COLUMN (DC) STIMULATION (st). S.J. Jabbur, E. El-Chaer*, S.F. Atweh and N.E. Saadé, Faculty of Medicine, American University of Beirut, Beirut, Lebanon.

Pain inhibition by activation of a DC-brainstem-spinal loop can be partially antagonized by α -adrenergic antagonists (S.F. Atweh et al., *Soc. Neurosci. Abstr.* 12:617, 1986). This study investigates the possible involvement of locus coeruleus (LC) in a descending adrenergic path of the above loop. In decerebrate-decerebellate cats with cervical spinal cuts (at C₁ and C₂) that allow activation of (and/or interactions between) isolated DCs and anterolateral columns (ALCs), the responses of 55 LC neurons were examined. Forty-four neurons were discharged by DCst (mean latency 10.36 \pm 0.72 ms) and 41 neurons were discharged by ALCst (mean latency 16.54 \pm 1.69 ms) and 35 neurons discharged to both inputs. In neurons discharging only to ALCst (n=5), conditioning DCst inhibited the evoked and spontaneous firing. Peripheral receptive fields could be determined mainly in spinal cuts that allowed the ALC to connect to the periphery to the brain and typically involved large areas of the body surface, bilaterally or ipsilaterally.

Our results substantiate the lack of anatomically-demonstrable direct projections from the DC nuclei to LC and support an indirect connection through relays in the brainstem. (Supported by grants from LNRC and DTS Fund).

RECEPTOR SUB-TYPE AND SECOND MESSENGER MEDIATING SEROTONIN HYPERALGESIA IN THE RAT. Y. O. Taiwo and J. D. Levine*. Procter & Gamble, Cincinnati, Ohio 45239-8707 and UCSF San-Francisco, CA 94143-0724.

The intradermal injection of serotonin, a hyperalgesic inflammatory mediator, in male Sprague-Dawley rats, produces a dose-dependent lowering of mechanical paw-withdrawal thresholds that was not attenuated by procedures known to interrupt the known indirect mechanisms of hyperalgesia.

Serotonin hyperalgesia was selectively mimicked and antagonized by several 5-HT_{1A} agonists [8-OH-DPAT and DP-5-CT] and antagonists [spiroxatrine and spiperone]. 5-HT_{1B} [CGS-12066B; and TFMPP], 5-HT_{2+1C} [DOI, α -m-5-HT; mesulergine and ketanserin] and 5-HT₃ [2-m-5-HT, phenylbiguanide; quipazine and ICS 205-930] agonists and antagonists, respectively, were without effect.

The hyperalgesia produced by the 5-HT_{1A} agonist [8-OH-DPAT] was markedly enhanced by GTP- γ -S and cholera toxin but not significantly altered by pertussis toxin. Furthermore, 8-OH-DPAT hyperalgesia was significantly prolonged by the phosphodiesterase inhibitor- rolipram.

These data suggest that serotonin hyperalgesia is mediated by the activation of 5-HT_{1A} receptors and is positively linked to intracellular c-AMP through stimulatory guanine regulatory proteins - a mechanism similar to that of other directly acting hyperalgesic agents

Supported by NIH grant NS21647.

PRICKLE AND PAIN IN NORMAL AND HYPERALGESIC SKIN: EVIDENCE THAT LOW THRESHOLD MECHANORECEPTORS ARE RESPONSIBLE FOR THE PAIN OF SECONDARY HYPERALGESIA. F. Cervero*, R.A. Meyer and J.N. Campbell. Dept. of Neurosurgery, School of Medicine, The Johns Hopkins University, Baltimore, MD 21205.

We have studied in ten normal volunteers the sensation of prickle evoked by woollen fabrics applied to the skin of the forearm before and after an intradermal injection of 25 μ g of capsaicin, a procedure known to induce a large area of mechanical hyperalgesia around the site of injection. Five woollen fabrics (two non-prickly, two very prickly and one intermediate) were presented, in a blind manner, to the volar skin of the forearm. The subjects were asked to rate fabric-induced prickle and pain using visual-analog scales from 0 to 100. Each fabric was presented 5 times in pseudorandom order so that each fabric was preceded once by every other one. On day one the fabrics were applied to normal skin. On day two the test was presented immediately before the intradermal injection of 25 μ g of capsaicin. Twenty minutes after the injection the fabrics were presented again in the region of secondary hyperalgesia induced by capsaicin. On day 3 or 4 the test was carried out again once the capsaicin-induced hyperalgesia disappeared. The results showed that sensations of fabric evoked prickle remained unchanged in hyperalgesic skin. In contrast, all fabrics, including those judged as non-prickly in normal skin, evoked pain when applied to hyperalgesic skin. These results are consistent with the hypothesis that low threshold mechanoreceptors mediate hyperalgesia to mechanical stimuli, and moreover, that nociceptors that serve prickle sensation are not sensitized to mechanical stimuli in skin rendered hyperalgesic by injection of capsaicin.

120.11

A-FIBER NOCICEPTORS WITH A FAST RESPONSE TO HEAT ARE ABSENT IN MONKEY GLABROUS SKIN. R.-D. Treede*, R.A. Meyer, and J.N. Campbell. Johns Hopkins U., Baltimore, MD 21205, Univ. Hospital Eppendorf, D-2000 Hamburg 20.

Human behavioral data indicate that first pain to heat can only be elicited in hairy skin, but not in glabrous skin (Brain Res 266, 1983, 203-208). We now demonstrate that this is paralleled by an absence of A-fibers in monkey glabrous skin with a fast response to heat. Standard teased-fiber techniques were used to record from mechano-heat sensitive A-fiber nociceptors (AMHs) in glabrous (n=64) and hairy skin (n=58) of anesthetized monkey. Fibers were classified based on their response to a 30 s, 53°C stimulus, delivered by a laser (0.1 s rise time). All 64 AMHs in glabrous skin responded to this stimulus with a latency of more than 2 s and a discharge rate that increased with time and reached a maximum near the end of the stimulus. In contrast, only 1/3 of the hairy skin AMHs had similar properties. The remainder started to discharge within 1 s. A subset of these hairy AMHs (n=14) had their peak discharge within 1 s and a mean activation latency of 170 ms and are thought to account for first pain sensation (Pflugers Arch Suppl 415, 1990, R108). The slow heat response of AMHs in glabrous skin does not appear to be due to the thick epidermis, since a fast response to heat is observed for C-fiber nociceptors (CMHs) in glabrous skin. The occurrence of the maximum discharge at the end of the stimulus for the glabrous AMHs may reflect the time course of sensitization, which is chemically mediated. Fast heat responses, which would be consistent with a direct transducer mechanism, occur only for a subset of the hairy skin AMHs, and for CMHs in both skin types. (Support: NIH NS-14447 and DFG Tr236/1-1).

CORRELATION OF CAPSAICIN-INDUCED CHANGES IN PAIN RATING WITH LASER EVOKED POTENTIAL AMPLITUDE. A. Beydoun, T.J. Morrow¹ and K.L. Casey¹. Depts. of Neurology and Physiology¹, Univ. of Michigan and Neurol. Res. Labs., VA Med. Center, Ann Arbor, MI 48105.

Cutaneous stimulation with infrared laser pulses activates finely myelinated (A delta) nociceptive afferents and evokes a cerebral potential (LEP: 250-350 ms; 20-90 μ V). If the LEP reflects the activation of cerebral mechanisms mediating pain, then changes in pain rating of the laser stimulus should correlate with LEP amplitude. Capsaicin depletes putative neurotransmitters of unmyelinated (C) nociceptive afferents. If typically applied capsaicin also affects A delta afferents, it should systematically attenuate LEP amplitude and laser pain rating. Methods: In a single blinded experiment, five normal volunteers applied capsaicin (0.75%) to the dorsum of one hand and vehicle cream to the other 3 times daily for up to 6 weeks. At weekly intervals before, during and after discontinuation of capsaicin, we determined the thresholds for light touch (Von Frey), deep pain (pressure algometer), pinch pain (hemostat), heat pain (contact thermode) and cold pain (Peltier device). Equal intensity laser stimuli (60 ms pulses) were delivered to the dorsum of the right and left hands of each subject, who rated pricking pain intensity on a visual analog scale. The LEP were averaged (n=25, 0.2-40Hz, CZ-A1A2) and the amplitude of the potential was measured. An analysis of variance was performed to compare right-left differences for the psychophysical measurements and the LEP. A linear regression analysis was used to correlate the laser pulse sensory rating and the amplitude of the evoked potential. Results: Capsaicin produced highly significant right-left differences (p<0.001) for laser pulse sensory rating and the amplitude of the LEP. There was also a highly significant correlation between the laser pulse sensory rating and LEP amplitude (r=0.72, p<0.001). There was no statistically significant right-left difference for the light touch, pinch pain, heat pain, cold pain and deep pain thresholds (ANOVA). Conclusions: 1) With the stimulus parameters used here, LEP amplitude is highly correlated with the intensity of laser-induced pricking pain. 2) In this study, LEP amplitude changes were not correlated with the thresholds of other thermal or mechanical sensory modalities. 3) Capsaicin reversibly inactivates A delta nociceptive afferent transmission.

SYMPATHECTOMY DOES NOT ABOLISH BRADYKININ-INDUCED HYPERALGESIA TO HEAT IN HUMAN. R.A. Meyer, K.D. Davis, S.N. Raja, and J.N. Campbell. Johns Hopkins Univ., Baltimore, MD 21205

Bradykinin is an endogenous peptide that is thought to be involved in the hyperalgesia associated with injury. Based on paw withdrawal data in chemically sympathectomized rats, Levine, et al. (Nature 323, 1986, 158-160) proposed that hyperalgesia following bradykinin injection is dependent on an intact peripheral sympathetic nervous system. We sought to test this hypothesis in human subjects. Since intradermal injections of bradykinin produces a dose-dependent hyperalgesia to heat (but not mechanical) stimuli in human subjects (Raja, et al., Pain, Suppl. 5, 1990, S130), we tested for heat hyperalgesia in a patient diagnosed to have sympathetically maintained pain (SMP) in the left leg. An ipsilateral surgical lumbar sympathectomy relieved her pain. Three years later her SMP returned in her left leg, although her right leg was completely normal. Following a contralateral (right) surgical sympathectomy her SMP was again eliminated. Immediately before and 6 months after this sympathectomy on her right side, we tested her verbal pain ratings to heat stimuli before and after intradermal injection of bradykinin (10 nmoles in 10 μ l saline) or saline near her right ankle. Pronounced hyperalgesia to heat stimuli occurred after the bradykinin (but not after saline) injection. The magnitude of the hyperalgesia produced by bradykinin after the sympathectomy was similar to that produced before. We conclude that the heat hyperalgesia produced by bradykinin does not require an intact sympathetic nervous system in human. (Supported by NIH NS-14447 and NS-26363)

PAINFUL THERMAL STIMULATION PRODUCES DECREASED BLOOD FLOW IN CONTRALATERAL PARIETAL CORTEX IN AWAKE HUMANS. R.A. STEA*, N.M. SZEVEERENYI*, S.H. MANGLOS*, R.T. STEVENS, F.D. THOMAS*, A.V. APKARIAN. Depts. Neurosurg. and Radiology, SUNY HSC, Syracuse, N.Y. 13210.

Single Photon Emission Computed Tomography (SPECT) with Tc-99m HMPAO is a measure of regional cerebral blood flow (rCBF) and neural activity. In this study, SPECT with MRI localization was used to measure rCBF changes during pain perception. Volunteers were fitted with a headholder to allow reproducible positioning in SPECT and MRI scanners. SPECT images were obtained while the subject's hand was immersed in moderately painful hot water (46-48°C). Control images were obtained with neutral temperature water. Software was developed to objectively normalize, translate and rotate data in identical orthogonal planes. SPECT stimulus minus control images were superimposed on corresponding MRI sections to provide a change distribution analysis.

In all three subjects rCBF decreased an average of 25% (>2SD) in the contralateral parietal cortex in proximity to primary somatosensory cortex. This decrease was 14 counts/pixel by ROI analysis (p-value 0.022, df=16). In one subject, the painful stimulus was given to the opposite hand as well. This produced a contralateral decrease in rCBF of 30% (33.3 counts/pixel, p-value 0.0017, df=10 ROI analysis). In another subject a vibratory stimulus to the left third digit produced an increase in rCBF in the contralateral parietal cortex (10.1 counts/pixel, p-value 0.006, df=6 ROI analysis). There was no significant change in frontal, temporal or occipital lobes or cingulate gyrus. These results suggest, in contrast to an earlier PET study (Talbot et al., Science 251:1355, 1991), that painful stimulation primarily produces inhibition in the contralateral parietal cortex while innocuous stimulation produces activation in this area.

120.13

HYPERALGESIA AND ALLODYNIA-TWO TYPES OF PAINFUL ALTERED SENSATION WITH DIFFERENT PATHOPHYSIOLOGY. U. Lindblom*, P. Hansson*, and H. Fields, Dept. of Neurology, Karolinska Hospital, 104 01 Stockholm, Sweden and ¹Dept. of Neurology, UCSF, San Francisco, CA, 94143.

Hyperalgesia may be described as a steepened stimulus-response function. In patients with acute pain and sensitized nociceptors the function will be shifted towards lower stimulus strengths. In patients with neurogenic pain, on the other hand, it is reasonable to expect an increased threshold to pain due to loss of afferent fibres or damage to central pain pathways.

Magnitude estimation of pain intensity as a function of graded thermal pain stimuli, in patients with neurogenic pain and increased threshold to thermal pain, resulted in a steeper slope in the painful region as compared to the control area. Based on our findings we propose that the IASP definition of hyperalgesia may be amended to "An increased response to a nociceptive stimulus". This definition would apply also to patients with increased pain due to sensitization of nociceptors.

For allodynia, clinical characteristics are different from hyperalgesia and a monotonous stimulus-response function may not apply.

NEURONS IN HUMAN Vc RESPOND TO NOXIOUS HEAT STIMULI. M. Seike, FA Lenz, YC Lin, FH Baker, RH Gracely, RT Richardson. Dept Neurosurg, Johns Hopkins Hosp, Baltimore, MD 21205 and NAB-NIDR-NIH, Bethesda, MD 20892.

The previous abstract suggests that neural elements signalling thermal and pain sensations might be located in an area near the postero-inferior border of Vc. In order to test whether sensations evoked by TMS were due to excitation of neurons we examined cells for evidence of a response to noxious stimulation.

Sites within thalamus were characterized by: the neuronal receptive field to innocuous mechanical stimulation (RF) and the projected field evoked by TMS (PF). RFs were found for most cells in Vc but for no cells in c. During recordings from cells in Vc noxious heat and a control stimulus were applied within the RF and PF identified for that site. In c, stimuli were applied within the PF. At some sites in c stimuli were also applied within the V2, V3, ulnar and median nerve distributions. Both stimuli were applied (duration approx. 5s) several times in random order. The noxious heat stimulus was a probe heated to 51-53°C which was rated at 5-8/10 on a visual analog scale but which did not produce hyperalgesia. The control stimulus was a thermal neutral probe otherwise identical to the noxious heat probe. The change in firing rate (response) during applications of heat were compared to control responses.

Responses to noxious heat were significantly greater than control for 4 of 49 cells in Vc and 0 of 21 cells in c. Noxious heat responses were up to 6 times greater than control. No evidence of sensitization of the responses to heat or control stimuli was observed. Thermal sensations were not evoked by TMS at any of the sites where cells responding to noxious heat were recorded. These results suggest that the input of thermal and pain signalling pathways to neurons in Vc is at least as strong as that to neurons in c, postero-inferior to Vc. (E Lilly Corp, NIH NS28598 K08-NS1384)

120.14

SENSATIONS EVOKED BY MICROSTIMULATION IN THE AREA OF HUMAN VENTROCAUDAL NUCLEUS (Vc). FA Lenz, M Seike, YC Lin, RT Richardson, FH Baker, RH Gracely. Dept Neurosurg, Johns Hopkins Hosp, Baltimore, MD 21205 and NAB-NIDR-NIH, Bethesda, MD 20892.

It has been suggested that an area near the postero-inferior border of Vc is involved in nociception. However, sensations evoked by stimulation of this area vary between investigators and between patients. We have now employed cross-modality training to measure sensations evoked by threshold microstimulation (TMS) in unanesthetized patients undergoing thalamotomy for tremor.

Vc was identified as the region where a majority of cells had 'lemniscal' response properties including small receptive fields and a constant response to repeated stimulation. Along trajectories through Vc from antero-superior to postero-inferior, recordings of spontaneous activity were used to identify three distinct regions: b - where numerous cells were recorded, c - where cells were sparser and firing rates were slower than b, d - where only fibers were recorded. Along these trajectories, cells with 'lemniscal' properties were almost exclusively located within b, and the transition from cells with 'lemniscal' properties to those without occurred within -0.1 to 0.5mm of the b/c border.

Four patients were trained to use a questionnaire to describe sensations evoked by different types of cutaneous stimulation preoperatively and by TMS intraoperatively. Evoked sensations were usually paresthetic (50/64 sites) but sometimes had a thermal component (13/64). A thermal component was observed more frequently in c (8/21) than in Vc (3/35, p<0.05) and was always warm in c. Thermal sensations were evoked in c and/or at the posterior margin of Vc in each patient studied. The sensation of pain was evoked once, in region d. These results demonstrate that, in psychophysiologically trained patients, TMS reproducibly evokes thermal but not painful sensations from an area near the postero-inferior border of Vc. (E Lilly Corp, NIH NS28598 K08-NS1384)

PAIN MODULATION: OPIOIDS II

121.1

EFFECTS OF EPIDURAL MORPHINE AND LIDOCAINE ON SOMATIC AND VISCERAL PAIN. M. Kaneko*, Y. Saito, Y. Kirihara* and Y. Kosaka* Dept. of Anesthesiology, Shimane Med. Univ., Izumo, Shimane, 693 JAPAN.

The purpose of this study is to evaluate the analgesic effects of epidural anesthesia with morphine, lidocaine and a mixture of morphine and lidocaine.

This protocol was approved by Animal Care and Use Committee of Shimane Medical University. Female Sprague-Dawley rats weighing 250-300g were implanted epidural catheter at the level of Th13/L1. Tail flick (TF) test was employed for response to somatic stimuli. Colorectal distention (CD) test which were modified from Ness and Gebhart (Brain Res, 1988,153) was used for response to visceral stimuli. The thresholds in TF and CD test were measured before and 5 to 180 min after the epidural injection of saline, morphine of 1 to 10 µg, lidocaine of 200 to 800 µg or a mixture of morphine and lidocaine in a volume of 40 µl.

Morphine and lidocaine increased the threshold of CD test as well as TF test in dose-dependent fashion. The mixture of low dose morphine and lidocaine that produced little analgesic effect alone produced greater analgesic effects in both TF test and CD test. The results suggested the possibility of the synergistic interaction of epidural morphine and lidocaine.

121.2

EFFECT OF MORPHINE WITH COCAINE ON ANALGESIA, ALERTNESS, AND CARDIO-RESPIRATORY PARAMETERS A. Pertovaara, T. Kauppi*, and E. Mecke*. Dept. of Physiol., Univ. Helsinki, Helsinki, Finland.

Cocaine enhanced morphine-induced analgesia in the formalin test, hot plate test and heat-induced tail withdrawal test in intact rats. However, in spinal rats a similar combination of cocaine with morphine had no effect in the tail withdrawal test. The formalin test was the most sensitive one to the drug effects. Morphine at the dose 6 mg/kg produced maximal analgesia in the formalin test accompanied by significant hypolocomotion/sedation, bradycardia and bradypnea. At an equianalgesic dose of morphine (3 mg/kg)-cocaine (5 mg/kg)-combination no significant changes in heart rate, respiratory rate or locomotion/alertness were observed. Also, skin blood flow changes determined by the laser Doppler flow method were not significant. The results indicate that cocaine enhances morphine-induced analgesia, due to supraspinal/spinopetal mechanisms. However, the morphine-induced bradypnea, bradycardia and hypolocomotion/sedation are concomitantly attenuated by cocaine. It is possible to combine low, subanalgesic doses of cocaine and morphine to produce powerful analgesia with minimal undesirable side-effects.

121.3

EFFECTS OF SPINAL [DAla², NMePhe⁴, GLY⁵-o]ENKEPHALIN (DAG) ON THERMALLY-EVOKED CARDIOVASCULAR AND CATECHOLAMINE RESPONSES IN HALOTHANE ANESTHETIZED RATS. J.G. Hamra, T.L. Yaksh and M.B. Brown, Dept. of Anesthesiology, Univ. of California, San Diego, La Jolla, CA 92093.

In many species, surgical stress evokes hypertension, tachycardia and catecholamine secretion. Using DAG, a mu opioid agonist, the role of opioid receptors in the sympathetic response to activation of small unmyelinated somatic afferents was examined. Male Sprague-Dawley rats were implanted under halothane anesthesia with chronic intrathecal (IT) catheters. Following a 5-7 day recovery period, the rats were anesthetized with 3.0% halothane and the tail artery cannulated for monitoring blood pressure. Rats were subjected to one of three experimental protocols: anesthesia (1.5% halothane), anesthesia followed by immersion of the distal 1/3 of the tail in 60°C water for 60 sec, and anesthesia plus IT injection of 10 µg of DAG, followed by tail immersion 30 minutes following IT injection. Heart rate (HR), blood pressure (BP) and catecholamine levels remained stable during the one hour of anesthesia. Tail immersion resulted in a marked increase in BP and HR ($\Delta=30\pm5.8$ mm Hg and 49 ± 1.5 bpm, respectively, $P<0.05$), while norepinephrine but not epinephrine levels increased ($\Delta=115.2\pm48.2$ ng/ml). The IT injection of DAG resulted in a mild, transient decrease in baseline BP but not HR, and blocked the rise of BP and HR noted after tail immersion. IT injection of DAG significantly decreased norepinephrine levels following tail immersion. Thus, it appears that opioid receptors in the spinal cord play a role in modulating pain-evoked sympathetic responses to activation of small unmyelinated afferent fibers. (NS07329)

CLOCINAMOX: CHARACTERIZATION OF A SYSTEMICALLY-ACTIVE IRREVERSIBLE OPIOID RECEPTOR ANTAGONIST IN THE MOUSE TAIL-WITHDRAWAL ASSAY. Timothy F. Burke*, Sandra D. Comer*, James H. Woods and John W. Lewis*. Depts. of Psychology and Pharmacology, University of Michigan, Ann Arbor, MI, and Reckitt and Coleman Pharmaceutical Division, Kingston-upon-Hull, England.

Morphine and fentanyl produced dose-dependent increases in tail-withdrawal latency and were fully effective at doses of 32 and 1 mg/kg, respectively in the mouse warm water (55°C) tail-withdrawal assay. Naltrexone (1-100 mg/kg) produced parallel rightward shifts in the dose-response curves for both agonists with pA₂ values of 5.85 ± 0.53 (95% C.L.) and 5.39 ± 0.83 , respectively. Clocinamox (14β-(p-chlorocinnamoylamino)-7,8-dihydro-N-cyclopropylmethyl normorphinone mesylate; 0.32 mg/kg) also shifted these dose-response curves to the right. The highest dose tested (32 mg/kg) produced an insurmountable antagonism up to lethal doses of the agonists. Interestingly, clocinamox (3.2 mg/kg) produced a shift down in the morphine dose-effect curve but only produced a parallel rightward shift in fentanyl's dose-effect curve. This result may indicate a difference in efficacy between morphine and fentanyl. The duration of antagonist action of clocinamox (32 mg/kg) was found to be approximately 8 days with its peak effect at 1 hour. Naloxone, when co-administered with 32 mg/kg clocinamox 2 days prior to determination of morphine's dose-effect curve, prevented the shift down produced by clocinamox in a dose-dependent manner. Thus, clocinamox may be producing its antagonist effect *in vivo* by irreversibly inactivating opioid receptors. Research supported by USPHS Grants DA-00254 and DA-05405.

ENKEPHALIN ANALOGS AS SYSTEMICALLY ACTIVE ANTINOCICEPTIVE AGENTS: O- AND N-ALKYLATED DERIVATIVES OF THE DIPEPTIDE AMIDE SC-39566. Barnett S. Pitzele, Robert W. Hamilton*, Kathleen D. Kudla*, Awilda Stapelfeld, Michael A. Savage*, Michael Clare*, Donna L. Hammond, Don W. Hansen, Jr., Janice M. Thompson, Elaine Rohrbacher, Linda L. Tam, Patricia C. Contreras, Searle, 4901 Searle Pkwy, Skokie, IL 60077.

The Dipeptide Amide SC-39566, a simplified enkephalin analog, has been shown to be a parenterally and orally active opioid antinociceptive agent. A number of O- and N-alkylated analogs and derivatives of SC-39566 were synthesized. Mouse behavioral data show that substitutions at the tyrosine and propylamide nitrogens reduce potency, while substitution at the alanine nitrogen is less critical. Biochemical and behavioral data will be discussed.

SC-39566

DO DIFFERENT KAPPA OPIOIDS MEDIATE ANALGESIA VIA DIFFERENT RECEPTORS AT SPINAL AND SUPRASPINAL SITES? P. Max Headley* and Juan F. Herrero* (SPON: Brain Research Association) Dept Physiology, Medical School, University Walk, Bristol BS8 1TD, UK.

Kappa opioids reduce the responses of spinal neurones to peripheral noxious stimuli (Parsons & Headley, 1989, Brit. J. Pharmac. 98: 523-551). We have now examined electrophysiologically (a) the relative degrees to which kappa actions are produced at spinal vs supraspinal sites and (b) whether the effects may be mediated at more than one receptor. Reflexes to noxious pinch stimuli were recorded as single motor unit responses in hindlimb flexor muscles of rats anaesthetized with alpha-chloralose. The spinal cord was either sectioned or left intact with sham spinalization surgery. ED₅₀ values in spinalized animals for 5 selective kappa opioid ligands were 7mg/kg for U-50,488, 5mg/kg for U-69,593, 3mg/kg for PD-117,302, 0.08mg/kg for CI-977 (see Hunter et al, 1990, Brit. J. Pharmac. 101: 183-189), and 0.3mg/kg for GR-103,545A (see Hayes et al, 1990, Proc. I.N.R.C., Int. Cong. Ser. 914: 214-215). With the cord intact, potencies were greater - 1.5-2 fold for U-69,593 and PD-117,302, 4-6 fold for U-50,488, 12-16 fold for CI-977 and 80-120 fold for GR-103,545A. All drug effects were reversed by i.v. naloxone; U-50,488, U-69,593 and PD-117,302 required less than 0.5mg/kg; CI-977 sometimes needed 1mg/kg and GR-103,545A up to 10mg/kg. These different agonist and antagonist potencies indicate that the various agents were activating different populations of receptors and that these varied between spinal and supraspinal sites. If these agents are selective for kappa receptors then this implies actions at kappa receptor subtypes. [Supported by the Wellcome Trust and the Spanish Ministry for Education and Science. We thank Upjohn, Parke-Davis Research Unit and Glaxo Group Research for gifts of compounds].

MORPHINE ANTAGONIZES U50,488-INDUCED ANTINOCICEPTION IN THE SQUIRREL MONKEY. R. M. Craft, L. A. Dykstra and J. J. Yarbrough, Psychology Department, University of North Carolina, Chapel Hill, NC 27599-3270.

In a previous study, we showed that several kappa opioid agonists antagonized the antinociceptive effects of mu opioid agonists in a squirrel monkey analgesia procedure (Craft and Dykstra, 1990). The purpose of the present study was to determine whether a mu agonist would antagonize the antinociceptive effects of a kappa agonist. The mu agonist morphine was administered in combination with a dose of the kappa agonist U50,488 that produced a 75% of maximal antinociceptive effect. Morphine (0.03-0.3 mg/kg) did not antagonize U50,488's effects during the first component of the session (15-25 min after injection of U50,488), but dose-dependently antagonized U50,488's effects during the second, third and fourth components of the session (40-100 min after injection of U50,488). The effects of morphine in combination with U50,488 were then redetermined in morphine-tolerant monkeys. As in non-morphine tolerant monkeys, morphine dose-dependently antagonized U50,488's effects during components 2, 3 and 4; however, the doses required to antagonize U50,488's effects in morphine-tolerant monkeys were 1 log unit higher than those in non-tolerant monkeys. When the pretreatment time for morphine was increased from 30 to 60 min, morphine still only antagonized U50,488's effects during components 2, 3 and 4. In contrast, when the pretreatment time for U50,488 was increased from 10 to 35 min, morphine antagonized U50,488's effects during all four components of the session. In summary, the mu agonist morphine partially antagonized the antinociceptive effects of the kappa agonist U50,488, suggesting that U50,488's antinociceptive effects may be mediated by multiple mechanisms in the squirrel monkey shock titration procedure. The fact that chronic morphine administration produced tolerance morphine's kappa antagonist effects suggests that the antagonism of U50,488's antinociceptive effects by morphine may be mu receptor-mediated. INTRAVENOUS (IV) MORPHINE-INDUCED INHIBITION OF THE TAIL-FLICK (TF) REFLEX AND SPINAL NOCICEPTIVE TRANSMISSION: PERIPHERAL AND CNS SUBSTRATES. A. Randich, C.L. Thurston, P.S. Ludwig*, J.D. Robertson*, C. Rasmussen and G.F. Gebhart, Dept. of Psychology., UAB, Birmingham, AL, 35294 and Dept. of Pharmacol., UI, Iowa City, IA, 52242.

Inhibition of the TF reflex produced by 1.0 mg/kg of IV morphine in pentobarbital-anesthetized rats was significantly attenuated by bilateral cervical vagotomy, local anesthesia (0.5 µl of 4% lidocaine) of the nucleus tractus solitarius (NTS), somatotoxic lesions (0.5 µl of 10 µg of ibotenic acid) of the nucleus raphe magnus (NRM), or complete spinal cord block. The antinociception was unaffected by either local anesthesia of the periaqueductal grey (PAG) or bilateral transections of the dorsolateral funiculi (DLFs).

IV administration of 0.5 mg/kg of IV morphine resulted in significant inhibition of responses of lumbosacral spinal dorsal horn neurons to noxious heating of the hindpaw and this effect was significantly attenuated by bilateral cervical vagotomy. This research was supported by NIH grants 22966 and 24958.

A ROLE FOR PERIAQUEDUCTAL GREY (PAG) H_2 RECEPTORS IN THE SUPRASPINAL ACTIONS OF SYSTEMIC MORPHINE. J.W. Nalwalk* and L.B. Hough. Dept. Pharmacology & Toxicology, Albany Medical College, Albany, NY 12208.

Previous studies support the hypothesis that brain histamine (HA) and H_2 receptors are mediators of morphine (MOR) antinociceptive responses, although the anatomical localization of the relevant H_2 receptors is unknown. To assess the importance of PAG H_2 receptors, the effect of the H_2 antagonist tiotidine (TIOT) was determined on nociceptive thresholds in the presence and absence of MOR in rats. Intracerebral TIOT (1 ng, 10 min, PAG at the level of the dorsal raphe) significantly attenuated antinociception (52°C hot plate) induced by systemic MOR (5.6 and 10 mg/kg, 30 min, sc). The inhibitory effect of PAG TIOT was surmounted by a higher dose of MOR (17.8 mg/kg, 30 min, sc). In contrast to hot plate results, PAG TIOT at all doses tested had no significant effect on MOR-induced changes in tail flick latencies. PAG TIOT (up to 30 ng) produced no effect on hot plate or tail flick responses in the absence of MOR. Microinjection mapping studies of the PAG showed TIOT to be most effective in the caudal ventrolateral PAG, an area previously shown by microinjection to exhibit MOR antinociception. Within the PAG, this overlap between TIOT-sensitive sites and antinociceptive MOR sites suggests that MOR may act, in part, in the PAG to release HA. Taken together with previous studies showing PAG HA injections cause analgesia, these data strongly suggest a role for PAG HA and H_2 receptors in supraspinally mediated MOR antinociception (Supported by DA-03816).

RESPONSE OF NEURONS IN ROSTRAL VENTROMEDIAL MEDULLA TO LOCAL NANOLITER INFUSIONS OF MORPHINE. M.M. Heinricher, M.M. Morgan and H.L. Fields. Depts. of Neurology and Physiology, Univ. of Calif., San Francisco, CA 94143

Neurons in the rostral ventromedial medulla (RVM) are known to contribute to opioid antinociception. Two classes of physiologically characterized RVM neurons that show distinct responses to morphine (MOR) given systemically, intrathecally or by microinjection into the PAG have been identified: "off-cells," which are thought to have a net antinociceptive action, are activated by MOR, whereas "on-cells," postulated to have a pro-nociceptive role, are invariably depressed. Because microinjection of morphine into the RVM is itself antinociceptive, the present study used local infusion of MOR to characterize the role of connections among RVM neurons in this effect.

Activity of on- and off-cells was recorded before and after local infusion of MOR (0.5-2 μ g in 50-200 nl). These injections, which generally had no effect on tail flick latency, produced variable decreases in on-cell firing (10% to complete suppression). Changes in off-cell firing, when present, were generally modest (10-20% increase, although larger effects were seen). These effects were partially antagonized by naloxone (1 mg/kg, i.p.). In contrast, when higher MOR concentrations were used (5 μ g in 100 nl), both on- and off-cells showed a progressively broader and lower amplitude action potential that eventually disappeared. This effect was not reversed by naloxone, indicating a local anesthetic effect.

Thus, local infusion of small quantities of MOR variably depresses on-cell firing, and results in a modest increase in off-cell firing. This reinforces the importance of the on-cell as the focus of direct opioid action within the RVM. In addition, since iontophoretically applied MOR has no effect on off-cell firing, these results are consistent with the suggestion that on-cells in RVM are inhibitory to off-cells.

EFFECT OF MORPHINE ON HISTAMINE RELEASE IN THE RAT PERIAQUEDUCTAL GREY. K.Barke and L.B.Hough Dept. of Pharmacology and Toxicology, Albany Medical College, Albany, NY 12208.

Previous studies have demonstrated that histamine (HA) microinjections into the periaqueductal grey (PAG) cause analgesia. Further, HA H_2 receptor antagonists block both HA and morphine (MOR)-induced analgesia when given into the PAG. Taken with recent anatomical evidence for the existence of histaminergic nerve terminals in the PAG, these studies suggest that MOR may act in part by releasing HA in the PAG, but no direct evidence for this exists. Thus, the hypothesis that analgesic doses of MOR increase extracellular HA levels in the PAG was tested in conscious rats by *in vivo* intracerebral microdialysis. Sequential doses of 5.6 and 12.8 mg/kg of MOR (s.c.) caused a highly significant dose-dependent increase ($p < 0.001$) in PAG HA levels ($239\% \pm 64\%$ and $294\% \pm 71\%$ respectively, mean \pm SEM, $n=5$). In a different group of animals in which the probe was placed more laterally in the midbrain reticular formation, no significant increase in MOR-induced HA release was observed ($n=5$). In addition, a separate experiment, with sequential saline injections demonstrated no significant effect on HA release in the PAG ($n=3$). These results demonstrate that MOR can increase HA release in the rat PAG, a site where MOR and HA are known to have analgesic action. The cellular origin and mechanism of this MOR effect remains to be explored (Supported by DA-03816).

KAPPA OPIOID AGONISTS PRODUCE HYPOALGESIA ON THE TAILFLICK TEST AFTER APPLICATION TO THE AMYGDALA IN PENTOBARBITAL ANESTHETIZED RATS F.J. Helmstetter, E.L. Brozoski & J.A. Frost*, Department of Psychology, University of Wisconsin, Milwaukee, WI 53211

Prior work has shown that the amygdala is a critical forebrain structure involved in some environmentally-mediated forms of antinociception (Helmstetter et al, Neurosci Abst, 1988). This study represents our first attempt to directly modulate nociceptive reflexes by manipulating the amygdala. Adult male rats were prepared with chronic cannulae aimed at the amygdala. Subjects were anesthetized with sodium pentobarbital (50mg/kg i.p.) and their latency to tailflick in response to a radiant heat source was recorded at 2 min intervals. After baseline trials animals received a bilateral infusion (1.0 μ l/ 1 min) of 0, 5.0, 10.0 or 20.0 μ g of the kappa opioid agonist MR2034. This resulted in a dose-related elevation in response latency lasting more than 25 min. In a similar experiment bremazocine HCl, a kappa agonist with reported mu antagonist properties, also produced a long-lasting hypoalgesia arguing against a mu-dependant effect. We propose that kappa agonists directly or indirectly activate amygdalar projections to brainstem antinociceptive systems and that this circuit is involved in some forms of stress-induced hypoalgesia.

BINDING OF TRANSDUCIN (G_{α} -[35 S]GTP γ S) TO CYCLIC GMP PHOSPHODIESTERASE SUBUNITS IMMOBILIZED ON NITROCELLULOSE MEMBRANES. J.J. Erdos and J.K. Northup*. Dept. of Pharmacology and Psychiatry, Yale Univ. Sch. of Med., New Haven, CT 06510.

(G_{α} -[35 S]GTP γ S) at a specific activity of approximately 1000 Ci/mmol was able to bind its effector, cyclic GMP phosphodiesterase (cGMP PDE $\alpha\beta\gamma$) immobilized on nitrocellulose at dilutions of 1 - 10 nM. Binding was not decreased by extensive washing and crosslinking the G_{α} -[35 S]GTP γ S to the cGMP PDE $\alpha\beta\gamma$ with 1 mM disuccinimidyl suberate prior to washing did not increase the signal. Likewise there was no increase in sensitivity visualizing the crosslinked G_{α} using polyclonal antisera to G_{α} and 125 I secondary antibody. G_{α} -[35 S]GTP γ S at 9.5 nM was able to detect a minimum of 2.1 ng cGMP PDE $\alpha\beta\gamma$ with the binding being linear from 70 ng to 70 μ g. Treatment of cGMP PDE $\alpha\beta\gamma$ with 10 μ g/ml trypsin which proteolyzes the γ subunit essentially eliminated binding. These results support the theory that the site of interaction of cGMP PDE heteromer with G_{α} is the γ subunit. Further the ability of G_{α} -[35 S]GTP γ S to remain stably associated with cGMP PDE immobilized on nitrocellulose suggests that G_{α} subunits can be used to identify effectors expressed in E. Coli.

122.2

PHOSPHORYLATION OF THE MAJOR LIGHT-DEPENDENT SUBSTRATE IN THE LIMULUS PHOTORECEPTOR IS MEDIATED BY Ca^{2+} BUT NOT BY PROTEIN KINASE C. B.G. Calman* and B-A Battelle, The Whitney Laboratory, St Augustine, FL 32086.

The major light-dependent phosphoprotein in the Limulus photoreceptor, a 46 kD protein, (Edwards et al., 1989) can be phosphorylated *in vitro* in the presence of Ca^{2+} and CAM (calmodulin) (Wiebe et al., 1989). We have examined the possibility that the 46 kD protein is a substrate for PKC using homogenates of Limulus lateral eyes and ventral photoreceptors. Stimulation of endogenous PKC-like activity with PTS, DAG, and 100 μ M Ca^{2+} resulted in the consistent phosphorylation of proteins with approximate molecular weights of 210, 185, 160, and 130 kD. Phosphorylation of the 46 kD protein was marginally enhanced in 10 of 16 experiments on the lateral eye. A specific PKC inhibitor, pseudosubstrate peptide PKC(19-36), reduces the PTS/DAG/ Ca^{2+} stimulated phosphorylation of all substrates but does not inhibit the phosphorylation of the 46 kD protein stimulated by 1 mM Ca^{2+} . Ca^{2+} -stimulated phosphorylation of the 46 kD protein is blocked by calmodulin inhibitors, including mastoparan and calmidazolium. We conclude that the major light-dependent phosphorylation in the Limulus photoreceptor is not mediated by PKC, but by another Ca^{2+} -regulated kinase, probably a Ca^{2+} /CAM-regulated kinase. Supported by NIH (EY06232) and NSF (BNS-8607660).

ION CHANNELS UNDERLYING REGENERATIVE AND PROLONGED DEPOLARIZATIONS IN CONE PHOTORECEPTORS. Steven Barnes, Micheline C. Deschenes* and L.W. Haynes. Neuroscience Research Group, University of Calgary, Calgary, Alberta, Canada T2N 4N1.

Cone photoreceptors may generate a Ca-dependent action potential followed by a prolonged depolarization in response to current injection or surround illumination. Lasansky (J.Physiol. 310:205, 1981) implicated a Cl conductance increase during the prolonged depolarization and Thoreson and Burkhart (J.Neurophys. 65:96, 1991) supposed that Ca-activated Cl channels mediate this conductance change. In patch-clamped isolated cones we confirm that L-type Ca channels are responsible for the action potential and show that Ca-activated Cl channels together with elevated $[Cl]_i$ sustain the prolonged depolarization.

Ca-activated Cl current ($I_{Cl}(Ca)$) is seen in most voltage-clamped tiger salamander cones dialysed with CsCl or KCl intracellular solution following step depolarizations that activate L-type Ca channels in normal NaCl saline. Only cells exhibiting $I_{Cl}(Ca)$ under voltage-clamp can produce prolonged depolarization under current clamp. 100 μ M niflumic acid blocks $I_{Cl}(Ca)$ and eliminates the prolonged depolarization, even though the cone still musters a shortened, Ca-dependent spike. Addition of Ba, which produces larger inward currents through Ca channels, blocks several types of K channels and does not activate $I_{Cl}(Ca)$, supports brief (~250 ms) action potentials with no prolonged depolarization.

If E_{Cl} is made negative to the cones rest potential (as shown by Maricq and Korenbrot, 1988, Neuron 1:503) prolonged depolarization does not occur, rather, $I_{Cl}(Ca)$ contributes to membrane hyperpolarization. Unless E_{Cl} is normally high (e.g. >-20 mV) prolonged depolarization is likely an artifact of $[Cl]_i$ enhancement due to dialysis, as here, or leakage from KCl-filled microelectrodes.

SELECTIVE FLUORESCENT STAINING OF CONE OUTER SEGMENTS WITH CHLORIDE TRANSPORT BLOCKERS. J. Kleinschmidt. Dept. of Ophthalmology, New York University Medical Center, New York, NY 10016.

SITS, DIDS, and other stilbene disulfonates are widely used, effective blockers of many chloride membrane transport systems and chloride channels. These compounds at 0.5 mM concentration strongly hyperpolarize salamander horizontal cells and abolish their light responses (J. Kleinschmidt, Invest. Ophthalm. Vis. Sci. (Suppl.) 30, 124, 1989). Since SITS and DIDS fluoresce blue when excited with UV light, fluorescence microscopy might reveal the distribution of binding sites for these compounds. I now report that when isolated goldfish, salamander or Xenopus retinæ are incubated with 25 μ M DIDS or 250 μ M SITS under the same conditions which block horizontal cell responses, UV-excited blue fluorescence is found to be localized selectively to cone outer segments. Different cone types appear to be stained to different extents. Under the same incubation conditions, 10 mM Procion Yellow M4RAN (see Laties & Liebman, Science 168, 1475-1477, 1970) or 5-500 μ M FITC do not stain cone outer segments. Goldfish and human red blood cells or rbc ghosts (10^8 anion exchangers/cell) show no visible fluorescence at these concentrations of DIDS or SITS under the same excitation and viewing conditions. These findings indicate a high density of SITS/DIDS binding sites on cone outer segments. Whether these sites are anion binding sites of an anion transporter, anion channel or some other anion binding protein, remains to be determined.

Supported by NIH grant EY05213.

DEPOLARIZING PHOTORESPONSES IN PHOTORECEPTORS OF THE PARIETAL EYE OF LIZARDS. G. A. Engbreton and E. Solessio*. Institute for Sensory Research and Department of Bioengineering, Syracuse University, Syracuse, New York 13244.

The parietal eye of lizards is a highly organized photoreceptive organ. Its cone-like photoreceptors synapse directly onto ganglion cells. Despite the lack of interneurons this simple eye encodes information about the intensity and chromatic qualities of light stimuli.

Local ERG's recorded in the lumen (analogous to subretinal space) consist of a negative-going 4 to 6 mV response to monochromatic stimuli. Chromatic adaptation was used to isolate two antagonistic spectral components with maximal sensitivities at 440 and 495 nm. Responses to green stimuli were characterized by a rapid initial transient and exponential decay at "OFF". Blue stimuli limited the amplitude of the initial transient and yielded a strong lumen-negative "OFF" response. Superfusion with low Ca^{2+} Ringers solution slowed the ERG but did not eliminate the components. We believe the source of the signal lies in the mass activity of photoreceptor cells.

We have recorded from, stained, and identified parietal eye photoreceptor cells. Typical resting membrane potentials were -50 to -60 mV. Responses to light were depolarizing with an amplitude of up to 20 mV. The latency of the response was similar to that of the ERG. As observed in the ERG, responses to green stimuli exhibited a fast initial transient whereas responses to blue stimuli were characterized by a strong "OFF" transient. We have not yet determined if the presence of the two spectral mechanisms in the intracellularly-recorded photoreponse originates in synaptic interactions between two populations of photoreceptors, or in the presence of a bistable photopigment.

122.4

EFFECTS OF IODOACETATE ON $[H^+]_o$ OUTSIDE ROD PHOTORECEPTORS IN CAT. F. Yamamoto and Y. Honda*. Dept. of Ophthalmology, Kyoto University, Kyoto, 606 Japan

Measurements of $[H^+]_o$ by intraretinal microelectrodes showed that pH outside dark-adapted rods was relatively acidic in the dark, with maximum acidity (pH 7.04) in the outer nuclear layer. Hypoxia in the dark further acidified the extracellular space surrounding rods (Yamamoto, F. and Steinberg, R.H., Soc. Neurosci. Abstr. 15:206, 1989). Illumination produced intraretinal alkalization that was largest (up to 0.2 pH units) in outer nuclear layer (Borgula, G.A. and Steinberg, R.H., IOVS Suppl. 25:289, 1984). It is commonly known that iodoacetate is an inhibitor of triose phosphate dehydrogenase and causes a lowering of the metabolic energy production (Noell, W.K., 1951). We studied the effect of iodoacetate on subretinal pH, hypoxic acidifications and light-evoked alkalizations using double-barrel H^+ -selective microelectrodes in the intact cat eye, *in vivo*. Intravenous infusion of iodoacetate (5 mg/kg) produced rapid and prominent intraretinal alkalization in the subretinal space, with an increase of trans-epithelial potential in the dark. After the injection, the hypoxic acidifications were completely suppressed while there was a little change in the amplitude of light-evoked alkalization. These results suggest that the hypoxic acidification originates from the glycolysis of rod photoreceptors and also the subretinal acidification in the dark is related to rod glycolysis.

122.6

IDENTIFICATION OF 11-*cis* RETINAL IN THE CHICKEN PINEAL J.H. Sun¹, R.J. Reiter¹, N.L. Mata², A.T.C. Tsing² ¹ Dept. of Cell & Struct. Biol., Univ. Texas Health Science Center, San Antonio, Tx 78284; ² Div. of Life Sciences, Univ. Texas at San Antonio, San Antonio, Tx 78249

Direct evidence is not available that 1) rhodopsin-like photopigment exists in the chicken pineal and that 2) this visual pigment is responsible for the light sensitive mechanism in the gland. Therefore, the objective of this study was to test for the existence of visual pigment in the chicken pineal through the identification of 11-*cis* retinal. 11-*cis* and all-*trans* retinals were extracted from light and dark adapted chicken pineals and analyzed by high performance liquid chromatography (HPLC) using the formaldehyde method (Suzuki et al., Vision Res. 26:425,1986). 11-*cis* retinal was initially identified by coelution with an authentic standard. Further characterization was carried out by collecting the retinal from the HPLC eluant, subjecting it to reduction by sodium borohydride and then identifying the derived 11-*cis* retinol using HPLC. Proportions of 11-*cis* retinal to total pineal retinals were also studied from decapitated heads after light and dark adaptation. Analyses of dark adapted, pooled chicken pineals revealed equal proportions of 11-*cis* and all-*trans* retinals at two hours after dark and at night. Two hours of light adaptation resulted in the reduction of the 11-*cis* proportion (from 50%) to 26% of total retinals. These observations suggest that 11-*cis* retinal exists in the chicken pineal and that it undergoes light-induced *cis* to *trans* isomerization in a manner similar to the visual pigment chromophores in the vertebrate retina. 122.8

CAN BIREFRINGENCE EXPLAIN THE POLARIZATION ANALYZING CAPABILITY OF TELEOST DOUBLE CONES?

M. Rowe*, N. Engheta*, and E.N. Pugh, Jr. Inst. of Neurological Sciences and Depts. of Electrical Engineering & Psychology, Univ. of Pennsylvania, Philadelphia, PA 19104.

Behavioral experiments have demonstrated that double cones mediate a differential polarization sensitivity in the green sunfish, *Lepomis cyanellus* (Neurosci. Abs. 16:406). In an attempt to understand the mechanism by which double cones confer this ability to obtain information about the polarization of light, mathematical models have been created to determine if birefringence in these structures can explain the animals' differential sensitivity to light linearly polarized at different angles. Solving Maxwell's equations for a highly simplified geometry, and then expanding plane waves with orthogonal polarizations into the solutions thus obtained indicates that geometrical birefringence is a viable mechanism which may underly the behavioral responses. Although promising, the results obtained with this model, which has a step index of refraction profile, indicate that such an effect cannot account for the behavioral data, since the difference in transverse electric field strength between waves excited by the two initial polarization states would not be large enough if the photoreceptors have a uniform refractive index as in this step index model. Electron micrographs from the retina of *L. cyanellus* indicate that the index of refraction in the double cones may vary continuously from a maximum in the center to some minimal value at the periphery (S.S. Easter, personal communication). We anticipate that a graded index model which more closely approximates the double cone structure will lead to a larger difference in the transverse electric field strength for the two types of incident wave. Currently models which incorporate this assumption of a smoothly graded profile are being developed, along with measurements of the guiding properties of double cones in whole mounted retinas.

IDENTIFICATION OF RED-GREEN AND BLUE SENSITIVE CONES IN THE GOLDFISH RETINA BY PHOTORECEPTOR-CLASS SPECIFIC ANTIBODIES. S.C. Sharma. Department of Ophthalmology, New York Medical College, Valhalla, NY 10595.

Antisera raised against synthetic peptides generated from amino acid sequences for cDNAs of human pigment polypeptides (Lerea *et al.*, Neuron 3:367, 1990) was used in the present study to discern the photoreceptor subtypes in the retina of common goldfish. These polyclonal antibodies selectively label red- and green-sensitive cone opsin (antisera 4942A) and blue-cone opsin (antisera 108B) in human retina and cross react well with goldfish cones.

Based upon labelling pattern in whole-mounted and sectioned goldfish retina, only 12-15% of the entire retina was comprised of blue-sensitive cones. Nearly 80% of the retina was comprised of red-green cones. Distribution of both red-green and blue cone was found to be higher in the ventral than the dorsal retina. Supported by N.I.H. EY 01426.

COMPUTED SPREAD OF VOLTAGE BETWEEN CONES IN MONKEY FOVEA. A. Hsu, R.G. Smith, and P. Sterling, Inst. for Neurological Sciences and Dept. of Anatomy, Univ. Pennsylvania, Phila., PA 19104.

Spatial resolution by the foveal cone array is apparently limited by optical blur (5.4 μ m diam. Gaussian at 1/e amplitude, 2mm pupil), summation across the cone aperture (3 μ m diam.), and cone spacing (3 μ m, center to center). Evidence of gap junctions between neighboring pedicles of foveal cones suggests that electrical coupling might cause additional signal spread. We computed the degree of spread using a compartmental model. A cone's outer segment and inner segment plus soma was simulated as 2 spheres; the axon was simulated as a cable (250 μ m long, 1.5 μ m diam.); and the pedicle was modeled as a sphere (7 μ m diam.). Membrane Resistance was 15 k Ω -cm². Cones were square-packed in a 15x15 array and coupled to 4 nearest neighbors with inter-cone conductance at 2.7 x 10³ pS.

The voltage arising from current evoked at a cone outer segment spread to neighboring cone pedicles, decaying exponentially with a space constant of 3 μ m. Convoluting this exponential with the blur due to optics and summation across the cone aperture gave a spread function with a Gaussian peak and an exponential skirt (diam. at 1/e 9.3 μ m). Changing membrane resistance by 2-fold altered the diameter of the spread function by less than 1 μ m; changing coupling conductance by 2-fold altered the diameter of the spread function by less than 2 μ m.

Psychophysical experiments suggest that signal blur is entirely accounted for by optical factors at high luminance. Conceivably, therefore, cone coupling occurs at low luminance. Since low luminance is served mainly by M ganglion cells, modest spatial averaging between cone pedicles might improve contrast sensitivity at no cost to spatial acuity. Supported by EY08124.

ULTRASTRUCTURE OF *LIMULUS* PHOTORECEPTORS IN EXPERIMENTAL PROTOCOLS: PHYSIOLOGISTS' FAVORITE RECIPES. Brad Hanna¹, Robert N. Jinks², Hui-juan Zhang³, Leonard Kass³, George H. Renninger¹, and Steven C. Chamberlain^{2,4}. ¹Biophysics Group, U. of Guelph, Guelph, ONT, ²Dept. of Bioengineering and ³Dept. of Zoology, U. of Maine, Orono, ME; and ⁴Institute for Sensory Research, Syracuse U., Syracuse, NY.

Most physiological experimentation using the *Limulus* ventral eye has used simple excision and incubation in seawater. One significant alternative approach has been excision and incubation in an organ culture medium (*J. Gen. Physiol.* 72:539). We have compared the ultrastructure of photoreceptors excised in light and maintained for 5 hrs in darkness in seawater or organ culture with that of cells fixed *in situ* (*J. Gen. Physiol.* 80:839). Organ culture incubation produces cells with ultrastructure similar to those fixed *in situ*. Two major differences are observed in cells incubated in seawater. The layers of glia covering the R-lobe are ultrastructurally disrupted, and the fused quintuple membrane between adjacent microvilli normally seen in dark adapted rhabdom is absent. The reduction of microvillar fusion is reminiscent of structural light adaptation in the lateral eye (*J. Neurosci.* 4:2792) and probably accounts for the lower total resistance of cells maintained in seawater compared to those maintained in organ culture. Recent enzymatic treatments to enable whole-cell recording from ventral photoreceptors have yielded cells with essentially normal light responses (*ARVO Abstr.* 31:389). Many of these cells have nearly *in situ* ultrastructure, except that the glial covering is vastly attenuated and the mitochondrial matrix is vacuolized suggesting that mitochondria may have relatively minor roles in the light responses measured. Similar enzymatic treatments to dissociate the retina of the lateral eye have produced promising whole-cell recordings (*ARVO Abstr.* 31:389). The ultrastructure of these cells varies over a range from essentially normal to trauma response characterized by extensive vacuolization, breakdown of the rhabdom, and a number of lysosomal pathway structures.

LATERAL SIGNAL PROPAGATION VIA CONE TELODENDRITES IN TIGER SALAMANDER RETINA. Vaishali Merchant* and Steven Barnes, Neuroscience Research Group, University of Calgary Faculty of Medicine, Calgary, Alberta, Canada T2N 4N1.

Fine neurites extending laterally up to 45 μ m from cone pedicles could provide pathways by which signals from distant cells might modify the cones' receptive field. The extent to which synaptic input arising distally in a telodendrite is electrotonically decremented at the cell body could limit this form of lateral interaction and was studied using computer simulations of the cone membrane.

Patch-clamped, lucifer yellow-filled cones in slices were morphologically and electrically analysed to determine passive and active properties. Cones had on average five telodendrites extending from the pedicle for 14.5 ± 11.2 μ m (mean ± S.D., N=5 cones), an input resistance of 911 ± 680 Mohm at -40 mV and capacitance of 26.3 ± 8.9 pF (N=14). An earlier model (Kraft and Burkhardt, 1988, JCN 249:13) indicated that communication between walleye cone cell bodies and telodendrites was good bidirectionally. Our work suggests a much higher value of membrane resistivity (40 kohm-cm²) than the previous microelectrode work, where low input resistance shunted the signal-shaping actions of voltage-gated ion channels. Even so, when implemented with homogeneous membrane properties and ionic currents I_h, I_{KX}, and I_{Ca} (using the program Manuel with thanks to David Perkel of UCSF), our simulations give predictions similar to the earlier work (e.g. coupling ratios >88%). But inclusion of inhomogeneities yields different results. For example, increasing telodendrite Ca channel density leads to distinct synaptic responses in the different cone regions. Strategic placement of synaptic conductances or addition of leak conductance to the cell body increases electrical separation of telodendrites and the soma. The simulations suggest mechanisms that could modify telodendrite-cell body coupling. [Supported by the AHFMR and the MRC].

122.12

SIGNAL-DETECTION CHARACTERIZATION OF NEURAL CODE EFFICACIES IN SINGLE PHOTORECEPTORS: EFFECT OF STIMULUS INTENSITY AND LIGHT ADAPTATION. Zixi Cheng* and Gerald S. Wasserman, Sensory Coding Laboratory, Dept. of Psychological Sciences, Purdue University, West Lafayette IN 47907-1364.

The multiple meaning theory of neural coding and its extension, the task dependence theory, both suggest that different features of identical neural signals (i.e., codes) may represent information (see Nisly and Wasserman, *Psychological Bulletin*, 1989, 106, 483-496). Why should more than one neural code exist? One possibility, suggested by the work of Cohn (*IEEE Transactions on Systems*, 1983, 13, 873-881), is that different codes are differentially efficacious in different circumstances. We therefore measured the efficacy of several neural codes in different circumstances. We recorded intracellularly from photoreceptors of *Limulus* and characterized code efficacy by measuring the detectabilities (i.e., by measuring d') of various codes while varying stimulus intensity and the state of adaptation. We found reliable differences in code efficacy which were reliably altered by intensity and adaptation.

CORRELATION OF PHOTORECEPTOR STRUCTURE AND LIGHTING ENVIRONMENT: IMPLICATIONS FOR PHOTOSTASIS. Eric P. Hornstein* and Steven C. Chamberlain. Institute for Sensory Research and Department of Bioengineering, Syracuse University, Syracuse, NY.

Why is photosensitive membrane shed and synthesized? A common assumption is that cumulative age and light damage require its periodic replacement. Alternately, the daily cycling of photosensitive membrane may serve to compensate for seasonal changes in light flux, i.e. to maintain photostasis. If the main purpose of photoreceptor membrane turnover is the maintenance of photostasis, then species living in environments with no seasonal changes in light intensity might lack this process. Indeed, recent studies of the photoreceptors of the deep sea species, *Bathynomus giganteus* and *Rimicaris exoculata*, suggest that they may have minimal or no turnover of light sensitive membranes. Specifically, the absence of conventional membrane turnover is suggested by the hypertrophy of the rhabdomeral segment (R-segment) and the atrophy of the arhabdomeral segment (A-segment) so that there is essentially no room for the shedding and synthesis processes to proceed.

We have surveyed the photoreceptor structure of fifteen invertebrate species from a variety of habitats. Our morphometric measure is the ratio of the volume of the R-segment to the volume of the A-segment. This ratio is typically significantly less than one for species living in cyclic lighting with seasonal changes in daily light flux. For deep sea species living in noncyclic lighting, the ratio is greater than one. Absent cyclic lighting, there seems to be no significant cycling of the phototransductive membrane. Animals living in noncyclic lighting include both those such as *R. exoculata* which live in extremely dim environments and those which prey on bioluminescent species such as *B. giganteus* that live in relatively bright environments. Aging or deleterious effects of cumulative light absorption do not themselves appear to require cycling of photosensitive membrane. Perhaps photostasis is a general principle in visual systems which mandates membrane turnover for animals living in seasonally varying cyclic lighting. Supported by NIH EY03446.

CONSEQUENCES OF RETINAL DETACHMENT ON GENE EXPRESSION IN *XENOPUS LAEVIS* EYECUPS. G. Glaesener-Cipollone¹, M.W. Kaplan², C.B. Sternitt² and R.D.ernald³. ¹Inst. Gen. and Microbiol., Univ. Wuerzburg, FRG, ²Dow Neurol. Sci. Inst., Portland, OR, ³Stanford, CA.

Retinal photoreceptors require an intimate connection with pigmented epithelial cells (RPE) for normal functioning. In many species, detachment of the retina from the RPE produces pronounced changes in photoreceptors, for example the inhibition of disk shedding and the disorganization of disk renewal (Kaplan et al. 1990).

We have studied whether retinal detachment affects gene regulation in photoreceptors by analyzing the production of opsin, transducin and retinal regeneration slow protein (RDS) mRNA. Experiments were carried out in *Xenopus laevis* retinas that had been maintained in eyecup cultures for up to 4 days. The mRNA abundance in attached and isolated retinas was measured by Northern blot analysis. Additionally, in situ hybridization on retinal tissue sections were carried out to reveal the specificity of the RNA probes and to support the quantitative data found with the Northern blots.

In order to exclude changes in RNA transcription induced by a day-night rhythm we collected freshly excised *Xenopus laevis* retinas at different times of the day and investigated the opsin, transducin and RDS mRNA abundance by Northern blot analysis. No profound changes in the abundance of any of the investigated mRNAs could be detected indicating that the regulation of the mRNA transcription does not underlie a cyclic rhythm.

The Northern blot analysis indicated that neither the opsin nor the RDS transcription were affected by retinal detachment. In contrast, a clear decrease in transducin mRNA abundance appeared. This suggests that the apposition of the retina with the RPE is not a necessary precondition for the normal expression of opsin and RDS but plays an important role in the regulation of transducin gene expression.

A VITAMIN A₂-BASED VISUAL SYSTEM IN A FULLY TERRESTRIAL VERTEBRATE. J. Provencio, A.C. Bizzell* & R.G. Foster. Dept. of Biology, Univ. of Virginia, Charlottesville, VA 22901.

Current dogma states that freshwater vertebrates possess vitamin A₂-based photopigments (pigments containing 11-*cis*-3,4-didehydroretinal as the functional chromophore). Conversely, marine and terrestrial vertebrates have vitamin A₁-based pigments (11-*cis*-retinal chromophore). Those animals that only spend a portion of their life cycle in freshwater, such as migratory fish and amphibians, possess both chromophores, but regulate the relative concentrations with respect to the environment. Using high performance liquid chromatography (HPLC), we have demonstrated the first example of an exclusively vitamin A₂-based visual system in a completely terrestrial vertebrate, *Anolis carolinensis*.

HPLC analysis of retinoid oxime extracts from *Anolis* eyes reveals a vitamin A₂-derived chromophore. No vitamin A₁-derived chromophore was detectable. Spectral analysis of the *Anolis* syn 11-*cis* oxime isomer yields a λ_{max} of 368 nm with a "cis peak" absorbance of 304 nm. The elution time and spectral profile of this extract corresponds precisely with vitamin A₂-derived retinoid oxime standard. This study suggests that a long wavelength photopigment may reside within the retina of *Anolis*. (Supported by an NSF Grad. Fellowship to IP and Jeffress Memorial Trust J-213 to RGF.)

ONTOGENETIC LOSS OF UV PHOTO-SENSITIVITY IN RAINBOW TROUT, DETERMINED USING OPTIC NERVE COMPOUND ACTION POTENTIAL RECORDING. L. Beaudet, H.I. Browman, and C.W. Hawryshyn. Dept. of Biology, University of Victoria, P.O. Box 1700, Victoria, B.C., Canada V8W 2Y2.

We characterized the photopic spectral sensitivity of ON and OFF responses from small (< 20 g) and large (> 55 g) rainbow trout (O. mykiss, RT) using various adapting backgrounds. The ON responses of three small RT exhibited sensitivity peaks corresponding to UV, S, M, and L wavelength photoreceptor mechanisms. The UV sensitivity peak was one log unit higher than those for the M and L mechanisms, and 0.5 log unit higher than the S mechanism peak. When a UV and S wavelength adapting background was added, the relative sensitivity of the UV peak was depressed by two log units, the S peak by one log unit, while the sensitivities of the M and L photoreceptor mechanisms were unchanged. The ON response from three large RT did not exhibit a selectively depressed UV peak, indicating that sensitivity to these wavelengths was not generated by a UV mechanism; these fish were not UV photo-sensitive. The relative sensitivity of the OFF response was always lower than that for the ON and was characterized by broader peaks in the UV and M parts of the spectrum. L.B. was supported by a NSERC Canada Postgraduate Scholarship, H.I.B. by a MRC Canada Postdoctoral Fellowship, and C.W.H. by a NSERC Canada URF and Operating Grant (# URF 0043984).

122.16

REGULATION OF MELATONIN SYNTHESIS AND NAT ACTIVITY BY A PHOTORECEPTOR-LIKE PHOSPHODIESTERASE. M. Max, T. Silliman*, M. Menaker. Department of Biology, University of Virginia, Charlottesville VA 22901

Zaprinast, (M&B 22,948) has been shown to have a dual effect on purified photoreceptor phosphodiesterase (PDE). Zaprinast competitively and specifically inhibits the light- or trypsin-activated form of PDE; but partially stimulates the dark form of PDE. We find that Zaprinast, at doses similar to those used to inhibit purified PDE, blocks the light-induced suppression of melatonin production from perfused photosensitive trout pineal glands, (*Salmo trutta*). It also partially suppresses melatonin production in darkness. These results suggest that a photoreceptor-like PDE mediates the light-induced suppression of melatonin.

We also find that Zaprinast blocks light-induced suppression of the activity of trout pineal serotonin N-acetyltransferase (NAT), the penultimate enzyme in the melatonin synthesis pathway, without increasing its activity in darkness. When 10 μ M Zaprinast is combined with a threshold light stimulus, NAT activity is elevated above dark levels. In darkness, with 10 μ M Zaprinast, NAT activity is partially suppressed. We hypothesize that: In darkness a photoreceptor-like PDE is active at a low rate and sets the upper limit of NAT activity; the dark PDE activity is stimulated by Zaprinast, which results in a partial suppression of NAT activity and melatonin production; in light, the PDE becomes sensitive to inhibition by Zaprinast, which therefore increases NAT activity and blocks the suppressive effect of light on melatonin synthesis.

Because photosensitive pinealocytes contain many of the same molecules known to mediate the effects of light in retinal photoreceptors, it has often been suggested that they also share similar phototransduction cascades. If our interpretation of the effects of Zaprinast reported above is correct, it supports this idea and suggests that a critical feature of retinal phototransduction, the activation of PDE by light, is involved in the photic regulation of pineal melatonin synthesis.

RESTORATION OF RHODOPSIN LEVELS IN RETINOID-DEPRIVED RATS AFTER VITAMIN A REPLETION. D.-M. Chen¹, M.L. Katz² and W.S. Stark¹.

¹Div. of Biol. Sci. and ²Dept. of Ophthalmol., U. of Missouri, Columbia 65212. In rats deprived of the retinoid precursors of the visual pigment chromophore 11-*cis* retinal, rod cell pigment rhodopsin levels gradually decline. After 23 weeks of deprivation, rhodopsin levels are less than 15% of normal. The density of the protein component of the visual pigment (opsin) remains unchanged, although outer segment volume is reduced by about 60%. Thus, rod cells of retinoid-deprived rats contain a large amount of chromophore-free opsin. Experiments were conducted to determine whether the effects of deprivation could be reversed by rapidly repleting retinoid-deprived animals with vitamin A. Dark-adapted rats that had been fed a diet lacking retinoids other than retinoic acid for 23 weeks were given a single i.m. injection of all-*trans* retinol. At various times following injection, electroretinograms (ERGs) were recorded from a number of animals. Before injection, ERG thresholds of the deprived animals were an average of 3.5 log units higher than those of rats that had been fed a retinoid-adequate diet. Maximum ERG response amplitudes were decreased by an average of 37%. Partial recovery of visual sensitivity was observed as early as 4 hrs after retinol administration. By 7 days after injection, the ERG thresholds and maximum amplitudes had returned to almost control levels. Direct measurement of rhodopsin levels in the retinas of treated animals also indicated that visual pigment levels recovered quickly after retinol administration. An increase in rhodopsin levels was observed as early as 3 hrs after vitamin A injection. The early rapid recovery of rhodopsin levels once chromophore precursors were made available suggests that the chromophore-free opsin synthesized by retinoid-deprived animals can be converted to functional rhodopsin if 11-*cis* retinal becomes available. Continued recovery until normal sensitivity is achieved suggests that outer segment size eventually returns to normal.

122.20

THYROXINE-INDUCED LOSS OF ULTRAVIOLET PHOTO-SENSITIVITY IN RAINBOW TROUT, *Oncorhynchus mykiss*. H.I. Browman and C.W. Hawryshyn. Dept. of Biology, Univ. of Victoria, Victoria, B.C., Canada V8W 2Y2.

We used thyroxine to induce a precocial loss of UV sensitivity in rainbow trout (RT). During their normal ontogeny, RT are UV sensitive (360 nm peak) to 40-50 g and, over this weight range, a transition to loss of UV sensitivity occurs. Three fish (12-17 g) were treated with 300 ug/l thyroxine (in their aquarium water; the solution was changed daily) for 35 days (treatment fish). The other three fish (12-17 g) were handled in an identical manner, but no thyroxine was added to their aquaria (control fish). The spectral sensitivity of the same six RT was measured, using a heart-rate conditioning protocol, before treatment, and after 15 and 35 days. Prior to treatment, all fish exhibited sensitivity peaks corresponding to UV, S, M, and L photoreceptor mechanisms. At 15 days, the UV peak in treatment fish was shifted towards 400 nm, broadening the S peak, while the M and L peaks were unchanged. There was no change in control fish. At 35 days, treatment fish exhibited sensitivity peaks corresponding to S, M, and L photoreceptor mechanisms; there was no UV peak. Control fish were unchanged. We conclude that elevated levels of thyroxine induces a precocial transition in spectral sensitivity identical to that which occurs during normal ontogeny. H.I.B. was supported by a MRC Canada Postdoctoral Fellowship, and C.W.H. by a NSERC Canada URF and Operating Grant (# URF 0043984).

123.1

GABA IMMUNOREACTIVE NEURONS AND TERMINALS IN THE AUDITORY BRAINSTEM AND THALAMUS OF THE NORTHERN LEOPARD FROG, *RANA PIPIENS PIPIENS*. J.C. Hall, Zoology Dept., University of Tennessee, Knoxville, TN 37996.

Immunohistochemical localization of γ -aminobutyric acid (GABA) was used to identify GABAergic neurons and terminals in the auditory brainstem and thalamus of *Rana p. pipiens*. The antiserum against GABA that I used was kindly provided by Dr. R.M. Buijs and Dr. C.W. Pool of the Netherlands Institute for Brain Research, Amsterdam.

Preliminary observations revealed immunoreactive puncta surrounding unlabeled cell bodies in all primary auditory nuclei including the dorsolateral nucleus, superior olivary nucleus and, superficial reticular nucleus in the caudal brainstem; the laminar nucleus, principal nucleus and, magnocellular nucleus in the torus semicircularis, or auditory midbrain; and the posterior nucleus and central nucleus in the thalamus.

In the caudal brainstem, GABA immunoreactive cell bodies were found only in the superior olivary nucleus. In the torus semicircularis, immunolabeled cell bodies were observed in both the principal nucleus and the magnocellular nucleus; though, the vast majority of labeled cell bodies were located in the magnocellular nucleus. Both the posterior and central thalamic nuclei contained immunopositive cell bodies but, they were few in number.

GABA has been identified as an inhibitory neurotransmitter in the auditory system of birds and mammals. The results of this study indicate that GABA likely mediates inhibitory interactions in the auditory pathway of frogs as well. I am currently conducting studies to test this hypothesis. (Supported by BRSG RR-07088)

123.3

GABA AND GLYCINE RELEASE FROM GUINEA PIG INFERIOR COLLICULUS AFTER ABLATION OF DORSAL NUCLEUS OF LATERAL LEMNISCUS. S.J. Potashner, A. Shneiderman, M.B. Chase*, C. Benson, and J.M. Rockwood*. Dept. of Anatomy & Center for Neurological Sci., Univ. Connecticut Health Center, Farmington, CT, 06030.

The dorsal nucleus of the lateral lemniscus (DNLL) receives many of the auditory projections that ascend to the inferior colliculus (IC) and projects bilaterally to the IC as well as to the contralateral DNLL. The projection to the contralateral IC may be inhibitory, as over 90% of its axonal endings have pleomorphic vesicles (J. Comp. Neurol. 286:28 '89) and many DNLL cells contain GABA-like immunoreactivity (Brain Res. Bull. 13:585 '84). The projection to the ipsilateral IC provides half the number of synaptic endings furnished by the contralateral projection, and only 70% have pleomorphic vesicles.

To determine if GABA and glycine could be transmitters of DNLL neurons projecting to the IC, we measured the electrically-evoked release of exogenous ^3H -GABA and ^{14}C -glycine from each IC *in vitro* 2-4 days after destroying neurons in the left DNLL with injections of kainic acid. The release of both compounds was Ca^{++} -dependent. Glycine release was unaffected by DNLL lesions. GABA release was depressed in direct proportion to the degree of neuronal loss in the lesioned DNLL. After complete ablation of the left DNLL, GABA release in the contra- and ipsilateral IC was reduced by 51% and 25% respectively. These findings are consistent with the hypothesis that DNLL projections to the IC which contain pleomorphic vesicles mediate the synaptic release of GABA. (Supported by DC00199 from NIH-NIDODD)

GLYCINE AND GABA IMMUNOSTAINING DEFINES FUNCTIONAL SUBREGIONS OF THE LATERAL LEMNISCAL NUCLEI IN THE MUSTACHE BAT. D.T. Larue, T.J. Park, G.D. Pollak, and J.A. Winer. Dept. of Molecular and Cell Biology, Univ. of California, Berkeley, CA 94720 and Dept. of Zoology, Univ. of Texas, Austin, TX 78712.

We studied the distribution of GABA and glycine immunoreactive cells and axons in the mustache bat to find the sources of inhibitory neurons projecting to the central nucleus of the inferior colliculus (ICC). We injected WGA-Apo-HRP-Gold (WAHG) into the ICC and immunostained both free-floating 50 μm , and post-embedded 1 μm -thick sections.

The intermediate nucleus (INLL) is very prominent and contains many cells and puncta immunoreactive for GABA, glycine, or both. The dorsolateral region of the INLL that projects to the 60 kHz sonar signal representation in the ICC has a remarkable concentration of both GABA+ and Gly+ puncta as well as Gly+ somata. The region projecting to the 90 kHz representation in the ventrolateral part of the nucleus (J. Wenstrup et al. unpublished observations) has a similar pattern. No such neurochemical differentiation of a tonotopic subregion has been previously reported.

The ventral nucleus of the lateral lemniscus is divided into dorsal and ventral parts. The dorsal part of the ventral nucleus (VNLLd) has both GABA+ and Gly+ cells and puncta without the striking columnar organization seen in the ventral part. Both GABA+ and Gly+ cells project to the IC. The columnar (ventral) part of the ventral nucleus (VNLLv) consists of rows of cells that are almost exclusively Gly+, and receive many GABA+ and fewer Gly+ puncta. Tonotopically projecting bands of Gly+ cells across the columns in VNLLv are labeled by colocalization with WAHG injected into the ipsilateral ICC. This projection is the major source of Gly+ axons and puncta in the mustache bat IC as it is in the guinea pig and chinchilla, (Saint Marie and Baker, Brain Res. 524:244-253 1990).

The Gly+ cells from the monaural nuclei, INLL and VNLL, project ipsilaterally to the IC. An ipsilateral projection from Gly+ cells also occurs in the superior olivary complex, (see Saint Marie et al., J. Comp. Neurol. 279:382-396 1989; Park et al., 1991, this vol.). No crossed projection to the IC from Gly+ cells has been reported. How these ipsilateral glycinergic influences might shape acoustic response properties in the ICC awaits further study.

123.2

ACETYLCHOLINESTERASE DIFFERENTIALLY STAINS PARALLEL PATHWAYS IN THE BARN OWL'S AUDITORY BRAINSTEM. R. Adolphs, Div. of Biology 216-76, Caltech, Pasadena, CA 91125.

Auditory nuclei in the brainstem of the barn owl, *Tyto alba*, stain differentially with acetylcholinesterase (AChE) histochemistry. At the level of the cochlear nuclei, nucleus angularis showed very intense staining of fibers and cell bodies, whereas n. magnocellularis showed only a weak staining of cell bodies and no fiber staining. Nucleus laminaris, which receives bilateral input from n. magnocellularis, showed very faint staining of terminals surrounding cell bodies. In the lemniscal nuclei, nucleus ventralis lemnisci lateralis pars posterior (VLVp) stained more intensely than the adjacent pars anterior (VLVa). In the inferior colliculus (IC), the shell of the central nucleus, which is a terminal field both of n. angularis and VLVp, stained more intensely than did the core of the central nucleus, which is a terminal field of n. laminaris. The external nucleus of IC stained intensely also.

These staining patterns suggest that nuclei or subdivisions of nuclei which process interaural level differences (n. angularis, VLVp, the shell of IC) stain more strongly for AChE than do those nuclei which process interaural time differences (n. magnocellularis, n. laminaris, VLVa, the core of IC). Moreover, this staining pattern is complementary to that seen with calbindin-immunohistochemistry (Takahashi et al., J. Neurosci. 7(6): 1843-1856 (1987)).

Results from baby owls indicate that the staining pattern seen with AChE has already formed at 15 days post hatching.

R.A. is a Howard Hughes Medical Institute Fellow.

123.4

THE ORGANIZATION OF GABAergic NEURONS IN THE CAT MEDIAL GENICULATE BODY: A QUANTITATIVE IMMUNOCYTOCHEMICAL STUDY OF POST-EMBEDDED MATERIAL. D.M. Huchton*, D.T. Larue, J.Y.-M. Sun*, and J.A. Winer. Department of Molecular and Cell Biology, University of California, Berkeley, California 94720-2097.

The cat medial geniculate body contains three main divisions and many smaller subdivisions that differ in their neuronal architecture, patterns of cortical and midbrain connectivity, and functional organization. Previous work in several species has shown that GABA is the likely transmitter for many thalamic local circuit neurons. The purpose of this study is to compare the intrinsic organization of these nuclei using 1 μm -thick sections of plastic-embedded material immunostained with an antiserum to GABA. If the number, type, and arrangement of GABAergic cells is similar between subdivisions, perhaps thalamic local circuitry is highly conserved in mammals despite otherwise important species differences in the absolute number of GABAergic neurons.

The major findings are (i) that divisions differ significantly in the proportion of GABAergic cells, the ventral division having 34%, the dorsal division 26%, and the medial division 21%. We find (ii) striking differences in the proportion of GABAergic neurons along a caudal-to-rostral axis in each division: the number in the ventral division increased (from 29 to 38%), the dorsal division decreased (32 to 16%), and the medial division increased four-fold (9 to 39%). There is (iii) a statistically significant difference in cell size between the GABAergic and immunonegative cells only in the dorsal and the medial divisions. Finally, (iv) GABAergic cells average about 12 μm in diameter, and have a spindle-shaped perikaryon from which slender dendrites arise without a preferred orientation.

These results suggest a basic similarity in the form, though not the number, of GABAergic neurons in different medial geniculate body divisions. These regional differences may be correlated with caudal-to-rostral differences in physiological processing reported in the auditory thalamus (C. Rodrigues-Dageaff et al., Hearing Res. 39:103-126, 1989).

Supported by United States Public Health Service grant RO1 NS16832-11.

We thank Dr. R.J. Wenthold for the antiserum.

123.6

GLYCINE AND GABA IN THE SUPERIOR OLIVARY COMPLEX OF THE MUSTACHE BAT: PROJECTIONS TO THE CENTRAL NUCLEUS OF THE INFERIOR COLLICULUS.

T.J. Park, D.T. Larue, J.A. Winer, and G.D. Pollak. Dept. of Zoology, Univ. of Texas, Austin, TX 78712 and Dept. of Molecular and Cell Biology, Univ. of California, Berkeley, CA 94720.

The superior olivary complex (SOC) is the first binaural region of the auditory system. Both the lateral (LSO) and medial (MSO) nuclei are highly developed in the mustache bat and both send major projections to the central nucleus of the inferior colliculus (ICC). We studied the distribution of GABA and glycine immunoreactive cells and axons in the SOC to assess the inhibitory inputs to these nuclei and the inhibitory projections they send to the ICC. To examine projection cells from SOC to the ICC, we combined immunostaining with retrograde labelling from ICC injections of WGA-Apo-HRP-Gold in both 50 μm - and 1 μm -thick post-embedded sections.

In the LSO, about 30% of the cells are Gly+ and project ipsilaterally to the ICC as in the cat (Hutson et al., Soc. Neurosci. Abstr. 13: 548, 1987; Saint Marie et al., J. Comp. Neurol. 279: 382-396, 1989). There is a dense array of Gly+ fibers in the neuropil and axosomatic puncta on Gly+ and immunonegative cell bodies. The distribution of GABA, however, is striking: in the lateral limb there are a few GABAergic cells in a sparse GABA+ neuropil, while medially there is an abrupt change to a dense plexus of GABA+ fibers and puncta devoid of GABA+ cells. Adjacent, post-embedded serial sections show that, unlike the cat, many immunonegative somata receive both Gly+ and GABA+ puncta.

In the MSO, roughly half the cells are Gly+, or GABA+, and sometimes both, and all cells receive axosomatic Gly+ puncta. Gly+ cells as well as immunonegative cells project to the ipsilateral ICC, in contrast to the guinea pig and chinchilla, in which MSO projection cells did not transport ^3H -glycine (Saint Marie and Baker, Brain Res. 524: 244-253, 1990).

In light of the specialized nature of the mustache bat's auditory system both the parallels and differences from other mammals in neurochemical circuitry may provide insights into the role of the two inhibitory transmitters for information processing including mechanisms for sound localization. Supported by U.S.P.H.S. grants RO1 DC00268 (GDP) and RO1 NS16832-11 (JAW).

We thank Dr. R. J. Wenthold for the antisera.

123.7

NEURONS OF LAYER VI IN CAT PRIMARY AUDITORY CORTEX (AI): STUDY WITH GOLGI METHOD AND GABA AND GAD IMMUNOCYTOCHEMISTRY. J.J. Prieto and J.A. Wimer. Department of Molecular and Cell Biology, University of California, Berkeley, California 94720-2097.

In cat primary auditory cortex layer VI is unique since it is the origin of four different types of efferent neural pathways: ipsilateral corticocortical, commissural, corticothalamic, and corticocortical. The aim of this study is to describe its cell types in Golgi material, and to suggest which are GABAergic.

Layer VI contains two sublayers, VIa and VIb. The former has a predominantly vertical internal arrangement, dominated by the apical dendrites of pyramidal cells; the latter appears more horizontal due both to the disposition of the dendritic arbors of the cells in it and a dense fiber plexus running parallel to the border with the white matter.

Several cell types occur in Golgi material. Besides the classical small and medium-sized pyramidal cells, which are common in sublayer VIa, there are atypically-oriented pyramidal cells whose apical dendrite runs parallel to the pia (tangential pyramidal cells), or is perpendicularly directed towards the white matter (inverted pyramidal cells). Both cell types were more common in sublayer VIb. Fusiform pyramidal cells display two principal dendrites, arising from the somatic poles; these cells are oriented either perpendicular or parallel to the pia. Among the non-pyramidal cells, small, medium-sized and large multipolar cells were found, together with bipolar cells.

The distribution, form, and number of GABA- or GAD-immunoreactive neurons in layer VI were studied in adult animals in 25 μ m-thick sections. All of the non-pyramidal cell types contain GABAergic members. Strikingly, many of the cell profiles in our GAD material resembled inverted pyramidal cells. In other cortical areas spinous inverted pyramidal cells may have corticocortical axons while smooth inverted pyramidal cells project locally. Perhaps these two populations have different connections, and use different neurotransmitters.

This research was supported by United States Public Health Service Grant RO1 NS16832-11, and by a personal fellowship (J.J.P.) from the Consellería de Cultura Educación y Ciencia (Generalitat Valenciana). We thank D.T. Larue for technical assistance and Drs. E. Mugnaini, D.E. Schmechel and R.J. Wenthold for the antisera.

123.9

GLUTAMATE STIMULATED PHOSPHATIDYLINOSITOL METABOLISM IN THE AVIAN COCHLEAR NUCLEUS. L. Zirpel, N.M. Nathanson and R.L. Hyson. Hearing Research Laboratories and Depts. of Pharmacology and Physiology & Biophysics, Univ. of Washington, Seattle, WA 98195.

Neurons of the second-order auditory nucleus, nucleus magnocellularis (NM), of young chicks undergo dramatic changes in morphology and metabolism upon cessation of excitatory afferent input from the eighth nerve. The cellular mechanisms of this afferent regulation are not known. One possible mechanism is via neurotransmitter-mediated activation of a second messenger system. Synaptic transmission from eighth nerve terminals to NM neurons is mediated by an excitatory amino acid. The excitatory amino acid, glutamate, has been shown to stimulate phosphatidylinositol (PI) metabolism in rat hippocampal slices and cultured cerebellar neurons. PI metabolism generates the intracellular second messengers DAG and IP₃. It is therefore plausible that glutamate stimulation of PI metabolism is involved in afferent regulation of NM neurons by eighth nerve activity. The goal of this study was to establish the functional presence and pharmacology of glutamate stimulated PI metabolism in NM neurons.

Samples of NM isolated from transverse brain slices of 4- to 16-day-old chicks were maintained in oxygenated Ringer's and incubated with ³H-inositol in the presence of LiCl. Antagonists, when used, were added 10 min. prior to agonist. The water soluble products of PI metabolism (including IP₃) were quantified and normalized to total lipid incorporation of ³H-inositol. Our results show that glutamate (2.5 μ M - 1 mM) reliably increases PI metabolism in NM 20-50% above control levels. Addition of the kainate/AMPA receptor antagonist, CNQX and the NMDA receptor antagonist, APV potentiates this response to glutamate. In addition, aminocyclopentyl-1,3-trans-dicarboxylate (ACPD, 2.5-100 μ M), increases PI metabolism in NM 50-80% above control levels. Thus, glutamate can stimulate PI metabolism in the chick brainstem auditory system and the pharmacology of this phenomenon is similar to that reported for other preparations. 123.11

C-FOS IMMUNOHISTOCHEMISTRY REVEALS NO SHIFT OF TONOTOPIC ORDER IN THE CENTRAL AUDITORY SYSTEM OF DEVELOPING RATS. E. Friauf, Dept. of Animal Physiology, Univ. of Tübingen, D-7400 Tübingen, Fed. Rep. Germany.

Developmental alterations in the tonotopic maps of the mammalian central auditory system have been described in only a few species (gerbil: Sanes et al, JCN 279:436, '89; bat: Rübamen et al, J Comp Physiol 165:755, '89; mouse: Romand and Ehret, Dev Brain Res 54:221, '90). I have identified isofrequency bands in rat central auditory nuclei by labeling them immunohistochemically for Fos. Fos is the protein product of the proto-oncogene c-fos, which can be expressed in neurons following sensory stimulation. Awake, unrestrained rats between postnatal day 10 (P10) and P30 (onset of hearing is P12) were stimulated with pure tone pulses (1, 4, 16 or 50 kHz; 100 ms on/off at 80 dB SPL) for 1.5 hrs. Brains were processed for Fos-like immunoreactivity (Fos-ir) using the PAP technique. Fos-ir neurons were present at all ages, but isofrequency bands became apparent only after P14. Isofrequency bands were prominent in the inferior colliculus and in all three subdivisions of the cochlear nucleus (dorsal, posteroverentral and anteroventral) and were further analyzed. Their locations at P30 coincided remarkably well with those described by electrophysiology and [¹⁴C]-2-deoxyglucose in adult animals. Age-related changes of the location of isofrequency bands, i.e. alterations in the tonotopic maps, were not detected in any auditory nucleus. In addition, high-frequency areas were responsive as early as low frequency areas, indicating that cochlear transduction of high frequencies is functional as soon as hearing is. These findings contradict the earlier reports. Since systematic shifts in the spatial encoding of frequency have been found in the developing cochlea of gerbils (Echteler et al, Nature 341:147, '89) and are thought to be the underlying process for changes in central auditory nuclei, it is interesting to see if these shifts occur in the rat cochlea, too. This may clarify whether the hypothesis of shifting place code holds for all vertebrate species.

EXPRESSION OF GLUTAMATE RECEPTOR SUBUNIT mRNAs IN DEFINED CELL TYPES IN THE RAT COCHLEAR NUCLEUS. C. Hunter, T. Yu*, N. Yokotani*, K. Wada, and R.J. Wenthold. Lab of Neurochemistry, NIDCD, NIH, Bethesda, MD. 20892.

A number of cDNAs for the ionotropic class of the glutamate receptor (GluR) have recently been identified (Keinanen et al, Science 249: 1990), and these subtypes form heteromeric complexes with different physiological responses to applied agonists in vitro. These complexes, present on primary neurons in the cochlear nucleus, likely mediate the excitatory responses to complex sounds. We have used *in-situ* hybridization histochemistry to localize GluR receptor subtypes to cells in the rat cochlear nucleus. Within the dorsal cochlear nucleus (DCN), GluR-A and GluR-C oligodeoxy- nucleotide probes hybridized primarily to mRNAs in medium sized cells in layer 1, likely cartwheel cells. GluR-B and GluR-D probes by contrast, hybridized to multipolar shaped cells and a limited number of cells in layer 1. Large cells in the deep layer of the DCN were also labeled with GluR-D. The posterior division of the ventral cochlear nucleus (VCN) showed hybridization to medium sized, round cells in the globular bushy cell area with GluR-C and GluR-D probes. GluR-C, in addition, bound to a small group of cells in the vicinity of the octopus cell area. At rostral levels in the VCN, moderate hybridization to large spherical cells was observed with GluR-C and GluR-D probes. Cells within the granule cell cap of the VCN were seen to hybridize primarily with GLUR-B and GluR-D probes. The correlation of GluR receptor subtypes with physiologically and neuroanatomically identified cell types within the cochlear nucleus complex may help to delineate the molecular basis for sensory processing within the auditory system.

123.10

LOCALIZATION OF CALBINDIN, PARVALBUMIN AND GABA IMMUNOREACTIVITY IN NEURONS IN THE GERBIL BRAINSTEM AUDITORY NUCLEI. I.R. SCHWARTZ and P.B. EAGER* Sect. of Otolaryngology, Yale Univ. Sch. of Med., New Haven, CT 06510

In a continuing study of chemical markers which may distinguish subsets of GABAergic neurons we have examined the distribution and colocalization of calbindin (CaBP), parvalbumin (PV) and GABA immunoreactivity (IR) in frozen and vibratome sections of adult gerbil auditory brainstem.

In the superior olivary complex (SOC) virtually all neurons in the medial nucleus of the trapezoid body (MNTB) showed colocalization of PV-, CaBP- and GABA-IR. PV also produced heavy labeling of neurons in the lateral and medial superior olives (LSO, MSO), while CaBP labeled fewer LSO neurons and a few MSO neurons, both more lightly than MNTB neurons. Only an occasional neuron was GABA-IR in the MSO or LSO, although many were in the ventral nucleus of the TB. No neurons were stained by PV or CaBP in the dorsomedial periolivary nucleus (DMPO) although DMPO neuropil was consistently stained by both. SOC labeling differed from that reported in the rat by Webster et al (Neurosci. Letts. 111: 252-257, 1990) where only terminals labeled with CaBP in the MSO and LSO.

PV heavily stained neurons in all lateral lemniscal (LL) nuclei, while CaBP stained a smaller number in the ventral and intermediate nuclei of the LL (VNLL, INLL) and only a few scattered cells in the dorsal nucleus (DNLL). With PV the labeled neurons appeared in columnar arrays, especially in INLL and VNLL.

In the inferior colliculus (IC) results were similar to those reported by Coleman et al (ARO Absts. 14:43, 1991) in the rat with PV labeling many cells in the central nucleus and CaBP labeling a different population of cells in the external nucleus and dorsal cortex of IC. GABA labeling was similar to the pattern seen with PV. PV also labeled neurons and processes in the deep layers of the superior colliculus (SC). GABA and CaBP had similar staining patterns in the SC, small neurons were stained in a heavily stained neuropil in the SC superficial layers.

There are consistently different patterns of colocalization observed in different auditory nuclei for GABA, CaBP and PV.

Supported by NIH grant DC00132.

123.12

DISTRIBUTION AND ORIGIN OF SEROTONIN IN GUINEA PIG COCHLEAR NUCLEUS. K.R. Moore*¹, H.B. Britton*¹, A.M. Thompson^{1,2}, C.D. Ross¹, and G.C. Thompson^{1,2}. Depts. of ¹Otorhinolaryngology and ²Anatomical Sciences, University of Oklahoma Health Sciences Center, Oklahoma City, OK 73190.

With immunohistochemical staining, we have localized the putative neurotransmitter serotonin in all three divisions of the guinea pig cochlear nucleus. Serotonin-like immunoreactivity was present in fibers and terminals whose distribution varied among cochlear nucleus divisions: the dorsal and anteroventral cochlear nuclei contained the highest density. No immunoreactive cell bodies were observed in the cochlear nucleus or in any other auditory regions. Therefore, we have initiated experiments to determine the non-auditory source of the positive staining in cochlear nucleus.

The retrograde tracer HRP was pressure-injected into cochlear nucleus, and we looked for labeled neurons in regions containing serotonergic cell bodies. After large HRP injections, neurons of the caudal interstitial nucleus situated within the medial longitudinal fasciculus were retrogradely labeled. A few other cell bodies scattered along the midline were also retrogradely labeled. Therefore, preliminary evidence indicates that a non-auditory nucleus may be a source of serotonin in the cochlear nucleus.

PHARMACOLOGY OF BINAURAL INTERACTION IN THE MOUSE LATERAL SUPERIOR OLIVE. Shu Hui Wu* and Jack B. Kelly. Laboratory of Sensory Neuroscience, Psychology Department, Carleton University, Ottawa, Canada K1S 5B6.

The pharmacology of evoked responses in the lateral superior olive (LSO) was examined in a brain slice preparation of the mouse superior olivary complex. Brain slices (400 μ m thick) were taken through the superior olive of C57 BL/6J mice and were maintained in a continuously circulating, oxygenated saline solution. Glass micropipettes (50-80 M Ω) were inserted into the LSO under visual control. Stimulating electrodes were placed on the trapezoid body ipsilateral and contralateral to the superior olivary complex. Pharmacological agents were applied to the slice by redirecting the flow of solution in which the tissue was emerged. Results indicate that ipsilateral excitatory responses are mediated largely by non-NMDA receptors. Application of non-NMDA antagonists, CNQX or DNQX, had the effect of blocking extracellular spikes elicited by ipsilateral trapezoid body stimulation. In contrast, the NMDA antagonist, APV, had no effect on the vast majority of cells tested in either normal or 0 Mg⁺⁺ solution. Simultaneous ipsilateral and contralateral stimulation of the trapezoid body resulted in the inhibition of ipsilaterally produced spikes. This inhibitory effect was mimicked by application of glycine and was completely blocked by application of strychnine to the bath. This result supports the growing body of evidence that contralateral inhibition in LSO is glycinergic. Unexpectedly, application of NMDA in relatively low concentrations completely blocked the inhibition produced by contralateral stimulation. These data indicate that NMDA as well as non-NMDA receptors play a role in regulating binaural interactions in the superior olivary complex.

123.15

DEVELOPMENTAL PHARMACOLOGY OF EXCITATORY AMINO ACID TRANSMISSION IN THE CHICK COCHLEAR NUCLEUS (NUC. MAGNOCELLULARIS). N. Zhou and T. N. Parks. Dept. of Anatomy, Univ. of Utah Sch. of Med., Salt Lake City, UT 84132.

During development, excitatory amino acid (EAA) receptors can, in addition to their role in normal signal processing, influence the differentiation and synaptic connectivity of neurons. To examine developmental changes in EAA receptors in auditory neurons, we studied the pharmacology of transmission between the cochlear nerve and nuc. magnoocellularis (NM) in chickens aged embryonic day (E) 14 to posthatching day (P) 40, using previously-described methods for bath application of drugs and recording of electrically-evoked field potentials in brain slices (*Neurosci.* 16: 171). Postsynaptic responses in NM (reflected by the N1 potential) are insensitive to the N-methyl-D-aspartate (NMDA) receptor antagonists 3-(-)-2-carboxypiperazin-4-ylpropyl-1-phosphonate (CPP) and dibenzocycloheptimine (MK-801) but can be blocked reversibly at all ages by the competitive non-NMDA receptor antagonist 2,3-dihydroxy-6-nitro-7-sulfamoyl-benzo(F)quinoxaline (NBQX). The EAA agonists kainic acid (KA), α -amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) and NMDA can also block postsynaptic currents in NM in a reversible and dose-dependent fashion via depolarization block. The suppressive effects of NMDA, but not of KA or AMPA, are blocked completely by CPP or MK-801. The potency of NMDA decreases greatly with increasing age; the IC₅₀ is about 85 μ M at E14 but at E21 2 mM NMDA produces only a 6% reduction in the N1 amplitude. The potencies of AMPA and NBQX decrease by about 3-fold and 10-fold, respectively, between E14 and hatching, whereas the potency of KA appears to increase slightly across the ages studied. The results demonstrate the existence of functional NMDA receptors on NM neurons and suggest that during the last week of embryonic life, when NM neurons undergo dramatic morphological and functional transformations (*Curr. Top. Dev. Biol.* 21: 309), there are concurrent changes in the number, affinity and/or efficacy of both NMDA and AMPA receptors.

Supported by USPHS grant DC00144. We thank Dr. T. Honore for the NBQX.

PATTERNS OF GAD AND GLYCINE IMMUNOREACTIVITY IN THE INFERIOR COLLICULUS OF TWO SPECIES OF BAT. B.B. Johnson*, E. Covey and J.H. Casseday. Department of Neurobiology, Duke University, Durham, NC, 27710.

Inhibitory mechanisms are involved in auditory signal processing, and the two amino acids, glycine and GABA, appear to be major inhibitory transmitters in the auditory system. We examined the distribution of glycine- and GABA-like immunostaining in the inferior colliculus of two FM bats, *Eptesicus fuscus* and *Nycticeius humeralis*, by using immunoglobulins directed against glycine and the GABA-synthesizing enzyme, glutamic acid decarboxylase (GAD). In both species, the immunostaining patterns were almost identical for a given immunoglobulin. There were no glycine-reactive cells in the IC. Glycine-reactive fibers and puncta occupied a crescent-shaped band that extended from the dorsolateral to the ventromedial part of the central nucleus of the inferior colliculus (ICc). In the rostrocaudal dimension, this region occupies approximately the central one-half of the ICc. These fibers appear to be continuous with glycine-reactive fibers in the lateral lemniscus. GAD-positive cell bodies are distributed in patches mainly in the ventromedial and lateral parts of the ICc and in the pericentral areas of the IC. Staining of puncta with the GAD antibody is dense except in the area that contains glycine-reactivity. In fact there is little overlap of GAD and glycine immunoreactivity. Most of the overlap is in the ventromedial region. This unequal distribution raises the possibility that there may be different regions of the ICc in which one or the other of these putative inhibitory amino acid neurotransmitters predominates. Research supported by NIH grants DC 287 and DC 607.

123.14

Comparison between AChE histochemical staining and ChAT immunocytochemistry in the rat cochlear nuclei.

D.E. Vetter, C. Cozzari*, B.K. Hartman* and E. Mugnaini. Lab of Neuromorphology, Box U-154, Univ. of Connecticut, Storrs, CT 06269-4154 and *Dept. of Psychiatry, Univ. of Minnesota, Box 392 Mayo, 420 Delaware St. SE, Minneapolis, MN 55455

The cochlear nuclei (CN) contain a rich complement of acetylcholinesterase (AChE) positive and choline acetyltransferase (ChAT) positive structures. Osen et al. (1984) demonstrated four AChE positive elements: 1) scattered cell bodies in VCN and in granule cell domains; 2) a fiber plexus consisting of irregularly oriented axons and mossy fibers; 3) a diffuse neuropil staining; and 4) dense patches, usually in the granule cell domain of DCN. By light microscopic ChAT immunocytochemistry, we demonstrate the occurrence of scattered immunoreactive cell bodies and fibers in the major subdivisions of the CN. Axon terminals surround non-immunoreactive cells and their proximal dendrites in AVCN and PVCN, while in DCN the terminals are more diffusely arranged in the deep layers. The DCN molecular layer contains scattered immunoreactive terminals and fibers while the deeper layers contain scattered immunoreactive cell bodies. The AChE positive diffuse neuropil staining may correspond to ChAT positive terminals. Dense patches in DCN are absent after ChAT immunocytochemistry and may not, therefore, represent enzyme related to neurotransmission. Pre-embedding immunoelectron microscopy indicates that ChAT positive terminals constitute a heterogeneous population. Some of these terminals synapse on granule cells as rosettes and have an extrinsic origin.

NMDA-RECEPTORS IN SOUND-AZIMUTH ANALYZING NUCLEI OF CAT HINDBRAIN. B. N. Baker, K. K. Glendenning and R. B. Masterton. Dept. Psychology, Florida State University, Tallahassee, FL 32306.

In cat, the lateral superior olive (LSO) provides a neural representation of the interaural spectrum difference for sound localization (Boudreau & Tsuchitani, '70). The medial superior olive (MSO) acts as a 'coincidence detector' providing an analysis of interaural time differences for the same purpose (Yin & Chan, '90). Both LSO and MSO are known to receive excitatory glutamatergic and inhibitory glycinergic input, with the glutamatergic input acting mostly on quisqualate-type (and not kainate-type) receptors.

In further pursuit of the nature of the excitatory input to LSO and MSO, we have now found receptor-binding evidence for the presence of NMDA receptors both in LSO and MSO. Two putative NMDA-receptor ligands, CGS19755 and CGP39653, show significant binding both in LSO and MSO and each is displaced by glutamate itself.

Although the density of the NMDA receptors is only about 10% of the density of the quisqualate receptors, it suggests the presence of voltage-sensitive synapses. Therefore, LSO and MSO may have the capacity for modifying their input-output relationships perhaps in a manner useful for maintaining accurate sound localization during head and pinna growth. Supported by NIH DC197.

INFERRED CONTRIBUTIONS OF LOW AND HIGH SPONTANEOUS-RATE AUDITORY NEURONS TO THE COMPOUND ACTION POTENTIAL. E.M. Relkin and J.R. Doucet*. Institute for Sensory Research and Dept. of Bioengineering, Syracuse Univ., Syracuse, NY 13244.

The recovery of auditory neurons from prior stimulation depends on the spontaneous rate (SR) of the neuron. Low SR neurons recover more slowly compared to high SR neurons. Thus, it is possible to reduce the relative contribution of low SR neurons to a population response by preceding a test stimulus with a conditioning stimulus, and recording the response to the test stimulus at a time after the conditioner when the high SR neurons are mostly recovered and the low SR neurons are not.

Compound action potentials (CAP) were recorded in chinchillas for the response to a 12 kHz tone-burst preceded by an 80 dB SPL conditioning toneburst at the same frequency. The CAP was recorded for many time delays of the test stimulus relative to the conditioner and for many test-stimulus intensity levels. CAP waveforms were reduced relative to control waveforms recorded with no conditioner for delays up to 400 ms. Recovery of the waveform is consistent with the recovery of two populations of neurons with different latencies and recovery rates. The inferred properties of the two populations are also consistent with direct measurements of recovery for single auditory neurons.

123.19

REPRESENTATION OF THE COCHLEA IN THE AUDITORY BRAINSTEM OF THE OPOSSUM, *MONDELPHIS DOMESTICA*. F.H. Willard, Melissa C. Stenner,* and Frank J. Daly*, Department of Anatomy, University of New England, Biddeford, ME 04005.

The development of cochleotopic order in the auditory system of *Monodelphis domestica* is being investigated. To provide an end point in this study, the topographic pattern of the projections from cochlea through cochlear nucleus (CN) to midbrain in the adult has been examined. Small pledgets of HRP were placed in the apex or base of the cochlea in a series of 15 adult animals. In a second series of 10 animals, small injections of HRP from a glass micropipette were made into the inferior colliculus of the midbrain. Survival of all animals was 24 hours. Tissue was sectioned frozen or with a vibratome, and reacted with tetramethylbenzidine. In the first series of animals, labeled sheets of fibers were found coursing through the ventral and into the dorsal CN consequent to the cochlea placement of HRP. Specifically, apical placements resulted in labeled caudolateral sheets of auditory nerve fibers in the CN, while basal placements labeled rostromedial sheets of fibers. In the second series of animals, ventromedial placements of HRP into the midbrain resulted in labeled rostromedial sheets of neurons in contralateral CN, while dorsolateral placements labeled caudolateral sheets of neurons. When data from the two studies were collapsed onto single plots, the labeled sheets of midbrain-projecting neurons were in register with the sheets of labeled auditory nerve fibers. The close spatial alignment of auditory nerve laminae with those of midbrain-projecting neurons, demonstrates a mechanism for maintaining the fidelity of the cochleotopic map as it passes through the cochlear nucleus and into the midbrain.

123.20

RESPONSE OF AUDITORY NEURONS TO APPARENT AUDITORY MOTION. W.W. Wilson* and W.E. O'Neill, Program in Neuroscience, Univ. of Rochester Med. Ctr., Rochester, NY 14642

The interaural intensity difference (IID) of a sound between the two ears is thought to be a cue to the location of that stimulus. Dynamically changing IID would be produced by a moving sound source and may serve as a cue to auditory motion. We tested this possibility by recording the response of single units in the inferior colliculus (IC) of an awake mustached bat to a dichotic stimulus simulating a sound moving between the ears.

Best frequency (BF) tone bursts were presented through earphones to the contralateral (CL) ear at 10 dB above minimum threshold (MT) and simultaneously to the ipsilateral (IL) ear at intensities changing sequentially in 10 dB increments to produce IIDs from -30 to +30dB and back to -30dB IID condition. The response of the neuron to a particular IID was compared for increasing IID trains, decreasing IID trains, and a static train of stimuli at the same IID presented in succession.

Increasing IID trains generally elicited a greater response at most IIDs than decreasing IID trains. Most units showed a greater response in the increasing IID case than at that same IID in the static case. In the decreasing IID case, these same cells had a response similar to or lower than static responses. These units were excited by low IIDs and inhibited by high IIDs, suggesting facilitation when changing from excitatory to inhibitory IIDs and inhibition in the opposite direction. (Sponsored by NRSA fellowship 1 F31 MH10107-01 from NIMH)

AUDITORY SYSTEM: CENTRAL PATHWAYS II

124.1

A COMPARISON OF ONSET LATENCIES OF AUDITORY RESPONSES TO CLICK IN DIFFERENT BRAINSTEM AREAS OF THE CONSCIOUS CAT. B. Hoang, C.D. Woody, X.F. Wang, E. Gruen*. UCLA Med. Ctr., MRRRC, BRI, Los Angeles, CA 90024.

Recordings from the following areas showed increases in discharge to 1ms, 70db clicks: cochlear nucleus (CO), dentate (D), interpositus (IP), cerebellum (C), inferior colliculus (IC), medial geniculate (MG), supragenulate (SG), lateral superior olive (OSL), superior colliculus (SC), and lateral geniculate (LG). Latencies of response compared within a single animal ranged from 4-8ms (CO, OSL, MG and D) to 20-28ms (C, IP, SG and LG). Other latencies were 12-16 ms (IC) and 16-20 ms (SC). Latencies of response from within-animal recordings were substantiated by combined data from more than one animal for the following areas: C, CO, OSL, D, LG, and IP. The across-animal latency for MG was 12-16 ms. The latency for C in one other animal with more lateral recordings was 12-16 ms. Other investigators have shown auditory responses of comparable latencies to those in our conscious-animal recordings in the following areas in anesthetized cats: IC (Rose et al., *J. Neurophysiol.*, 1963 - with shorter latencies in some IC regions), MG (Nelson et al., *J. Neurophysiol.*, 1963), CO (Kiang, *Acta oto-laryng.*, 1965), and OSL (Galambos et al, *Amer. J. Physiol.*, 1959). (Supported by NS25510)

124.3

APPARENT EXPECTATION IN INTERSTIMULUS-INTERVAL-SPECIFIC EVENT RELATED POTENTIALS TO OMITTED STIMULI IN THE ELECTROSENSORY PATHWAY OF ELASMOBRANCHS. T.H. Bullock and M.H. Hofmann*. Dept. Neurosci., Univ. Calif., San Diego, La Jolla, CA 92093-0201 and Dept. Anatomy, Univ. Göttingen, Germany.

Comparing a lateral line modality with the previously studied (Bullock et al., *J Neurophysiol* 64:903-914) visual omitted stimulus potentials (OSP), we recorded multiunit activity and slow local field potentials (LFP) in the electrosensory system in rays (*Platyrhinoidis triseriata*) during and after trains of microvolt pulses in the bath, with special attention to end-of-train effects, at four levels from peripheral nerve to cerebrum. LFPs occur after the due-time of the first omitted stimulus, visible on each sweep down to 2 Hz, larger at higher frequencies. They resemble OFF response to single long current pulse. Independent of stimulus intensity, OSPs are on schedule, with a constant, long (60-100 ms) latency from the due-time - as though the system has an expectation. The OSP depends on a sufficient duration and regularity (vs jitter) of the conditioning train. OSP appears already in the nerve; dorsal nucleus of medulla, mesencephalic lateral nucleus and a deep nucleus in cerebrum show progressively later, broader first main OSP peaks, plus labile late waves, to >700ms. Our telencephalic loci cannot follow >0.1 Hz; their OSP arises after trains causing no EPs except to the first stimulus. Inhibitory processes dominate until excitatory rebound due to omitting a stimulus. One or two induced rhythms (IR) of the frequencies: 4-7, 16-20 or 55-75 Hz often follow the main OSP for >1s. Each is labile, most prominent in medulla; shorter and smaller in midbrain and inconspicuous at best in forebrain. IR tend to synchronize in medulla and midbrain. ERPs such as OSP and IR and properties such as apparent expectation on schedule over a range of ISIs do not require higher brain levels or the complexities of the retina. They can appear in primary medullary sensory nuclei of the octavolateralis system, to be modified in midbrain and forebrain.

124.2

EVIDENCE FOR A NEW, PRIMARY AUDITORY TRANSMISSION PATHWAY BETWEEN THE COCHLEAR NUCLEUS, THE SUBCEREBELLAR DENTATE NUCLEUS, THE ROSTRAL THALAMUS, AND THE MOTOR CORTEX OF CATS. C.D. Woody, X.F. Wang, V. Chizhevsky*, J. Landeira-Fernandez and E. Gruen*. UCLA Med. Ctr., MRRRC, BRI, Los Angeles, CA 90024.

Short latency (4-10 ms) responses to 70 db click stimuli were recorded at the above loci in conscious cats. The response latencies in motor cortex (Sakai and Woody, *J. Neurophysiol.*, 1980) were as short as those reported in classical auditory receptive cortex. Injections of PHA-L were made in the dentate nucleus. Fibers were traced between dentate nucleus and rostral thalamus, a region shown recently to respond at latencies of 6-8 ms to click stimuli (Woody et al., *J. Neurosci.*, 1991). Fibers were also traced between dentate and dorsal and ventral cochlear nuclei. Since cell bodies were also observed, these fillings were thought to be retrograde. (Previously described fiber connections with vestibular, caudate and VA nuclei were also found.) The evidence suggests that an ascending auditory transmission pathway exists between cochlear nuclei, dentate nucleus, rostral thalamus and motor cortex. The proposed auditory pathway appears to have functional significance since ablation of classical auditory receptive regions of cortex that receive classical collicular-geniculate-cortical projections does not prevent acquisition of short latency Pavlovian conditioned blink responses to click CS that depend on the motor cortex for development (Woody et al, *J. Neurophysiol.*, 1974). (Supp. NS25510, HD05958.)

124.4

ELEVATION SENSITIVITY OF AZIMUTH SENSITIVE NEURONS IN CAT PRIMARY AUDITORY CORTEX (AI). F.R. Samson*, P. Barone, J.C. Clarey, and T.W. Imig. Dept. of Physiol., Kansas University Med. Cir., Kansas City, KS 66103.

Responses of single units (CFs 6 - 28 kHz) were studied in AI of barbiturate anesthetized cats using broadband noise burst stimuli that varied in azimuth, elevation and sound pressure level (SPL). Unilateral ear occlusion revealed that some cells derived azimuth sensitivity strictly from binaural cues, and others exclusively or predominantly from monaural cues. Responses to sound source elevations between $\pm 67.5^\circ$ using SPLs that ranged between 0 and 90 dB were obtained for 30 cells at best azimuth. Elevation functions, averaged over SPL, were obtained for each cell, and those with elevation functions modulated $\geq 75\%$ were considered elevation sensitive. Spatial receptive fields (SRF) were obtained for 15 cells using a single SPL that in the case of nonmonotonic cells was the best level. Monaural and binaural cells differed in elevation sensitivity. The vast majority of monaural cells (12/14) were elevation sensitive, most were tuned to relatively narrow ranges of elevation, and the elevation tuning of 2 cells that were tested with ear occlusion was shown to derive from monaural cues. In contrast, binaural cells were less sensitive to elevation. Most (4/6) EI (excitatory input from one ear, inhibitory input from the other) cells were elevation insensitive, and the sensitive ones were broadly tuned to elevation. A hemifield SRF was obtained for one EI cell. Binaural cells receiving excitatory or facilitatory inputs from each ear varied in elevation sensitivity. Five of 15 were insensitive, and those that were sensitive could be either broadly or narrowly tuned. Supported by NIDCD grant # DC00173.

124.5

EFFECT OF BANDWIDTH ON NEURONS' AZIMUTH TUNING IN CAT MEDIAL GENICULATE BODY (MGB) AND PRIMARY AUDITORY CORTEX (AI). P. Barone, J.C. Clarey, W.A. Irons, F. Samson, and T.J. Imig. Dept. Physiol., Univ. Kansas Med. Ctr., Kansas City, KS 66103, USA.

The azimuth-level response areas to free-field broadband noise (BBN) and tone-burst stimulation at characteristic frequency (CF) were compared in 41 MGB and 130 AI high-CF neurons in barbiturate-anesthetized cats. A small number of forebrain cells (N=23) was also tested with bandpass noise (BPN) of various bandwidths. Azimuth sensitivity was assessed by the degree of modulation of the average azimuth function, and azimuth selectivity was assessed by the range of azimuths that produced greater than 75% responsiveness relative to maximum. The vast majority of forebrain cells showed the same azimuth preference to the two stimuli (i.e., contralateral, ipsilateral or midline), although many showed greater selectivity (92/171: 53.8%) or sensitivity (59/171: 34.5%) to BBN compared to CF-tones. These effects were particularly apparent in cells that responded to a narrow range of azimuths near the midline or the lateral poles ($\pm 90^\circ$). Some cells required only narrow BPN centered about CF to generate an azimuth response similar to BBN and more selective than tones; fewer cells required a wider BPN that encompassed excitatory and non-excitatory regions of the cell's frequency response area. The latter result suggests that inhibitory frequency domains may contribute to the directional selectivity of some cells. In a few thalamic cells the presence of such domains was confirmed using two-tone stimulation. The fact that cells responded at a significantly lower discharge rate to noise compared to tones ($t=4.14$, $df=170$, $pr<0.001$) also suggests an inhibitory influence, apparent only with broadband stimulation. Acute ear occlusion manipulations showed that cells that derived their directional selectivity principally from monaural spectral cues showed quite dramatic decreases in selectivity and sensitivity when stimulated with a CF-tone. In contrast, cells that derived their selectivity from binaural excitatory-inhibitory interactions tended to show similar azimuth responses to noise and tones.

124.7

AN AUDITORY AFTEREFFECT FOR MOTION IN THE FREQUENCY DOMAIN. Z. Shu, N. V. Swindale, C. A. Laszlo, and M. S. Cynader. Departments of Ophthalmology and Electrical Engineering, Univ. of British Columbia, Vancouver, B.C., Canada V5Z 3N9.

Adaptation aftereffects in the visual system have been much studied and used as tools in investigating the functional mechanisms of vision. In audition, however, although there have been studies on adaptation to frequency- and amplitude-modulated signals, little work has been done on other adaptation aftereffects. This has been partly due to difficulties in generating analytic stimuli analogous to those used in studies of visual adaptation. By using a novel auditory stimulus, which has either a notch- or a peak-shaped spectrum with the position of the notch or peak varying with time over a certain frequency range, we have been able to demonstrate an auditory motion aftereffect analogous to the well known visual motion aftereffect.

A two-alternative forced choice experiment was designed to measure the velocity of the moving peak or notch in a brief test stimulus at which the subject perceived the stimulus as stationary, under different adaptation conditions with different adapting velocities. The task of the subject was to judge the direction of motion of the peak or notch in the test stimulus. The adapting stimulus, which typically lasted for 3 minutes, was either a peak or a notch which moved up or down at a constant velocity. The results show that after adaptation to motion in one direction, a stationary test stimulus will be more likely perceived as moving in the opposite direction. This aftereffect, analogous to the visual motion aftereffect, indicates that the auditory system may process time-varying stimuli with mechanisms functionally similar to those in the visual system.

124.9

LOCAL INTERNEURONS IN THE AUDITORY BRAINSTEM OF THE BARN OWL. I. Walford, and C. E. Carr. Dept. of Zoology, Univ. Maryland, College Park, MD 20742.

In the barn owl, sensitivity to interaural time differences (ITDs) arises in the brainstem nucleus laminaris (NL). NL receives auditory input from the cochlear nucleus magnocellularis (NM). GABAergic terminals surround both NM and NL neurons. The role of the GABAergic terminals in NM is unknown, while the GABAergic terminals in NL play a role in shaping the response to ITDs (Fujita and Konishi, 1991). Furthermore, models of binaural interactions in NL suggest that inhibition is required for ITD sensitivity (Gruen et al., 1990).

Since the source of these GABAergic terminals in the barn owl is unknown, we used immunohistochemical and tract tracing techniques to identify the cell bodies of origin and to suggest the nature of the inhibitory input.

GABAergic terminals in NM originate from 3 sources: the superior olive (Carr et al., 1989), neurons dorsal to NM in the floor of the 4th ventricle and a population of interneurons caudal and lateral to NL. The olivary neurons may receive binaural inputs, while the other 2 groups are located in or around the auditory nerve root.

GABAergic terminals in NL appear to originate from interneurons in the magnocellular efferent tract, lateral to the medial vestibular nucleus and medial to NL. Medium-sized fusiform spiny cells extend their dendrites parallel to the ipsilateral magnocellular axons, and the dendrites of small ovoid cells ramify below NL.

VARIABILITY IN DISCHARGE RATE OF COCHLEAR NUCLEUS NEURONS DURING DEVELOPMENT. J.L. Fitzakerley, J. McGee, and E.J. Walsh. Boys Town National Research Hospital, Omaha, NE 68131.

Many theories regarding information coding in sensory systems are based upon discharge rate analyses, and variability in neuronal discharge rate is an inherent complication in these measures. As a result of the need to use rate-based analyses in ongoing investigations, this study was designed to assess the variability of both acoustically-evoked and spontaneous discharge rates in developing animals. Standard extracellular recording techniques were used to study neurons in the cochlear nucleus of kittens throughout postnatal development. Overall levels of spontaneous activity were low in the youngest animals, and many neurons exhibited marked variability in spontaneous rate (SR). At all ages, SR variability was dependent upon rate, with SR being less stable in low-SR units than in high-SR units. Acoustically-evoked discharge rates were also more variable early in development, with the largest differences between immature and mature animals occurring at near threshold intensities. This variability was apparently related to a decreased ability to respond to succeeding stimulus presentations, suggesting that fatigue and/or a lack of synaptic security may be responsible for the observed variability in acoustically-evoked discharge rate.

SALICYLATE INDUCED CHANGES IN LOUDNESS THRESHOLDS AT VARYING FREQUENCIES IN RATS. J.F. Brennan and P.J. Jastreboff. Dept Psychology, Univ of Massachusetts/Boston, MA 02125 and Dept Surgery, Univ of Maryland Sch Med., Baltimore, MD 21201.

Shifts in auditory intensity thresholds for 31 different frequencies (1-16 kHz) were tested in 15 pigmented rats using bar press behavior. Rats were trained in 5 progressive stages of difficulty until they were able to detect a standard tonal probe (10 kHz, 62 dBC) by depressing the response bar for 2 s (S+) or to detect no probe (S-) by releasing the bar after the onset of a light signal. Groups of 5 rats received either saline injections or salicylate injections of either 200- and 300-mg/kg 2 hrs prior to the 45-min testing session. A total of 7 tonal frequencies (S+ probes) were interspersed with about a third as many S- probes on each session, and the order of frequencies was counterbalanced across testing days and subjects. For each frequency series initial probes began at 62 dB and decreased in 5 dB units until an error was recorded, at which time the series increased in 2.5 dB units until detection, followed by a decrease in units of 1 dB. The results indicated that salicylate injections induced threshold shifts at selected frequencies. (NIH DC00299).

AXONAL ARBORIZATIONS IN THE MEDIAL GENICULATE NUCLEUS OF FERRETS: COMPARISON OF ARBORS FROM THE INFERIOR COLLICULUS WITH INDUCED INPUTS FROM RETINAL GANGLION CELLS. S.L. Pallas, J. Hahn and M. Sur. Dept. of Brain & Cognitive Sci., M.I.T., Cambridge, MA 02139.

In a previous study (Pallas et al., Soc. Neurosci Abstr. '89), we reported on the morphology of adult ferret retinal axon arbors which project into the auditory thalamus (MGN) following partial removal of retinal targets and deafferentation of the MGN in neonates. In the present study, we describe the morphology of arbors in the MGN from inferior colliculus (IC) axons in normal ferrets, and compare them to the retinal axon arbors in MGN of the "rewired" ferrets.

We used the *in vitro* method of bulk-filling axons with HRP in the brachium of the IC to label individual axon arbors in the MGN. These axons have well-formed terminal arbors in the MGN, with a wide variety of bouton shapes and sizes. Many boutons are quite large (10-30 μm) and crumpled. The arbor volume varies from 0.63 to 26.56 $\times 10^6 \mu\text{m}^3$ (mean= 7.34 $\times 10^6 \mu\text{m}^3$, SE= 2.39, n=11). Axon diameters vary from 0.4 to 1.4 μm (mean= 0.9 μm , SE= 0.1, n=11).

Although IC axons to the MGN in normal ferrets and retinal axons to the MGN in rewired ferrets have similar axon diameters, IC arbors are much larger in volume (retinal axon arbor volume range 0.02 to 1.68 $\times 10^6 \mu\text{m}^3$, mean= 0.72 $\times 10^6 \mu\text{m}^3$, SE= 0.10, n=26) and branch/bouton density is qualitatively much lower.

These results suggest that axon arbor morphology is somewhat independent of target identity. Also, since the induced retinal axon arbors are much more spatially restricted than arbors of normal IC axons, it is likely that the two-dimensional spatial information from the retina is preserved as a retinotopic map in the MGN of rewired ferrets.

CYTOLOGY AND SYNAPTIC RELATIONSHIPS IN THE COCHLEAR NUCLEUS OF THE ALLIGATOR LIZARD. D.D. Wright*, M.R. Szpir, D.K. Ryugo. Center for Hearing Sciences, Departments of Otolaryngology-HNS and Neuroscience, Johns Hopkins University School of Medicine, Baltimore, MD 21205.

In order to understand the structural basis for acoustic signal processing in vertebrates, we have been investigating the organization of neurons and synaptic inputs in the cochlear nucleus of the alligator lizard (*Gerrhonotus multicarinatus*). The cochlear nucleus of this species receives primary afferent information from two morphologically and functionally distinct types of cochlear nerve fibers (Szpir et al., JCN 295:530-547, 1990). In the present study we describe the anatomy of cell types and synapses in the cochlear nucleus of the alligator lizard.

The neurons of the cochlear nucleus were characterized on the basis of their light microscopic appearance in Nissl preparations and their corresponding ultrastructural features. We found seven morphologically distinct cell types: four large- and three small-cell types. Each cell type was confined to one of the four subdivisions of the cochlear nucleus. In addition, we investigated the ultrastructure of HRP-labeled cochlear nerve terminals as well as that of unlabeled terminals. Cochlear nerve terminals have round synaptic vesicles and form somatic and dendritic synapses with the neurons in all subdivisions of the cochlear nucleus. All subdivisions also contained three types of unlabeled synaptic terminals exhibiting either round, pleiomorphic or flattened vesicles.

The presence of different cell populations in the four subdivisions suggests that acoustic information may be further channeled into several functionally specialized pathways that originate in the cochlear nucleus. (Supported by NIH grants DC00232, DC00979 and DC00119)

124.13

MORPHOLOGY OF THE DORSAL COCHLEAR NUCLEUS (DCN) IN YOUNG AND OLD C57BL/6J AND CBA/J MICE. J.F. Willott, L.S. Bross*, S.M. McFadden, and P. Burke*. Dept. Psychol., Northern Illinois Univ., DeKalb, IL 60115.

In C57 mice, which exhibit progressive age-related cochlear sensorineural degeneration, the size of neurons in each layer of the DCN decreased gradually between age 2 and 29 mos. (old age). The number of neurons in layer 3 (but not layers 1 and 2) decreased significantly between 1.5 and 7 mos. and between 12 and 24 mos. Volume of DCN layers 1 and 3 decreased with age, but volume of layer 2 remained stable. In CBA mice, which hear well during old age, neuron size and number showed only a trend toward a decrease in all three DCN layers and only in the oldest mice. Volume of layers 1 and 3 increased during the first year of life, then decreased during the second year. Layer 2 volume showed little age-related change.

Layer 3 receives more 8th nerve input than other layers, so the effects of age-related loss of 8th nerve fibers in C57 mice would be expected to impact layer 3 in particular. In fact, cell counts and volume decreased most markedly in layer 3 of aging C57 mice.

DO DORSAL COCHLEAR NUCLEUS PARALLEL FIBERS EXCITE FUSIFORM CELLS VIA AN EXCITATORY AMINO ACID NEUROTRANSMITTER? P.S. Palombi, P.M. Backoff* and D.M. Casparv. Dept. of Pharmacology, SIU School of Medicine, Springfield, IL 62702

Fusiform cells of the dorsal cochlear nucleus (DCN) appear to receive excitatory inputs on their basal dendrites from VIIIth nerve fibers and on their apical dendrites from the parallel fiber axons of granule cells; they also receive inhibitory inputs onto their proximal dendrites and somata. These neurons often display buildup (BU) or pauser/buildup (PBU) temporal response patterns. In forward masking paradigms, while most cochlear nucleus neurons display a masked response, BU/PBU neurons often show no masking or even a potentiation of the probe response (Boettcher et al. *Hearing Research*, 48(1990) 125-144). In studies of anesthetized chinchilla DCN neurons, we presented two tones at characteristic frequency, 20 to 40 dB above threshold, separated by 0 to 75 ms. Extracellular single unit recordings from 14 of 17 DCN cells with characteristic BU/PBU temporal response patterns displayed an increased discharge rate during the second, or probe, tone; only one cell showed masking of the probe tone. Several cells also displayed altered temporal response patterns to the probe with induction of or change in chopping rate. The molecular layer of the DCN displays high concentrations of the excitatory amino acid (EAA) glutamate, selective uptake and release of D-aspartate, and high levels of zinc-containing neurons. These characteristics, which are similar to the cerebellar granule cell system/parallel fiber system, and *in vitro* electrophysiologic data suggest that an EAA is a good candidate for the neurotransmitter used by DCN parallel fibers. One possible mechanism for the potentiation of DCN cells seen in the masking paradigm described above is potentiation of excitatory input to the basal dendrites of DCN fusiform cells by EAA-mediated excitatory input to the apical dendrites from parallel fibers, just as depolarization of hippocampal neurons is potentiated by NMDA receptor activation. This mechanism could account for the increasing activation of fusiform cells observed in DCN, resulting in units displaying BU/PBU temporal discharge patterns, potentiation in a forward masking paradigm, and increased chopping. Ionophoretic studies are underway to further test this hypothesis. (Supported by NIH DC00151-10)

TOPOGRAPHIC DISTRIBUTION OF THE PROJECTION FROM THE PRIMARY AUDITORY CORTEX TO THE INFERIOR COLLICULUS IN ALBINO RATS.

Carrascal, E.*(1), García-Méndez, J. A.*(2), Lanciego, J. L.*(1), and Collia, F. (1). 1- Cátedra de Histología, Fac. de Medicina, Univ. de Salamanca. (España) 2- Cátedra de Histología, Colegio Univ. de Avila. Univ. de Salamanca (España).

PHA-L was injected into the primary auditory cortex (Te1), in order to determine the distribution of cortical fibres in the inferior colliculus (IC). The location of the injections were stereotaxically determined according to Zilles et al. (1985) and the injections were placed in a rostro-caudal sequence through Te1. Small to medium size zones of injection in Te1 (ranged from 360 µm. to 900 µm.) afforded in the IC an arrangement of the fibres in restricted groups of axonal fascicles which gave it the appearance of bands. The number of bands varied, depending on the extent of the injection in Te1 although small-medium size injections gave 1 or 2 bands and in the greatest injections up to 3 bands. The rostral most zone of Te1 projects to the caudal-most part of the external cortex, the medial part of the dorsal cortex and the medial part of the central nucleus. The anterior zone of Te1 projects to the central zone of the dorsal cortex and forms 2 to 3 bands of labeled axons in the medial and central parts of the central nucleus. The fibres from the central zone of Te1 strongly innervates the external cortex, like the posterior middle of the medial part of the dorsal cortex with the dorsal superficial cortex being practically free of fibres, and scattered fibres in the central nucleus, and the lateral periaqueductal gray matter. The caudal part of Te1 supplies fibres to the superficial layers of the external cortex at the rostral and middle levels, the dorsal part of the central nucleus, and the central part of the dorsal cortex. The results demonstrate a topographically and highly organized projection from Te1 to all subdivisions of the IC, including the central nucleus, each of which has a distribution of the fibres forming definite and specific bands. TONOTOPIC ORGANIZATION, ARCHITECTURE AND CONNECTIONS OF AUDITORY CORTEX IN MACAQUE MONKEYS. A. Morel, P.E. Garraghty, M.K. Schwaber, P. Burch-Sims, and J.H. Kaas. Dept. of Psychology, Vanderbilt University, Nashville, TN 37240.

Detailed microelectrode best-frequency maps of macaque monkey auditory cortex revealed two complete frequency representations in the lateral bank of the lateral sulcus, primary area A-I, and the rostral area, R. Confirming previous observations, we found a progression from high to low best frequencies in a caudal to rostral direction in A-I. Rostral to A-I, in R, best frequencies reversed and progressed from low to high in a caudal to rostral direction, so that A-I and R share a low-frequency border. A-I and R together are coextensive with a densely myelinated zone that reacts darkly for acetylcholinesterase and cytochrome oxidase, and has intense uptake of 2-deoxyglucose under normal ambient sound conditions. Several distinct architectonic subdivisions compose a belt of cortex surrounding A-I and R. Connection patterns with A-I and R, as demonstrated by injections of several different tracers (fluorescent dyes, WGA-HRP) in physiologically identified loci, and best frequencies of neurons recorded in a limited number of sites suggest that portions of the belt cortex medial and lateral to A-I and R are tonotopically organized. Belt auditory cortex also differs from A-I and R in having long cortical connections, such as with the prefrontal cortex, as well as projections from the medial pulvinar. PHYSIOLOGICAL CORRELATES OF THE VOICE ONSET TIME BOUNDARY IN AUDITORY CORTEX. M. Steinschneider, C. Schroeder, J. Arezzo and H.G. Vaughan, Jr. Albert Einstein College of Medicine, Bronx, NY, 10461.

Voice onset time (VOT) is the interval between stimulus onset and onset of a speech sound's periodic segments. A short duration VOT produces a percept of a voiced consonant such as /d/, whereas longer durations elicit the percept of an unvoiced consonant such as /t/. The VOT duration which elicits an ambiguous percept is called the boundary, and for the /d/-/t/ distinction is about 30 msec. We investigated the cortical encoding of VOT by examining laminar profiles of auditory evoked potentials, current source density and multiple unit activity elicited by the syllables /da/ and /ta/ in auditory cortex of an awake macaque. VOT was varied from 0 to 80 msec in 20 msec increments. We hypothesized that response differences would distinguish between voiced (/d/) and unvoiced (/t/) consonants.

VOT is reflected by two different response patterns which are time-locked to the onset of the voiced and unvoiced speech segments. In the first, responses time-locked to the unvoiced and voiced segments occur at all VOT durations and do not distinguish between voiced and unvoiced consonants. In the second, response bursts time-locked to the later onset of voiced segments are accentuated to the unvoiced consonant /t/ with VOTs 40 msec or longer. Auditory evoked potentials recorded in the far-field also display the second response pattern.

We conclude that voiced and unvoiced consonants elicit responses in auditory cortex that are differentiated by time-locked activity to voicing onset. This activity may play an important role in speech discrimination. (supported by DC00657, MH06723 and the J.S. McDonnell Foundation)

REPRESENTATION OF MULTI-FREQUENCY SOUNDS IN THE AUDITORY CORTEX OF CATS. I. Neiken*, Y. Prut* and E. Vaadia. Dept. of Physiology, Hadassah Medical School, Jerusalem, Israel 91010.

Properties of single unit and population activities in the primary auditory cortex (AI) of cats have been studied in response to multi-frequency sounds. The stimuli spaces consisted of two-frequency signals, four-frequency signals and quasi-harmonic complexes composed of nine frequencies. Since the number of possible combination of parameters was very large, new methods for studying the response to large stimuli spaces have been developed. One of them is based on an analysis of variance of the single responses to large number of combinations of parameters. The second is an automatic procedure for finding combinations eliciting large responses. The results show strong interactions between the sound components. Usually, the strongest response is for a frequency combination, of which none of the components is exactly at the best frequency of the unit. Also, the distance between components of the best combinations tend to be relatively large, much beyond the width of the single-frequency receptive field. It is proposed that the units in AI are not simple bandpass filters, but are "searching" for combined spectral features, approximating matched filters in the spectral domain. This research was supported by the Fund for Basic Research administered by the Israel Academy of Sciences and Humanities.

DENDRITIC MORPHOLOGY AND LOCAL COLLATERALIZATION OF INFRAGRANULAR PYRAMIDAL NEURONS IN CAT PRIMARY AUDITORY CORTEX. H. Ojima¹, C.N. Honda^{1,2}, E.G. Jones^{1,3}. ¹Neural Systems Laboratory, Frontier Research Program, RIKEN, Wako, 351-01 Japan. ²University of Minnesota, Minneapolis, MN 55455. ³University of California, Irvine, CA 92717.

Nine pyramidal neurons in infragranular layers of cat primary auditory cortex (AI) were intracellularly penetrated under physiological control and injected with biocytin. Cells were located in relation to the tonotopic map in the AI.

Layer V pyramids could be subdivided into two types on the basis of dendritic morphology and collateral distribution. Layer VI neurons were more heterogeneous.

Cells, located at the border between layers IV and V, had a large cell body and a thick dendrite extending to layer I where it branched considerably. These cells had few or no recurrent collaterals and, unlike neurons in layer II and III, no terminal bushes were formed in the vicinity of the cell body. Several long horizontal collaterals emerged from the main axon and extended in all directions in the tangential plane. Along these horizontal collaterals, many boutons were distributed at short intervals.

Cells located in the deeper portion of layer V emitted no long horizontal collaterals but had a dense bush of recurrent collaterals above the cell body, extending into layers II and III. A thin dendrite reached layer I where it branched little.

Cells in layer VI had a thin ascending dendrite that branched more frequently than that of layer V neurons and terminated in layer III. Collateral axon distributions varied from cell to cell; some cells had both terminal bushes in the vicinity of the cell and horizontal collaterals and others formed only recurrent bushes distributing in layer III.

OLIVOCOCHLEAR NEURONS IN THE ADULT HAMSTER.

D.D. Simmons^{1,2}, I. Raji-Kubba¹, and J.K. Moore². ¹Dept. of Biology and Brain Research Institute, UCLA, Los Angeles, CA 90024 and ²House Ear Institute, Los Angeles, CA 90057

The mammalian olivocochlear system is morphologically, spatially, and chemically heterogeneous. In order to study the development of olivocochlear (OC) efferent neurons in the hamster, the morphological and chemical identities of these neurons have to be established in the adult. The OC cell bodies were labeled retrogradely via biocytin injections. Such injections labeled cells bilaterally in periolivary (PO) regions but only ipsilaterally within the lateral superior olive (LSO). The cells labeled in PO regions had areas that ranged from 250-700 μm^2 and shapes that varied from fusiform to spherical. The majority (roughly 60%) of PO cells were found ipsilaterally and were intensely staining. Within the LSO, cells labeled tended to be smaller (200-400 μm^2), had generally spherical shapes and were stained lightly. In all species studied to date, both PO and LSO efferent neurons are ChAT positive but only the lateral OC system shows immunoreactivity to CGRP. In hamster, immunoreactivity to CGRP antibody was found mostly in LSO and only rarely in PO regions. The CGRP-positive cells in LSO had similar morphology and distribution as the retrogradely biocytin-labeled cells. In the cochlea, CGRP-positive terminals were found underneath inner hair cells from base to apex. The densest staining occurred toward the middle regions. These results suggest that the hamster is similar to other rodent species in the locations, morphology and chemistry of OC neurons. These data will be compared with other immunocytochemical results.

TEMPORAL ANALYSIS OF AMPLITUDE MODULATED SIGNALS: A COMPUTER SIMULATION OF PERIODICITY CODING NEURONS.

G. Langner, Zoological Institute, Technical University of Darmstadt, 6100 Darmstadt, Germany

In the range of typical fundamental frequency of many biological sound sources, i.e. below 1kHz, periodic envelope fluctuations elicit the perception of periodicity pitch. Such fluctuations or modulations are temporally coded in the peripheral auditory system and analyzed by neuronal correlation mechanisms in the central auditory system, resulting in a computational periodicity map at the level of the auditory midbrain (Langner and Schreiner, Soc., Neurosci. Abstr. 15, Part 1, p. 1116, 1989). A computer model has been presented composed of a trigger neuron, a triggered integrator ('reducer'), a triggered oscillator, and a coincidence detector (Langner et al., Soc., Neurosci. Abstr. 13, Part 1, p. 546, 1987). It includes only components resembling major neuron types of the auditory brainstem, like chopper and pauser neurons. The present paper compares results obtained from the computer model with those obtained in various recordings of periodicity coding neurons. The simulations are successful in describing modulation transfer functions (MTFs) of neurons, details of temporal response patterns (onsets and time courses of responses), and variation of MTFs with variations of signal parameters (carrier frequency).

A RESONANCE MODEL OF MICROSECOND TIME SENSITIVITY IN NUCLEUS LAMINARIS OF THE BARN OWL. J.C. Pearson, C.D. Spence*. David Sarnoff Research Center, CN5300, Princeton, NJ 08543.

In the barn owl, the azimuth of sound source direction is largely determined by the interaural phase difference (IPD) spectrum. This binaural information is first represented in nucleus laminaris, whose neurons are tuned in frequency and IPD up to ~10kHz, with corresponding temporal sensitivity of ~10 μsec . They have low spontaneous rates that equal the out-of-phase binaural rate, and their in-phase binaural rate is twice the monaural rate. They receive ~50 synapses from each nucleus magno-cellularis, whose frequency tuned neurons spontaneously fire at ~100sec⁻¹ and noisily phase-lock with little change in the average rate.

How can μsec sensitivity be achieved in the face of msec synaptic integration time constants and the noise in the inputs? We present simulations that demonstrate that standard neuronal biophysics cannot account for this phenomena because the noisy oscillating synaptic input produces a very small ripple in membrane potential that is swamped by random fluctuations.

Perhaps laminaris neurons contain some kind of neuronal resonator that, in effect, amplifies the oscillating synaptic potentials relative to the noise. This is suggested by the fact that the hair cells of some animals resonate, albeit at much lower frequencies than 10kHz. We present simulations that show that this idea is theoretically feasible. We determine the relationships between the "Q" of the resonator and the filtering characteristics of the membrane needed to jointly satisfy the conflicting constraints of signal amplification and short response latency.

IDENTIFICATION OF CELLS IN THE COCHLEAR AND DENTATE NUCLEI AFTER ELECTROPHYSIOLOGICAL RECORDING IN CONSCIOUS CAT. J. Landeira-Fernandez, C.D. Woody, X.F. Wang, V. Chizhevsky*, and E. Gruen*. UCLA, Depts. Anatomy, Psychiatry, and Psychology, MRR, BRI, Los Angeles, CA 90024.

Cells in the cochlear and dentate nuclei were marked by intracellular injection of biocytin made immediately after electrophysiological recording in a conscious cat. Elongate, fusiform cells of 20 μ length were found in the fusiform layer of the dorsal cochlear nucleus, and a non-fusiform cell of 10 μ diameter resembling a granule cell was found in the molecular layer of the dorsal cochlear nucleus. The morphologies were in agreement with those described by Brawer et al (J. Comp. Neurol., 155, 251-300, 1974) and Rhode et al (J. Comp. Neurol., 213, 426-447, 1983). Most cells showed pauser responses to click stimuli. Among the cells identified in the dentate nucleus, using Chan-Palay's classification (Cerebellar Dentate Nucleus, Springer, 1977), were a large asymmetrical cell of somewhat smaller size than that illustrated (fig. 3-15, E2) by Chan-Palay and a small multipolar cell of approximately 10 μ in diameter. Both were located in the ventromedial portion of the dentate nucleus. A small bridging cell with a perikaryon 10 μ in width was also identified in the dorsomedial portion of the dentate nucleus. Preliminary results suggest that some of the cell types identified in the dentate nucleus may have a short latency auditory response. (Supported by NS 25510 and by a Brazil CNPq fellowship.)

125.1

LEARNING OF SENSORI-MOTOR SEQUENCES BY PREFRONTAL CORTICAL CIRCUITS: A MODEL

E. Guigon*, X. Mondon*, B. Dorizzi*, Y. Burnod*, J. Hirsch.

Inst. Neurosc. Paris and URA CNRS 1121, Paris XI, Orsay, France.

We propose a neural network model of prefrontal (PF) circuits which can learn temporal sequences with 5 constraints:

1. The training protocol is the same as that used in monkeys to learn a spatial delayed response task.
2. Computation and learning are done by units which model local circuits of neurons in the cortex, with two processing steps: (i) inputs of common origin are tuned through learning within specific layer-divisions of the unit, (ii) the mutual interactions between layers are also adjustable by learning.
3. The maps which model the PF cortex are part of a coherent architecture which includes visual and visuo-motor processing. Properties of these cortical microcircuits account for a common adaptive mechanism to learn the different aspects of behavior such as sensori-motor coordinate transformations and invariant recognition.
4. The specific properties of processing units modelling PF circuits are compared to other cortical regions. We suggest that PF neurons have two specific properties to process conditional sequences with greater efficacy: (i) a bistable state as a the substratum of long-lasting activities (working memory) and (ii) a three-step learning mechanism controlling this bistable state.
5. The temporal properties of units are related to those of ionic channels and synapses of PF neurons. We discuss the specific activation rules in relation with the recent findings in PF neurons of a I_A -like potassium current (I_p). Its inactivation results in a steady firing (C. Hamon & F. Crepel, this volume). Furthermore, learning rules take into account the role of NMDA receptors in synaptic plasticity in PF neurons (J. Hirsch & F. Crepel, 1991, Exp. Brain Res., in press).

125.3

SIMULTANEOUS RECORDING OF SINGLE UNITS IN THE FRONTAL CORTEX OF MONKEYS PERFORMING A DELAYED RESPONSE TASK

E. Vaadia, M. Abeles, A. Aertsen, H. Bergman, H. Cohen, I. Halman, Y. Prut and E. Shtoyerman Dept. of physiology, The Hebrew University - Hadassah Medical school, Jerusalem 91010, Israel.

In a previous study we reported that coherent activity of pairs of neurons in the frontal cortex may be related to behavioral events. This study was designed to further test the hypothesis that the neural code for higher brain function resides in correlated activation of selected neurons.

Two monkeys were trained to perform arm reaching task with two paradigms; The monkey touched a central key to switch on a central light. After a delay of 3-6s ('pre-cue' period), one of two target keys was illuminated for 200ms. Then, after 1-32s ('delay' period) the central light dimmed ('Go signal'). In the first paradigm ('GO'), the monkey had to release the central key within 600 ms and touch the target key. In the 'NO-GO' paradigm the monkey had to maintain touch for 1200ms after the GO signal. The activity of up to 16 neurons was recorded simultaneously by an array of 6-10 electrodes arranged in a circle of 1000 μ diameter. Raster-displays, time interval histograms, autocorrelograms, cross-correlograms and joint-PST histograms were computed separately for the 'pre-cue' and the 'delay' periods in each of the behavioral paradigms. The raster displays indicated that in each recording site neurons firing rate is modulated in relation to several behavioral events while others are 'indifferent'. Preliminary crosscorrelation analysis demonstrated that spike trains of some of the neurons may be uncorrelated during performance of one behavioral paradigm and become correlated during performance of the other paradigm.

125.5

POPULATION CODING OF MOVEMENT DIRECTION IN PRECENTRAL CORTEX DURING A MOVEMENT-SEQUENCE DELAY TASK R.E. Ketner, J.K. Marcario and M.C. Clark, Dept. Psych., Prog. Neural Science, Indiana University, Bloomington, IN 47405.

Past work indicates that many single-neuron responses in precentral cortex are correlated with the direction of movement. Even so, individual neurons are only broadly tuned to a particular direction of movement called the neuron's preferred direction, and cannot account for the precisely directed movements that are observed. To explain movement accuracy one must assume that directional information is stored in a distributed fashion over a population of broadly tuned neurons. This view has been demonstrated using a population code that sums vector contributions from large populations of neurons; each neuron's contribution is in its preferred direction with a magnitude related to its change in firing rate from baseline. This population code works well in describing both single-direction and tracking movements.

The current experiments show that the code also works for a rapid sequence of directed movements. Two rhesus monkeys were trained in a movement-sequence delay task that was divided into 2 sensory, 2 delay, and 3 movement periods. Analyses of 328 neurons indicate neurons with statistically significant tuning during each period (18, 14, 19, 26, 47, 46, 45%). Population analyses based upon these tuned neurons indicate that there is accurate directional information during all 7 periods. The average angular difference between observed and predicted movement direction was 6, 22, 9, 7, 7, 10, and 9 degrees. Preferred directions were generally similar when more than one movement period was tuned. Population analyses based upon the average preferred direction during the three preferred directions also predicted movement direction accurately. The average error was 18, 20, 26 degrees for the movement periods. (Supported by NSF grant BNS-8919867)

FUNCTIONAL RESPONSES OF DORSOLATERAL PREFRONTAL NEURONS: AREAL DISTRIBUTION AND RELATION TO DELAYED ALTERNATION PERFORMANCE. S. Carlson, H. Tanila*, I. Linnankoski*, H. Kahila*, and M. Grönroos*. Dept. Physiol., Univ. Helsinki, 00170 Helsinki, Finland.

In the present work we studied the responses of single prefrontal neurons to various visual, auditory, and somatosensory stimuli and correlated the neuronal firing to movements of the eyes, face and limbs of the monkey (*Macaca arc-toides*) with the method described by J. Hyvärinen (Brain Res 1981:206:287-303). Several of the neurons were also studied while the monkey performed a spatial delayed alternation task. About 45% of the neurons could not be activated by any of the stimuli used. Approximately 30% responded to visual stimulation only and about 7% to visual and some other type of stimulation. Pure auditory (3%) and somatosensory (3%) responses were also found and about 13% of the neurons fired in relation to the movements of the eyes or limbs. The areal distribution of the functional responses is largely in line with anatomical studies of the connections of the prefrontal cortex.

SIMULTANEOUSLY RECORDED ACTIVITY IN MOTOR AND PREMOTOR CORTICES OF MONKEY DURING ARM-MOVEMENT SEQUENCES. J.K. Marcario, R.E. Ketner and M.C. Clark, Dept. Psych., Prog. Neural Science, Indiana University, Bloomington, IN 47405.

Pairs of simultaneously recorded single-units were recorded from the motor and premotor cortices of two rhesus monkeys during a movement-sequence delay task described in the companion abstract. Individual neurons were isolated using spike sorting algorithms on stored waveforms. Neural activity was categorized according to the average amount of activity during each of four task periods, yielding 15 possible classifications: initiation (I), sensory (S), delay (D) and motor (M) responses, plus all combinations of the four primary categories (i.e. IM, SD, ISD, etc.). Three main groups were observed: units that fired during arm movements (the I and M periods), units that fired during the periods between arm movements (the S and D periods), and units that responded both during and between arm movements. 142 neurons were recorded simultaneously from the same electrode tip in 50 pairs and 14 triples. Each triple was considered to consist of 3 pairs of units, thus yielding a total of 92 pairs of simultaneously recorded units analyzed. 27% of unit pairs were considered equal because both units of the pair belonged to the same category (e.g. M-M), 26% were considered similar because both units of the pair belonged to the same group (e.g. IM-M), 20% were considered complementary because one unit belonged to the arm-movement group and the other to the between-arm-movement group (e.g. IM-SD), and the remaining unit pairs (27%) were deemed mixed. These results suggest a variety of responses among pairs and triples of simultaneously recorded units that may reflect a diversity in local processing in the motor and premotor cortices, including motor preparation and sensory-motor integration. Examination of single-trial histograms further supports this view. (Supported by NSF grant BNS-8919867)

125.6

COMPARISON OF NEURONAL RESPONSES IN THE PRECENTRAL CORTEX WITH EMG ACTIVITY DURING AN ARM-MOVEMENT SEQUENCE DELAY TASK. M.C. Clark, J.K. Marcario, and R.E. Ketner, Prog. in Neural Science, Dept. of Psychology, Indiana University, Bloomington, IN 47405.

EMGs were collected from arm and trunk muscles of rhesus monkeys and human subjects performing a movement-sequence delay task. Each trial was initiated by pressing a center button when a cue light was illuminated. Two out of four target buttons were illuminated during a sensory period while the center button remained depressed. After a 2.5-3.5 second random delay period, the subject pressed the "remembered" target buttons in the appropriate sequence for a reward. The task allows the separation of initiation, sensory, delay, and movement responses. We have compared the EMG data with the neuronal activity recorded from the motor and premotor cortices of rhesus monkeys. Neuronal single-unit activity was classified into different categories based upon statistically significant levels of firing activity. We have found basically two groups of neuronal responses: those that fire during movements and those that fire during the sensory-delay period. EMG patterns were found to be similar to a subset of neuronal responses in the precentral cortex. Cortical responses were more varied. EMG activity was observed primarily during movement periods and did not show sensory-delay period activity without accompanying movement period activity. Thus, the precentral neurons active only during the sensory-delay period, had no counterpart in the EMG responses. This suggests that the sensory-delay period responses represent processing in the precentral areas that is not directly involved in muscle control, but may instead indicate other processes including sensory-motor integration and motor preparation. (Supported by NSF grant BNS-8919867)

125.7

PREPARATORY NEURONAL ACTIVITY IN PREMOTOR CORTEX DURING AN INSTRUCTED-DELAY PERIOD: RELATION TO CONTRA- AND IPSILATERAL ARM MOVEMENTS. D.J. Cranmond and J.F. Kalaska. CRSN, Dépt. de physiologie, Université de Montréal, Montréal, Canada, H3C 3J7.

Experiments using Instructed-Delay (ID) tasks have implicated neuronal activity recorded in the premotor cortex (PM) in the preparation of contralateral arm movement. This DELAY period activity may be encoding either details of the impending movement such as joint motion or muscle activity, or spatial attributes of the movement such as its trajectory and target location. In an attempt to distinguish among these possibilities, we studied PM discharge while a monkey made movements with identical trajectories in an ID task, with contralateral (CL) and ipsilateral (IL) arms. A rhesus monkey made movements from a central starting position in 8 directions to targets when a red LED was illuminated (GO, CONTROL task). In the ID task a green LED (CUE) was illuminated at the target in the second half of the centre hold period after which the target GO signal was illuminated. Results were obtained from 22 PM neurones: 19/22 (86%) cells discharged after the CUE in the ID task when using the CL arm, which in 18/19 cells was tuned and centred on a preferred direction (PD). Of these 18 DELAY cells, 17 (94%) cells were also active in the DELAY period when the IL arm was used. Three measures of neuronal activity during the DELAY period did not vary significantly between the IL or CL arm. These were: PDs (mean difference 1.4° per cell), level of cell discharge (26.1 & 24.7 imp/sec), and latencies after CUE onset (165.6 & 169.1 msec). Likewise, only small variations in cell PDs (1.4° per cell), discharge levels (26.8 & 26.9 imp/sec), and onset latencies (146.7 & 148.3) were recorded between CL and IL arms after the GO signal in the CONTROL task. In comparison, motor cortex (MC) cells rarely showed preparatory activity in the ID task. They were strongly active after the GO signal in the CONTROL task using the CL arm and weakly active with IL arm movements, and the PD of this activity differed widely with the two arms. Thus PM activity seems related to more general aspects of the movement, such as its spatial trajectory or endpoint, while MC activity is more specifically related to the details of the response. MOTOR CORTICAL CELL ACTIVITY IN A VISUALLY GUIDED ISOMETRIC FORCE PULSE TASK.

M. Taira*, J. Ashe, N. Smyrnis*, and A.P. Georgopoulos. Dept. of Neurosci., Johns Hopkins Sch. of Med., Baltimore, MD 21205.

We trained a monkey to produce force pulses (Fs) on a 2-D isometric handle (Massey et al., *Exp. Brain Res.* 83: 446, 1991) in a direction (Fv) indicated by a visual target, both in the absence of force bias and under 8 static force bias conditions (Fb) of different directions. A force feedback cursor indicated on the display the net force ($F_n = F_s + F_b$) exerted on the handle: The task was to exert such Fs so that $F_n = F_v$. In the absence of force bias ($F_b = 0$), Fs was in the direction of Fv; however, in the presence of force bias, as the force exerted increased, Fs changed continuously in direction and magnitude, so that at any moment $F_n = F_s + F_b = F_v$. Thus in these cases the net force, F_n , was dissociated from the active force, Fs, exerted by the animal. We wanted to find out whether the neuronal population vector calculated in time would reflect the direction of Fs or that of F_n . For that purpose we recorded the activity of 132 cells in the arm area of the motor cortex during performance of the task. The activity of 57% cells during the reaction time was directionally tuned. The population vector, calculated every 10 ms following the onset of the target, pointed in the direction of the net force, F_n (which coincided with Fv) and not in the direction of Fs. This result suggests that when a dynamic force pulse is initiated, the motor cortex might be involved with the specification of the visually-defined net force rather than with the actual total force output. (Supported by NIH, ONR, UCP.)

125.8

MOTOR CORTICAL CELL ACTIVITY IN A MEMORIZED DELAY TASK. N. Smyrnis*, J. Ashe, M. Taira*, J.T. Lurito, and A.P. Georgopoulos. Bard Labs., Department of Neuroscience, The Johns Hopkins Univ. School of Medicine, Baltimore, MD 21205.

We trained a monkey to move a handle from the center towards lights on a planar working surface. The information concerning the direction of the movement was provided by the peripheral light, and the triggering of the movement by turning off the center light. We recorded the activity of 121 cells in the arm area of the motor cortex during 3 main tasks: In the 1st task, the center light was turned off at the same time as the peripheral light was turned on. In the 2nd task, the peripheral light was turned on for 300 ms, after which it was turned off. This marked the beginning of the memorized waiting period (450-950 ms) during which there was no peripheral light. Then the center light was turned off to trigger the movement in the memorized direction. In the 3rd task, the peripheral light came on for 300 ms, as before, but remained on throughout the trial. We found that 52/121 (43%) cells changed activity during the memorized waiting period (2nd task). Moreover, 27/52 (52%) cells changed activity in the memorized (2nd) task, but not in the simply delayed (3rd) task. Finally, the neuronal population vector calculated every 20 ms pointed in the memorized direction (2nd task). These results indicate that the motor cortex is involved in processing information concerning memorized movement directions. Moreover, this processing can be visualized using the neuronal population vector analysis. (Supported by NIH, ONR, HSFP.)

BEHAVIORAL INVARIANTS ENCODED IN MOTOR CORTICAL

ACTIVITY. A.B. Schwartz, A. Kakavand* and J.L. Adams. Div. of Neurobiology, Barrow Neurological Inst., Phoenix, AZ 85013

We examined two behavioral correlates associated with the production of drawn figures. The speed of drawing is inversely correlated to the 2/3 power of the curvature of the drawn figure. This exponent is consistently found in human adults but varies greatly in young children. These movements are produced in segments, demarcated by points in the trajectory where angular acceleration is zero.

Having developed an algorithm leading to a neural representation in the motor cortex of movement trajectory, we asked the question: Are the behavioral features characteristic of the movement present in the activity of motor cortical cells? Monkeys drew spirals and figure eights on a touchscreen monitor as unitary activity was recorded from motor cortex. The directionally-sensitive unitary responses from different cells were added vectorially to form a time series of population vectors throughout the movement. Population vectors were added tip-to-tail, producing neural images of the trajectory. These images resembled closely the figures drawn by the monkeys. The movement trajectory and the neural image both obeyed the 2/3 power law. Also very similar were the number of segments and the duration of each segment in both the movement and the neural representation of the movement. This strongly suggests that the behavioral features, to which these drawing movements conform, are present in the activity of motor cortical cells. (NIH 26375)

126.2

DIRECTION CONTROL IN HUMANS WITH MOTOR CORTEX LESION. I.W. Martin*, J.P. Donoghue and J.N. Sanes. Center for Neural Science and Laboratory of Motor Control, Brown University, Providence, RI 02912.

One current hypothesis about the function of the primary motor cortex (MI) is that it controls movement direction. In support of this notion is the finding that MI neurons have discharge patterns that are tuned to the direction of voluntary movement. A corollary of this hypothesis might be that humans with lesion of MI would show deficits in direction control of voluntary movement. Previously, we showed (Kernan et al. 1990) that an MI lesion did not dramatically affect directional errors for straight line or parabolic shaped movements performed at a subjects' chosen speed. However, the chosen speed of MI lesion subjects was significantly slower than that of normal subjects. It is possible that movement direction control of MI lesion subjects is disrupted when they perform movements at speeds equal to those obtained by normal subjects.

Subjects with CT or MR defined focal lesion involving MI and normal controls performed planar reaching via-point movements for which normal subjects commonly employ parabolic paths; these paths by their nature have continuously changing direction. The movements were instructed to be done as fast as possible or at one's own speed. Path curvature and movement time of the first half of each of 30 movements at each speed were analyzed, with curvature measuring the ability to reproduce the presumed ideal path. For the movements performed at their own speed, MI subjects had movements that were slightly straighter, but were significantly slower (1 sec vs 0.5 sec) than normal. When the MI subjects performed movements in about the same time as normal, the curvature of their movements approximately that of normal subjects. Therefore, from these data, we would reject the hypothesis that MI lesion does not disrupt direction control of parabolic reaching movements performed rapidly. This hypothesis rejection casts doubt on the role of MI in participating in overall movement direction control. Nevertheless, MI may participate in other important aspects of preparation and execution of movement direction. 126.3

PARIETAL CORTEX ACTIVATION DURING VISUALLY GUIDED REACHING MOVEMENTS IN HUMANS MEASURED WITH PET. C. Kertzman, U. Schwarz, T. Zeffiro, and M. Hallett. Human Motor Control Section, MNB, NINDS and LSR, NCI, NIH, Bethesda, MD 20892.

Lesions of the posterior parietal cortex (PPC) in humans can result in difficulty in visually guided reaching within the proximal extrapersonal space. However, it is not clear to what extent this reflects a disruption in the process of computing information about current hand position and its intended movement in space, compared to spatial information concerning target location. To test the hypothesis that parietal cortex is involved in the motor component of reaching, we measured regional changes in cerebral blood flow (rCBF) in six control subjects using PET under 6 conditions: fixation with visual targets presented in either the right or left visual field and during reaching with the left or the right hand in either visual field. Subjects maintained central fixation while reaching, and visual targets were presented randomly on a screen within arm's reach. The subject's blood flow data was registered in 3D with corresponding brain MRI data. PET images obtained from corresponding fixation and reaching conditions were subtracted, and regions of interest were examined using an ART2 type neural network that clustered local maxima. A center of mass was determined for each cluster, and its location was projected back onto the corresponding MR image.

Bilateral activation was found in the superior and inferior parietal lobules in all subjects, particularly along the intraparietal sulcus and in precuneus. Some subjects showed asymmetric enhancement of the hemisphere contralateral to the arm used and not contralateral to the visual field in which the targets appeared; changing the arm changed the side of enhanced activity. Additional regions of focal rCBF were found in frontal cortex, cingulate gyrus, and occipital cortex.

These results confirm the role of PPC in the guidance of hand movements toward visual targets and suggest that its mapping of the target is more in limb coordinates than in field coordinates.

126.5

DISCHARGE PROPERTIES OF NEURONES WITHIN PRIMATE FACE SOMATOSENSORY CORTEX SI DURING TRAINED MOTOR TASKS. L.-D. Lin, G.M. Murray, and B.J. Sessle. Fac. of Dentistry, Univ. of Toronto, Toronto, Canada, M5G 1G6

Our recent studies in awake monkeys have shown that most tongue SI neurones alter their activity during a trained tongue-protrusion task but not during a trained biting task. The aim of this study was to determine if neurones in face SI also alter their activity in these two trained orofacial movements and if they do so in a selective manner. Extracellular single unit recordings were made in two awake monkeys (*M. fascicularis*) trained to perform the tongue-protrusion and biting tasks. A total of 71 face SI neurones with a mechanoreceptive field localized to the hairy upper or lower lip were recorded and 17 of them analyzed in both tasks. The activity of these neurones was related to both tasks (30%, 5/17), to the tongue task only (35%, 6/17), or unrelated to both tasks (35%, 6/17). The probability was significantly greater (Sign test, $p < 0.05$) that a neurone was related to the tongue task than to the biting task. In addition, 8 of the 11 tongue task-related neurones showed an increase and 3 a decrease in activity during the tongue task whereas 4 of the 5 biting task-related neurones showed an increase and 1 a decrease in activity during the biting task. These data suggest that some neurones in face SI as well as in tongue SI may selectively alter their activity in relation to different trained orofacial tasks and that these activity patterns may be utilized in the sensorimotor integration of orofacial movements. GATING OF CUTANEOUS INPUT TO SELECTED MOTOR CORTEX NEURONS DURING PREHENSION. N. Picard, G. Cadorel, and A.M. Smith. C.R.S.N., Université de Montréal, Québec, Canada H3C 3J7.

Three *M. fascicularis* monkeys were trained to grasp, lift and hold within a position window an object of varying weight and texture. The monkeys scaled the grip and lifting forces appropriately for the object weight and texture. Single units with cutaneous receptive fields were recorded from the hand area of the motor cortex where low-threshold (< 30 μ A) intracortical microstimulation (ICMS) elicited discrete digit movements. The neural activity was recorded in blocks of trials in which different combinations of object weight and texture were displaced. In an other condition, a force-pulse perturbation was delivered to the object during holding to produce a slip force on the fingers. Nearly two-thirds (67/128) of cutaneous cells were sensitive to object texture. The contribution of cutaneous afferents to the cell discharge was suggested by the a failure to find a correlation with grip force, by the responses to object slips induced by the perturbation and by the increased discharge frequency of certain neurons with rougher textures. A small number (11) of cells with cutaneous receptive fields on the glabrous skin of the digits were not active during the task despite the fact that their receptive fields were directly stimulated by the pinch. In all cases, ICMS delivered at these recording sites evoked contraction of muscles which, although active during grasping, had actions which would reduce grip force. Examples include extensor pollicis longus, abductor pollicis and extensor digitorum communis. Some of these cells were identified pyramidal tract neurons (PTN). Cutaneous afferents to the motor cortex provide information about texture and slip of surfaces in contact with the skin. In addition, these afferents appear to be selectively prevented from exciting neurons related to actions opposed to the goal of the task. Supported by MRC and NSERC of Canada and le Fonds FCAR du Québec.

126.4

FIRING PATTERNS AND PROPERTIES OF NEURONES IN PRIMATE TONGUE MOTOR CORTEX (MI) IN RELATION TO SWALLOWING. R.E. Martin*, G.M. Murray and B.J. Sessle. Faculty of Dentistry, Univ. of Toronto, and *The Toronto Hospital, Canada M5G 1G6.

Our recent studies have shown that some neurones in tongue MI of awake monkeys alter their firing rates during swallowing. The aim of this study was to determine the swallow-related firing patterns and mechanoreceptive field properties of these neurones. Extracellular single neurone recordings were made from tongue MI (defined by intracortical microstimulation; $\leq 20 \mu$ A) while the awake monkey (*M. fascicularis*) swallowed a fruit juice reward associated with successful performance of a tongue protrusion task. EMG activity from the genioglossus muscle was simultaneously recorded and swallowing was defined by a characteristic EMG activity pattern. For each of 37 tongue MI neurones examined, firing rates during swallowing and the 50ms period immediately preceding the swallow, were compared statistically with those during a control period (ANOVA and post hoc comparisons). Swallow-related activity patterns occurred in 28 (76%) of the neurones; of these, 36% (10/28) showed a significant ($p < .05$) alteration of firing rate only during the 50ms period preceding the swallowing, 25% (7/28) only during the swallow, and 39% (11/28) exhibited altered firing during both the swallow and the preceding 50ms period. In addition, 54% (15/28) had a mechanoreceptive field on the superior tongue surface. These findings suggest that tongue MI may be involved in the initiation and/or regulation of oral movements associated with swallowing. Supported by Canadian MRC.

INACTIVATION OF SENSORY CORTICO-CORTICAL INPUT AFFECTS NEURONAL ACTIVITY IN CAT MOTOR CORTEX. R. Izraeli and L.L. Porter. Dept. of Anatomy, USUHS, Bethesda, MD 20814.

The effects of input from a functionally distinct region of somatosensory cortex (area 2), on the ipsilateral motor cortex (area 4) were studied. Extracellular single and multi-unit activity was simultaneously recorded from area 2 and area 4 of anesthetized cats. Cells with matching or overlapping receptive fields (RFs) were isolated in both cortices. Subcutaneous or deep stimuli which evoked cell responses in both sites, were delivered to the RF area. Evoked potentials (EPs) and cell activity were monitored before and after injection of lidocaine in area 2. Lidocaine reversibly abolished cell activity and cell responses at the injection site, which in turn affected the EPs recorded in area 4. In several sites a reversal in polarity from positive-negative to negative-positive was noted. In other sites the EP amplitude was affected. The positive component usually decreased, while the negative phase increased at some sites, and decreased in others. Our results indicate that input from area 2 affects motor cortex activity, but further studies are needed to determine how it interacts with other sources of information.

126.8

EFFERENT NEURONS AND SUSPECTED INTERNEURONS IN MOTOR CORTEX OF THE AWAKE RABBIT. H.A. Swadlow. Dept. of Psychology, University of Connecticut, Storrs, CT 06268.

Efferent neurons and suspected interneurons (SINs) were studied in rabbit motor cortex. Microstimulation of this region yielded low-threshold movements of the rostral vibrissae, sinus hairs or phillum. Axonal properties and sensory receptive fields were examined in four efferent populations: callosal (CC) neurons, neurons projecting to ipsilateral S-1 (C-IC), and descending corticofugal neurons of layer 5 (CF-5) and layer 6 (CF-6). Suspected interneurons (SINs) responded with a hi-frequency (> 600 Hz) burst of spikes to stimulation of ventrolateral thalamus.

Receptive field position within this area corresponded roughly to the position of twitches produced by microstimulation, and receptive field sizes were much larger than seen in S-1. SINs had the largest receptive fields and the highest spontaneous firing rates of any population. CF-5 neurons had high axonal conduction velocities (median value ~ 12 m/s), intermediate spontaneous firing rates (median = 3.5 spikes/sec), and had the largest receptive fields of any efferent population. In contrast, CC, C-IC and CF-6 populations each had low axonal conduction velocities (medians all < 2 m/s), low spontaneous firing rates (medians all < 0.5/sec), and had smaller receptive fields. Whereas nearly all SINs and CF-5 neurons responded to peripheral sensory stimulation, many CC, C-IC and CF-6 neurons did not.

These differences among efferent neurons and SINs of motor cortex mirror similar differences among corresponding populations studied in S-1, S-2 and V-1 (Swadlow, H. A., *J. Neurophysiol.*, 59: 1162-1187, 1988; 62: 288-308; 63: 1477-1498; in press, 1991). These data suggest that a common physiological plan underlies the operations of functionally and morphologically diverse neocortical regions and that efferent analysis may be pivotal to understanding this plan.

126.9

Functional consequences of branching in primate cortico-motoneuronal (CM) cells. K.M. Bennett* and R.N. Lemon, Anatomy Dept., Cambridge University, England, CB2 3DY.

Primate CM cells branch to produce monosynaptic facilitation of several hand muscles. As this system is important for fractionated finger movement we examined CM cell activity and its functional output during precision grip. Two *Macaca nemestrina* monkeys performed a low force (0.5-1.5N) precision grip. Levers moved by the index finger and thumb were then held within a target zone for 1-2s. PTNs were used for the spike-triggered averages of up to 8 forelimb muscles. Post-spike facilitation (PSF) revealed a CM connection. 16 CM cells, with PSF of 2 target muscles, were analysed. The muscles cocontracted during the hold periods. During movement they contracted independently of each other. With low discharge, each CM cell produced PSF of both muscles during the hold phase. Maximum discharge was seen with the independent activity of ONE muscle. PSF of this muscle was enhanced in this period. 8 cells produced no PSF of one muscle when it was independently active.

Thus each CM cell exerts PSF of its target muscles both when they are cocontracted and during periods of EMG fractionation. Modulation in the relative activity of target muscles is associated with clear changes in the firing pattern and facilitatory influence of the CM cell. This contributes to the fractionation of muscle activity during independent finger movement.

126.11

SYNCHRONIZED 25-35 HZ OSCILLATIONS IN SENSORIMOTOR CORTEX OF AWAKE MONKEYS. V.N. Murthy and E.E. Fetz, Department of Physiology & Biophysics and Regional Primate Research Center, University of Washington, Seattle, WA 98195.

Local field potentials and activity of some units recorded in sensorimotor cortex of awake rhesus monkeys showed transient synchronous oscillations between 25 and 35 Hz. These oscillations occurred more frequently during performance of tasks involving fine finger control (eg., retrieving raisins from a Klüver board) than during repetitive alternating wrist movements. During the former tasks, oscillatory spindles typically consisted of 5-15 cycles and recurred once or twice per second. More sustained oscillations could also be evoked by cutaneous stimulation of the arm. In the motor cortex the spindles did not appear in any regular relation to the EMG activity of forelimb muscles, but cycle-triggered averages of EMG sometimes revealed synchronous effects in both flexor and extensor muscles. The polarity of the oscillations reversed at a cortical depth between 250 and 500 μ m, suggesting an intracortical source of these fields. Simultaneous recording from cortical sites separated by up to 10 mm in the anterior-posterior direction [estimated 20 mm tangential intracortical distance] or up to 8 mm mediolaterally revealed that oscillations could occur coherently over these distances. The spindles occurred most robustly and extensively in the precentral gyrus; these appeared to be intermittently phase-locked with more localized spindles in the postcentral gyrus. During the oscillatory episodes, single units often discharged preferentially during a particular phase of the oscillations and could become synchronized with other units separated by estimated distances up to 15 mm. Thus, neurons in the pre- and post central cortex can be transiently recruited into coherent activity during the oscillatory events. [Supported by NIH: NS12542 & RR00166.]

126.13

LATERALIZATION OF GAMMA BAND EEG ACTIVITY DURING ATTENTION-DEMANDING TASKS IN 23 MEDICAL STUDENTS. M.B. Levin, and M.L. Reite, Colo. Psych. Hosp., Univ. of Colo. Hlth. Sci. Cntr., Denver, CO 80220.

High frequency (30-80 Hz) electroencephalographic (EEG) activity has been attributed to several aspects of brain intercommunication, from the mediator of attention to the means by which areas of cortex communicate with one another and with other areas of the brain. This study examined the power in the 36-44 Hz EEG band (referred to here as 40 Hz activity) over areas of cortex in normals during attention demanding tasks. Twenty-three right handed medical students, 11 females and 12 males, were recruited for this study. Six electrodes, referenced to linked ears, were placed on the scalp; over left and right frontal, central, and parieto-occipito-temporal cortex. EEG data was obtained during a visual-motor task such that it represented the subject's being in a "state of readiness" to push a button. The data was adjusted for muscle activity via a mathematical technique which treated activity in the 36-44 Hz and 62-78 Hz bands as amplitude modulated signals with 40 Hz and 70 Hz carrier waves respectively. The power in the 40 Hz band due to brain independent of muscle was calculated as the difference between the 40 Hz and 70 Hz "demodulated" EEG data averaged over time. Normalized laterality values of 40 Hz activity were determined over time for the frontal, central, and parietal areas. Statistical analysis demonstrated significantly increased left, over right, central 40 Hz power just prior to motor response. There were no significantly different normalized laterality values for the parietal or frontal regions. Furthermore, a figure rotation task for which no motor response was required demonstrated no significant changes in laterality value. This lateralization of 40 Hz power over the central cortex may represent a component of the event-related desynchronization described as a decrease in alpha activity over left central cortex during right hand voluntary movements.

126.10

MOTOR CORTICAL ACTIVITY DURING VOLUNTARY GAIT MODIFICATIONS MAY SPECIFICALLY ENCODE MUSCLE ACTIVITY AT A SINGLE JOINT. T. Drew, Dept. Physiologie, Université de Montréal, Québec, Canada, H3C 3J7.

The discharge patterns of 91 identified pyramidal tract neurones (PTNs) in the forelimb region of area 4 were recorded in a task in which unrestrained, chronically implanted cats were required to make a coordinated modification of their gait in order to step over moving obstacles attached to a treadmill belt. The results showed that 52% of these cells (48/91) increased their discharge rate by greater than 20% during the swing phase of the contralateral limb when the cat stepped over the obstacle. An analysis of the discharge patterns of the task-related cells over different kinds of obstacles showed that some cells were temporally related to the onset and offset of activity in specific muscles rather than discharging throughout the movement. 22 cells discharged during early and mid-swing and appeared to be principally correlated with the periods of activity in either elbow flexors or shoulder protractors, while a further 12 cells increased their discharge frequency only in late swing and were better correlated to the changes in wrist dorsiflexor muscle activity required to control the placement of the foot. These results suggest that some PTNs specifically code parameters of muscle activity around single joints in these multi-articulate movements, despite the widespread spinal branching of PTNs, and despite the fact that microstimulation through the recording electrode during locomotion frequently evoked transient increases in the activity level of muscles acting around different joints. (Supported by the MRC and FRSC).

126.12

INTRACELLULAR CORRELATES OF OSCILLATORY ACTIVITY OF CORTICAL NEURONS IN AWAKE BEHAVING MONKEYS D.F. Chen & E.E. Fetz, Regnl. Primate Res. Ctr. & Dept. of Physiology & Biophysics, Univ. of Washington, Seattle, WA 98195

Synaptic interactions between pairs of neurons in sensorimotor cortex were documented by spike-triggered averages (STAs) of membrane potentials (MPs) in awake monkeys performing a step-tracking task. Intracellular (IC) recordings were obtained with K-methylsulfate electrodes, while extracellular spikes from neighboring "EC" cells were recorded with carbon-fiber electrodes. To analyze the interspike membrane potential trajectories, we also compiled averages of the MPs for various fixed intervals between pairs of IC action potentials (APs). The 14 IC cells analyzed to date all had stable resting MPs of at least -50 mV, overshooting APs and a wide range of firing rates during rest or task performance. These neurons can be divided into three groups according to their AP width and interspike MP trajectories. Cells of one group (n = 4) had narrow spikes (0.5 ms) with a fast initial repolarization, which suddenly changed to a slower repolarization lasting 4 - 9 ms, followed by a 20 - 25 ms depolarizing rebound to the resting level or to a subsequent AP. These four cells had a strong tendency to fire around 25 - 35 Hz. The other two groups showed no significant rebound trajectories and did not fire preferentially around 30 Hz. In three of the four "30 Hz" IC cells, STAs of MPs revealed subthreshold oscillatory potentials at 25 - 40 Hz, due to common synaptic input to the EC and IC cells. This evidence suggests that some cortical neurons have a distinctive membrane potential trajectory that may play a "pacemaker" role in making them fire preferentially at about 30 Hz. In addition, subthreshold oscillatory common input potentials suggest synaptic interconnections between these cells that would further contribute to this tendency. LOCALIZED OSCILLATORY ACTIVITY IN THE SENSORIMOTOR CORTEX IN MOTIONLESS PERIODS OF A REPETITIVE MOTOR TASK E. Lado, U. Ribary, L. Lopez, R. Jagow, A. Mogilner, R. Llinás, Center for Neuromagnetism, Dept. of Physiology and Biophysics, New York University Medical Center, New York, NY 10016, USA.

Using a 14 channel MEG system (BTi), the magnetic field pattern produced by neural activity was recorded while human subjects performed a simple movement once every few seconds. Several trials were combined to yield measurements from 30 - 35 scalp locations. Analysis of the data demonstrated that there is a consistent increase in average signal power at higher frequencies (>10 Hz) during pre- and post-motor periods, relative to the average power observed at the time of movement onset. The averaged movement evoked magnetic field revealed no fast activity. The topographic distribution of signal power over the scalp was consistent with that of a current source located in the sensorimotor region. If the assumption is made that a single source generated the signal, it is then possible to compute the average phase relationship between all scalp locations by using cross correlational techniques. Given these assumptions, it could be shown that the two maxima evident in the topographic maps of field power corresponded to the positive and negative field extrema of a localized source. Recent experiments using a 37 channel MEG system (BTi) have permitted simultaneous recording of a large area of scalp, over the motor region. Analysis of this data revealed well organized but complex relationships between signals recorded from different locations. These complex relationships force a reevaluation of the traditional single dipole source as a model for understanding cortical activity and suggest new interpretations for focal activity in the cortex based on the analysis of phase. From these findings it is clear that well localized and task related neuronal activity occurs that cannot be observed in averaged evoked recordings. Moreover, the richness of the phase relationship between signals recorded from different scalp locations calls for an equally rich model of cortical activity.

LAYER V CONTAINS A SUBSTRATE FOR REORGANIZATION OF MOTOR CORTEX MAPS. K.M. Jacobs, B.W. Connors and J.P. Donoghue Center for Neural Science, Brown University, Providence, RI 02912

Blocking inhibition via local cortical application of bicuculline (bic) leads to reorganization of motor cortex (MI) similar to that seen after nerve lesion or changes in sensory feedback (Jacobs and Donoghue, 1991). These results suggest that the cortex contains a substrate for MI reorganization. We hypothesize that MI map changes are due to alterations in horizontal connections between adjacent motor cortex representations. In order to test this hypothesis and identify the cortical architecture which could contribute to reorganization, we recorded field and intracellular potentials from *in vitro* coronal slices of rat MI. Field potentials were recorded at regularly spaced intervals through the depth of cortex, while stimulating electrically in layer V, 500 μ m medial to the recording sites. The largest amplitude potential was a negativity recorded in layer V. Using current-source-density analysis this was identified as the site of the largest current sink, suggesting that a strong horizontal pathway exists within layer V. Next, the recording electrode was moved laterally in layer V away from the stimulation site in steps of 250 μ m. Area, peak amplitude, and slope of the field negativity all decayed with distance. At distances greater than 1.0 mm, the field response was nearly absent. When bic was applied locally within 100 μ m of the layer V recording site (which was 1.0 to 1.5 mm lateral to the stimulation site), the field negativity increased, revealing a connection between horizontally-distant layer V sites which is normally suppressed by inhibition. Intracellular recordings showed that epsps could be evoked by stimulation in layer V, 1.0 mm away from the recorded cell. The stimulus-evoked epsp amplitude was enhanced and firing elicited after local application of bic within 100 μ m of the recorded cell. These results demonstrate that strong excitatory connections exist between horizontally-distant sites in layer V and that these connections are normally masked by inhibition. Therefore, layer V appears to contain a substrate sufficient to reorganize motor cortex representations. Supported by NIH NS 22517, 25074 and March of Dimes 5-562.

CONTRIBUTION OF APICAL DENDRITES TO SOMATIC MEMBRANE PROPERTIES OF LAYER V PYRAMIDAL CELLS IN NEOCORTEX. A.E. Telfeian, L.J. Cauler and B.W. Connors. Section of Neurobiology, Brown University, Providence, RI 02912.

A unique but enigmatic feature of large pyramidal cells is the apical dendrite. To explore the role of apical dendrites we recorded and stained (with biocytin) pyramidal cells of layer Vb in slices of rat SI cortex. Cuts were made along the layers IV-V border to dendrectomize neurons. Populations of cut and control pyramidal neurons had similar proportions of intrinsic firing properties (about 40% regular-spiking, 33% intrinsically bursting and 48% oscillating), spike sizes, V_m s and time constants (τ_p and τ_i). R_{in} s for nonbursting neurons in cut and uncut slices were very similar, however the mean R_{in} for dendrectomized bursting cells was about double that of control bursting cells. The effects of dendrectomy were also tested in a compartmental model of a large layer V pyramidal cell using the program NEURON (M. Hines); simulated removal of the apical dendrite only increased R_{in} by 5% to 20% (depending upon choice of specific internal resistivity, from 350 to 75 Ω cm). We conclude that 1) amputation of most of a large apical dendrite does not impair the viability of a neuron, 2) the contribution of the apical dendrite to the active and passive behavior of the soma is usually small; in particular, intrinsic bursting does not depend upon the apical dendrite. Supported by NIH and ONR.

SIMULATIONS OF DENDRITIC INTEGRATION IN RECONSTRUCTED PYRAMIDAL AND NONPYRAMIDAL NEURONS OF NEOCORTEX. L.J. Cauler, M.S. Wehr*, I. Bülthoff* and B.W. Connors. Sect. Neurobiology, Brown Univ., Providence, RI 02912.

The diverse shapes and physiology of neurons in the neocortex suggest that each cell type may process synaptic inputs in a distinctive way. We recorded from spiny and smooth neurons from layers II to V in the rat SI barrel-field *in vitro*, measured R_{in} , τ 's and intrinsic firing properties, and synaptically activated distal dendrites via axons of layer I. Each cell was filled with biocytin, its morphology was quantified, and a passive electrotonic model was generated with the program NEURON (kindly supplied by M. Hines). Likely ranges of membrane parameters were determined for each cell, and steady-state and transient analyses were performed. Nonpyramidal cells were the most electrotonically compact, followed closely by the proximal regions (basal and apical oblique dendrites) of pyramidal cells: e.g. unitary excitatory synaptic conductances (1 nS peak) applied to the dendrite tips generated EPSPs of about 0.1-1 mV in the somata. The distal apical tufts of large layer V pyramidal cells were strikingly different, however; somatic EPSPs generated by simulated tuft (layer I) synapses were extremely small and slow. Because layer I synapses can generate strong, fast excitation experimentally (Cauler & Connors, NS abst., 1990), we suggest that active conductances in apical dendrites facilitate distal synaptic inputs. Supported by NIH and ONR.

PHYSIOLOGICAL AND PHARMACOLOGICAL STUDIES OF EXCITATORY SYNAPTIC POTENTIALS FROM LAYER II-III TO LAYER V CELLS OF THE CAT MOTOR CORTEX *IN VITRO*. C. Capaday and E.E. Petz. Department of Physiology & Biophysics, University of Washington, Seattle, WA, 98195.

Intracellular data was obtained from 60 cells in Layer V of neocortical slices from area 4-gamma of the cat. To date the results from 14 cells have been analyzed. Layer II-III was electrically stimulated by 100 μ s square pulses at 1.5 to 2 times threshold for eliciting an EPSP in layer V cells. These EPSPs were completely eliminated by perfusion of solution containing 5 mM Kynurenate, which blocks all 3 types of excitatory amino acid receptors. The EPSP amplitude of most (n=11) layer V cells was independent of the membrane potential over the range from -65 mV to -95 mV. Perfusion of Mg^{++} free solution increased the amplitude and duration of the EPSPs 1.5 to 2.5 times. In the Mg^{++} free solution the amplitude of the EPSPs increased with hyperpolarization, in marked contrast to their behaviour in normal solution. This observation implies that NMDA-receptors normally contribute to the excitatory synaptic current of these cells. Furthermore, when APV (a specific NMDA-receptor blocker) was added to the Mg^{++} free solution the enhanced EPSPs were reversibly reduced. These results may be relevant to mechanisms of motor learning and provide a basis for the observation of LTP in pyramidal tract neurons.

DENDRITIC ELECTROGENESIS IN NEOCORTEX NEURONS *IN VITRO*. Y. Amitai*, A. Friedman*, B.W. Connors* and M.J. Gutnick*. Dept. Physiology, Ben-Gurion University of the Negev, Beersheva, Israel, and *Div of Biology & Medicine, Brown University, Providence, RI, USA.

The complexity of the neocortical neuropil has hindered study of dendritic electrical properties. We recorded intracellularly from pyramidal cell dendrites in coronal slices of rat and guinea pig parietal neocortex, maintained *in vitro*. In some recordings, the dendritic impalement site was confirmed anatomically by dye injection; in others, it was inferred from the distinctive pattern of activity. In all recordings, depolarizing pulses evoked at least two types of spikes, fast and slow, which arose from different voltage thresholds and were clearly distinguishable from typical somatic spikes. TTX caused the disappearance of fast spikes, leaving repetitive generation of broad spikes.

These data indicate that in neocortex, the dendritic membrane contains voltage-dependent channels that are sufficient to initiate and sustain regenerative events.

Morphological characteristics of double-labelled axotomized corticospinal neurons studied *in vitro*. G.-F. Tseng, D.A. Prince. Dept. of Anat., Col. of Med., Nat'l. Taiwan U. and Dept. Neurol. & Neurol. Sci., Stanford U., Sch. of Med., Stanford, CA 94305

Identified normal and axotomized corticospinal neurons were studied in a slice preparation using a double-labelling technique (Tseng et al., '91, J. Neurosci. Meth., in press). Axotomy and labelling were performed at C2-3 cervical levels on 4-5 week old albino rats. Axotomized cells were studied intracellularly at 3, 9, and 12 months after surgery. Physiologically, axotomized differed from normal cells by higher input resistances, lower rheobase currents, steeper f-I relationships, higher steady state spiking frequencies, and fewer cells had identifiable sAHP. Other passive membrane properties were comparable to those of normal neurons. Synaptically, there seems to be a decrease in the incidence of IPSPs been evoked in response to layer I stimuli.

Morphologically, axotomized corticospinal neurons had smaller somata and maintained a pyramidal shape. Sholl's analysis at 40 micron increments revealed a basal dendritic arborization comparable to that of normal cells. In addition, the basal dendritic domain, the apical dendritic width, measured at 80 microns from the center of the soma, and the maximal number of distal, apical dendritic branches were also comparable to those of normal cells. Like normal cells, superficial layer ascending axon collaterals were only rarely identified in axotomized neurons.

These results indicate that distantly axotomized corticospinal neurons maintained their dendritic and local axonal arbors while their somata became smaller. Their high input resistance and steep f-I slope will make them hyperexcitable (as compared to normal cells) upon stimuli. Thus both physiological and morphological data suggests that axotomized cortical neurons may participate actively in cortical functioning instead of regress into an inactive state. PARABOLIC FLIGHT STUDIES IN ASTRONAUTS: OCULAR TORSION IN NOVEL GRAVITY STATES PREDICTS SPACE MOTION SICKNESS. Shirley G. Diamond and Charles H. Markham, Dept. Neurology UCLA School of Medicine, Los Angeles, CA 90024-1769.

Studies in hypo- and hypergravity of parabolic flight examined ocular torsion during 10 to 20 parabolas in 9 former astronauts seated upright. Those who had space motion sickness (SMS) on prior space missions had high scores of disconjugate eye torsion on NASA's KC-135 aircraft, while those free of SMS had low scores. This finding suggested a predictive test of SMS. A follow-up asked: 1) Would tilting the prior subjects null their torsional asymmetry in hypergravity? 2) Could a predictive test be obtained in fewer parabolas? 3) Would results in additional astronauts support the earlier findings? Four new and 4 prior high score astronauts were studied in 5 positions: 4 parabolas each in upright, 5° and 10° right and left ears down. Results showed 1) tilting did not alter torsional asymmetry and a tilted protocol was not as clear a discriminator of SMS propensity as was the upright; 2) four parabolas in the upright position were not sufficient to effectively differentiate those who had SMS from those who had not; 3) the 4 new astronaut subjects showed 2 with high scores and 2 with low scores of torsional asymmetry on the KC-135. The high scorers had had SMS on their space missions and the low scorers did not, supporting results of the earlier study. We conclude eye torsion on the KC-135 may offer a simple predictive test of SMS.

DISCHARGE PROPERTIES OF AFFERENTS INNERVATING THE POSTERIOR CRISTA IN THE ISOLATED HALF HEAD OF THE TURTLE. A.M. Brichta and J.M. Goldberg. Dept. of Pharmacological and Physiological Sciences, Committee on Neurobiology, University of Chicago, Chicago, IL 60637.

As a first step in developing an *in vitro* preparation of the posterior crista of the turtle, *Pseudemys scripta*, we have recorded afferent activity in the isolated half-head. Fibers innervating this end organ were identified by their responses to pitch rotations. Most units have a background discharge of 5-30 spikes/s. Some are regularly and others irregularly discharging. A coefficient of variation (cv*), normalized to a mean interval of 50 ms, varies between units from 0.1-0.8. Different fibers respond to sinusoidal rotations with maximum sensitivities of 0.1-30 spikes·s⁻¹/deg·s⁻¹. Based on responses to 0.1-3 Hz rotations, the units can be divided into three groups. Group 1 consists of regular, intermediate and irregular units whose gain and phase leads re head velocity both increase with cv*. Discharge leads head velocity by <45°. The most regular units of the group have response dynamics resembling the torsion pendulum model. Group 2 are irregular units whose gain and phase leads are larger than those of irregular group 1 afferents. Group 3 are irregular units responding to a combination of head jerk and head acceleration.

There are four kinds of afferents terminating in the turtle posterior crista: calyx, dimorphic, and two varieties of bouton units (Brichta and Peterson, *Soc. Neurosci. Abstr.* 16: 735). Intra-axonal labelling studies are needed to match the morphological and physiological groups. (Supported by ONR Contract N00014-88-k-0381).

COMPARISON OF HAIR-CELL POPULATIONS AND AFFERENT INNERVATION PATTERNS IN THE CRISTAE OF THE SQUIRREL MONKEY AND THE CHINCHILLA. C. Fernández*¹, A. Lysakowski*² and J.M. Goldberg². Depts. of ¹Surgery and of ²Pharmacological and Physiological Sciences, The University of Chicago, Chicago, IL 60637.

The structural organization and afferent innervation patterns in the chinchilla cristae have been described (*J. Neurophysiol.* 60:167-181, 1988). We now report that the organization of the cristae in the monkey differs substantially from that in the chinchilla. In the latter species, there is an ≈1:1 ratio of type I and type II hair cells in all regions of the epithelium. Hair-cell counts indicate that in the monkey type I outnumber type II hair cells by a ratio of ≈3:1. The ratio is higher in the central zone (≈5:1) than in the peripheral zone (≈2:1). As might be expected from the differences in hair-cell ratios, innervation patterns are distinctive in the two species. Comparisons are based on data from 301 monkey and 368 chinchilla units labeled with horseradish peroxidase. In both species, calyx units are concentrated in the central zone and bouton units in the peripheral zone; dimorphic units are seen throughout the sensory epithelium. Three differences reflect the relative paucity of type II hair cells in the monkey: a) the percentage of calyx units is 3x larger in this species; b) the percentage of bouton units is 1.5x smaller; and c) central dimorphic units have half as many bouton endings. Calculations indicate that in both species each type II hair-cell receives an average of ≈20 afferent boutons. This suggests that the afferent innervation in each species is matched to its hair-cell population. 127.2

DO LABYRINTHINE AFFERENTS EXCITE HAIR CELLS? S.L. Cochran. Dept. Life Sciences, Indiana State University, Terre Haute, IN 47809.

Glutamate (but not NMDA agonists), when bath-applied to the isolated labyrinth of the frog, results in an increase in EPSP and action potential frequency, as well as afferent depolarization. The increase in EPSP frequency suggests that hair cells have non-NMDA receptors, which depolarize the hair cells and increase transmitter release. This increase in EPSP frequency precedes afferent depolarization and persists in 10 nM TTX (which blocks afferent action potentials) suggesting that glutamate acts by directly depolarizing hair cells, rather than indirectly depolarizing hair cells due to K⁺ release accompanying afferent spiking and depolarization. Since the afferents are 'glutamatergic' and since reciprocal synapses have been reported between hair cells and afferents (Dunn, 1980, *J. Comp. Neurol.* 193: 255-264), it is possible that afferent activity can modify transmitter output from hair cells. However, an analysis of the intervals between EPSPs indicates no increase in the probability of occurrence of an EPSP following an action potential and no correlation between EPSP amplitude and either the interval between EPSPs or the amplitude of the subsequent EPSP. Preliminary ultrastructural investigations confirm the presence of vesiculated profiles in the afferents, but typical active zones (from afferent to hair cell) seem to be absent. These findings suggest that afferent activity does not synaptically modulate release of transmitter from hair cells, although hair cell activity may influence adjacent hair cell activity through the glutamate-like transmitter released at hair cell-afferent synapses.

127.4

ORGANIZATION OF EIGHTH NERVE EFFERENTS IN THE TURTLE, *PSEUDEMYX SCRIPTA*. A. Fayyazuddin, A.M. Brichta, and J.J. Art. Dept. of Pharm. & Physiol. Sciences, Committee on Neurobiology, The University of Chicago, Chicago, IL 60637.

As part of a larger study aimed at understanding the efferent contribution to auditory and vestibular control we have begun to characterize the organization and location of the C.N.VIII efferent axons and cell bodies in the turtle, *Pseudemys scripta*.

Following unilateral extracellular injections of horseradish peroxidase (HRP) into the posterior branch of the eighth nerve we observed retrogradely labelled cells confined to both ipsi- and contralateral medial reticular nuclei. Efferent cell bodies ranged in size from 96 to 389 μm² (mean ± s.d.; 199 ± 96), but there was a bimodal distribution in their size spectra, suggesting the presence of two groups. The larger group (89%) had a mode of ≈160 μm² and the smaller group (11%) had a mode of ≈330 μm². Further evidence of two groups of efferents came from measurements of parent axon diameters, prior to bifurcation, as they entered the midline bundle within the medial longitudinal fasciculus (MLF). Efferent axon average diameters (1.37 ± 0.45 μm) size spectra revealed the presence of two groups with modes of ≈1.6 μm and ≈2.8 μm respectively. To ascertain if these differences may reflect variations in efferent terminal patterns we have begun a quantitative analysis of individual anterogradely filled efferent terminals following HRP injections into the MLF. Our preliminary results suggest that small diameter axons have few if any bifurcations as they course within the peripheral nerve and supply only one end organ. In contrast, large diameter axons were seen to bifurcate extensively and supplied more than one end organ.

Taken together these results suggest that eighth nerve efferents may be subdivided into two possible subgroups based on their structure and spatial organization. (Supported by NINCDC DC 00454, and ONR N00014-88-k-0381).

127.6

TOPOGRAPHIC DISTRIBUTION OF FIBERS PROJECTING TO THE SEMICIRCULAR CANAL CRISTAE IN THE CHINCHILLA. V. Honrubia¹, E. Naito¹, Y. Naito¹, M. Ross², & L. Hoffman¹. ¹Victor Goodhill Ear Center, UCLA School of Medicine, Los Angeles, CA 90024 and ²NASA Ames Research Center, Moffett Field, CA 94035.

The number and distribution of nerve fibers in the semicircular canal cristae of chinchillas were investigated through thin (1 μm) plastic-embedded histologic sections, serial reconstructions and computer-based graphic methods.

There is a systematic organization of fibers reflecting the topography of the receptor area in the crista. Nerves projecting to individual cristae branch first from the single canal nerve into two bundles, one for each transverse half of the crista. Thereafter each "hemineur" subdivides again in two, one bundle for half of the utriculopetal and utriculofugal slopes of the crista. As the fibers enter the stroma of the receptor organ, the fibers beneath the center of the crista further subdivide into small bundles containing 30-40 fibers. These bundles are comprised of fibers with a broad distribution of diameters, comparable to that of the entire canalicular nerve (Carney et al., *ARO Abstracts* 13:364, '90). Fibers proceed in a straight trajectory and without bifurcation in the direction of the crista apex. Fibers within each bundle were found to innervate an apex-to-perimeter slab of the neuroepithelial surface, 30-50 μm in width. Individual fibers followed a straight course until they reached the level along the crista slope of their eventual innervation destination, at which time they turned sharply toward the neuroepithelial surface. The bundles destined to the periphery of the crista run in a lateral position in the canalicular nerve and innervate hair cells in the lateralmost ends of the crista. The majority of fibers in these bundles are of smaller diameter (<3 μm).

The morphological organization of the nerve suggest that information from different areas of the crista travels in the vestibular nerve in discrete channels according to crista location. In view of the well known size dependent differences in fibers response dynamics, the vestibular nerve not only sends information about different types of head motion, but this information might also represent a topographical map of the cristae within the CNS.

EYE MOVEMENTS AND BRAINSTEM NEURONAL RESPONSES EVOKED BY CEREBELLAR AND VESTIBULAR STIMULATION IN CHICKS. S. du Lac and S.G. Lisberger, Dept of Physiology, UCSF, San Francisco CA 94143.

Inputs from the cerebellar floccular onto brainstem vestibular neurons are essential for adaptive changes in the vestibulo-ocular reflex. As a step toward developing an *in vitro* preparation for studying the cellular and synaptic nature of those changes, we have characterized floccular and vestibular interactions in the intact chick. We placed stimulating electrodes in the horizontal vestibular ampulla and the flocculus of 3-6 week old ketamine anesthetized chicks. Stimulation-evoked eye movements were monitored with a scleral search coil and brainstem neuronal responses were recorded extracellularly.

Electrical shocks to the vestibular ampulla evoked brief, contralaterally directed movements in both eyes. Although single shocks to the flocculus elicited no response, conjunctive floccular and vestibular stimulation significantly reduced the vestibularly-evoked movement. Trains of current pulses applied to the flocculus and ampulla evoked eye movements directed toward and away from the side of stimulation, respectively. Recordings from the brainstem revealed a number of neurons that were activated by ipsilateral vestibular stimulation (at latencies of 0.7 to 3.1 msec) and inhibited by ipsilateral floccular stimulation. In units with no spontaneous activity, we found that floccular stimulation reduced the probability of a vestibularly-evoked spike. The duration of floccular inhibition in spontaneously active neurons ranged from 9 to 38 msec. Our sample included neurons in the lateral, medial, and superior vestibular nuclei. Similarities between these findings and those of comparable studies in mammals indicate that the chick will provide a good model system for cellular and synaptic studies of the vestibulo-ocular reflex. (supported by NIH training grants EY-07058 and EY-06318 and by the McKnight Foundation)

EFFECTS OF MK-801 ON ADAPTIVE VESTIBULO-OCULAR REFLEX MODIFICATIONS IN THE GOLDFISH

J.G. McElligott¹, T.L. Carter¹, and R. Baker² ¹Dept. of Pharmacology, Temple University School of Medicine, Phila., PA 19140, and ²Dept. of Physiology and Biophysics, N.Y.U. Medical Center, New York, NY 10016

Goldfishes can produce large and rapid adaptive vestibulo-ocular reflex (VOR) gain modifications which can serve as a model for studying neuroplastic changes in the sensori-motor system. VOR modification experiments investigated the influence of the NMDA antagonist, MK-801, which is known to affect other neuroplastic changes. After initial calibration measurements of the VOR in light and dark, goldfishes received either an intramuscular control injection of fish Ringer's solution or MK-801 (1mg/kg). This dose of MK-801 did not alter the unmodified gain of the VOR in the light or dark. VOR gain modification was initiated approximately 30 minutes after the injection and continued for a 3 hour period. Training towards a gain of 2X was accomplished by presenting visual stimuli 180 degrees out of phase with the vestibular platform rotating about the vertical axis (1/8 Hz \pm 20 deg). Control injected fishes immediately produced a significant gain change (0.82 gain change/hr). For the fishes that received the MK-801 injection, there was no gain change during the first 30 minutes. The subsequent VOR gain change was reduced considerably (0.34 gain change/hr). However, after 3 hours these fish produced a gain change comparable to that of the control animals. Another group of fishes received a similar injection of MK-801. However, VOR modification did not commence until at least 2 hours after the injection. For this 2 hour delayed modification group, the MK-801 had a more pronounced effect. No increase in VOR gain above baseline occurred during the first 60 minutes of modification. Subsequently, the rate of gain change was less (0.2 gain change/hr) than observed in the first set of experimental animals. Even after 5 hours of modification the final gain achieved by these fishes was less than that reached by the other animals that were modified for 3 hours. Thus, intramuscular injection of MK-801 is able to hinder modification of VOR without affecting the unmodified VOR. (Supported by a grant from NIH DC 01094)

127.11

DISTINCTIVE DYNAMICS OF FLOCCULUS RECEIVING NEURONS IN THE RABBIT VESTIBULAR NUCLEUS. J.S. Stahl and J.L. Simpson, Dept. Physiology & Biophysics, NYU Med. Ctr., New York, N.Y. 10016.

We have demonstrated (SfN Abst. 15: 206.6) that for 0.2 Hz rotation in the light, the average firing rate of vestibular neurons receiving direct floccular inhibition (FRNs) leads that of vestibular neurons lacking a floccular input (nonFRNs). We now report that this phase lead is present for a wide range of stimulus conditions. Neurons were recorded in awake rabbits. The sample was restricted to cells that received from the flocculus and/or projected to oculomotor midbrain structures. For sinusoidal rotation in the light, FRNs (n=26) led nonFRNs (n=14) at all frequencies in the tested band (0.05-0.8 Hz). The lead increased monotonically, from 8.6° at 0.05 Hz to 19.4° at 0.8 Hz. The phase differences were significant (p<0.05 or better). For rotation in the dark, FRNs (n=22) led nonFRNs (n=10) by 13.7° at 0.05 Hz and 22.1° at 0.8 Hz, and again the phase difference was significant at all frequencies. The fundamentals of the firing rates of the two cell groups were also compared for triangular optokinetic stimulation at 0.1 Hz. FRNs (n=52) led nonFRNs (n=20) by 18.7°, and the phase difference was significant at p<0.0001. For both FRNs and nonFRNs, the relationship of firing rate to eye movement could be modeled by a 2-pole, 1-zero transfer function, differing only in that the time constants were longer for the FRNs. If the phase lead of FRNs is produced by the signal contributed by the floccular Purkinje cells, then these observations suggest that one role of the flocculus is to control the phase of the net premotor signal. The flocculus could sample vestibular nucleus signals, enhance the velocity component, and return the altered signals. It would thereby counterbalance an excessive integration (in the mathematical sense) postulated to occur in the brainstem circuitry. (Supported by NIH Grant NS-13742.)

127.8

LATENCY OF ADAPTIVE VOR SHOWS RESPONSES WHICH ARE DEPENDENT ON THE LENGTH OF ADAPTATION. T.T. Khater, K.J. Quinn, J.F. Baker and B.W. Peterson, Northwestern University Medical School, Chicago, IL 60611

When an animal is first exposed to a new visuo-vestibular stimulus, its VOR adapts in a way that minimizes retinal slip. To measure VOR latencies during development of adaptation, we recorded daily the eye movements evoked by randomly occurring velocity transitions between $\pm 19^\circ/s$ earth-horizontal whole body rotation (HWBR) in total darkness with a CNC eye coil system in 5 cats. The cats were outfitted with $\times 0.25$ or $\times 2.2$ magnifying lenses for up to 5 days, and subjected to 2 h of HWBR daily. In another series of experiments, cats were trained using 2 h "cross-axis" coupling of HWBR with a synchronous vertical rotation of a projected random spot pattern that had 1.5X the amplitude.

Vertical eye movements elicited by HWBR after 2 h of cross-axis adaptation had latencies of 13-15 msec and in 7/15 cases included a second component beginning at 70-80 msec. These two components also appeared with latencies of 11-14 msec and 67-77 msec in the adaptive changes elicited by $\times 0.25$ or $\times 2.2$ lenses, which were revealed by subtracting control from adapted horizontal eye movements. The early component increased strongly during the initial and subsequent daily periods of HWBR but declined while the cat wore the lenses in its cage. The longer latency component increased slowly both during HWBR and unrestrained wearing of the lenses. These data suggest that adaptation occurs most rapidly in the shortest (presumably brainstem) pathway, which, however, requires continuous strong mismatched visual-vestibular signals to maintain its activity. ALTERATION IN THE VESTIBULO-OCULAR REFLEX (VOR) PRODUCED BY MUSCIMOL INJECTIONS INTO THE VESTIBULAR NUCLEI. J. Yokota, H. Reisine, T. Raphan, B. Cohen Depts. of Neurol. & Physiol., Mt Sinai Sch. of Med., NY10029 & Dept. of CIS, Brooklyn College, CUNY, NY11210

Slow phase eye velocity (SP Vel) related to velocity storage can be elicited by electrical stimulation of the vestibular nuclei (VN; Yokota et al, 1990). In this study we recorded single units and electrically stimulated VN to determine locations from which velocity storage could be induced. We then injected 0.5 μ l of muscimol, a GABA_A agonist. Animals developed spontaneous nystagmus with downward rotatory horizontal slow phases. The downward component was affected by head position re gravity; the minimum position was ipsilateral side down. The most common pattern of VOR dysfunction was a bilateral reduction in the VOR time constant (Tc) with preservation of VOR gain. In this condition steady state SP Vel during off-vertical axis rotation (OVAR) as well as OKAN were also lost bilaterally. Quick phases of vestibular nystagmus were not affected, but there was some inability to hold eye position. A second pattern of dysfunction occurred after injection into areas where neurons responded to otolith input. There was an isolated loss of SPVel of OVAR with preservation of VOR and OKAN gain and Tc. The first pattern with bilateral reduction in VOR and OKAN Tc with preservation of VOR gain suggests that areas of VN associated with the velocity storage integrator had been inactivated. The isolated loss of ipsilateral OVAR SP Vel with preservation of OKAN and the VOR Tc suggests that areas of VN associated with head velocity estimation from the otoliths had been disrupted. LECTIN BINDING PATTERNS OF VESTIBULAR HAIR CELLS.

R.A. Baird, N.A. Schuff*, and J. Bancroft*, R.S. Dow Neurol. Scis. Inst., 1120 NW 20th Avenue, Portland, OR 97209.

Vestibular hair cells exhibit regional differences in hair bundle morphology and physiological response properties. To see if these cells express distinct surface glycoconjugates, we applied lectins with different carbohydrate specificities to vestibular endorgans of the bullfrog and guinea pig.

In the bullfrog sacculus, three lectins - CON A, RCA-I, and WGA - labeled only supporting cells while a fourth, VVA, indiscriminately labeled the hair bundles of saccular hair cells. CON A and RCA-I labeled the hair bundles of hair cells in the utriculus and semicircular canals, regardless of their epithelial location. The labeling of WGA and, to a lesser extent, VVA, was confined to specific regions. In the utriculus, these lectins labeled the hair bundles of extrastriolar, but not striolar, hair cells. In the semicircular canals, they labeled the hair bundles of peripheral, but not central, hair cells. Similar patterns of staining of both Type I and Type II hair cells were seen in the utriculus and semicircular canals of the guinea pig. These staining patterns were preserved in isolated hair cells after enzymatic digestion.

Our results indicate that receptors for a variety of lectins exist on vestibular hair cells and suggest that lectins can be useful probes for identifying vestibular hair cells from central and peripheral epithelial regions. Supported by NIDCD 00355, NASA 2-651, and OLSHF.

CYTOCHROME OXIDASE (CO) STAINING IN SCARPA'S GANGLION AND THE MEDIAL VESTIBULAR NUCLEUS (MVN) POST-HEMILABYRINTHECTOMY (HL). A.A. Perachio^{1,2,3}, G.A. Kevetter^{1,3} and R. Kassir¹. Dept. Otolaryngol.¹, Physiol. & Biophys., Anat. & Neurosci.³, Univ. TX Med. Br., Galveston, TX 77550.

We have previously reported that, following HL in the gerbil, the activity rates and dynamic responses of horizontal canal-related MVN neurons are not restored during vestibular compensation in the number of active neurons or in dynamic function, especially in the nucleus ipsilateral to the damaged labyrinth. We have now used CO staining to examine how this measure of oxidative metabolism may be used to assess vestibular afferents and the MVN at various stages recovery from HL. End organs of one labyrinth were removed by aspiration in adult gerbils. Animals were sacrificed at 1 or 72 hrs, 2 weeks, 1 month and 3 months post-HL. Microdensitometry, using a computer-assisted image analysis system, was performed on 500 primary afferents. Areal measures of staining density were made from multiple sites bilaterally in the rostral MVN that contain vestibulo-ocular neurons some which were retrogradely labelled. Primary afferents innervating the intact labyrinth at 1 hr post-HL stained darker than those on the injured side. However, by 72 hrs post-surgery, the two sides stained equivalently. In the MVN, CO staining was statistically equal bilaterally at 1 hr and 72 hrs. By 2 weeks post-HL both primary afferents and rostral MVN exhibited significantly greater CO activity on the intact side. This difference remains significant at 3 months post-HL. These findings support the results of electrophysiological evidence of a persistent asymmetry in central vestibular and peripheral afferent neurons following behavioral signs of vestibular compensation. (Supported by NASA Grant NAG 2-26).

MULTIPLICATIVE LEARNING RULES SIMULATE PROPERTIES OF VOR PLASTICITY. K.J. Quinn, N. Schmajuk, S.A. Rude, J.F. Baker and B.W. Peterson. Northwestern Univ., Chicago, IL 60611.

Errors requiring adaptation of the vestibulo-ocular reflex (VOR) can be characterized in terms of gain and/or phase deficits. We are exploring how the CNS can use the only known available error signal (retinal image slip velocity - RSV) to adjust these properties. This credit assignment problem facing an adaptive VOR network is solved by a multiplicative learning rule, utilizing three signals likely to be available to brain stem neurons participating in VOR function: head position (HP), head velocity (HV) and RSV (Soc. Neurosci. Abstr., 1990, 304.13). Here we describe the characteristics of the algorithm in greater detail and compare its function with known characteristics of VOR plasticity.

The algorithm has been implemented in a neural network based on a control systems representation of the VOR. It uses two rules: the product of RSV*HP is used to adjust the weight of a pathway carrying a position signal; the product of RSV*HV is used to adjust the weight of a pathway carrying a velocity signal. This learning rule is sufficient to account for adaptive responses required across the complete spectrum of possible gain and phase changes. Sensitivity of these products to gain or phase errors changes with frequency of head movement but the algorithm still provides proper compensation. Topography of the model response is similar to that described for phase reversal experiments and cross-axis adaptation acquisition. A modified implementation of this algorithm using products of pre- and post-synaptic activation levels, also predicts differential acquisition of phase advanced vs phase lagged cross-axis adaptive responses. (see Powell, et al. this session). Supported by EY05289, EY06485, EY07342, NS07223.

PRIMATE LINEAR VESTIBULO-OCULAR REFLEX (LVOR) DURING HORIZONTAL MOTION ALONG AXES BETWEEN NASO-OCCIPITAL (NO) AND INTERAURAL (IA). D.L. Tomko and G.D. Paige. Vestibular Research Facility, NASA Ames Research Center, Moffett Field, CA 94035-1000

We previously described squirrel monkey LVORS during motion in the horizontal plane along NO and IA axes. NO LVOR amplitudes increased as gaze eccentricity relative to the motion axis increased and as binocular fixation distance decreased. Further, to fixate visual targets during forward head motion and rightward gaze, eyes must move to the right, but when looking left, the eyes must move to the left.

In this study, the LVOR was measured (binocular search coils) during horizontal motion (5.0 Hz) along several axes between and including NO and IA. This reorients the head, and therefore otolith input, relative to the axis of motion. We hypothesize that the LVOR would still follow the same gaze-dependent kinematics relative to the axis of motion, regardless of eye position in the head or the orientation of the head relative to the motion axis. This requires integration of eye position (e.g., efference copy) with otolith inputs in order to determine the angle of the eye relative to the axis of linear motion. Results confirmed that the LVOR is indeed governed by eye position relative to linear motion.

EFFECTS OF ROLL TILT ON PITCH VERTICAL VESTIBULO-OCULAR REFLEX (VOR). S.A. Rude, K.D. Powell, J.F. Baker. Department of Physiology, Northwestern Univ., Chicago, IL 60611.

The horizontal vestibulo-ocular reflex (VOR) during low frequency oscillations is more accurately compensatory when tested in body orientations that introduce a dynamic gravity stimulus (Rude and Baker, '88). For pitch vertical VOR, however, a dynamic gravity stimulus increases accuracy of the VOR in the upright position and decreases accuracy of the VOR in the supine position (Rude, et al., NS abstr '88). Inaccurate non-upright position vertical VOR is related to a predominance of upward direction slow phase eye movements. We are studying slow phase eye movement asymmetry and eye position drift at various roll tilts.

Using search coils and electro-oculography, eye movements were recorded in the dark from 4 cats during static tilt, or during inter-aural axis pitch in their sagittal plane (0.01 Hz $\pm 30^\circ$), after rolling the cats to angles from 0° (upright) to 180° (supine).

Peak slow phase velocities were greater at all angles for upward vs. downward eye movement in the orbit. Asymmetry of slow phase velocity was slight at the 0° tilt, substantial at $\pm 90^\circ$ tilt, and at 180° tilt vertical eye movements showed a continuous upward slow phase regardless of sinusoidal rotation stimulus phase. Furthermore, experiments employing a static tilt with no oscillation revealed a consistent upward drift of the eyes in all cats, varying in magnitude with angle of tilt from 0° (smallest) to 180° (largest). The drift was not present in the light.

Upward drift may be a linear VOR response to the altered saccular stimulus during tilt. Asymmetrical slow phase eye velocity responses to rotation were a close fit to a sinusoid with an offset term, suggesting that the observed steady drifts were involved in producing the asymmetries.

OTOLITH RESPONSES TO LINEAR OSCILLATIONS IN ALERT SQUIRREL MONKEYS. C.J. Somps and D.L. Tomko. Vest. Res. Fac., NASA Ames Res. Ctr., Moffett Field, CA 94035

The linear vestibulo-ocular reflex (LVOR) stabilizes visual images on the retina during linear displacements of the head (Paige and Tomko, 1991). How vestibular neural mechanisms produce the compensatory eye movements of the LVOR is unknown. In the present study, the activity of otolith afferents was recorded in alert squirrel monkeys subjected to earth-horizontal, sinusoidal linear oscillations, a stimulus known to produce a robust LVOR. All units were spontaneously active, and modulated by linear oscillations. Discharge waveforms were triphasic, and amplitudes averaged 100 to 200 μ V. Discharge rates in upright, stationary animals ranged from 16 to 126 spikes/sec and averaged 60 spikes/sec. Interspike intervals were regular in most units (coefficients of variation (CV) between 0.03 and 0.1), and were less regular in others (CVs > 0.1). For 0.5 Hz oscillations, regular units exhibited sensitivities to linear oscillations averaging 22 spikes/sec/g and small phase leads averaging 10° . Sensitivities (23 spikes/sec/g) remained similar and phases slightly lagged the stimulus (8°) with 1.5 Hz oscillations. Units with CVs greater than 0.1 had higher sensitivities (118 spikes/sec/g) and larger phase leads (27°) than regular units. For units whose polarization vectors were calculated, vectors were found to lie roughly in either the utricular or saccular plane. Units sensitive to angular accelerations (canal afferents) were not sensitive to linear oscillations. Given LVOR gains of 10-20°/sec/g and phases slightly leading head velocity (30°), a phase shift of -90° and a gain of 0.1-1°/impulse must be provided central to the otolith afferents. SPATIAL ORIENTATION OF VELOCITY STORAGE DURING POST-ROTATORY NYSTAGMUS. M.J. Dai, T. Raphan, B. Cohen, C. Schnabolk, Dept. of CIS, Brooklyn College, CUNY, NY 11210, and Depts of Neurol. & Physiol. Mt. Sinai Sch. of Med., NY 10029

Studies of cross-coupling during OKN and OKAN in tilted positions show that the yaw axis eigenvector lies close to the spatial vertical (Dai et al. 1991). In this study we determined whether the same principles apply when the vestibular system is activated by stopping in a tilted position after head rotation. Velocities were induced during off-vertical axis rotation (OVAR) that exceeded the saturation velocity of velocity storage, and yaw and pitch components were measured after monkeys were stopped in side down positions. Steady state slow phase eye velocity during OVAR was predominantly in yaw with oscillating pitch and roll components. When stopped side down, the yaw time constant of the post-rotatory nystagmus was shorter than when upright, and a pitch component developed whose vector direction was a transformation of the vector from the yaw axis in the body frame to the corresponding direction in the spatial frame. A model of velocity storage from OKAN predicted the behavior of the pitch component during vestibular stimulation. Thus, the vestibular system utilizes velocity storage according to the same organizational principles of orientation as during OKN and OKAN. Supported by EY04148, NS00294.

CONVERGENCE OF COMPLEMENTARY SEMICIRCULAR CANAL INPUTS ONTO VESTIBULAR NUCLEI NEURONS. J.D. Dickman. Depts. of Surgery (Otolaryngology) and Anatomy, Univ. of Mississippi Medical Center, Jackson, MS 39216.

How do vestibular nuclei neurons synthesize the information from the paired complementary semicircular canals into a unified output signal? Experiments were conducted to answer this question by recording extracellular single fiber responses from vestibular nuclei neurons elicited by individual stimulation of ipsilateral and contralateral horizontal semicircular membranous ducts using mechanical micropushers (Dickman & Correia, *J. Neurophysiol.*, 1989, 62, 1090-1101). Experiments were conducted in awake, decerebrate pigeons that were paralyzed (Pancuronium) and ventilated (250 ml/min O₂/CO₂). Sinusoidal (0.01 - 10 Hz) displacements ($\pm 1 - \pm 2.5\mu$) of the exposed ipsilateral horizontal membranous duct were delivered first, followed by identical stimulations of the contralateral horizontal duct. To date, complete protocols have been recorded in only a few vestibular nuclei neurons, with all cells responding to independent ipsilateral and contralateral horizontal canal mechanical stimulation. Mean (\pm SEM) gain and phase values (N = 7) from responses produced by ipsilateral canal sinusoidal stimulation (0.1 Hz, $\pm 2.5\mu$) were 8.3 (± 3.3) spikes \cdot sec⁻¹/ μ and 34° (± 5.4) lead relative to peak inward pusher position, respectively. Contralateral horizontal duct stimulation (0.1 Hz, $\pm 2.5\mu$) produced much smaller responses with a mean gain of 1.6 (± 0.5) spikes \cdot sec⁻¹/ μ and a mean phase of 185° (± 3.5) lag re peak inward pusher position. This corresponds to an approximately 5:1 gain ratio (ipsi:contra) and a 219° difference in response phase between ipsilateral and contralateral stimulation. Higher frequency stimulations of the ipsilateral canal produced responses similar to those observed at 0.1 Hz. However, contralateral canal stimulations above 1.0 Hz either silenced the neuron or produced no detectable modulated response. Supported in part by NIH BRSG grant 2S07RR05386.

VESTIBULO-OCULAR REFLEX (VOR) DIRECTION ADAPTATION TO PHASE ADVANCED VS PHASE DELAYED OPTOKINETIC STIMULI. K.D. Powell, K.J. Quinn, S.A. Rude, B.W. Peterson, J.F. Baker. Dept. Physiology, Northwestern Univ., Chicago, IL 60611.

The VOR can adjust its direction and gain and introduce phase lags (Powell et al., NS abstr '89) to reduce retinal slip. Are signals available to VOR neurons to allow adaptive VOR phase advances? To study this, 7 alert cats were VOR adapted to either a phase advanced or phase delayed vertical optokinetic stimulus.

VOR adaptation consisted of 2 hr of horizontal whole body rotation at 0.25Hz coupled to vertical rotation of a field of spots. The phase of the optokinetic sinusoid was 45° advanced or 45° delayed with respect to the vestibular stimulus. Vertical and horizontal VOR at .02 - 2.5Hz were measured with EOGs in the dark before and after adaptation. The adaptive response was calculated as the difference between the pre and post adaptation vertical VOR during horizontal rotations.

The average adaptive VOR gain from .02-1.0Hz was greater in phase lag experiments than in phase advance experiments. At 0.25Hz, adaptation to phase delay had an average gain of .09, phase of -22°, and adaptation to phase advance had an average gain of .04, phase of +11°. Highest gains for phase delay experiments were recorded at low frequencies while highest gains for phase advance experiments were seen at high frequencies. The diminished ability of the VOR to adapt its direction in response to phase advanced stimuli is shared by certain VOR models (Quinn et al., this vol.) and suggests that phase delayed signals are more readily available to VOR neurons than phase advanced signals. SPATIAL AND TEMPORAL PROPERTIES OF OTOLITH-SENSITIVE HORIZONTAL CANAL (HC) NEURONS IN THE VESTIBULAR NUCLEUS AS A FUNCTION OF LINEAR ACCELERATION FREQUENCY. G.A. Bush¹, A.A. Perachio², D.E. Angelaki³, Depts. of Otolaryngol.¹ and Physiology & Biophysics², Univ. Tex. Med. Br., Galveston, TX 77550, Dept. of Physiology³, Univ. of Minn., Minneapolis, MN.

Otolith-sensitive HC vestibular nuclei neurons were characterized for their responses to sinusoidal linear translation in the horizontal head plane over the frequency range 0.2-1.4 Hz (peak acceleration, $\pm 0.10g$) in the decerebrate rat. The spatial response properties of the neurons were determined by systematically varying the direction of the applied force vector by statically repositioning the head in the horizontal plane with respect to the direction of travel at each frequency. 89% of the neurons (operationally referred to as broadly tuned neurons) exhibited response gains that were not proportional to the cosine of the angle between the direction of the applied force vector and the cell's maximum sensitivity vector. Each neuron could be described by a maximum (S₁) and a minimum (S₂) sensitivity vector which were in spatial and temporal quadrature. There was a significant linear correlation between the S₁ and S₂ magnitudes. The slope of the linear regression was frequency dependent. Two classes of neurons were distinguished by their S₁ response vectors as frequency was increased: 1) *Dynamic* neurons exhibited a gain enhancement of S₁ with increased phase lags, a moderate attenuation of S₂ and a decreasing S₂/S₁ and 2) *Low Dynamic* neurons which exhibited a moderate gain attenuation of S₁ with small phase lags, a gain enhancement of S₂ and an increasing S₂/S₁. Therefore, given the temporal quadrature and the frequency dependent linear relationship between S₁ and S₂, broadly tuned neurons encode two dimensions where either S₁ or S₂ could be the time derivative of the other depending on the cell's dynamics. (Supported by NASA NAG 2-26, NIH DC00385)

VISUAL SUPPRESSION OF TORSIONAL VESTIBULAR NYSTAGMUS IN RHESUS MONKEYS. Straumann D, Suzuki M*, Henn V, Hess BJM, and Haslwanter Th*. Neurology Dept, University Hospital, Zürich, Switzerland, and Otolaryngology Dept, Dokkyo University, Koshigaya Hospital, Saitama, Japan.

Juvenile rhesus monkeys, placed on a motorized turntable, were rotated at constant velocity and then decelerated about an earth-vertical axis. The animals were implanted with dual search coils to measure eye movements in three dimensions. By changing the monkey's body position (upright, ear-down, supine), postrotatory nystagmus was elicited in the horizontal, vertical, or torsional direction. Peak slow phase eye velocity (Vp) and time constant of velocity decay (Tc) were compared between decelerations in the dark and in the light. In all nystagmus directions, illumination reduced the time constants (Tc) to values around 5 s. Peak velocities (Vp) were markedly attenuated in the horizontal and vertical directions (around 50%), but the effect of light on Vp in the torsional direction was small (less than 20%). These findings were independent of the velocity step size. We conclude that the two components of optokinetic nystagmus not only differ in their dynamics, but also in their dimensionality: The indirect pathway (optokinetic system) operates in all three dimensions, while the direct pathway (pursuit system) is only effective in the horizontal and vertical directions. Supported by SNF 3100-28008.89 and 31-25239.88 (ESPRIT-MUCOM 3149).

VESTIBULAR SYSTEM DEVELOPMENT IN THE FLATFISH, Pseudopleuronectes americanus. W. Graf, B. Evans and S. Callager. The Rockefeller University, N.Y., NY 10021; Inst. Neuroscience, Univ. Oregon, Eugene, OR 97403; Woods Hole Oceanographic Institution, Woods Hole, MA 02543.

During metamorphosis, flatfish undergo a 90° side tilt to become bottom-adapted adults. Simultaneously, the eye on the down side is pushed over to the up side. Compensatory eye movements during swimming in the now asymmetric animals are subserved by a unique central nervous connectivity involving rearranged second-order vestibular neuron connections.

The ontogeny of this flatfish-specific connectivity was studied in larval winter flounders using [³H]thymidine autoradiography. There is widespread cell proliferation throughout the entire brain at day 1 post hatching. Specific cell divisions involving vestibular neurons occur at about day 26-30 post hatching. Occasional labelling in vestibular neurons is present in subsequent stages before metamorphosis. An increase in cell division activity is noticeable around the period leading to the metamorphic climax (day 54-68 post hatching).

Although there is a clear indication of newly appearing vestibular neurons prior to and during metamorphosis, further experiments are necessary to ascertain whether these particular cells are the ones which provide the new neural circuitry to support the adult flatfish's compensatory eye movements.

Supported by NIH grant DC-00239.

NMDA Receptor Antagonist Microinjected Unilaterally into the Vestibular Complex Induces Postural Syndromes in Normal Rats. Jennifer D. Porter and Merle E. Meyer, Dept. Psychology, Univ. of Florida, Gainesville, FL 32611.

Neurotransmitters involved in the vestibular system are largely uncharacterized. However, Glutamate and Aspartate have been suggested as possible neurotransmitters between primary vestibular afferents and second-order vestibular neurons. The purpose of our study was to evaluate the roles of NMDA and non-NMDA receptor antagonists microinjected unilaterally into the vestibular nuclei. Microinjections of AP-5, a specific NMDA receptor antagonist, into the vestibular nuclei of the normal rats induced postural disorders which were similar to those observed following unilateral labyrinthectomy.

128.5

EFFECTS OF CHRONIC HYPER-GRAVITY ON THE RIGHTING REFLEX AND VESTIBULAR ENDORGAN MORPHOLOGY IN THE RAT. N.G. Däumlin, M.D. Ross*, R.A. Fox, M.J. Corcoran*, L.K. Cutler*, and L.C. Wu*. Life Science Division, NASA Ames Research Center, Moffett Field, CA 94035

As part of an effort to identify the neural mechanisms underlying adaptation to altered gravity, behavioral and morphological studies have been carried out on rats exposed to hyper-gravity for a maximum of 16 days. To assess changes in vestibular function and neuromuscular coordination induced during adaptation to 2-G, the righting reflex was tested by dropping each rat 45 cm from a supine position into a tank of warm water. The landing altitude of each animal and time to resurface following the drop were determined from video images. Animals were tested within 20 - 30 minutes of removal from the centrifuge, and then again after 48 hours and 8 days. Immediately after removal, half of the 2-G and none of the Control animals failed to right. In addition, the 2-G animals took significantly longer to resurface following the drop than the Controls, with some 2-G animals swimming in a downward rather than upward direction. Righting and resurfacing returned to normal over the recovery period.

To assess the possibility that these behavioral changes may be due in part to changes in processing of vestibular (particularly otolith) input at the periphery, the neuroepithelium of the utricular maculae of centrifuged and control animals was studied. Results indicate that there was a 30% reduction in the number of synapses of macular Type II hair cells in the 2-G animals, but no change in the Type I hair cells. Since this reduction was not seen in the Rotation Control group, it is likely that the increased G component, rather than the rotational component of centrifugation, was responsible for this change. Additional work is required to determine whether this change in morphology results in an increased threshold for linear acceleration and thus underlies the deficits seen in righting and resurfacing in 2-G-adapted animals.

128.7

SPATIO-TEMPORAL CONVERGENCE (STC) IN OTOLITH NEURONS. D.E. Angelaki, Dept of Physiology, Univ of Minnesota, Minneapolis, MN 55455.

It has been recently demonstrated that some primary otolith afferents (Dickman et al., Brain Res, in press) and most vestibular nuclei neurons (Bush and Perachio, Soc Neurosci Abstr 14:330, 1988) encode two spatial dimensions and can be described by two vectors that are in temporal and spatial quadrature (Angelaki, IEEE TBE, in press). These neurons are called broadly-tuned (BT) and are characterized by a non-zero tuning ratio which is defined as the ratio of the minimum over the maximum sensitivity of the neuron. BT neurons exhibit response gains that do not vary as the cosine of the angle between the stimulus direction and the cell's maximum sensitivity vector and response phase values that show a dependence on stimulus orientation. These responses were observed with pure linear acceleration; thus spatio-temporal convergence (STC) between primary otolith afferents and/or otolith hair cells could be possible. Simulations of STC in the inputs to primary otolith afferents and vestibular nuclei neurons have revealed several interesting points. First, when BT neurons linearly summate inputs from two narrowly-tuned (NT) units, the greatest tuning ratio is achieved with equal input gains. The smaller the phase difference between the input vectors, the larger orientation differences are required to produce a tuning ratio of a certain value. Orientation and phase differences of 30-40° would create tuning ratios of approximately 0.10-0.15 in primary otolith afferents. Second, when multiple inputs are considered, the greater the number of converging inputs, the smaller the tuning ratio of the BT neuron. The tuning ratio is very sensitive at small numbers of input units, whereas the larger the number of converging inputs, the smaller the effect. For more than 10-20 input units, the tuning ratio can be considered independent of the number of inputs. Further, if the inputs comprise two populations (with different gain and phase values at a given stimulus frequency), the greatest tuning ratio is obtained when the largest population has the lowest gain. Supported by NASA NGT 50581.

RELATION BETWEEN C1 TERMINAL ARBORIS AND SPATIAL PROPERTIES OF MEDIAL VESTIBULOSPINAL TRACT NEURONS (MVSNS). S.I. Perlmutter, L.D. Barke*, Y. Iwamoto*, K.D. Powell, J.F. Baker, B.W. Peterson, Northwestern Univ. Med. School, Chicago

Directional sensitivity of neck muscles for 3-D rotations depends on spatial properties of vestibulospinal cells and appropriate distribution of their signals in the spinal cord. In decerebrate cats, HRP or Neurobiotin was injected intraaxonally at C1 in 21 MVSNS monosynaptically activated from ipsi- or contralateral labyrinth. A vector representing the rotation producing maximal activation was derived from responses to 0.5 Hz rotations in 2-11 vertical planes and yaw. Neurons were tested for antidromic activation from IIIrd nucleus and C6 ventral funiculus.

MVSNSs terminating above C6 had many C1 collaterals (1/1.5 mm, on average), which usually projected to similar regions of the gray matter. Axons preferentially innervated the ventral horn (especially motor nuclei, laminae VII and VIII), but some branches extended toward the central cervical nucleus or intermediate laminae. Cells with excitation vectors near the horizontal canal axis projected to wide areas of the ventral horn, including extensor and flexor motor nuclei. Neurons with vectors near one vertical canal axis had more restricted projections to motor nuclei, interpretable as excitatory and inhibitory substrates for compensatory movements. Collaterals of cells with convergent canal input arborized within narrower regions. Axons activated from C6 had fewer collaterals in C1 (1/3.8 mm); 4/6 (2 with significant type II yaw responses; 2 with spatio-temporal convergent behavior) did not branch within motor nuclei.

Significant divergence of single canal, and narrower distribution of more processed, signals occurs at the spinal level, suggesting functional specialization of MVSNSs, and substrates for spatial transformations in the vestibulocollic reflex. NS17489, EY06485, EY05289, EY07342

VELOCITY CHARACTERISTICS OF OPTOKINETIC AND VESTIBULAR EYE MOVEMENTS IN NORMAL HUMANS. M.J. Morrow, R.W. Baloh, K.M. Jacobsen*, C. Mai*, J. Burrows*. Department of Neurology, UCLA, Los Angeles, CA 90024

We measured OKN, VOR and VOR fixation-suppression (VOR-Fix) in normal subjects. A full-field striped drum was used to test OKN and VOR-Fix. VOR was measured in darkness. Subjects were examined with low frequency (0.025-0.2 Hz) sinusoidal stimuli at multiple peak velocities up to 120°/sec. We analyzed plots of smooth eye velocity vs. stimulus velocity to assess linear (gain) and non-linear (saturation) elements of responses. Linear portions of eye vs. stimulus velocity plots had slopes averaging 0.95 for OKN and 0.02 for VOR-Fix. OKN responses saturated at velocities of 70-80°/sec. OKN velocity limits were independent of drum accelerations up to 150°/sec². VOR-Fix eye velocities did not exceed 10°/sec; VOR never saturated. VOR-Fix peak eye velocities were close to those predicted by subtraction of OKN peak velocities from VOR peak velocities.

At low stimulus frequencies, gain approaches ideal values of unity for OKN and zero for VOR-Fix; responses to high velocity stimuli are limited by velocity saturation. Velocity dynamics of VOR fixation-suppression can be explained by cancellation of vestibular signals with oppositely directed smooth eye tracking signals.

INTRAVENTRICULAR INJECTION OF CALMIDAZOLIUM CHLORIDE DECREASES SPONTANEOUS NYSTAGMUS FOLLOWING UNILATERAL LABYRINTHECTOMY IN THE GUINEA PIG. A.J. Sansom*, C.L. Darlington*, C.J. Keenan*, P.F. Smith*, D.P.D. Gilchrist* & D.K. Bilkey. Department of Psychology and the Neuroscience Centre, University of Otago, Dunedin, New Zealand.

In order to determine whether Ca²⁺-mediated intracellular pathways are involved in the behavioural recovery which occurs following a unilateral labyrinthectomy (UL), (vestibular compensation) we examined the effects of intraventricular injections of calmidazolium chloride (R24571), a calmodulin antagonist and inhibitor of several Ca²⁺-dependent enzymes, on the time course of compensation of spontaneous nystagmus (SN). Each experimental animal (n=4) received 3 injections of calmidazolium chloride (1 µL, 0.5 mM, dissolved in DMSO and artificial cerebrospinal fluid (ACSF), pH 7.0), beginning 30 mins after a UL and spaced at 2 h intervals thereafter. Control animals received injections of the vehicle, DMSO plus ACSF (n=2), or ACSF alone (n=1), using identical procedures to the experimental group. Animals which received calmidazolium injections showed reduced SN compared to control animals (p < 0.05, t-test) during the first 15 hrs post-UL, following which SN compensated at a normal rate. During the period of SN suppression, animals still showed vestibulo-ocular eye movements. These results suggest that intracellular pathways associated with Ca²⁺ may contribute to vestibular compensation.

VESTIBULAR DISORDERS IN CHORNOBYL CLEAN-UPPERS. Trimus K. ECA Foundation, Lukianivsky Str. 27, Apt. 47, Kiev-71, Ukraine, GSP25601.

Vertigo is one of the frequent early complaints of the nuclear lesion. This study was to elucidate if it is related to the vestibular lesion. 273 persons the Chernobyl clean-uppers were examined before going to the station. We used mostly the routine tests: Uemura, Flucudas; writing and stepping; tracking and indicating tests. The abnormality degree was expressed in the score table with the range from 0 to 20, the greater the score - the more expressed disorder. The 5 score was decided to be the sign of the disorder. From all the group there was allowed to work at the station 187 or 68.5% persons. From the persons examined 197 (72.2%) were working at the station during the accident (the doses are unknown), and 76 (27.9%) never been in contact with radiation before. All the persons examined have passed the medical commission and were allowed to work in the zone. Among them 32.5% of those were in the zone beforehand and 32.9% of those who never contacted radiation were considered to be practically absolutely healthy. According to our data out of those who were in the zone 37.1% were not allowed to work, and out of those who had not been in the zone only 14.5% were not allowed to work. The difference is statistically significant. The total # of those who had well expressed vestibular disorders (10 and more) was 18 persons, that means 6.6% from all the examined, among them were in the zone 17 persons (94.4%). In most part of this group of people were diagnosed vascular disorders by therapists. The data presented allowed us to suspect the vestibular lesion to be one of the earliest symptoms of the nuclear damage.

PHYSIOLOGICAL RESPONSES TO VISUALLY INDUCED MOTION SICKNESS

Benton D. Lawson, Fred A. Sunahara, and James R. Lackner
Ashton Graybiel Spatial Orientation Laboratory, Brandeis Univ., Waltham, MA, 02254.

We studied the relationship between severity of motion sickness (MS) and heart rate (HR), blood pressure, forearm blood flow, respiration rate, and gastric rhythm (electrogastrograms).

14 Subjects received 10 min. of optokinetic stimulation at 60 deg/sec. Symptoms of MS and physiological responses were monitored throughout stimulation, and during 10 min. baseline and recovery periods.

Subjects were divided into high, medium, and low MS groups. Analyses of variance with contrasts were performed on 4 time periods: baseline, early stimulation, late stimulation, and recovery. Only HR showed a significant change that was related to MS group (ANOVA $F=7.1$, $p<.05$ for high vs low MS from baseline to late stimulation). HR increased 9bpm +/- 5 for the high ms group and 1bpm +/- 3 for the low ms grp. 4/5 cases of HR >100 bpm occurred during onset of stimulation and prior to onset of MS. All 5 cases were in naive subjects (regardless of MS group). HR and the other physiological responses varied considerably within and across subjects.

The physiological responses did not reliably distinguish individuals, subject groups, or time periods based on severity of MS.

RETICULOSPINAL NEURONS AND VERTICAL VESTIBULOSPINAL REFLEXES. P. Bolton, T. Goto*, R.H. Schor, V.J. Wilson, Y. Yamagata*, B.J. Yates. Rockefeller University, New York, NY 10021; Eye & Ear Institute, Pittsburgh, PA 15213.

To examine the contribution of the reticulospinal (RS) system to vestibulospinal reflexes, we have studied, in the decerebrate cat, responses of medial ponto-medullary RS neurons to natural vestibular stimulation. Neurons projected to neck, lower cervical, thoracic, or lumbar levels, as determined by antidromic stimulation of medial and lateral reticulospinal tracts. Sinusoidal stimuli in vertical planes were used to determine response vector orientation and nature of the vestibular input (otolith, O; canal, C; otolith-canal convergence, O+C; spatial-temporal convergence, STC). Features of the responses of 67 RS neurons were prominent otolith input (32 neurons), less frequent otolith-canal convergence (12 O+C, 6 STC), and only 1 cell with pure canal input; 16 cells could not be fully characterized, although canal input was not apparent. This pattern of vestibular input contrasts sharply with that of vestibulospinal neurons, where the most frequent input is from vertical canals (Wilson et al, JNP 1990). Vector orientations were almost exclusively in the roll quadrants. Our results suggest the RS system plays an important role in the production of gravity-dependent postural reflexes.

THE INITIAL VESTIBULO-OCULAR REFLEX AND ITS CANCELLATION IN HUMANS WITH UNILATERAL VESTIBULAR DEFECTS J.L. Johnston and J.A. Sharpe, The Toronto Hospital Neurological Centre and Playfair Neuroscience Unit, University of Toronto, Toronto, Canada M5T 2S8

We investigated the horizontal vestibulo-ocular reflex (VOR) in 5 patients, 1 to 51 months after unilateral vestibular deafferentation, using transient, unpredictable chair movement (Mean head velocity: 34 deg/s, Mean head acceleration: 331 deg/s/s) and magnetic search coil recordings of head and eye motion. Trials were conducted in darkness (VOR) and with a head-fixed target (VOR cancellation). Initial VOR gains during the first 80 ms after head motion were asymmetric, with lower gains for head motion toward the side of the lesion. Initial vestibular smooth eye movement accelerations decreased at peak head acceleration, both toward and away from the side of the lesion. All patients had significantly worse cancellation of the VOR when head motion was toward the lesioned side; the severity of this deficit correlated inversely with the age of the lesion. Unilateral loss of vestibular information impairs cancellation of the reduced contralateral VOR during combined eye-head tracking toward the side of the lesion. These results suggest that the VOR cancellation system employs disfacilitation of the intact side to drive cancellation when head motion is toward the lesioned side. Supported by the R.S. McLaughlin Foundation and MRC of Canada Grant MT5404 and ME3509.

NMDA-MEDIATED LTP AND LTD IN THE MEDIAL VESTIBULAR NUCLEI. S. Grassi*, G. Capocchi, G. Della Torre*, M. Zampolini, V. Pettorossi* Ins. Human Physiology* and Cl. Neurology, Univ. Sch. of Med. Perugia, Italy

We studied the effect of High Frequency Stimulation (HFS) of ipsilateral primary vestibular afferents on the field potentials recorded in different portions of Medial Vestibular Nuclei (MVN). The involvement of NMDA receptors was assayed using DL-APV. The experiments were performed on rat brain-stem slices maintained in vitro with artificial liquor.

In agreement with previous reports the field potential test (0.05 Hz) was not modified during perfusion with DL-APV. Long Term Potentiation (LTP) of the monosynaptic component was observed in the ventral portion of the MVN following HFS (4 trains 200 Hz, 1 sec., 5 sec. interval) in 6 out of 9 slices; the mean increase of the field potential amplitude was 27.4%. The induction of LTP was blocked under APV perfusion (100µM). In the dorsal portion of MVN HFS did not significantly affect the monosynaptic component but induced Long Term Depression (LTD) of the polysynaptic component in 6 out of 7 slices. LTD was not observed under DL-APV and completely disappeared under bicuculline perfusion (50µM).

Our results show that LTP and LTD can be induced in different portions of MVN and are dependent on the activation of NMDA receptors. LTD could be due to potentiation of the GABAergic interneurons which modulate the excitatory polysynaptic transmission. We suggest that LTP and LTD could play a role in the vestibular plasticity phenomena such as habituation to prolonged stimulation, rebalancing after hemilabyrinthectomy and visuo-vestibular recalibration.

OPIOID RECEPTORS NEUROPHARMACOLOGY IN THE VESTIBULAR AFFERENTS. R. Vega*, E. Soto and M.E. Pérez*. Ciencias Fisiológicas, Universidad Autónoma de Puebla, P.O. Box 406, Puebla 72000, México.

This study was designed to determine the effects of opiate drugs on the electrical activity of the semicircular canal afferents of the vestibular system.

Experiments were done on larval axolotls (*Ambystoma tigrinum*). Multiunit spike activity was recorded from the anterior vestibular nerve by a suction electrode. Naloxone, D-Ala-Leu-Enkephalin (DALE), D-Ala-Met-Enkephalin (DAME) and D-Ala-Gly-Phe-Ol Enkephalin (DAGO) were applied by pressure, ejecting 20 µl each time. Naloxone (10^{-4} to 10^{-8} M), produces a dose-dependent increase of the vestibular afferents discharge. Both DAME and DALE (10^{-10} to 10^{-4} M) induced a biphasic effect. DALE inhibited at low doses (less than 10^{-5}) and excited at greater doses. In contrast, DAME excited at low doses (less than 10^{-4}) and inhibited at greater doses. DAGO (10^{-10} to 10^{-5} M) elicited a dose-dependent long lasting (> 5 min) excitatory effect at all the doses tested.

Our data indicate that the activity of vestibular afferent fibers may be regulated in a complex fashion by the activation of opioid receptors.

EFFECTS OF GINKGO BILOBA EXTRACT ON THE GUINEA PIG VESTIBULAR SYSTEM. T. Yabe, M. Chat*, E. Malherbe* and P.P. Vidal. Lab. de Physiologie Neurosensorielle, CNRS, Paris, FRANCE.

Previous studies have demonstrated that the administration of Ginkgo biloba extract (EGb) improves the compensation of the vestibular syndrome induced by VIIIth nerve transection. In order to investigate the mechanisms at play, the lateral vestibular nucleus of alert normal guinea pigs were perfused unilaterally with EGb. This perfusion always induced a stereotyped reversible postural syndrome which was the mirror image of the syndrome produced by the unilateral lesion of the otolithical receptors. This result supports the hypothesis that EGb has a direct excitatory effect on lateral vestibular nucleus neurons. In a second step, we measured the horizontal vestibulo-ocular reflex (HVOR) of normal and hemilabyrinthectomized guinea pigs following intraperitoneal (IP) injection of EGb. In the normal guinea pig, IP administration of EGb led to a reversible dose-dependent decrease of the HVOR gain without affecting the phase of the reflex. The same diminution of the gain was not found in hemilabyrinthectomized animals. These data help to explain the therapeutic effects of EGb in vestibular syndromes and strongly suggest an impact at the neuronal level.

CONJUGATE AND NON-CONJUGATE 3D EYE MOVEMENTS DURING STATIC AND DYNAMIC OTOLITH STIMULATION IN THE MONKEY.

*B.J.M. Hess, Th. Haslwanter**, Neurology Dept, University Hospital, CH-8091 Zürich, Switzerland

Rhesus monkeys were implanted on both eyes with dual scleral search coils for recording horizontal, vertical, and torsional eye position (3d ep). They were tested in the dark in 90° right/left side down, in supine/prone position, and during constant velocity rotations on a three-axes turntable. In side down position, vertical (only in dark) and torsional (in dark and light) left and right ep differed, resulting in a skew deviation. No such deviation was present in supine (prone) position. Pitch rotation evoked a sustained vertical nystagmus with cyclically modulated beating field. The horizontal but not the vertical or torsional component of the difference between the right and left ep was modulated, resulting in a change of the vergence angle (peak convergence in phase with gaze down). Yaw rotation in side down position (barbecue spit) or roll rotation elicited a sustained horizontal and torsional nystagmus, respectively. It was superimposed on a non-conjugate cyclic modulation of horizontal, vertical, and torsional ep. These findings will be discussed in the light of the presumed spatial arrangement of disynaptic excitatory utricular inputs to the oculomotor plant (Hess & Dieringer, *J Neurophysiol*, 1991).

AUGMENTATION OF CALORIC NYSTAGMUS BY VISUAL FIXATION IN PATIENTS WITH SPINOCEREBELLAR DEGENERATION AND PROGRESSIVE SUPRANUCLEAR PALSY. *H. IMAI, N. ISHIKAWA**, Dept. of Neurology, Jun-endo Univ. Sch. of Med., Tokyo 113, Japan.

Caloric nystagmus is suppressed by visual fixation in normal subjects. This visual suppression of horizontal caloric nystagmus is lost or significantly reduced by flocculus destruction. However, it is known that visual suppression of caloric nystagmus is abolished and, furthermore, caloric nystagmus is augmented by visual fixation frequently in patients with spinocerebellar degeneration. On the other hand, in patients with progressive supranuclear palsy (PSP), it was reported that the caloric test evoked tonic deviation of the eyes and head. We examined and observed both signs in 4 cases of multiple system degeneration in the wide sense: PSP, dentatorubropallidolusian atrophy, Joseph disease and familial spastic paraplegia. For the caloric test, the ear was irrigated with 50 ml of water at 20°C for 20 sec. From our results, the responsible neuronal groups of lesions will be in the neuronal circuit generating the quick phase of vestibular nystagmus: excitatory burst neurons (EBNs) in the PPRF and/or burster-driving neurons (BDNs) in the medullary reticular formation, a direct afferent to the EBNs.

NMDA AND APAMIN INDUCED OSCILLATIONS IN THE GUINEA PIG MEDIAL VESTIBULAR NUCLEI: AN IN VITRO AND IN VIVO STUDY. *M. Serafin, C. de Waele*, A. Khateb, P.P. Vidal, and M. Mühlthaler*, Dept. de Physiologie, CMU, 1211 Genève 4, Switzerland and *Lab. de Physiologie Neurosensorielle, CNRS, Paris, France.

We have recently identified in the guinea pig medial vestibular nuclei (MVN) two main neuronal cell types, A and B MVNn, differing by their intrinsic membrane properties. In addition, one subtype of B MVNn was distinguished by the characteristic presence of low threshold calcium spikes (LTS). Both A and B MVNn were depolarized by NMDA, which also induced a decrease in membrane resistance and an increase in the spontaneous firing rate. These effects could be blocked by D-AP5, a specific antagonist of NMDA receptors. Long-lasting NMDA application resulted in a persistent oscillatory bursting behavior when the cells were maintained under a sustained membrane hyperpolarization of 10-30 mV. These oscillations were however restricted to the subtype of B MVNn without LTS. Neither type A nor type B+LTS MVNn could ever be brought to oscillate in presence of NMDA. These NMDA-induced oscillations were TTX-resistant, but could be eliminated either by D-AP5, or by replacing sodium with choline. Another similar type of oscillation could be triggered with apamin, presumably by blocking calcium-activated potassium conductances. However these oscillations were resistant to D-AP5 and could be eliminated by TTX. In vivo, perfusion of the MVN with apamin resulted in long-lasting head oscillations. It is therefore speculated that these oscillations might be of functional importance and might in particular play a role in the rhythmic firing of vestibulospinal neurones during locomotion (Supported by a Swiss NSF grant n° 31-26495.89 and the French Ministère des Affaires Étrangères).

ACTIVATION OF BRAINSTEM NUCLEI FOLLOWING CENTRIPETAL ACCELERATION IN THE RAT. *G. D. Kaufman, J. H. Anderson†, A. J. Beitz*, Departments of Veterinary Biology and Otolaryngology†, University of Minnesota, St. Paul, MN 55108.

A sheep polyclonal antisera to the Fos protein (Cambridge) was used to identify activated neurons in rat brainstem following 90 minutes of earth-horizontal centripetal acceleration at 2 G. In one set of experiments, 250 gram Long-Evans (pigmented) rats were partially restrained inside metal cones in darkness and positioned either on-axis or ~50 cm eccentric from the axis of rotation which was earth vertical. Within one hour after the centripetal stimulus, the rats were anesthetized, perfused, and the brains processed for immunohistochemistry. Compared to the on-axis animals, the off-axis rats had significantly greater Fos labeling in the area postrema (AP), solitary nucleus (sol), vagal nucleus, vestibular nuclei, interstitial nucleus of Cajal (inC), and the dorsomedial cell column (DMCC) of the inferior olive. On-axis animals had no Fos-immunolabeling in the DMCC, but did have some in areas associated with stress (Locus coeruleus, central grey, and adrenergic cell groups), similar to the off-axis rats. Room controls had little to no Fos immunolabeling in any of the nuclei. In another set of experiments, rats were restrained inside the cones with a skull cap so that the position of the vestibular labyrinth was fixed relative to the gravito-inertial force. When rats were lightly anesthetized (Chloral hydrate, ~300mg/kg, IP) for the duration of the spin, the off-axis animals showed no DMCC labeling, but did label trochlear neurons. Anesthetized on-axis rats revealed intense AP and sol immunolabeling, and light immunostaining of the beta subunit in the medial accessory olivary nucleus. Our data defines some of the temporal and spatial CNS sequelae to sustained, hypergravity stimulation, and describes an otolith-olivary pathway which may be important in vestibular adaptation and compensation. THE EFFECTS OF TARGET DISTANCE ON COMPENSATORY PITCH HEAD MOVEMENTS PRODUCED DURING LOCOMOTION. *J. J. Bloomberg*¹, M. F. Reschke*¹, B. T. Peters*² and W. P. Huebner*²* (SPON: F. Kutyna)¹Space Biomedical Research Institute, NASA Johnson Space Center, Houston, TX, and ²KRUG Life Sciences, Houston, TX.

Berthoz and Pozzo (1988) have suggested that gait motor programs operate in a "top-down" fashion to preserve gaze stability during locomotion. To further investigate this hypothesis we had three subjects walk (6.4 km/h) on a motorized treadmill while visually fixating an earth-fixed target positioned in the center of view either near (30 cm) or far (2 m) from the head. Head movements were recorded using a video-based motion analysis system. During gaze fixation of both near and far targets, pitch head movements were compensatory for linear Z-axis head motion. The mean peak to peak amplitude of compensatory pitch head movements for all 3 subjects increased from $2.24 \pm 0.07^\circ$ (mean \pm S.E.) in the far target condition to $3.31 \pm 0.22^\circ$ in the near target condition, despite no significant change in mean peak to peak linear Z-axis head motion (3.03 ± 0.77 cm, far and 2.99 ± 0.82 cm, near). This result confirms that compensatory pitch head movements are driven by the need to stabilize gaze during locomotion. This stabilization is achieved through a synergistic combination of goal-directed eye and head movements. Gait instabilities experienced by astronauts upon return to Earth may be caused by in-flight adaptive acquisition of new motor strategies designed to maintain head and gaze stable in microgravity, but may be inappropriate for a terrestrial environment.

128.22

PHARMACOLOGY OF MEDIAL VESTIBULAR NEURONES IN GUINEA PIG BRAINSTEM SLICES: PRELIMINARY RESULTS. *N. Vibert*, M. Serafin, A. Khateb, P.P. Vidal and M. Mühlthaler*, Department of Physiology, CMU, 1211 Geneva 4, Switzerland.

We have recently identified in the guinea pig medial vestibular nuclei (MVN) two main neuronal cell types, A and B MVNn, differing by their intrinsic membrane properties (Serafin et al.; Exp. Brain Res. 1991). These cells, which had already been shown to respond to histamine and NMDA (Serafin et al.; Soc. Neurosci. Abst. 1990, 1991), were selected for further pharmacological studies. Both A and B MVNn were depolarized by serotonin, which also induced a decrease in membrane resistance and an increase in the spontaneous firing rate. At least on B MVNn, these effects seemed to be mediated through several receptor subtypes, including 5-HT 1 and 5-HT 2 receptors. Preliminary results also indicated that trans-ACPD, a new specific agonist for glutamate metabotropic receptors, also strongly depolarized and excited both types of MVNn. In contrast, they were apparently both hyperpolarized by application of GABA and glycine, which also provoked a decrease in their spontaneous firing rate. The effects of substance P were also studied; though it seemed to have no effect on A MVNn, it clearly depolarized and excited B MVNn. Together with preliminary studies concerning other neurotransmitters (including acetylcholine, norepinephrine and dopamine), these results point to a good pharmacological homogeneity of type B MVNn, whereas A MVNn appear to present much more heterogeneous responses. (Supported by the Swiss NSF, with N. VIBERT being a Swiss Confederation fellow)

INVESTIGATION OF THE NEURO-MUSCULAR SYSTEM OF *CONDYLACTIS GIGANTEA* (Cnidaria: Anthozoa). C. DellaCorte and W.O. McClure. Dept. Biol. Sci., Univ. of Southern Calif., Los Angeles, CA 90089.

The phylum Cnidaria has traditionally been considered structurally primitive. Recent studies, however, have shown specializations that are unexpectedly complex. We now report an ultrastructural study of the neuro-muscular system which is in agreement with more sophisticated organization. Transmission electron microscopy shows the presence of both discrete and bundled longitudinal muscle processes on the ectodermal surface of the mesoglea. Scanning electron micrographs show nerve tracts along the top of the muscle bundles. Many of the neurons appear unipolar, with cell bodies which lie above the neuronal fibers. Along their length, the fibers have varicosities which are presumed to provide synaptic contacts to surrounding structures. The cellular location of several neuron-related antigens was investigated using immunocytochemistry. Distribution of the immuno-stained product at the level of light microscopy shows highly selective localization at the ectodermal-mesogleal interface. Work is in progress to confirm the localization and function of this neural network. (Supported by the National Institutes of Health.)

LOCALIZATION OF MONOAMINERGIC AND ENKEPHALINERGIC CELLS IN THE BRAINSTEM AND DIENCEPHALON OF A CARTILAGINOUS FISH. S.L. Stuesse and W.L.R. Cruce. Neurobiol. Dept., N. E. Ohio Univ. Col. Med., Rootstown, OH 44272.

There are two major radiations of cartilaginous fish: elasmobranchs and holocephalians. We studied the organization of the brainstem and diencephalon of a holocephalian, *Hydrolagus colliei*, and compared it to our previous results on elasmobranchs. We used antibodies against three substances, tyrosine-hydroxylase (TH), leu-enkephalin (LENK), and serotonin (5-HT) and the peroxidase-antiperoxidase method to visualize immunopositive cells. TH+ cells were found in three locations, diencephalon (thalamus and hypothalamus), locus coeruleus, and myelencephalon (A1/A2 cell group). No substantia nigra (A9), ventral tegmental area (A10), or A5 cell group was seen. LENK+ and 5-HT+ cells were concentrated in raphe nuclei (raphes magnus, pallidus, obscurus, and centralis superior). The rostral ventral metencephalon contained a large 5-HT+ cell group (putative B7/B9), but the dorsal metencephalon did not (no dorsal raphe). The pre-tectal area contained numerous 5-HT+ and LENK+ cells. These cells have been described in teleosts and a lizard, but not in mammals. Thus the brains of these fish contain some, but not all, of the immunoreactive cell groups described in other vertebrates. An analysis of selected traits may give us insights into the evolution of these immunopositive cell groups. NIH grant NS25895.

129.5

THE VALVULA CEREBELLI RECEIVES PRIMARY LATERAL-LINE AFFERENTS FROM THE ROSTRUM OF THE UPPER JAW IN A SPINY EEL. M.F. Wullimann, M.H. Hofmann* and D.L. Meyer*. Brain Res. Institute, Univ. of Bremen, Postfach 33 04 40, 2800 Bremen 33, FRG & Dept. of Neuroanatomy, Sch. of Med., Kreuzberg 36, Univ. of Göttingen, 3400 Göttingen, FRG

In the spiny eel, *Macrogonathus aculeatus*, lateral-line nerve labeling with horseradish peroxidase (Böhringer) reveals that anterodorsal and, to a lesser degree, anteroventral lateral-line nerves project massively to the granular layer of the valvula cerebelli, throughout its rostrocaudal extent. The posterior lateral-line nerve terminates heavily in the corpus cerebelli. Thus, valvula and corpus cerebelli are supplied with mechanosensory input of different peripheral origins. The massive lateral-line input to the valvula in *Macrogonathus* originates mostly in mechanoreceptors located in the elongated rostrum of the upper jaw which is characteristic of masticambeloid fishes. This projection to the valvula, therefore, is likely to represent a unique specialization which arose with the evolution of the peculiar rostrum.

129.2

EFFECTS OF LESIONING THE TERMINAL NERVE ON GNRH IMMUNOCYTOCHEMISTRY IN THE ROUND STINGRAY, *D.E. Wright and L.S. Demski*. Sch. of Biological Sciences, Univ. of Kentucky, Lexington, KY 40506.

In order to distinguish the distribution of GnRH-immunoreactive (ir) fibers of the terminal nerve (TN) from those of mesencephalic GnRH cells, (Wright & Demski, *J. Comp. Neurol.*, 307: 49-56, '91) the white body (WB) ganglion and fibers of passage of the TN were lesioned via cauterization (unilateral, n=3; bilateral, n=5). Animals were sacrificed after survival times of 14-62 days. GnRH systems were immunocytochemically labeled with anti-salmon GnRH antisera. After 28 days, WB ablation resulted in loss of most of the immunoreactivity in TN GnRH fibers entering the dorsal forebrain. Scattered bipolar GnRH-ir cells (10-15µm) remained intact along the original TN pathway, contributing a few fibers to the TN system. GnRH-ir was virtually eliminated in the dorsolateral pallium, nucleus septi caudo-ventralis, rostromedial preoptic area, and diffuse areas of the forebrain. GnRH-ir fibers persisted in the habenula, fasciculus retroflexus, posterior hypothalamus, thalamus, lateral tegmentum, periaqueductal grey, tectum, ventral medulla and spinal cord. Thus, in lesioned animals, remaining labeled fibers probably originate from the mesencephalic GnRH cells.

129.4

THE OCTAVOLATERAL REGION OF AN ADVANCED RAY, *DASYTIS SABINA*. R. L. Puzdrowski and R. B. Leonard, Marine Biomedical Institute, University of Texas Medical Branch, Galveston, TX 77550.

In elasmobranchs, the medullary octavolateral region is characterized by a pair of cell plates termed C1 and C2 (Smeets, '83), which lie at the level of entrance of the posterior lateral line nerve (PLLN) and the trigeminal nerve, respectively. These cell plates lie within the terminal field of the primary afferents of the anterior lateral line nerves (ALLNs) (Bodznick and Schmidt, '84) and project to the midbrain (Barry, '87). In the Atlantic stingray, *Dasyatis sabina*, the presence of a third cell plate which we term C3, prompted us to examine the primary projections of the octavolateral nerves and the second order octavolateral projections to the midbrain using HRP and cobalt-lysine techniques.

The organization of the octavolateral nuclei in *D. sabina* is similar to that described in other elasmobranchs. The eighth nerve projects to the octaval column, the reticular formation, and to the vestibulolateral lobe of the cerebellum. The PLLN projects to the lateral portion of the intermediate nucleus. The ALLNs project to the medial portion of the intermediate nucleus, including cell plates C1 and C2, and to the magnocellular nucleus of the octaval column. Cell plate C3 lies just beneath the medial border of the cerebellar crest and extends from the level of the entrance of the eighth nerve, caudally to the rostral pole of the solitary nucleus. Cell plate C3 lies outside the terminal fields of the octavolateral nerves and thus appears not to receive primary projections. Injections of wheatgerm-HRP into the medial and lateral mesencephalic nuclei labels cells in the anterior octaval nucleus and C1, C2, and C3 contralateral to the injection site. The full connectivity of C3 remains to be elucidated. Supported by NIH grants DC00036 and NS11255.

CENTRAL TOPOGRAPHY OF ELECTRO- AND MECHANOSENSORY LATERAL LINE AFFERENTS IN THE CHANNEL CATFISH, *Ictalurus punctatus*. S. Singh* and J.G. New, Dept. of Biology, Loyola University of Chicago, Chicago, IL 60626

Afferent anterior lateral line nerve (ALLN) fibers innervating electro- and mechanoreceptor organs terminate within medullary and cerebellar nuclei. Electrosensory fibers terminate principally in the electrosensory lateral line lobe (ELLL) whereas mechanosensory fibers terminate primarily in the medial octavolateralis nucleus (MON). The purpose of this study is to determine the central projections of fibers in the principal ALLN branches to determine the topography within these nuclei.

Branches of the ALLN were exposed, transected, and horseradish peroxidase applied to the proximal root. After survival times of 10-14 days the fish were transcardially perfused, the brains removed, sectioned and the tissue developed according to standard HRP protocols.

Fibers of the superficial ophthalmic (SO) branch terminate laterally in the ELLL and medially in the MON. The hyomandibular (HM) nerve fibers terminate medially in the ELLL and laterally in the MON. In both the ELLL and MON fibers from the buccal (B) branch of the ALLN terminate between those of the HM and SO branches.

Our studies reveal that in both the MON and ELLL there exists a topographic organization of ALLN fibers. The patterns of the terminal fields within the two nuclei is reversed along the mediolateral axis of the two nuclei. The electrosensory system in the catfish may have evolved as a specialization of the mechanosensory system. The common origin of the ELLL and MON may explain the similar topography of ALLN projections, notwithstanding that the two systems detect different stimuli.

129.7

INNER EAR ENDORGAN PROJECTIONS IN THE CATFISH *Ictalurus punctatus*. C.A. McCormick and M.R. Braford, Jr. Dept. of Biology, Oberlin College, Oberlin, OH 44074

Previous studies revealed that eighth nerve projections in catfish species are specialized relative to those of non-teleost fishes (Finger and Tong '84; McCormick and Braford '88; Fritzsche et al. '90). This study extends these observations by examining individual projections of the 7 otic endorgans. Horseradish peroxidase applied to a given endorgan nerve branch was allowed to migrate for 18-27 hrs in exsanguinated specimens. HRP-labeled fibers were visualized in transverse sections using TMB (Mesulam, '78). The largest octaval nucleus, the descending, is composed of lateral and medial portions. The medial portion, which corresponds to the medial auditory nucleus of Finger and Tong ('84), receives input predominantly, and possibly exclusively, from the sacculae. The lateral portion of the descending nucleus has 3 zones. The dorsal zone receives a heavy saccular input and a very light lagenar and utricular input. The intermediate zone receives input from all otic endorgans. The ventral zone receives input mainly from the semicircular canals. The anterior octaval nucleus also has a lateral portion supplied by all otic endorgans and a medial portion in which saccular input predominates. The magnocellular nuc. receives input from all otic receptors. The tangential nuc. is supplied mainly by the semicircular canals. Supported by NSF BNS 8820095 and NSF BNS 8820858.

LOCALIZATION OF THYROTROPIN-RELEASING HORMONE-LIKE IMMUNOREACTIVITY IN THE CHINOOK SALMON. S. Matz* and T.T. Takahashi. Institute of Neuroscience, University of Oregon, Eugene, OR 97403

We studied the distribution of thyrotropin-releasing hormone (TRH)-like immunoreactivity in the brain of juvenile chinook salmon (*Oncorhynchus tshawytscha*) with the use of a polyclonal antibody. We found TRH-positive cell bodies in the preoptic area of the forebrain. Based on the size, morphology and position of these cell bodies, we assigned them provisionally to the posterior parvocellular preoptic nucleus. We also found TRH-positive cell bodies in the internal cellular layer of the olfactory bulb. Fine, beaded, TRH-positive fibers were also present in various regions throughout the brain, but were especially dense in the ventral hypothalamus and in the medial and posterior regions of the dorsal forebrain. TRH-positive fibers were also found in the areas surrounding the anterior commissure rostrally into the ventral telencephalon and caudally into the preoptic area. The staining described above required perfusion with 0.5% glutaraldehyde and 4% paraformaldehyde (in 0.1 M PBS). Perfusions with paraformaldehyde alone resulted in no staining. Preabsorption of the antibody with TRH eliminated all of the staining described above.

The localization of TRH-like immunoreactivity in the preoptic and hypothalamic regions is of particular interest since this system may control the release of thyroxine, a hormone involved in the imprinting of salmon to their homestream odor as well as many of the aspects of smoltification in salmon. The localization of TRH-positive cell bodies in the olfactory bulb and the wide distribution of fibers lends credence to the notion that TRH also has a neurotransmitter role.

GNRH IN THE SEXUALLY POLYMORPHIC TELEOST FISH, *PORICHTHYS NOTATUS*: IMMUNOCYTOCHEMISTRY AND *IN SITU* HYBRIDIZATION. M.S. Grober, D. Myers*, T. Myers* and A. Bass. Section of Neurobiology and Behavior, Cornell University; and Department of Physiology, New York State College of Veterinary Medicine, Ithaca, New York, 14853.

The plainfin midshipman, *Porichthys notatus*, exhibits two alternative male reproductive morphs: Type I males establish nests from which they call to attract females to spawn; smaller, and apparently earlier maturing Type II males attempt to sneak fertilizations with females that are paired with nesting Type I males. The organization of the gonadotropin releasing hormone (GnRH) system is being studied because of its known role in controlling the ontogeny of hormone-dependent sexual traits.

Using a monoclonal antibody to GnRH, it was found that females and both male morphs have similar distributions of GnRH-like immunoreactivity in the nervus terminalis ganglion (NT) and the preoptic area (POA). However, females had significantly more GnRH POA cells than either male morph. When corrected for body size, the POA of Type I males had significantly fewer GnRH-positive cells compared to females or Type II males, which were similar. Preliminary data indicate that juveniles have fewer GnRH POA cells than adults. These differences in GnRH POA cell number may reflect differential rates of development, and result in the alternative reproductive behaviors exhibited by the two male morphs.

To identify the mechanisms underlying GnRH dimorphisms, *in situ* hybridization is being used to probe for cells containing GnRH-mRNA. Thus far, using a DNA oligonucleotide probe developed to the putative nucleotide sequence of salmon GnRH, only the NT has been labelled. These preliminary results suggest that sexual polymorphisms may result from the differential distribution of GnRH-positive cells and/or the cell-specific expression of different GnRH peptides.

129.8

THE DISTRIBUTION OF AUTONOMIC AND VISCERAL SENSORY NERVE FIBERS IN THE BRAINSTEM, SPINAL CORD, AND GUT OF THE CATFISH, *ICTALURUS PUNCTATUS*. L. E. Goehler. Dept. C&S Biology, UCHSC, Denver, CO 80262.

The extrinsic nerves (vagal, splanchnic, sensory) innervating the vertebrate abdominal viscera provide the means by which the CNS regulates visceral functions. The aims of the present study were to trace the distribution of visceral nerves in the CNS and gut of the catfish, using the carbocyanin dye, DiI. In the brainstem, crystals of DiI placed on the abdominal branch of the vagus labeled fibers in the general visceral nucleus, as well as numerous somata in the caudal dorsal motor nucleus of the vagus. In the rostral spinal cord, crystals of DiI placed on the splanchnic nerve labeled fibers travelling in a dorsal tract, terminating in the lateral funicular nucleus and in a ventromedial subnucleus of the medial funicular nucleus. In the gut, crystals of DiI placed on the combined vagus/splanchnic labeled numerous fibers of the myenteric plexus, innervating unlabeled ganglia, as well as the submucosal plexus, oxyntic cells, and subepithelium.

MELANIN BINDING SITES IN FISHES. A.J. Vernadakis*, W.E. Bemis* and E.L. Bittman. Department of Zoology, Univ. of Massachusetts, Amherst.

Through its secretion of melatonin, the pineal complex of lower vertebrates exerts a range of physiological effects including regulation of diurnal rhythms, reproduction, metamorphosis, and body color change. Little is known about evolutionary trends in the distribution and characteristics of melatonin binding sites. *In vitro* autoradiography was used to examine binding in 20-micron frozen brain sections of amphioxus (*Branchiostoma lanceolatum*), hagfish (*Myxine glutinosa*), adult and larval lamprey (*Petromyzon marinus*), little skate (*Raja erinacea*), and rainbow trout (*Salmo gairdneri*). Tissue was incubated with 2-[¹²⁵I]-iodomelatonin (IMEL) under previously described conditions (J. Neuroscience 9:2581) in the presence or absence of unlabeled melatonin (1uM, in order to assess nonspecific binding). A concentration of 32pM IMEL was used for single point assays and competition studies.

No specific binding was found in hagfish or amphioxus, which lack a pineal complex. In skate and trout optic tectum, IMEL binding is highly specific (melatonin > NAS > 5-MT > 5-HT). Scatchard analysis revealed that tectal IMEL binding is of high affinity (K_d of 36, 38 and 50pM) and low capacity (B_{max} of 8.1, 19.8, and 21.8 fmol/mg protein in lamprey, skate and trout, respectively). In adult lampreys, intense specific IMEL binding is found in the optic tectum (layer I>II>III) and preoptic nucleus (pars parvocellularis>magnocellularis). Binding was less intense and consistent in the same areas of ammocoete brain. In skates and trout, intense specific binding is found in optic tectum and diencephalic preoptic and suprachiasmatic nuclei. These results indicate that specific melatonin binding sites represent a phylogenetically primitive vertebrate characteristic whose functions might include regulation of visual and endocrine responses to light. 129.12

ALLOMETRY OF THE TELEOST VISUAL SYSTEM IN RELATION TO ENVIRONMENT AND BEHAVIOR. Nico A.M. Schellart* (SPON: European Neurosc. Association). Lab. of Medical Physics, Acad. Med. Centre, Univ. of Amsterdam, Meibergdreef 15, 1105 AZ Amsterdam.

With a mathematical model, based upon the allometry of the eye, and the Stratum opticum (SO) and Stratum fibrosum et griseum superficiale (SFGS) of the optic tectum, the spatial visual performance of 28 species was estimated. To allow interspecific comparison, bodyweight was standardized. To establish allometric relations, the allometric function $y = kx^{d(1-\alpha/\beta)}$ is introduced (d depends on the dimensions of x versus y, k and α are constants to be fitted). This function was used in addition to the classical allometric function. The four variables of the model, i.e. the focal length of the eye, the surface of SO + SFGS, the thickness of SO + SFGS and the density of the optic projection (latter datum gathered from literature), together constituting the visual index, show mutually a high positive correlation. The visual index was obtained by multiplication of four parameters, each indicating the factor by which the respective variable deviates from the interspecific, body weight dependent mean.

It was found that the volume of SO + SFGS is, irrespective of fish size, proportional to the retinal surface. On average, this also holds interspecifically. The visual index shows a relation with published data about the psychophysical determined minimum resolvable angle.

The visual index, with a range of 1.7 log unit, appears to be interrelated with behavioral and environmental characteristics. Species with low indices are often benthic. However, the period of foraging during the diurnal cycle is not related in a simple way to the visual index. High indices are found among predatory and especially piscivorous species and among pelagic species living in clear waters.

129.13

RETINAL PROJECTIONS IN A CLUPEOMORPH TELEOST. *Ann B. Butler and R. Glenn Northcutt*. I.T.N.I., 4433 N.33rd St., Arlington, Va. 22207 and Scripps Inst. Oceanog. and Dept. Neurosci. A-001, Univ. Ca. San Diego, La Jolla, Ca. 92093. Retinofugal projections were studied in four Atlantic herrings (*Clupea harengus*) which received intraocular injections of HRP (Sigma) under MS222 anesthesia. After six days survival, the animals were perfused under anesthesia with phosphate buffer followed by 4% glutaraldehyde in buffer. Sections cut at 35µm were reacted with the Hanker-Yates [1977] protocol. A cytoarchitectonic analysis of nuclei was carried out on Bodian and cresyl violet serial sections before charting the projections.

Contralaterally, the retina projects sparsely to nuclei suprachiasmaticus (SC), anterior (A), and ventromedialis (VM) and to the periventricular nucleus of the posterior tuberculum (TPp). Dense terminal fields lie over nuclei intermedialis (I), pretectalis superficialis pars parvocellularis (PSP), corticalis (NC), pretectalis centralis (PC), and pretectalis periventricularis pars dorsalis (PpD). The dorsal and ventral accessory optic nuclei also receive contralateral projections. Ipsilateral projections reach I and PpD. A sulcus divides the tectum into two lobes. Contralateral retinal projections reach the dorso-medial lobe via the dorsal optic tract (DOT) and the caudolateral lobe via the ventral optic tract (VOT).

While the distribution of retinal projections to diencephalic and pretectal nuclei is similar to that in other teleosts, the presence of two tectal lobes innervated separately by the DOT and VOT appears to be apomorphic.

INTRASPECIFIC VARIATION IN IMMUNOREACTIVE GnRH IN THE POSTERIOR HYPOTHALAMUS OF AN AMPHIBIAN. *L.E. Muske, A. Loeffler*, R.J. Dreher*, F.L. Moore*. Biology Dept., Franklin & Marshall College, Lancaster PA 17604; Zoology Dept., Oregon State Univ., Corvallis OR 97331.

Recent reports of GnRH-immunoreactive (ir) neurons in the posterior hypothalamus or midbrain prompted a re-examination of the distribution of these cells in a urodele amphibian. Adult male and female *T. granulosa* were captured in March (breeding) or August (sexually inactive) and brains processed for immunocytochemistry. Sections were collected across sets of slides and treated with one of several GnRH antisera or with anti-FMRamide. Antibodies were localized with a commercial avidin-biotin-HRP preparation. Anti-mammalian GnRH #635 (Dr. L. Jennes) revealed a large population (up to 50 somata/25 µm section) of CSF-contacting neuronal perikarya in the ventral diencephalon of a few individuals. Where staining was robust, GnRHir periventricular neurons extended from the preoptic recess to the posterior margin of the infundibular recess. There was no apparent anatomic relationship between these neurons and the terminal nerve/septal/POA GnRH population. Since FMRamide immunolabeling was uniform across subjects, it appears that individual variability in GnRHir staining in the posterior hypothalamus is not an artifact of technique, nor is there any apparent association with sex or reproductive state. Supported by a Faculty Research Grant from Franklin and Marshall College.

BRAIN ATLAS OF TRH mRNA EXPRESSION IN DEVELOPING AND ADULT FROG: CONTIGUOUS ROWS SPANNING ANTERIOR-TO-POSTERIOR FOREBRAIN SHOW ORIGINAL RELATIONSHIPS BETWEEN DISCRETE NUCLEI. *Y.P. Loh and W.P. Hayes*. Laboratory of Developmental Neurobiology, NICHD, Bethesda, MD 20892.

Little is known about how discrete vertebrate brain nuclei have evolved and diversified, or about their phylogenetic relationships. Comparative findings in cytoarchitecture and connectivity remain the basis for arguing CNS homology, but as discussed elsewhere this approach can be equivocal (Northcutt, 1984 *Amer. Zool.* 24). Recent molecular findings showing that gene structure and CNS distribution are highly conserved for neuropeptides have led us to examine how adult patterns of expression for several neuropeptides are established in *Xenopus*. To this end, embryonic to adult brains were examined by *in situ* hybridization histochemistry using oligonucleotide probes (Hayes and Loh, 1990 *Development* 110). The focus here is on the gene encoding thyrotropin-releasing hormone (TRH), because its incipient pattern in forebrain at embryonic day 3.5 (stage 42) arises from bilateral rows of TRH cells (Loh and Hayes, 1989 *Neurosci. Abstr.* 15).

Serial sections showed that the embryonic anterior-to-posterior TRH rows continue to undergo progressive anteriorization during larval development; non-contiguous expression was also seen in discrete areas of olfactory bulb, optic tectum, hindbrain brainstem and retina. Adopting the new forebrain nomenclature of Northcutt (1981, *An. Rev. Neurosci.* 4) and Neary and Northcutt (1983, *JCN* 213), TRH cells formed a path spanning over ten contiguous ventral nuclei from lateral septum to posterior tuberculum, crossing the telencephalic-diencephalic border at the anterior preoptic area to the lateral amygdala and thalamic eminence, and continuing in lateral pallidum, nucleus accumbens and ventral striatum. Thus, TRH expression forms a continuum mapping embryonic relationships between adjacent brain nuclei. This in turn, suggests that in phylogeny the sculpting of discrete forebrain nuclei was preceded by the simpler TRH expression pattern.

EXPERIMENTAL EMBRYOLOGICAL EVIDENCE OF THE PLACODAL ORIGIN OF GnRH AND FMRF-amide NEURONS OF THE TERMINAL NERVE AND PREOPTIC AREA IN SALAMANDERS. *R.G. Northcutt and L.E. Muske*. Dept. Neurosciences, UCSD, La Jolla, CA 92093; Dept. Biology, Franklin and Marshall College, Lancaster, PA 17604.

To test the hypothesis that neurons of the terminal nerve and preoptic area arise from the olfactory placode, this placode was bilaterally extirpated in 30 stage 26-29 axolotls (*Ambystoma mexicanum*) and the embryos reared for at least four months. Experimental and control juveniles were anesthetized and perfused with cold 4% buffered paraformaldehyde (pH 7.4). The brains were removed, embedded in 10% gelatin and postfixed for 12h. Experimental and control brains were paired and run in tandem. Transverse or horizontal frozen sections were cut and incubated with commercial antisera made in rabbit to GnRH or FMRF-amide (1:4000). Antibodies were localized using a metal intensified peroxidase-antiperoxidase reaction. About half the experimental cases exhibited no olfactory organs, nerves or bulbs and no forebrain GnRH reactive cells or fibers; in the same cases, no FMRF-amide reactive cells or fibers occurred in the position normally occupied by the terminal nerve but did occur in other positions. In control cases, GnRH and FMRF-amide reactive cells and fibers of the terminal nerve and preoptic area were observed in the same blocks. This is the first direct experimental evidence that ganglionic cells of the terminal nerve and preoptic area arise from the olfactory placode. (Supported in part by NIH grants NS24669 and NS24869.)

ANATOMY OF THE OLFATORY AND VOMERONASAL SYSTEMS IN AMPHIUMA TRIDACTYLUM AND SIREN INTERMEDIA. *H.L. Eisthen, D.R. Sengelau, and D.M. Schroeder*. Program in Neural Science, Indiana University, Bloomington, IN 47405.

Jurgens (1971) and Bertmar (1981) suggest that the vomeronasal (VN) system arose in tetrapods as an adaptation to terrestriality, a view which has led to the assumption that the VN system is absent in aquatic amphibians. Conversely, Broman (1920) and Parsons (1971) conclude that presence of the VN system is plesiomorphic in vertebrates and that the olfactory system is evolutionarily newer. We are conducting studies of the phylogenetic distribution of these chemosensory systems in aquatic salamanders. We have previously described the anatomy of the olfactory and VN systems in relatively derived aquatic salamander species. However, we have found that the VN system is absent in mudpuppies, leaving open the possibility that mudpuppies represent the ancestral condition and that the presence of the VN system in larval and neotenic salamanders is a derived character-state.

We have examined the forebrain and nasal cavities of two salamander species from families that are considered primitive relative to mudpuppies. In the three-toed amphiuma (*Amphiuma tridactylum*, family Amphiumidae) olfactory epithelium is located in grooves throughout the medial portion of the nasal cavity. As in other salamanders, the lateral portion of the nasal cavity contains VN epithelium. Preliminary evidence suggests that the nasal cavity of lesser sirens (*Siren intermedia*, family Sirenidae) lacks a lateral diverticulum, but *Siren*, like *Amphiuma*, possesses a clearly-defined accessory olfactory bulb dorsocaudal to the main olfactory bulb, indicating the presence of a VN system.

The presence of olfactory and VN systems in derived and primitive salamanders indicates that the presence of both systems is the ancestral condition in aquatic salamanders. We conclude that the VN system did not arise as a terrestrial adaptation.

NUCLEUS BASALIS SINGLE UNIT ACTIVITY AND CONDITIONED CORTICAL AROUSAL IN THE RABBIT. P.J. Whalen, B.S. Kapp and J.P. Pascoe, Dept. of Psychology, Univ. of Vermont, Burlington, VT 05405

Our current research is concerned with the neurobiological substrates of conditioned arousal. The cholinergic basal forebrain neurons within the subthalamic substantia innominata (SI; Grove, 1988), referred to also as nucleus basalis (NB) are believed to contribute to cortical arousal. This arousal response is indexed by a decrease in EEG high voltage slow activity (0-4 Hz; delta) and the presence of EEG low voltage fast activity (Buzsaki et al., 1988). The present study sought to determine if the activity of SI neurons is correlated with the conditioned cortical EEG arousal response.

New Zealand rabbits received differential Pavlovian conditioning trials in which a tone of one frequency (the CS+) immediately preceded an electrical stimulus (the US) to the pinna, while a tone of another frequency (the CS-) was never followed by the US. A Fourier analysis of the neocortical frontal EEG revealed that a significantly larger EEG arousal response emerged over trials to the CS+ than to the CS- ($p < .05$).

The majority of recorded neurons were located in the SI at the level of the anterior commissure. Many of these neurons increased their firing rate significantly more to the CS+ than to the CS- ($p < .05$), similar to the discrimination seen in the EEG arousal response. Furthermore, the spontaneous activity of these same neurons was found to correlate negatively with spontaneous fluctuations in the EEG. That is, neuronal activity increased with decreased EEG slow activity, and decreased with increased EEG slow activity ($p < .05$). Supported by NSF grant BNS 9010760.

SINGLE UNIT ACTIVITY IN MESOPONTINE PERIBRACHIAL AREA (PB) NEURONS THAT PROJECT TO THE THALAMUS DURING PAVLOVIAN CONDITIONING IN RABBITS. J.P. Pascoe & B.S. Kapp, Dept. Psychology, The University of Vermont, Burlington, VT 05405 USA.

We reported previously that activity in many PB neurons is altered significantly during presentations of both novel stimuli and an auditory stimulus (CS) that has acquired affective significance consequent to Pavlovian conditioning procedures (Pascoe & Kapp, 1990). We are now testing the hypothesis that such activity occurs in at least some PB neurons that project to the thalamus, and in this way may contribute to learning-related changes in the activity of thalamic neurons.

PB neurons were activated antidromically by stimulation of one or more thalamic sensory relay nuclei with an average latency of 1.8 ms. Activity in these neurons during CS presentations was either unchanged, increased at a short latency (<15ms), or decreased at a longer latency (>100ms). For a given neuron, responses to novel stimuli were of the same pattern as those to the CS but were more robust initially and habituated rapidly. Other neurons with similar patterns of sensory-evoked activity were activated orthodromically by stimulation of the thalamus at an average latency of 3.0 ms, including some that also were activated orthodromically by stimulation of the amygdaloid central nucleus. This research demonstrates learning-related phenomena in PB neurons that (a) project to the the thalamus and (b) may serve to modulate sensory processing and transmission within the thalamus during learning. SINGLE UNIT RECORDINGS OF SOMATOSENSORY AND AUDITORY EVOKED RESPONSES IN THE ANTERIOR INTERPOSITUS NUCLEUS IN THE NAIVE RABBIT.

J. Tracy, C. Weiss and R.F. Thompson, Neurosciences Program, University of Southern California, Los Angeles, CA 90089-2520.

The cerebellar deep nuclei have been implicated as necessary for classical conditioning of the rabbit nictitating membrane response (NMR). Previous studies have shown that lesions as small as 1 cubic mm in the anterior-lateral portion of the anterior interpositus nucleus (IPA) are sufficient to abolish NMR conditioning (Lavond, et al. 1984). We are undertaking a single unit mapping of the IPA of naive rabbits to determine which areas respond to the auditory and somatosensory stimuli typically used during conditioning trials.

Preliminary results show that responses to either auditory stimulation, somatosensory stimulation, or both occur consistently in the IPA. Several response types have been recorded. Evoked excitatory responses tend to occur within a 5-50 msec latency and inhibitory responses within 20 to 100 msec latencies. The majority of cells show a variety of "on" responses to the effective stimulus. A few cells exhibit an on-off response pattern. These cells, typically found 1.0 mm anterior to lambda, increase in firing frequency and then shortly thereafter (200-400 msec) turn off. The most responsive region ranges from 0.5 mm posterior to 1.0 mm anterior to lambda. Dorsal/ventral positions within the interpositus appear to contribute little to response specificity.

Thus, while no specific topographic arrangement of afferent response is yet apparent, there are clearly areas of response with greater and lesser complexity. Cells that respond to more than one type of stimuli are seen in the anterior-lateral area while the those recorded in the more anterior, posterior, and medial regions respond more selectively, or not at all.

130.2

CHOLINERGIC CONTRIBUTION TO CORTICAL ELECTRO-ENCEPHALOGRAPHIC (EEG) CONDITIONED RESPONSES (CRs) IN THE RABBIT. B.S. Kapp, P.J. Whalen and S.L. Thurm*, Dept. of Psychology, University of Vermont, Burlington, VT 05405.

We have reviewed evidence suggesting that the amygdaloid central nucleus (ACe) contributes to the expression of CRs indicative of arousal in the rabbit (Kapp et al. 1990). This hypothesis is supported by the observation that electrical stimulation of the ACe in rabbit elicits EEG arousal, manifested in an inhibition of high voltage slow activity (0-4 Hz) and the presence of low voltage fast activity. This arousal is blocked by atropine sulfate (Kapp et al. 1990, 1991). In the present study, one of a series designed to assess the role of the ACe in conditioned arousal, we examined the effects of cholinergic antagonists on the expression of conditioned EEG arousal in the rabbit.

New Zealand rabbits received Pavlovian differential conditioning trials in which a tone of one frequency (the CS+) immediately preceded a brief electrical stimulus (the US) to the pinna while a tone of another frequency (the CS-) was never followed by the US. A Fourier analysis of the frontal cortical EEG demonstrated that over conditioning trials a significantly larger EEG arousal response emerged in response to the CS+ than to the CS-. Atropine sulfate (8 mg/kg i.v.) administered following the establishment of this discrimination blocked the EEG response to both CSs, whereas the peripherally-acting atropine methyl nitrate (8 mg/kg) exerted little effect. The results suggest a significant cholinergic contribution to conditioned EEG arousal. An examination of the contribution of the ACe to conditioned EEG arousal is now in progress. Supported by NSF grant BNS 9010760.

130.4

AIR PUFF EVOKED PURKINJE CELL COMPLEX SPIKE ACTIVITY IS DIMINISHED DURING CONDITIONED RESPONSES IN EYEBLINK CONDITIONED RABBITS. D. J. Krupa, C. Weiss, and R. F. Thompson, Neurosciences Program, University of Southern California, Los Angeles, CA 90089-2520.

Previous Purkinje cell recording studies in eyeblink conditioned rabbits found very few cells which responded with a complex spike to an air puff unconditioned stimulus (US). Also, recordings from the dorsal accessory inferior olive (DAO) demonstrate decreased activity on paired CS-US trials in trained rabbits. These data suggest that conditioning related inhibition of the DAO, and/or its afferents, results in a reduced probability of US evoked complex spikes.

In the present study, Purkinje cells from HVI and surrounding areas were recorded in rabbits during paired tone-airpuff (isi=250 ms) conditioning trials. Interspersed throughout the paired trials were airpuff alone trials. In well trained rabbits, Purkinje cells which responded to the airpuff alone with a complex spike ($n=10, p=.8$) did not respond to the airpuff with a complex spike ($p=.2$) on paired CS-US trials. Five more airpuff responsive cells have been recorded from rabbits very early in training. On paired trials (0% CRs), these cells continued to respond to the US with a complex spike.

Five cells were found which responded with a complex spike to the tone CS as well as the sound of the airpuff US (airpuff was aimed away from the rabbit). However, on paired trials in well trained rabbits, these complex spikes were not diminished.

These data suggest that inhibition of the US input to the cerebellum is mediated by the CR pathway and is selective for somatosensory responsive Purkinje cells. Supported by the McKnight Foundation, NSF BNS-8718300 and ONR N00014-88-K0112 to RFT.

SUBCULAR CELLS THAT PROJECT TO THE MEDIAL PREFRONTAL CORTEX ARE NOT NECESSARY FOR CLASSICALLY CONDITIONED BRADYCARDIA IN RABBITS. Mark E. Chachich, Brian Maxwell*, Conrad Terry* & D.A. Powell, VA Medical Center, Department of Psychology, University of SC and Department of Neuropsychiatry and Behavioral Science, University of SC School of Medicine, Columbia, SC.

Rabbits and rats received horseradish peroxidase injections in the medial prefrontal cortex and retrograde label was examined in the ventral hippocampus and associated subiculum. As previously reported (e.g., Ferino et al, *Exp Brain Res*, 1987, 65, 421-426), labeled cells were observed in dorsal and ventral subiculum and in the CA1 hippocampal field in the rat. Although scattered cells were observed in the dorsal subiculum of the rabbit, no labeled cells were seen the hippocampus proper or the ventral subiculum. Instead the strongest projection to the medial prefrontal cortex in the rabbit appears to arise from the postsubiculum. Separate groups of rabbits with sham, postsubicular, or dorsal subicular lesions were subjected to classical heart rate conditioning in which a 4 sec, 75 db tone was the conditioned stimulus and a 3 mA paraorbital shock was the unconditioned stimulus. However, no significant differences were observed between the lesion and sham groups in either the acquisition or magnitude of conditioned bradycardia.

Supported by VA Institutional Research Funds

130.7

AN ANALYSIS OF NEURONAL ACTIVITY IN THE MEDIAL PREFRONTAL CORTEX AND THE AMYGDALA DURING CLASSICAL HEART RATE CONDITIONING IN RABBITS. D.A. Powell, Brian Maxwell* & Conrad Terry*. VA Medical Center, Columbia, SC 29201, Department of Psychology, University of SC and Department of Neuropsychiatry and Behavioral Science, University of SC School of Medicine, Columbia, SC.

Multiple unit recording electrodes were chronically implanted in either area 32 of the medial prefrontal cortex (PFC) or the lateral, central, or basolateral nucleus of the amygdala in rabbits. Multiple unit activity was recorded during adaptation, acquisition and extinction of classical heart rate conditioning in which a 4 sec tone served as the conditioned stimulus (CS) and a 250 msec paraorbital shock was the unconditioned stimulus. As expected, conditioned heart rate decelerations were obtained. These cardiac changes were accompanied by CS-evoked increases in neuronal output in both the medial PFC and the amygdala that were significantly greater than that obtained during either adaptation or extinction. However, in general the latency to peak response and the magnitude of the response was greater in all the nuclei of the amygdala than in the prefrontal cortex. These data provide further support for the participation of both the medial PFC and amygdala in classically conditioned bradycardia. Supported by VA Institutional Research Funds

130.9

DIFFERENCES IN ACQUISITION AND EXTINCTION OF CONDITIONING-RELATED NEURONAL ACTIVITY IN RABBIT CEREBELLAR CORTEX AND INTERPOSITUS NUCLEUS. T.J. Gould, D.P. Miller & J.E. Steinmetz. Dept. of Psych., Prog. in Neural Science, Indiana University, Bloomington, IN 47405.

Neural recordings from lobule HVI of cerebellar cortex and the interpositus nucleus (INP) during classical eyelid conditioning revealed increases in activity that formed an amplitude-time course model of the learned response (McCormick & Thompson, *J. Neurosci.* 4, 1984). These data and a number of cerebellar lesion studies have suggested that the cerebellum may be a critical site of plasticity associated with classical conditioning. The goal of the present study was to compare rates of acquisition and extinction of CR-related activity in the INP and HVI. After implanting recording electrodes into both the INP and HVI, 11 animals were classically conditioned with a tone CS and an air puff US until a conditioning criterion was reached on 3 consecutive sessions. Animals then received unpaired extinction presentations of the US and CS until a baseline eyelid response (i.e., less than 5% CRs) was observed on CS alone trials for three consecutive sessions. During all phases of training, behavioral and neural responses were monitored. In 2 rabbits, neuronal models were observed in both the INP and HVI. CR-related activity developed in the INP about one-half a session prior to its development in HVI and simultaneously with the production of behavioral CRs. In 9 other animals, CR-related activity was not seen in both areas due to improper placement of one of the electrodes. These rabbits were trained to criterion, however, and given extinction training. Four animals showed CR-related activity in the INP and five animals showed CR-related activity in HVI. At 5 of 6 INP sites, the neuronal model disappeared at the same time the behavioral CR extinguished. At 6 of 7 HVI sites, however, the neuronal model decreased to some extent but some CR-related activity remained for several sessions after the behavioral CR disappeared. In sum, although both the INP and HVI showed CR-related activity, the excitatory neuronal model did not develop at the same time (i.e., CR-related activity in the INP developed about one-half session prior to that in HVI). Furthermore, CR-related activity at the two sites did not extinguish at the same time (i.e., CR-related activity in the INP extinguished with the behavioral CRs while CR-related activity in HVI remained for a period of time after extinction of behavioral CRs). 130.11

EFFECTS OF RED NUCLEUS STIMULATION ON A PAVLOVIAN UNCONDITIONED RESPONSE (RABBIT EYEBLINK) T. Canli, K. Whitney*, and N.H. Donegan. Dept. of Psychology, Yale Univ., New Haven, CT. 06520.

A core assumption of an influential class of Pavlovian conditioning models (Rescorla-Wagner, SOP; see Donegan, *et al.*, *Psych. Learn. & Motiv.*, 23, 1989) is that signaling a Pavlovian US by an associated CS diminishes US processing. This is thought to contribute significantly to phenomena such as the negatively accelerated acquisition curve, the Kamin blocking effect, and the conditioned diminution of the UR. Within the context of rabbit eyeblink conditioning, we proposed that one way a CS can associatively diminish US processing is by activating the projection from the magnocellular division of the red nucleus to the contralateral trigeminal spinal nuclei, that, from the work of Dostrovsky, is assumed to be inhibitory (Donegan *et al.* 1989).

To begin evaluating these proposals, we assessed the effect of stimulating the red nucleus on the ability of a peri-orbital shock US to elicit an eyeblink UR. Twenty three male New Zealand rabbits had pairs of stimulating electrodes chronically implanted in the magnocellular region of both red nuclei. Each electrode site was tested by giving subjects 22 US-alone and 22 stimulation -> US trials presented in an intermixed, counterbalanced sequence. Brain stimulation consisted of a 100 msec train of 2 msec pulses at 200 Hz. Current intensity ranged from 100 to 400 μ A, depending on the amount and kind of behavior elicited. The US was a 50 msec train of 5 msec pulses at 100 Hz, 2.5 to 4 mA. On stimulation -> US trials, the onset of the stimulation train preceded the US by 150 msec (Weiss *et al.*, *Neurosci. Abs.*, 11: 182, 1985). Stimulation of the posterior or central regions within the red nucleus, or the dorsolateral border of the posterior region, in most cases produced a diminution of the peak UR amplitude compared to US-alone trials. When both eyes were tested, diminution was more consistently seen on the contralateral eye. Stimulation of a small region at the ventral border of the anterior portion of the red nucleus tended to potentiate UR amplitude. In pilot studies, we are finding that similarly stimulating the region of the anterior, lateral interpositus nucleus of the cerebellum consistently diminishes the amplitude of the eyeblink UR in the ipsilateral eye.

EFFECTS OF INTERPOSITUS NUCLEUS OR RED NUCLEUS LESIONS ON RABBIT CLASSICAL CONDITIONING-RELATED THALAMIC AND HIPPOCAMPAL NEURAL ACTIVITY. L.L. Sears and J.E. Steinmetz. Program in Neural Science, Indiana University, Bloomington, IN 47405.

The cerebellum and hippocampus appear to be involved in rabbit classical eyelid conditioning. Both structures evidence neural activity that precedes and models the topography of the learned behavioral response. Acquisition of the learned response, however, and the development of training-related neural activity in the hippocampus requires an intact cerebellum (Sears & Steinmetz, *Beh. Neurosci.* 5, 1990). In an initial attempt to determine how important training-related activity from the cerebellum may be transmitted to higher brain areas, a series of lesion and recording studies were completed.

Multiple-unit recordings from the ventral lateral thalamus in rabbits chronically implanted with either interpositus (N=7) or red nucleus (N=7) lesion electrodes revealed neural activity that formed an amplitude-time course model of the learned response. The neural activity and conditioned eyelid responses were abolished following interpositus nucleus electrolytic lesions. Red nucleus lesions, however, blocked conditioned responses without altering ventral lateral thalamic neural activity suggesting that the observed thalamic activity was dependent on direct cerebellar efferents. In a second group of rabbits with chronically-implanted hippocampal recording electrodes, lesions were made in either the ventral lateral thalamus (N=6) or red nucleus (N=6) following acquisition of learned responses. Lesions in the thalamus or red nucleus did not effect training-related activity in the hippocampus. The results of these studies indicate that training-related activity in the hippocampus is not dependent on cerebellar pathways to the red nucleus or ventral lateral thalamus.

RABBIT CLASSICALLY CONDITIONED EYELID RESPONSES FAIL TO REAPPEAR AFTER INTERPOSITUS LESIONS AND EXTENDED POSTLESION TRAINING. J.E. Steinmetz and S.S. Steinmetz*. Program in Neural Science and Department of Psychology, Indiana University, Bloomington, IN 47405.

A number of laboratories reported complete abolition of classically conditioned eyelid responses (CRs) after cerebellar interpositus nucleus lesions (e.g., McCormick & Thompson, *Science*, 223, 1984). Recently, the relative permanence of this lesion effect has been challenged (Welsh & Harvey, *J. Neurosci.*, 9, 1989; Kelly *et al.*, *Behav. Brain Res.* 38, 1990). One possibility is that the reappearance of CRs in lesioned rabbits is related to the amount of postlesion training given. To test this hypothesis, to date, we have trained 3 rabbits to asymptotic responding (15 days) using a 350 ms tone CS and a 100 ms coterminating air puff US. The rabbits were then given electrolytic lesions of the left interpositus and paired training reinstated for an extensive number of sessions. During all sessions, the CS-US interval on 108 paired trials and a 2.5 sec period after tone onset on 12 tone-alone test trials were examined for CRs. After 100 postlesion sessions, training was switched to the right side for 5 sessions then switched back to the left side. Our results to date have shown a permanent abolition of CRs after interpositus lesion. One rabbit has received more than 180 postlesion sessions (over 20,000 trials), a second rabbit, more than 100 postlesion sessions (over 12,000 trials) and a third rabbit, more than 25 postlesion sessions (3000 trials). For the 3 rabbits combined, percent CRs has exceeded 10% on paired trials only 18 times with a maximum of 19% reached on 1 session. On test trials, eyeblinks have been generally observed on 0-2 trials per sessions ($M = 1.1$). Postlesion responding on test trials exceeded 16.7% on only 19 sessions distributed somewhat randomly across training and rabbits. The number of responses observed on paired and test trials are similar to spontaneous blinking rates that would be expected over the respective time intervals. Training of the right eye produced rapid and robust acquisition of CRs. These data provide evidence that extended postlesion training fails to produce classically conditioned responses after interpositus lesions, a finding that argues against the possibility that postlesion changes in the brain, capable of supporting classical eyelid conditioning, occur after destruction of the interpositus nucleus. CONTRIBUTION OF NMDA-MEDIATED NEURONAL ACTIVITY TO CLASSICAL CONDITIONING OF THE RABBIT NICTITATING MEMBRANE AND CONDITIONING-RELATED POTENTIATION OF PERFORANT PATH-GRANULE CELL RESPONSES. G.B. Robinson, University of New Brunswick, Fredericton, New Brunswick, E3B 6E4 Canada.

We previously demonstrated that the NMDA antagonist MK801 impairs acquisition of the classically conditioned rabbit nictitating membrane (NM) response (Stillwell and Robinson, *Neurosci. Abstr.*, 1990). MK801 also reduces the magnitude of long-term potentiation (LTP), a candidate neural learning and memory mechanism. Several LTP-like effects occur with NM conditioning that, if similar to electrically-induced LTP, also should be affected by MK801. MK801 (0.05 and 0.10 mg/kg, sc) was administered to New Zealand rabbits 75 minutes prior to each daily conditioning session (108 trials). A 400 ms tone (1 KHz, 82 db) served as the CS and coterminated with a corneal airpuff US (5 psi, 100 ms). Hippocampal granule cell responses were evoked by perforant path stimulation midway between each trial and 220 ms after tone onset within each trial.

MK801 decreased the rate of acquisition of the NM conditioned response but did not disrupt conditioning-related potentiation of either the perforant path-granule cell population spike or EPSP. MK801 also did not alter the suppression of spike amplitude during tone presentations. These results raise the possibility that the conditioning-related potentiation is not dependent on NMDA-mediated neuronal activity. (Supported by MRC and NSERC)

ROLE OF SUBCEREBELLAR DENTATE NUCLEUS IN SHORT LATENCY AUDITORY TRANSMISSIONS USED AS CS FOR PAVLOVIAN EYEBLINK CONDITIONING. X.F. Wang, C.D. Woody, and E. Gruen*. UCLA Med. Ctr., MRRC, BRI, Los Angeles, CA 90024.

Patterns of activity were recorded from single units of the dentate and cochlear nuclei during conditioned blinking produced by forward pairing of a 70 db click as CS with glabella tap and hypothalamic electrical stimulation (570-10ms ISI; see Hirano et al., Br. Res. 1987)

The proportion of units of the dentate nuclei that responded to the CS with increased discharges of 4-8 ms latency was significantly greater ($X^2 = 5.47$, $p = 0.02$) after conditioning with forward pairing of the CS than after pseudoconditioning with backward pairing of the CS with UCS. This finding suggests that these adaptations are sensitive to associative features of stimulus presentation and may thus support the conditioned behavior.

Earlier studies by other investigators failed to show adaptive changes in activity of neurons of the inferior colliculus with conditioning to auditory CSs. In contrast, the dentate nucleus represents an auditory relay nucleus at which associatively induced changes in activity are found. The changes in activity also permit discrimination of a forward paired click CS from a backward paired hiss DS. (Supported by NS25510.)

Effects of CS presentation on US-elicited activity in the deep cerebellar nuclei during the early stages of NM response conditioning in rabbit. B. Y. Yang and D. J. Weisz. Departments of Neurological Surgery and Behavioral Neuroscience, University of Pittsburgh, Pittsburgh, PA 15260.

Lesion studies have revealed that the anterior interpositus nucleus (AIP) in the cerebellum is critical for the acquisition of conditioned nictitating membrane (NM) responses in rabbit. Because of its role in acquisition, we chose this nucleus for electrophysiological investigations of the potential interactions of the conditioned stimulus (CS) and unconditioned stimulus (US) during the early stages of NM response conditioning. Specifically, we hypothesized that CS presentation would alter US-elicited activity in this nucleus. This experiment is based on our model of conditioning which states that neuronal plasticity underlying behavioral conditioning grows out of CS alterations in US-elicited neuronal activity.

Thus far, we have recorded from 24 single cells in the anterior interpositus and 34 single cells in the cerebellar dentate nucleus (DN) in a total of 32 animals. All recordings were made on the first day of conditioning prior to the appearance of CRs. Ten cells in the AIP and 13 cells in the DN exhibited excitatory responses to both CS and US presentation. In 10/10 of these AIP cells the CS facilitated the US-elicited response at a 500 msec CS-US interval, which supports NM response conditioning. Either no effect or an inhibition by the CS of US-elicited activity was seen at a 30 msec CS-US interval, which does not support conditioning. In 13/13 DN cells the CS inhibited US-elicited activity at the 500 msec CS-US interval. These results indicate that CS-US interactions in the deep cerebellar nuclei begin very early in training, depend on the CS-US interval, and vary depending on the anatomical locus. The initial CS-US interactions in the AIP and DN may represent the early stages of CR acquisition, and the AIP and DN may have different roles during this process. (Supported by MH42800)

NORMAL ACQUISITION AND EXTINCTION OF EYEBLINK CONDITIONING IN HIPPOCAMPECTOMIZED RATS. Beth A. Christiansen and Nestor A. Schmajuk. Department of Psychology, Northwestern University, Evanston, IL 60208.

The effect of hippocampal lesions on acquisition and extinction of eyeblink conditioning in rats was examined with the procedure described by Schmajuk and Christiansen (1990). Male albino rats received either sham, cortical control or hippocampal lesions. After a two week recovery period and two days of habituation, animals were trained in a delay conditioning paradigm. The conditioned stimulus was a 2,000 Hz, 98 dB, 500 ms tone; the unconditioned stimulus was a 4 psi, 150 ms air puff; the interstimulus interval was 350 ms; and the intertrial interval was 60 s.

Animals received 50 trials daily. After each animal reached a criterion of 8 out of 10 conditioned responses (CR) in a given block, extinction began and continued until the animal achieved a criterion of one CR in a block of 10 consecutive trials. No significant lesion effects were found during acquisition ($F(2,5) = .30$, $p > .05$). Although there was a trend toward slower extinction in hippocampal animals, no significant lesion effects were found during extinction ($F(2,5) = 1.88$, $p > .05$). Similar results were reported for acquisition (e.g., Solomon & Moore, 1975) and extinction (e.g., Berger and Orr, 1983) of the rabbit nictitating membrane response.

In both rabbits and rats, acquisition of the delay conditioned eyeblink/nictitating membrane response seems to be preserved after hippocampal lesions, but impaired after cerebellar lesions (Skelton, 1988; Thompson, 1989). Therefore, similar neural substrates might be involved in both species.

130.14

MULTI-CHANNEL SINGLE UNIT RECORDING IN THE BRAINSTEM DURING ACQUISITION OF THE CONDITIONED NICTITATING MEMBRANE RESPONSE IN THE RABBIT. Y. Bracha*, M. Webster* and J.B. Bloodedl. Barrow Neurological Institute, Phoenix, AZ 85013.

A new method was developed to record simultaneously from up to 12 channels of single or multiple unit data in order to monitor neuronal activity during the acquisition of the classically conditioned nictitating membrane/eyelid response in the rabbit. The chronically implantable microdrive houses three vertical, independently-moveable electrode systems each with the capacity to carry a bundle of four 13-25 μ m microwires. The microdrive together with the electrodes and the preamplifiers can remain mounted on the head when the animal is returned to its cage between recording sessions.

Albino New Zealand rabbits were trained using a standard delay paradigm for conditioning the nictitating membrane reflex. The experiments were designed to record from the same neurons before, during, and after the acquisition of the conditioned behavior and to compare the responses obtained during these three periods. In each naive animal, training was initiated after the isolation of up to 10 neurons. If the rabbit did not learn the task in one session, recordings from the same cells or from neurons in the same area were obtained the next day as training continued. Recordings performed in the red nucleus, spinal trigeminal nucleus, and lateral tegmental field demonstrated that this technique could be used to reliably isolate multiple single units for recording sessions lasting up to 240 trials. The data indicate that modifications of the cell discharge patterns accompany the acquisition of the conditioned behavior in all three recording sites.

130.16

HIPPOCAMPAL RESPONSES TO A COMPLEX TONE DURING DISCRIMINATION/REVERSAL JAW MOVEMENT CONDITIONING. L. Dreshfield and S. Berry. Dept. of Psychology, Miami University, Oxford, Ohio 45056.

In order to assess the generality of conditioned hippocampal unit responses obtained during NM and CJM conditioning, bilateral recordings were made from CA1 during go/no go jaw movement discrimination/reversal training. Electrodes were implanted under general anesthesia (Ketamine 50 mg/kg; Rompun 10 mg/kg IM) in 10 New Zealand white rabbits. In the task, one tone (CS+) signalled delivery of a saccharin solution 500 msec later; another tone (CS-) signalled no saccharin. One kHz and 8 kHz tones were counterbalanced as CS+ and CS-. Neural responding was greater to the 1 kHz tone throughout training, and was significantly elevated in the group that received 1 kHz-saccharin pairing during reversal ($F(1,8)=5.26$, $p < .05$). Behaviorally, discrimination or reversal was significantly faster when the 1 kHz tone was the CS+ ($t(6)=4.0$, $p < .01$). Animals given unpaired stimuli ($n=3$) did not display any changes in neural activity. Post hoc evaluation of the tones showed that chamber acoustics added a 2.5 kHz component to the 1 kHz tone, perhaps making it more salient than the 8 kHz tone. Salience differences between stimuli affect learning rate (Scavio & Gormezano, 1974), and may alter tone-evoked hippocampal activity (Best & Best, 1976). These results provide clear evidence for hippocampal involvement during learning and suggest that stimulus salience is coded by hippocampal neurons.

SORTING OF SINGLE-UNITS FROM MULTI-UNITS: LIMBIC CORTICAL AND THALAMIC CORRELATES OF DISCRIMINATIVE AVOIDANCE LEARNING. Y. Kubota, E. Kang, A. Poremba and M. Gabriel. Dept. of Psych. and Beckman Institute, Univ. of Illinois, Urbana IL 61801.

Past studies of the effects of lesions have implicated the cingulate cortex (CC) and limbic thalamus (LT) in mediation of discriminative avoidance conditioning in rabbits. Neurons in these areas encode the associative significance of the positive (footshock predictive) and negative (not shock predictive) tone conditional stimuli (CS+ and CS-, respectively) and processes leading to initiation of the conditioned avoidance response (CR, stepping in an activity wheel). Here, CC and LT multi-unit activity in rabbits performing at an asymptotic level was submitted to waveform classification using micro-computer based software (BrainWave Systems, Inc.). Sorted single-units were examined for differential responses to CS+ and CS- and for firing preceding and coinciding with the onset of the CR. Seventy-four percent of cells fired more to one CS than to the other. These differences could be pre-wired, but significantly more cells discriminated in favor of CS+ than in favor of CS- ($p < .02$), indicating that the discrimination was a product of conditioning. Consistent with a previous study of isolated single units (Kubota, Y., et al., *Neurosci. Abstr.*, 12:518, 1986), two patterns of firing were observed in relation to CR production: increase in firing rate (FR) preceding CR and lower FR in trials with CR than in trials without CR, the latter found only in area 24 and the mediodorsal (MD) nucleus. These consistencies provided preliminary validation of the waveform sorting routine. Additional results not previously seen were: 1) cells in anterodorsal and laterodorsal nuclei showed most massive pre-CR firing; 2) virtually no pre-CR increase was seen in area 24 cells in well-trained rabbits; and 3) cells with higher FR to CS- than to CS+ were found in the MD nucleus and in the CC. (Supported by AFOSR and NIH).

PREDICTION OF CONDITIONED AVOIDANCE RESPONSES BY CS-RELATED NEURONAL DISCHARGES IN CINGULATE CORTEX AND LIMBIC THALAMUS OF RABBITS. E.Kang and M.Gabriel, Dept. of Psychol. and Beckman Inst., Univ. of Illinois, Urbana, IL 61801.

This study concerns the neural mediation of discriminative avoidance conditioning of rabbits wherein a conditioned response (CR, stepping in an activity wheel) to an auditory positive conditional stimulus (CS+) prevents a footshock 5 sec. after CS+ onset. This conditioning results in the development of discriminative activity, i.e., greater neuronal discharges 15 - 500 msec. after CS+ onset, than after a negative CS (CS-) which does not predict shock. The discriminative activity develops in limbic areas (below) essential for learning. Here are reported analyses of neuronal data of trained rabbits indicating that the discharges evoked by CS+ presentations followed by CRs did not differ in magnitude from the discharges evoked by CS+ presentations not followed by CRs. This outcome was obtained in parvocellular and magnocellular anteroventral thalamic nucleus (N=9, 16), medial dorsal nucleus (N=23), anterior cingulate cortex (area 24, N=21) and in four layers in each of two regions of the posterior cingulate cortex (areas 29c/d and 29b, N=26, 31). These results are incompatible with motoric, arousal, or attentional interpretations of the elicited activity, but they are consistent with a mnemonic retrieval interpretation. A consistent elevation of baseline (pre-CS) neuronal activity occurred prior to CS- presentations only, on trials in which CRs occurred, relative to no-CR trials, in certain layers of area 29 and in all thalamic areas. No such elevation of the baseline occurred in area 24. The elevated baseline activity may reflect activation preparatory to locomotion, accounting for the erroneous CRs on CS- trials. The appearance of this activation process in certain areas signifies distinctive functions of these areas (Supported by NIH and AFOSR).

130.21

A SYSTEM FOR MULTICHANNEL NEURONAL RECORDING DURING DIFFERENTIAL APPETITIVE CONDITIONING OF RABBITS. M. Gabriel, D. Tchong*, Y. Kubota, E. Kang, A. Poremba and C. Cuppennell*, Dept. Psych. and Beckman Inst., Univ. of Ill., Urbana IL 61801.

A new microcomputer-based data collection system was implemented for recording brain neuronal correlates of appetitive conditioning, in order to directly compare the activity with extensively documented neuronal correlates of avoidance conditioning (Gabriel, M. *Prog. in Brain Res.*, 85:467-483, 1990). In both tasks, an instrumental response (stepping in a large activity wheel to avoid shock and head extension performed in a restraining box to contact a drinking tube) yields the desired outcome when performed in response to a .5 sec. tone conditional stimulus (CS+). Non-response to a second tone (CS-) which does not signal reinforcement is also learned. Trials are presented daily (60 with each CS in a quasi-random sequence). Appetitive training of water-deprived rabbits involves drinking tube insertion 5 sec after CS presentation. Contact with the tube following the CS+ yields 3 ml. of water but responses following the CS- induce tube-withdrawal and no water. Multi-unit activity and EEG records from six interconnected brain areas are sampled during training. Five rabbits trained to date reached asymptotic discrimination in 4-6 training sessions, responding on an average of .50 more of the CS+ than of the CS- trials. Average post-CS multi-unit histograms and field potential profiles in posterior cingulate cortex, the anteroventral thalamic nucleus and hippocampal subfield CA1 were similar to those recorded in other rabbits during avoidance learning, for which those areas are essential. In both tasks, the discharges became discriminative (i.e., greater in response to the CS+ than to the CS-) during training. However, hippocampal discrimination during appetitive conditioning was much greater than that seen during avoidance conditioning. Future studies of the neuronal activities in concurrently trained rabbits are planned to elucidate the neural mediation of contextual control of the learned behavior. (Supported by AFOSR and NIH.)

MONOAMINES AND BEHAVIOR: DEVELOPMENT, INGESTION AND SEX

HYPERACTIVITY IN THE OFFSPRING OF NICOTINE TREATED RATS: ROLE OF THE MESOLIMBIC DOPAMINERGIC PATHWAY. S.A. Richardson, V.J. Massari, and Y. Tizabi, Dept. of Pharmacology, Howard University, College of Medicine, Washington, D.C. 20059

Recent reports have linked hyperactivity in children to cigarette smoking by the mother during pregnancy. Since it has been shown that nicotine-induced hyperactivity in adult rats is associated with increased dopamine (DA) concentration in the nucleus accumbens (NACC), this study was designed to determine whether similar biochemical changes may also occur in the hyperactive offspring of nicotine treated dams. Timed-pregnant Sprague Dawley rats were implanted subcutaneously on gestational day 4 with osmotic-mini pumps releasing saline or nicotine (3mg/kg/day) for 14 days. Male offspring were tested twice (at 19 and 21 days) for their locomotor activity using a Digiscan Monitor and sacrificed 24 hours after the last test. The NACC, frontal cortex (FC), and ventral tegmental area (VTA) were microdissected and DA concentration was measured in the following groups: hyperactive offspring of nicotine treated dams (Nic-H), non-hyperactive offspring of nicotine treated dams (Nic-NH) and non-hyperactive offspring of saline treated dams (Sal-NH). DA concentration in the NACC of the Nic-H (49.2±2 pg/ugPr) was not significantly different from the Sal-NH (55.5±6pg/ugPr) or the Nic-NH (38.6±2pg/ugPr). However, there was a significant decrease in the DA concentration in the NACC of the Nic-NH compared to the Sal-NH (p<0.05). DA concentration in the VTA of the Nic-H (26±4pg/ugPr) was significantly higher (p<0.05) than the Nic-NH (15.7±1pg/ugPr) but did not show a significant difference compared to the Sal-NH (20.8±2). DA concentrations in the FC were similar in all groups (Sal-NH, 1.9±0.3pg/ugPr; Nic-NH, 1.7±0.3; Nic-H, 1.7±0.1). These data suggest that the biochemical basis of hyperactivity in the offspring of nicotine treated dams is different from nicotine-induced hyperactivity in the adult rats.

130.20

AMYGDALA LESIONS BLOCK ACQUISITION OF DISCRIMINATIVE ACTIVE AVOIDANCE LEARNING IN RABBITS. A. Poremba and M. Gabriel, Dept. of Psych. and Beckman Inst., Univ. of Ill., Urbana, IL 61801

Multi-unit recording and lesion studies have shown that the rabbit anterior cingulate cortex (ACC) and the mediodorsal thalamic nucleus (MDTN) comprise an early learning circuit involved in mediating the initial stages of active avoidance learning, wherein a conditioned response (CR) of stepping in an activity wheel to a CS+ tone prevents a footshock US 5 sec. after CS+ onset. (No footshock follows a CS- tone presentation on trials randomly sequenced with the CS+). In contrast, the anteroventral thalamic nucleus (AVTN) and the posterior cingulate cortex mediate asymptotic performance, but not original acquisition (Gabriel, M., *Progress in Brain Research*, 85:467-83, 1990). Amygdaloid basolateral nucleus (BLN) neurons are interconnected with the ACC and the MDTN and they exhibit early training-induced activity (TIA): increased CS evoked excitation and development of greater neuronal discharges to the CS+ than to the CS-, suggesting that BLN neurons participate in the early learning circuit. To test this hypothesis, bilateral electrolytic lesions were centered in the BLN (small lesion group), and larger lesions included BLN and other amygdaloid areas (large lesion group). As expected, BLN lesions impaired behavioral acquisition in the early training stages (p<.01), and reduced TIA in the ACC (p<.01) and MDTN (1>p>.05). Unexpectedly, small and large lesions impaired TIA in the AVTN (p<.01) and the large lesions blocked acquisition of the CR (p<.01). These results are compatible with the hypothesis that BLN neurons are involved in mediating the early stages of CR acquisition. However, the severe learning impairment due to the large lesions and the attenuation of AVTN TIA suggest that amygdala neurons are involved in learning-relevant processes in addition to those mediated by the early learning circuit. (Supported by NIH and AFOSR).

HETEROGENEOUS NEURONAL DAMAGE OF RAT BRAIN DOPAMINERGIC SYSTEMS FOLLOWING NEONATAL INTRACISTERNAL 6-HYDROXYDOPAMINE TREATMENT. H. OKAMURA, C. YOKOYAMA, Y. IBATA, Dept. of Anatomy and Psychiatry, Kyoto Pref. Univ. Med., Kyoto 602, Japan.

Neonatal intracranial treatment of 6-hydroxydopamine (6-OHDA) causes the destruction of the dopaminergic neurons and induces various behavioral changes at adult age after loading of dopamine agonists. Previous biochemical studies have revealed the severe depletion of dopamine and its metabolites in the basal ganglia, but the affected region has not been fully investigated. In the present study, we investigated the damaged area of dopaminergic neurons by ABC-immunocytochemistry using anti-tyrosine hydroxylase serum. Desipramine pretreated (20 mg/kg) neonatal Wistar rats were injected with 6-OHDA (100 ug/5 ul, 2 times) intracisternally, and their behavior after Ro-4-4602 (50 mg/kg) and L-DOPA loading (100 mg/kg, i.p.) was evaluated at 6 weeks of age. Only the rat showing self-mutilation behavior was used in the present study. Dopaminergic neurons and terminals were severely depleted in the caudate-putamen, the substantia nigra, the nucleus accumbens, the ventral tegmental area and the tuberculum olfactorium, but almost unaffected in the insula of Calleja, limbic cortex, hypothalamus, and raphe nuclei. The result has revealed that the neonatal 6-OHDA treatment induces region-specific neuronal damage on dopaminergic neurons, and suggests that this heterogenous destruction is a base of abnormal behavior induced by dopamine agonist loading.

131.3

THE EFFECT OF NEONATAL 6-HYDROXYDOPAMINE LESIONS IN RATS ON HABITUATION TO A NOVEL ENVIRONMENT. S. S. Moy*, D. A. Eckerman*, H. Criswell, and G. R. Breese. Department of Psychology, University of North Carolina, Chapel Hill, NC 27599

Selective dopamine lesions were given to ten rat pups at three days of age, while sham lesions were performed on ten control animals. At four months of age, the activity levels and spatial behavior of these subjects were measured in an activity pattern monitor. Rats were given hour-long sessions, one per day, across five days. Midway through the fifth session, the animals were given an acute stressor (handling for 30 seconds). In contrast to previous reports, the lesioned group was significantly hypoactive in comparison to the control animals. In addition, examination of locomotor paths indicated that the lesioned animals failed to develop the increasingly organized and patterned spatial behavior observed in control animals, demonstrating a deficit in normal habituation to a novel environment. No significant effect of the brief handling was observed. The animals are not yet available for postmortem analyses, which will provide the correlations between extent of dopamine depletion, level of activity, and degree of habituation (measured by the patterning of locomotor paths) both within sessions and across sessions.

131.5

RATS DOPAMINE LESIONED ON DAY 3 OF NEONATAL LIFE ARE SUBSENSITIVE TO 6-HYDROXYDOPAMINE TREATMENT AS ADULTS ON TESTS OF BRAIN STIMULATION REWARD. Sidhu, K.S., Levesque, C.P.*, and Stellar, J.R. Northeastern University Dept. of Psychology, Boston, MA 02115.

Previously, adult rats dopamine (DA) lesioned at day 3 of neonatal life were shown to be subsensitive to D1 and D2 DA receptor blockade in a test of lateral hypothalamic self-stimulation (LHSS) reward (Sidhu et al., Neuroscience Abstracts, 1990). In this study, adult rats previously DA lesioned at day 3 of life received adult ICV injections of 25ug/ul 6-OHDA after pretreatment with pargyline (40mg/kg) and desmethylimiprimine (25mg/kg). Following the adult lesion, these rats showed an initial LHSS reward deficit, but recovered in three days using the rate-frequency method. Three of four control animals with sham neonatal lesions given the 6-OHDA adult lesion, stopped responding for LHSS. Neonatal DA lesioned animals exhibited transient weight loss following the adult lesion, but stabilized after 10 days post lesion. Control animals lost weight following the adult lesion, did not maintain eating and drinking behaviors, and eventually died within one week. (Supported by the Whitehall Foundation)

131.7

CHRONIC DOPAMINE ANTAGONIST DURING DEVELOPMENT ALTERS THE D1 AND D2 MEDIATION OF SENSORIMOTOR BEHAVIOR. J.P. Bruno, B.J. Johnson, D.R. Abrams, T. Mitra, T.A. Reader, and K.M. Dewar Dept. of Psychology, Ohio State Univ. Columbus, OH 43210; Dept. de Physiologie, Univ. de Montreal, Que.

Age at the time of DA denervation differentially affects the contributions of D1 and D2 receptors to sensorimotor behavior. 6-OHDA-induced DA depletions on Day 3 enable D1 and D2 receptors to mediate sensorimotor function independently whereas activity of both D1 and D2 receptors is required in controls and rats depleted on Day 20. The present study determined whether temporary blockade of D1 and D2 receptors during various periods of development can replicate the effects of 6-OHDA-induced denervations.

Male rats were injected every 12 hrs with the mixed D1/D2 antagonist flupentixol (1.0 mg/kg/day) or saline from Days 3-20 or Days 20-37 and then tested, at varying ages, for sensorimotor deficits after D1, D2, or D1 + D2 antagonists. Rats treated from Days 3-20 and tested 1 week later resembled rats that had been denervated with 6-OHDA. They were insensitive to the behavioral effects of D1 or D2 antagonists, but just as sensitive as controls to the effects of combined D1 + D2 antagonists. This insensitivity declined with time. In contrast, flupentixol administration from Days 20-37 only slightly altered the sensitivity of animals to DA antagonists. These data suggest that receptor stimulation during certain early stages of postnatal development are necessary for the normal development of D1 and D2 mediation of sensorimotor function. We are presently studying the age-dependent effects of chronic flupentixol on DA receptor density and distribution.

131.4

PRENATAL STRESS ALTERS BRAIN CATECHOLAMINERGIC ACTIVITY AND POTENTIATES STRESS-INDUCED BEHAVIOR IN ADULT RATS. L. K. Takahashi, J. G. Turner*, and N. H. Kalin. Dept. Psychiatry, Univ. Wisconsin Med. Sch., Madison, WI 53792 and Middleton Veterans Hospital, Madison, WI 53705.

We demonstrated previously that prenatally stressed (PS) rat pups have increased hormonal and behavioral responses to stress. This study examined whether these characteristics persist into adulthood. Due to the importance of brain catecholaminergic (CA) systems in mediating stress responses, we also measured the activity of NE and DA systems.

PS and control male rats (80-100 days) received 5 foot shocks (1.0 mA, 1 s). During testing, defensive freezing was measured. ACTH and corticosterone were measured by RIA. Brain CA levels were determined by HPLC.

PS rats showed a high level of freezing ($p < .05$). Cortical MHPG/NE and DOPAC/DA ratios were also elevated in PS rats ($p < .05$). Hormone concentrations, however, did not differ between groups. Prenatal stress produces persistent behavioral alterations suggestive of increased defensive responsiveness accompanied by increased CA activity. These changes may compromise an adult's ability to adapt to stressful events.

Supported by NIMH grant MH-43986.

IS DENSITY OF REINFORCEMENT RESPONSIBLE FOR THE DIFFERENTIAL EFFECT OF DA ANTAGONISTS ON RAT PUPS DURING TWO INGESTION TESTS? A. Tyrka* and G.P. Smith. Boume Laboratory, NY Hospital-Cornell Medical Center, White Plains, NY 10605.

The D₁ antagonist, SCH 23390, and the D₂ antagonist, raclopride, significantly inhibit intake of 10% sucrose in independent ingestion tests (II, pups continuously lick sucrose from the bottom of a beaker) but not when sucrose is continuously infused in oral catheter (OC) tests on postnatal days (PN) 7 and 14 (Tyrka & Smith, 1991). Since pups normally ingest twice as much in OC tests as in II tests, it is possible that DA antagonists do not decrease intake in OC tests because reinforcement is more dense in OC tests.

To test this possibility, PN 7 and 14 pups were deprived for 4 h and orally infused with 10% sucrose at a rate that produced intakes equivalent to those in II tests. Vehicle, SCH 23390, or raclopride (doses were the ID₅₀ for II or 4X ID₅₀) was given ip at -15 min. Only SCH 23390 (ID₅₀ on PN 7) decreased intake significantly (see Table).

Drug	PN 7		PN 14	
	Dose (ug/kg)	Intake	Dose (ug/kg)	Intake
Saline		1.9 ± 0.1		2.4 ± 0.1
SCH 23390	60	1.4 ± 0.1*	14	2.4 ± 0.2
SCH 23390	240	2.3 ± 0.1	57	2.5 ± 0.2
Raclopride	194	1.6 ± 0.2	208	2.8 ± 0.2
Raclopride	776	2.0 ± 0.1	832	2.3 ± 0.3

Note. Intake values are mean ± SEM percent body weight gained for 8-10 pups per condition. *less than saline, $p < 0.05$.

Since no dose of either antagonist produced decreased intakes comparable in magnitude to decreases in II tests, the differential effect of DA antagonists in the two tests is not explained by the density of reinforcement.

DOPAMINE DEPLETIONS IN NEONATAL RATS ALTER THE D1 AND D2 CONTRIBUTIONS TO MOTORIC BEHAVIOR.

D.R. Abrams and J.P. Bruno. Dept. of Psychology, Ohio State University, Columbus, OH 43210

Residual DA neurons remain critical for the expression of sensorimotor function in rats depleted of DA as neonates. However, blockade of either D1 or D2 receptors is sufficient to induce sensorimotor deficits in normal rats whereas both receptor subtypes must be blocked to produce deficits in rats depleted of DA as neonates. These results suggest that D1 and D2 receptors are independently capable of supporting sensorimotor functions in rats depleted of DA as neonates but not in controls. The present experiments examined this hypothesis by studying the behavioral effects of D1, D2, and mixed D1 + D2 agonists.

Three-day-old male rats received intraventricular injections of 6-OHDA (100 µg + DMI) or its vehicle and were tested for agonist-induced behaviors as adults. The data reveal both quantitative and qualitative differences between the two groups of animals. Both vehicle- and 6-OHDA-treated rats exhibited locomotion and low-level stereotypy after the D2 agonist quinpirole and high-level stereotypy after the mixed D1 + D2 agonist apomorphine. DA-depleted animals were far more sensitive than controls. In contrast, the D1 agonist SKF 38393 produced locomotion and high-level stereotypy in depleted animals while producing intense grooming in controls. The ability of specific antagonists to block these effects will also be discussed.

131.9

NEURAL MECHANISMS IN THE CONTROL OF SENSORIMOTOR BEHAVIOR IN RATS DEPLETED OF DOPAMINE AS NEONATES. B.J. Johnson and J.P. Bruno.

Dept. of Psychology, Ohio State University, Columbus, OH 43210

Rats depleted of dopamine (DA) with 6-OHDA as neonates are spared from the sensorimotor deficits seen in comparably damaged adults. Residual striatal DA neurons are involved in the expression of these behaviors in rats depleted of DA as neonates but the functional interactions between D1 and D2 receptors differ qualitatively from those seen in controls. In normal animals intra-striatal injections of either D1 or D2 antagonists induce deficits whereas administration of both antagonists is required to impair rats depleted as neonates. The present data extended this observation in two ways. First, we observed similar roles for accumbens D1 and D2 receptors in mediating sensorimotor behavior in controls and rats depleted as neonates. Microinjections of the D1 antagonist SCH 23390 or the D2 antagonist clebopride into the accumbens produced sensorimotor deficits in adult controls but had no effect on rats depleted of DA as neonates. Injections of both antagonists synergistically produced deficits in each group of animals.

Second, we determined the role of striatal D1 and D2 receptors in mediating acetylcholine (ACh) release in order to determine whether the depletion-induced changes at the behavioral level paralleled at the synaptic level. Using *in vivo* microdialysis in awake animals, we determined that in both adult controls and rats depleted of DA as neonates, D2 agonists inhibit ACh release while D1 agonists stimulate ACh release. Thus, the depletion-induced changes in receptor mediation of sensorimotor behavior do not coincide with receptor mediation of striatal ACh release.

DIFFERENCES IN THE BRAIN MONOAMINE LEVELS IN THE BLOW FLY UNDER THREE FEEDING CONDITIONS. S. Ye, W.J. Bell and N.A. Dahl. Department of Physiology and Cell Biology, and Department of Entomology, University of Kansas, Lawrence, KS 66045.

HPLC systems with electrochemical detection were used to determine the levels of 3,4-dihydroxyphenylethylamine (dopamine) and 5-hydroxytryptamine (5-HT) in the brains of satiated, starved, and recently food-stimulated starved flies, *Phormia regina* Meigen. Our preliminary data indicate that the brain dopamine level is lower in starved flies than in satiated flies. No significant difference in the 5-HT level was found among the three treatment groups. The short-term feeding regulation mechanism in the blow fly seems to be associated with an unidentified compound found in the fly's brain. The level of this compound increases significantly after the fly ingests a small amount of food (sucrose).

N-0923, A SELECTIVE DOPAMINE D2 RECEPTOR AGONIST, DECREASES FOOD INTAKE AND BODY WEIGHT IN RATS. J.D. Belluzzi, D. McKenna* and L. Stein*, Whitby Research Inc., Irvine, CA 92715 and *Department of Pharmacology, University of California, Irvine, CA 92717.

The anti-obesity effects of the dopamine D2 receptor agonist (-)-2-(N-propyl-N-2-thienylethyl)amino-5-hydroxytetralin HCl (N-0923) were evaluated in rats. Intraperitoneal injections of N-0923 prior to the daily 2-hr feeding period produced anorexia at all doses tested (0.3-3 mg/kg) and induced body weight loss up to 12% within 3-4 days at the highest dose. N-0923 was more potent than either *d*-amphetamine or apomorphine in producing weight loss and its effects were stereoselective. The (+) isomer (N-0924) failed to reduce body weight at 10 times the lowest effective dose of N-0923.

Continuous 24-hr infusion of N-0923, using Alzet implantable osmotic pumps or transdermal patches in free-feeding animals, induced a similar pattern of anorexia and weight loss at both doses tested (50 and 200 µg/hr). Anorexia was produced at doses that did not induce stereotypy or hyperactivity. The anti-obesity effects were independent of starting body weight or state of food deprivation and the weight loss could be maintained by continuous infusion for nearly 1 month. As in the case of acute dosing, continuously administered N-0923 was more potent than *d*-amphetamine and its effects were stereoselective. N-0924 (500 µg/hr) did not significantly reduce body weight.

131.10

CONSUMPTION OF A PALATABLE MEAL PREFERENTIALLY INCREASES INTERSTITIAL CONCENTRATIONS OF DOPAMINE IN THE NUCLEUS ACCUMBENS. G.G. Nomikos, C. Wilson, G. Damsma, H.C. Fibiger. Division of Neurological Sciences, University of British Columbia, Vancouver, Canada.

Interstitial concentrations of dopamine (DA) and its metabolites were examined in the nucleus accumbens and the striatum of rats during feeding behavior using on-line brain microdialysis. Rats were trained to consume under freely feeding conditions a palatable liquid meal (Sustacal). Both the training and the test sessions were performed in a chamber that was partitioned by a screen. The animals were first confined to one compartment (anticipatory phase) and then they were allowed to drink the Sustacal (consummatory phase). At the test session and during the anticipatory stage DA from the nucleus accumbens increased to 110% in groups that were trained and tested with Sustacal, trained but not tested with Sustacal, and trained and tested with water. Subsequently after removal of the screen and initiation of feeding, DA gradually increased to 130% only in the group trained and tested with Sustacal. Striatal DA was enhanced to 110% during the anticipatory phase, but did not increase significantly further after Sustacal consumption. These data provide neurochemical evidence that DA transmission is preferentially enhanced in the nucleus accumbens during consumption of a palatable meal.

131.12

BASELINE-DEPENDENT FEEDING RESPONSES TO AMPHETAMINE: EFFECTS OF INTRA-ACCUMBENS ALPHA-FLUPENTHIXOL ADMINISTRATION. T. L. Sills, J.P. Baird & F. J. Vaccarino. Department of Psychology, University of Toronto, Toronto, Ont., M5S 1A1.

Previously we have shown that a low dose of amphetamine (AMP) stimulates sugar intake in low baseline feeders and inhibits intake in high baseline feeders. Furthermore, there is evidence suggesting that nucleus accumbens (ACB) dopamine (DA) mediates AMP's effects on feeding. The present study examined the effects of intra-ACB DA blockade, using alpha-flupentixol (FLU), on the feeding response to AMP, administered to high and low baseline feeders.

Baseline chow and sugar intake was measured for one hour each day for seven days in male Wistar rats with bilateral ACB cannulae implants. Subsequently, all rats received either systemic saline or AMP (0.125 mg/kg) in combination with intra-ACB saline or FLU (10µg) in a counterbalanced order. Following injections, animals were returned to their home cages and their intake of chow and sugar measured for 1.5 hours.

Animals were divided into high and low feeders based on a median split of their baseline sugar intake. Consistent with previous results, AMP stimulated feeding in low baseline feeders. This effect was blocked by intra-ACB FLU administration. AMP had no effect on feeding in high baseline feeders, though intra-ACB FLU significantly attenuated intake and this was reversed by AMP administration. These results support the notion that increased DA transmission mediates AMP-induced increases, as well as naturally elevated levels of sugar intake.

This research was supported by a NSERC grant to FJV.

NIGROSTRIATAL DOPAMINERGIC ACTIVITY, AS DETERMINED BY *IN VIVO* ELECTROCHEMICAL DETECTION, DURING FOOD CONSUMPTION AND CONDITIONED CONSUMATORY BEHAVIOR. T.J. Brozoski, K. Stenvers, A. Athorp*, G. Skeen, E.L. Brozoski, K.M. Oeth, and J. Green*. Dept. of Psychology, Grinnell College, Grinnell, IA 50112.

Dopaminergic activity, as measured by *in vivo* electrochemical detection of dopamine metabolites, was quantified during feeding and conditioned consumatory behavior without food, in the nigrostriatal system of food-deprived rats. Following 24-hr food deprivation, dopamine activity increased during feeding periods in both the dorso-anterior caudate-putamen and the substantia nigra *pars compacta*. In contrast, no increase in dopamine activity occurred during conditioned consumatory behavior when food was not available. Momentary increments in caudate, but not nigral, dopamine were found to accompany the delivery of food pellets during the initial part of feeding periods. These results were interpreted as supporting the hypothesis that the nigrostriatal dopamine system is a component of the brain reinforcement network, and further taken to indicate that dopamine release is linked to the reinforcing stimulus properties of nutritive reinforcers rather than the motor activity associated with consumption. It was found, however, that increasing food deprivation beyond 24 hrs, to 48 hrs, attenuated the dopaminergic response to feeding, suggesting that other factors are also involved.

131.15

STRAIN DIFFERENCES IN ADAPTATION TO REPEATED STRESSORS: VARIATIONS OF THE INTAKE OF A PALATABLE DIET. J. Griffiths, N. Shanks and H. Anisman. Dept. of Psychology, Carleton University, Ottawa, Ontario K1S 5B6, Canada.

Exposure to footshock over 14 days produced strain dependent differences in the intake of a palatable liquid diet. All strains of mice, however, showed some degree of adaptation, such that food intake following repeated stressor exposure equalled that of nonstressed animals. Exposure to a series of different stressors yielded more pronounced reductions in food intake. Moreover, while an adaptation was apparent in some strains, in other strains the decline of intake ordinarily produced by an acute stressor became progressively more pronounced or did not vary with continued stressor exposure. These data were related to strain differences in the variations of NE and DA utilization and levels associated with acute stressors, as well as the adaptation of amine activity associated with the chronic stressor regimen. Additionally, the data were related to the strain-specific alterations in responding for electrical brain stimulation (possibly reflecting an anhedonia), previously observed in this laboratory.

EFFECTS OF QUINELORANE ON YAWNING, PENILE ERECTION AND SEXUAL BEHAVIOR IN THE MALE RAT. P.C. Doherty, P.A. Wisler* and M.M. Foreman. Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, IN 46285.

Quinelorane, a selective D₂ agonist, stimulates sexual activity in male rats and monkeys. Dopamine agonists also increase the occurrence of erections in these species. The following experiment was performed to determine if quinelorane could induce erections in male rats, and to establish the relationship of such drug induced erections to the effects of this compound on sexual activity. Adult male Sprague-Dawley rats were given sub-cutaneous injections of saline vehicle or quinelorane (dose range: 0.1 - 100 µg/kg) just prior to a 30 min observation period for the display of yawning and erections. Quinelorane induced significant increases in both erections and yawns at the 3 µg/kg dose. Additional increases in erection were observed at 10 and 30 µg/kg with a slight decline occurring at 100 µg/kg. Yawning was sharply increased at 10 µg/kg and then decreased rapidly at 30 and 100 µg/kg. Quinelorane was more potent than quinpirole and apomorphine in inducing erections, and in reducing ejaculation latency (EL) in tests of copulatory behavior. However, quinelorane caused significant reductions in EL at doses lower than those needed to induce erections. These findings indicate that in addition to its stimulatory effect on sexual activity, quinelorane can also increase the occurrence of spontaneous erections in male rats.

131.16

COPULATION INCREASES DOPAMINE ACTIVITY IN THE MEDIAL PREOPTIC AREA. R. C. Eaton, J. Moses and E. M. Hull. Department of Psychology, State University of New York at Buffalo, Amherst, NY. 14260

Previous studies, employing tissue punch techniques, have reported increased dopaminergic activity in the preoptic area following copulation in male rats (Ahlenius et al. 1987, Hoffman et al. 1987 & Mas et al. 1987). More recently, using in vivo microdialysis, Pfaus et al. (1990) and Pleim et al. (1990) have reported an increase in dopamine (DA) and its metabolites in the nucleus accumbens during copulation.

The MPOA, which has a small dopamine innervation, plays an important role in the regulation of copulatory behavior. Pfaus (1990), using in vivo voltametry, showed an increase of catecholamine (CA) activity in the MPOA during copulation. However, DA and norepinephrine (NE) oxidize at the same voltage and therefore are not dissociable with this technique.

We examined dopaminergic activity in the MPOA during copulation using microdialysis. Baseline levels were established in each of 15 male Long-Evans rats. A receptive female was then placed into the testing chamber and testing continued for 80 minutes. Samples were analyzed by HPLC-EC.

Animals that copulated and had the microdialysis probe in the MPOA (n=7) showed a significant increase in DOPAC ($p < 0.002$) and HVA ($p < 0.05$) levels. An additional animal with the correct probe placement, that did not copulate, failed to show the rise in DOPAC. Animals that copulated, but had incorrect probe placements, showed no increase in DOPAC or HVA.

We have demonstrated that endogenous levels of DOPAC and HVA in the MPOA are increased by copulation. Roth et al. (1976) suggest that short term changes in central DOPAC levels provide a useful index of activity of central dopaminergic neurons. These data support an increase of DA activity in the MPOA during copulation.

DRUGS OF ABUSE—OPIOIDS: DOPAMINE AND DEPENDENCE

132.1

DEPRESSION OF BASAL DOPAMINE RELEASE AND SENSITIZATION TO MORPHINE-INDUCED STIMULATION IN THE VENTRAL STRIATUM DURING ABSTINENCE.

Acquas E.* Carboni E.* and Di Chiara G. Institute of Experimental Pharmacology and Toxicology, University of Cagliari, Italy.

In order to investigate the role of mesolimbic DA in opiate dependence, we studied by brain dialysis the changes in DA release in the mesolimbic ventral striatum occurring after morphine withdrawal in morphine dependent rats. Male rats (Wistar-Kioto, 300-350 g) were given s.c. (twice a day for 14 days) increasing doses (from 10 to 140 mg/kg) of morphine hydrochloride. At various times after withdrawal the rats were implanted with dialysis probes in the caudal nucleus accumbens-ventral striatum. Stabilized output of DA 1, 3 and 5 days after withdrawal from morphine was about one fifth than in saline controls. Seven days after withdrawal DA-output was still significantly lower (about 40%) than in controls. Administration of morphine (5.0 mg/kg s.c.) stimulated DA output maximally by about 35% in controls but failed to change it after one day of withdrawal. In contrast, 3, 5 and 7 days after withdrawal, morphine (5 mg/kg s.c.) stimulated DA-release more effectively than in controls. This effect was particularly marked after 3 days of withdrawal (max 250%). In view of the role assigned to the mesolimbic DA system in motivation, depression of DA transmission in the mesolimbic system and sensitization to the DA-releasing effect of morphine might play a role in the motivational mechanisms which sustain the self-administration of opiates in dependent subjects.

132.2

THE IDENTIFICATION OF OPPOSING TONICALLY ACTIVE ENDOGENOUS OPIOID SYSTEMS WHICH MODULATE THE MESOLIMBIC DOPAMINERGIC SYSTEM. R. Spanagel*, N. Brose, A. Herz* and T.S. Shippenberg. Department of Neuropharmacology, Max-Planck-Institut für Psychiatrie D-8033 Martinsried, F.R.G.

The mesolimbic dopaminergic (DA) pathway has been implicated in mediating the motivational properties of opioids and other drugs of abuse. However, the neuroanatomical sites of action of opioids and also the endogenous opioid systems which modulate this reward pathway remain unclear. These issues were examined by the use of in vivo microdialysis and administration of highly selective opioid ligands. The microinjection of DAMGO, a selective μ -agonist, into the ventral tegmental area (VTA) (the site of origin of A10 DA neurons) resulted in significant increases in DA release and metabolism in the nucleus accumbens (NAC) (the major projection site of A10 DA neurons). However, DAMGO infusions into the NAC via the microdialysis probe did not affect DA release or its metabolites. The selective blockade of μ -receptors by CTOP within the VTA produced significant decreases in DA basal release and metabolism. In contrast, CTOP infusions into the NAC were without effect. The selective k -agonist U 69853 microinjected into the VTA was without any effect on DA overflow and metabolites. In contrast, U 69853 infusion into the NAC resulted in a dose dependent significant decrease in DA release and metabolism. Infusions of the k -antagonist nor-BNI into the NAC which selectively blocked k -receptors in this region dose dependently increased basal DA release within the NAC. These data demonstrate that tonic activation of μ - and k -receptors is required for the maintenance of basal DA release in the NAC. Such findings may have implications for the treatment of opiate dependence and disorders of mesolimbic DA function. Supported by the Bundesgesundheitsamt, Berlin

132.3

VENTRAL PALLIDUM OPIATE AND GABA ANTAGONIST MICROINJECTIONS DISPLAY REGIONAL DIFFERENCES AS MEASURED BY INTRACRANIAL SELF-STIMULATION. P. Johnson, A.D. Paul*, J.R. Stellar. Psychol. Dept., Northeastern Univ., Boston, MA. 02115

Ventral Pallidum (VP) microinjections of the mu opiate specific agonist, DAGO, and the GABA_A specific antagonist, picrotoxin, have been shown to increase motor activity in a behavior activation paradigm (Austin et al. J. Pharm & Exper Ther., 252(3):1990, 1370-77). When tested using the self-stimulation rate-frequency paradigm, rostral VP injection of DAGO (1.23, 13.56 ug/0.5ul) produced dose-dependent reward and motor/performance decreases, while caudal VP injection produced reward and performance increases. Picrotoxin (0.03, 0.1 ug/0.5ul) appeared to have no effect on reward for any placement, but followed the DAGO regional pattern with regard to performance.

THE EFFECTS OF LESIONS OF THE HABENULAR NUCLEI ON THE DEVELOPMENT OF SENSITIZATION TO THE ACTIVATIONAL EFFECTS OF MORPHINE ADMINISTERED REPEATEDLY INTO THE VTA. D. Funk and J. Stewart. Center for Studies in Behavioral Neurobiology, Department of Psychology, Concordia University, Montreal, Canada, H3G1M8

Repeated intermittent injection of morphine into the cell body region of the midbrain dopamine (DA) neurons results in sensitization of its behavioral activating effects. The midbrain DA systems are regulated in part by an inhibitory projection from the habenular nuclei. To determine whether changes in this inhibitory projection from the habenular nuclei might participate in the development of sensitization to the behavioral activating effects of intra-ventral tegmental area (VTA) injections of morphine, groups of rats were given electrolytic lesions of the habenular nuclei and treated every third day for 6 days with bilateral injections of 5 µg/0.5 µl/side morphine or saline. Lesions did not affect the acute locomotor activation seen following intra-VTA morphine, nor the sensitization of locomotor activity seen when morphine was administered repeatedly. Intra-VTA morphine did, however, result in high levels of stereotyped gnawing and licking in lesioned animals. Interestingly, increases in these behaviors did not appear to result in the reduction of locomotor activity normally seen when levels of stereotypy are high. Though these findings confirm the idea that the habenular nuclei exert an inhibitory influence on the activity of the DA systems, they do not suggest that changes in the habenular influence underlie sensitization to the behavioral activating effects of morphine seen with repeated administration.

132.7

OPIOID EFFECTS IN THE VTA AND VENTRAL PALLIDUM: MEDIATION BY GABA AND MESOLIMBIC DOPAMINE. M.A. Klitenick and P.W. Kalivas. Dept. of VCAPP, Washington State University, Pullman, WA 99164-6520.

A variety of evidence lends support to a circuit posited to be comprised of the VTA, nucleus accumbens (NAS) and ventral pallidum (VP) and that increased dopaminergic transmission within this circuit results in an increase in locomotor activity. The present experiments addressed two aspects of this circuit. In the first experiment the effects of morphine administration on extracellular levels of GABA was assessed using *in vivo* microdialysis in the VTA. The second experiment investigated the modulatory role of GABA in the VTA on the activity elicited by opioid injections into the VP. In the first experiment it was found that morphine, administered through the dialysis probe, into the VTA produced a significant decrease in extracellular levels of GABA. This is in agreement with the results of other studies suggesting that within the VTA, an indirect action by morphine via GABAergic afferents on dopamine neurons, or disinhibition, is the mechanism involved in the increased dopaminergic activity in the terminal fields and the resultant hyperactivity. In the second experiment, the increase in locomotor activity elicited by injections of DAMGO into the VP were blocked by intra-VTA injections of the GABA_B agonist baclofen. Furthermore, disruption of dopaminergic transmission by 6-OHDA lesions of the NAS reversed this blockade. These results and those of other studies suggest that the locomotor activity elicited by activation of the VP may be under the tonic control of the mesocorticolimbic dopamine system. These data suggest that the tonic inhibitory influence of GABAergic afferents can be blocked by opioids, thus indirectly activating the dopaminergic system leading to an increase in locomotor activity.

132.4

EFFECTS OF REPEATED MORPHINE TREATMENT ON THE SENSITIVITY OF DOPAMINE RECEPTORS IN THE NUCLEUS ACCUMBENS. M. Jezlorski and F.J. White. Wayne State University School of Medicine, Dept. of Psychiatry, Cellular and Clinical Neurobiology Program, Neuropsychopharmacology Lab, Lafayette Clinic, Detroit, MI 48207.

Acute administration of morphine induces increased locomotor activity in rats, a stimulation that is enhanced upon repeated application of morphine. Evidence suggests that the mesolimbic dopamine (DA) projection to the nucleus accumbens (NAc) may be implicated in the development and expression of this behavioral sensitization. Results reported from our laboratory indicate that a schedule of cocaine treatment that produces a similar pattern of sensitization increases the sensitivity of DA receptors on neurons in the NAc, an alteration that appears to be restricted to D1 DA receptors. To examine whether comparable changes in DA receptor sensitivity are associated with morphine-induced sensitization, single unit electrophysiological experiments were conducted on NAc neurons in morphine-treated rats (10 mg/kg/day i.p., 14 days). Rats were tested for sensitization prior to recording; ambulation counts were elevated five-fold on the 14th day of morphine treatment when compared to the first day. However, the ability of iontophoretic DA to inhibit the firing of NAc neurons was similar in vehicle-treated and morphine-treated rats, indicating no difference in DA receptor sensitivity. Further experiments will be conducted to investigate the individual responses of D1 and D2 receptors on NAc neurons after repeated morphine treatment. (Supported by USPHS grants DA-04093 and MH-40832 and by the State of Michigan.)

132.6

MICROINJECTIONS OF SELECTIVE µ AND δ OPIOID AGONISTS INTO THE VENTRAL TEGMENTUM INCREASE EXTRACELLULAR NUCLEUS ACCUMBENS DOPAMINE: AN IN VIVO MICRODIALYSIS STUDY.

D.P. Devine, P. Leone, D. Pockock, and R. A. Wise. Center for Studies in Behavioral Neurobiology, Department of Psychology, Concordia University, Montreal, Canada H3G 1M8.

The putative involvement of ventral tegmental area (VTA) µ and δ opioid receptors in modulation of mesolimbic dopaminergic activity was assessed using *in vivo* microdialysis and HPLC with electrochemical detection. Independent groups of chloral hydrate anesthetized (400 mg/kg, supplemented when needed) male Long-Evans rats were given intracranial microinjections of selective µ and δ opioid agonists aimed at the VTA, and extracellular nucleus accumbens (NAS) dopamine (DA) and DOPAC were assayed. VTA microinjections of DAGO (selective µ agonist) or DPDPE (selective δ agonist) resulted in dose-dependent increases in NAS DA and DOPAC. VTA microinjections of CTOP (selective µ antagonist) also produced dose-dependent increases in NAS DA, suggesting the possibility that CTOP may exert a partial agonist activity following intracranial administration. Pretreatment with VTA CTOP antagonized DAGO-mediated increases in NAS DA, but failed to antagonize DPDPE-mediated increases in NAS DA. After CTOP pretreatment, NAS DOPAC increases were roughly equivalent following DAGO or DPDPE administration. These results suggest that VTA µ and δ opioid receptors may each be involved in opioid disinhibition of mesolimbic DA neurons. The specific roles played by VTA µ and δ opioid receptors in regulation of NAS DA release is being further examined using the selective δ antagonist naltrexone.

132.8

ALTERATIONS IN THE MOTIVATIONAL EFFECTS OF OPIOIDS FOLLOWING PROLONGED PAIN: INVOLVEMENT OF THE MESOLIMBIC SYSTEM. T.S. Shippenberg. Dept. of Neuropharmacology, Max-Planck-Institute for Psychiatry, D-8033 Martinsried, FRG.

Place conditioning and microdialysis were used to examine the influence of prolonged pain associated with Freund's adjuvant (FA)-induced inflammation on the motivational effects of opioids. µ-receptor agonists (Ag) functioned as appetitive reinforcers in naive rats, producing dose-related place preferences. κ-Ag produced place aversions. 6-hydroxydopamine lesions of the n. accumbens (NAC), but not other areas, abolished both effects of opioids. Microdialysis revealed that µ-Ag increased NAC dopamine (DA) release: κ-Ag decreased release. Rats injected with FA 7-days prior to conditioning showed place preferences in response to µ-Ag and an increase in NAC DA release. κ-Ag failed to produce aversive effects in FA-rats and did not alter DA release. These data demonstrate that κ-Ag lack aversive effects in subjects with prolonged pain and suggest that pain-induced changes in such effects result from alterations in endogenous κ-opioid systems which modulate mesolimbic DA activity.

MORPHINE ADMINISTERED TO THE VENTRAL TEGMENTAL AREA PRODUCES PLACE PREFERENCE CONDITIONING IN THE NEONATAL RAT. G. Rossi and G. A. Barr. Biopsychology Doctoral Program, Dept. of Psych., Hunter College-CUNY, NY, NY 10021 and Dept. Devel. Psychobiol. New York State Psychiatric Inst., NY, NY 10032.

When given peripherally, morphine is known to produce a conditioned place preference (CPP) in adult and infant rats. In adults, morphine injected into the ventral tegmental area (VTA) is reinforcing and likely acts by activating mesolimbic dopamine neurons. Little is known of the neurobiological basis of reinforcement in the immature animal and whether or not similar reinforcement mechanisms are present throughout development. Therefore, we have begun to examine the neural mechanisms underlying the reinforcing properties of abused drugs in the infant rat. Pups were injected with one of 4 doses (.05, .15, .45, 1.35 µg) of morphine or the vehicle directly into the VTA and were immediately confined to an odor-cued environment for 30 minutes. They were then tested for a preference between the cued environment and unadulterated wood shavings. The low dose of morphine (.05 µg) injected into the VTA significantly increased duration of time spent in the conditioned environment, demonstrating a preference for the conditioned area over the unscented area; the most effective injection sites were directly into the VTA. Stimulation of structures just outside the VTA, and higher doses of morphine were ineffective. On the basis of these findings we conclude that the neural substrates of opiate reward in the neonate may be similar to those of the adult. (Supported in part by DA-06600)

132.11

THE BEHAVIORAL AND PHARMACOKINETIC PROFILE OF HIGH DOSE BUPRENORPHINE ADMINISTERED SUBLINGUALLY IN HUMANS. S.L. Walsh, K.L. Preston*, M.L. Stitzer*, S.L. Dickerson*, E.J. Cone* and G.E. Bigelow*. Dept. of Psychiatry, Johns Hopkins University School of Medicine and NIDA Addiction Research Center, Baltimore, MD 21224

Buprenorphine (BUP) is a mixed opioid agonist-antagonist which is currently being investigated as a treatment for opiate dependence. The purpose of this study was to evaluate the subjective and physiological actions and pharmacokinetics of BUP across a wide range of doses in non-dependent experienced opioid abusers (N=4). Sessions were conducted once weekly; sublingual BUP doses were 0, 1, 2, 4, 8, 16 and 32 mg. Physiological and subjective indices were monitored for 96 hours post-dosing; BUP blood levels were analyzed by radioimmunoassay.

BUP doses, 2 mg and higher, produced equivalent decreases in respiration rate and concomitant increases in heart rate with no effect on blood pressure. BUP produced significant and long-lasting pupillary constriction which was present for 48 hours or longer. The dose-effect function for subjective effects (e.g. magnitude and liking) was an inverted-U, with dose-related increases up to 8 mg and then a leveling off and downturn at 16 and 32 mg, respectively. In general, the pharmacokinetic data indicate that blood levels were dose- and time-related up to 32 mg. Clinically significant blood levels (3 ng/ml) were observed up to 96 hours following administration of 32 mg BUP. These data indicate that BUP's effects on subjective and physiological responses are not dose-dependent and may reach a ceiling at doses as low as 2 mg. These effects are not solely attributable to the pharmacokinetic actions of BUP.

RHYTHMIC FICTIVE SWALLOWING AS AN INDEX OF NALOXONE-PRECIPIATED MORPHINE WITHDRAWAL IN THE RAT. D. Bieger, C.W. Loomis and L. Young. Basic Medical Sciences, Faculty of Medicine and School of Pharmacy, Memorial University, St. John's, Nfld., Canada A1B 3V6

Twitch-like repetitive activity of ventral neck musculature which occurs in the rat during naloxone-precipitated opioid withdrawal has been proposed as a quantitative measure of physical dependence. The present study was aimed at defining i) the physiological nature of this response and ii) its utility in evaluating the exposure of supraspinal structures after intrathecal opioid administration at the lumbar level. Male Sprague Dawley rats (300-400g) were implanted with intrathecal catheters for continuous infusion of morphine (5µg/h) or saline (1 µl/h) via mini-osmotic pumps for 4 d (groups A and B). Uncatheterized rats were given either s.c. morphine 25mg/kg bid. for 4 d (group C) or no treatment (group D). Tail flick latency and paw pressure withdrawal were determined once daily. On day 4, animals were anesthetized with urethane and fitted with intrapharyngeal and esophageal balloons for recording of respective intraluminal pressures. Baseline and i.v. naloxone (NAL) (0.5 or 1.0 mg/kg)-induced responses were determined over 3 to 4 h. Our results show that in opioid-treated, but not untreated rats, NAL induced rhythmic fictive swallowing (RFS). The number of swallows recorded in the first 5 min post injection was 40±24, 11±26, 1.3±1.5 and zero for groups C,A,B and D, respectively. The preliminary data indicate: 1. the previously reported twitch activity of ventral neck muscles during opioid withdrawal is a component of swallowing; 2. rate of NAL-induced RFS correlates with the total morphine dose and presumably with the degree of physical dependence; 3. lumbar intrathecal infusion of an antinociceptive dose of morphine causes supraspinal signs of physical dependence; 4. spinal catheterization and/or intrathecal saline infusion may lead to activation of supraspinal opioid mechanisms. Supported by MRC (Canada).

CONDITIONED PLACE PREFERENCE (CPP) PRODUCED BY INTRANIGRAL MORPHINE. A.A. Baumeister, M. Hurry*, R. Leoni*, B.W. Curtis* and T. Chaney*. Department of Psychology, Louisiana State University, Baton Rouge, LA 30803.

Bilateral guide cannulae were implanted 1 mm above the caudal substantia nigra of male Sprague Dawley rats. One week later animals were allowed to explore the CPP apparatus (an alley having one white and one black compartment) for twenty minutes on two consecutive days. The amount of time spent in each side of the alley on day two (pretest) was recorded. On days three and five rats received intranigral injection of saline, then were confined to one side of the apparatus for twenty minutes. On days four and six they received intranigral morphine (10 nmol/0.5 µl/side) followed by confinement to the other side of the apparatus for twenty minutes. The side of the apparatus paired with morphine was independent of pretest scores and was counterbalanced. On day 7 animals were tested for place preference (posttest) during a 20 minute period. No injection was given before the posttest. The mean percent of time that the animals spent on the side paired with intranigral morphine was significantly increased, $t(21) = 2.84, p < 0.01$, on the posttest (63.2%) compared to the pretest (53.5%). No place preference was observed when morphine was injected 1 mm caudal to this site. This study suggests that the substantia nigra may play a role in morphine reward. (Supported by NIDA grant DA05907)

132.12

SUBSTANCE P(1-7) INHIBITS WITHDRAWAL JUMPING BEHAVIOR IN MORPHINE-DEPENDENT MICE. J.S. Kreeger* and A.A. Larson.

Department of Veterinary Biology, University of Minnesota, St. Paul MN 55108

Human patients who take morphine for treatment of chronic pain reportedly do not develop tolerance/dependence to the extent predicted. The N-terminal metabolite of the putative pain neurotransmitter SP, SP(1-7), has been demonstrated to have biological activity, specific binding sites and to interact with mu-selective opiate binding sites in the CNS. The purpose of this study was to determine the effects of SP(1-7) on the development of opiate dependence and the expression of withdrawal. Morphine-dependent, male, Swiss-Webster mice were injected with SP(1-7) and withdrawal jumping monitored over a 15 min period after a challenge with naloxone (s.c.). Doses of 0.5 and 1.0 nmol of SP(1-7) intrathecally (i.t.) 30 min prior to 20.0 mg/kg naloxone in mice receiving 25.0 µg of morphine sulfate (MS) i.t. once daily, for 3 days significantly decreased withdrawal jumping ($p < 0.01$). SP(1-7) (1.0 nmol) coadministered i.t. with MS on days 1 and 2 or days 1, 2, and 3 of the dependence protocol had no effect on withdrawal jumping in response to naloxone. Coadministration of SP(1-7) with MS on day 3, however, caused a decreased withdrawal jumping ($p < 0.05$), suggesting that SP(1-7) alters the expression of withdrawal rather than the development of dependence. Parenteral administration of 1.0 nmol of SP(1-7) with naloxone (i.p.) in MS-dependent mice also decreased withdrawal jumping ($p < 0.01$). Spinal and supraspinal effects of SP(1-7) appear to differ as injection of 1.0 nmol of SP(1-7) into the right cerebral ventricle immediately prior to naloxone (s.c.) significantly increased, rather than decreased, jumping behaviors ($p < 0.01$). From these data, it appears that the N-terminal portions of SP and SP metabolites may play a role in the expression of withdrawal in morphine-dependent mice. (NIDA 04090,04190,00124, and 07234)

EXCITATORY AMINO ACID ANTAGONISTS DO NOT BLOCK MORPHINE WITHDRAWAL BEHAVIORS. G. Aston-Jones, C. Chiang, Y. Zhu, R. Valentino, and M. Page. Div. Behav. Neurobiol., Dept. Mental Health Sci., Hahnemann Univ., Philadelphia, 19102.

Recent studies revealed that antagonism of excitatory amino acids (EAAs) in brain (Rasmussen and Aghajanian, 1989) or within LC (Akao et al., 1990) strongly attenuated morphine withdrawal-induced activation of LC neurons. As LC hyperactivity may play a role in opiate withdrawal, we studied the effects of several EAA antagonists on behavioral indices of morphine withdrawal. Rats were pretreated continuously for 6 days with morphine delivered from chronically implanted osmotic minipumps (34 mg/kg/day). Animals were then given an EAA antagonist or vehicle and subsequently administered naltrexone (1 mg/kg, ip) to precipitate withdrawal. Withdrawal behaviors scored included jumping, wet dog shakes, head shakes, teeth chattering, chewing, diarrhea, rhinorrhea, lacrimation, ptosis, and piloerection. None of the antagonists tested by icv (kynurenic acid, 11-33 µmoles, n=3; AP5, 20-35 nmoles, n=4; CNQX, 3.5 nmoles, n=2; or CGS19755, 1.2 nmoles, n=2) or by ip administration (CGS19755, 3.8 mg/kg, n=2) consistently decreased any withdrawal behavior. Jumping and wet dog shakes appeared to be increased by the EAA antagonists given icv. Higher doses for each agent induced profound ataxia, precluding withdrawal assessment.

These results indicate that EAA antagonists of either NMDA or non-NMDA receptors do not prevent naltrexone-precipitated morphine withdrawal. As LC withdrawal hyperactivity is attenuated by doses of kynurenic acid or CNQX that were ineffective on behaviors scored here, these components of the morphine withdrawal syndrome may not depend on LC hyperactivity. Alternatively, the effects of these antagonists on LC neurons may differ in conscious vs. anesthetized animals. Nonetheless, our results are consistent with observations (Britton et al., 1984) that lesions of the ascending NE projections from LC do not attenuate behavioral signs of opiate withdrawal. Although LC may not mediate these behavioral manifestations of opiate withdrawal, its hyperactivity may be involved in other withdrawal phenomena (e.g. related to mood, state or craving). Supported by PHS grant DA 06214.

EFFECTS OF ACUTE/CHRONIC MK-801 ON NALOXONE-PRECIPIATED JUMPING IN MORPHINE-DEPENDENT MICE. K.L. Marquis, M.J. Piesla*, E.A. Muth and C.A. Roast. Wyeth-Ayerst Research, CN 8000, Princeton, NJ 08543.

It has been recently reported that chronic coadministration of the excitatory amino acid antagonist MK-801 with morphine retards the development of tolerance and reduces the degree of dependence produced by the opiate in rats (Trujillo and Akil, Science 251:85-87, 1991). The current study was conducted to examine the acute and chronic effects of MK-801 on a measure of opiate dependency, naloxone (NAL)-precipitated jumping, in mice. Male CF-1 mice (Charles River) were made dependent on morphine by either the implantation of a 75 mg morphine pellet (P) for 3 days or by the administration of morphine (10 mg/kg sc) by injection (I) twice daily for 9 days. In P-dependent mice, 0.05 and 0.1 mg/kg NAL (ip) produced an average (X) of 87.3 and 118.6 jumps in 10 minutes, respectively. The acute administration of 0.1 mg/kg ip MK-801 (30 min prior to NAL), did not alter the number of jumps precipitated by 0.1 mg/kg ip NAL (X=99.3) but significantly reduced the number of jumps which occurred following 0.05 mg/kg ip NAL (X=11.4) in P-dependent mice. Likewise, in I-dependent mice, in which a dose of 1.0 mg/kg ip NAL produced an average of 26 jumps, the acute administration of MK-801 (0.17 mg/kg ip) abolished jumping behavior. In contrast, the acute administration of 0.054 mg/kg ip MK-801 in I-dependent mice increased jumps (X=56), but not significantly. The chronic coadministration of MK-801 (0.054-0.17 mg/kg ip) with morphine (injection) did not significantly affect the average jumps precipitated by NAL (1 mg/kg ip). While the effects of chronic MK-801 on opiate dependency did not occur in the current study, a clear effect of acute administration of MK-801 on this measure was observed. This effect may depend on the intensity of the withdrawal reaction as controlled by the level of dependency and/or dose of naloxone.

IgG FROM NEUROPEPTIDE FF ANTISERUM REVERSES MORPHINE TOLERANCE. J.R. Lake, M.V. Hammond*, R.C. Shaddox*, L.M. Hunsicker*, J.M. Cannon-Searcy*, H.-Y.T. Yang¹ and D.H. Malin. Univ. of Houston-Clear Lake, Houston, TX 77058 & ¹NIMH Neuroscience Ctr. at St. Elizabeth's, Washington, D.C. 20032.

Neuropeptide FF (NFFF, F8Fa) appears to play a role in opiate dependence and abstinence syndrome (Malin et al., Peptides 11:969,1990). The present study assessed the role of NFFF in opiate tolerance. Twelve rats were rendered tolerant by 7 days s.c. infusion of 0.57 mg/kg/hr morphine via Alzet osmotic minipump. They were then tested for pain sensitivity (tail flick with 15 sec. cut-off) and injected i.c.v. with 22 µg IgG from NFFF antiserum or control serum. Sixty mins. later they were injected with 6 µg morphine i.c.v. and retested 5, 12 and 20 mins. later. The table shows their morphine analgesia as % of maximal possible effect. The morphine analgesia of 5 non-tolerant rats is also shown for purposes of comparison. IgG from NFFF antiserum virtually restored the morphine response to levels shown by non-tolerant rats.

	% Max. Analgesic Response to 6 µg morphine i.c.v. (M±SEM)		
Non-tolerant/no IgG	56.2 ± 18.8	95.3 ± 4.7	100.0 ± 0.0
Tolerant/control IgG	7.9 ± 3.8	8.2 ± 4.6	16.8 ± 10.3
Tolerant/NFFF IgG	57.3 ± 13.5	90.7 ± 7.2	89.5 ± 7.8

In contrast, IgG from NFFF antiserum did not affect analgesic response to i.c.v. morphine in 12 opiate-naive rats. These results are consistent with the hypothesis that endogenous NFFF contributes to opiate tolerance.

132.19

THE ACOUSTIC STARTLE RESPONSE AS A MEASURE OF BEHAVIORAL DEPENDENCE IN RATS. R.S. Mansbach, L.H. Gold and L.S. Harris. Dept. of Pharmacology & Toxicology, Medical College of Virginia, Richmond VA 23298

There are at present few objective measures of behavioral disruption following chronic administration of abused drugs. Those measures which are available often are difficult to establish and fail to identify drugs that do not produce a classical withdrawal syndrome. The acoustic startle response (ASR) was examined in the present study as a potentially sensitive behavioral index during naloxone-precipitated morphine withdrawal. Groups of 6-8 male rats were implanted with 2 pellets (s.c.) containing 75 mg each of morphine sulfate or placebo. The ASR was elicited by 40-msec, 122 or 107 dB[A] noise bursts delivered at 30- or 60-sec intervals. Pre-implant startle tests revealed no differences between placebo and morphine groups. In Experiment 1, administration of 0.05-0.2 mg/kg s.c. naloxone 5 min prior to startle testing induced large, dose-dependent startle decreases in morphine-dependent rats but no change or increases in placebo rats also injected with naloxone. In Experiment 2, a modified procedure involving fewer startle trials and fewer test days revealed unmistakable and significant disruption of the ASR following 0.2 mg/kg naloxone. Startle responses in placebo-pellet rats were not significantly affected by naloxone. The ASR decreases in morphine rats were accompanied by body-weight loss in all subjects, but weights of placebo-pellet rats were unaffected. Evidence of conditioned abstinence in both startle and body weight measures was also observed. These data support the use of startle-response measures in examining behavioral and pharmacological factors leading to drug abuse relapse. Supported by PHS grant DA-00490.

qEEG CHARACTERISTICS OF TWO DOSAGE REGIMENS DURING BUPRENORPHINE MAINTENANCE AND WITHDRAWAL IN HEROIN-DEPENDENT SUBJECTS. R. Herring*, B. Koeppl*, W. Pickworth, R.E. Johnson*, P.J. Fudala, J.H. Jaffe* and N. Khazan. NIDA/Addiction Research Center, Baltimore, MD 21224.

In outpatient studies, chronic daily buprenorphine (BUP) administration to opioid-dependent subjects has been found to be an efficacious treatment associated with reduced illicit opioid use. In the present study quantitative EEG (qEEG) was used to compare BUP daily vs. alternate-day treatment. EEG data from 16 of 24 subjects enrolled in this study is reported. All subjects were rapidly inducted onto sublingual BUP (2, 4, and 8mg) over 3 days then maintained on 8mg through study day 18. For the next 18 days, Group 1 (n=8) continued to receive 8mg BUP daily, while Group 2 (n=8) received 8mg BUP or placebo on alternate days. Daily placebo was then administered for an additional 16 days. EEG was recorded from Fz, C3, C4 and Pz leads two and a half hours after drug administration and EEG power spectra were computed. Upon BUP withdrawal, a significant decrease in EEG total power and in alpha and theta power emerged associated with a higher alpha frequency; effects characteristic of BUP/Opioid abstinence (LUKAS et al., Clin. Pharmacol. Ther., 30: 127-132, 1984). The Pz lead, rich with alpha wave activity demonstrated the highest drop in EEG total power. While on alternate-day BUP, Group 2 showed no significant EEG correlates of opioid withdrawal on placebo days. However, self-reported increase in "urge" for an opioid; increase in subjective dysphoria scale score and pupillary dilatation in Group 2 were previously reported. These differences support the premise that BUP may produce a more effective opioid maintenance when administered daily. Nevertheless, the "urge" to use an opioid even on placebo days was not greater than that of Group 1 which exhibited little day to day fluctuation.

INHIBITION OF MORPHINE TOLERANCE AND DEPENDENCE BY MK-801: BEHAVIORAL AND NEUROCHEMICAL STUDIES. K.A. Trujillo, D.M. Bronstein and H. Akil. Mental Health Research Institute, University of Michigan, Ann Arbor, MI.

We have previously reported that the non-competitive N-methyl-D-aspartate (NMDA) receptor antagonist MK-801 inhibits the development of morphine tolerance and dependence. Since learning has been found to influence tolerance and dependence, and since MK-801 interferes with learning, it is possible that this drug inhibits tolerance and dependence primarily by interfering with learning processes. A series of studies was designed to explore this possibility. Learning cues were manipulated either 1) by repeatedly injecting animals in the presence or absence of specific environmental cues, or 2) by chronically treating animals using osmotic mini-pumps and morphine pellets. Preliminary results indicate that MK-801 interferes with tolerance and dependence even in the absence of associative cues, suggesting that the actions of this drug are not simply due to its effects on learning. MK-801 may therefore act more directly on the neural changes responsible for opiate tolerance and dependence.

In addition to studying the behavioral interactions between morphine and MK-801 we have also begun to examine the effects of these drugs on brain opioid peptides. Preliminary results suggest that MK-801 attenuates the ability of morphine to increase striatal prodynorphin peptides. Effects on β-endorphin are currently being analyzed. These results suggest that MK-801 interferes not only with the development of opiate tolerance and dependence, but also with specific neurochemical changes associated with these phenomena.

NICOTINE TOLERANCE AND DEPENDENCE: A BEHAVIORAL ASSESSMENT USING SCHEDULE CONTROLLED RESPONDING, LOCOMOTOR ACTIVITY, AND SENSORIMOTOR REACTIVITY. D. HELTON, J. TIZZANO, D. MODLIN*, AND K. RASMUSSEN. Lilly Research Laboratories, Eli Lilly and Company, Greenfield, IN 46140.

Previous studies have demonstrated that chronic nicotine (NI) treatment produces tolerance and dependence. Sensitive behavioral measures have been used to describe the magnitude and time course of behavioral disruptions resulting from abrupt removal of NI. The present experiments extend previous findings using a battery of behavioral measures following abrupt NI cessation. NI (0, 10 or 20 mg/kg/day) was continuously administered for 12 days in rats (10/group) by surgically implanting Alzet osmotic mini-pumps subcutaneously. The first experiment evaluated effects using a light/dark discrimination task. There were no significant effects on percent correct responding, or rate of responding during NI administration, or for 5 days following removal of NI. The second experiment evaluated effects on locomotor activity and auditory startle responding. Chronic NI administration produced significant dose-dependent increases in locomotor activity during the first 5 days of exposure, but no significant alterations were seen in activity levels following NI removal (0-5 days). However, during NI withdrawal (1-5 days), significant increases were seen in startle amplitude in both NI groups compared to controls. These studies indicate that the expression of NI tolerance and dependence is dependent on the behavioral task employed.

[³H]DTG BINDING IN RAT HIPPOCAMPUS: A SIGMA SITE? Duncan P. Taylor, Diana Marrero*, and Jennifer Defnet*. CNS Neuropharmacology, Bristol-Myers Squibb Co., Wallingford, CT 06492-7660.

The role of the σ binding site in brain function is unknown. Several compounds with affinity for this site, such as BMY 14802 (Taylor et al., 1990; Moon et al., 1990), have been found to be active in models of neuroprotection. Recently, Debonnel et al. (1990) showed that σ ligands, such as 1,3-di-o-tolylguanidine (DTG), potentiate NMDA-induced hippocampal neuron activation, and this effect could be blocked by haloperidol and BMY 14802. We investigated the pharmacologic specificity of *in vitro* [³H]DTG binding in the rat hippocampus and compared it to our previous studies of σ sites using the same ligand in whole guinea pig brain as well as (+)-[³H]-3-PPP in rat cortex. Some interesting differences were noted: stereoselectivity for enantiomers of BMY 14802, butaclamol, dextrorphan and dexoxadrol was lost, and reversed stereoselectivity for the enantiomers of cyclazocine and N-allylnormetazocine was seen. In addition, phencyclidine was more potent in the rat hippocampus. Our data suggest not only that [³H]DTG labels a σ type of binding site in rat hippocampus, but that this site may be a heterogeneous mixture of multiple subtypes of σ sites or that the rat hippocampus may contain a different subtype than the guinea pig brain or the rat cortex.

133.3

STRUCTURAL CLASSES OF COMPOUNDS WITH POTENT AFFINITY FOR BRAIN SIGMA BINDING SITES B.K. Koe, C. B. Fox*, and L.A. Lebel. Central Research Division, Pfizer Inc., Groton, CT 06340

Interest in brain sigma binding sites stems from the potent affinity of several classes of therapeutic or potential therapeutic drugs for these sites, such as antipsychotics (haloperidol, rimcazole, BMY 14802); antidepressants (sertraline (5-HT uptake blocker), opipramol (tricyclic), clorgyline (MAO inhibitor)); antiischemic agents (ifenprodil, SL 82.0715). Moreover, a link to glutamate NMDA receptors is suggested by the effects of sigma ligands on NMDA induced activation of hippocampal neurons *in vivo*. These diverse compounds can be grouped into several structural types: 1-substituted piperidine (SC 50691); 1,3- (3-PPP, 3-PPPP) and 1,4- (haloperidol, ifenprodil, SL 82.0715) substituted piperidines; 1,2,6-substituted piperidine (lobeline); 1,2,3,4-substituted piperidines (SKF 10047, dextromethorphan, pentazocine); and structures with phenylbutylamine-like (sertraline, clorgyline, opipramol, GBR-12909, haloperidol, BMY 14802, rimcazole, JO 1784), phenylpentylamine-like (U-50488, BD 737, proadifen, caramiphen), or phenyltolylamine-like (carbetapentane) separation between phenyl and a basic amine. We report on two new sigma ligands that potently inhibit (\pm)-[³H]3-PPP binding *in vitro* to rat brain membranes and *in vivo* to brain of intact mice. Their structures fall within the classes described: E-2020 (IC₅₀ 5.8 nM, ID₅₀ 2.7 μ mol/kg p.o.), an acetylcholinesterase inhibitor, and 3,4-dichlorobenzylloxymethyl-2-piperidine (IC₅₀ 4.5 nM, ID₅₀ 0.27 μ mol/kg i.p.), a dexoxadrol derivative with little affinity for PCP binding sites.

133.5

PHENCYCLIDINE DISRUPTS SENSORY GATING IN THE RAT VIA A NORADRENERGIC MECHANISM. Christine L. Miller*, Robert Freedman*, Herbert Nagamoto*, and Paula Bickford-Wimer*. Depts. of Pharmacology¹ and Psychiatry², Univ. Colorado Health Sci. Ctr., and Vet. Admin. Med. Ctr., Denver, CO 80262

Various forms of psychosis in humans are accompanied by disruption of auditory sensory gating measured in the P50 wave response to paired clicks. Similar disturbances in auditory sensory gating in the rat are observed after administration of the psychotomimetic drug phencyclidine (PCP). PCP interacts with sigma receptors, and NMDA receptors, and can also act as an indirect catecholamine agonist. The present study addressed the question of which of these actions of PCP are important in the loss of sensory gating. Two equivalent tones, separated by 500 msec, were presented to chloral hydrate anesthetized Sprague-Dawley rats. An evoked potential of 30 to 50 msec latency was recorded in the CA3 region of the hippocampus in response to the first tone and was diminished in amplitude to the second (sensory gating). Administration of PCP (1-5 mg/kg, i.p.), and other sigma ligands, caused an increased ratio of the 2nd response to the 1st response (gating is lost). The NMDA antagonist effects of PCP do not appear to be significant in this paradigm, since the NMDA antagonist CPP has little effect on auditory gating at i.p. doses up to 16 mg/kg. Lesioning of noradrenergic input to the hippocampus, with DSP4, blocks the effects of PCP on auditory gating. It is possible that PCP exerts its gating effects by increasing noradrenergic activity through a sigma receptor mechanism. This work was supported by VA Medical Research Services and USPHS Grants DA-02429 and MH-38321.

PD 128298, A NOVEL SELECTIVE LIGAND FOR SIGMA BINDING SITES: CHARACTERISTICS AND FUNCTIONAL ACTIVITY. T. A. Pugsley, Y. H. Shih*, S. Whetzel*, F. Ninteman* J. Wiley*, M. D. Davis, L. Meltzer, H. Tegle*, and T. Heffner. Dept. of Pharmacol. and Chem., Parke-Davis Pharmaceutical Res. Div., Warner-Lambert Co., Ann Arbor, MI 48105.

Although the functional role of sigma sites remains obscure, studies suggest a role of this site in: a) modulation of motor behavior, smooth muscle contraction and phosphoinositide metabolism; b) enhancement of norepinephrine release; c) inhibition of neuronal firing rates. This study describes the binding characteristics and functional activity of 3-phenyl-1-(1,2,3,6-tetrahydro-1-propyl-3-pyridinyl)-1-propanone oxime, monohydrochloride (PD 128298).

PD 128298 potently displaced [³H]-(-)-3-PPP from guinea pig brain sigma binding sites with an IC₅₀ value of 1.6 nM, similar to that of haloperidol and lower than that of DTG; it displaced [³H]-DTG binding with an IC₅₀ of 19 nM. It was at least 400-fold selective for sigma versus other binding sites. *In vitro* PD 128298, like DTG and haloperidol, inhibited the contractions of the guinea pig ileum elicited by electrical stimulation. *In vivo* PD 128298 (5-20 mg/kg, s.c.) was active in a behavioral despair test and in potentiating the behavioral effects of methamphetamine in self-stimulating rats. No consistent effects of PD 128298 on locomotor activity in rodents was observed. Neurochemical studies indicated modest increases in the synthesis and extracellular levels of dopamine in rat striatum. No extrapyramidal-like effects were induced by PD 128298 in haloperidol sensitized monkeys. These findings with PD 128298 may aid in understanding the potential functional effects of sigma ligands.

133.4

BMY-14802, A SIGMA LIGAND AND POTENTIAL ANTIPSYCHOTIC DRUG, REVERSES AMPHETAMINE-INDUCED CHANGES IN STRIATAL SINGLE-UNIT ACTIVITY IN FREELY MOVING RATS. G.V. Rebec, Z.R. Wang*, and J.L. Haracz. Prog. Neural Science, Dept. Psychology, Indiana University, Bloomington, IN 47405.

Preclinical evidence suggests that BMY-14802, which has a high affinity for sigma but not dopamine receptors, may be an effective neuroleptic (Taylor and Dekleva, *Drug Develop. Res.*, 11:65, 1987). Virtually all neuroleptic drugs currently available for clinical use antagonize at least some of the actions of amphetamine. To determine the extent to which this action also applies to BMY-14802, we assessed the effects of this drug on amphetamine-induced changes in the activity of single striatal neurons in awake, behaving rats. Consistent with previous reports (Haracz et al., *Brain Res.*, 489:365, 1989), 1.0 mg/kg d-amphetamine typically activated movement-related neurons (25 of 26) but suppressed the activity of cells whose firing rate was unrelated to movement (9 of 12). Subsequent administration of BMY-14802 (10-20 mg/kg) generally reversed the effects of amphetamine on both types of cells, but this effect was more apparent for movement-than non-movement-related cells (80% vs 40%, respectively). Behavioral analyses indicate that BMY-14802 also reversed amphetamine-induced behavioral activation. Taken together, these results suggest that although BMY-14802 antagonizes the behavioral effects of amphetamine, this potential neuroleptic does not act homogeneously in opposing the action of amphetamine on striatal neurons. [Supported by USPHS Grant, DA-02451]

133.6

IN VIVO AND IN VITRO BINDING ACTIVITIES OF A SERIES OF HALOGENATED ARYL-PIPERAZINES AT THE SIGMA SITE. D.J. Wilson¹*, S.J. Vine¹*, M. Nobbs¹*, G.C. Ormandy¹, R. Ferris², D.R. Riddall¹*, Wellcome Research Labs, Kent, U.K. and R.T.P., N.Carolina, USA².

The characteristics and functional role of the sigma receptor has received much attention recently. However, due to the lack of functional assays, the importance of the sigma receptor remains largely unknown although recent investigations have suggested it to be a target for the development of antipsychotic drugs. The development of novel selective sigma ligands would thus be of value in defining the role of the sigma receptor. We have investigated the structure-activity relationship for a series of halogenated aryl-piperazines. *In vitro* binding studies were carried out on guinea pig membranes incubated in 50mM Tris-HCl, pH7.7, 27°C with [³H]-DTG, [³H]-PPP, [³H]-dextromethorphan or [³H]-SKF10047. Our studies have revealed a number of highly potent compounds (pK_i about 9.2) with at least 1000 fold selectivity compared with binding to PCP, dopamine D1, D2, noradrenaline α_1 , α_2 , β , acetylcholine muscarinic and serotonin 5HT₂ receptors. A number of these compounds were then tested in binding studies *in vivo*. Compounds were administered intraperitoneally (ip) or orally (po) to mice to determine their ability to displace the specific binding of [³H]-SKF10047 (ip) to sigma sites in the brain. These compounds were potent displacers of specific [³H]-SKF10047 binding with ED₅₀'s of around 0.1 mg/kg ip or po, relative to haloperidol which has an ED₅₀ of 0.8 mg/kg ip. Thus, these compounds may serve as important tools *in vitro* and *in vivo* for defining the functional role of the sigma site, and the therapeutic potential of ligands interacting with this receptor.

133.7

DuP 734 IS A NOVEL SIGMA RECEPTOR ANTAGONIST. S.W. Tam, G.E. Steinfels, P.J. Gilligan*, J.F. McElroy, V.J. DeNoble, A.L. Johnson*, and L. Cook*. Central Nervous System Diseases Research, The Du Pont Merck Pharmaceutical Company, Wilmington, DE 19880-0400

The sigma receptor has been suggested to play a role in the etiology of schizophrenia, and sigma receptor antagonists may be useful as antipsychotics without the serious motor side effects of neuroleptics. DuP 734 (1-(cyclopropylmethyl)-4-(2'-4"-fluoroethyl)-2'-oxoethyl) piperidine HBr) is a novel compound with potent binding affinity for sigma (K_i = 10 nM) and 5-HT₂ (K_i = 15 nM) receptors and weak binding affinity for dopamine receptors (K_i > 1000 nM), and 29 other receptors, ion channels and second messenger systems.

Since sigma receptors have been demonstrated to be associated with dopamine neurons of the substantia nigra, extracellular single unit recording techniques were used to study the DuP 734 antagonism of the effect of the selective sigma ligand (+)-3-(3-hydroxyphenyl)-N-(1-propyl)piperidine [(+)-3-PPP] on dopamine neuronal activity in the substantia nigra of the rat. DuP 734 dose-dependently antagonized the inhibition of dopamine neuronal activity produced by a single i.v. dose of 0.5 mg/kg of (+)-3-PPP with an ED₉₀ of 0.99 mg/kg i.v..

The sigma receptor agonists (+)-SKF 10,047 and phencyclidine both induced turning behavior in rats with unilateral lesion of the substantia nigra. DuP 734 dose-dependently antagonized the turning induced by (+)-SKF 10,047 and phencyclidine with oral ED₅₀s of 2.4 and 5.4 mg/kg, respectively.

In conclusion, DuP 734 is a potent orally active sigma receptor antagonist.

133.9

THE NOVEL ANTIPSYCHOTIC DuP 734 PREFERENTIALLY INCREASED DOPAMINE TURNOVER IN THE FRONTAL CORTEX IN RAT BRAINS. C. Rominger and S.W. Tam. Central Nervous System Diseases Research, The Du Pont Merck Pharmaceutical Company, Wilmington, DE 19880-0400.

The effects of acute administration of the potent sigma and 5-HT₂ receptor antagonist DuP 734 on the turnover of dopamine and serotonin in discrete brain regions of the rat were studied *ex vivo*. Rats were euthanized by microwave irradiation focused on the brain. DuP 734 preferentially and significantly increased the level of dopamine and its metabolites, 3,4-dihydroxyphenyl acetic acid (DOPAC) and 4-hydroxy-3-methoxyphenylacetic acid (HVA) in the frontal cerebral cortex at 1 and 3 mg/kg, s.c.. At a higher dose of 9 mg/kg s.c., DuP 734 also significantly increased dopamine turnover in the nucleus accumbens, caudate putamen and hypothalamus but not in the substantia nigra and ventral tegmentum. In contrast, the haloperidol-induced increase in dopamine turnover was not selective between the frontal cerebral cortex, caudate putamen, and nucleus accumbens at 0.01-0.1 mg/kg s.c. DuP 734 at 1 and 3 mg/kg s.c. increased 5-HT turnover in the ventral tegmentum but not in the other brain regions studied. Haloperidol 0.01-0.1 mg/kg s.c. had no effect on 5-HT turnover in these brain regions. The results indicate that DuP 734 is relatively selective in modulating the dopamine neuronal activity in the mesocortical areas, and has a much weaker activity in affecting dopamine neuronal activity in the nigro-striatal pathway which mediates motor activity. These results support the hypothesis that DuP 734 is a novel antipsychotic with low potential for extrapyramidal symptoms.

133.11

[³H]DuP 734-LABELED SIGMA RECEPTORS IN GUINEA PIG BRAIN: AUTORADIOGRAPHIC LOCALIZATION STUDIES. J. A. Heroux, S. W. Tam and E. B. De Souza. CNS Diseases Research, The Du Pont Merck Pharmaceutical Company, Wilmington, DE 19880-0400.

The psychotomimetic effects of certain cycloalkyls and benzomorphanes that interact with sigma receptors has led to the hypothesis that these sites may be important in the etiology of schizophrenia. DuP 734 [1-(cyclopropylmethyl)-4-(2'-4"-fluorophenyl)-2'-oxoethyl] piperidine is a novel sigma receptor antagonist. The receptor binding specificity and neuroanatomical distribution of [³H]DuP 734-labeled sigma receptors in guinea pig brain were examined using quantitative autoradiography. [³H]DuP 734 binding to slide-mounted sections of guinea pig brain was saturable and of high affinity (K_d: 3.9 nM). Competition studies yielded the following rank order of potency: DuP 734 > haloperidol > (+)-pentazocine > (-)-butaclamol > DTG > (+)-SKF 10,047 > (+)-3-PPP > (-)-pentazocine > (-)-butaclamol > U50,488H > (-)-SKF 10,047 > cinanserin > PCP >>> MK801, sulpiride. High densities of [³H]DuP 734 binding sites displaceable by haloperidol were present in the dorsal and ventral bands of Broca as well as in the ventral pallidum. The mammillary complex of the hypothalamus, central gray, red nucleus of the midbrain, pontine reticular nucleus, purkinje cell layer of the cerebellum and dorsal and ventral horns as well as the central gray matter of the spinal cord all showed enrichments of [³H]DuP 734 binding sites. Lower levels of binding were present in the cerebral cortex and basal ganglia and negligible specific binding was present in the white matter tracts. The kinetic and pharmacological characteristics and distribution of [³H]DuP 734 binding sites in brain are similar to those previously reported for sigma receptors.

133.8

THE PHARMACOLOGY OF A SIGMA RECEPTOR ANTAGONIST ANTIPSYCHOTIC: DuP 734. L. Cook*, S. W. Tam, W. K. Schmidt and K. W. Rohrbach. Central Nervous System Research, The Du Pont Merck Pharmaceutical Company, Wilmington DE 19880-0400

DuP 734 (1-(cyclopropylmethyl)-4-(2'-4"-fluoroethyl)-2'-oxoethyl) piperidine HBr) presents a novel profile of activity in a battery of test procedures designed to distinguish antipsychotic therapeutic activity and neuroleptic side-effect potential. Its receptor binding profile shows affinity for sigma and 5HT₂ and not to dopamine receptors.

Similar to haloperidol, DuP 734 potently antagonizes mescaline induced effects (ED₅₀=0.35 mg/kg po) as well as isolation induced aggression (ED₅₀=1.9 mg/kg po) in mice. However, unlike haloperidol, it only weakly antagonizes apomorphine induced climbing (ED₅₀=14 mg/kg po) in mice and failed to inhibit conditioned avoidance (CAR) or escape (CER) behavior at 23 mg/kg po or produce catalepsy at 77 mg/kg po in rats. DuP 734 suppresses operant responding (VI60) and 5HTP induced head twitch in rats (ED₅₀'s of 6.6 and 1.8 mg/kg po respectively). The overall profile of DuP 734 indicates activity in some procedures reflecting antipsychotic activity (mescaline antagonism and aggression) while showing weak activity in a dopamine dependent procedure (apomorphine climbing) and no activity in procedures associated with neurological side-effect liability (catalepsy and CER).

Although DuP 734 itself does not antagonize CAR activity, it enhances the potency of haloperidol in CAR by 3X (the ED₅₀ for haloperidol is shifted from 0.94 to 0.32 mg/kg po), while not effecting the ED₅₀ of haloperidol for CER or catalepsy. This indicates a specific facilitation of the therapeutic activity of haloperidol. The combination treatment with the sigma receptor antagonist DuP 734 thus provides an improved antipsychotic margin of safety for haloperidol.

133.10

[³H]DuP 734: A RECEPTOR BINDING PROFILE IN BRAIN OF A HIGH-AFFINITY NOVEL SIGMA RECEPTOR ANTAGONIST. S. G. Culp, D. Rominger, S. W. Tam and E. B. De Souza. Central Nervous System Diseases Research, The Du Pont Merck Pharmaceutical Company, Wilmington, DE 19880.

Schizophrenia is associated with alterations in the regional brain densities of sigma and D₂ dopamine receptors and it has been suggested that sigma receptor antagonists may represent novel antipsychotic agents. DuP 734 [1-(cyclopropylmethyl)-4-(2'-4"-fluorophenyl)-2'-oxoethyl] piperidine, is a novel sigma receptor ligand which antagonizes the behavioral effects of known hallucinogens without binding to or antagonizing D₂ dopamine receptors. The *in vitro* binding properties of [³H]DuP 734 in homogenates of guinea pig brain were examined. Specific [³H]DuP 734 binding (10 μM haloperidol-displaceable) in cerebellum was dependent on pH and membrane protein concentrations, saturable and of high affinity (K_D = 228 ± 34 pM; B_{max} = 3856 ± 340 fmol/mg protein). [³H]DuP 734 binding was substantially reduced by treatment of the membrane with proteases and completely abolished by heat denaturation. The pharmacological characteristics of [³H]DuP 734 binding in cerebellum were similar to those previously reported for sigma receptors in brain [DuP 734 > haloperidol > (+)-pentazocine > DTG > (+)-3-PPP > (-)-pentazocine > amitriptyline > (-)-butaclamol > (+)-SKF 10,047 > (-)-3-PPP > (+)-butaclamol > (-)-SKF 10,047 > PCP >> MK801]. [³H]DuP 734-labeled sigma receptors were heterogeneously distributed in CNS (pons/medulla ≅ hypothalamus > spinal cord > cerebellum > hippocampus ≅ thalamus ≅ cerebral cortex ≅ striatum). In summary, DuP 734 binds with high affinity to sigma receptors in brain and represents a potential antipsychotic agent.

133.12

ABSORPTION AND DISTRIBUTION OF A TRITIATED SIGMA ANTAGONIST (NPC 16377) AFTER ORAL ADMINISTRATION IN THE RAT AND MOUSE. Marie Rock*, Carolyn Falt*, Venkatoraman Balasubramanian, Theresa Hartman*, David B. Clissold, Michael Pontecorvo and John Ferkany. CNS Division, Nova Pharmaceutical Corporation, Baltimore, MD 21224.

An absorption and distribution study was conducted in rats and mice after oral administration (125 mg/kg) of tritiated NPC 16377. The radiolabeled compound (S.A. 48 Ci/mole) was 99% pure by HPLC and TLC. Other studies have shown that pharmacological activity in the mouse occurs approximately 45 minutes after a single oral administration (125 mg/kg) of NPC 16377. However, the compound did not demonstrate pharmacological activity in the rat unless either a 475 mg/kg dose was given, when effects were seen at 1 hour, or repetitive dosing was done (125 mg/kg), with activity observed on the 5th daily dose. Organ distribution (brain, fat, stomach, liver, kidney and lung) was performed at 3 hours, 24 hours and 48 hours post dose. Blood levels were measured at 0.5, 1, 3, 6, 12, 24, 48 and 72 hours post dose. The results of this study showed a close correlation of blood and brain levels. The mouse demonstrated 18,000 DPM/gm brain tissue at 3 hours and 5000 DPM/gm brain tissue at 48 hours, whereas the rat did not achieve levels of 5000 DPM/gm until 48 hours. In rats, a lower dose (75 mg/kg) produced brain tissue levels which were significant and paralleled the blood levels.

133.13

NPC 16377, A POTENT, SELECTIVE SIGMA LIGAND: NEUROPROTECTIVE ACTIONS. B.E. Jones, D.B. Clissold, M.J. Pontecorvo, E.W. Karbon, M.E. Abreu, R. Erickson and J.W. Ferkany. CNS Research and Medicinal Chemistry, Nova Pharmaceutical Corporation, Baltimore, MD 21224.

Studies were undertaken to evaluate the neuroprotective efficacy of the sigma agent NPC 16377. Adult male gerbils (60-80g) anesthetized with halothane, were fitted with a loose silastic ligature placed around the carotid artery and passed through a double lumen cannula protruding out the nape of the neck. The day after surgery ischemic insult (duration 5 min) was accomplished by pulling tight the ligature. NPC 16377 was administered either i.p. (10 or 35 mg/kg) 30 and 10 min prior and 60 min post insult or p.o. (150 or 200 mg/kg) 60 min prior and 60 min post insult. Body temperature was maintained for at least three hour post-insult by a heating lamp. Gerbils were allowed to recover to 72 hrs. Neuroprotection was assessed by microscopic examination. A six point rating scale was applied (0 = no damage; 1 = 10% or less cells damaged; 2 = 10-25% damage; 3 = 25-50% damage; 4 = 50-75% damage; 5 = 75% or greater damage) to the CA1 region of the hippocampus. Significant neuroprotection was noted in the 35 mg/kg i.p. (0.6 ± 0.5) group compared to control (4.2 ± 0.7) and 150 mg/kg p.o. (2.8 ± 0.5) and 200 mg/kg p.o. (1.6 ± 0.5) groups compared to control (4.5 ± 0.4). The data indicates that NPC 16377 is an effective neuroprotectant following either i.p. or p.o. administration.

133.15

NEUROCHEMICAL AND NEUROENDOCRINE EFFECTS OF NPC 16377 - A POTENT AND SELECTIVE SIGMA LIGAND. M.E. Abreu, L.A. Martin, R. Erickson, E.W. Karbon, M.J. Pontecorvo and J.W. Ferkany. CNS Research and Medicinal Chemistry, Nova Pharmaceutical Corporation, Baltimore, MD 21224.

A number of studies have suggested a relationship between compound affinity for the sigma receptor and antipsychotic/psychotomimetic activity. Based on the recent identification of NPC 16377 as a potent and selective sigma agent, studies were initiated to evaluate neurochemical and neuroendocrine effects of NPC 16377 as compared to typical and atypical antipsychotic agents as well as with other characterized sigma agents. Male Sprague-Dawley rats were injected (ip) with behaviorally-relevant doses of compounds and brain regions and plasma samples were obtained 60 minutes later. Dopamine (DA) and DOPAC levels were measured in striatum, frontal cortex and nucleus accumbens using HPLC with electrochemical analysis and plasma ACTH, corticosterone and prolactin were measured by RIA. Neither NPC 16377 nor ifenprodil (IFN) increased DA turnover (DOPAC/DA ratio), in any of the brain regions studied while BMY 14802 (BMY), clozapine (CLZ) and haloperidol (HAL) elicited significant dose-dependent increases in all brain regions. Except for IFN, NPC 16377 and other compounds increased plasma ACTH and corticosterone levels. Interestingly, NPC 16377 caused a significant suppression of plasma prolactin levels while all other compounds (HAL, IFN, BMY and CLZ) exhibited dose-dependent increases in prolactin. These results provide evidence for a unique neuroendocrine and neurochemical profile associated with acute administration of the sigma selective ligand, NPC 16377, as compared to other agents exhibiting activity at the sigma receptor.

133.17

EFFECTS OF NPC 16377, A POTENT AND SELECTIVE SIGMA LIGAND, ON THE ELECTROPHYSIOLOGICAL PROPERTIES OF MESENCEPHALIC DOPAMINE-CONTAINING NEURONS IN THE RAT. P. D. Shepard and H. Romeyn. MD Psychiatric Res. Cntr., Baltimore, MD 21228.

The aminoalkoxychromone derivative NPC-16377 (NPC) is a highly potent and selective sigma ligand with a low affinity for the dopamine (DA) D₂ receptor (Erickson et al., Karbon et al., this meeting). Preclinical pharmacological studies have indicated that NPC exhibits many of the same biochemical and behavioral effects ascribed to antipsychotic drugs (APDs) possessing a reduced liability for producing extrapyramidal side effects (Abreu et al., Clissold et al., *ibid*). In an effort to determine whether NPC exhibits an electrophysiological profile characteristic of "atypical" APDs, extracellular single unit recording techniques are being used to assess the effects of this compound on the activity of DA-containing neurons in the substantia nigra (SNc) and ventral tegmental area (VTA) of the chloral hydrate anesthetized rat. Systemic administration of NPC (8 - 128 mg/kg, i.v.) produced a dose-dependent increase in the activity of SNc (ANCOVA F(6,36) = 16.7 p < 0.001) and VTA (F(5,50) = 5.9 p < 0.01) DA-containing neurons. Both the proportion of neurons excited by the drug as well as the magnitude of the excitation varied considerably between individual neurons. None of the cells sampled exhibited a significant change in firing rate in response to doses below 8 mg/kg. A single bolus injection of NPC (16 mg/kg, i.v.) failed to antagonize the rate-decreasing effects of an autoreceptor-selective dose of apomorphine (10 µg/kg, i.v., n=6). However, comparable doses of the drug were found to partially antagonize the inhibitory effects of d-amphetamine (0.8 mg/kg, i.v., n=10). These data are consistent with the results of recent behavioral studies in which NPC has been found to antagonize the locomotor stimulant effects of indirect but not direct-acting DA agonists (Clissold et al, this meeting).

133.14

BEHAVIORAL PROFILE OF NPC 16377, A POTENT AND SELECTIVE SIGMA LIGAND. D.B. Clissold, T. Hartman*, H. Valentine, M.E. Abreu, R. Erickson, E.W. Karbon, M.J. Pontecorvo and J.W. Ferkany. CNS Research and Medicinal Chemistry, Nova Pharmaceutical Corporation, Baltimore, MD 21224.

NPC 16377 (NPC) has been described as a potent and selective ligand at sigma sites in brain membranes. Because sigma selective compounds may represent novel therapeutics for the treatment of psychoses, the effects of NPC were explored in a variety of tests predictive of antipsychotic or neuroleptic potential.

In rats, NPC (i.p. and p.o.) as well as clozapine (Clozaril, CLO, i.p., p.o.), BMY 14802 (BMY, i.p., p.o.) and Haloperidol (Haldol, HAL, i.p.) reduced avoidance but not escape behavior in the conditioned avoidance paradigm. In mice, NPC, HAL, CLO and BMY reversed d-Amphetamine-stimulated hyperlocomotion following p.o. administration, but only HAL and NPC did so at doses that did not reduce spontaneous locomotion. NPC (i.p.) also reversed d-Amphetamine stimulated hyperlocomotion in rats. NPC and CLO, in contrast to BMY and HAL, did not affect apomorphine-induced climbing in mice until locomotor suppressant doses were administered. Consistent with results from sigma binding studies, NPC effectively reversed the behavioral actions of (+)SKF 10047. At doses 10-fold greater than those eliciting behavioral responses in mice, NPC (p.o.) failed to impair rotarod performances or induce catalepsy; lethality was also absent until extreme doses were administered. The data are consistent with the suggestion that potent and selective sigma ligands, in particular NPC, may have antipsychotic properties.

133.16

IN VITRO AND IN VIVO BINDING PROPERTIES OF NPC 16377, A POTENT AND SELECTIVE LIGAND FOR SIGMA BINDING SITES. W. Karbon, M. Bailey*, S. Borosky, M. Abreu, L. Martin, R. Erickson, K. Natalie*, M. Pontecorvo and J. Ferkany. Nova Pharmaceutical Corporation, Baltimore, MD 21224-2788.

Several studies have implicated sigma binding sites in mediating the behavioral effects of several potential antipsychotic and cerebroprotective agents including rimcazole, BMY 14802 and ifenprodil. We have recently synthesized a series of potent sigma agents, exemplified by NPC 16377, which has been tested for its ability to interact with CNS binding sites both *in vitro* (Table 1) and *in vivo*.

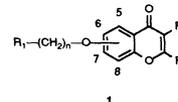

TABLE 1 IN VITRO BINDING PROPERTIES OF SIGMA AGENTS

Compound	DTG	PPP	IC ₅₀ (nM) versus [³ H]		
			Sulpiride	Ketanserin	8-OH-DPAT
NPC 16377	36	43	2671	1184	9110
Haloperidol	7	4	0.7	24	18700
Ifenprodil	16	52	170	nt	nt
BMY 14802	237	275	3030	419	837

NPC 16377 also inhibited [³H] SKF 10,047 binding *in vivo*, having ID₅₀ values of 1.4 and 2.9 mg/kg following i.p. and p.o. administration, respectively, but did not inhibit [³H] raclopride binding at doses up to 50 mg/kg i.p. The results of these studies indicate that NPC 16377 is a potent and selective ligand for sigma binding sites.

133.18

AMINOALKOXYCHROMONES AS SELECTIVE SIGMA RECEPTOR BINDING AGENTS. R.H. Erickson, K.J. Natalie, Jr., W. Bock*, Z. Lu*, J. Clifton*, W.J. Rzesotarski*, D.J. Meloni*, F. Farzin*, R.J. Patch*, M.J. Pontecorvo, M.A. Bailey*, K. Naper*, and E.W. Karbon. CNS Division, Nova Pharmaceutical Corporation, Baltimore, MD 21224.

Recent reports have suggested that a sigma receptor antagonist lacking activity at dopamine D₂ receptors might possess antipsychotic activity yet would be devoid of the undesirable extrapyramidal side effects common to most antipsychotics currently in use. We have discovered that aminoalkoxychromones (1) are potent and selective sigma receptor ligands. We present the results of our structure-activity studies on (1) which led to the development of NPC 16377, a potent sigma ligand which exhibits selectivity versus not only dopamine D₂ receptors but also a variety of other neuroreceptors.

SYMPOSIUM. TROPHIC AGENTS AND THE DEVELOPMENT AND MAINTENANCE OF NEURONS. R. W. Oppenheim, Wake Forest Univ. (Chairperson); Y.-A. Barde, Max Planck Institute; Lars Olsen*, Karolinska Institute; M. V. Chao*, Cornell Univ. Med. Sch.; F. Collins, Synergen, Inc.; J. McManaman, Baylor College of Med.

This symposium is dedicated to the pioneering work of R. Levi-Montalcini and V. Hamburger on cell death and trophic interactions. In recent years substantial progress has been made in identifying new trophic agents and in characterizing the cellular and molecular mechanisms that mediate biological responses to neurotrophic molecules. Y.-A. Barde and Lars Olsen will describe studies on the three members of the NGF family: NGF, BDNF and NT-3. New discoveries regarding trophic agent receptors and their actions will be summarized by M.V. Chao. F. Collins will discuss the role of CNTF in mediating both neuronal survival during development and the response to injury of peripheral neurons in adult animals. Finally, J. McManaman will describe studies on a new, putative trophic agent, CDF, that acts on developing motoneurons to affect their survival and differentiation.

EXCITATORY AMINO ACIDS: RECEPTORS II

139.1

COMPARISONS BETWEEN THE FUNCTIONAL PROPERTIES OF GLUTAMATE RECEPTORS NATIVE TO CA3 HIPPOCAMPAL NEURONS AND RECOMBINANT GLUTAMATE RECEPTORS. T.A. Yerdorm, N. Burnashev*, P. Jonas*, P.H. Seeburg*, and B. Sakmann*. Max Planck Institut für medizinische Forschung und ZMBH Heidelberg, Germany.

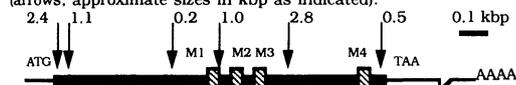

We have compared the functional properties of non-NMDA receptors found on the soma of CA3 rat hippocampal pyramidal neurons with those of transiently expressed recombinant glutamate receptor (GluR) subunits. Currents induced by kainate, AMPA and glutamate were measured in outside-out macropatches taken from pyramidal cells of brain slices and in HEK cells transfected with various combinations of cloned subunits. Currents mediated by both native and recombinant GluRs showed rapid and profound desensitization in response to fast application of 300 μ M AMPA and glutamate but not to 300 μ M kainate. Steady state currents in native membranes exhibited current-voltage relationships with prominent outward rectification (chord conductance ratio for 300 μ M kainate $G(+80)/G(-80) = 2.66 \pm 0.16$, $n=5$). Recombinant homomeric GluR-B channels as well as heteromeric combinations containing GluR-B also showed outward rectification (300 μ M kainate $G(+80)/G(-80)$ for GluR-B = 2.87 ± 1.04 , $n=4$; for GluR-A/B = 1.90 ± 0.14 , $n=5$). Combinations not containing GluR-B showed marked inward rectification ($G(+80)/G(-80) \approx 0$). This suggests that native GluRs in CA3 pyramidal cells contain at least a GluR-B subunit. Single channel amplitudes were estimated by noise analysis and in each case the apparent conductance of channels activated by kainate was different from that of channels opened by glutamate or AMPA. In native membranes the kainate-activated conductance was 3.0 ± 0.2 pS ($n=9$) whereas AMPA opened channels with an apparent conductance of 7.2 ± 0.7 pS ($n=9$). The estimated conductances in recombinant GluR-A/B combinations were 0.26 ± 0.05 pS ($n=9$) for kainate and 1.3 ± 0.1 pS ($n=10$) for glutamate. AMPA conductances were similar to those produced by glutamate and the differences between glutamate and kainate conductances were also seen with other homo- and heteromeric subunit combinations. Comparisons of other properties such as desensitization rate may help define the possible subunit structure of these neuronal receptors more clearly.

139.3

GLUTAMATE AND KAINATE RECEPTOR GENES AND SUBFAMILIES P. Gregor, X. Yang*, V. I. Teichberg* and G. R. Uhl. Lab. of Mol. Neurobiol., Natl. Inst. on Drug Abuse /ARC, & Dept. of Neurol. and Nsci., JHUSM, Box 5180, Baltimore, MD 21224. #Dept. of Neurobiol., The Weizmann Inst. of Sci., 76100 Rehovot, Israel.

The chicken kainate (K) binding protein (KBP) is a 49 kDa polypeptide abundant in cerebellar Bergmann glia. Cloning of its cDNA has revealed that KBP displays features typical of ligand-gated ion channels and that it is encoded by a single copy gene producing two major transcripts of 4 and 6 kb.

We have now isolated the structural portion of the chicken KBP gene on a 16 kbp genomic fragment, and report here that its intron/exon organization is homologous to that of ligand-gated ion channels. The analysis shows at least 6 introns in the coding region (arrows; approximate sizes in kbp as indicated):

Reverse transcription/PCR of brain poly(A)-RNA with primers adjacent to the 1.1 kbp intron suggests the presence of several transcripts. We speculate that alternate splicing might also generate the 93 kDa polypeptide, which we have shown to be immunologically related to KBP.

We have also cloned two cDNA fragments encoding new GluR subunits, termed GluR6 and GluR7. These belong to a novel subfamily, together with the previously characterized, but unclassified, subunit GluR5 (77% nucleotide sequence identity).

These data confirm and extend the evidence for diversity of excitatory amino acid receptors.

Supported by NIDA (G.R.U.), and by ALS and Alzheimer's assoc. (V.I.T.)

SYMPOSIUM. NEURAL NETWORK MODELS OF VERTEBRATE SENSORIMOTOR SYSTEMS. B. Peterson, Northwestern Univ. (Chair); S. Grillner, Karolinska Inst.; D. Bullock*, Boston Univ.; J. Bower, Caltech; E. Fetz, Univ. of Washington

Neural network models have evolved to the point where investigators with a detailed working knowledge of neural pathways that mediate vertebrate sensorimotor behaviors can use them to gain insights into how these pathways may function. This symposium concentrates on such anatomically and physiologically based modeling efforts. Grillner will describe a realistic hybrid model of the lamprey locomotor system that simulates both biophysical and pharmacological properties of individual neurons and behavior of circuits of which they form a part. This network replicates the alternating swimming rhythm and its modulation by sensory, intersegmental and supraspinal mechanisms. Bullock will describe a model spinal cord network of Renshaw cells and Ia interneurons that achieves independent control of muscle length and joint stiffness in neuromuscular systems that conform to the size principle of motor unit recruitment and also generates realistic tri-phasic EMG bursts during movement. Bower will describe structurally realistic models of cerebellar cortex and olivo-cerebellar circuits intended to shed light on the role of the cerebellum in the motor control of sensory performance. Peterson will describe neural networks that model dynamic and adaptive properties of the vestibuloocular reflex (VOR) and that suggest where changes must occur in brainstem-cerebellar VOR circuits to produce experimentally observed adaptive changes in gain, phase and direction of the VOR. Fetz will discuss dynamic recurrent networks that simulate a step-tracking task by transforming changes in target position into appropriate patterns of motor unit activity; these networks provide new insights into the connections and response patterns of premotoneuronal cells recorded in monkeys. In addition to their functional relevance, these models are of theoretical interest since attempts to deal with realistic systems and actual observed data have forced the modelers to devise new approaches that do not always follow the paths taken by more abstract modelers.

139.2

MOLECULAR CLONING AND DEVELOPMENTAL ANALYSIS OF A THIRD ISOFORM OF RAT GLUR-4. V. Gallo, L.M. Upson, W.P. Hayes and A. Buonanno, Unit on Mol. Neurobiol. and Section on Cell. Neurobiol., LDN, NICHD, NIH, Bethesda, MD 20892.

The glutamate receptor GluR-4 has been proposed to have two spliced isoforms (flip and flop; Sommer et al., Science 249, 1583, 1990). By screening a rat cerebellar library, we have isolated a cDNA obtained from a third transcript (GluR-4c) of the glutamate receptor gene GluR-4. This additional isoform of the flop version of GluR-4 encodes a protein that has a C-terminus segment of 36 amino acids different from the previously described GluR-4 flip/flop. Transcripts synthesized from the GluR-4c cDNA form kainate/AMPA-activated channels in oocytes (see Winters et al., Soc. Neurosci. Abs., 1991). Using oligonucleotide probes specific for the three isoforms, transcripts of 6.2, 4.2 and 3.0 kb derived from the GluR-4 gene were identified. Northern blots revealed that the levels of the three transcripts increase during cerebellar development, with a maximal increase between postnatal day 1 (P1) and 8 (P8). The 6.2 and 4.2 transcripts are present in cultured cerebellar granule cells and astrocytes, but the 3.0 kb transcript is present only in granule cells. *In situ* hybridization histochemistry revealed that the GluR-4c transcripts are preferentially expressed in cerebellar granule cells and Bergmann glial cells. In P1 and P8 cerebella, granule cells were labelled also in the external germinal layer, before their migration into the internal granule cell layer. GluR-4 flip- and flop-specific oligonucleotide probes also showed that the flip GluR-4 isoform labelled the granule cell layer only faintly, whereas both probes labelled Bergmann glial cells in the Purkinje cell layer.

DIVALENT ION PERMEABILITY AND PHARMACOLOGY OF CLONED KAINATE/AMPA RECEPTORS EXPRESSED IN OOCYTES. J.F. McGurk, R.S. Roginski, R.S. Zukin and M.V.L. Bennett, Dept. Neuroscience, Einstein Coll. Med., Bronx, NY 10461.

The GluR-1, -2, -3 and -4 glutamate receptor genes of rat brain encode channels activated by both kainate and AMPA. Each gene encodes RNAs that undergo alternate splicing to yield receptor variants termed "flip" and "flop". GluR-1 "flip" and "flop" and GluR-3 "flop" clones were transcribed and the cRNAs injected into *Xenopus* oocytes. Oocytes injected with either the GluR-1 or GluR-3 cRNAs generated large (>1500nA) inward currents when perfused with 500 μ M kainate and voltage-clamped at -100mV. Subunit cRNAs injected singly or GluR-1 "flip" and GluR-3 "flop" injected together directed translation of channels permeable to $Ca^{2+} > Sr^{2+} > Ba^{2+} > Co^{2+} = Mg^{2+}$. The current-voltage relation of these receptor channels in normal Ringer's solution showed inward rectification. This rectification was also evident in medium in which the only permeant cation was one of the divalent cations listed above. In GluR-1 "flip"-injected oocytes currents were elicited by L-glutamate ($EC_{50} = 25 \mu$ M; Hill coefficient (n) ~ 1), kainate ($EC_{50} = 60 \mu$ M; $n \sim 1$) and AMPA ($EC_{50} = 7 \mu$ M; $n \sim 1$). GluR-3 "flop"-injected oocytes showed a modest shift in the dose-response for kainate ($EC_{50} \sim 100 \mu$ M) with no change in n , as well as much reduced responses to L-glutamate and AMPA. Kainate and AMPA responses were blocked by the relatively selective antagonist CNQX ($IC_{50} = 0.5 \mu$ M at 100 μ M kainate and 3 μ M at 5 μ M AMPA). The IC_{50} for CNQX block in GluR-3 "flop"-injected oocytes is near 0.3 μ M (at 50 μ M kainate). Cloned kainate/AMPA receptors exhibit properties different from those of receptors expressed from rat brain mRNA.

CALCIUM MAY DIRECTLY PERMEATE KAINATE RECEPTORS IN CULTURED CEREBELLAR PURKINJE NEURONS R.J. Miller, J.R. Brorson, D. Bleakman and P.S. Chard, Department of Physiological and Pharmacological Sciences, The University of Chicago, Chicago IL 60637.

Glutamate receptors of the non-NMDA classes have been thought to have low permeability to Ca^{2+} . However, a Ca^{2+} -permeable subtype of the kainate (KA) receptor has recently been described. We have examined the effects of KA upon cerebellar Purkinje neurons, which lack NMDA receptors. About one half of neurons cultured from E16 rat embryos were identified as Purkinje neurons by immunocytochemical labelling for calbindin D-28k. Most neurons lacked any direct response to NMDA (10-50 μ M) when synaptically mediated responses were blocked with TTX (1 μ M) and CNQX (10 μ M). We used whole cell voltage clamp recording and simultaneous amphotericin B perforated patch clamp/ fura-2 microfluorimetry to examine KA induced inward currents and $[Ca^{2+}]_i$ increases. In Na^+ free solutions, with the cerebellar neurons voltage clamped at -80mV, KA (10-50 μ M) induced inward currents and increases in somatic $[Ca^{2+}]_i$. Such responses could be blocked by CNQX (10 μ M). Removal of the extracellular Ca^{2+} abolished the $[Ca^{2+}]_i$ responses. KA-induced $[Ca^{2+}]_i$ increases were also seen in physiological (Na^+ containing) solutions. These results suggest that KA receptors in these neurons may have appreciable Ca^{2+} permeability.

Cloning, expression and gene structure of a G-protein coupled glutamate receptor. K.M. HOJAMED, W. ALMERS, Dept. of Physiol. and Biophys., Univ. of Washington, Seattle, WA 98195 and J.L. KUIJPER*, T.L. GILBERT*, B.A. HALDEMAN*, P.J. O'HARA*, E.R. MULVIHILL*, E.S. HAGEN*, Zymogenetics Inc., Seattle, WA 98105

Metabotropic glutamate receptors (GluGRs) couple to G-proteins rather than acting as ligand-gated ion channels. A cDNA for a GluGR was cloned from rat cerebellum. It encodes a large protein of 1199 amino acids (AAs). This protein may be divided into three domains: a large (577 AAs) N-terminal that is probably extracellular, a large (312 AAs) C-terminal that is probably intracellular, and a central region (310 AAs) with the 7 hydrophobic transmembrane sequences typical of other G-protein coupled receptors. The GluGR gene contains at least two introns which define the coding region of the central domain and separate it from the two others. The GluGR has no detectable sequence similarity with other known G-protein coupled receptors, and hence represents a prototype for a new receptor family. Its N-terminal has limited similarity to the egg peptide hormone receptor from sea urchins, a peptide receptor with guanylate cyclase activity. Agonists for the GluGR cause IP_3 -driven, Ca^{2+} -activated Cl^- current in *Xenopus* oocytes. The half-maximal concentrations are quisqualate (0.7 μ M), glutamate (12 μ M), l-ibotenate (32 μ M), and *trans*-ACPD (0.38 mM). Aspartate, kainate (1 mM), or NMDA, AMPA (0.1 mM) had no discernible effects. AP3 antagonized the responses, and pertussis toxin blocked the transduction pathway. This pharmacological profile is expected for metabotropic GluGRs. Supported by NIH # AR-17803.

RESPONSE TO METABOTROPIC GLUTAMATE RECEPTOR ACTIVATION IN CEREBELLAR PURKINJE CELLS

T. Knöpfel, I. Vranesic* and C. Staub*

Brain Research Institute, University of Zürich, CH-8029 Zürich (Switzerland)

Excitatory amino acids (EAA) interact with receptors which operate ion channels (e.g. NMDA and AMPA receptors) as well as with receptors coupled to second messenger systems (i.e. metabotropic receptors). We have investigated the response to activation of metabotropic EAA receptors in slice cultured Purkinje cells which were voltage-clamped (-55 to -65 mV) and superfused with a balanced salt solution containing 0.5 μ M TTX.

Bath application of AMPA (1 - 2 μ M), quisqualate (0.25 μ M) or *t*-ACPD (50 - 100 μ M) induced an inward current. The AMPA-current was abolished by CNQX, while inward currents induced by quisqualate or *t*-ACPD were partially reduced or left unchanged, respectively, by this AMPA receptor antagonist. This pharmacological profile suggests that the CNQX insensitive inward current was mediated by a metabotropic EAA receptor.

This inward current was not blocked by Ba^{2+} (1 mM), Mg^{2+} (10 mM), TEA (10 mM) or Cs^+ (1 mM), thus does not appear to be generated by a block of potassium conductances as described in hippocampal pyramidal cells (Nature, 347:765-767). We demonstrated that the inward current was associated with a rise in $[Ca^{2+}]_i$, as measured with fura-2 and can be attributed to a Na^+/Ca^{2+} exchanger current following the release of Ca^{2+} from internal stores.

HIGH AFFINITY 3H -MK801 BINDING TO MOUSE BRAIN NEURONS IN CELL CULTURE IS SENSITIVE TO NMDA ANTAGONISTS. L.M. Nowak*, B.G. Gurshtman*, C. Pouloupoulou*, M.M. Salpeter* and G.A. Weiland*, Depts of Pharmacology* and Neurobiology & Behavior^o, Cornell Univ., Ithaca, NY 14853.

The uncompetitive NMDA antagonist MK801 binds with high affinity to activated NMDA channels. Under conditions where the NMDA channels close (e.g. addition of the competitive antagonist APV), MK801 can be "trapped" at its binding site. Anticipating that by taking advantage of this capacity to trap MK801 we might be able to use 3H -MK801 as a probe of NMDA channel distribution for high resolution autoradiography, we designed a set of conditions for obtaining specific 3H -MK801 binding to NMDA channels in intact neurons. Forebrains from 15-17 day mouse embryos were grown in cell culture using conventional methods. Binding assays were performed on mixed neuron and glial cell cultures (7-10 days *in vitro*) or on glia cultures (2-3 mos. *in vitro*) at room temperature. Cultures were incubated for 60 min with 3H -MK801 in a balanced salt solution containing (in mM): 150 NaCl, 2.5 KCl, 1.0 $CaCl_2$, 10 Hepes-Na (pH 7.5), 1.0 dithiothreitol, 3% sucrose and 300 nM tetrodotoxin. Saturation binding done in the presence of 10 μ M L-GLU and 2 μ M glycine gave evidence for two sites in mixed cultures and one site in glia cultures. The low affinity (apparent $K_D \sim 300$ nM to 2 μ M) binding was APV insensitive and present on both glial cultures and in mixed cultures. Whether this site represents uptake remains unclear since saturation was not easily demonstrated. In contrast, high affinity binding ($K_D \sim 0.5$ to 5 nM; B_{max} 10-30 pM/35 mm culture dish) was saturable, inhibited by 3 mM APV, stimulated by GLU plus glycine, and only present in cultures containing neurons. This is consistent with high affinity binding being associated with NMDA receptor-channels. Supported by NS24467 to LMN and GM10422 to MMS.

ACTIVATION OF THE ACPD SUBTYPE OF EXCITATORY AMINO ACID RECEPTOR DECREASES SYNAPTIC INHIBITION IN HIPPOCAMPAL AREA CA1. M.A. Desai and P.J. Conn, Department of Pharmacology, Emory University School of Medicine, Atlanta, GA 30322.

Glutamate-stimulated phosphoinositide hydrolysis is mediated by a novel subtype of excitatory amino acid receptor termed the ACPD receptor. To determine the physiological role of ACPD receptor activation, we examined the effects of *trans*-ACPD (a selective agonist at this site) on evoked extracellular field potentials from each of the three major regions of the hippocampus. We report that *trans*-ACPD increased population spike amplitude in areas CA1, and CA3, and induced formation of multiple population spikes in area CA1, but not area CA3. In contrast, *trans*-ACPD caused a decrease in population spike amplitude in the dentate gyrus. Evidence suggests that the effect of *trans*-ACPD in areas CA1 and CA3 are at least partially mediated by direct excitatory effects on pyramidal cells. We now report that *trans*-ACPD also decreases synaptic inhibition in area CA1. This was seen as a decrease in paired-pulse inhibition of extracellular field potentials and a decrease in the fast and slow components of intracellular IPSPs evoked by stimulation of Schaffer collateral afferents. This disinhibition is likely to contribute to induction of multiple population spikes, an effect of ACPD that is only seen in area CA1. Thus, *trans*-ACPD enhances excitatory synaptic responses in area CA1 by a combination of direct excitatory effects on pyramidal cells and by a decrease in synaptic inhibition. (Supported by N.I.H. Grant NS28405-01).

GLUTAMATE MEDIATED TRANSMISSION OF INSPIRATORY DRIVE TO PHRENIC MOTONEURONS IS INHIBITED BY AP4 AT PRESYNAPTIC SITE. J.L. Feldman, J.J. Greer, & J.C. Smith, Systems Neurobiology Lab., Dept. Kinesiology, UCLA, Los Angeles, CA 90024-1527.

Excitatory amino acids (EAAs) mediate inspiratory drive to phrenic motoneurons largely via monosynaptic bulbospinal projections. AP4 strongly inhibits inspiratory activity of phrenic motoneurons. The inhibition is not associated with a change in phrenic motoneuron input resistance or resting membrane potential. In addition AP4 does not block the depolarization induced by either quisqualate, kainate or glutamate. The present study was designed to answer two fundamental questions pertaining to these earlier findings: 1) What is the identity of EAAs mediating inspiratory drive to phrenic motoneurons? 2) Is the site of AP4 inhibitory action pre or postsynaptic?

Spontaneous respiratory drive was recorded from cranial nerve (X) and C4 (phrenic) ventral roots in *in vitro* neonatal rat brainstem-spinal cord preparations (n=6). A barrier at the spinomedullary junction allowed for the addition of drugs to bathing solutions surrounding either the spinal cord or brainstem. Three sets of experimental protocols were followed: i) 500 μ M DHK (EAA uptake inhibitor) was added to the solution bathing the spinal cord while the preparation spontaneously generated respiratory activity for 30 minutes. The solution bathing the spinal cord (1 ml) was analyzed for the presence of amino acids by HPLC. ii) Protocol i) was repeated with the descending bulbospinal respiratory drive abolished by the addition of 3.0 μ M CNQX to the solution bathing the brainstem. iii) protocol i) was repeated with the phrenic motoneuron activity depressed by the addition of 100 μ M DL-AP4 to the solution bathing the spinal cord.

Removing inspiratory synaptic drive to spinal motoneurons (protocol ii) decreased the amount of glutamate to $24 \pm 7\%$ of that collected in the presence of inspiratory drive (protocol i). The addition of AP4 in the presence of inspiratory drive (protocol iii) decreased the concentration of glutamate to $12 \pm 8\%$ of control. Aspartate levels were unchanged in all cases. Thus, we conclude: 1) Glutamate is the primary EAA mediating synaptic transmission of inspiratory drive to phrenic motoneurons. 2) AP4 acts presynaptically to reduce the amount of glutamate released from bulbospinal terminals. DETERMINANTS OF THE AMPLITUDE AND TIME COURSE OF EXCITATORY SYNAPTIC EVENTS IN THE RAT HIPPOCAMPUS. CF Zorumski, LL Thio, GD Clark & DB Clifford. Washington Univ Med Sch, St Louis, MO 63110.

Quisqualate responses in vertebrate CNS neurons desensitize rapidly and profoundly. This rapid desensitization is blocked by the lectin wheat germ agglutinin (WGA) (Neuron, 5, 61, 1990). We examined the effect of WGA on evoked excitatory postsynaptic currents (epscs) in pairs of cultured postnatal rat hippocampal neurons to determine whether desensitization regulates excitatory synaptic transmission. Evoked epscs mediated by non-NMDA receptors decayed with a time constant of 6.5 ± 0.3 ms (\pm SEM) at -70mV which is comparable to the 100μ M quisqualate channel burst duration of 6.4 ± 0.2 ms at -80mV. Evoked epscs increased in amplitude by $100 \pm 27\%$ and decayed $42 \pm 11\%$ more slowly after treatment with 580nM WGA. The time constant of decay increased from 5.8 ± 0.6 ms to 7.9 ± 0.5 ms. Similarly, spontaneous miniature epscs recorded in 1μ M TTX increased in amplitude by $53 \pm 11\%$ and decayed $48 \pm 23\%$ more slowly after WGA treatment. These changes were not accompanied by a change in mepsc frequency. Combined with the WGA-induced increase in quisqualate-gated channel burst length (Soc Neurosci Abstr, 16, 547, 1990), these results suggest that the decay of evoked epscs is determined by channel burst length and that desensitization regulates excitatory synaptic strength.

VISUALIZATION OF THE TURTLE EYE-BLINK REFLEX ARC WITH THE ACTIVITY-DEPENDENT DYE SULFURHODAMINE. J.C. Houk and L. Keifer. Dept. of Physiology, Northwestern University Medical School, Chicago, IL 60611.

To examine mechanisms underlying adaptive plasticity in the cerebellar circuit, we have used the *in vitro* turtle brainstem-cerebellum in which to study the conditioned eye-blink reflex (Keifer & Houk, Soc. Neurosci. Abs. 16: 763, 1990). One technique to study the spatial distribution of neuronal activity specific to the unconditioned and conditioned reflex responses is the application of the dye sulfurhodamine 101. This dye, when applied to the bath containing the *in vitro* preparation, appears to be taken up in an activity-dependent manner by neuronal cell bodies and dendrites that are activated by an electrical stimulus (Houk et al., Soc. Neurosci. Abs. 15: 612, 1989). We report here the visualization of the turtle eye-blink reflex arc during physiological monitoring of the unconditioned reflex response.

The neural correlate of the eye-blink reflex was evoked by a single shock to the trigeminal nerve in the *in vitro* turtle brainstem-cerebellum and recorded from the abducens nerve as a burst of action potentials. During physiological recording of the reflex, a 0.1% solution of sulfurhodamine 101 was added to the bath. The dye was applied for 50 min while the reflex was activated once every 30 s. The preparation was then washed for 20 min in normal saline and immersion fixed in 4% paraformaldehyde. Using rhodamine epifluorescence, well-labeled cell bodies were observed unilaterally in the trigeminal, abducens, and accessory abducens nuclei. Neurons in the superior and magnocellular reticular formation, as well as the raphe, were also labeled. In two cases the reflex arc was clearly visualized as the axonal projections from the trigeminal nucleus to abducens and accessory abducens were well labeled. Bath application of CNQX, which blocks the reflex response, during sulfurhodamine application results in no label in the trigeminal, abducens or accessory abducens nuclei. These results support the hypothesis that uptake of sulfurhodamine is activity-dependent since the sites labeled in these experiments are specific to the reflex under study. Further, this dye will provide a useful tool to study active regions in the nervous system involved in the acquisition of the conditioned eye-blink response.

THE ROLE OF AMYGDALA CENTRAL NUCLEUS IN ASSOCIATIVE LEARNING. M. Gallagher & P. C. Holland* Department of Psychology, University of North Carolina, Chapel Hill, NC 27599 and Department of Psychology, Duke University, Durham, NC 27706.

A common view of the learning function served by the amygdala central nucleus (CN) is that of associating the emotional significance of events with relevant cues for those events. For example, animals with CN damage are viewed as deficient in the ability to acquire conditioned fear. Our results indicate another function for CN that emphasizes its role in attentional processing.

Our research using appetitive Pavlovian procedures revealed that rats with neurotoxic damage of the central nucleus (CN) are deficient in conditioned but not unconditioned orienting behavior. This suggests that CN damage may produce impairment in other tasks that require attention to the conditioned stimulus (CS). Although animals normally ignore a redundant CS that is added to a predictive CS (blocking), either increasing or decreasing reinforcement magnitude can direct attention to a redundant CS and produce learning (unblocking). Indeed, unblocking caused by a downshift in reinforcement magnitude uniquely requires an attentional process to account for conditioning to the redundant CS. Rats with CN damage exhibited unblocking in response to an increase, but not in response to a decrease, in reinforcement magnitude. These, and other data, support a role for CN in attentional (CS) processing.

FUNCTIONAL BRAIN SYSTEMS FOR DIFFERENTIAL CONDITIONING OF TONE-SIGNALLED REWARD DEMONSTRATED USING 2-DEOXY-2-FLUORO-D-GLUCOSE AUTORADIOGRAPHY. F. Gonzalez-Lima¹, F.J. Helmstetter², and J. Agudo³. ¹Dept Psychol and Inst Neurosci, Univ of Texas at Austin, Austin, TX 78712; ²Dept Psychol, Univ of Wisconsin at Milwaukee, Wisc 53201; ³Dept Cell Biol, Univ of Valladolid, Spain.

Five groups of rats were injected with 2-DG and exposed to two FM tones of low and high frequencies. In group 1 the low tone was paired with water reward (CS+) and in group 2 the high tone was paired. In group 3 stimuli were explicitly unpaired and in group 4, randomly presented. Group 5 was conditioned but satiated prior to 2-DG testing. Two kinds of changes were observed in the auditory system: 1) enhanced responses of the brainstem nuclei such as cochlear were always dependent on the learned signal value of CS+ vs. CS- in thirsty and satiated rats; 2) at higher levels such as the inferior colliculus, increases in activity to CS+ were dependent on the reinforcing value, i.e. if CS+ was presented to satiated rats, no enhanced responses were observed. Nonauditory structures with learning-related 2-DG increases during conditioning with two CSs or one CS included caudate-putamen and intralaminar thalamus. Additional structures changed during CS+/CS- differentiation of drinking response included reticular thalamus, flocculus and facial nucleus, all with suppression of 2-DG uptake. This metabolic suppression of neural substrates with the two CSs, provide for the first time a neuroanatomical basis for the behavioral process of response inhibition described by Pavlov during CS+/CS- differentiation. (R01 MH43353)

140.4

EFFECTS OF RHINAL CORTICAL OR LIMBIC LESIONS ON FEAR REACTIONS IN RHESUS MONKEYS. M. Meunier, J. Bachevalier, E.A. Murray, P.M. Merjanian, and R. Richardson, Lab. Neuropsychology, NIMH, Bethesda, MD 20892.

The fear reactions of monkeys with ablation of the rhinal cortex (N=3) were compared to those of monkeys with damage to the amygdala either alone (N=3) or in combination with the hippocampus (N=3) and of unoperated controls (N=4). The stimuli used were a toy snake, a taxidermic monkey head, a human wearing a mask, and an object covering food. The 4 stimuli were shown for 20 sec each on each of 3 days. Monkeys with lesions of the rhinal cortex showed more freezing behavior than the normal controls, particularly in the presence of the masked human, combined, paradoxically, with an absence both of facial expression and of submissive behavior. Animals with amygdalotomy, by contrast, displayed a total loss of fearful reactions, fewer aggressive responses than normals, and an increased tendency to examine objects, often orally. These data suggest that the rhinal cortex interacts complexly with the amygdala in the mediation of fear.

140.5

EFFECTS OF ANTERIOR RHINAL CORTICAL LESIONS ON DELAYED NONMATCHING-TO-SAMPLE IN RHESUS MONKEYS. E.A. Gaffan* and E.A. Murray. Dept. Psych., Reading Univ., Reading, U.K. and Lab. Neuropsychol., NIMH, Bethesda, MD 20892.

Prior work had indicated that rhesus monkeys with aspiration lesions of the amygdaloid complex (A) plus subjacent portion of the anterior entorhinal cortex were impaired on a version of delayed nonmatching-to-sample (DNMS) employing a single pr. of repeatedly used objects (Mishkin and Oubre, 1976, *Soc. Neurosci. Abstr.* 2:1127), and the deficit was attributed to the A damage. Because complete removals of the rhinal cortex (comprised of both the entorhinal cortex and perirhinal cortex) alone have been found recently to yield severe impairments on DNMS, we tested whether damage to the anterior rhinal cortex (Ant Rh) is responsible for the deficit on DNMS with a single pr. Naive rhesus monkeys were trained on versions of DNMS with both 20 prs. and a single pr., received either Ant Rh lesions, neurotoxic lesions of A, or were kept as unoperated controls, and were retrained postoperatively on both versions of DNMS. Preliminary results indicate that monkeys with Ant Rh lesions relearned DNMS with 20 prs. as rapidly as the controls, but they took significantly longer than controls to relearn the single-pr. version (Ant Rh, \bar{X} =310 trials and 82 errors; Con, \bar{X} =0 trials and 0 errors). The deficit on single-pr. DNMS reported earlier to follow A removal by aspiration is due, at least in part, to Ant Rh damage.

140.7

EFFECTS OF NEONATAL LESIONS OF THE AMYGDALOID COMPLEX OR HIPPOCAMPAL FORMATION ON THE DEVELOPMENT OF VISUAL RECOGNITION MEMORY. J. Bachevalier and M. Mishkin. Lab. Neuropsychology, NIMH, Bethesda, MD 20892.

Assessment of the effects of early combined amygdalo-hippocampal lesions on the development of cognitive functions in monkeys pointed to a severe, long-lasting impairment in visual recognition memory, but sparing of the ability to form visual discrimination habits (Bachevalier and Mishkin, *Soc. Neurosci.*, 14:1, 1988). Here we investigated the separate contributions of the amygdaloid complex and hippocampal formation to the development of recognition memory. Six monkeys with neonatal damage to the amygdaloid complex and rostral entorhinal cortex (A+) and 6 with neonatal damage to the hippocampal formation, caudal entorhinal cortex, and parahippocampal gyrus (H+) were tested at 10 months of age in delayed nonmatching-to-sample, with trial-unique objects. Delay intervals ranged up to 2 min and list lengths up to 10 objects. The H+ group did not differ from normal controls, whereas the A+ group was significantly impaired, though their impairment was not as severe as that of the earlier group with combined lesions. The data suggest that, in the monkey, either the amygdala, the rostral entorhinal cortex, or both contribute more than the hippocampal formation to the development of recognition memory.

140.9

RECOGNITION MEMORY IMPAIRMENT IN MONKEYS WITH SELECTIVE HIPPOCAMPAL LESIONS. R.P. Clower, P. Alvarez-Royo, S. Zola-Morgan, and L.R. Squire. UCSD Depts. of Neuroscience and Psychiatry, La Jolla, CA 92093 and V.A. Medical Center, La Jolla, CA 92161.

Work with an animal model of human amnesia in the monkey has shown that the hippocampal formation and the neuroanatomically related perirhinal and parahippocampal cortices are critical components of the medial temporal lobe memory system (Zola-Morgan and Squire, 1990). Findings from patient R.B. suggested that ischemic damage limited to the hippocampus can produce clinically significant amnesia. In the monkey, however, identification of the separate contributions to memory of the hippocampus itself has not been possible because a direct surgical approach necessarily damages underlying cortex (i.e., posterior entorhinal and parahippocampal cortex). One important question is whether surgical lesions limited to the hippocampus produce detectable memory impairment.

Using magnetic resonance imaging to help establish stereotaxic coordinates, we have successfully produced circumscribed, bilateral lesions of the hippocampus (the H lesion), including the CA fields, the dentate gyrus, and the subiculum, but sparing parahippocampal, perirhinal, and entorhinal cortex (Alvarez-Royo et al., *S.N. Abs.*, 1990). Four monkeys with the H lesion were compared to seven normal animals and three monkeys with lesions that included the hippocampus, parahippocampal cortex, and posterior entorhinal cortex (the H+ lesion) on delayed nonmatching to sample, a benchmark task of recognition memory in the monkey. At a delay interval of 10 minutes, H monkeys were as impaired as animals with the H+ lesion. Preliminary results from two additional memory tasks, delayed retention of easy object discriminations and concurrent object discrimination, indicate that H animals perform as well as normal animals and better than H+ animals. Together, these findings suggest that lesions limited to the hippocampus are sufficient to produce a memory impairment, but one that is overall less severe than the impairment associated with lesions that also damage adjacent cortex.

140.6

LONG-TERM EFFECTS OF NEONATAL LIMBIC LESIONS ON TACTILE RECOGNITION IN RHESUS MONKEYS. L. Malkova, J. Bachevalier, and M. Mishkin. Lab. Neuropsychology, NIMH, Bethesda, MD 20892.

Four animals with neonatal amygdalo-hippocampal lesions (AH), 4 with neonatal cortical area TE lesions (TE), and 6 normal controls (N) were trained in tactile delayed nonmatching-to-sample (DNMS) at the age of 6-7 years. The animals in Group TE were unimpaired, reaching criterion on 10-sec DNMS in 510 trials and averaging 77% on 30-120 sec delays, as compared to scores of 430 trials and 83%, respectively, in the normal controls. By contrast, none of the animals in Group AH reached the criterion in 1000 trials, though two did so with additional correction training. On 30-120 sec delays, these two animals averaged 68%. Despite their impairment in tactile recognition, Group AH animals performed as well as the normal controls in a tactile discrimination task. These data, together with the long-lasting visual recognition loss found earlier in Group AH, indicate that early damage to limbic structures results in a permanent, global, sensory memory loss.

140.8

NEUROPATHOLOGICAL AND BEHAVIORAL FINDINGS IN A MODEL OF GLOBAL ISCHEMIA IN THE MONKEY. N.L. Rempel, R.P. Clower, D.G. Amaral, S. Zola-Morgan, L.R. Squire. Depts. of Neuroscience and Psychiatry, UCSD, La Jolla, CA 92093, and V.A. Med. Center, San Diego, CA.

Patient R.B. became amnesic following an ischemic episode that resulted in a bilateral lesion of the entire CA1 field of the hippocampus. We have developed a model of global ischemia in the monkey (*S.N. Abs.* 15, 341, 1989). Four monkeys subjected to 15 min of ischemia (ISC) were tested on a battery of amnesia-sensitive tasks, including delayed nonmatching to sample (DNMS). We have now completed a thorough neurohistological examination of the brains from these animals.

Neuropathology: CA1 pyramidal cells were counted in Nissl-stained coronal sections in four quadrants (rostral to caudal) of the hippocampus. The results were compared to similar counts from 4 normal monkeys of approximately the same age and weight. Cell loss was more prominent in the caudal than in the rostral extent of the hippocampus. Specifically, in 3 animals, cell loss averaged 10% in the rostral 3 quadrants, and 30% in the caudal-most quadrant. Losses were even more striking in the fourth monkey, which had 70% cell loss in the rostral 3 quadrants and nearly 100% in the caudal quadrant. Total volume of the CA1 field was also reduced (~30% on average), suggesting that ischemia produces substantial losses in overall CA1 pyramidal cell number. Preliminary examination reveals no significant damage in other brain structures that have been implicated in memory function.

Behavior: ISC monkeys were as impaired on DNMS as monkeys with lesions of the hippocampal formation and adjacent cortex (H+). The impairment was still detectable 6-8 months after surgery. However, the ISC lesions produced significantly less impairment than H+ lesions on other memory tasks.

These findings suggest that ischemia consistently produces CA1 cell loss in monkeys, and that this loss produces enduring deficits in memory. The finding that the ISC lesion produced overall less memory impairment than H+ lesions suggests that the ISC animals (and by extension, patient R.B.) did not have widespread neuropathology affecting memory that was undetected by histological examination.

140.10

POSTOPERATIVE ACQUISITION OF DELAYED NONMATCHING TO SAMPLE WITH SHORT (0.5 SEC) DELAYS IS NOT IMPAIRED BY HIPPOCAMPAL FORMATION LESIONS IN MONKEYS.

P. Alvarez-Royo, S. Zola-Morgan, and L. R. Squire. UCSD Depts. of Neuroscience and Psychiatry, La Jolla, Ca 92093, and V.A. Medical Center, San Diego, Ca.

The delayed nonmatching to sample (DNMS) task is widely used to evaluate recognition memory in monkeys. In most studies, monkeys are initially trained using a delay interval of 8-10 seconds. Monkeys with large medial temporal lobe lesions that include the hippocampus, amygdala, and the perirhinal, entorhinal and parahippocampal cortices (H+A+ lesions) as well as monkeys with lesions of the hippocampal formation that include parahippocampal cortex (H+ lesions) can achieve high levels of performance at these delays (90% correct). However, they require significantly more trials than normal animals to reach this performance level. This impairment raises two possibilities: the learning of the nonmatching rule itself may be impaired, or, alternatively, the 8 second delay may be sufficiently long that memory-impaired animals have difficulty bridging it.

One way to distinguish between these two possibilities is to train monkeys using very short delays, thus decreasing the memory requirements of the task. Overman et al. (1990) trained monkeys at a 1-sec. delay and showed that H+A+ lesions did not impair postoperative relearning of the nonmatching rule. The question remains, however, as to how well animals with medial temporal lobe lesions would perform without the benefit of preoperative training. We prepared a group of monkeys with H+ lesions and trained them postoperatively on the DNMS task along with a group of normal monkeys, using a very short delay (0.5 sec). The animals with H+ lesions learned the task normally at this delay. However, they then performed significantly worse than normal animals at longer delays of 1 and 3 minutes. These data suggest that the impairment in learning the DNMS task commonly observed after lesions involving medial temporal lobe structures is not due to an impaired capacity to learn the nonmatching rule, but rather to a difficulty in bridging the 8-10 sec delays used for training the animals. The data also provide evidence that immediate (short-term) memory is independent of the medial temporal lobe memory system.

LESIONS OF THE PERIRHINAL AND PARAHIPPOCAMPAL CORTICES IN MONKEYS PRODUCE A MODALITY GENERAL AND LONG LASTING MEMORY IMPAIRMENT. W.A. Suzuki, S. Zola-Morgan, L.R. Squire, and D.G. Amaral. Group in Neurosciences and Dept. of Psychiatry, UCSD, La Jolla, CA 92093, V.A. Medical Center, San Diego, CA, 92161, and The Salk Institute, San Diego, CA 92138.

The perirhinal and parahippocampal cortices provide about 70% of the direct cortical input to the hippocampal formation, a structure long associated with memory function. We have recently shown that bilateral lesions limited to the perirhinal and parahippocampal cortices (PRPH I group) in the monkey produce a severe visual memory deficit on three amnesia-sensitive tasks, including the delayed non-matching to sample (DNMS) task (Zola-Morgan et al., 1989). We now present evidence from a second group of monkeys with PRPH lesions (PRPH II group) that the memory deficit produced by this lesion occurs in both the visual and tactual modalities, and endures for several years. The presence of a modality-general and enduring memory impairment is an important characteristic of human amnesia. The PRPH II group, like the PRPH I group, was severely impaired on the visual DNMS task. The PRPH II group was also impaired on a newly developed tactual version of the DNMS task. The lesioned animals required more trials than normal animals to learn the task (PRPH II = 1991, Normals = 995), and performed worse than normal animals when the delay intervals were increased (Mean of 3 longest delays PRPH II = 63% Normals = 75%). When the PRPH II group was retested on the visual version of DNMS two years after surgery, they still exhibited a severe memory deficit.

In summary, as in human amnesia, the PRPH lesion produces a memory impairment that is modality general and long lasting. These findings emphasize the importance of the perirhinal and parahippocampal cortices for normal memory function and suggest that damage to these areas may underlie at least part of the memory deficit exhibited in amnesic patients such as patient H.M.

LOCALIZATION OF SPINAL CORD INTERNEURONS WITH PUTATIVE MONOSYNAPTIC CONNECTIONS TO SYMPATHETIC PREGANGLIONIC NEURONS: A TRANSDORSAL TRANSPORT STUDY USING WHEAT GERM AGGLUTININ. J. Cabot, J. Carroll, and V. Alessi. Dept. of Neurobiology & Behavior, SUNY at Stony Brook, Stony Brook, NY 11794-5230.

In vivo and *in vitro* physiological studies have conclusively established that sympathetic preganglionic neurons (SPNs) receive segmental and intersegmental spinal inputs. The anatomical locations of the spinal cells of origin of such inputs are largely unknown. This study provides light microscopic data which suggest that neurons in the base of dorsal horn and in the intermediate spinal gray of the rat thoracic spinal cord provide segmental, presumably monosynaptic, input to SPNs. These findings are consistent with other recent observations in another vertebrate (pigeon) using a different trans-synaptically, transneuronal transported marker, Fragment C of tetanus toxin (Cabot et al., *Neurosci.* 40: 805).

Male Sprague-Dawley rats were sacrificed 3-6 days after injections of either wheat germ agglutinin (WGA) or a combination of WGA and cholera toxin B subunit (CTB) into the superior cervical ganglion. Following intracardiac perfusion, the last cervical spinal cord segment (C8) and the first 3 thoracic spinal cord segments (T1-3) were sectioned in the transverse plane, incubated in anti-WGA, anti-CTB or in a combination of anti-WGA and anti-CTB, and then reacted using standard ABC immunohistochemical protocols.

SPNs were retrogradely labeled with WGA and/or CTB in all sympathetic nuclei (I₁, I₂, IC, CA) in T1 and rostral T2; in I₁ and I₂ in caudal C8; in I₁, IC and CA in caudal T2 and rostral T3. Transneuronal labeled neurons were immunopositive for WGA only and exhibited perinuclear, somal and proximal dendritic accumulations of small WGA-positive granules. Transneuronal WGA-labeled neurons were found: (1) throughout the lateral portions of the reticulated region of lamina V, but were most concentrated dorsolaterally in this general region; (2) in the lateralmost region of lamina IV in continuity with the dorsolateral border with lamina V; and (3) in the lateral aspects of dorsal lamina VII. Transneuronal labeled neurons were observed to be ipsilateral to labeled SPNs and to be most prevalent within the T1 and rostral T2 spinal segments. (Support in part by HL24103).

141.3

Responses of Splanchnic Sympathetic Preganglionic Neurons to Stimulation in the Caudal Raphe Nuclei. S.F. Morrison. Dept. of Physiology, Northwestern University Medical School, Chicago, IL 60611.

Single stimuli applied to the rostral ventrolateral medulla (RVLM) have previously been shown to excite splanchnic SPNs in one of four characteristic patterns with response latencies that appear to be related to the conduction velocities of RVLM-spinal sympathoexcitatory neurons. The present study was undertaken to determine the response patterns of splanchnic SPNs to similar stimulation in vasomotor regions of the caudal raphe nuclei (raphe pallidus and raphe obscurus; midline, from -5 to 3 mm rostral to the calamus scriptorius (CS)) and to compare, for the same SPN, the patterns evoked by raphe and RVLM stimulation. Rats were anesthetized with urethane and chloralose and in some the brainstem was transected caudal to the inferior colliculus. Stimulation in the raphe obscurus 1 mm rostral to the CS inhibited SPNs (onset: <15 ms, nadir: 70-80 ms). Stimuli in the raphe pallidus at the level of the RVLM excited SPNs at either a short (30-50 ms) or a long (110-150 ms) latency. For individual SPNs, the excitatory responses evoked by raphe pallidus stimulation were similar in character and latency to those produced by RVLM stimulation. These results support the hypothesis that individual SPNs are selectively innervated by supraspinal inputs in a manner that may be related to their functional role. A potential interaction between the pathways underlying raphe and RVLM stimulus-evoked excitations of SPNs is also suggested. Supported by NIH HL-47196.

HEMODYNAMIC FLUCTUATIONS AND SPINAL VASOMOTOR TONE IN BRAIN DEATH. J. Ishise, Y. Kita* and S. Murakami*. Section of Emerg. Med. and Intensive Care Unit, Kanazawa Univ. Sch. of Med. Kanazawa, Japan, 920.

Although the brain stem including Medulla oblongata (MO) is no longer functioning in brain death, slow periodic perturbation of blood pressure (BP) and heart rate (HR) are occasionally seen. The mechanism of these autonomic functions is investigated by a new analysis method for HR variability in combination with neuropathological examinations.

Ten patients fulfilled the criteria of brain death, arterial BP, ECG and respiratory activities were continuously recorded. A power spectrum analysis of HR fluctuations was performed with a fast Fourier transform algorithm and the power (%) of three different frequency spectra of 0.00-0.05Hz, 0.05-0.15Hz and 0.15-0.5Hz was calculated. MO, the cervical and upper thoracic spinal cord were taken out at autopsy performed at least four days after brain death, each specimen was processed for light microscopic examinations, stained with HE, KB, LFB-PAS and Bodian.

Both systolic and diastolic pressure showed irregular up and down changes ranging from 5 to 50mmHg, of which frequency was 8-16/hour depending on patients. Changes corresponding to the mechanical ventilation were seen but no changes correlating to Mayer wave (0.05-0.15Hz) were observed. HR showed slow fluctuations (0.00-0.05Hz), which was supposed to represent a vasomotor tone. Light microscopy showed complete autolysis in MO and medullo-cervical junctions in all cases and the gray matter including neurons and fibers projecting into the white matter of both anterior and posterior horn i.e. components of the reflex arc remained almost intact below the level of C3/4. Neurons of Nucleus intermediolateralis of the thoracic spinal cord also remained intact.

In conclusion, these results strongly suggest that slow periodic perturbation of BP and HR in brain-dead patients derive from a vasomotor tone originating from sympathetic neurons of the thoracic spinal cord.

BARORECEPTOR ACTIONS IN BRAIN STEM CARDIO-RESPIRATORY NEURAL NETWORKS. B.G. Lindsey, A. Arata, K. F. Morris, Y. M. Hernandez and R. Shannon. Dept. Physiol. & Biophysics, Univ. South Florida Med. Ctr., Tampa, FL 33612.

We studied the effects of baroreceptor stimulation on brain stem cardiorespiratory related neurons with ongoing network interactions identified by correlation analysis of their simultaneously recorded spike trains. Baroreceptors were stimulated in 24 anesthetized, vagotomized, artificially ventilated cats by inflation of an embolectomy catheter in the descending aorta or local pressure changes in the carotid sinus. Spike trains were recorded in parallel from the regions of n. tractus solitarius, rostral ventrolateral medulla (RVLM), n. ambiguus - lateral reticular n., and the medullary raphe n. Respiratory and cardiac related neurons were identified by cycle triggered histograms. Of 361 neurons tested, the firing rates of 78 increased, 115 decreased, and 168 showed no change. Responsive cells were elements of 185 pairs of neurons that exhibited short-time scale correlations. We detected baroreceptor modulation of distributed neural assemblies with up to 13 concurrent functional relationships among the constituent neurons. The data provide evidence for many network interactions, including: (a) baroreceptor mediated inhibition of ventral respiratory group inspiratory (I) neurons and concurrent excitation of their I modulated raphe targets; (b) inhibition of RVLM neurons by baro-excited raphe neurons; (c) inhibition of baro-inhibited raphe neurons by baro-inhibited RVLM neurons; (d) convergent excitation of raphe neurons by baro-excited raphe and caudal lateral medullary neurons. This approach allows analysis of the parallel processing of baroreceptor information and network dynamics. Supported by NS19814 & BRSG S07 RR05749.

EVIDENCE FOR A KYNURENATE-INSENSITIVE GLUTAMATE RECEPTOR IN THE NUCLEUS TRACTUS SOLITARIUS (NTS). Corinn M. Pawloski* and Frank J. Gordon. Dept. of Pharm., Emory Univ. Sch. of Med., Atlanta, GA 30322. Previous studies from this laboratory (JPET 250:953-961, 1989) and others (Talman, Neurosci. Lett. 102:247-252, 1989) have questioned whether L-glutamate (GLU) is a neurotransmitter of baroreceptor information in the NTS. Microinjections into the NTS of the excitatory amino acid (EAA) receptor antagonist, kynurenate (KYN) abolish baroreceptor reflexes, but fail to affect cardiovascular responses evoked by injections of GLU into the NTS. One possible explanation for these results is that exogenously-administered GLU might act at receptors that are not blocked by KYN and are inaccessible to synaptically released GLU. One candidate for this KYN-insensitive receptor is the metabotropic EAA receptor that is selectively activated by the agonist trans-D,L-1-amino-1,3-cyclohexanedicarboxylate (ACPD). The purpose of the present studies was to determine if KYN-insensitive ACPD receptors are present in the NTS. Rats were anesthetized with urethane, paralyzed and artificially respired. Multibarrel glass pipettes were placed into the NTS which was functionally identified by microinjection (50 nl) of GLU (74 pmol). Microinjections of KYN (2 nmol) into the NTS abolished aortic baroreflexes and markedly reduced depressor responses evoked by subsequent microinjections of N-methyl-D-aspartate (NMDA; 2.6 pmol) and α -amino-3-hydroxy-5-methylisoxazole-4-propionate (AMPA; 0.1 pmol). Microinjections of ACPD (7.4 to 74 pmol) into the NTS produced dose-related depressor responses that were not reduced after KYN-blockade. Depressor responses produced by GLU were potentiated by KYN. These data demonstrate the presence of a KYN-insensitive ACPD EAA receptor in the NTS. Moreover, they suggest a potential explanation for previous observations where cardiovascular responses evoked by microinjections of GLU into the central nervous system are unaffected by KYN pretreatment. In addition, these results suggest that GLU remains a viable candidate neurotransmitter of baroreflex information in the NTS.

BLOCKADE OF NMDA RECEPTORS IN NUCLEUS TRACTUS SOLITARIUS INHIBITS BARO- AND CHEMORECEPTOR REFLEX RESPONSES TO STIMULATION OF CAROTID SINUS NERVE IN RAT. H. Ohta and W.T. Talman. Department of Neurology, University of Iowa and VAMC, Iowa City, IA 52242.

The carotid sinus (CSN) and aortic depressor nerves (ADN) terminate in the nucleus tractus solitarius (NTS). Our previous studies have suggested that NMDA receptors in NTS are integral to transmission of baroreceptor afferent signals of ADN. In the present study we have sought to define the cardiovascular reflex responses elicited by stimulation of CSN in rat and to determine if NMDA receptors in NTS mediate those responses. The left CSN was isolated through a lateral incision in the neck of Sprague Dawley rats anesthetized with chloralose. Stimulation (200 μ A, 2 ms, 20 sec) of CSN produced frequency-dependent (<50 Hz) depressor and bradycardiac responses that followed transient increases in arterial pressure and respiratory rate. These responses were blocked by ipsilateral injection into NTS of 2% lidocaine or 10 mM MK-801 (50 nl). The injection of MK-801 selectively blocked responses to microinjection of NMDA, but not other excitatory amino acid agonists, into NTS. These results suggest that CSN carries functional baro- and chemoreceptor afferents and that cardiovascular responses to stimulation of CSN, as is the case with ADN, are mediated through NMDA receptors in NTS. CENTRAL PATHWAY OF THE VON BEZOLD-JARISCH (B-J) REFLEX IN THE RAT. A.J.M. Verberne and P.G. Guyenet. Dept. of Pharmacol., Univ. of Virginia, Charlottesville, VA 22908.

The central pathway involved in the sympathoinhibitory and hypotensive response of the B-J reflex elicited by iv 5-HT or phenylbiguanide (PBG) was studied in halothane-anesthetized, paralyzed rats. 5-HT (2.5 ug/kg) or PBG (5 ug/kg) produced marked, transient reductions in lumbar sympathetic nerve discharge and modest reductions of blood pressure. These effects were blocked by the 5-HT₃ receptor antagonist MDL 72222 (100 ug/kg, i.v.). The sympathoinhibitory responses to PBG and 5-HT were blocked by bilateral microinjection of kynurenic acid (KYN, glutamate receptor antagonist; 5 nmol/100 nl) into the caudal ventrolateral medulla (CVL) but not the rostral ventrolateral medulla (RVL). B-J reflex was also inhibited by bilateral microinjection of bicuculline methiodide (BIC, GABA receptor antagonist; 100 pmol/50nl) into RVL but not CVL. Bilateral KYN (1.25 nmol/25 nl) into the solitary tract nucleus also inhibited the B-J reflex. Xanthurenic acid, a KYN analogue with no glutamate receptor antagonist activity, was ineffective. Barosensitive neurons in the RVL were inhibited by B-J reflex activation (47/57 units) while some (10/57 units) underwent an excitation/inhibition sequence. This inhibition was blocked by iontophoretic BIC (n=12 cells) but not by strychnine (glycine receptor antagonist) (n=8 cells). These findings underline the similarity between the medullary pathways mediating the B-J and arterial baroreceptor reflexes. (HL 28785)

141.6

PROCESSING OF CARDIOPULMONARY AFFERENT INPUT WITHIN NUCLEUS TRACTUS SOLITARIUS (NTS) INVOLVES ACTIVATION OF SOLUBLE GUANYLATE CYCLASE (GC). S.J. Lewis, H. Ohta, B. Machado, J.N. Bates* and W.T. Talman. Depts. Pharmacol., Neurol. and Anesth. & Cardiovasc. Ctr., Univ. of Iowa and VAMC, Iowa City, IA 52242.

Microinjection of the nitrosothiol S-nitrosocysteine (SNC) into the NTS of anesthetized rats produces dose-dependent hypotension and bradycardia. This study examined (1) whether actions of SNC, glutamate or N-methyl-D-aspartate (NMDA) within NTS involve activation of soluble GC and (2) whether inhibition of GC activation within NTS modifies vagal cardiopulmonary afferent reflexes elicited by i.v. 5-HT. Unilateral microinjection of methylene blue (MB, 250 pmole) into the NTS of rats anesthetized with chloralose significantly inhibited hypotensive and bradycardiac effects of SNC and NMDA, but not glutamate, injected at the same site in NTS. 5-HT-induced reductions in arterial pressure and heart rate were attenuated 1 min after bilateral microinjection of MB (250 pmole/NTS) (pre vs post, -46 \pm 6 vs -8 \pm 2 mmHg and -188 \pm 12 vs -58 \pm 9 bpm; p<.05). These results suggest that actions of SNC and NMDA and processing of cardiopulmonary afferent input into NTS involve activation of soluble GC. (Support: HL-14388, HL-32205, NS-24621, and VA Merit Review)

141.8

INHIBITION OF CHEMORECEPTOR (CR) INPUT TO NUCLEUS TRACTUS SOLITARIUS (NTS) NEURONS DURING BARORECEPTOR (BR) STIMULATION. S.W. Mifflin. Dept. of Pharmacology, The University of Texas Health Science Center, San Antonio, TX 78284.

Previous studies of NTS neurons have found no evidence for convergence of inhibitory BR and excitatory CR synaptic inputs which might explain the inhibitory interactions between BR and CR reflexes in the regulation of sympathetic nerve discharge. The possibility that presynaptic inhibitory interactions occur between BR and CR inputs to NTS neurons remains. To examine this, in pentobarbital anesthetized, mechanically ventilated and paralyzed cats, extracellular recordings were obtained from 16 NTS neurons activated by lingual artery injection of <100 μ l of CO₂ saturated bicarbonate and not by increases in arterial pressure (AP) evoked by inflation of a balloon-tipped catheter in the abdominal aorta. All values are mean \pm SD. Post-stimulus time histograms of discharge evoked by electrical stimulation of the carotid sinus nerve (CSN) were obtained at control levels of AP (136 \pm 27 mmHg) and during elevations in AP (173 \pm 25 mmHg). In 6 of the 16 cells, CSN evoked discharge was reduced 42% \pm 9% (range = 30-52%) (p<.05, Wilcoxon signed rank test) during an increase in AP. In the remaining 10 cells, elevations in AP had no discernible effect on CSN evoked discharge. During increases in AP, the action potential showed no consistent changes in amplitude, duration or A-B break which might suggest postsynaptic inhibition. Inhibition of CSN evoked discharge during an increase in AP was attenuated by bilateral vagotomy and section of the contralateral CSN in 2 cells tested. These results suggest that excitatory CR inputs to some NTS neurons are inhibited by BR activation and this inhibition might be presynaptic in origin. (Supported by NIH grant HL-41894)

141.10

ROLE OF THE ROSTRAL VENTROLATERAL MEDULLA (RVLM) IN THE MEDIATION OF HYPOTHALAMIC AND SOMATO-SYMPATHETIC PRESSOR RESPONSES. James M. Kiely and Frank J. Gordon. Dept. of Pharmacology, Emory Univ. School of Medicine, Atlanta, Ga. 30322

These studies investigated the relative role of synaptic vs. axonal neural transmission in the RVLM in the production of centrally-mediated pressor responses. Rats were anesthetized with urethane, bilaterally vagotomized, paralyzed and respired. Hypothalamic pressor responses of 30-40 mmHg were produced by monopolar electrical stimulation (150 μ A, 100 Hz, 1.0 msec pulse duration) of the perifornical (PFH) and paraventricular (PVN) hypothalamic nuclei. Somatosympathetic pressor reflexes of 30-40 mmHg were evoked by electrical stimulation (300 μ A, 20 Hz, 1 msec pulse duration) of sciatic nerve afferents. All pressor responses could be abolished by ganglionic blockade with chlorisondamine (5 mg/Kg, i.v.). Multibarrel glass pipettes were placed bilaterally into the RVLM which was functionally identified by microinjections of L-glutamate. All pressor responses could be reversibly abolished after blockade of both synaptic and axonal transmission in the RVLM was produced by injection (50 nl) of 20% lidocaine. After recovery of the pressor responses, synaptic transmission in the RVLM was interrupted by medullary injections of a neurotoxic dose of kainic acid (1 nmol/50 nl). Kainate-induced inactivation of cell somata in the RVLM abolished somatosympathetic pressor reflexes, but attenuated PFH pressor responses by only 35%. Pressor responses evoked from the PVN were not affected by injections of kainate into the RVLM. These results indicate that both synaptic and axonal transmission within the RVLM participate in the production of centrally-mediated pressor responses. (Supported by NIH Grant HL 36907)

141.11

INHIBITION OF 5-HT UNIT FIRING AND SYMPATHETIC DISCHARGE BY 8-OH-DPAT IN THE BARORECEPTOR DENERVATED CAT. K.A. King*, R.B. McCall and J.M. McCall. Cardiovascular Diseases Research, The Upjohn Company, Kalamazoo, Michigan 49001

It has previously been demonstrated that, in the baroreceptor intact cat, the 5-HT_{1A} agonist 8-OH-DPAT produces inhibition of midline medullary 5-HT cells at i.v. doses lower than those required to produce sympathoinhibition. It is possible that this difference is observed because at low doses, the hypotension produced by 8-OH-DPAT elicits a reflex increase in sympathetic nerve discharge (SND), thereby masking a small inhibitory effect of the drug. Midline 5-HT neurons do not receive baroreceptor inputs, and therefore exhibit the effect of the drug at all doses. The purpose of this study was to determine if reflex baroreceptor activation is responsible for the apparent difference in sensitivity to the effects of 8-OH-DPAT. 8-OH-DPAT (1 to 100 ug/kg, i.v.) was administered to 11 baroreceptor denervated cats while recording SND and 5-HT unit discharge simultaneously. 5-HT unit firing was inhibited by 50% following 1 ug/kg of 8-OH-DPAT, and was completely inhibited by a 3 ug/kg dose. SND was inhibited by 37% following 10 ug/kg, and a dose of 100 ug/kg was required to completely inhibit SND. These results were not different from those observed in sham operated animals (N=6). The difference in the sensitivity of midline medullary 5-HT unit firing and SND to the inhibitory effects of 8-OH-DPAT is therefore not due to compensation by the baroreceptor reflex.

141.12

COMPARISON OF THE EFFECTS OF CLONIDINE AND 8-OH DPAT ON SYMPATHOEXCITATORY NEURONS IN THE ROSTRAL VENTROLATERAL MEDULLA. R.B. McCall and M.E. Clement. The Upjohn Co., Kalamazoo, MI 49001.

The effects of intravenous and iontophoretic clonidine were determined on the firing rates of sympathoexcitatory neurons in the rostral ventrolateral medulla of the cat. Individual neurons were initially identified using spike triggered average of sympathetic activity and responses to baroreceptor activation. Twenty six neurons displayed activity which were temporally related to sympathetic nerve discharge, were inhibited during baroreceptor activation and were antidromically activated from the intermedialateral cell column. Individual neurons had firing rates ranging from 0.75 to 4.1 Hz (mean=1.67 Hz) and axonal conduction velocities of 1.4 to 3.9 m/s. As reported in the rat, we found that sympathoexcitatory neurons could be differentiated based on their sensitivity to clonidine. Approximately 50% of the neurons were inhibited by clonidine. There was only a weak correlation between the inhibition of unit activity and whole sympathetic nerve activity. The discharge rates of the remaining neurons were either not altered or were increased by clonidine. Unlike the rat, these two groups of neurons could not be further differentiated on the basis of axonal conduction velocity or discharge frequency. In contrast, intravenous 8-OH DPAT inhibited all sympathoexcitatory neurons. There was a remarkable correlation between the inhibition of unit activity and whole sympathetic activity. The central antihypertensive mechanism of these drugs will be discussed.

CALCIUM CHANNELS: PHYSIOLOGY AND PHARMACOLOGY II

142.1

ANTI-w-CONOTOXIN GVIA ANTIBODIES: A VALUABLE TOOL FOR THE IDENTIFICATION OF THE w-CONOTOXIN RECEPTOR OF RAT BRAIN.

A.M. Snowman, M.W. McEnery, A.H. Sharp, and S.H. Snyder. Dept. of Neuroscience, The Johns Hopkins Univ. School of Medicine, Baltimore, MD

[125]I-w-conotoxin GVIA (w-CTX), a peptide toxin from the venom of the carnivorous cone snail *Conus geographus*, binds with picomolar affinity to the pre-synaptic N-type calcium channel of neurons. To date, the w-CTX receptor has been refractory to isolation. We have produced anti-w-CTX antisera that are specific for the w-CTX peptide and do not cross-react with other toxins which compete for [125]I-w-CTX binding to the receptor. The anti-w-CTX antibodies have been immobilized on a Protein A Sepharose column and loaded with excess ligand. Under these conditions, the w-CTX receptor is retained on the column. When used in tandem with photoaffinity cross-linking experiments, we identify a 240 kDa protein that specifically incorporates derivatized w-CTX and is greatly enriched in our receptor preparation.

142.2

w-AGA-IVA, A NOVEL PEPTIDE ANTAGONIST FROM AGELENOPSIS APERTA SPIDER VENOM, BLOCKS RAT BRAIN SYNAPTOSOMAL CALCIUM CHANNELS. M.E. Adams and V.J. Venema*. Department of Entomology, University of California, Riverside, CA 92521.

We have identified a novel peptide toxin from venom of the funnel web spider, *Agelenopsis aperta*, which antagonizes rat brain calcium channels with high potency and selectivity. This toxin, w-Aga-IVA, constitutes about 1% of total protein in the venom and belongs to a family of peptides known as "Type IV" w-agatoxins. The biochemical properties and pharmacological selectivity of w-Aga-IVA are strikingly different from previously described w-agatoxins and w-conotoxins. w-Aga-IVA is composed of 48 amino acids, including 8 cysteines. Its amino acid sequence is unrelated to known calcium channel antagonists. w-Aga-IVA, unlike w-Aga-IIA and w-Aga-IIIa, does not inhibit high affinity binding of [125]I-w-conotoxin GVIA to rat brain synaptosomal membranes, suggesting a different selectivity for this toxin. In accordance with this interpretation, w-Aga-IVA blocks depolarization induced ⁴⁵Ca entry into rat brain synaptosomes (EC₅₀ = 15 nM), whereas w-Aga-IIIa or w-conotoxin GVIA are inactive when tested at micromolar concentrations. Further evidence for the unique selectivity of w-Aga-IVA is provided by electrophysiological studies showing that the toxin blocks high threshold Ca current in rat Purkinje neurons (see Mintz *et al.*, next abstract). Type IV w-agatoxins thus offer novel pharmacological tools for biochemical and functional analyses of Ca channels in the mammalian brain.

Supported by NIH grant NS24472.

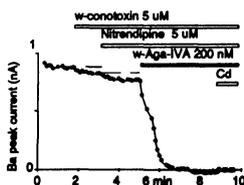

142.3

SELECTIVE BLOCK OF THE P-TYPE CHANNEL IN CEREBELLAR PURKINJE NEURONS BY THE SPIDER NEUROTOXIN w-AGA-IVA. L.M. Mintz, V.J. Venema*, M.E. Adams, and B.P. Bean. Dept. of Neurobiology, Harvard Med. Sch., Boston MA 02115 and Dept. of Entomology, Univ. California, Riverside CA 92521.

The peptide w-Aga-IVA isolated from *Agelenopsis aperta* venom was tested on voltage-gated Ca channels in freshly dissociated rat (P7-P15) cerebellar Purkinje neurons, using whole cell recordings of Ba (5 mM) currents.

The major component of the high-threshold Ca current in rat Purkinje cells is unaffected by w-conotoxin and nitrendipine (Regan *et al.*, Neuron 6:269, 1991). This "P-type" current is completely and potently blocked by w-Aga-IVA (K_d < 7 nM). Reversal of block was extremely slow if cells were washed while held at -90 mV but was accelerated >1000 fold by voltage-steps to +70mV.

In contrast, even 100 nM w-AgaIVA had no effect on T-type currents or Bay K 8644-enhanced L-type currents in rat DRG neurons. L-type currents in rat cardiac muscle cells were also untouched.

In rat CA1 hippocampal neurons, rat DRG neurons and frog sympathetic neurons, 100 nM w-AgaIVA slowly blocked a small fraction of high-threshold current, suggesting that other channel types may be weakly sensitive to the toxin.

142.4

BLOCKADE OF VOLTAGE-SENSITIVE CALCIUM CHANNELS BY ARYLAMINE TOXINS FROM SPIDER VENOM. EF Nemeth, LD Artman*, TN Parks, H Jackson. Natural Product Sciences, Inc., 420 Chipeta Way, Salt Lake City, UT 84108.

The venom of the spider *Agelenopsis aperta* contains two main classes of toxins: low molecular weight arylamines and peptides of 5-12 kD. The former toxins block glutamate receptors whereas the latter affect Na⁺ or Ca²⁺ channels. We have examined the ability of arylamines to act on Ca²⁺ channels by assessing their effects on influx of extracellular Ca²⁺ monitored by fura-2 in two cell types: primary cultures of neurons (rat cerebellar granule cells; RCGCs) and a cell line of vascular smooth muscle (A7r5; VSM). In both cell types, depolarizing concentrations of K⁺ caused rapid and sustained increases in [Ca²⁺]_i which were abolished in the absence of extracellular Ca²⁺ and inhibited by nifedipine (1 μM). Ca²⁺ influx in these cells thus occurs largely through "L-type" Ca²⁺ channels. The arylamine toxins (α-agatoxins) AG 489 and AG 505, the most abundant α-agatoxins in this venom, blocked increases in [Ca²⁺]_i evoked by K⁺-depolarization in each cell type. The IC₅₀ for AG 489 in RCGCs and VSM was 44 and 158 μM, respectively. AG 505 blocked increases in [Ca²⁺]_i with IC₅₀s of 10 and 26 μM in RCGCs and VSM, respectively. The synthetic toxin FTX was ineffective in RCGCs at concentrations up to 300 μM. AG 489 and AG 505 did not block Ca²⁺ influx through receptor-operated, voltage-insensitive Ca²⁺ channels in parathyroid cells when tested at concentrations as high as 300 μM. These two arylamine toxins thus block voltage-sensitive Ca²⁺ channels in diverse cell types. They are, however, about 100-fold more potent as blockers of NMDA receptor-mediated increases of [Ca²⁺]_i in RCGCs. Nonetheless the results demonstrate that at concentrations above 1 μM, α-agatoxins from *Agelenopsis aperta* inhibit various Ca²⁺ influx pathways in excitable tissues. Perhaps there are some common structural features between the ion channel associated with the NMDA receptor and that of voltage-sensitive Ca²⁺ channels that allow arylamine toxins to block Ca²⁺ influx through both channel types.

FTX INHIBITS TRANSIENT Ca^{2+} -CURRENT OF RAT NEUROHYPOPHYSIAL NERVE TERMINALS. J.R. Lemos and G. Wang. Worcester Foundation for Experimental Biology, 222 Maple Avenue, Shrewsbury, MA 01545

Funnel-web spider toxin (FTX) specifically blocks a novel Ca^{2+} -conductance ("P") in Purkinje cells (Llinas, et al. 1989; *Proc. Natl. Acad. Sci.* 86:1689). In the intact neurohypophysis, FTX reduced the magnitude of the calcium spike (Salzberg, et al., 1990; *Biophys. J. Abstr.* 57:305a). Here we examined the effects of FTX on the Ca^{2+} -currents (I_{Ca}) which presumably underlie the Ca^{2+} spike of isolated rat neurohypophysial nerve terminals.

Using the whole-cell patch clamp technique, the nerve terminal I_{Ca} was elicited with either 10 mM Ca^{2+} or Ba^{2+} . The I_{Ca} , with both transient and long-lasting components, was recorded by depolarizing from -90 mV to +10 mV for 1 second. 50 μ M Cd^{2+} reversibly eliminated both components of I_{Ca} . In the presence of FTX (0.5-5 μ M/ml) in the bath solution, however, only the transient component of I_{Ca} was reduced in a dose-dependent manner. 0.5 μ M/ml FTX decreased this component by 52.1%, whereas 5 μ M/ml inhibited it by 67%. No shift in the I-V curves for either component was observed. Furthermore, there are no significant differences between the effects on the Ca^{2+} -mediated and the Ba^{2+} -mediated current. The inhibition of the current by FTX was reversed by washing. In contrast, the toxin had minimal effects on the long-lasting component of I_{Ca} , elicited from either -90 mV or -40 mV, of the nerve terminals. In the same preparation, however, FTX strongly inhibited the long-lasting I_{Ca} of the *pars intermedia* cells.

These results suggest that the portion of neurohypophysial I_{Ca} that is sensitive to FTX could belong to the P-channel family. The P current is also considered to be responsible for presynaptic calcium spikes in the squid. The properties and functions of the FTX-blocked I_{Ca} in the nerve terminals will have to be further investigated. FTX was a kind gift of Drs. Cherksey and Llinas. Supported by NSF and NIH grants to J.R.L.

ELEMENTARY PROPERTIES OF CALCIUM CHANNELS IN CEREBELLAR PURKINJE CELLS. M.M. Usowicz, M. Sugimori & R.R. Llinás. Dept. of Physiology and Biophysics, New York University Medical Center, New York, NY 10016.

Recent experiments have indicated that cerebellar Purkinje cells possess P-type Ca channels that are pharmacologically distinct from T-, N- and L-type Ca channels. We have examined the elementary properties of Ca channels in Purkinje cells. Cell-attached patch recordings were made from adult Purkinje cells in thin cerebellar slices of the guinea-pig (Edwards et al, *Pflügers Archiv* 414:600), with patch-pipettes filled with (in mM): 110 BaCl₂, 10 HEPES, 0.5 μ M TTX, pH 7.4 with TEA-OH. Currents were recorded in two different regions of the cell; either from the soma or from the dendrite, usually at a bifurcation 30 - 100 μ m from the soma.

The threshold of activation for single-channel Ba currents was -30 to -15 mV from a holding potential of -90 mV, consistent with the absence of low voltage-activated Ca channels from adult Purkinje cells. Currents arising from a small population of channels were maximal at about 20 mV, when elicited in multi-channel patches by a depolarizing ramp change in command potential. (All potentials have been calculated for a resting potential of -60 mV). Channel openings were to a main conductance level of about 17 pS (slope conductance) and, less frequently, to a lower conductance level of about 10 pS.

AN UNCONVENTIONAL TRANSIENT Ca CURRENT IN GABA-ergic NEURONS OF RAT THALAMIC RETICULAR NUCLEUS J.R. Huguenard and D.A. Prince. Dept. of Neurology & Neurological Sciences, Stanford Univ. Medical Center, Stanford, CA 94305.

Both thalamocortical relay neurons (TCs) and the GABAergic cells of the nucleus reticularis (nRt) possess transient Ca^{2+} currents (I_T) that underlie bursts of fast Na^+ -mediated spikes, however both the morphology and the proposed function of these bursts are different. Because burst duration is relatively long in nRt, during such bursting its efferents produce prolonged inhibition in relay nuclei. The resultant hyperpolarization in TCs contributes to deactivation of a powerful I_T , causing them to switch from tonic to phasic firing pattern, and thus influences the coherence of sensory information relayed to the cortex.

To test the hypothesis that these differences in burst generation reflect fundamental differences in the underlying T currents, we used patch clamp techniques to study whole-cell currents in acutely isolated rat nRt cells. These neurons generated a slow transient Ca^{2+} current (I_{TS}) that had similarities to I_T recorded in TCs, including steady-state inactivation properties, and sensitivity to blockade by divalent cations (Ni^{2+} , Cd^{2+}), amiloride, and anticonvulsants. However, I_{TS} inactivated relatively slowly and in a nearly voltage-independent manner, with a time constant (τ_{in}) near 90 ms between -60 and -30 mV at 23°C. By contrast, τ_{in} for I_T varies between 50 and 20 ms in the same voltage range. Furthermore, I_{TS} was activated with a higher threshold (-55 mV) compared to I_T (-65 mV), and activation of I_{TS} occurred over a broader voltage range. Finally, deactivation was slower for I_{TS} ($\tau = 520$ ms at -90 mV) compared to I_T ($\tau = 320$ ms).

We conclude that neurons in nRt possess a different form of T channels than those in TCs. Because I_{TS} inactivates relatively slowly, and the rate of inactivation is not markedly increased by depolarization, burst firing in nRt is not terminated as rapidly as in TCs. Prolonged barrages of ipsips onto TCs result, with consequent emergence of burst firing in thalamocortical efferents. Supported by NIH grants NS06477 and NS12151.

POLYAMINE BLOCK OF P-TYPE CALCIUM CHANNELS. B. Cherksey*, R. Goodnow, M. Sugimori*, K. Nakanishi and R. Llinas*. Dept. of Physiology and Biophysics*, NYU Medical Center, New York, N.Y. 10016 and Dept. of Chemistry, Columbia University, New York, N.Y. 10027

FTX, the specific blocker of the neuronal P-type calcium channel isolated from the venom of funnel-web spiders has been reported to be a low molecular weight, non-aromatic polyamine. In previous studies, we had synthesized and tested the mixed condensation product of spermidine with the amino acid arginine and found that the mixture had FTX-like activity (Cherksey, B., et al. 1989 *Biol. Bull.*, 177, 321). We have now prepared well-characterized synthetic FTX analogues and have tested them for their electrophysiological activity in guinea pig cerebellar slices.

Three arginine-polyamine adducts were prepared for these studies: FTX(4:3), FTX(3:4) and FTX(3:3), where the numbers 3 and 4 indicate the number of methylene groups separating the amino groups in the polyamine. Other polyamines tested included ones in which lysine was substituted for arginine and polyamines in which the triamine was replaced by diamines with carbon numbers from 8 to 12.

Electrophysiological assay of the activity of the FTX's was performed in the current clamped guinea pig Purkinje cell. In this assay system, FTX(3:3) and FTX(4:3) were found to block the P-type calcium channel in micromolar concentrations while FTX(3:4) was found to be inactive. FTX(3:3) exhibited the greatest potency being approximately 10 times as active as FTX(4:3). When elevated concentrations of the compounds were tested (into the millimolar level) no block of sodium or potassium conductances was seen.

Substitution of lysine for the arginine in the synthetic FTX's resulted in a loss of P-channel blocking activity. The amino acid - diamine conjugates were found to exhibit potassium channel blocking activity when tested against brain homogenate and non-neuronal tissue in the lipid bilayer system.

Our results suggest that simple polyamines and polyamine-amino acid conjugates exert substantial, specific effects on ionic channels and may prove to be important natural global channel modulators manufactured by the body and found in the brain.

CALCIUM CHANNELS IN RAT CEREBELLAR NEURONS

Daniela Pietrobon*, Gabriella Calderini* and Lia Forti*
C.N.R. Center Physiology of Mitochondria, University of Padova, Fidia Research, Abano Terme, Italy

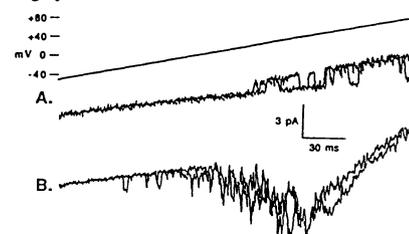

Single channel recordings from rat cerebellar granule cells frequently show two types of calcium channels which are neither L- nor T-type calcium channels. These channels have conductances of 15 and 20 pS respectively. In both types of channels steady state inactivation occurs at relatively negative voltages, both channels being totally inactive at a holding potential of -40 mV. Both types of channels do not inactivate during a 700 msec long test pulse. However they activate at different voltages. With 90 mM barium ions as charge carriers the 15 pS channel starts to activate around -30 mV while the 20 pS channel starts to activate around 0 mV. Less frequently we have observed two other types of calcium channels, of 19 and 7 pS respectively, which are neither L- nor T-type. The L-type channels in these neurons, like those in cardiac cells (Pietrobon & Hess 1990 *Nature* 346:651), have two different gating modes: besides the typical short-opening mode they have a mode of activity characterized by much longer open times. Both the probability of entering the long opening mode and the mean time the channel spends in this mode are voltage dependent. At negative voltages the average duration of the long-opening mode is much longer in cerebellar than in cardiac cells. Moreover, the voltage dependence of the rate of exit from the long opening mode is less pronounced in neurons than in myocytes.

UNITARY AND CLUSTERED SINGLE CALCIUM CHANNELS ON A CHOLINERGIC NERVE TERMINAL E.F. Stanley, LB NINCDS, Bld. 9 Rm 1E124, NIH, Bethesda MD 20892.

We have previously characterized inward Ca current in a presynaptic nerve terminal using the sheet-like calyx terminal of the chick ciliary ganglion (*J. Neurosci.* 11:985). In this study single channel currents were recorded from both the external, non-synaptic aspect of the calyx and the internal, transmitter release face.

The external face of the calyx exhibited only outward single channels while single calcium channels were recorded from the internal, release face of the nerve terminal. These calcium channels were recruited at -30 mV, had a conductance of 11 to 13 pS in 110 Ba and were often highly clustered.

Ramp depolarizations for an external face patch (A) and a release-face patch (B) (inward current down).

EVIDENCE FOR L- AND TWO MODES OF T-TYPE CURRENT IN INSULIN SECRETING CELLS. T.G.Hales & B.Ribalet. Dept's of Physiol. and Anesthes., Center Health Sci. UCLA. LA. CA. 90024.

Tail current analysis was used to characterize Ca currents in the insulin secreting cells, HIT and RIN. Ca currents were recorded using the whole-cell patch-clamp technique. The pipette contained an NMDG based solution supplemented with BAPTA and ATP. The bath contained a NaCl based saline with Ca^{2+} (3 mM) and TTX. Tail currents evoked by repolarizing the membrane to -100 mV following a depolarizing pulse of 8 ms were fitted by the sum of three exponentials, $\tau_1=0.2$, $\tau_2=2.2$ and $\tau_3=17$ ms. The thresholds of activation for τ_1 , τ_2 and τ_3 components were -40, -60, and -40 mV and their $\frac{1}{2}$ maximal amplitudes occurred at 0, -28, 14 mV, respectively. Consistent with τ_1 being deactivation of L-type current this component ran down during the course of most experiments, was inhibited by 36% by nifedipine (1 μ M) and increased by 94% by substituting Ba^{2+} for external Ca^{2+} . The slower deactivating τ_2 and τ_3 components had common properties. Their amplitudes were stable throughout most experiments, relatively insensitive to nifedipine (1 μ M) and reduced in the presence of external Ba^{2+} by approximately 28%. Also, replacing external Na^+ by Tris had no effect on τ_1 , but inhibited τ_2 and τ_3 by 70% and 60%. Together, these observations suggest that τ_1 and τ_2 are the time constants of deactivation of L- and T-type currents. The similar properties of τ_2 and τ_3 components, led to our proposal that τ_3 is the time constant of deactivation of a second mode of T-type channels. With increased length of depolarization the amplitude of τ_2 decayed (75 s^{-1}). For pulses to >20 mV, the decay of τ_2 was accompanied by a simultaneous increase (75 s^{-1}) of τ_3 amplitude, suggesting a transition between two modes of T-type channels. At less depolarized potentials the transition of T-type channels from mode 1 to mode 2 may explain the apparent inactivation of Ca currents, mode 2 channels being predominantly closed below -20 mV. The existence of L- and two modes of T-type Ca channels may determine the shape of voltage-activated Ca currents in HIT and RIN cells.

142.12

PARVALBUMIN IS AN INTRACELLULAR NEURONAL Ca^{2+} BUFFERING PROTEIN. P.S. Chard, D. Bleakman and R. J. Miller. Dept. of Pharmacol. and Physiol. Sci., Univ. of Chicago, Chicago, IL 60637.

Cytosolic high affinity Ca^{2+} binding proteins such as parvalbumin and calbindin are thought to regulate the free $[Ca^{2+}]_i$ through rapid sequestration. Interest in these proteins and their role in Ca^{2+} buffering has increased with the finding that their concentrations are altered in certain CNS dysfunctions (e.g. status epilepticus and Alzheimer's disease). Introduction of these proteins into neurons would aid in elucidating their role in $[Ca^{2+}]_i$ homeostasis. Using combined whole cell patch clamp/Fura-2 based microfluorimetry we have examined the effects of intracellular introduction of the Ca^{2+} binding protein parvalbumin on the buffering of $[Ca^{2+}]_i$ in cultured dorsal root ganglion neurons (DRG). 5-12 day old DRG neurons in culture were replated 1 hour prior to the experiment. These cells stained negatively for parvalbumin. I_{Ca} 's and subsequent increases in $[Ca^{2+}]_i$ were evoked at 0mV from a holding potential of -80mV for either 80ms or 320ms duration (whole cell patch clamp with, in mM; 140CsCl, 1Mg, 10HEPES, 3.6 ATP and an ATP regenerating system in the pipette and 140TEACl, 2Ca in the bathing solution). Cells of similar size on the same coverslip were examined in the absence or presence of parvalbumin (250 μ M - 1mM). Buffering of the rise in $[Ca^{2+}]_i$ was more effective in the parvalbumin containing cells than in control cells. The observed rise in $[Ca^{2+}]_i$ which was initially large, decreased during the timecourse of the experiment in a manner disproportionate to the size of the I_{Ca} . In some cells with a recorded peak I_{Ca} of 300-600pA the rise in $[Ca^{2+}]_i$ was virtually abolished. In 4 pairs of cells where the recorded I_{Ca} and corresponding rise in $[Ca^{2+}]_i$ was normalized to the cell size, parvalbumin reduced the peak rise in $[Ca^{2+}]_i$ by $42 \pm 23\%$ ($P < 0.001$, paired t-test). There was no observed change in the inactivation kinetics of the macroscopic I_{Ca} in contrast to changes observed with 1mM BAPTA in the patch pipette. These results demonstrate that parvalbumin, in a concentration range which occurs in neurons, can effectively contribute to intracellular Ca^{2+} buffering.

RETINA AND PHOTORECEPTORS: GANGLION CELLS

143.1

SIZE, STRATIFICATION AND MORPHOLOGY OF THE MIDGET, PARASOL AND SMALL BISTRATIFIED GANGLION CELLS OF THE HUMAN RETINA. D.M. Dacey and M.R. Petersen. Depts. of Biological Structure and Ophthalmology, The University of Washington, Seattle, WA 98195.

We have intracellularly injected ganglion cells in wholemounts of the human retina maintained *in vitro*. Over 1000 HRP-filled cells provide the first detailed picture of the diversity of human ganglion cell types. Here we focus on the midget and parasol cells and compare them with a third, clearly identified type termed the *small bistratified* cell. Human midget ($n=300$) and parasol cells ($n=250$) show a larger mean dendritic field diameter than their counterparts in the macaque monkey, this difference being greatest (about 2 fold) in the central retina. Radial sections through midget and parasol dendritic trees show that, as in the macaque, these cells can be divided into a pair of types that occupy distinct inner and outer strata of the inner plexiform layer (ipl). The midget cells stratify broadly to completely overlap and extend beyond a more narrow parasol cell strata. The inner and outer types can also be distinguished morphologically: inner cells have larger cell bodies and larger and more densely branched dendritic trees than outer cells.

The small bistratified cell ($n=46$) can be uniquely distinguished by its small and distinctly bistratified tree. Dendritic field diameter is the same as, or slightly larger than that for parasol cells at all eccentricities sampled, but somal diameter is small, about the same as for a midget cell. The two dendritic strata are narrow and occupy the same depth in the ipl as the parasol cells. The parasol-like dendritic tree size combined with the midget-like soma size suggests that the small bistratified cells would show broad-band type receptive field size but be relatively rarely sampled by a recording electrode. A good candidate, also consistent with the cell's bistratified morphology, is the non-concentric, color opponent cell (DeMonasterio and Gouras, *J. Physiol.*, 251:157, 1975).

143.3

HOMOCYSTEIC ACID (HCA)-EVOKED CURRENT IN RAT RETINAL GANGLION CELLS. Dongxian Zhang and Stuart A. Lipton. Dept. of Neurology, Children's Hospital & Progr in Neuroscience, Harvard Med Schl, Boston, MA 02115.

HCA, one of the sulfur-containing amino acids, is an endogenous excitatory amino acid in the retina. HCA has been proposed to be a neurotransmitter released by bipolar cells (Neal & Cunningham, *Neurosci. Lett.* 1989;102:114-9). Also, in the rat retina HCA immunoreactivity has been observed in the inner nuclear and ganglion cell layers as well as in the outer and inner plexiform layers (Ortega et al., *Eur. J. Neurosci. Suppl.* 1990;3:119). To begin to explore the potential role of HCA as a transmitter impinging on retinal ganglion cells, whole-cell recordings with patch electrodes were performed on isolated rat retinal ganglion cells in culture. With $[Mg^{2+}]_o = 0$, HCA (200 μ M) induced inward currents when ganglion cells were held at $V_H = -60$ mV. HCA-evoked currents were of relatively small amplitude (10-40 pA) and displayed a characteristic increase in noise, similar to that observed previously in NMDA-activated currents of rat retinal ganglion cells (Aizenman, Frosch & Lipton, *J. Physiol.* 1988;396:75-91). Furthermore, HCA-evoked currents were completely blocked by the NMDA receptor antagonist APV (200 μ M). These observations suggest that HCA activates the NMDA receptor of retinal ganglion cells. Thus, HCA should be considered as a neurotransmitter candidate in the rat retina.

143.2

NEUROPEPTIDE Y IMMUNOREACTIVITY IDENTIFIES A SUBGROUP OF GAMMA TYPE GANGLION CELLS IN THE CAT RETINA. J. J. Hutslar, C. A. White & L. M. Chalupa. Dept. Psychology & Center for Neurobiology, University of California, Davis, CA 95616.

Retinal ganglion cells (RGCs) in the cat have been traditionally classified on the basis of their morphological and functional properties. Recently, it has been discovered that alpha ganglion cells can be subdivided on the basis of their immunoreactivity for somatostatin (White & Chalupa, 1991). We now report that neuropeptide Y (NPY) identifies a different subgroup of cat RGCs. In the adult retina about 1,800 neurons distributed throughout the ganglion cell layer are immunoreactive for NPY. Their highest density (about 50 cells/mm²) is at the area centralis, with a decline in cell density towards the periphery (10-12 per mm², 10 mm from AC). The somas of these neurons are typically round, although many appear elliptical or spindle shaped. Somal size remains relatively constant across the retinal surface, ranging in diameter from 14 μ m at the AC to 16 μ m near the periphery. Colchicine pretreatment revealed 2 to 5 sparsely branching primary dendrites. In many cases a presumptive axon could be followed for over 500 μ m into the nerve fiber layer. These morphological properties of the NPY immunoreactive neurons are consistent with what has been described for small to medium sized gamma cells (Stone & Clarke, 1980; Kolb et al., 1981). In addition, deposits of rhodamine latex microspheres into the LGN and SC resulted in retrograde labeling of NPY immunoreactive cells. Immunoreactive neurons not labeled by the tracer as well as those without an axon entering the fiber layer may be displaced amacrine cells. The precise proportion of ganglion cells within this population as well as their projection patterns are being investigated. (Supported by EY-03991 from the NEI).

143.4

CHARACTERIZATION OF NICOTINIC ACETYLCHOLINE RECEPTORS ON ISOLATED GOLDFISH RETINAL GANGLION CELLS. B.E. Yazejian and G.L. Fain. Department of Ophthalmology, Jules Stein Eye Institute, UCLA School of Medicine, Los Angeles, CA 90024-7008.

Although vertebrate retinal ganglion cells have been shown to give nicotinic responses to applied acetylcholine (ACh), the properties of the receptors have not yet been well characterized. We have recorded whole-cell membrane currents from enzymatically isolated goldfish retinal ganglion cells while applying drugs through a U-tube. ACh, as well as nicotine and DMPP, evoked cation-selective currents which were rapidly desensitizing and highly inwardly rectifying. No outward currents were seen at positive potentials for E_{Na} , $s \geq 0$ mV although small outward currents were seen above E_{Na} when E_{Na} was shifted to negative potentials by substituting some of the external Na (Na_o) with glucose. Replacing 70% of the Na_o with NMDG completely blocked the response; this effect was at least in part pharmacologic since NMDG at only 1mM reversibly blocked $58 \pm 19\%$ of the response to 30 μ M ACh ($n=2$). Responses to 30 μ M ACh were also reversibly blocked: $63 \pm 7\%$ by 300 μ M curare ($n=8$), $61 \pm 2\%$ by 300 μ M hexamethonium Cl^- ($n=4$) and in 3 of the 6 cells tested, $50 \pm 2\%$ by 100 μ g/ml α -BTX. At least some of the block of the ACh response by mecamylamine (MEC) was use-independent since a 2s pre-application of 300 μ M MEC irreversibly blocked the response to 30 μ M ACh tested 60s later.

143.5

GLYCINE RECEPTORS MAY LIE IN THE SURROUND PATHWAY OF MOUSE RETINAL GANGLION CELLS.

Charlene Stone and Lawrence Pinto, Northwestern Univ., Neurobiology Dept., Evanston IL 60208

We investigated the receptive field properties of retinal ganglion cells in isolated, superfused retinas of *spastic* mutant mice; normal littermates were used as controls. Extracellular recordings of responses to centered circular and annular stimuli were used to construct peri-stimulus-time histograms. In the mutant retina, annular stimuli did not elicit the surround-type response observed in the control; instead, a center-type response was recorded. However, in both phenotypes responses to large centered circular stimuli were smaller than to stimuli of intermediate size, demonstrating an antagonistic influence of the surround mechanism. These results suggest that a glycine receptor may normally be required for the transmission of excitatory signals from the surround mechanism. Spatial frequency tuning curves, obtained with sinusoidally-modulated gratings, were dominated by the center mechanism and therefore were not affected by the *spastic* mutation. Finally, we examined the effect of strychnine on the response to centered circular stimuli. Very low concentrations of strychnine attenuated the light response in mutant retinas (apparent $K_1 = 8.1 \times 10^{-13}M$). In control retinas, the light response was also attenuated by strychnine but the apparent K_1 was much higher ($1.0 \times 10^{-7}M$). Perhaps the expression of a novel retinal form of the glycine receptor, with a higher affinity for strychnine, is unmasked by the *spastic* mutation. EY01221.

143.7

FUNCTIONAL ROLE OF PUSH-PULL BIPOLAR CELLS IN UNIFIED MODEL OF X AND Y RETINAL GANGLION CELLS. P. Gaudiano, Dept. of Cognitive & Neural Systems, Boston University, Boston, MA 02215.

The feed-forward shunting network has been shown to possess properties that make it well suited for spatial information processing in the retina. These properties include adaptive gain control, relative contrast processing, and suppression of uniform backgrounds (Grossberg, *J. Theor. Biol.*, 27:291, 1970; Sperling, Perc. & Psych., 8:143, 1970). However, time-domain analysis shows that those properties that lead to good spatial processing can result in poor temporal processing. This problem is solved by addition of a push-pull preprocessing layer. The anatomical interpretation of the resulting model is structurally analogous to known retinal circuitry as described by McGuire and Sterling (*J. Neurosci.*, 6:907, 1986): light impinging on cones depolarizes one type (ON) and hyperpolarizes a second type (OFF) of bipolar cell. At a given location, both bipolar cell types converge upon individual ganglion cells: the ON bipolar excites ON-center ganglion cells, while the OFF bipolar inhibits them. A complementary arrangement exists for OFF-center ganglion cells. The model shows that X and Y cells may consist of the same formal mechanism acting in different parametric regimes. In agreement with morphological and physiological data, an increase in receptive field center (RF) size changes the model's response from X-like to Y-like (Saito, *J. Comp. Neurol.*, 221:279, 1983). Specifically, simulated X cells exhibit sustained responses; approximately linear spatial summation; null responses to modulated gratings. Simulated Y cells exhibit transient responses; spatial phase-independent and spatial frequency-dependent on-off (nonlinear) responses to modulated gratings. This duality results from mathematical properties of the push-pull network, which can selectively enhance sustained or transient response components on the basis of RF morphology.

143.9

INDEPENDENT ON AND OFF COMPUTATIONS OF RETINAL DIRECTIONAL SELECTIVITY IN RABBIT. N.M. Grzywacz¹ and F.R. Amthor², ¹Smith-Kettlewell Inst., 2232 Webster St., San Francisco, CA 94115, and ²Dept. of Psychol. and NRC, Univ. of Alabama at Birmingham.

It has been hypothesized that the bistratification of the dendritic trees of ON-OFF directionally selective ganglion cells of the rabbit retina could provide a substrate for direct ON and OFF excitatory inputs. This is consistent, for example, with the good match between the extents of the receptive-field regions in which ON and OFF responses are elicited and the dendritic ramifications in the inner and outer sublamina of the inner plexiform layer. However, it is not clear whether ON and OFF inputs remain segregated or interact via the facilitatory or inhibitory mechanisms underlying retinal directional selectivity.

We used an apparent motion paradigm that simulate moving edges to investigate facilitatory and inhibitory ON-OFF interactions. The data show that an ON stimulus does not produce significant preferred-direction facilitation of the response to an OFF stimulus. Similar results are found for OFF-ON interactions and for null-direction inhibition. Hence, facilitation and inhibition are probably not due to a general effect on the ganglion cell, but appear to be specifically related to directional selectivity. Further support for this conclusion comes from the spatio-temporal profile of facilitation and inhibition. The spatial distribution of facilitation is narrower than the receptive-field center. Therefore, it is unlikely that facilitation arises from a general elevation of the excitatory input to the ganglion cell. Likewise, the time courses of the inhibition in the receptive-field center and in the surround are different. Thus, the mechanism of the inhibition underlying directional selectivity is distinct from the mechanism mediating the general surround inhibition.

Supported by EY05070, ONR N00014-91-J-1280, and NSF BNS-8809588.

143.6

SYNAPTIC CONDUCTANCE FOR LINEAR OPERATION OF ON-ALPHA GANGLION CELL. Michael A. Freed, Ralph Nelson, Peter Sterling, and Robert G. Smith LNP, NINDS, NIH, Bethesda, MD 20892 and Dept. Anat., U. PA Sch. Med., Phila. PA 19104

A ganglion cell polarizes in proportion to stimulus contrast in the range below half-saturation. We investigated the On-alpha ganglion cell of cat retina to learn how synaptic conductances sum to produce this linear voltage response.

On-alpha somas (n=3), located in the area centralis (AC) of an eyecup preparation, were impaled with 100 MΩ microelectrodes. A cell was injected with current and stimulated with half-saturating contrasts (0.2 mm bar for 1 s, 647 nm, $-6 \log(q \mu m^{-2} s)$). Slope conductance (dI/dV) in the dark was 8-9 nS. The light-evoked conductance increase was ~1 nS. If all 1600 synapses on an On-alpha cell released a quanta within the cell's integration time, each causing a 0.3 nS conductance, a total of 380 nS would result. This is 38-fold more than measured conductances. This suggests that less than 3% of the synapses release quanta per integration time during a half-saturating stimulus.

We implemented a compartmental model of a reconstructed On-alpha cell from the AC ($R_m = 9500 \Omega \cdot cm^2$). The simulated On-alpha cell summed synaptic conductances in a linear fashion only when individual conductances were quantal and spread out over the dendritic arbor. Larger conductances, as might occur when multiple quanta impinge on a single dendritic branch, caused saturation of the synapse's driving force and significant nonlinearity. This suggests that On-alpha cell responses to low-contrast stimuli are due to linear summation of intermittent and spatially distributed quantal synaptic conductances.

A SILICON NETWORK FOR MOTION DISCRIMINATION THAT USES SPATIO-TEMPORAL INTERPOLATION. T. Delbrück, Computation and Neural Systems Program 139-74, Caltech, Pasadena CA 91125.

I have designed and tested a silicon motion discrimination network. An integrated one-dimensional circuit receives visual input from adaptive high-gain receptors. The receptor output capacitively couples into a single first order unidirectional delay line running along the receptor array. The delay line interpolates and predicts a motion signal such that the delay between stages is the delay of one element. Hence an input motion signal piles up on the delay line in a wave-like fashion; if the input is moving at the speed of the delay line the piling is maximal. Motion in the opposite direction does not pile up; a series of small pulses are the only result. An impulse response traveling along the unidirectional delay line does not change its integrated area, instead the pulse becomes smaller and more spread out in time. Hence, unidirectionality is not itself enough for motion discrimination; a nonlinearity is required. An expansive, even, nonlinearity locally transforms the signal on the linear delay line into a motion discrimination that is sign-of-contrast invariant. The temporal resolution and tuning for velocity of a particular stage are initially broad but become sharper the longer the motion has continued. This model most resembles the Adelson and Bergen energy model for motion discrimination; the main difference is that the silicon model is wire-efficient: a single delay line encodes the entire spatial dimension for one direction of motion.

143.10

MULTINEURONAL SIGNALLING BY RETINAL GANGLION CELLS. M. Meister, L. Lagnado, and D. A. Baylor, Dept. of Neurobiology, Stanford University, Stanford, CA 94305.

How do the optic nerve fibers encode the visual information transmitted to the brain? We would like to understand how the aggregate response of the retinal ganglion cell population to a given visual stimulus should be interpreted. Is it completely determined by the receptive fields of the individual neurons? Or do different neurons join in signalling certain features, such that the firing of one cell acquires different meaning depending on the activity of another?

Using a multielectrode array to record from the isolated retina, we have been able to monitor simultaneously the action potentials of up to 100 ganglion cells within a region of 0.5 mm diameter. The photoreceptor layer is stimulated with a "white noise" display: a checkerboard pattern in which each pixel flickers randomly among different colors. By correlating the spike train of each neuron with the visual stimulus at different times and spatial locations, one can compute each cell's spatial receptive field, response time course, and spectral sensitivity. Studies of the salamander retina have revealed receptive fields of the type known from single-cell recording. We are now in a position to extend the receptive field concept to the combined firing of several cells, and to test whether ganglion cells act independently or in concerted fashion as they encode visual information.

CONTRAST DEPENDENCE OF DISPLACEMENT DETECTION:
PSYCHOPHYSICS AND PHYSIOLOGY

Christian Wehrhahn^{DM}, Barry Lee^E, Gerald Westheimer^S and Jan Kremers^{hfl}

^{DM}MPI für biologische Kybernetik, Tübingen, Germany

^{E, hfl}MPI für biophysikalische Chemie, Göttingen, Germany

^SDept of Molecular and Cell Biology, University of California, Berkeley CA

Thresholds were obtained for the just-detectable displacement of a bright block stimulus seen against a uniform background. By varying the luminances of the block and the background, contrast could be controlled. Experiments were performed in the near periphery of the retina, 6.7 deg. from the fovea. When contrast is reduced from near unity to about .2 there is little change in threshold, but further reduction in contrast produces a progressive increase in threshold.

Physiological experiments were performed in the monkey; discharges were recorded from P- and M- ganglion cells with receptive fields at retinal eccentricities comparable to the psychophysical experiments. Contrast dependence of M-cell responses to target displacement was plotted and could be well matched to the psychophysical results with identical stimulus conditions and retinal position. P-cell responses were weak and bore little relation to the psychophysical results. The signals processed for the detection of small displacements are thus carried by the M-pathway.

143.12

SPATIAL PRECISION OF MACAQUE GANGLION CELL RESPONSES TO MOVING STIMULI. B.B. Lee, C.F. Wehrhahn, J. Kremers* and G. Westheimer. Max Planck. Inst. F. Biophys. Chem., 3400 Göttingen, FRG.

Psychophysical performance on vernier tasks depends on contrast. For a briefly flashed offset edge target, thresholds increase exponentially below a Michelson contrast of 0.2. We measured sensitivity to location of flashed edges and response variability in M- and P-cells of the macaque retina as a function of contrast, and shown it is likely that the M-cell signal provides a substrate for the central mechanism for vernier localization (ARVO, 1991).

We now extend this analysis to moving achromatic and chromatic borders, measuring responses to these stimuli as a function of contrast. To estimate the precision of the ganglion cell signal we used a cross-correlation measure between individual responses. This measure indicated a much higher degree of coherence and hence spatial precision in the M-cell compared to the P-cell signals, especially at low achromatic contrasts. The data do not provide a model for vernier performance, but such models must be constrained by the retinal input. M-cells seem likely to provide the signal for this type of performance; the P-cell signal is too noisy.

143.13

CONTRAST GAIN CONTROL IN THE PRIMATE RETINA.

E.A. Bernardete*, E. Kaplan, and B.W. Knight*. Lab. of Biophysics, The Rockefeller University, New York, NY 10021.

Contrast provides the major signal for image processing in vision. Work on the cat retina has shown that a nonlinear feedback mechanism, the contrast gain control, adjusts the temporal response of retinal ganglion cells according to the unsigned average of contrast over a large region of the retina. Here we report the existence of similar processes in the primate retina.

Retinal ganglion cell activity was monitored as synaptic (S) potentials in the LGN of anesthetized and paralyzed macaque monkeys. The contrast of sinusoidal gratings produced on a CRT was temporally modulated with a sum of 8 sinusoids in order to calculate temporal transfer functions. The data fit a model (Victor, '87) that describes both the dynamics of photoreceptors and the contrast gain control.

We found that increasing stimulus contrast changes the temporal frequency response of magnocellular-projecting (M) cells, but not of parvocellular-projecting (P) cells. M cells show a nonlinear response to contrast characterized by a selective attenuation of low temporal frequencies that can be attributed to a change in the time constant of the contrast gain control. P cells, on the other hand, respond linearly to contrast across a wide range of temporal frequencies. This difference in dynamics suggests that M cells receive nonlinear input from retinal elements which do not influence the activity of P cells. This similarity between the monkey M population and cat retinal ganglion cells further supports the view that P cells represent a new specialization not found in lower mammals.

NEUROENDOCRINE REGULATION I

144.1

GROWTH HORMONE (GH) STIMULATES SOMATOSTATIN (SRIF) RELEASE AND mRNA LEVELS IN THE RAT HYPOTHALAMUS. M.C. Aguila and S.M. McCann. Department of Physiology, Neuroendocrine Division, UT Southwestern Medical Center, Dallas, TX 75235-9040.

GH suppresses its own secretion by stimulating SRIF release. Thus, the possible regulation of GH releasing factor (GRF), SRIF release and its mRNA by GH was studied in the hypothalamus of male rats *in vitro*. The median eminences (ME's) were incubated in buffer containing 10^{-7} to 10^{-11} M GH for 30 min. SRIF and GRF released into the medium were quantitated by RIA. The release of SRIF from ME fragments was significantly increased ($p < 0.001$) by 10^{-9} M GH. However, 10^{-9} M GH inhibited ($p < 0.01$) GRF release from the ME. To determine the effect of GH on SRIF mRNA levels, PVN explants were cultured during 6 hrs in medium with 10^{-7} to 10^{-11} M GH. Levels of SRIF mRNA (determined by a S_1 nuclease protection assay) were significantly elevated ($p < 0.01$) by 10^{-9} M GH. Likewise, 10^{-9} M GH significantly stimulated the release of SRIF and GRF from PVN explants at 30 min and 6 hrs. These results demonstrate a dual action of GH on GRF release and indicate the presence of an inhibitory feedback system within the hypothalamus on the regulation of GH secretion which is mediated by increased release and transcription of SRIF and decreased release of GRF from the ME.

144.2

GROWTH HORMONE (GH)-RELEASING HEXAPEPTIDE GHRP STIMULATES GH RELEASE VIA CENTRAL GH-RELEASING FACTOR (GRF) PATHWAYS. G.S. Tannenbaum and C.Y. Bowers*. Depts. of Neurology & Neurosurgery and Pediatrics, McGill University, Montreal, Quebec H3H 1P3; and Tulane University Medical School, New Orleans, LA.

The synthetic hexapeptide GHRP is a potent secretagogue of GH, however its mechanism of action remains unknown. In the present study, we examined the temporal pattern of GH responsiveness to varying doses (1, 5, 10 and 20 μ g) of GHRP and GRF(1-29)NH₂ alone and in combination, and assessed the possible involvement of endogenous hypothalamic GRF. Six-hour (1000-1600 h) GH secretory profiles were obtained from free-moving adult male rats iv administered GHRP and GRF at times of spontaneous peaks (1100 h) and troughs (1300 h) in GH secretion. At peak times, GHRP stimulated GH release in a dose-dependent manner ($r = 0.89$; $p < 0.02$); the magnitude of the response was similar to that induced by GRF, except at the 1 μ g dose. Moreover, the GH response to GHRP was cyclical with GHRP-induced GH release significantly greater during peak compared to trough periods (459.5 ± 77.1 vs 213.9 ± 46.3 ng/ml at 5 μ g dose, $P < 0.01$; 704.3 ± 134.7 vs 219.6 ± 42.5 ng/ml at 20 μ g dose, $P < 0.05$), similar to that observed with GRF, the latter known to be due to the cyclic increased release of endogenous somatostatin. Comparison of the mean GH response when GRF (1 μ g) and GHRP (5 μ g) were administered simultaneously (931.8 ± 77.3 ng/ml) with the additive effect of the GH responses to GRF (1 μ g) and GHRP (5 μ g) administered separately (1077.9 ± 112.3 ng/ml) revealed no significant differences. Passive immunization with a specific GRF antiserum virtually obliterated the GH response to 5 μ g GHRP compared to normal sheep serum controls given the same dose of GHRP (19.3 ± 7.6 vs 293.1 ± 21.2 ng/ml; $P < 0.001$). These results demonstrate that 1) GHRP is a potent GH secretagogue but it does not act synergistically with GRF in the adult male rat; 2) GHRP does not disrupt the cyclical release of endogenous somatostatin; and 3) the GH response to GHRP is dependent on central GRF pathways.

144.3

GROWTH HORMONE REBOUND SECRETION FOLLOWING SOMATOSTATIN WITHDRAWAL IS CAUSED BY CALCIUM INFLUX.

MB McFarlane*, TO Bruhn and IMD Jackson. Division of Endocrinology, Brown University/Rhode Island Hospital, Providence, RI 02903.

It is well established that somatostatin (SRIF) is a potent inhibitor of growth hormone (GH) secretion, and that prior exposure to SRIF enhances basal and growth hormone-releasing factor (GRF)-induced GH secretion *in vivo* and *in vitro*. While the intracellular mechanisms involved in the action of SRIF have been described in detail, little is known about the events causing a burst of GH secretion following SRIF termination. We used a perfusion system to evaluate the post-SRIF rebound release of GH. Anterior pituitaries from male SD rats were gently dispersed with neutral protease and placed in perfusion columns on a bed of Sephadex G-10. After perfusion with Minimum Essential Medium (MEM) to evaluate basal GH release, 10 nM SRIF was perfused for 40 minutes, suppressing GH levels by 54.5±3.6% (p<0.01). The SRIF treatment was followed by a return to either normal MEM, Ca²⁺-free MEM with 1.5 mM EGTA or normal MEM with 2 mM cobalt chloride (Co²⁺). Upon return to normal MEM, GH levels increased to 186.9 ±15% (p<0.05) over basal release with peak levels reaching 261.4±25.4% (p<0.01). By either blocking calcium channels with Co²⁺ or removing Ca²⁺ from the perfusion medium we were able to completely abolish the GH rebound event. Moreover, we could produce a GH rebound secretory event by treatment with Co²⁺-containing or Ca²⁺-free media followed by normal MEM. Our findings suggest that the post-SRIF GH rebound secretion requires Ca²⁺ influx, an event which can be mimicked by simply interfering with Ca²⁺ balance. Because prolonged exposure to SRIF is known to prevent Ca²⁺ uptake by somatotrophs, it seems likely that termination of SRIF will cause GH rebound release due to a sudden increase in intracellular calcium.

IONIC CURRENTS IN PRIMARY CULTURES OF DISPERSED GOLDFISH PITUITARY CELLS. J.P. Chang, C.J. Price, R.M. Jobin* and J.L. Goldberg. Dept. of Zool., Univ. of Alberta, Edmonton, Alberta, Canada T6G 2E9.

Gonadotropin releasing hormone (GnRH) stimulation of gonadotropin and growth hormone secretion from goldfish pituitary cells appears to involve calcium influx through voltage-gated calcium channels. These secretion responses to GnRH are attenuated by phenylalkylamine and dihydropyridine calcium channel antagonists. Furthermore, both GnRH and potassium induce elevations in intracellular calcium in an extracellular calcium-dependent manner as measured by Fura-2 fluorescence. As an initial step in investigating the role of voltage-dependent ion channels in mediating hormone release from goldfish pituitary cells, we characterized the excitable membrane properties of these cells using tight-seal whole-cell recordings. Current clamp recordings revealed that these cells are electrically excitable. Single action potentials were evoked by depolarizing current pulses. Voltage clamp recordings revealed a fast inward sodium current and both a fast transient, and a sustained outward potassium current. After sodium and potassium currents were eliminated by ion substitution, a high-voltage activated calcium current was uncovered (Vholding: -70 mV). This current showed little inactivation over 100 ms, and was reduced 30-50% by verapamil or nifedipine. In preliminary experiments under total-current recording conditions, bath application of GnRH elicited a transient 50 pA inward current. These results are consistent with the involvement of voltage-gated ion channels in stimulation of hormone release.

GALANIN (GAL) CONTROL OF PROLACTIN (PRL) RELEASE IN THE RAT. V. Rettori*, A.G. Reznikov and S.M. McCann. Department of Physiology, UT Southwestern Medical Center, Dallas, TX 75235-9040.

The action of GAL injected intraventricularly (3V) was compared in ovariectomized (OVX) versus OVX EB-primed (P) (50 µg estradiol benzoate (EB) s.c. 72 hrs before) conscious rats. GAL induced a release of PRL in OVX animals; however, in the EB-P rats it had no effect. GAL had no effect on PRL release from hemipituitaries (APs) of castrated males, but the response to TRH (25 ng/ml) was augmented. GAL (10⁻¹⁰-10⁻⁶M) had a suppressive effect on AP PRL release in females, but enhanced increased release from TRH. In APs of EB-P females basal release of PRL was suppressed by 10⁻⁸-10⁻⁶M GAL. The dramatically enhanced response of EB-P APs to TRH was not altered by GAL. In the OVX rat GAL stimulates PRL release by hypothalamic action since GAL suppressed release of PRL by APs incubated *in vitro*. The lack of response to GAL in the EB-P animals may be via high levels in the AP causing lack of response to the small quantity of GAL injected. 3V injection of GAL antiserum had no effect in OVX rats, but augmented the surge of PRL in OVX-EB+progesterone-primed animals indicating a physiologically significant inhibitory effect on PRL release. HYPOTHALAMIC PRE-PROSOMATOSTATIN mRNA EXPRESSION IN TRANSGENIC MICE WITH EXCESS OR DEFICIENT GROWTH HORMONE. D.L. Hurlley and C.J. Phelps. Department of Anatomy, Tulane University School of Medicine, New Orleans, LA 70112.

In two spontaneous mutations causing hypopituitary dwarfism in mice (Snell and Ames), concomitant deficits in hypothalamic immunoreactive somatostatin (SST) levels have been observed. The present studies were undertaken to determine the effect of specific transgenically engineered GH deficiency or excess on CNS expression of somatostatin mRNA. Transgenic dwarf mice produced by selective destruction of endogenous GH cells via expression of a genomic insert of rat GH-diphtheria toxin A chain construct ([Tg (GH, DT-A+Mt-1, GHRF) Bri 78], Behringer *et al.*, *Genes Develop.* 2: 453, 1988) were examined for CNS expression of SST by *in situ* hybridization. Transgenic GH-excess (giant) mice ([Tg (Mt-1, GHRF) Bri 11], Hammer *et al.*, *Nature* 315: 413, 1985), which harbor metallothionein (MT)-hGHRH inserts, were also studied. An ³⁵S-labelled RNA probe (R. Goodman, New England Med. Ctr.) complementary to the 520 nt preproSST mRNA was hybridized to tissues under standard conditions. SST mRNA in hypothalamic anterior periventricular neurons was comparable for control animals and transgenic dwarfs. Signals in non-GH regulatory regions such as cortex were also comparable. SST mRNA signals were elevated in anterior periventricular neurons of the giant mice compared with brains of normal controls. Non-GH regulatory regions displayed levels of SST mRNA similar to those of normal animals. Thus, feedback effects of pituitary hormones upon hypophysiotrophic neurons may occur at a transcriptional level. However, while increased GH levels result in increased transcriptional activity in hypothalamic SST neurons, the absence of GH of transgenic dwarfs does not result in decreased steady-state levels of SST mRNA. Supported by PHS grant NS25987 (CJP).

EVIDENCE FOR SEX SPECIFIC EXPRESSION OF PROTRH PEPTIDES IN CULTURED ANTERIOR PITUITARY CELLS. T.O. Bruhn, T.G. Bolduc*, D.B. MacLean and I.M.D. Jackson. Div. Endocrinology, Brown Univ./RI Hospital, Providence, RI 02903.

We have recently demonstrated that thyrotropin-releasing hormone (TRH) and another ProTRH peptide, PreProTRH₂₅₋₅₀, are synthesized by anterior pituitary (AP) cells kept in monolayer culture for at least 7 days. In contrast, TRH was undetectable during the first 3 days of culture or when AP tissue was directly extracted following removal. The objective of this study was to determine whether the synthesis of TRH by cultured AP cells is influenced by gender. Pituitaries from male (m) and female (f) 15 day old rats were separately dispersed and cultured for up to 18 days. Levels of TRH in "female" cultures were 736 ± 40 compared with 2741 ± 165 fmoI/well (p<0.01) in "male" cultures. Marked differences in TSH and GH (m 1.8 and 2.2 x greater than f, p<0.01) and LH and FSH contents (f 1.4 and 1.5 x greater than m, p<0.05) but not PRL and ACTH were evident at 3 days in culture. Sex differences in GH contents (m 1.5 x greater than f, p<0.05) persisted throughout the time course of culture while TSH, LH, FSH, PRL, ACTH contents were not significantly different at 18 days. Immunohistochemical studies using antisera directed against 4 different epitopes of the ProTRH molecule revealed positive staining in approximately 10% of the cell population. While these cells had the appearance of gonadotrophs, thyrotrophs or somatotrophs, further studies are needed to determine the cell type expressing ProTRH peptides. In conclusion, we have found a marked sex difference in TRH expression by cultured AP cells. We are currently exploring this further by investigating the role of gonadal steroids administered *in vivo* on subsequent TRH expression by AP cells *in vitro*.

SMS 201-995 INHIBITS ESTROGEN-INDUCED PITUITARY TUMOR FORMATION: EFFECTS ON GALANIN AND PROLACTIN. J.E. Hyde, Dept. of Anatomy and Neurobiology, University of Kentucky College of Medicine, Lexington, KY 40536.

Estrogen (E) induces prolactinoma formation in Fischer 344 rats. In addition to its effects on prolactin (PRL), E also increases galanin gene expression within the anterior pituitary (AP). We have shown that galanin and PRL secretion from AP cells are inhibited by somatostatin. The objectives of this study were to examine if the somatostatin analog SMS 201-995 (Sandostatin) affects 1) E-induced pituitary tumor growth, and 2) galanin or PRL levels in the AP. Ovariectomized F344 rats (n=4-5/group) were implanted with 17β-estradiol-containing or empty capsules (sc), and Alzet osmotic pumps containing SMS 201-995 (Sandoz; 1.5 mg/pump) or saline. After 2 weeks, the AP were analyzed for hormone content by RIA. E treatment increased AP size 2.5-fold, and this effect was completely antagonized by SMS 201-995. E increased plasma PRL levels compared to controls (794.5 ± 56.0 vs. 15.6 ± 1.5 ng/ml). SMS 201-995 reduced the elevated PRL levels (32.6 ± 2.7 ng/ml). Galanin levels in the AP were increased by E (310.3 ± 28.4 vs. controls 1.9 ± 0.1 ng/mg protein). SMS 201-995 alone decreased galanin levels in the AP (1.3 ± 0.1 ng/mg protein). Galanin levels were increased with E plus SMS 201-995 (406.4 ± 43.6 ng/mg protein). AP PRL levels paralleled galanin content. Conclusions: SMS 201-995 1) prevents E-induced pituitary tumors in F344 rats, and 2) increases the AP contents of galanin and PRL in E-exposed rats, possibly by inhibiting hormone release. These studies suggest that SMS 201-995 may be useful in the treatment of some prolactinomas. (Supported by American Cancer Society #IN-163)

COMPARISON OF BIOLOGICAL ACTIVITIES OF ENDOTHELIN-1, -3, SARAFOTOXIN S6b AND S6c IN RAT PITUITARY CELL CULTURE. B. Kanyicska and M.E. Freeman, Dept. of Biol. Sci., Florida State Univ., Tallahassee, FL 32306.

Natural isopeptides of the endothelin/sarafotoxin peptide family were used to study structure-activity relationship and to characterize the endothelin receptors in the pituitary gland. In order to establish the time- and concentration dependency of the responses of pituitary cells in culture, the effect of endothelins (ET-1, ET-3) and sarafotoxins (S6b and S6c) on anterior pituitary hormone secretion was investigated over a wide range of concentrations (from 10^{-15} to 10^{-6} M) and incubation times (from 1 to 48 hours). ET-1, ET-3, S6b and S6c elicited an inhibition of prolactin (PRL) secretion and stimulated the release of luteinizing hormone (LH), follicle stimulating hormone (FSH) and thyroid stimulating hormone (TSH) from primary monolayer cultures of anterior pituitary cells obtained from female rats. None of the peptides effected growth hormone (GH) secretion, regardless of concentration and incubation period tested. The incubation time necessary to elicit maximal responses varied greatly from 3 h to 48 h, depending either on the peptide applied or on the hormone assayed. The concentration of peptides necessary for the half maximal response (EC_{50}) was calculated using non-linear regression analysis of dose-response curves. ET-1 was the most potent inhibitor of PRL secretion (ED_{50} : 0.78 pM) and also the most potent releaser of LH (0.11 nM), FSH (0.45 nM) and TSH (0.6 nM). Interestingly, the relative rank order of potency of ET-like peptides were similar for all four pituitary hormones: ET-1>S6b>ET-3>>S6c. This suggests, that pituitary lactotroph, gonadotroph and thyrotroph cells possess the same or very similar set of ET-receptor(s). These data also indicate the relative importance of certain structural elements to ensure persistence and/or potency of ET-like peptides. Supported by NIH, NICHD, HD-11669.

STRUCTURE ELUCIDATION OF A PINEAL DECAPEPTIDE WITH ANTIGONADOTROPIC AND DOPAMINE RELEASING ACTIVITY. B. Benson and I. Ebels*, Dept. of Anatomy, Univ. of Arizona, Tucson, AZ 85724.

An antigonadotropic peptide was purified from more than ten kilograms of defatted bovine pineal glands. The peptide was extracted with 0.2 N acetic acid and partially purified by serial ultrafiltration and Sephadex G-25 chromatography. Low M_r peptides were further separated by serial HPLC on semipreparative C-8 columns with aqueous binary and ternary gradient mobile phases consisting of acetonitrile (ACN) and trifluoroacetic acid (TFA). Final isolation was achieved by HPLC on a 1.0 X 25 cm, C-8 60 Å column with ternary gradient mobile phases containing ACN, TFA, methanol and $NH_4C_2H_3O_2$ as ion-pairing reagent. Automated amino acid analysis of the homogenous antigonadotropic peptide yielded Thr, Phe, Pro, Tyr and Ser; automated microsequence analysis revealed the primary structure:

NH_2 -Ser-Phe-Pro-Thr-Thr-Lys-Thr-Tyr-Phe-Pro-COOH
When injected intravenously into unanesthetized male rats either the natural or a synthetic decapeptide of identical structure reduced serum levels of LH and PRL, probably via stimulatory effects on hypothalamic dopamine release. (Supported by N.I.H. grant #HD 19521)

EFFECTS OF SUBSTANTIA NIGRA GRAFTS ON THALAMIC NUCLEI AND BASAL GANGLIA OUTPUT. A. Zainos-Rosales*, R. Aguilar-Roblero, J.L. Mendoza-Ramirez* and R. Drucker-Colin, Instituto de Fisiología Celular, UNAM, Ap. Pos. 70-600 México, D.F. 04510 México.

Turning behavior induced by apomorphine in rats with a previous unilateral lesion of mesostriatal dopaminergic pathway with 6-OHDA, is reduced by intrastriatal or intraventricular fetal substantia nigra grafts (FSNG). Several studies have shown that this type of graft induces a recovery of supersensitive dopamine receptors. No studies have shown a functional influence of the graft beyond the denervated striatum. The aim of this study was to determine the effects of fetal substantia nigra grafts on the striatal output nuclei: substantia nigra reticulata (SNR), globus pallidus (GP) and entopeduncular nucleus (EP) by means of the 2-deoxyglucose autoradiographic method. Male Wistar rats were lesioned unilaterally with 6-OHDA and turning behavior was tested. These animals received FSNG (15-17 days) and turning was tested again in all animals for 8 weeks. At the end of this period, rats received an intravenous administration of [^{14}C]-2-deoxyglucose (10 μ Ci/100gr). The rats were divided as follows: Group A: intact rats plus saline; Group B: intact rats plus apomorphine; Group C: 6-OHDA-lesioned rats plus saline; Group D: 6-OHDA-lesioned rats; Group E: 6-OHDA-lesioned rats plus FSNG with decrease in turning behavior and Group F: 6-OHDA-lesioned rats plus non-dopaminergic graft. The results show an asymmetrical change in glucose consumption in SNR and EP but not in GP, in groups D, E, and F, between left and right sides. However in Group F this asymmetrical change is decreased in SNR because of an enhancement in glucose consumption in the non-lesioned side. This effect was not found in EP in Groups D, E and F. On other hand, we found a bilateral enhancement in the thalamic nuclei (TN) only in Group E (around 50% with regard to Group B). Our results suggest that FSNG has a moderate influence on striatal output nuclei, but has a much greater effect on TN. Lesioning TN has been used as a therapeutic method for parkinsonian patients. This study presents some evidence for the participation of TN in a rodent model of Parkinson's disease.

AROMATIC L-AMINO ACID DECARBOXYLASE (AADC) ACTIVITY IN THE HYPOTHALAMUS (HT) DURING THE ESTROUS CYCLE: EFFECTS OF AGING. P.S. Mohankumar, S. Thyagarajan and S.K. Quadri, Neuroendocrine Research Laboratory, Kansas State University, Manhattan, KS 66506.

A surge in luteinizing hormone (LH) occurs during the afternoon of proestrus (PE) in young (Y; 4-5 months) rats. This LH surge is reduced in amplitude and its onset is delayed in middle-aged (MA; 8-10 months) rats. Several studies have indicated that neurotransmitters, especially the catecholamines (CA), play an important role in the regulation of the LH surge. However, very few studies have examined the activity of the enzymes involved in the synthesis of the CA. In this study, we investigated the activity of AADC, which synthesizes dopamine (DA) from l-dopa, in the medial preoptic area (MPA) and the arcuate nucleus (ARC) of the HT. Groups of Y animals were sacrificed at 1000, 1200, 1400, 1600, 1800 and 2000 hrs on the day of PE. Groups of MA and old (O; 18-22 months) animals were sacrificed at 1400, 1600, 1800 and 2000 hrs on the day of PE and during pseudopregnancy, respectively. The MPA and ARC were punched out from brain sections and stored in 0.32 M sucrose at -70°C. The punches were homogenized at the time of assay, and the homogenates were incubated with the substrate and cofactors at 37°C for 30 min. DA was isolated using a cation exchange resin and quantified using high performance liquid chromatography. In the MPA of Y animals, AADC activity increased significantly from 246.4 ± 37.6 pg/ug protein at 1000 hrs to 533.1 ± 188.4 pg/ug protein at 1400 hrs ($p < 0.05$). In MA and O animals, there were no significant changes in AADC activity, though there was a trend to increase at 1600 hrs in MA animals. In the ARC of Y animals, AADC activity was high at 1000 hrs (407.7 ± 114.4 pg/ug protein) and decreased significantly at 2000 hrs (73.8 ± 24.7 pg/ug protein, $p < 0.05$). In MA and O animals, AADC activity showed no significant changes. These changes in AADC, through its effects on CA synthesis, might contribute to the age-related changes observed in the LH profile. EFFECTS OF REFRIGERATION AND TISSUE CULTURE ON DOPAMINE PRODUCTION AND TRANSPLANT SURVIVAL OF FETAL MESENCEPHALIC DOPAMINE CELLS. J.X. Qi, P. Patino, E. Kriek, C. Kruse, C. Hutt, and C.R. Freed, Depts. Med., Pharm., Surg., Univ. Colo. Sch. Med., Denver, CO 80262.

Because of delays between recovery and transplant of fetal dopamine cells into patients with Parkinson's disease, we have studied the transplant survival of fetal cells after short term refrigeration or tissue culture. Effects of 24 refrigeration (8-10 degrees C) in high K^+ (30 mM) or high Na^+ (150 mM) buffer were examined. Survival in tissue culture was estimated by the accumulation of homovanillic acid (HVA). Results showed that transplants of fresh tissue or tissue refrigerated either in high Na^+ or high K^+ buffer showed high quality transplants both behaviorally (>95% decrease in ipsilateral circling to methamphetamine 5 mg/kg i.p.) and histologically. Cells held in tissue culture for one week showed less good behavioral effects (72% decrease in methamphetamine circling) and in histologic appearance. Refrigeration in Na^+ or K^+ buffers prior to tissue culture did not reduce the rate of production of HVA in tissue culture over one week. We conclude that 24 hr refrigeration of mesencephalic dopamine cells does not hurt transplant survival of rat mesencephalic dopamine cells while one week in tissue culture prior to transplant produces lower quality transplants.

EFFECTS OF NIGRAL GRAFT ON SUBSTANCE P AND ENKEPHALIN EXPRESSION IN THE GLOBUS PALLIDUS AND SUBSTANTIA NIGRA IN 6-OHDA-LESIONED RATS. D. Gaudin, B. Lavoie, A. Parent and P.J. Bédard, Centre de Recherche en Neurobiologie., Hôp. Enfant-Jésus, Depts Pharmacology and Anatomy, Laval Univ., Québec, (QC), CANADA G1K 7P4.

Studies by Young et al, 1986 and more recently by Gerfen et al., 1991, using *in situ* hybridization, have shown that the degeneration of dopaminergic nigrostriatal pathway resulted in a differential modulation of the neuropeptides substance P (SP) and enkephalin (ENK) in the striatum. In this perspective, we have investigated two structures receiving important striatal inputs: the substantia nigra pars reticulata (SNr) and the globus pallidus (GP). The effects of dopaminergic depletion and intra-striatal fetal dopaminergic graft on the expression of SP and ENK have been immunohistochemically studied in the rat bearing a 6-OHDA-lesion. Eight female rats were lesioned with 6-OHDA in the left substantia nigra and 4 untreated animals were used as control. The animals were tested for circling with amphetamine (2.5mg/kg) and apomorphine (0.25mg/kg). Four rats received a striatal graft of 1.5×10^6 cells taken from the ventral mesencephalon of 13-14 day old rat embryos. The results analysed by a computerized image-analysis system, showed a decrease of SP in SNr and an increase of ENK in GP in lesioned rats. These changes were normalized in animals which received striatal grafts. [Supported by MRC du CANADA, Network of Excellence on Neural Regeneration and Functional Recovery and FCAR]

MORPHOLOGICAL AND BEHAVIORAL DRAWBACKS OF PHASEOLUS VULGARIS LEUCOAGGLUTININ-LABELING OF A FETAL DOPAMINERGIC CELL SUSPENSION PRIOR TO GRAFTING IN THE DENERVATED RAT CAUDATE-PUTAMEN. H.W.M. Steinbusch, M.J. Dolleman, Van Der Weel and A. Nijssen, Dept. Pharmacology, Faculty of Medicine, Free University, Amsterdam, The Netherlands

Unilaterally 6-hydroxydopamine (6-OHDA) lesioned rats were allocated into three groups, which all received an injection of a fetal dopaminergic cell suspension in the denervated caudate-putamen. The first group (T-Pha) received dopaminergic cells, which were incubated with Phaseolus vulgaris leucoagglutinin, the second group (T-saline) received cells submitted to the same incubation procedure, but without Pha-L and the third group (T) received simply dissociated cells. Upon 8 weeks survival morphological analysis showed a punctate Pha-L staining of fiber particles and some pale Pha-L stained spots, presumably cell bodies, inside the grafts of group T-Pha. Pha-L labeled grafts were significantly decreased in graft volume and contained markedly less dopamine-immunoreactive (DA) cells in comparison to the grafts of groups T-saline and T. The ratio DA, cell type I (cell with $3 \leq$ processes) / DA, cell type II (cell with ≥ 4 processes) was in group T-saline and group T approximately 8 and in group T-Pha 3. Thus, the primary effect of Pha-L was a selective neurotoxicity to DA, cell type I neurons. Concerning our behavioral data the labeled grafts did not cause a recovery from lesion induced motor asymmetries in the d-amphetamine induced rotations. On the contrary, upon 7 weeks survival an increased number of amphetamine induced rotations was found in group T-Pha while in group T-saline and group T a (restricted) decrease of rotational behavior occurred. In apomorphine induced rotations there was no difference between the three groups. In conclusion, Pha-L can not be used successfully as a marker for host-graft interactions, using fetal dopaminergic cells in long term survival experiments.

PERIPHERAL NERVE SEGMENTS PROVIDE A SUBSTRATUM FOR RELIABLE AND EXTENDED SURVIVAL OF ADRENAL MEDULLA TRANSPLANTS IN THE BRAIN. L.C. Doering, Department of Biomedical Sciences, Division of Anatomy, McMaster University, Hamilton, Ontario, CANADA L8N 3Z5.

Solid grafts of the adrenal medulla (AM) can survive for up to 1 year in the sciatic nerves of adult rats. This finding prompted the intracerebral grafting of peripheral nerves as a local environment to promote the survival of chromaffin cells within the CNS.

Small aspiration cavities were initially made over the striatum in adult Lewis rats. After 2-4 weeks a 1.0 cm length of sciatic nerve was inserted into the cavity. After an additional 2-4 weeks, grafts (0.5-1.0 mm²) of adult AM were finally implanted into the core of the nerves.

The peripheral nerve-AM complexes were studied by electron microscopy and immunohistochemistry. Antibodies against tyrosine hydroxylase (TH) and dopamine- β -hydroxylase (DBH) were used to identify the AM, and Schwann cells were labeled with the antibodies 192-IgG and Rat-401. All the AM transplants consisted of 1.0 - 2.0×10^3 chromaffin cells positive for TH and DBH after 6 months of survival (longest time point studied).

In conclusion, intracerebral sciatic nerve segments provide an excellent tissue environment for the consistent long term viability of chromaffin cells and open new avenues to truly examine the efficacy of the AM transplant. (Supported by The Parkinson Foundation of Canada)

NORMALIZATION OF SPONTANEOUS ACTIVITY OF SUBSTANTIA NIGRA PARS RETICULATA CELLS, MODIFIED AFTER 6-OHDA-LESION, BY NIGRAL GRAFTS INTO THE STRIATUM. L. Tremblay, D. Gaudin, H. Richard* and P.J. Bédard, Centre de Recherche en Neurobiologie, Hôp. Enfant-Jésus, Depts Pharmacology and Physiology, Laval Univ., Québec, (QC), CANADA G1K 7P4.

The results of several studies have shown that the interruption of the nigrostriatal pathway causes an increase of firing rate of the substantia nigra pars reticulata (SNr) cells. Recently, we have shown that the intra-striatal graft of fetal dopaminergic cells corrected the 6-OHDA-induced changes of D-1 receptors that appear to be localized on striatonigral neurons. This study was performed to evaluate the effects of a graft implanted into the striatum on neuronal activity of SNr cells modified by the degeneration. Female rats were lesioned with 6-OHDA in the left substantia nigra. The animals were tested for circling with amphetamine (2.5mg/kg) and apomorphine (0.25mg/kg). The rats which displayed circling with these two drugs were then divided into two groups. One group received a graft of 1.5×10^6 cells taken from the ventral mesencephalon of 13-14 day old rat embryos. The other group was not grafted. 6 months after the graft we performed single cell recordings of nigral reticulata neurons under ketamine anesthesia.

The analysis confirmed the increase of the firing rate on the side ipsilateral to the lesion and showed that the frequency is also elevated on the contralateral side. The graft of fetal nigral neurons normalized the firing pattern of the SNr on both sides. This study is the first to demonstrate, with an electrophysiological approach, that nigral grafts placed in the striatum have a transsynaptic action. [Supported by MRC of CANADA, Network of Excellence on Neural Regeneration and Functional Recovery and FCAR].

ADRENAL MEDULLA GRAFTS RESTORE STRIATAL SYMMETRY. E.I. Curran and J.B. Becker, Neuroscience Program and Department of Psychology, The University of Michigan, Ann Arbor, MI 48109.

Intraventricular adrenal medulla grafts decrease the rotational behavior induced by amphetamine (AMPH) or apomorphine (APO). We have previously shown that adrenal medulla grafts differentially effect these two behaviors. Some animals express a decrease in both AMPH- and APO-induced turning, but others exhibit a decreased response exclusively to AMPH or APO. One mechanism that may distinguish animals that express a decreased behavioral response to AMPH from those that show a decreased response to APO may involve a decrease in the asymmetry in DA release between the intact and the denervated striatum. To examine this hypothesis, we used *in vivo* microdialysis techniques to determine basal and AMPH-stimulated DA release within the intact and the denervated striatum of rats with adrenal medulla grafts that resulted in a decrease in AMPH-induced turning, APO-induced turning, or were noneffective.

The symmetry in AMPH-stimulated DA release is restored in animals with a graft-induced decrease in AMPH-induced turning. This effect is significantly greater than that observed in rats with adrenal medulla grafts that decreased APO-induced turning and animals with no recovery. This increase in striatal symmetry was associated with significantly higher basal and AMPH-stimulated DA release within the denervated striatum. These results suggest that: (1) A decrease in AMPH-induced turning involves changes in extracellular DA concentrations within the denervated striatum that contribute to an increase in striatal symmetry, and (2) Graft-induced recovery in the behavioral response to APO does not appear to involve this mechanism. (Supported by NS22157).

Recovery in hemiparkinsonian rats after intracaudal implantation of IL-1 containing pellets. J.Wang*, R.J.Plunkett*, J.G.Sheng*, E.H. Oldfield* and K.S. Bankiewicz, CNS Implantation Unit, Surgical Neurology, NINDS, National Institutes of Health, Bethesda, MD 20892.

Solid tissue implantation and/or surgical trauma to the MPTP-lesioned caudate nucleus in hemiparkinsonian monkeys leads to behavioral improvement, the mechanism of which may be ingrowth of remaining host dopaminergic fibers. The mechanism for stimulation of such fiber growth is under investigation. One possibility is a secretory product of microglia cells which are present at the site of implant or trauma. In a previous experiment we demonstrated that neonatal microglia, which release interleukins, when implanted into 6-OHDA-lesioned hemiparkinsonian rats leads to behavioral recovery which is associated with the sprouting of host dopaminergic fibers. In the current experiment, slow release polymer pellets loaded with IL-1 were stereotaxically implanted into the lesioned caudate of hemiparkinsonian rats.

27 gangliectomized male Sprague-Dawley rats were rendered hemiparkinsonian either by intra-nigral (partially lesioned-PL) or intra-bundle (totally lesioned-TL) injections of 6-OHDA. 6 groups were studied: unimplanted PL (n=5) and TL (n=4) rats, placebo implanted PL (n=4) and TL (n=4) rats, IL-1 implanted PL (n=4) and TL (n=6) rats. Amphetamine-induced rotation was tested weekly for 4 weeks after the lesion and 8 weeks after implantation.

There was no change of turning in any of the studied groups except the IL-1-implanted PL rats. In this group turning was reduced by 85% ($p < 0.001$) between 4-8 weeks after implantation. In all animals with decreased turning there were tyrosine hydroxylase immunopositive fibers in the medial and lateral caudate. We also observed significant gliosis around the implanted pellets, as well as in the entire caudate. Biochemical analysis of the implanted and sprouted areas revealed increased tissue levels of dopamine on medial part of the caudate nucleus only in the IL-1 implanted PL rats. Secretory products (trophic factors?) that are released from the host IL-1-stimulated astrocytes may be responsible for dopaminergic fiber sprouting and behavioral recovery.

A REAL-COLOR AND DIGITAL IMAGE ANALYSIS OF XENOIMPLANTED RABBIT DOPAMINERGIC NEURONS. J.J. López-Lozano and B. Brera. Neurobiology Lab., Dept. of Exp. Surgery. Clínica Puerta de Hierro, 28035 Madrid, Spain

In earlier works, we have shown that for rabbit ventral mesencephalic neurons (RVMN) of different postconceptional ages to survive in the unilaterally denervated striatum of adult rats, the animals need to be immunosuppressed. Failure in this respect (ie, via administration or individual variability in CyA levels) or lack of immunosuppression cause the implanted cells to be rejected, onset of which occurs one week later. In contrast, RVMN implanted into the striatum of rats with therapeutic CyA levels were able to survive for long periods of time (6 mo), integrate and develop to a mature TH-phenotype. As an extension of these studies, this report applies image analysis to assess and quantify morphologically and morphometrically the implanted cells and their relationships with the host. Rabbit embryos of 16-18 days were decapitated and their ventral mesencephalon was denervated by an enzymatic-mechanical procedure as described (Brain Res 1989;86:351). Then, a suspension of cells was stereotaxically injected into 6-OHDA denervated striatum of CyA-treated rats (10 mg/kg ip). At intervals of 1-6 mo, their striata were morphologically and morphometrically analyzed by TH and GFAP-ICC and Nissl-stain under an Olympus microscope interfaced to an IMCO-10 (Kontron)-MIP operative system (Micron). This study will evaluate in depth: 1) the morphological and morphometric values of VMN (area, perimeter, diameter, polarity, type of cells, etc.); 2) quantitative information regarding the a) location, migration and percentage of implanted cells according to the implantation site; b) the measurement of neural projections and the relationship with the host (innervation area, spatial location, etc.). EFFECTS OF DOPAMINE D1 AND D2 RECEPTOR SELECTIVE AGENTS ON DOPAMINE RELEASE AS MONITORED BY *IN VIVO* VOLTAMMETRY IN INTRASTRIATAL GRAFTS OF DOPAMINERGIC NEURONS.

Moukhes H., Forni C., Salin P., Nieoullon A. and Daszuta A. Neurochemistry Unit, LNF, CNRS, 13402 Marseille, France.

Intrastriatal grafts of fetal tissue containing dopamine (DA) neurons have been shown to induce functional recovery in 6-OHDA lesioned rats. In order to evaluate the integration of the transplanted dopaminergic neurons in the host circuitry, we have investigated the effect of dopamine D1 and D2 receptor selective drugs on DA release measured by *in vivo* voltammetry, in both grafted striatum and contralateral control striatum. Previous data obtained in the laboratory by using this method have shown that the development of grafted cells could be related to changes in the amplitude of the signal given by the multifiber carbon electrode (Forni et al., Expl. Brain Res., 76, 75-87, 1989). In similar conditions, after stabilization of the signal observed between 3 and 7 weeks post-grafting, the effect of the D2 antagonist raclopride, dopamine D1 agonist SKF 38393 and D1 antagonist SCH 23390, were tested following i.p. or s.c. injections in freely moving grafted and normal rats. Raclopride (0.5 mg/Kg) was without effect on DA release, SCH 23390 (0.1 mg/Kg) induced a small (20%) increase, while the opposite effect could be observed in the voltammetric signal following SKF 38393 injection (10mg/Kg). Similar data were obtained from both sides of the grafted animals and in the normal control group. Administration of mixed agonist/antagonist will be used to further examine the possible occurrence of a "local" functional "striato-nigral feedback loop" in the grafted striata.

NITRIC OXIDE MEDIATES GLUTAMATE-INDUCED ENDOGENOUS ADP-RIBOSYLATION IN CEREBELLAR GRANULE CELLS. J. T. Wroblewski, R. Raulli and E. Costa. Fidia-Georgetown Institute for the Neurosciences, Georgetown Univ. Sch. of Med., Washington, DC 20007.

In primary cultures of cerebellar granule cells the stimulation of ionotropic N-methyl-D-aspartate (NMDA)-sensitive glutamate receptors leads to a Ca^{2+} -dependent activation of nitric oxide (NO) synthase and enhanced NO formation. Sodium nitroprusside (SNP) which releases NO has been shown to enhance the activity of endogenous ADP-ribosyltransferases causing in granule cell homogenates the incorporation of ^{32}P label from [^{32}P]NAD into a 45 kD protein band. This effect was also produced in a dose-dependent manner by the direct application of NO to granule cell homogenates confirming that the action of SNP is mediated by NO. The incubation of intact granule cells with glutamate caused a decrease in the ability of SNP to induce ADP-ribosylation in cell homogenates, suggesting that glutamate receptor stimulation may enhance the activity of endogenous ADP-ribosyltransferases. The effect of glutamate was abolished by the NO synthase inhibitor N^G-monomethyl-L-arginine indicating that it is mediated by NO formation. This effect was also inhibited by CPP, the selective antagonist of NMDA-sensitive glutamate receptors. Among other glutamate receptor agonists an even stronger decrease of the radioactive band was obtained with NMDA and a partial decrease with kainate, while AMPA was inactive. In contrast, pretreatment of granule cells with quisqualate, the agonist of the metabotropic glutamate receptor caused an enhancement of the ability of SNP to cause ADP-ribosylation in cell homogenates. These results suggest that the activation of glutamate receptors may affect the activity of endogenous ADP-ribosyltransferases resulting in ADP-ribosylation of GTP-binding proteins and thereby in the regulation of neurotransmitter receptor action at the level of recognition site-effector coupling

146.3

INHIBITION OF N-METHYL-D-ASPARTATE-INDUCED CALCIUM INFLUX IN CEREBELLAR NEURONS BY SODIUM NITROPRUSSIDE IS NOT MEDIATED BY NITRIC OXIDE. L. Kiedrowski, E. Costa and J. T. Wroblewski. Fidia-Georgetown Institute for the Neurosciences, Georgetown University School of Medicine, Washington, DC 20007.

In primary cultures of cerebellar granule cells sodium nitroprusside (SNP) acting through the release of nitric oxide (NO) stimulates guanylate cyclase and causes cGMP accumulation. SNP also inhibited, in a dose-dependent manner ($IC_{50} = 8.2 \mu M$), the $^{45}Ca^{2+}$ influx enhanced by N-methyl-D-aspartate (NMDA). This SNP effect was time-dependent, reached a maximum if SNP was added 10 min prior to NMDA, and disappeared when measured 10 min after SNP withdrawal. SNP also inhibited the NMDA-induced NO synthase activation, as measured by the conversion of [3H]arginine to [3H]citrulline. However, SNP failed to inhibit NO synthase activation induced by the Ca^{2+} ionophore A23187 suggesting that SNP had no direct effects on NO synthase activity but decreased Ca^{2+} availability to this Ca^{2+} /calmodulin-dependent synthase. The action of SNP was selective for $^{45}Ca^{2+}$ influx induced by the activation of NMDA receptors and failed to decrease the action of kainate. SNP also failed to inhibit the rate of $^{45}Ca^{2+}$ efflux from preloaded cells suggesting that its action is due to decreased Ca^{2+} entry, rather than enhanced Ca^{2+} extrusion. The fact that SNP was more potent and less rapid in inhibiting $^{45}Ca^{2+}$ influx than in producing the NO-mediated stimulation of cGMP formation suggested that its action may be produced not by the released NO but by $[Fe(CN)_6NO]^{2-}$ or $[Fe(CN)_6H_2O]^{2-}$ ions. In fact, the photolysis of SNP yielded a compound that inhibited NMDA-induced $^{45}Ca^{2+}$ influx but failed to enhance cGMP formation. The inhibitory action of SNP was also mimicked by $[Fe(CN)_6]^{4-}$ but not by $[Fe(CN)_6]^{3-}$, $[CN]^-$, Fe^{2+} , Fe^{3+} or $[NO_2]^-$ ions.

146.2

NITRIC OXIDE SYNTHASE: MOLECULAR CHARACTERIZATION AND FUNCTIONAL EXPRESSION OF THE CLONED GENE. D. S. Bredt, P. M. Hwang, C. Glatt, T. M. Dawson, M. Fotuhi, V. Dawson, C. Lowenstein, C. D. Ferris, R. R. Reed, and S. H. Snyder. Johns Hopkins U. Sch. of Med. Baltimore

Nitric oxide (NO), first identified as endothelial derived relaxing factor, is now recognized as a major neuronal messenger molecule. Nitric oxide is generated in the brain and vasculature from arginine and NADPH by a calcium dependant enzyme. Our discovery that NO production also requires calmodulin enabled us to purify nitric oxide synthase (NOS) to homogeneity. Tryptic peptides of NOS were sequenced and used to isolate the cDNA from rat brain. The clones isolated included a 4.6 kb open reading frame which codes for a 160 kD polypeptide similar to the apparent mass of purified NOS. The carboxy-terminal half of the amino acid sequence shares high similarity with cytochrome P450 reductase, while the amino-terminal half is unlike any known protein. The cDNA codes for functional NOS as expression in kidney cells yield high levels of NOS protein and enzyme activity. Mapping of NOS protein and mRNA throughout the body reveals discrete neuronal localizations and an absolute overlap with neuronal NADPH diaphorase. Cells transfected with NOS cDNA histochemically stain for NADPH diaphorase establishing that NOS catalytic activity accounts for diaphorase staining of neurons in brain. NADPH diaphorase positive neurons are uniquely resistant to degenerative, ischemic, and excitotoxic insults. Transfection of NOS cDNA into neuronal cells should help clarify the role of NO as a mediator of neurotoxicity.

146.4

PLATELET-ACTIVATING FACTOR IS A MEDIATOR OF *fos* EXPRESSION INDUCED BY A SINGLE SEIZURE IN RAT HIPPOCAMPUS. V.L. Marcheselli, J.P. Doucet, and N.G. Bazan. LSU Eye Center and Neuroscience Center, New Orleans, LA 70112.

Electroconvulsive shock (ECS) and convulsant drugs (e.g. pentylenetetrazol) induce a rapid increase of *fos* expression in brain. At the same time, a rapid activation of phospholipase A_2 occurs (BBA 218:1, 1970), and platelet-activating factor (PAF), as well as free polyunsaturated fatty acids, accumulate. We have shown that a PAF antagonist, BN-50730, injected intraperitoneally, partially inhibits the *fos* mRNA expression induced by ECS (Soc Neurosci Abs 16:629, 1990). To ensure access of the PAF receptor antagonist to the brain, we injected, 30 min prior to the experiment, BN-50730 solubilized in DMSO (2.5 mg/270-300 g body weight rats) intracerebroventricularly. Under these conditions we found 90% inhibition ($p < 0.001$, $n=6$) of *fos* mRNA induction in hippocampus by single ECS. Control animals were rats similarly injected with vehicle alone or sham-operated ones. The accessibility of the drug to the sites of action may play a role in this effect. BN-50730 is a potent PAF antagonist of the high-affinity intracellular binding sites (J Biol Chem 265:9140, 1990) but not of the sites located on the synaptic plasma membranes (Trans Am Soc Neurochem 22:187, 1991). BN-52021, a weak noncompetitive PAF antagonist of intracellular binding sites, is ineffective in decreasing ECS-stimulated *fos* expression. These results suggest that a) PAF *in vivo* may play a role as a mediator of *c-fos* expression in brain, and b) that intracellular PAF-binding sites may be involved in the activation of immediate-early gene expression during seizures. Supported by NINDS NS23002.

DISTRIBUTION OF PROTEIN KINASE C δ IN THE RAT BRAIN.

I. Merchenhaller, A. Negro-Vilar and W. Wetzel. LMIN, NIEHS, NIH, Research Triangle Park, NC 27709

Protein Kinase C (PKC) represents a family of isoenzymes that consists of at least nine members with clearly related but distinct structures. PKC α , - β , - γ , - δ , - ϵ , - ζ , and - η are characterized by stringent dependencies on Ca $^{2+}$, phospholipid and diacylglycerol. By contrast, PKC δ , - ϵ , - ζ and - η exhibit Ca $^{2+}$ -independent activities. We have selected the PKC δ isoenzyme for these studies and report, for the first time, its distribution in the rat brain. When vibratome sections are stained with polyclonal PKC δ antisera and the PAP technique, we have found that, while PKC δ is distributed throughout the brain, it is confined to specific nuclei and fiber tracts. In the telencephalon, PKC δ -immunopositive (PKC δ -i) perikarya were present in the lateral septum, the central nucleus of the amygdala, the diagonal band, and the basal caudate-putamen. In the diencephalon, the majority of PKC δ -i perikarya were seen in the thalamus and the medial geniculate bodies. In the hypothalamus, the magnocellular subdivisions of the hypothalamic paraventricular nucleus, the supraoptic nucleus, and the accessory magnocellular nuclei were distinctly stained. Perikarya in the arcuate and periventricular preoptic nuclei were lightly stained. In the brainstem, immunopositive perikarya were observed in the substantia nigra, the medial vestibular nuclei, the inferior cerebellar peduncle, the inferior olive, and the nucleus of the solitary tract. In the cerebellum, some of the Purkinje cells appeared to be immunopositive, and some of them seemed to be heavily innervated by PKC δ -i climbing fibers. PKC-i fibers and nerve terminals were seen in the cerebral cortex, the lateral septum, the internal zone of the median eminence and the neural lobe, the inferior cerebellar peduncle, and the cerebellar nuclei. These morphological observations indicate that PKC δ is associated with a variety of functions in the central nervous system.

FLUCTUATION OF RAT BRAIN CA $^{2+}$ POOLS IN KAINIC ACID INDUCED LIMBIC SEIZURE STATUS. Ajay Verma, David J. Hirsch, Ted M. Dawson, Charles Glatt, and Solomon H. Snyder. Department of Neuroscience, Johns Hopkins School of Medicine, Baltimore, MD 21205.

Microinjection of kainic acid into a unilateral amygdala in rats elicits limbic seizure status involving predominantly unilateral limbic structures. Such seizure activity markedly increases Ca $^{2+}$ influx (1) and local cerebral glucose utilization (2) in limbic structures on the kainic acid-injected side. Elevated metabolic demand and endoplasmic reticulum (ER) modifications (3) may reflect neuronal efforts to correct excessive cytoplasmic Ca $^{2+}$ levels via calcium ATPases. Using in vitro 45Ca $^{2+}$ autoradiography, we have examined ATP dependent ER Ca $^{2+}$ uptake in fresh-frozen 20 μ M sections of rat brain during limbic seizure status. Two hours after kainic acid injection into the left amygdala ER 45Ca $^{2+}$ uptake was markedly stimulated in the ipsilateral amygdala, cerebral cortex, hippocampus, and discrete thalamic nuclei as well as the contralateral cerebellar hemisphere and vermis. This pattern reflects the activation of neuronal structures involved in seizure propagation. Mechanisms underlying modulation of these calcium pools, as well as their pharmacological and 2nd messenger sensitivity will be presented.

SEROTONIN TRANSLOCATES CA $^{2+}$ -ACTIVATED PKCS WITHOUT TRANSLOCATING CA $^{2+}$ -INDEPENDENT PKCS IN THE NERVOUS SYSTEM OF APLYSIA. W. S. Sossin and J. H. Schwartz. Center for Neurobiology and Behavior, HHMI, College of Physicians & Surgeons, Columbia University, New York, NY 10032.

Ca $^{2+}$ -activated and Ca $^{2+}$ -independent PKCs are present in the nervous system of the marine mollusk *Aplysia californica* (Kruger et al., *J. Neurosci.* in press). Sensitizing stimuli or application of the facilitatory transmitter, serotonin, to intact isolated ganglia produce the presynaptic facilitation of sensory-to-motor neuron synapses that underlies behavioral sensitization, which is a simple form of learning. Activation of PKC can also produce this presynaptic facilitation (Braha et al., *Proc Natl Acad. of Sci.* 87, 2040-2044 1990). To determine which type of PKC is activated, we developed a sensitive and selective assay to measure both Ca $^{2+}$ -activated and Ca $^{2+}$ -independent PKC activities in crude supernatant and membrane fractions of nervous tissue. This assay is based on the specific binding of the Ca $^{2+}$ -activated PKCs to phosphatidylserine micelles in the presence of Ca $^{2+}$ and makes use of a novel synthetic peptide with sequences conforming to phylogenetically conserved pseudosubstrate regions of the Ca $^{2+}$ -independent kinases. We provide evidence that the presynaptic facilitation is produced by a Ca $^{2+}$ -activated isoform: application of serotonin increases the amount of the Ca $^{2+}$ -activated PKC translocated to membrane. Under these conditions, no Ca $^{2+}$ -independent kinase activity is translocated.

146.8

CALCIUM INDUCED CALICIUM RELEASE IS DEMONSTRATED IN RAT AND CHICKEN BRAIN MICROSOMES. David J. Hirsch, Ajay Verma, and Solomon H. Snyder. Department of Neuroscience, Johns Hopkins School of Medicine, Baltimore, MD 21205.

Using autoradiographic techniques, we have shown that endoplasmic reticular (ER) Ca $^{2+}$ is selectively concentrated in different brain areas. Release of Ca $^{2+}$ by IP $_3$ also varies markedly in different brain regions (1). Regulation of the ER Ca $^{2+}$ pools resistant to IP $_3$ in different brain regions is unclear. In the present study we directly demonstrate Ca $^{2+}$ induced Ca $^{2+}$ release (CICR) in rat and chicken brain microsomes. To demonstrate CICR in rat brain microsomes we loaded ER Ca $^{2+}$ pools over a range of free Ca $^{2+}$ concentrations. In rat brain microsomes 45Ca $^{2+}$ accumulation increases with elevated Ca $^{2+}$ levels plateauing between 1-10 μ M Ca $^{2+}$ with half maximal 45Ca $^{2+}$ uptake being apparent at 0.25 μ M. ER 45Ca $^{2+}$ uptake was reduced between 10-100 μ M free Ca $^{2+}$ resulting in approximately three fold less uptake at 100 μ M than at 1 μ M. Reduced net accumulation of 45Ca $^{2+}$ at the higher free Ca $^{2+}$ levels appears to reflect opening of the Ca $^{2+}$ induced Ca $^{2+}$ release (CICR) channel as it was sensitive to inhibitors of CICR (2). Thus, this release is prevented by 5 mM magnesium and the local anaesthetics tetracaine and procaine. The maximal effect of tetracaine is observed at approximately 3 mM. Adenine nucleotides, on the other hand, stimulate CICR. 10 mM ATP allows release of Ca $^{2+}$ to be triggered by lower free Ca $^{2+}$ concentrations.

ISOLATION OF A FRACTION OF ENDOPLASMIC RETICULUM (ER) FROM BOVINE ADRENAL MEDULLA, HIGHLY ENRICHED IN A THAPSIGARGIN-SENSITIVE 45-CALCIUM UPTAKE ACTIVITY. D.Mathiasen*, L.M.Røssum* and M.Treiman. Institute of Medical Physiology C, Biotechnology Center for Signal Peptide Research, Panum Institute, Blegdamsvej 3C, DK-2200 N, Denmark.

Regulation of the intracellular calcium (Ca) in excitable cells is in part determined by energy-dependent Ca uptake into non-mitochondrial Ca stores. In order to study the properties of this Ca uptake, a fraction of ER from bovine adrenal medulla was isolated with only minor contamination by plasma membranes, mitochondria and chromaffin granules. Following centrifugation at 380g x 20min, the supernatant was centrifuged at 28,000g x 20min, and the resulting supernatant at 105,000g x 1h. The microsomal pellet, enriched in cytochrome C-reductase (RSA=4.7), was further fractionated on a sucrose density gradient (15-30%), 95,000g x 16h. A light fraction (15-16% sucrose) was identified containing 4.6% of the total gradient protein, and 2.6%, 0.6% and 0% of marker activities for ER, plasma membranes and mitochondria, respectively. ATP-dependent 45-Ca uptake activity in this fraction was 4-5 nmoles/mg protein (plateau at 30min) at 50nM free Ca. 80% of this uptake was inhibited by thapsigargin 100nM.

VASOPRESSIN-INDUCED INTRACELLULAR CALCIUM RESPONSES IN SINGLE RAT CORTICOTROPHS. B.J.Canny and D.A.Leong, Dept. of Int. Med., University of Virginia, Charlottesville VA 22908.

In a previous study we have shown that increasing concentrations of vasopressin (AVP) increase the number of cells that secrete corticotropin (ACTH) while having little effect on the amount of ACTH secreted by each cell. Since the cytoplasmic free calcium ion concentration ($[Ca^{2+}]_i$) is important in stimulus-secretion coupling in corticotropes, we have used fura-2 videomicroscopy to examine the role of $[Ca^{2+}]_i$ in regulating this phenomenon in single rat corticotropes post-identified using a specific ACTH reverse hemolytic plaque assay. Three distinct $[Ca^{2+}]_i$ profiles were observed in response to a range of AVP concentrations; (i) no change in $[Ca^{2+}]_i$, (ii) a low amplitude increase in $[Ca^{2+}]_i$ (step increase), and (iii) a high amplitude increase in $[Ca^{2+}]_i$ followed by a fall to a new level above baseline (spike/plateau response). The number of corticotropes exhibiting each of the 3 responses to increasing concentrations of AVP is shown below.

[AVP]	No change	Step	Spike/Plateau
10^{-12} M	6	4	-
10^{-10} M	-	4	4
10^{-8} M	1	-	6

With increasing AVP concentrations the proportion of cells responding with a spike/plateau of $[Ca^{2+}]_i$ increased; this was associated with a corresponding decrease in the proportion demonstrating either no change or a step increase. As the secretion of ACTH from a single corticotrope in response to AVP is either on or off (i.e. the amount of ACTH secreted from each cell is not a function of AVP concentration), we propose that secretion may be associated with spike/plateau responses and not step increases in $[Ca^{2+}]_i$.

ALZHEIMER'S DISEASE: NEUROPATHOLOGY I

147.1

SELECTIVE DISTRIBUTION OF ALZHEIMER'S DISEASE LESIONS IN THE VISUAL CORTEX. R.K. Tikoo and R.O. Kullis, Department of Neurology, The University of Iowa College of Medicine, Iowa City, Iowa 52242-1053.

In Alzheimer's disease (AD), lesions in the primary visual cortex consist primarily of senile plaques (SP) and amyloid angiopathy (AA). Virtually nothing is known, however, about the mechanisms leading to these lesions, and about their effect - if any - on cortical function. In order to begin to address these issues, we analyzed their three-dimensional spatial distribution to test several hypotheses on their role in the pathophysiology of AD. Series of transverse and tangential sections of the primary visual (striate) cortex from five histologically confirmed patients with Alzheimer's disease were stained using the Nissl, thioflavin-S and Bielschowsky methods. Over 130,000 SP were arbitrarily classified into 4 types: "diffuse," "classical," "amyloid (core)" and "(predominantly) neuritic." Plaques and AA were then plotted in each section and their distribution reconstructed in three dimensions using computers. There are several clearcut, consistent patterns to the distribution of SP and AA. Among the most striking: AA appears to have a predilection for layer IVC in all sections examined. A high density of SP was noted in layers II-IVA and in the boundary between layers IVC and V. Plaque density was assessed: (a) per type of lesion (all layers); diffuse=45%, classic=15%, amyloid=2.6%, neuritic=36%; (b) per layer (all types); I=0.2%, II-IVA=23%, IVB=1%, IVC=23%, V=1%, VI=17%. A detailed breakdown per type of lesion and layer will be presented, together with three-dimensional reconstructions and analyses of the spatial distribution of these lesions. Our findings indicate that AD lesions have a predilection for well-defined compartments in the striate cortex. These patterns of distribution implicate cortico-cortical connections and local neuronal circuits, but not thalamo-cortical connections in the pathophysiology of AD.

147.3

TANGLE-ASSOCIATED NEURITIC CLUSTERS (TANCs): A NEW LESION IN ALZHEIMER'S DISEASE (AD) AND AGING. D.G. Munoz & D. Wang, Department of Pathology, University of Western Ontario, London, Canada.

Senile plaques and neurofibrillary tangles (NFT) are the two major tissue lesions in AD. Mature senile plaques epitomize aberrant sprouting, the process of excessive proliferation of neuronal processes. The sprouting-inducing factor is thought by many to be β /A4 protein. Many sprouted, dystrophic neurites in the crown of senile plaques are loaded with chromogranin A, a soluble protein of large dense core synaptic vesicles. NFTs have not been associated with neuritic sprouting, but using double label immunocytochemistry we show that some extracellular NFTs are associated with clusters of chromogranin A-labelled dystrophic neurites. These tangle-associated neuritic clusters (TANCs) are present in the hippocampus of all 14 AD patients and in 10 of 23 normal elderly controls, as well as in the nucleus basalis of Meynert of AD brains. We postulate that TANCs represent aberrant sprouting induced by a factor bound to certain extracellular NFTs. Since the tangles in TANCs are not recognized by antibodies to native or synthetic β /A4 peptide, the latter may not be the sprouting-inducing factor, at least in TANCs.

ABNORMALITIES IN OLFACTORY BIOPSIES OF ALZHEIMER'S PATIENTS. Edward W. Johnson, Bruce W. Jafek, Pamela M. Eller, Christopher M. Filley, Mary Chapman, and John C. Kinnamon, Rocky Mountain Taste & Smell Center and UCHSC, Denver, CO 80262.

Abnormalities in human olfactory epithelium can be associated with certain pathological states which involve loss of smell. In light of this and in conjunction with a project in the Depts. of Neurology and Psychiatry at the Univ. of Colorado Health Sciences Center involving patients with Alzheimer's Disease (AD), we have tested and biopsied eight AD patients and two age-matched controls. So far all of the AD patients have tested hyposmic or anosmic. Biopsies from three of these patients have shown that the olfactory epithelium had an abnormal appearance reminiscent of dysfunctional epithelium. Concentrated above the olfactory tissue were scattered particles. Using a Kevex 8000 X-ray Microanalytical Unit in conjunction with a JEOL 2000EX Electron Microscope, we determined that these particles were silicon crystals. In this preliminary screening these crystals were not observed over small areas of the respiratory epithelium of these patients. At the light microscopic level no similar particulate matter has been seen over the nasal epithelia of control subjects. Efforts are continuing to test and obtain biopsies from additional AD patients and age- and environment-matched controls to determine if there are consistent changes in the ultrastructure of the olfactory epithelium of AD patients and to see if these preliminary findings of silicon crystals over the olfactory epithelium of only the AD patients is a consistent observation.

147.4

IMMUNOHISTOCHEMICAL STUDY OF ALZHEIMER PATHOLOGY IN PATIENTS WITH KNOWN SEVERITY AND DURATION OF ILLNESS. P. V. Arriagada, J. H. Growdon, E.T. Hedley-Whyte, B.T. Hyman, Mass General Hospital, Harvard Medical School, Boston, MA 02114.

Our recent analysis of the relation between the number and distribution of neurofibrillary tangles (NFT) and senile plaques (SP) and the severity of cognitive impairment and duration of Alzheimer's disease (AD) suggested a positive correlation between NFT in association cortex and both Blessed Dementia Scale and duration of illness. Surprisingly, no correlation between clinical parameters and SP was found. As an extension of this study, we further examined the brains of 10 individuals with the clinical and pathological diagnosis of AD who had a Blessed Dementia Scale (BDS) recorded within 15 months prior to death. Preparations from the hippocampal formation, entorhinal cortex, amygdala, neocortical areas 8, 9, 20, 21, 17 and 18, and raphe nucleus and locus coeruleus were stained with thioflavine S (thio S) and also immunohistochemically with both Alz-50 (P. Davies, Albert Einstein) and anti- β /A4 amyloid (D. Schenk, Athena Neuroscience) antibodies. The BDS correlated best with the number of NFT in association cortices ($R=0.67$, $p=0.032$). In 2 patients with BDS score less than 30, NFT were restricted mainly to limbic areas and rarely found in neocortical association areas, whereas individuals with a higher (worse) BDS score had increasing numbers of thio S or Alz-50 positive NFT in association cortex. Total SP or regional SP counts (thioS) were not correlated with duration or severity of illness. Neither the number of β /A4 and Alz-50 positive SP in association cortex (area20) and in hippocampus (CA1) nor the ratio of Alz-50/ β /A4 SP in these areas correlated with BDS or duration. Our results suggest that NFT rather than SP are most strongly correlated with clinical symptoms in Alzheimer's disease. Supported by NIA P50 AG05134, AG08487, and the Brookdale Foundation.

147.5

Transmitter specific abnormal neurites are present in amyloid positive plaques prior to the appearance of paired helical filament (PHF) containing processes. W.C.Benzing, E.J. Mufson@, and D.M. Armstrong. FGIN, Georgetown Univ., Washington, D.C. 20007, @Rush Preb., St. Luke Hosp., Chicago, IL 60612.

Immunocytochemical methods were used to examine the relationship between neurotransmitter containing swollen neurites, beta-amyloid deposition, and PHF containing neurites in the amygdala of post-mortem brain tissue from a group of patients with Alzheimer's disease (AD), age matched controls (AMC) and age matched non-demented subjects which had considerable numbers of senile plaques (i.e. high plaque (HPC) controls). The HPC may represent a preclinical stage of AD. Using Thioflavin-S as a histological marker for senile plaques (SP), the amygdala of AD and HPC cases could be divided into regions of low and high plaque density. The regions of low plaque density were characterized by few, if any, SP in HPC and moderate numbers of SP in AD. In contrast, regions of high plaque density contained numerous SP in HPC and an even greater number in AD. In all regions, beta-amyloid immunostaining revealed a much greater number of SP than could be visualized by Thioflavin-S. In the "low plaque" regions of HPC, swollen neurites immunostained with antibodies to various neurotransmitters were observed in many of the beta-amyloid-immunoreactive (BA-IR) plaques. Few if any PHF-immunoreactive (PHF-IR) processes could be found in these regions, except in the most severely affected HPC cases. However, when these same "low plaque" regions were examined in AD cases, both transmitter- and PHF-immunostained swollen processes were found within many BA-IR plaques. High plaque regions of both HPC and AD cases contained dense accumulations of BA-IR plaques, PHF-IR plaques and transmitter containing swollen neurites. These data suggest beta-amyloid deposition and the formation of transmitter-containing swollen neuritic processes occur early in AD and that these events occur prior to the formation of PHF containing SP.

THE EARLIEST SYMPTOMS OF ALZHEIMER DISEASE: ANATOMIC CORRELATES. B.T. Hyman, P.V. Arriagada, A. McKee, J. Ghika, S. Corkin and J.H. Growdon. Neurology and Neuropathology, Mass. General Hospital, Boston, MA 02114 and Dept. of Brain and Cognitive Sciences and Clinical Research Center, MIT, Cambridge MA 02139.

An articulate 82 year old physicist, still active in his work, came to the Mass. General Hospital Memory Disorders Unit because he and his family detected declining memory and work performance during the past 9 months. The neurological examination was normal. The Blessed Dementia Scale score was 4 (just outside the normal range). On a short series of cognitive tests, his performance resembled that of age-matched controls. Based on the clinical history, the diagnostic impression was early Alzheimer's disease. The patient died of a myocardial infarction 7 weeks later. Autopsy showed marked Alzheimer neuropathological changes. Forty cytoarchitectural areas were surveyed using thioflavine S, and Alz-50 and anti- β A4 immunostains. Neurofibrillary tangles (NFT) were most prominent (>10/mm²) in the entorhinal cortex, hippocampus, amygdala, inferior temporal gyrus, and the dorsal raphe, and were rare in other cortical areas. Senile plaques (SP) were prominent (>20/mm²) in widespread association areas and in the amygdala, and were less numerous in primary sensory areas. Alz-50 positive SP were present mainly in limbic areas, and were far less common than β A4 SP.

These results emphasize that Alzheimer patients with extremely mild cognitive impairment may already have substantial neuropathological changes, and that the entorhinal cortex, hippocampus, and amygdala contain NFT early in the disease. We suggest that clinical symptoms emerge as multiple sites of distributed neural systems become affected, and as compensatory mechanisms fail. Supported by the Brookdale Foundation, NIA P50 AG05134, AG08487 and RR-00088. We thank P Davies (Einstein) and D. Schenk (Athena), for Alz-50 and anti- β A4 antibodies.

HUMAN OLFACTORY EPITHELIUM (OE) IN AGING AND DISEASE JO Trojanowski, PD Newman*, WD Hill, and VM-Y Lee*, Dept. of Path. & Lab. Med., Univ. of Penn. Sch. of Med., Phila., PA 19104-4283.

We characterized human OE cells and dystrophic OE neurites. Keratin 8 was present in each class of OE cell. Sustentacular cells lacked other cell type specific polypeptides, and differed from neurons and basal cells, both of which expressed neural cell adhesion molecules (N-CAMs) and microtubule associated proteins. Basal cells expressed NGF receptors (NGFr) while OE neurons did not. Unlike their perikarya, olfactory axons expressed NGFr, vimentin and GAP-43, but OE neurons and axons were negative for peripherin and neurofilament (NF) proteins. Olfactory nerves differed from other nerves which were positive for all 3 NF subunits and peripherin, in addition to vimentin and GAP-43. Dystrophic OE neurites were GAP-43 positive, connected to olfactory neurons, and contained proteins not found in normal OE nerves. These neurites were present in 11/11 Alzheimer disease patients, 11/14 subjects with other neurodegenerative diseases, 6/8 normal adults, but not in 9/9 fetal and neonatal cases.

The molecular phenotype of different human OE cells is distinct, and dystrophic OE neurites are frequent in adults with and without a neurological disease.

MAPPING DEGENERATING PROCESS IN ALZHEIMER BRAINS: DEMONSTRATION OF A STRONG HETEROGENEITY IN SPORADIC CASES. P. Vermersch*, B. Frigard*, A. Delacourte; U156 INSERM, 59045 Lille, FRANCE

Alzheimer's disease (AD) pathology is known to be prominent in associative cortical areas and in the hippocampus, but most previous studies have examined histologic characteristics of AD in a limited range of brain regions.

We have described a reliable and early marker of the degenerating process in AD: a triplet of abnormally phosphorylated Tau proteins named Tau 55, 64 and 69, accumulates in neurons of AD brains (Delacourte et al, Acta Neuropathol., 1990, 80:111-117), its presence and distribution being strongly correlated with both symptoms of dementia and distribution of tangles, respectively. Here we present a semi-quantitative evaluation of these proteins in all cortical areas according to Brodmann's classification.

Five patients were diagnosed antemortem as probable AD according to NINCDS-ADRDA criteria and subsequently confirmed at autopsy to have definite AD. Tissue samples from all cortical areas were homogenized in the Laemmli sample buffer (1:10) and heat treated. Proteins were resolved on 10-20% SDS gel gradients, transferred on nitrocellulose and immunodetected with our anti-PHF which specifically detects Tau 55,64,69. For each sample, a semi-quantification of the immunodetection intensity for Tau 55,64,69 was independently performed by three of us (scale from 0 to 10). The final score was the mean of each observer's score for each Brodmann's area. The good level of interobserver agreement was confirmed by Kappa test using the Fleiss's method.

Our study reveals that all Brodmann's areas were implicated in the neurodegenerating process. In all patients, all temporal and most associative areas of the neocortex were dramatically impaired. Primary areas, especially visual areas 17 were relatively well spared. However, a strong topographical heterogeneity was evident, as reflected by the differential distribution of the neurobiological markers of the disease, respectively to the postero-anterior asymetry.

147.8

BRAIN-BEHAVIOR CORRELATIONS FOR AUDITION AND VISION IN A VERY MILD CASE OF ALZHEIMER'S DISEASE (AD). S. Corkin, D.D. Kurylo, R. Dolan, B.T. Hyman, P.V. Arriagada, A. McKee, J. Ghika, and J.H. Growdon. Dept. of Brain and Cognitive Sciences and Clinical Research Center, MIT, Cambridge, MA 02139, and Neurology and Neuropathology Services, Mass. General Hospital, Boston, MA 02114.

It is difficult to specify precisely the relation between behavioral impairments in AD and the underlying neuropathology for two reasons: (1) Test performance in advanced AD is globally affected by the severity of dementia and may not reveal selective deficits, and (2) the interval between last testing and death is usually protracted so that the state of the brain at autopsy differs from that at testing. The present case study was free of these concerns: The patient was only mildly demented, and died 2 days after the last test. The 82-year old man (see abstract by B.T. Hyman et al.) performed auditory tests (sound localization, perception of complex tones, phoneme and timbre discrimination, and tonal memory) and visual tests (texture and color discrimination and flicker and motion detection). At autopsy, we examined auditory and visual cortices, optic tract, LGN, and superior colliculus. For audition, test performance was normal; the number of SPs were ranked as follows: primary auditory cortex < auditory association cortex < multisensory cortex. For vision, test performance was impaired in most conditions. The optic tract and LGN appeared normal and the superior colliculus showed mild gliosis. The number of SPs increased as follows: area 17 < 18, 20, 21 < 38. NFTs were rare in primary auditory and visual cortices but were present in high-order association cortex. Sensitive markers for visual dysfunction clearly demonstrated deficits in this very mild AD patient that were not due to overall cognitive decline. We conclude that visual disorders may appear early in AD in relation to abnormalities of high-order visual areas.

STAGING OF ALZHEIMER'S DISEASE: NEURO-PATHOLOGICAL CONSIDERATIONS. H.Braak and E.Braak. Dept. of Anatomy, J.W.Goethe University, D-6000 Frankfurt/Main 70, Germany,

Series of sections through entire hemispheres of seventy five autopsy brains from both non-demented individuals and cases of presenile and senile dementia of the Alzheimer type (AD and SDAT) were examined for presence of A4-amyloid deposits and neurofibrillary changes. Differentiation of stages could not be based upon features of the distribution pattern of A4-amyloid deposits. Neurofibrillary tangles and neuropil threads (but not neuritic plaques), in contrast, showed - with increasing severity of affection - a consistent sequence of changes in their pattern of distribution rendering differentiation of six stages of Alzheimer's disease possible. Recognition of these stages required qualitative evaluation of only a few key preparations. Speed and simplicity turned out to be particular advantages of the proposed morphological staging of Alzheimer's disease (supported by the Deutsche Forschungsgemeinschaft).

147.11

TEMPORO-FRONTAL DIFFERENCES IN ALZHEIMER'S DISEASE ASSOCIATED PROTEIN - A BIOCHEMICAL STUDY. R. Ravid, J.J. Van Heerikhuizen*, D.F. Swaab*, W. Kamphorst*, H.A. Ghanbari. Netherlands Institute for Brain Research, Amsterdam; Pathological Institute, Free University, Amsterdam, The Netherlands; Abbott Laboratories, Illinois, USA.

Using a recently developed enzyme linked immunoassay (ALZ-EIA), levels of Alzheimer's disease associated protein (ADAP) were measured in homogenates of freshly frozen frontal or temporal cortex samples of human brain from thirty rapid autopsies (post mortem interval 2-4 hours). Brain tissue samples included 3 groups of specimens: Alzheimer's disease (AD); controls without neurological or psychiatric disease (NC); dementias other than AD (NAD), i.e. cases of Parkinson's disease and Pick's disease. The AD group had substantial ADAP levels in frontal and temporal lobe specimens, which were significantly higher than either the normal or the NAD group. It is apparent from these data that the ALZ-EIA clearly distinguishes ADAP levels in AD brain from those of controls and other NAD brains. In addition a regional difference was present between frontal and temporal lobe specimens. The biochemical ALZ-EIA offers a rapid, easily performed and quantitative diagnostic test which may serve as a valuable aid to the clinico-pathological diagnosis of Alzheimer disease. We would like to acknowledge the Netherlands Brain Bank for supplying human brain specimens.

NEUROBIOLOGY OF SCHIZOPHRENIA

148.1

BRAIN MORPHOLOGY AND SCHIZOPHRENIA. A. Breier, R.W. Buchanan,* R. Munson,* A. Elkashef,* F. Gellad,* Maryland Psychiatric Research Center, Baltimore, MD 21228

Previous antemortem and postmortem studies have yielded inconsistent data regarding morphologic abnormalities of specific brain structures in schizophrenia. We have used magnetic resonance imaging (MRI) to examine the morphologic characteristics of specific brain regions in 19 healthy volunteers and 44 chronic schizophrenic patients. Schizophrenic patients, in comparison to healthy controls, had significant reductions in right and left amygdala/hippocampus volumes; right prefrontal volume and trend reductions in left prefrontal cortex; and no significant differences in right and left caudate volumes. A secondary analysis revealed reductions in right amygdala, and trend reductions in the left amygdala and left hippocampus. In addition, prefrontal white matter but not gray matter was reduced in the schizophrenic patients. Moreover, schizophrenic right white matter volume was significantly related to right amygdala/hippocampus volume ($r=.34$, $p=.03$) which is data that provides preliminary support for a hypothesis of abnormal cortico-limbic connection in schizophrenia. Furthermore, performance on the Stroop color-word conflict test, a neurocognitive task, was significantly related to left ($r=.44$, $p=.01$) and right ($r=.42$, $p=.02$) amygdala/hippocampus volume in the schizophrenic patients. The implications of these data for the pathophysiology of schizophrenia are discussed.

148.3

INCREASED GABA-A RECEPTOR BINDING IN SUPERFICIAL LAYERS OF SCHIZOPHRENIC CORTEX. F.M. Benes, S.L. Vincent, G. Alsterberg, E.D. Bird, J.P. SanGiovanni. Dept. of Psychiatry and Program in Neuroscience, Harvard Medical School; Mailman Research Center, McLean Hospital, Belmont, MA 02178.

A recent investigation has demonstrated decreased numbers of interneurons in the anterior cingulate and prefrontal areas of post-mortem schizophrenic brain. Because there were reductions of interneurons in layers II-VI, it was hypothesized that the missing neurons might be GABAergic basket cells and that their loss would result in a compensatory upregulation of the GABA-A receptor. To test this hypothesis, a high resolution emulsion technique for localizing the GABA-A receptor was applied to normal ($N=8$) and schizophrenic ($N=6$) specimens of anterior cingulate cortex. The results of a computer-assisted quantitation of autoradiographic grains indicate a preferential increase of bicuculline-sensitive 3H -muscimol binding on neuronal cell bodies of layers II (84%) and III (74%), but not V and VI, of the schizophrenic cases. There were no differences in the average size of neuronal cell bodies in any of the layers in control and schizophrenic cingulate cortex. The neuropil in layer I also showed significantly greater GABA-A binding in the patient group. The differences in the schizophrenic group did not appear to be due to confounding effects because both young and old schizophrenic cases showed increased GABA-A binding, as did a neuroleptic-naïve patient. Since superficial cortical layers mediate cortico-cortical integration, the data reported here are consistent with the possibility that schizophrenia may involve a deficit in inhibitory activity regulating associative information processing in the cingulate region. Supported by MH00423, MH42261 and the Scottish Rite Foundation.

148.2

ABNORMAL EXPRESSION OF 2 MICROTUBULE-ASSOCIATED PROTEINS IN THE HIPPOCAMPAL FORMATION IN SCHIZOPHRENIA. S.E. ARNOLD, V.M.-Y. LEE*, R.E. GUR, J.Q. TROJANOWSKI, University of Pennsylvania School of Medicine, Phila., PA 19104-4283.

Immunohistochemistry with a panel of 15 monoclonal antibodies was used to study the expression of neuronal cytoskeletal proteins in the hippocampal formations of 6 patients with schizophrenia, 6 normal controls and 6 with neurodegenerative disorders. In 5 of the 6 subjects with schizophrenia, prominent and specific alterations were found in the distribution of 2 microtubule-associated proteins (MAPs), MAP2 and MAP5, which were anatomically selective for the subiculum and entorhinal cortex. In contrast, the immunoreactivity of other cytoskeletal proteins (i.e., tau, tubulins and selected neurofilament protein phosphoisoforms) was similar for all subjects. Defects in the expression of MAP2 and MAP5, both of which contribute to the establishment and maintenance of neuronal polarity, could underlie some of the cytoarchitectural abnormalities described in schizophrenia and impair signal transduction in the affected dendrites. The subiculum and entorhinal cortex interconnect the hippocampal formation with widespread cortices and subcortical nuclei and play important roles in higher cognitive functions. Hence, novel pathologic lesions that distort the polarized geometry of neurons could play a role in the emergence of aberrant behavior in schizophrenia.

148.4

BORNA DISEASE VIRUS SEROLOGY IN SCHIZOPHRENIA. R. W. Waltrip, R. W. Buchanan,* A. Breier, W. T. Carpenter, A. Summerfelt,* K. M. Carbone. Maryland Psychiatric Research Center, P.O. Box 21247, Baltimore, MD 21228.

Preliminary data is presented from an ongoing study comparing Borna disease virus (BDV) seropositive (S+) and seronegative (S-) patients with schizophrenia (Sz). BDV is an incompletely characterized RNA virus that naturally causes an immunologically-mediated mononuclear encephalitis in horses and sheep in central Europe. Experimentally, BDV effects can range from asymptomatic infection through social behavioral abnormalities to fatal meningoencephalitis. Antibody (Ab) studies in humans suggest an association with neuropsychiatric disease with reported rates varying from 2-3% in normals to 6.8% in a mixed psychiatric cohort. We have detected 13(16%) S+ in 81 patients with Sz and 1(5.6%) S+ in 18 normal volunteers using indirect immunofluorescence (IFA). Antibodies from S+ localize to the same intracellular antigen as antibodies from a BDV infected rabbit by double-antibody IFA. A 60kD BDV-specific protein was radioimmunoprecipitated by S+, but not S-, human sera from each of two independently developed persistently BDV infected cell lines. Virus neutralization titers, magnetic resonance imaging (MRI) volumetric data, and MRI findings regarding CNS inflammation will be presented.

148.5

ELEVATED STRIATAL DOPA DECARBOXYLASE ACTIVITY IN VIVO IN PSYCHOSIS. J. Reith, H. Kuwabara*, C. Benkelfat*, G. Savard*, F. Andermann*, G. Chouinard*, A. Sherwin*, S. Dyve*, P. Cumming*, D. Jolly*, S. Lal*, S. Bachneff*, & A. Gjedde. Positron Imaging Laboratories, Montreal Neurological Institute, McGill University, Canada H3A 2B4.

To test the hypothesis that an abnormality of dopaminergic neurotransmission may contribute to psychosis, we determined regional cerebral DOPA decarboxylase activity in 4 patients with intractable complex partial seizures (CPS) with psychosis, 8 patients with intractable CPS without mental disturbances, 4 schizophrenic patients and 12 healthy volunteers, using [¹⁸F]fluoro-L-DOPA and positron tomography. The enzyme activity was calculated on the basis of a kinetic model, yielding the rate of conversion of FDOPA to FDOPAMINE [Gjedde et al., PNAS (USA) 88:2721, 1991]. Patients were scanned by a Scanditronix PC2048 15 plane PE tomograph after i.v. injection of 3-6 mCi [¹⁸F]fluoro-L-DOPA. All patients were neuroleptic-naïve, or received neuroleptics for brief periods only at least one year prior to the scan. The estimates of decarboxylation rates in units of h⁻¹ were (±SEM),

Region	Controls(12)	CPS(8)	CPS+Psychosis(4)	Schizophrenia(4)
R Caudate	4.7±0.3	4.3±0.3	6.1±0.4*	6.6±0.7**
R Caudate	4.9±0.2	4.8±0.4	6.8±1.8	7.0±0.6***
L Putamen	4.6±0.4	4.3±0.3	5.5±0.3	6.3±0.5*
R Putamen	4.8±0.3	4.4±0.3	5.2±0.2	5.8±0.7

***P < 0.001, **P < 0.02, *P < 0.05

The estimates indicate a significant increase of in vivo dopa decarboxylase activity in neostriatum in patients with psychotic episodes.

148.7

A POSITRON EMISSION TOMOGRAPHY STUDY OF REGIONAL CEREBRAL BLOOD FLOW DURING PROBLEM SOLVING IN MONOZYGOTIC TWINS DISCORDANT FOR SCHIZOPHRENIA. K.F. Berman, E.F. Torrey*, A. Abi-Dargham, C. Randolph, P.J. Anderson*, D.B. Weinberger. NIMH, Clinical Brain Disorders Branch, Neuroscience Center at St. Elizabeth's, Washington, D.C. 20032.

To explore further the previously described finding of hypofunction of the prefrontal cortex ("hypofrontality") in schizophrenia we used the oxygen-15 water method for measuring regional cerebral blood flow (rCBF) with positron emission tomography in five pairs of monozygotic twins (two female and three male pairs, mean age 34) who were discordant for the illness. rCBF was measured during four cognitive conditions: the Wisconsin Card Sorting Test (WCS), Raven's Progressive Matrices (RPM), and two sensorimotor control tasks (one each for the WCS and RPM). Data were collected on the Scanditronix PC2048-15B brain tomograph which produces 15 slices with reconstructed resolution of 6-6.5 mm in three planes. rCBF for each pixel was normalized (i.e. expressed as a percentage of the whole brain mean).

In each of the five pairs the affected twin was more hypofrontal than the well co-twin during both WCS and RPM. The statistical difference between dorsolateral prefrontal cortex rCBF of well and ill co-twins was significant (for WCS: mean(±SD) left 141.6±8.2 vs. 127.8±8.4 P<.003, right 146.8±12.6 vs. 129.7±11.2 P<.007; for RPM: left 145.5±14.3 vs. 129.6±9.1 P<.03, right 152.1±13.5 vs. 136.7±11.9 P<.03; Paired T Test). Differences during the sensorimotor control tasks were also observed, but were less consistent and less robust (for WCS Control: left P<.08, right P<.20; for RPM Control: left P<.05, right P<.08). These data suggest that hypofrontality can be demonstrated in most, if not all, patients with schizophrenia if adequate control groups are used. These results also indicate that non-genetic factors are important determinants of hypofrontality in schizophrenia.

RITANSERIN ANTAGONISM OF MCPP EFFECTS IN NEUROLEPTIC-FREE SCHIZOPHRENIC PATIENTS. J.H. Krystal, J.P. Seibyl, M.L. Wong, G.R. Heninger, and D.S. Charney. Schizophrenia Res. Cntr., Yale U. Sch. of Med., West Haven VA Med. Cntr, West Haven, CT 06516

The serotonin (5-HT) partial agonist m-Chlorophenylpiperazine (MCP) produces an exacerbation in the positive symptoms of schizophrenia in unmedicated patients. Behavioral or endocrine effects of MCP appear to be blocked by clozapine, but not haloperidol treatment. In order to identify receptors relevant to the behavioral effects of MCP, the capacity of ritanserin, an antagonist of 5-HT_{1C} and 5-HT₂ receptors, to block MCP effects was assessed in schizophrenic patients. METHODS: In an ongoing study, schizophrenic patients off neuroleptics for at least two weeks (N=4), completed four test days over two weeks in a randomized double-blind design. Medications included MCP (0.1 mg/kg, i.v. over 20 min.), MCP following ritanserin (10 mg., p.o.), ritanserin, or placebo. Behavioral, physiologic, and plasma hormone levels were evaluated prior to medication and for 3 hours post-infusion on each test day. Findings in a larger sample of patients will be presented at the meeting. IMPLICATIONS: The ability of ritanserin to block the behavioral or biochemical effects of MCP may provide useful information concerning the contributions of brain 5-HT systems to psychosis or the mechanisms of action of clozapine.

MAZINDOL AUGMENTATION OF TYPICAL ANTIPSYCHOTICS IN NEGATIVE SYMPTOM SCHIZOPHRENICS. J. Seibyl, J. Krystal, R. Johnson*, L. Brenner*, G. Heninger, D. Charney. Dept. of Psychiatry, VA Medical Center and Yale Univ., West Haven, CT 06516.

Mesofrontal dopamine (DA) deficits have been implicated in negative schizophrenic symptoms including affective flattening, withdrawal, and avolition. Consistent with this, most schizophrenics experience minimal negative symptom improvement or even worsening with standard neuroleptic treatment. Mazindol is a long-acting agent that blocks DA reuptake at the dopamine transporter site. We tested the responses of positive and negative symptoms to mazindol augmentation of neuroleptic in partially-refractory, stable outpatient schizophrenics. METHODS: In an ongoing study, outpatients stabilized on neuroleptic medication were enrolled in a double-blind, placebo controlled trial of mazindol (2 mg/day) augmentation of typical neuroleptic agents. Weekly Brief Psychiatric Rating Scale (BPRS), Positive and Negative Symptom Scale (PANSS), AIMS, Webster EPS ratings, and fasting prolactin and HVA were obtained for four weeks prior to mazindol/placebo augmentation and for six-eight weeks after randomization. RESULTS: The first six patients receiving active mazindol demonstrated a 30-40% reduction of BPRS and PANSS negative symptom ratings. Increases in positive symptoms were noted in one patient who received a pilot dose of mazindol 8 mg/day. No other increases in positive symptoms were seen in patients treated with mazindol 2 mg/day. There was a modest reduction of extrapyramidal side effects and 1/6 patients showed worsening of tardive dyskinesia with mazindol. Subjectively, 5/6 patients experienced increased mood, energy, and affective reactivity and correctly guessed the identity of the randomized medication. CONCLUSIONS: Preliminary data suggests mazindol may be a useful adjunct to standard neuroleptic medication for treating refractory negative symptoms in otherwise stable outpatient schizophrenics.

FRONTO-TEMPORAL RIGHT-LEFT ASYMMETRY IN NORMALS BUT NOT IN SCHIZOPHRENIC PATIENTS PERFORMING A CONTINUOUS VISUAL GRAY SCALE DISCRIMINATION TASK.

H.H. Holcomb, B. Gordon, H. Loats, T. Gastineau, N. Cascella*, D. Ross*, R.F. Dannals, H. Ravvert, A. Wilson, and C.T. Tamminga. Maryland Psychiatric Research Center, Univ. Maryland; Cognitive Neurology, and Nuclear Medicine Division, Johns Hopkins Medical Institutes, Baltimore, Maryland 21205.

Many research groups have found the right hemisphere, especially the frontal and parietal lobes, to be important for attentional tasks. In this pilot study we used a series of visual continuous discrimination tasks in normal volunteers and schizophrenic patients, to better understand right-left hemisphere relationships in people with normal and impaired attentional resources. Activity patterns were assessed with 18F-2DG positron emission tomography, volumetrically registered with magnetic resonance image set.

Four normal volunteers (ages 22-34) and 3 schizophrenic patients (ages 25-32) were trained on a visual discrimination task. Each trial required the subject, right or left button press, to indicate his decision as to whether the square presented on a computer monitor was black or gray. By reducing contrast and brightness in preset increments the investigator effectively assured a constant accuracy level across subjects, 85 - 90% correct.

Metabolic activity patterns measured 8 mm above the AC-PC plane revealed marked (20%) metabolic asymmetry in the frontal and temporal lobes of normal volunteers. This was completely absent in two out of three schizophrenic patients. The inability to generate physiologically appropriate metabolic activity patterns in the presence of "normal" behavior, may be an important component of the schizophrenic syndrome.

148.10

OCULOMOTOR DELAYED RESPONSE TASKS IN SCHIZOPHRENIA: EVIDENCE FOR PREFRONTAL CORTEX DYSFUNCTION. D.W. Hommer, A.D. Radant and C. Peng. GRECC, Seattle VAMC and Dept. of Psychiatry and Behav. Sci., Univ. of Washington.

A growing body of evidence suggests that schizophrenia can be characterized by dysfunction in the prefrontal cortex and/or its associated basal ganglia thalamocortical circuits. We used infra-red oculo-graphy to examine the saccades of 15 schizophrenics, 11 alcoholics and 32 normals. A delayed saccade task was employed to test working memory and ability to suppress context inappropriate responses. The accuracy and latency of internally guided saccades that followed a 1.2 second delay were considered measures of working memory. Internally guided saccades that interrupted fixation during the delay period and were directed towards the cue, future location of the target provided a measure of context inappropriate responses. We also measured the accuracy and latency of visually guided saccades as well as the number of intrusive saccades that broke fixation during a task that did not require use of working memory. Neither the latency, accuracy or number of intrusive saccades differed among the groups during this task. During the delayed saccade task schizophrenics made only slightly less accurate memory guided saccades following the delay; the latency of these saccades did not differ among the groups. However, during the delay period, when fixation should have been maintained, schizophrenics made over twice as many intrusive saccades as normals or alcoholics (p<.001). The number of these context inappropriate saccades correlated significantly with clinical ratings of positive symptoms of schizophrenia (r=.58). These results are consistent with a failure of the prefrontal cortex to suppress interfering responses.

149.1

IDENTIFICATION AND CHARACTERIZATION OF IDAZOXAN TYPE IMIDAZOLE RECEPTORS IN BOVINE ADRENAL CHROMAFFIN CELLS. S. Regunathan, M.P. Meeley and D.J. Reis. Div. of Neurobiol., Dept. of Neurol. & Neurosci., Cornell Univ. Med. Coll., New York, NY 10021.

Clonidine and related imidazolines bind to α_2 -adrenergic as well as imidazole receptors (IR) in brain and peripheral tissues. We sought to identify and characterize IR in bovine adrenal chromaffin cells (ACC). The binding of ^3H -idazoxan to membranes (P_2) prepared from ACC was measured. Idazoxan binds with high affinity (K_D 5nM, B_{max} 680 fmole/mg protein) and other drugs inhibited the binding with the rank order of potency: cirazoline>idazoxan>clonidine>ameloide>detomedine>phenotolamine>rilmenidine. Compounds that did not inhibit the binding (K_D >10 μM) were epinephrine, p-iodoclonidine, SKF86466, cimetidine and imidazole-4-acetic acid, thus compatible with idazoxan type IRs. Both endogenous clonidine-displacing substance (CDS) and 4-aminopyridine, a K^+ channel blocker, inhibited the binding with an IC_{50} of 7 units and 10 μM , respectively. The inhibition of binding by CDS or cirazoline was not modified by Gpp_{NHPP} , a GTP analogue. The ^3H -idazoxan binding sites were identified both in plasma and mitochondrial membranes of chromaffin cells. In cultured chromaffin cells all agents that bind to IR increased the influx of ^{45}Ca and released catecholamines, CDS being most potent. We conclude that in ACC (a) idazoxan type IRs with high affinity for CDS, but not α_2 -adrenergic receptors, are present in both mitochondrial and plasma membranes; (b) it is not a G-protein coupled receptor; and (c) IRs may be involved in release of catecholamine by modulating Ca^{2+} influx.

149.3

CHARACTERIZATION OF α_2 -ADRENERGIC RECEPTORS IN THE SHEEP SPINAL CORD BY AUTORADIOGRAPHY. B.A. Buckliff, J.C. Eisenach, R.M. Boozee. Section on Obstetric Anesthesia and Department of Physiology and Pharmacology, Wake Forest University Medical Center, Winston-Salem, NC 27157-1009.

α_2 -Adrenergic receptors have been shown to play an important role in nociceptive processing. Quantification and localization of these receptors and their subtypes will be important in further characterization of nociceptive processing and drug development. Therefore, we characterized the α_2 -binding conditions of [^{125}I] iodoclonidine with sheep spinal cord tissue sections by high-resolution autoradiographic techniques. Four adult sheep were anesthetized and thoracic spinal cord was removed. Serial sections of 25 microns thickness were thaw-mounted onto chrome-alum/gelatin-subbed slides, incubated in 50mM Tris-HCl/10mM MgCl_2 (pH7.5) for 30 min at room temperature and then incubated at varying concentrations of [^{125}I] iodoclonidine (.05nM to 1.5nM) for 90 min at room temperature. Non-specific binding was defined as binding which was not inhibited by 100 μM phenotolamine. Analysis of the saturation experiments was performed using EBDA, and saturability of binding was determined by LIGAND. [^{125}I] iodoclonidine bound to a single population of binding sites over the concentration range studied. Non-regression linear analysis determined the binding to be saturable and of high affinity ($K_D = .5\text{nM}$). The amount of non-specific binding was low. Localization of α_2 -receptors in the sheep spinal cord was performed using [^{125}I] iodoclonidine (.5nM) as the ligand. Non-specific binding was defined as mentioned previously. Films were developed 3 days after exposure. Images showed localization of α_2 -adrenoceptors to the superficial dorsal horn and intermediolateral cell column of the spinal cord. These studies define the binding conditions necessary for localization of α_2 -adrenergic receptors and demonstrate a high density of specific binding sites in the dorsal horn and intermediolateral cell column of the thoracic spinal cord. This information will be useful for further studies of α_2 -adrenoceptor subtypes at sites of hemodynamic control and analgesia.

α_2 -ADRENERGIC RECEPTOR ACTIVATION POTENTIATES DBcAMP-STIMULATED RAT PINEAL SEROTONIN N-ACETYLTRANSFERASE (E.C. 2.3.1.87) ACTIVITY. N.C. Schaad and D.C. Klein*. Sect. Neuroendocrinology, Laboratory of Developmental Neurobiology, NICHD, NIH, Bethesda 20892.

α_2 -Adrenergic receptors in the rat pineal gland were investigated. A single high affinity ($K_D = 4$ nM), low density ($B_{max} = 60$ fmole/mg protein) binding site was apparent from studies using the selective ligand ^3H -yohimbine. A possible role for these receptors was further investigated using biochemical techniques.

Activation of α_2 -adrenergic receptors did not influence cyclic AMP formation in the intact gland in the presence of isobutylmethylxanthine (IBMX), nor did it alter basal or forskolin-stimulated adenylate cyclase in membrane preparations. Alone, the α_2 -adrenergic agonist clonidine (1 to 30 μM) had no effect on the stimulation of serotonin N-acetyltransferase activity (E.C. 2.3.1.87; NAT). However, clonidine potentiated the stimulation of NAT activity induced by $\text{N}^6,2'$ -O-dibutyryl adenosine 3',5'-cyclic monophosphate (50 to 100 μM) or IBMX (100 to 500 μM). The EC_{50} for this effect of clonidine was 0.3 μM . Clonidine potentiation was inhibited by yohimbine, but not by prazosin, indicating an involvement of α_2 -adrenergic receptors. Similar potentiation was observed with two other α_2 -adrenergic agonists, oxymetazoline (1 μM) and UK 14304 (1 μM). These data suggest that α_2 -adrenergic receptors play a role in the regulation of rat pineal NAT activity, apparently by a mechanism which does not involve changes in cyclic AMP production.

COMPARATIVE MOLECULAR MODELING OF ADRENERGIC RECEPTOR SUBTYPES

Victor B. Cockcroft, D. J. Osguthorpe*, T. Schwartz***, G.G. Lunt. Molecular Graphics and Molecular Neuroscience Groups, Bath University, Bath BA2 7AY UK.

*Novo-Nordisk Research, Copenhagen, Denmark.

Energy optimised explicit atomic models have been constructed of the main subtypes of adrenergic receptors, α_1 , α_2 and β_1 , β_2 , β_3 . Hypothetical interactions are suggested to account for the pharmacological selectivities of a range of agonists (phenylephrine, clonidine, dobutamine, salbutamol) and antagonists (prazosin, yohimbine, practolol, butoxamine). In particular, a role is proposed for (i) transmembrane helix 7 (position 3; Phenylalanine/Asparagine) in the subdivision of α/β receptors, and (ii) transmembrane helix 4 (position 15; Proline, position 12; Serine) in the interaction of the β -hydroxyl group of adrenergic ligands. The basic usefulness of receptor modelling studies in by-passing problematic experimentation (such as mutagenesis-testing of chimaeric constructs which may have modified conformational stability), and in the future development of therapeutic drugs will be discussed. (We thank Dr. Ole Olsen, Novo-Nordisk for help in video preparation).

149.4

DIFFERENTIAL EXPRESSION OF α_2 -ADRENERGIC RECEPTOR SUBTYPE GENES IN HUMAN TISSUES. M. Scheinin, M. Perälä, H. Hirvonen, H. Kalimo, and K.E.O. Åkerman. Åbo Akademi and Univ. of Turku, Turku, Finland.

Genetic subtypes of α_2 -adrenergic receptors may mediate distinct physiological functions and are therefore possible targets for the development of subtype-selective drugs. We have investigated the tissue distribution of the expression of two human neuronal α_2 -adrenoceptor subtype genes, C4 and C10.

The plasmids pSP65 α_2 -C4 and pSP64 α_2 -C10 (Kobilka et al., Science 238, 650; Regan et al., PNAS 85, 6301) were used to generate antisense cRNA probes with ^{32}P -UTP as the label. After solution hybridization, single-stranded RNA was digested with RNase treatment.

In human fetal tissues, both receptor subtype mRNAs were abundantly expressed in all investigated major brain regions. In addition, expression of C10 was detected in spleen, kidney, adrenals, and skin, whereas C4 mRNA was detectable only in kidney and skin. Most regions of the adult brain also expressed both subtypes, but with marked quantitative differences. For example, cerebral cortex contained almost solely C10-mRNA, whereas the caudate nucleus expressed predominantly C4-mRNA. This is in accordance with the known distribution of the two receptor subtypes in human brain, based on pharmacological criteria. In peripheral tissues, C10 expression was most abundant in spleen and renal cortex, and expression of C4 was strongest in renal cortex and renal medulla.

These differences in the expression patterns of the two neuronal α_2 -adrenergic receptor genes warrant further investigation, and may provide a basis for the development of new, subtype-selective pharmacological agents with more targeted actions compared to currently used α_2 -adrenoceptor agonists and antagonists.

THE D3 DOPAMINE RECEPTOR COUPLES TO ION CHANNELS VIA A PTX-SENSITIVE G-PROTEIN WHEN EXPRESSED IN GH_4/C_1 CELLS. J. Rendt-1*, P. Falardeau-2, B. Giros-3*, J.C. Schwartz-3*, M.G. Caron-2, and G.S. Oxford-1. 1Dept. of Physiology, Univ. of N.C., Chapel Hill, NC 27599; 2Dept. of Cell Biology, Duke Univ. Med. Cntr., Durham, NC 27710; 3Unité de Neurobiol. et Pharmacol., INSERM, Paris, France.

Recently a novel form of dopamine receptor (D3R) was cloned from a rat brain genomic library which was screened with a probe coding for a D2 receptor sequence. Initial functional studies of this receptor expressed in COS-7 and CHO cells were negative as regards changes in cAMP levels and guanine-nucleotide dependence (*Nature* 347:146, 1990). We have reexamined the functionality of this receptor subtype in GH_4/C_1 cells transfected with a cDNA encoding the D3R. These cells do not normally express dopamine receptors. Utilizing whole-cell and nystatin-perforated patch clamp methods we have examined the ability of D3R agonists to alter resting and action potentials, and ionic conductances in transfected cells. Both dopamine (1 μM) and quinpirole (100-400nM) applied to individual cells via a U-tube caused the cessation of spontaneous action potentials accompanied in most cases by a membrane hyperpolarization (<10mV). Under voltage clamp conditions these agonists induced an outward current from a holding potential of -40mV. I-V curves for agonist-induced currents were assessed with voltage ramps and reversed direction near E_K and were sensitive to changes in $[\text{K}_o]$. Sulpiride (10 μM) blocked these effects as did pretreatment of cultures with PTX (350ng/ml, 6hrs). We conclude that in these cells the D3R couples to a K channel (normally activated by somatostatin receptors) via a PTX-sensitive G-protein to mediate the inhibitory responses. (Supported NS18788 and G.O. and NS19576 to M.G.C.).

149.7

COUPLING OF THE RAT D3 DOPAMINE RECEPTOR TO ADENYLYL CYCLASE IN GH4C1 CELLS. P. Falardeau, N. Godinot*, B. Giros, J.C. Schwartz*, and M. G. Caron, OGM, CHUL, Laval Univ., Québec, Canada, G1V 4G2, Dept Cell Biology, Duke Univ. Med. Ctr, Durham, NC, 27710

The gene for the D3 dopamine receptor was recently cloned and described as being homologous to the D2 receptor although the distribution of its mRNA in the central nervous system and its pharmacology are distinct from those of D2 receptors. When expressed in CHO cells, the D3 receptor lacks the high affinity component of agonist binding as well as its coupling to a signalling system, suggesting the absence of a suitable G-protein. Expression of D2 receptors in these cells leads to a guanine nucleotide-dependent coupling of this receptor to inhibition of cAMP. In order to determine which transduction system is coupled to this new dopamine receptor, a cDNA for the rat D3 receptor was transfected permanently into prolactin-secreting GH4 cells which lack the D2 receptor. The levels of expression of the D3 receptor, as defined by [3H] spiperone binding is 1.2pmol/mg of protein. Dopamine itself as well as other agonists, compete [3H] spiperone binding in a biphasic fashion (for NPA, $K_{Dhigh}=0.37nM$, 55%; $K_{Dlow}=49.3nM$, 45%). In the presence of Gpp(NH)p, a guanylnucleotide, the agonist competition curves are monophasic, indicating the presence of a G-protein interaction with this receptor. Moreover, inhibition of forskolin stimulated cAMP was assessed in this system. Stimulation of D3 receptors with quinpirole, an agonist selective for a D2 class of receptor, induces a decrease of intracellular cAMP stimulated with forskolin (83%) in a dose-dependent fashion ($IC_{50}=15nM$ for quinpirole). This decrease can be specifically reversed in presence of specific D2/D3 antagonists. These results show that the newly cloned D3 Dopamine receptor can be coupled to inhibition of adenylyl cyclase through a specific G-protein not present in CHO cells. These results further suggest that receptors may be the determinant of receptor-G protein specificity.

149.9

A SYNTHETIC C-TERMINAL PEPTIDE OF G_s BLOCKS G PROTEIN- β ADRENERGIC RECEPTOR INTERACTION IN PERMEABLE C6 GLIOMA CELLS. M.B.Lazarevic*, M. Watanabe, M. M. Rasenick and H.Hamm, Department of Physiology & Biophysics and the Committee on Neuroscience, University of Illinois College of Medicine, Chicago, IL 60680, U.S.A.

G protein- β adrenergic receptor coupling was studied in saponin-permeable C6 glioma cells by introducing synthetic peptides which correspond to various domains of the G proteins, α s and α i. Effects upon adenylyl cyclase activity were measured. The C-terminal peptide of α s, α s384-394, decreased isoproterenol stimulation of adenylyl cyclase in a dose dependent fashion, suggesting that it blocked activation of G α s by the isoproterenol-activated β adrenergic receptor. Synthetic N-terminal peptides and an inverted sequence "nonsense" peptide, did not elicit these effects. This peptide did not change the activity of adenylyl cyclase in the presence of forskolin or sodium fluoride. Activity of adenylyl cyclase catalytic unit extracted from membranes was not affected by peptide α s384-394.

These data suggest that this synthetic C-terminal peptide of α s, α s 384-394, binds to the G protein association domain on the β adrenoceptor and blocks the binding of the G protein to that site.

149.11

IMPORTANCE OF THE β_2 -ADRENERGIC RECEPTOR PALMYTOYLATION IN THE DESENSITISATION PROCESS. S. Moffett*, B. Mouillac*, H. Bonin* and M. Bouvier Dept. of biochemistry, Université de Montréal, Montreal, Canada, H3C 3J7.

Prolonged agonist stimulation of the β_2 -adrenergic receptor (β_2 AR) leads to its functional uncoupling from the adenylyl cyclase (AC) stimulation pathway. Phosphorylation of the β_2 AR by the cAMP dependent protein kinase and the β_2 AR kinase contribute to this desensitization process. Recently, the palmytoylation of the cystein³⁴¹ (cys³⁴¹) of the β_2 AR has been proposed as an important factor in the coupling of the receptor to the AC system. Thus, to evaluate the role of the receptor palmytoylation in the desensitization process, a mutant receptor in which the cys³⁴¹ is replaced by a glycine (gly³⁴¹ β_2 AR) was constructed by site directed mutagenesis. Chinese hamster fibroblasts stably expressing the wild type (WT) β_2 AR or the gly³⁴¹ β_2 AR were then generated and used for the study. A 20' exposure of cells expressing the WT human β_2 AR to the agonist isoproterenol (1 μ M) induces a 33±6% reduction of the receptor's capacity to maximally stimulate the AC. In the cells expressing the gly³⁴¹ β_2 AR, the same treatment induces a 13±4% desensitization of the β_2 AR-stimulated AC. This significantly decreased desensitization of gly³⁴¹ β_2 AR is accompanied by a reduced agonist-mediated uncoupling of the receptor as assessed by its agonist binding properties. Indeed, whereas the agonist treatment completely abolishes the GTP sensitive component of the agonist binding in wt β_2 AR expressing cells, this was not the case in the cells expressing gly³⁴¹ β_2 AR. In contrast to the desensitization, the agonist induced phosphorylation of the receptor is not affected by the cys³⁴¹→gly³⁴¹ mutation. Incubation of the wt- and gly³⁴¹ β_2 AR expressing cells to isoproterenol leads to a 2 fold increase in the phosphorylation level of both receptors. Taken together these results suggest that uncoupling of the receptor from the AC stimulatory pathway not only involves phosphorylation but is also influenced by the palmytoylation status of the receptor.

149.8

SITE-SPECIFIC SYNTHETIC G_s PEPTIDES EVOKE HIGH AFFINITY BINDING TO β -ADRENERGIC RECEPTORS IN PERMEABLE C6 GLIOMA CELLS. M. Watanabe, M. B. Lazarevic*, H. Hamm and M. M. Rasenick, Department of Physiology & Biophysics and the Committee on Neuroscience, University of Illinois College of Medicine, Chicago, IL 60680, U.S.A.

A newly devised method for receptor binding assays in saponin permeable C6 glioma cells permits investigation of β -adrenergic receptor behavior under conditions where this receptor appears tightly coupled to G_s to effect activation of adenylyl cyclase. Although β -adrenergic agonists must be present to activate adenylyl cyclase, (i.e. GTP or GTP analogs have no effect alone), these compounds reduce the affinity of β -adrenergic receptors for agonists in permeable C6 cells. Since the carboxyl terminal domain of the G protein α subunit has been suggested to recognize the receptor, we attempted to ascertain whether peptides corresponding to this region would affect agonist binding affinity using the method of isoproterenol competition of [¹²⁵I] pindolol binding. Synthetic site-specific α s peptides (15-29, 354-372, 384-394) and α i2 peptides (8-22, 315-324, 345-355) were tested. Two α s peptides (354-372, 384-394), which correspond to carboxyl terminal part of α s subunit, increased agonist binding affinity for the β -adrenergic receptor, (i.e. left shifted the isoproterenol displacement curve for iodopindolol). Other synthetic peptides had no effect on receptor affinity. Since the receptor-G protein complex is thought to represent the high affinity state for agonists and free receptor corresponds to low affinity state, it is likely that the G_s C-terminal peptides may bind to the β -adrenergic receptor and promote high-affinity agonist binding.

149.10

IMMUNOCYTOCHEMICAL DEMONSTRATION OF LIGAND-REGULATED INTERNALIZATION AND RECYCLING OF BETA ADRENERGIC RECEPTORS. M.v.Zastrow*, C.J. Evans and B.K. Kobilka*, Dept. of Mol. and Cell. Physiology, HHMI, Stanford and Dept. of Psychiatry, UCLA.

We have examined agonist-induced redistribution of human β_2 adrenergic receptors in human 293 cells using a receptor-specific antiserum and immunocytochemical localization. Isoproterenol induces rapid and substantial loss of receptors from the cell surface and their accumulation in intracellular vesicles. This redistribution occurs with similar kinetics as receptor sequestration measured pharmacologically, with a $t_{1/2}$ of 2-5 minutes, and it occurs long before any detectable receptor down regulation is observed. Agonist-induced intracellular accumulation of receptors is blocked by the adrenergic antagonist alprenolol, and internal receptors are returned to the cell surface following removal of agonist. Neither receptor internalization nor its reversal is blocked by 95% inhibition of cellular protein synthesis with cycloheximide. These data provide direct evidence of rapid, ligand-regulated internalization and recycling of adrenergic receptors.

149.12

PRODUCTION OF SUPERSENSITIZED D2 AND/OR D3 RECEPTORS IN RATS. R.M. Kostrzewa, R. Brus*, and J. Guo*, Depts. of Pharmacology, College of Medicine, East Tennessee State Univ., Johnson City, TN 37614 and Silesian Academy of Medicine, 41-808, Zabrze, Poland

In an attempt to produce supersensitization of D2 receptors, rats were treated daily for the first 28 d from birth with quinpirole (2.6 mg/kg/d, i.p.). Starting at the 19th until the 32nd day, the acute quinpirole injection was associated with jumping behavior that could be attenuated by spiperone. In adulthood, acute quinpirole, in a dose as low as 25 μ g/kg, increased the yawning response to about 2-fold the level of controls. Similarly, the antinociceptive action of quinpirole was enhanced in these rats in the hot plate test of analgesia. This effect was attenuated by spiperone. These findings indicate that ontogenetic treatments with quinpirole will supersensitize specific effects of this agonist in rats that are studied as adults. The B_{max} and K_d for striatal D2 receptors was not changed by these treatments. Since extremely low doses of quinpirole elicit yawning behavior, it may be that D3, as well as D2 receptors, become sensitized for prolonged periods by this dosing regimen. This animal model may be useful for studying long-lived D2 receptor supersensitization. (Supported by the Scottish Rite Schizophrenia Research Foundation and Fogarty International Exchange Program)

ONTOGENY OF IMMEDIATE EARLY GENE RESPONSE TO COCAINE. Barry E. Kosofsky, Neil W. Kowall, and Steven E. Hyman, Departments of Neurology and Psychiatry, Massachusetts General Hospital, Boston, Massachusetts, 02114.

To investigate the mechanisms by which drugs of abuse interfere with normal brain development we have administered cocaine (40 mg/kg ip) to rat pups at various stages of maturation (P8, P15, P28, Adult). 45 minutes post-injection of cocaine the pups were sacrificed and regional brain analyses (cortex, striatum, cerebellum) performed to quantitate drug induced changes in immediate early gene (IEG) mRNA expression (proto-oncogenes *zif-268*, *c-fos*, *c-jun*). At the earliest age examined (P8) IEG induction was limited to striatum, where a 3 to 4-fold increase in *c-fos*, and a 2-fold increase in *zif-268* was evident. At ages P15, P28, and adult, cocaine induced all 3 IEG's (*c-fos*, *c-jun*, and *zif-268*) in striatum and cortex. In cerebellum, only *c-fos* was induced, 1.5-fold at P15 and P28, and 5-fold in the adult. The regional, cellular, and stage-specific selectivity of drug induced action suggests a regional and developmental continuum of CNS vulnerability consequent to maternal drug abuse during human brain maturation.

150.3

Effects of Chronic Cocaine on *c-fos* and Other Immediate Early Genes and on AP1 Binding in Rat Nucleus Accumbens. B.T. Hope and E.J. Nestler, Lab of Molecular Psychiatry, Yale University, New Haven, CT, 06508.

Chronic abuse of cocaine has long-term effects on both brain and behavior, many of which remain long after the acute effects of cocaine have dissipated. These long-term effects could involve alterations in neuronal gene expression. We have examined the effects of chronic cocaine (15 mg/kg, twice daily) on mRNA levels of the immediate early genes (IEG), *c-fos*, *c-jun*, *zif*, *fosB*, *junB*, in rat nucleus accumbens (NAc), a brain region implicated in drug reward. The protein products of these genes regulate gene expression. *c-fos*, *c-jun* and *zif* mRNA levels are increased 60 min after acute cocaine. Chronic cocaine treatment desensitizes the acute drug effect in that these mRNA levels no longer increase.

We have employed the gel shift assay to examine the effects of chronic cocaine on AP-1 binding in rat NAc. The AP-1 complex, composed of Fos, Jun, and related proteins, binds DNA and thereby regulates gene expression. AP-1 binding levels are increased 2 1/2 hours after acute cocaine. However, unlike the effects on IEG mRNA, AP-1 binding levels remain increased after chronic plus acute cocaine treatment. Indeed, 18 hours after the last injection of chronic cocaine, AP-1 binding levels are still increased. We suggest there is a change in the composition of the AP-1 complex and its regulatory function that contributes to the long-term addictive actions of chronic cocaine abuse.

COCAINE-INDUCED SEIZURES ALTER FOS AND DYNORPHIN IMMUNOREACTIVITY IN RAT I.E. Helton, J.B. Daunais and J.F. McGinty, Dept. of Anatomy and Cell Biology, East Carolina University School of Medicine, Greenville, NC 27858.

A toxic side effect of chronic, high doses of cocaine is the generation of seizures and sudden death. However, little is known about the neurochemical sequelae of cocaine-induced seizures. In this study rats were treated with escalating doses of cocaine over 14 days (Stripling and Ellinwood Pharmacol, Biochem. and Behav. 6, 571-579, 1977) to "kindle" seizures. Rats were perfused and their brains examined histochemically for changes in immediate early gene and peptide expression. Rats were handled for 2 days prior to the initiation of cocaine treatment to lower stress induced by handling. Sixteen rats were treated with increasing doses of cocaine: days 1-7, 55 mg/kg, days 8-12, 60 mg/kg, days 13-14, 65 mg/kg. Two rats died as a result of seizures and four rats were anesthetized and perfused within 90 mins of cocaine injection, after experiencing life threatening seizures on day 1, 4, 8, and 10. The remaining rats continued to receive daily injections and 40% of those eventually displayed seizures but the time to onset and the number of seizures were highly variable. Cocaine-induced seizures did not kindle gradually, but appeared to be all or none clonic convulsions with head bobbing and loss of righting reflex. Surviving rats were perfused with 4% buffered paraformaldehyde 1 or 3 hours after their last injection. Analysis to date only includes those rats that experienced multiple seizure events. Fifty μ m thick sections were cut throughout the forebrain and collected for immunocytochemistry. An increase in Fos-immunoreactivity (ir) was observed in the dentate granule cells of the hippocampal formation, striatum, piriform cortex, entorhinal cortex, neocortex and amygdala. A decrease in dynorphin-ir was observed in the hippocampal mossy fibers. Analysis of somatostatin and enkephalin-ir will also be reported. These data indicate widespread neurochemical changes in limbic forebrain following cocaine-induced seizures. Supported by DA03982.

INDUCTION AND SUPPRESSION OF STRIATAL PROTO-ONCOGENE EXPRESSION AFTER TREATMENT WITH COCAINE. J. Gu* and M.J. Iadarola, Neurobiology and Anesthesiology Branch, NIDR, NIH, Bethesda, MD 20892.

The *c-fos* proto-oncogene is induced in a variety of CNS regions by pharmacological, physiological and pathophysiological stimuli. Previous studies have shown that after metrazol or ECS seizures, *c-fos* mRNA is rapidly elevated but subsequently is resistant to re-induction for a variable length of time. One treatment that we have shown to markedly increase *c-fos* expression in rat striatum is injection of the indirect dopamine agonist, cocaine. Here we demonstrate that cocaine also causes a period of suppression of re-induction, the degree of which is dependent upon the frequency of administration. A single i.p. injection of 30 mg/kg of cocaine produced a peak increase in *c-fos* mRNA within 30 min. If, after the first injection and an interval of one hr, a second injection was given, the mRNA level was less than that following a single injection. The reset period requires at least a 2 hr interval. In contrast to the single acute injection, if multiple injections are given over a single day (4 X, 2 hrs apart) full re-induction is suppressed for more than 24 hr. Transcripts coding for Fos-related antigen 1 (Fra-1), another member of the Fos family, was not induced, even after repeated injections. However, mRNA coding for NGF-IA, a zinc-finger-containing transcription factor, was induced in striatum and showed a similar suppression of induction as did *c-fos*. Multiple injections also caused induction of *c-fos* and NGF-IA mRNAs (but not Fra-1 mRNA) in hippocampus as well as striatum. The present data suggest that a set of feedback controls is activated in striatum by dopaminergic stimulation to modulate the expression of several genes that code for transcriptional regulatory proteins.

150.4

COCAINE-INDUCED ELEVATION OF DYNORPHIN, FOS, AND PKC IMMUNOREACTIVITY IN RAT STRIATUM AND HIPPOCAMPUS. J.B. Daunais, T.E. Helton, W.T. Bohler, and J.F. McGinty, Dept. of Anatomy and Cell Biology, East Carolina University School of Medicine, Greenville, N.C. 27858.

Fos protein, Fos-related antigens (FRA), dynorphin (DYN), and PKC-alpha immunoreactivity (ir) are elevated by repeated administration of the indirect-acting dopaminergic agonist, cocaine. Cocaine HCl (Sigma) or saline was administered i.p. at 10, 20, or 30 mg/kg once daily X 10 days or 40 mg/kg i.p. X 3 days. The behavior of the rats was rated for one hour following treatment. Two hours following the final injection, the rats were transcardially perfused with 4% buffered paraformaldehyde, and 50 μ m serial sections were collected through the striatum and hippocampus (HPC) for immunocytochemistry (ICC).

DYN-ir was increased in patches and matrix in the dorsal and ventral striatum at the 30 and 40 mg/kg doses. DYN-ir was particularly increased in striatal patches and in the shell of the accumbens as the dose of cocaine increased.

FOS-ir and FRA-ir increased in a dose-dependent fashion, but had differing patterns of expression. In brains treated with 30 or 40 mg/kg, FRA-ir was moderately to heavily expressed in anterior cingulate, medial prefrontal, and piriform cortices, dorsomedial shell and the rostral-most anterior nucleus accumbens (NAc). Expression was extremely heavy throughout the dorsal striatum. In contrast, FOS-ir was low to moderate in the above cortical areas, and in the rostral NAc and dorsomedial shell of the NAc and in a patch-like pattern in the central medial dorsal striatum.

Cocaine appeared to have a biphasic effect on the expression of PKC in the striatum and hippocampus. At 10 mg/kg, PKC- α was intense in large, possible cholinergic or somatostatinergic, neurons in the striatum and in hilar neurons and CA3-2 pyramidal neurons in the hippocampus. These changes in PKC- α ir decreased as the dose of cocaine increased. No FOS/FRA-ir induction or alteration in DYN-ir was observed in HPC after cocaine at any dose. These data indicate widespread neurochemical changes after repeated high dose cocaine exposure. Supported by DA 03982.

CHANGES IN TYROSINE HYDROXYLASE mRNA LEVELS IN THE A10 REGION OF COCAINE-SENSITIZED RATS. B.A. Sorg, J.D. Steketee, R. Reeves*†, and P.W. Kalivas, Department of VCAPP and Program in Genetics and Cell Biology, Washington State University, Pullman, Washington 99164-6520.

Levels of the mRNA coding for tyrosine hydroxylase (TH) were measured in the A10 region of cocaine-sensitized rats. Animals were given one of three treatments: 1) control group = 7 days of saline treatment (1 ml/kg, i.p.); 2) acute cocaine group = 6 days of saline followed by cocaine treatment on day 7 (15 mg/kg, i.p.); and 3) cocaine-sensitized group = 7 days of cocaine (15 mg/kg, i.p.). Locomotor activity was measured following treatment on days 1 and 7. Twenty-four hr after the last injection, animals were sacrificed and micropunches of the A10 region were removed for subsequent Northern blot analysis of TH mRNA levels. No changes were detected in TH mRNA levels 24 hr after acute cocaine treatment. In contrast, the cocaine-sensitized group showed a strong linear relationship ($r = -0.951$) between levels of TH mRNA 24 hr after the last cocaine treatment and the levels of horizontal motor activity following the first day of cocaine treatment. A weaker correlation existed ($r = -0.749$) between TH mRNA levels and locomotor activity in response to the last cocaine injection. Thus, the higher the levels of locomotor activity in response to the cocaine treatments, the lower the levels of TH mRNA following the cocaine sensitizing treatment. These results suggest that there may be a compensatory response in A10 dopamine cells such that TH mRNA levels are regulated by the degree of cocaine-induced locomotor activity.

150.7

COCAINE-INDUCED MOTOR ACTIVITY IN MICE WITH GENETICALLY MANIPULATED MESOTELENCEPHALIC DOPAMINE SYSTEM. C. Vadasz^{1,2}, I. Laszlovszky¹, A. Fleischer¹, and I. Vadasz¹. N.S.Kline Institute for Psychiatric Res., Orangeburg, N.Y. 10962 and ²New York University Medical Center, 550 First Avenue, New York, N.Y. 10016.

The mesotelencephalic dopamine system was manipulated by genetic selection for high and low expression of mesencephalic tyrosine hydroxylase (TH/MES). This resulted in developing congenic mouse lines with significant differences in TH/MES. Since some of the cocaine-induced behaviors are thought to be mediated by dopaminergic mesostriatal systems, we tested the hypothesis that a common set of genes affect the mesotelencephalic DA system and cocaine induced running. Congenic mice with high (B6.C) and low (B6.I) TH/MES received i.p. injections of saline or cocaine (10, 20, or 30 mg/kg). B6.C animals exhibited significantly lower motor activity than B6.I mice at 10 mg/kg ($p < 0.003$) and 20 mg/kg ($p < 0.0007$). Scatchard analysis of [³H]WIN 35,428 binding in B6.C and B6.I striata demonstrated no significant differences in B_{max} and K_d . This suggests that common genes are implicated in the control of TH/MES and cocaine-induced running, however, these genes do not affect the density and affinity of the dopamine transporter in the striatum.

150.9

DOPAMINE D₂ RECEPTOR ALLELES IN SUBSTANCE ABUSERS. B. O'Hara, S. Smith*, A. Persico*, S. Farmer*, G. Cutting*#, D. Newlin*#, D. Gorelick+, and G. Uhl. Labs. of Mol. Neurobiol., Tx.+ & Etiol.®, NIDA/ARC, Depts. Neurol., Neurosci., #Peds., JHU Sch. Med., Box 5180, Baltimore, MD 21224.

The A1 allele of the dopamine D₂ receptor gene has been reported to be more prevalent in alcoholics than in nonalcoholics. These results have spurred attempts to replicate this initial finding, and have led us to examine whether subjects with substantial self-reported drug, alcohol or nicotine use also display elevated A1 allelic frequencies.

No robust association of the A1 allele and heavy substance use was found. However, a consistent trend toward higher A1 frequencies was present in heavy substance users of largely European descent (whites), but not in those of primarily African descent (blacks). Examination of allelic frequencies with respect to race revealed highly significant differences. A1 was present in 60% of 203 blacks and 33% of 121 whites. A1:A2:A3 allelic frequencies were .37:.60:.03 and .18:.82:.00, respectively. The racial differences in A1 and A3 frequencies suggest the possibility that further differences might be found among distinct white ethnic groups and underscore the need for caution in interpreting allelic associations when careful matching of ethnicity has not been performed.

ACUTE AND CHRONIC EFFECTS OF COCAINE ON DISCHARGE CHARACTERISTICS OF NORADRENERGIC LOCUS COERULEUS (LC) NEURONS: STUDIES IN ANESTHETIZED AND UNANESTHETIZED RATS. A.L. Curtis, E. Conti*, and R.J. Valentino. Dept. Mental Health Sci., Hahnemann University, Philadelphia, PA 19102, U.S.A.

Cocaine blocks monoamine reuptake and decreases LC spontaneous discharge rates. The present study characterizes acute and chronic cocaine effects on LC spontaneous discharge, sensory-evoked discharge, activation by stress, and activation by corticotropin-releasing factor (CRF) in anesthetized and unanesthetized rats. In anesthetized rats, cocaine (0.1-3.0 mg/kg, i.v.) decreased LC spontaneous discharge and LC discharge elicited by repeated sciatic nerve stimulation. The ratio of evoked/tonic discharge rate (signal-to-noise) was not significantly decreased by cocaine. Similarly, chronic cocaine (40 mg/kg/day for 14 days) administered by osmotic minipumps, decreased both LC spontaneous and sensory-evoked discharge, but not the signal-to-noise ratio. Neither acute or chronic cocaine blocked LC activation by i.c.v. CRF or by hemodynamic stress induced by nitroprusside infusion, indicating that cocaine does not attenuate all inputs that activate LC. These effects of cocaine are in contrast to those of monoamine reuptake blockers that are antidepressants, i.e., desmethylimipramine (at norepinephrine terminals) and sertraline (at serotonin terminals). Chronic antidepressant administration either increased the LC signal-to-noise ratio, or attenuated LC activation by hemodynamic stress. Acute cocaine had similar effects on LC responses in unanesthetized (auditory stimulation) as in anesthetized rats, but was one-third as potent. In conclusion, acute and chronic cocaine decreased LC spontaneous discharge and sensory-evoked discharge, but neither stress- or CRF-elicited LC activation suggesting that cocaine attenuates LC activation by specific stimuli. GENETIC DIFFERENCES IN DRUG SELF-ADMINISTRATION. J.M. Carney, M.S. Cheng*, J.F. Wu*, W.R. Landrum* and T.W. Seale. Dept. of Pharmacology, UK Med. Ctr., Lexington, KY, 40536 and Dept. of Ped., OUHSC, Oklahoma City, OK, 73190.

A wide variety of drugs have significant human abuse potential. These drugs have generally been demonstrated to function as positive reinforcers in animal tests. The present study was designed to characterize a mouse model of chronic drug self-administration and to demonstrate genetic differences in self-administration. Adult male C57BL/6J mice were used in the first study. Mice were implanted with chronic external jugular catheters and placed in individual resident cages. An operant lever and stimulus light was located at one end of the chamber. Mice were given access to response contingent (FRI) saline injection for 5 days prior to drug testing. Different groups of 3 mice each were given access to morphine (0.1 mg/kg/injection), cocaine (0.1 mg/kg/inj), methamphetamine (0.01 mg/kg/inj) and pentobarbital (0.32 mg/kg/inj). All mice initiated and maintained drug self-administration reliably above saline. In the second study, C57BL/6J and DBA/2J were tested at two cocaine doses (0.1 and 1.0 mg/kg/inj) C57 reliably self-administered cocaine. In contrast, DBA mice failed to initiate cocaine self-administration. At either dose, these data demonstrated that there are strong genetic determinants of the reinforcing properties of cocaine. Supported in part by NIDA grant 04028 and NIDA contract 87-42108.

Buprenorphine Fully Suppresses Spontaneous Activity in the Locus Coeruleus. D.A. Highfield, G. Sonti, S.J. Grant Dept. Psychology and Prog. in Neuroscience, Univ. Delaware, Newark, DE, 19716.

Buprenorphine is a synthetic opioid proposed as a potential treatment for cocaine craving. But little is known of buprenorphine's cellular mechanism of action. Commonly described as a partial opioid agonist, buprenorphine is now known to act differentially as an agonist at mu receptors and as an antagonist at kappa receptors.

Noradrenergic neurons in the locus coeruleus (LC) are known to contain mu opioid receptors, and morphine has a prominent inhibitory effect on LC neurons spontaneous activity. Therefore, the ability of buprenorphine to suppress LC activity would indicate whether buprenorphine acts as a full or partial agonist. Since hyperactivity of the LC neurons contributes to expression of the classic opiate withdrawal syndrome, buprenorphine's effect on LC neurons would be highly relevant to its clinical application.

Extracellular single unit activity was recorded from 50 LC neurons of chloral hydrate anesthetized rats using standard physiological and anatomical criteria. Buprenorphine (12-400 µg/kg, i.v.) suppressed LC activity in a dose dependent manner, with full suppression at 50-100 µg/kg. This suppression had a remarkably long duration of action, and could not be reversed by either higher doses of buprenorphine (up to 1 mg/kg) or by the opioid antagonists naloxone or naltrexone (up to 10 mg/kg). However, buprenorphine was blocked by pre-treatment with naltrexone (160-500 µg/kg) or the mu₁ selective antagonist naloxonazine (160 µg/kg).

These results are consistent with the hypothesis that buprenorphine is a full agonist at the mu receptors on LC neurons. Since buprenorphine appears to act identically to morphine in the LC, the apparent lack of spontaneous or precipitated withdrawal after chronic treatment with buprenorphine may be due to its long duration of action and resistance to reversal by antagonists.

CHRONIC BUPRENORPHINE ATTENUATES COCAINE PLACE PREFERENCE T. A. Kosten, PhD, D. W. Marby, BA,* & E. J. Nestler, MD, PhD. Dept Psychiatry, Yale Univ School Medicine, New Haven, CT 06519.

Previous research has shown that chronic buprenorphine (B) reduces cocaine (C) use among opiate addicts and suppresses C self-administration in primates. The present study investigates the effects of chronic B administration on the development of C conditioned place preference (CPP). CPP is another drug abuse model in which rats are exposed to C in a distinctive place and show enhanced preference for this place after training. Rats were injected with B (0.5 mg/kg s.c. 2x/day) or vehicle for 1 wk prior to and during CPP training. After baseline assessments, rats were trained by pairing either saline (S) or C injections (15 mg/kg i.p.) with side 1 for 4 days. CPP was assessed by comparing time spent on this side after training to baseline (change in min/30 min). Vehicle treated rats (n=12) trained with C showed an 8.6 ± 1.0 min CPP compared to the 0.7 ± 0.6 min shown by those rats (n=9) trained with saline. B treated rats (n=8) trained with C showed significantly less CPP at 3.9 ± 0.8 min. The B treated rats trained with S (n=6) showed a 1.9 ± 1.1 min CPP. Training with B alone without chronic treatment did not result in CPP (B: -1.6 ± 1.6 vs S: 1.0 ± 1.5 min). Because B is a mixed opiate agonist-antagonist, this effect may be dose-dependent. The effects of chronic treatment with other doses of B are currently being investigated.

Supported by NIDA grant #P50-DA04050.

151.1

EFFECTS OF TWO DOSES OF ETHANOL ON EEG ACTIVITY IN HEALTHY MALES H.L. Cohen, B. Porjesz*, and H. Begleiter, Dept. of Psychiatry, S.U.N.Y. Hlth Sci Ctr., Bklyn, Brooklyn, New York 11203

The present investigation examined the effects of placebo (P), low dose (LD) and high dose (HD) ethanol on EEG activity in 15 males (X=23.1 years) at low risk for the development of alcoholism. Five EEG recordings using the entire 10/20 system were made under each condition. Only one condition was presented per day and condition order was randomized. Blood alcohol levels were measured both prior to and at intervals of ca 28, 66, 94 and 132 minutes after P, LD or HD administration. The Fast Fourier Transform was used to calculate Power Spectral Densities for each EEG recording. Measures of the relative areas under the power spectral curve were made for each combination of the following frequency bands: slow alpha (SA, 7.5-10Hz), fast alpha (FA, 10.5-13.0Hz), slow beta (SB, 13.5-19.5Hz) and fast beta (FB, 20-26Hz) and electrodes: F3, F4, C3, C4, O1, O2, P3 and P4. Repeated measures MANOVA revealed that ethanol had significant effects in association cortex, i.e. at central leads C3 and C4 and frontal leads F3 and F4, rather than in sensorimotor cortex. These effects were dose-dependent and occurred primarily in the SA frequency band and suggest that there is differential sensitivity of both cortical region and EEG frequency band to the effects of ethanol.

Supported by grants AA-05524 and AA-02686 from NIAAA

151.3

CLASSICAL GENETIC ANALYSES OF RESPONSES TO SEDATIVE-HYPNOTIC AGENTS IN CROSSES DERIVED FROM LONG-SLEEP AND SHORT SLEEP MICE. C.M. de Fiebre, N.E. Colvey, J.M. Webner and A.C. Collins. Institute for Behavioral Genetics, University of Colorado, Boulder, CO 80309-0447.

A classical (Mendelian) genetic analysis of responses to eight sedative-hypnotic compounds (ethanol, urethane, trifluoroethanol, chloral hydrate, barbital, paraldehyde, methyprylon, pentobarbital) was conducted in crosses derived from mouse lines which were selectively bred for differential duration of loss of the righting reflex ("sleep-time") following ethanol. The sleep-time responses of these mice, the long-sleep (LS) and short-sleep (SS) mouse lines, and the derived F1, F2 and backcross (F1 X LS, F1 X SS) generations were measured for these eight agents. Generally, differences in responses among the generations were greater for water soluble compounds than were differences for more lipid soluble compounds. Also, the inheritance pattern seen for water soluble compounds could be explained primarily by additive genetic effects while the modes of inheritance for lipid soluble compounds were more complex. Furthermore, the genetic correlation between ethanol responsiveness and responsiveness to the other agents decreased with increasing lipophilicity. These results suggest that the selection of the LS-SS mouse lines was specific for water soluble anesthetic agents and was not a generalized selection for duration of anesthesia. Elucidation of the differential mechanisms by which water and lipid soluble agents act may lead to an improved understanding of the mechanisms of anesthesia in general as well as an improved understanding of the unique anesthetic actions of ethanol.

151.5

CHRONIC ETHANOL INTOXICATION: EFFECTS ON GABA_A AND NMDA RECEPTOR FUNCTION E. Sanna, M. Serra*, A. Cossu*, P. Fois*, A. Concas and G. Biggio Dept. Exper. Biology, Chair of Pharmacol., Univ. of Cagliari, 09123 Cagliari, Italy

Rats were intoxicated by forced ethanol (EtOH) administrations for 6 days and tested while still intoxicated and during withdrawal (WD). Three hours after the last EtOH ingestion, ³⁵S-TBPS binding to cortical membranes of EtOH-dependent rats was higher (25%) compared to control rats. However, both ³⁵S-TBPS binding and ³⁶Cl⁻ uptake measured in cortical membrane preparations were unchanged 12-24 hours after the last EtOH ingestion. Vice versa, EtOH-dependent rats tested during EtOH WD showed an increased sensitivity to the convulsant action of isoniazid. Moreover, EtOH abstinent rats were more susceptible also to the seizures elicited by kainic acid and other excitatory amino acids but not to those induced by strychnine. This effect was paralleled by an increase of ³H-MK 801 binding to hippocampal membranes. The pharmacological effects were no longer seen at 3 and 6 days of EtOH WD, while at 6 days we found a decrease of ³H-MK 801 to hippocampal membranes of EtOH-treated rats. These results indicate that, in contrast to the acute administration, chronic EtOH treatment may lead to a reduction in the function of GABA_A receptor complex. On the other hand, the GABA_A receptor complex may not be involved directly during EtOH WD. The role of excitatory neurotransmission in the expression of EtOH WD syndrome will be discussed.

151.2

FRONTAL GLUCOSE HYPOMETABOLISM IN CHRONIC ALCOHOLISM. M.H. Dao-Castellana*, Y. Samson, F. Legault*, J.L. Martinot*, A. Holler*, H.J. Aubin*, A. Feline*, A. Syrota*. Service Hospitalier Frederic Joliot, DRIPP, CEA, Orsay, France.

Neuropsychological and neuropathological data suggest that chronic alcoholism may result in frontal damage. Therefore, we measured cerebral glucose utilization (CMR_{glu}) with positron emission tomography (PET) and [18F]-fluorodeoxyglucose in 10 alcoholic subjects selected according to DSM-III-R criteria. PET studies were performed after 1-3 weeks of alcohol withdrawal. Frontal function was assessed by Stroop test and verbal fluency, and memory by Wechsler memory scale. Using magnetic resonance imaging studies performed at the same levels than PET images, three large lobar regions (frontal, parietal, and temporal), and four smaller areas (medial prefrontal, dorsolateral prefrontal, orbito-frontal, and internal temporal cortices) were defined. Regional CMR_{glu} values were normalized to mean cortical values. Compared to control values, a significant bilateral hypometabolism was found in the lobar frontal (p=.01), medial prefrontal (p=.002), and dorsolateral prefrontal (p=.005) cortices. The degree of medial prefrontal hypometabolism correlated with frontal tests (verbal fluency, p=.001; Stroop test time score, p=.02), but correlation with Wechsler memory scale did not reach statistical significance (p=.07). The degree of dorsolateral prefrontal hypometabolism correlated with the number of errors on Stroop test (p=.016). No other correlations were found with any other brain areas. Thus, the inner face of the frontal lobe, which includes the cingulate gyrus, and the dorsolateral prefrontal cortex may be specifically impaired by chronic alcoholism.

151.4

GENOTYPIC VARIATIONS IN ETHANOL'S PHARMACOLOGIC PROFILE AND ITS RELATION TO INHIBITORY AND EXCITATORY NEUROTRANSMITTERS S. Liljequist, Dept of Drug Dependence Research, Karolinska Institute, PO Box 60500, S-10401 Stockholm, Sweden.

Behavioral effects of ethanol were examined in CBA, C57, and NMRI mice. In NMRI animals, increasing doses of ethanol had a biphasic action on locomotor activity (stimulation followed by inhibition) whereas only inhibition was seen in C57 and CBA mice. Ethanol produced a similar dose-dependent and preferential increase in the DOPAC/DA (dopamine) ratio in the limbic forebrain as compared to striatum in all animals suggesting no direct relationship between ethanol-produced enhancement of DA release and ethanol-induced locomotor stimulation. C57, and especially CBA mice were more sensitive to the sedative actions (sleep time) of ethanol than NMRI mice. CBA mice were more sensitive to the convulsant effects of the GABA antagonist picrotoxin whereas no such differences were noted after administration of the specific GABA receptor antagonist bicuculline. In receptor binding studies the modulation of 3H-flunitrazepam binding by GABA and pentobarbital was similar in the forebrain of CBA and C57 mice. Further behavioral studies revealed that CBA mice differed in their response to non-competitive and competitive NMDA receptor antagonists as compared to C57 and NMRI mice. In summary, these data suggest that genotypic differences are present in the GABA and glutamate receptor systems and that a complex interplay between various inhibitory and excitatory neurotransmitter systems may determine the pharmacologic profile of ethanol.

151.6

MULTIPLE WITHDRAWALS FROM CHRONIC ETHANOL ALTERS INFERIOR COLLICULAR SEIZURE SENSITIVITY. T.J. McCown and G.R. Breese. Brain and Dev. Res. Ctr., Univ. of North Carolina, Chapel Hill, NC 27599

In rats, multiple withdrawals from chronic ethanol (EtOH) treatment significantly facilitates kindling in the inferior collicular cortex, but attenuates kindling in the amygdala (McCown and Breese, Alcoholism: Clin. Exp. Res. 14:394, 1990). Since the change in seizure susceptibility appears to be permanent, studies were designed to assess changes in parameters of seizure genesis. Rats received 6 cycles of a chronic EtOH/withdrawal treatment (EtOH liquid diet for 5 days followed by a 1 day withdrawal), or control liquid diet over the same period. Six days after the last withdrawal, the stimulation frequency for seizure genesis was significantly decreased in the multiple withdrawal group. No change was found in the control liquid diet group. Because local application of NMDA or bicuculline in the stimulation site also decreases the effective stimulation frequency, an increase in excitation or a decrease in inhibition could account for these findings. (Supported by NS 26595).

ENDOGENOUS OPIOIDS ARE INVOLVED IN THE HIGH ETHANOL PREFERENCE OF C57BL/6J MICE. S.R. George, G. Ng* and C. Naranjo*. Addiction Research Fdn. and Depts. Med. and Pharmacol., Univ of Toronto, Toronto, Ont., CANADA M5S 1A8

We have examined the role of opioid peptides in a model of high ethanol preference and consumption, using C57BL/6J mice (C57). Animals were housed in temperature and humidity controlled environmental rooms with a 12-hr light-dark cycle, and received tap water or 10% ethanol in a two-tube, free choice paradigm. C57 animals consumed an average of 10-15 gm EtOH/kg/day compared to 1-1.5 gm EtOH/kg/day in control DBA/2 mice. Ethanol preference in C57 was 50-60% of total daily fluid intake. Steady state concentrations of proenkephalin, Met-enkephalin or preproenkephalin mRNA were not significantly different between ethanol-naive C57 and DBA/2 mice. C57 had a significantly lower pain threshold that was increased by a mu opioid agonist, which also decreased ethanol consumption. Attempts to prevent endogenous opioid degradation by bestatin and captopril did not alter ethanol drinking in C57. Administration of ketorphan decreased ethanol consumption, as did administration of kyotorphin. Thus, manoeuvres that increased the concentrations of opioid transsynaptically served to decrease ethanol consumption in the model of C57BL/6J mice that demonstrate a high preference for ethanol.

151.9

AN ALLOCORTICOID-LIMBIC LINK MODULATES ETHANOL-SEEKING BEHAVIOR IN THE RAT. L. Pulvirenti#, S. Rassnick and G.F. Koob Dept. of Neuropharmacol., Res. Inst. Scripps Clinic, La Jolla, Ca 92037 and #Bioch. Psychopharmacol. Unit, Dept. of Neurol., Univ. of Pavia, Italy

Ethanol (EtOH) is a widely abused drug in humans and is self-administered by animals. The neural substrates and the intimate biochemical mechanism mediating its reinforcing action, however, remain still obscure. Electrophysiological and neurochemical evidence indicates that EtOH may activate the mesolimbic dopamine system, particularly within the NAC. To assess the functional significance of such interaction, we studied the effect of microinfusion of fluphenazine, a dopamine receptor antagonist, within the NAC, in rats trained to self-administer EtOH orally. Low doses of fluphenazine (2 and 4 µg/site) significantly reduced EtOH self-administration, without a significant effect on water responding in a two-lever choice paradigm. Since the integrated functional output of the NAC seems to be modulated by glutamate afferents arising from allocortical structures such as the amygdaloid complex and the hippocampal formation, we also evaluated the effect of pharmacological blockade of NAC glutamate receptors on EtOH self-administration. Intra-NAC microinjection of amino phosphonovaleric acid (AP-5, a NMDA receptor antagonist) at the dose of 1.5 and 3 µg/site significantly and selectively reduced responding for EtOH, while blockade of NAC quisqualate receptors was ineffective. These data indicate that a glutamate-dopamine link within the NAC may be part of the neural substrates that mediate EtOH-seeking behavior in the rat.

CHRONIC ETHANOL ADMINISTRATION INCREASES GABA_A RECEPTOR $\alpha 6$ SUBUNIT mRNA LEVELS IN THE RAT CEREBELLUM. A.L. Morrow¹, J. S. Herbert¹ and P. Montpied². ¹Center for Alcohol Studies, UNC Sch. of Med., Chapel Hill, NC 27599 and ²NIMH, Bethesda, MD 20892.

Chronic ethanol exposure alters the function of GABA_A receptor-gated Cl⁻ channels in the CNS. We have recently shown that prolonged ethanol inhalation reduces the expression of GABA_A receptor $\alpha 1$ and $\alpha 2$ subunit mRNAs in the rat cerebral cortex, with no effect on the level of $\alpha 3$ subunit transcripts [Alcohol 7:237-244 (1990); Mol. Pharm. 39: 157-163 (1991)]. In the present study, rats were administered alcohol by liquid diet for 2 weeks using a pair fed design. The rats drank 8-10 g/kg/day of 5-7.5% ethanol diet (BEC = 248±35 mg/dL) and exhibited tremors (100%) and audiogenic seizures (50%) following ethanol withdrawal. GABA_A receptor α subunit mRNA levels were quantified by Northern analysis using subunit specific oligonucleotide and cRNA probes. Cerebral cortical GABA_A receptor $\alpha 1$ subunit mRNA levels were altered as with chronic ethanol inhalation. In the cerebellum, chronic ethanol administration reduced the levels of GABA_A receptor $\alpha 1$ subunit mRNAs (4.8 and 4.4 kb) by 30-40% and increased the levels of GABA_A receptor $\alpha 6$ subunit mRNA (2.7 kb) by 30% (p<0.05, n=16). β -actin mRNA levels were also reduced by 29%, whereas poly(A)⁺ RNA levels were not significantly altered following chronic ethanol exposure by liquid diet. These data suggest that chronic ethanol exposure regulates GABA_A receptor gene expression by differential effects on the synthesis of specific subunits of GABA_A receptors.

REGIONAL DIFFERENCES IN FUNCTIONAL BRAIN ACTIVITY BETWEEN ALCOHOL PREFERRING (P) AND NON-PREFERRING (NP) RATS. M.J.Lewis, T.-K.Li, L.Lumeng, L.J. Porrino, Howard Univ., Wash.,DC 20059; Indiana Univ. Sch.Med.,Ind.,IN & VAMC; & Bowman Gray Sch.Med., Winston-Salem, NC. Research has shown that there are major differences in the content of monoamines between rats genetically bred for preference and non-preference for alcohol (A) intake. P rats have lower levels of serotonin and dopamine in selected brain regions in comparison to NP rats. To investigate further differences in brain activity of P and NP rats, the quantitative 2-[¹⁴C]-deoxyglucose (2-DG) method was used to map the distribution of rates of cerebral glucose in both lines. Quantitative autoradiographic analysis of 40 brain regions showed that levels of functional activity were higher in the olfactory tubercle (OT) and lower in the CA3 portion of hippocampus of P rats in comparison to NP rats. No significant differences in other brain regions were found. Previous studies with unselected rats has shown that A injection selectively increases metabolic activity in the OT. These data suggest the importance of the OT in the behavioral effects of A. (Supported by NIAAA grants AA06263, RR08016, and AA07611)

151.10

EFFECT OF CHRONIC ETHANOL INTAKE AT LOW DOSES ON BRAIN DOPAMINE RECEPTORS. E.Daniele*, S.Govoni*, M.D.Lograno*, F.Matteo*, V.Olgianti#, R.Cagiano*^, V.Cuomo*^. Pharmacobiol. Dept and ^Ins.Pharmacol. Univ of Bari; #Pierrel Res. Labs. Milano, Italy.

Brain dopaminergic (DA) circuits have been shown to be involved in ethanol (E)-induced tolerance, dependence and withdrawal. On the other hand, there are few studies exploring the effect of prolonged exposure to low levels of ethanol mimicking the pattern of consumption of the substance observed in southern part of Europe where alcohol can be considered a diet component. Along this line the present investigation studied, in the rat, the effect of a 8 week long treatment with 3% E in the drinking water. Striatal dopamine receptors were evaluated 2 and 24 hrs following E withdrawal by measuring the binding of tritiated spiperone and SCH 23390. The treated animals had an increased number of D1 receptors (respectively 130% and 108% at 2 and 24 hours). Kd values were superimposable in all groups. The biochemical data were in agreement with behavioral data in the same animals showing an enhanced motor response to amphetamine administration. The present results indicate that low levels of E for long periods of time are able to induce a significant increase of DA receptors. It should be stressed that the animals used in the present study did not show tolerance to acute E injection. This observation indicates that the changes of DA receptors may be dissociated from tolerance although it cannot be excluded that they may be important for the development of dependence.

151.12

OMEGA-CONOTOXIN AND DIHYDROPYRIDINE LABELLED CALCIUM CHANNELS ARE DIFFERENTIALLY AFFECTED BY ETHANOL IN NG 108-15 CELLS. S.Bergamaschi*, C.Lopez*, F.Battaini#, M.Parenti^, S.Govoni*, M.Trabucchi*#. Inst. Pharmacol. Sci., ^Dept. Pharmacol.Tox. and Ther. Univ. of Milan, #Dept. Exp.Med. Bioch.Sci. IInd Univ. of Rome, Italy.

Literature data indicate that ethanol (E) affects calcium homeostasis. To get insight into the mechanisms by which E alters calcium movements the present study investigated the effect of E treatment on omega-conotoxin (CgTx) and dihydropyridine (DHP) labelled calcium channels in NG 108-15 cells. Cells were differentiated with dibutyryl cAMP (1mM, 4 days). Both undifferentiated and differentiated cells were exposed to 200 mM E for 72 hrs. Iodinated CgTx and tritiated PN 200-110 were used to label calcium channels. Displacement experiments showed that the two ligands label two distinct binding sites. In undifferentiated cells ethanol exposure induced a large increase in DHP binding sites (Bmax: Control: 24±3.2, E: 42±5.3 fmol/mg prot.). In contrast CgTx binding sites were not modified by the treatment, suggesting that the two channels may be independently regulated and display a differential sensitivity to E. This view was further strengthened by experiments in differentiated cells where E induced a significant decrease in CgTx binding (Bmax:Control: 33±5.5, E: 19±3.5 fmol/mg prot.). Therefore E appears to disrupt the balance between the two channels favoring the expression of those labelled by DHP while leaving unaffected or inhibiting CgTx sensitive ones. The unbalance between the two channels may be relevant to the changes in neuronal activity which have been observed following ethanol intake.

152.1

ISOLATION AND IDENTIFICATION OF THE ZETA (ζ) RECEPTOR BINDING SITE. I.S. Zagon, S.R. Goodman, G. Allison*, and P.J. McLaughlin. Dept. of Neuroscience and Anatomy, Penn State Univ. College of Medicine, Hershey, PA 17033.

An opioid growth factor (OGF), [Met⁵]-enkephalin, interacts with the ζ receptor to regulate growth of normal and abnormal tissues and cells, including those of the nervous system. To identify the cellular and molecular nature of the ζ receptor, homogenates of S20Y neuroblastoma (NB) cells were electroporated, electrotransferred and ligand blotted with radiolabeled [Met³]-enkephalin. Four polypeptides were identified: 32, 30, 17, and 16 Kd. [Met³]-enkephalin and (-) naloxone, but not (+) naloxone, blocked the appearance of these polypeptides. Subcellular fractionation studies revealed these polypeptides to be located in the nuclear fraction; receptor binding assays confirmed these findings. Two-dimensional gel electrophoresis and ligand blotting were used to identify the 17 and 16 Kd polypeptides, and antibodies were made to these gel purified proteins. Western blotting with antiserum to either the 17 or 16 Kd proteins reacted with 4 polypeptides of 32, 30, 17 and 16 Kd, suggesting a relationship between these binding sites.

152.3

LONG-TERM EFFECTS OF MORPHINE ON MU-OPIOID RECEPTOR REGULATED ADENYLATE CYCLASE ACTIVITY AND NORADRENALINE RELEASE IN RAT BRAIN. A.N.M. Schoffelemeier, B.J. Van Vliet*, T.J. De Vries* and A.H. Mulder*. Dept. Pharmacol., Free Univ., Med. Fac., 1081 BT Amsterdam, The Netherlands.

In striatal slices from rat foetuses (E21) of morphine-dependent dams D-1 dopamine receptor-stimulated cAMP production, unlike that induced by forskolin, was markedly enhanced. However, the inhibitory effect of the mu-opioid receptor agonist DAMGO on the stimulated adenylate cyclase activity remained completely unchanged. Interestingly, identical effects were observed in primary neuronal cultures treated chronically with morphine. Similarly, chronic morphine treatment in vivo induced a profound increase of the electrically evoked ³H-noradrenaline release from fetal cortex slices without affecting the presynaptic inhibitory effect of DAMGO. Release induced by the calcium ionophore A23187 was unchanged in morphine-tolerant cortex slices.

These and other data indicate that tolerance to morphine may be due to adaptive changes in stimulatory effector proteins, such as Gs proteins and voltage-sensitive calcium channels, rather than to mu-opioid receptor desensitization, which at the same time may underly morphine withdrawal effects.

152.5

(+)-BENZOMORPHAN SIGMA LIGANDS STIMULATE STRIATAL DOPAMINE SYNTHESIS. R.G. Booth and R.J. Baldessarini. Div. of Medicinal Chemistry, Sch. of Pharmacy, Univ. of North Carolina, Chapel Hill, NC 27599, & Harvard Medical Sch. & McLean Hosp., Belmont, MA.

Dopamine (DA) synthesis in minced rat corpus striatum was assessed by measuring the activity of tyrosine hydroxylase (TH) with [1-¹⁴C]-L-tyrosine. At 0.1 μ M, the (+)-enantiomers of the 6,7-benzomorphan *N*-allylnormetazocine (NANM) and pentazocine (but not [-]-cyclazocine) significantly increased TH activity over basal levels by 15% and 20%, respectively. The (-)-benzomorphans were inactive at 0.1 μ M, and inhibitory at higher concentrations. The effect of (+)-NANM was not additive with stimulation of TH activity by excess forskolin and was reversed by the DA autoreceptor agonist S(+)-*N*-*n*-propylorapomorphine (NPA), suggesting a neuroregulatory mechanism involving cyclic-AMP. Stimulation of DA synthesis by (+)-NANM and (+)-pentazocine was fully blocked by the reported sigma "antagonist" BMY-14802 and by the (-)-benzomorphans, but not by the opiate antagonist naloxone. Ligands for phencyclidine, κ - and μ - opiate receptors had no significant stimulatory effect on TH activity. These results suggest that (+)-NANM and (+)-pentazocine may act as agonists at putative sigma receptors in striatum to modulate DA synthesis, perhaps by altering intracellular levels of cyclic-AMP. MOLECULAR MODELING OF SIGMA RECEPTOR LIGANDS: A MODEL OF BINDING BASED ON CONFORMATIONAL AND ELECTROSTATIC CONSIDERATIONS. T.-P. Su, K. Shukla* and T.M. Gund*. Neuropharmacology Laboratory, NIDA Addiction Res. Ctr., Baltimore, MD 21224 and Dept. of Chemistry, Chem. Engineering & Environmental Sci., New Jersey Inst. Tech., Newark, NJ 07102.

Sigma receptor ligands encompass many structurally dissimilar classes of substances. This report describes conformational and electrostatic potential (ESP) studies on several representative sigma ligands to derive a model pharmacophore. The ligands include haloperidol (HAL), (+)3-(3-hydroxyphenyl)-N-(1-propyl)-piperine (PPP), (+)pentazocine (PENT) and progesterone (PRO). Low energy conformations of these compounds were generated using the conformation generator program, RCG5. Quantum mechanical methods were used initially to calculate net atomic charges, which were then used to calculate the ESP on the Van der Waals surface using the ARCHEM program. The four molecules were superimposed to achieve the best fit. Thus, a pharmacophore model was produced as a triangle fitted onto the superimposed molecules. Fitting position (FP) 1 constitutes the nitrogens (N) of HAL, PPP and PENT and C-8 of PRO. FP 2 includes C-7 of PENT, C-2 of PPP, the center of the fluorophenyl ring of HAL and the center of ring B in PRO. FP 3 constitutes the lone pair of electrons on the N for PENT, PPP, HAL and the lone pair of electrons on the C-20 carbonyl oxygen in PRO. Consistency in the position of the ligand charges were also observed from the ESP calculations. The pharmacophore obtained from this study may help advance our understanding of the sigma receptor and assist in designing novel antipsychotic and neuroprotective agents.

152.4

CHRONIC D-AMPHETAMINE INHIBITS OPIOID ANTAGONIST-INDUCED SUPERSENSITIVITY. A. Duttaroy*, B. Billings*, J. Candido* and B.C. Yoburn. College of Pharmacy, St. John's University Queens, NY 11439.

Chronic opioid antagonist treatment (naltrexone: NTX) increases opioid receptor density and agonist potency. Since opioid abusers may administer nonopioids during treatment, we examined the effect of chronic d-amphetamine (AMP) on NTX-induced upregulation and supersensitivity.

Mice were implanted s.c. with a 15mg NTX or placebo (PLA) pellet for 8 days. Mice were injected with saline (SAL) or AMP (7.5 or 5.0mg/kg/day, s.c.) for 7 days beginning 24hr following implantation. Pellets were removed on the 8th day, and 24hr later mice were tested for morphine analgesia (tail flick) or brains were removed and binding studies conducted. Chronic NTX significantly enhanced the analgesic potency of morphine in SAL treated mice but not in mice treated with 5.0mg/kg AMP (ED₅₀=2.67, 1.47, 2.30, 2.32mg/kg; PLA-SAL, NTX-SAL, PLA-AMP, NTX-AMP; respectively). Similar results were observed for 7.5mg/kg AMP. In saturation studies, NTX increased [³H]DAMGO B_{max} 60-70% without altering K_d in both SAL and AMP treated mice. Studies with 2nm [³H]DPPE were similar. These studies indicate that daily AMP can limit the expression of NTX-induced supersensitivity but not receptor upregulation. The robust nature of receptor density increases contrasts with the more sensitive functional characteristics of opioid receptors (supported by NIDA DA 04185).

152.6

INCREASED DOPAMINE RELEASE IN VIVO AND ORAL-FACIAL MOVEMENTS FOLLOWING INTRAPERITONEAL ADMINISTRATION OF TWO SIGMA LIGANDS J.M. Walker, S.L. Patrick, R.L. Patrick†. Schrier Research Laboratory, Dept. of Psychology, †Section of Neurobiology, Division of Biology and Medicine, Brown University, Providence, RI, 02912.

Several lines of evidence suggest a role of sigma receptors in the modulation of midbrain dopaminergic neurons: 1) sigma receptors are concentrated in the dopamine-rich substantia nigra pars compacta; 2) unilateral microinjections of potent sigma ligands into the substantia nigra produces contralateral circling behavior that is blocked by 6-hydroxydopamine lesions; and 3) low systemic doses of DTG produce marked increases in glucose utilization in the substantia nigra. We now report the effects of 1,3-di-o-tolylguanidine (DTG) and (+)-pentazocine on extracellular dopamine levels studied using microdialysis in freely moving rats. Before each experiment, a guide cannula was implanted in the right caudate nucleus under nembutal anesthesia. Following a three day recovery period, animals were placed in a clear plexiglass chamber, and perfusion buffer was collected (1.5 μ l/min) before and after drug or vehicle injection. Simultaneously, the incidence of vacuous chewing movements and facial tremors was recorded. At the dose of 1 mg/kg i.p., DTG produced a 40% increase in extracellular dopamine levels (ANOVA: F_{1,11} = 15.9; P = 0.0021). (+)-Pentazocine produced a similar effect at 10 mg/kg (F_{1,10} = 8.7; P = 0.01). (+)-Pentazocine is thus about equipotent to morphine in the caudate. Behavioral observations revealed concurrent increases in the frequency of vacuous chewing movements (p < 0.05) and facial tremors (p < 0.05) at doses of the drugs that increased dopamine release. These data show that two putative sigma ligands induce significant behavioral and neurochemical effects following intraperitoneal administration.

152.7

SIGMA RECEPTORS LABELED WITH (+)[³H]-3-PPP AND [³H]DTG ARE DIFFERENTIALLY REGULATED BY HALOPERIDOL AND GUANINE NUCLEOTIDES. L. Stein and Y. Itzhak, Depts. of Biochemistry & Molecular Biology & Pharmacology, University of Miami School of Medicine, Miami, FL 33101.

Recent studies from our laboratory and others suggest the existence of multiple sigma receptor binding sites in the CNS of rodents. In the present study we examined the effect of repeated exposure of rats to the neuroleptic, haloperidol, on the binding of (+)-3-(3-hydroxyphenyl)-N-1-(propyl)piperidine [(+)-3-PPP] and 1,3-di-o-tolyl-guanidine (DTG) to sigma binding sites in rat brain, and the responsiveness of these sites to guanine nucleotides. Repeated exposure of rats to haloperidol (4mg/kg/day for 14 days) resulted in a 75% decrease in the number of (+)[³H]-3-PPP binding sites and abolished the sensitivity of these binding sites to GTP and Gpp(NH)p. A complete recovery of the total number of (+)[³H]-3-PPP binding sites and the responsiveness to guanine nucleotides was regained 28 days after the treatment with haloperidol was ceased. In contrast, [³H]DTG binding sites expressed neither sensitivity to the repeated exposure to haloperidol nor to guanine nucleotides. These findings further support the hypothesis that (+)-3-PPP and DTG label distinct "sigma" binding sites which are differentially regulated by haloperidol and guanine nucleotides.

CLONING OF G PROTEIN-COUPLED RECEPTORS FROM NG 108-15 CELLS BY POLYMERASE CHAIN REACTION. L.-Y. Liu, Chen, S. Li* and Y.-W. Chen*, Departments of Pharmacology and Microbiology and Immunology, Temple University School of Medicine, Philadelphia, PA 19140.

There is considerable homology within transmembrane domains of G protein-coupled receptors. A method was developed to clone new G protein-coupled receptors by using two oligonucleotide primers, corresponding to highly homologous regions within transmembrane domains III and VI, and performing polymerase chain reaction (PCR) on cDNA from the tissue of interest (Libert et al., Science 244: 569-572, 1989). We took a similar approach to clone potentially unknown G protein-coupled receptors from NG 108-15 cells. NG 108-15 cells express many receptors, including δ opioid, α_2 -adrenergic, muscarinic, B₂ bradykinin, substance K, 5-HT₃, P₂ purinergic, endothelin and cannabinoid receptors. mRNAs were isolated from confluent cells and reverse transcribed to cDNA. PCR was performed on cDNA with Taq polymerase and two primers with Sal I or EcoR I restriction site attached. PCR products, ranging from 300 to 1000 base pairs, were cloned into vector pGEM3Zi(+) and their nucleotide sequences were determined by the dideoxynucleotide chain termination method of Sanger. One clone representing partial sequence of a potentially new G protein-coupled receptor has been found. We are in the process of screening for more clones. These clones will be used to screen a cDNA library for full-length clones of G protein-coupled receptors. (Supported by NIDA grant 04745 and Sloan Foundation Fellowship)

Supraspinal antinociception produced by [D-Met²]-FMRFamide (DMFa) in mice. R. B. Raffa and C. D. Connelly, Drug Discovery Research, The R.W. Johnson Pharmaceutical Research Institute, Spring House, PA 19477-0776

The ability of Phe-Met-Arg-Phe-NH₂ (FMRFamide) or [D-Met²]-FMRFamide (DMFa) to produce antinociception in mice, or to block morphine-induced antinociception, was examined using the tail-flick and tail-immersion tests. DMFa dose-dependently produced antinociception following intracerebroventricular (i.c.v.) administration with ED₅₀ values (95% confidence limits) of 5.0 (2.2-7.2) and 12.8 (8.1-19.9) μ g in the tail-flick and tail-immersion (55°C) tests, respectively. In contrast, FMRFamide did not produce a maximal effect in the tail-flick test. Naloxone, administered s.c. 20 min prior to DMFa, dose-dependently attenuated DMFa-induced antinociception. The pA₂ value for naloxone was the same against i.c.v. morphine or DMFa and morphine-tolerant mice were cross-tolerant to the antinociceptive effect of DMFa. FMRFamide and DMFa produced rightward, parallel shifts of the morphine antinociceptive dose-response curve. These findings, that DMFa both elicited naloxone-sensitive antinociception and attenuated morphine-induced antinociception, are consistent with the view that FMRFamide-related peptides (FaRPs) are weak agonists at opioid receptors and, further, appear to reconcile the apparently chimeric agonist and antagonist properties of these peptides observed *in vivo*.

152.8

CLONING OF G-PROTEIN COUPLED RECEPTORS FROM SH-SY5Y NEUROBLASTOMA CELLS. L. Toll, C.J. Green* and C.M. Bitler*, SRI International, 333 Ravenswood Avenue, Menlo Park, CA 94025.

Based upon the method of Libert et al. (Science, 244, 569, 1989), G protein coupled receptors were cloned from the μ and δ opiate receptor-containing human neuroblastoma cell line SH-SY5Y. Primers from conserved regions in the third and sixth transmembrane spanning segments from G protein coupled receptors were synthesized. These primers were used in a polymerase chain reaction in conjunction with whole RNA from SH-SY5Y which was reverse transcribed, in order to amplify cDNA from G protein coupled receptors. Amplified cDNA was cloned into M13 and sequenced. Four distinct clones of putative G protein coupled receptors have been identified. One clone represents the human β_2 receptor sequence, one represents RDC4, a previously identified, but unknown receptor. The final two clones represent previously unidentified G protein coupled receptors. They have considerable homology with each other, and less homology with other known receptors. The amino acid sequences will be discussed.

152.10

EXPRESSION OF μ , δ , AND κ_3 BINDING SITES IN A HUMAN NEUROBLASTOMA CELL LINE. K.M. Standifer, J. Cheng, J.L. Biedler*, and G.W. Pasternak, Cotzias Laboratory of Neuro-Oncology and Laboratory of Cellular and Biochemical Genetics, Memorial Sloan-Kettering Cancer Center, New York, NY 10021.

Continuously cultured neuroblastoma and neuroblastoma hybrid cell lines have played an important role in the study of opioid receptor pharmacology. We now report that a human neuroblastoma cell line (SK-N-BE(2)-C) expresses μ , δ , and κ_3 opioid receptors in levels similar to those found in rat brain. Total opioid binding was measured with the non-selective ligand ³H-diprenorphine. Analysis of saturation data revealed a B_{max} of 490 fmol/mg protein and a K_D of 0.49 nM. Subtype selective assays were performed with ³H-DAMGO (μ), ³H-DPDPE (δ), ³H-U69593 (κ_1), and ³H-NalBzOH (κ_3). The total number of sites obtained by adding the B_{max} values from saturation studies of the selective assays closely approximated that seen with the non-selective ligand ³H-diprenorphine and can be broken down as follows: 50% μ , 16% δ , and 34% κ_3 . The μ binding comprised a combination of both μ_1 and μ_2 sites. We were unable to detect any specific κ_1 binding. Morphine (200 nM) inhibited forskolin stimulated cyclase by 30%, with a maximal inhibition of 60%. We are presently engaged in a more extensive characterization of these binding sites, as well as more functional aspects of the receptors.

152.12

SINGLE-DOSE PHARMACOKINETICS AND ABSOLUTE ORAL BIOAVAILABILITY OF CI-977 IN BEAGLE DOGS. C.M. BARKSDALE, S.E. ROSE*, D.A. TURLUCK*, G.D. NORDBLUM*, and D.S. WRIGHT*, Pharmacokinetics/Drug Metabolism Department, Parke-Davis Pharmaceutical Research Division, Warner-Lambert Company, Ann Arbor, Michigan 48105-2430.

CI-977, [5R-(5 α ,7 α ,8 β)]-N-methyl-N-[7-(1-pyrrolidinyl)-1-oxaspiro[4.5]-dec-8-yl]-4-benzofuranacetamide, hydrochloride, is a novel kappa opioid receptor agonist being evaluated as an analgesic. To determine the pharmacokinetics and absolute oral bioavailability of CI-977, six beagle dogs (3M, 3F) received single 150- μ g/kg PO and 15- μ g/kg IV doses in a crossover paradigm on separate occasions with a period of 4 weeks between treatments.

Blood samples were drawn at selected intervals up to 24 hours postdose, and plasma was analyzed with a validated radioimmunoassay procedure.

Mean C_{max} and t_{max} values after PO dosing were 3.44 ng/ml and 45.8 min, respectively. Harmonic mean elimination half-life and AUC(0- ∞) values were 66 min and 357 ng·min/ml for IV dosing and 326 min and 1,140 ng·min/ml for PO administration, respectively. Mean absolute oral bioavailability was 7.4%.

153.1

DEVELOPMENTAL EXPRESSION OF 5-HT_{1C} RECEPTOR mRNA IN RAT HYPOGLOSSAL NUCLEUS (n XII). W.H. Zhu*, J.T. Erickson, M.F. Czyzyk-Krzeska, E.E. Lawson and D.E. Millhorn. Dept. of Physiology, Univ. of N. Carolina, Chapel Hill, NC 27599.

nXII in rat is innervated by fibers that contain several neurotransmitters including serotonin (5-HT). The present study was undertaken to determine if nXII motor neurons express 5-HT receptor mRNA at different developmental ages (0, 7, 14, 21 & 28 days). Tissue sections (10 μm) through the entire extent of nXII were cut and mounted on gelatin-coated slides. A mixture of two ³⁵S-labeled oligonucleotide probes directed against sequences of mRNA that encode portions of the third cytoplasmic domain and carboxyl terminus of either the 5-HT_{1A} or 5-HT_{1C} receptor subtype were used for *in situ* hybridization. We found a high level of expression of 5-HT_{1C} receptor in the caudal aspect of nXII in 0 day old rats. This signal became progressively weaker during the first postnatal month and was indistinguishable from background labeling by 28 days. A strong unchanging signal for 5-HT_{1C} receptor mRNA was detected in the choroid plexus and in cells within the ventral aspects of the medulla throughout development. We failed to detect 5-HT_{1A} receptor mRNA in nXII at any developmental age. The significance of transient expression of 5-HT_{1C} in nXII is unknown but could be involved in regulation of the upper airway patency during prenatal and early postnatal development. (HL33831, HL34919, AHA, ALA)

153.3

LONG-TERM SURVIVAL OF MONOAMINERGIC NEURONS IN REAGGREGATE TISSUE CULTURE. A. Heller, H.K. Choi, L. Won and P.C. Hoffmann. Dept. of Pharmacological and Physiological Sciences, University of Chicago, Chicago, IL 60637.

In three-dimensional reaggregate tissue culture, cells interact to permit recapitulation of their normal neurochemical and morphological development *in vivo* (Kotake et al., J. Neurosci. 2:1307-1315, 1982). We have succeeded in maintaining dopaminergic (DA) and serotonergic (5-HT) neurons in three-dimensional reaggregate tissue culture for periods up to 4 months. Dissociated cells from embryonic mice of mesencephalic tegmentum (containing DA and 5-HT neurons) and corpus striatum (a target area for monoaminergic neurons) were reaggregated in 3.5 ml of media containing serum which had been dialyzed to remove endogenous 5-HT. After 1 month in culture, the reaggregates were transferred to 30 ml of media. Following 4 months in culture, the reaggregates were analyzed for DA and 5-HT levels, tyrosine hydroxylase (TH)-immunocytochemistry and histofluorescence. These reaggregates show increasing endogenous levels of DA (118.8 ± 2.7 ng/mg protein; an approximately 3-fold increase over 3 week old cultures), while 5-HT levels (38.2 ± 2.7 ng/mg protein) appear to plateau at an earlier point in development (4 weeks). DA perikarya, processes and patches of punctate varicosities were observed by TH-immunocytochemistry and Falck-Hillarp histofluorescence. The ability to culture monoaminergic neurons over their normal developmental period *in vivo*, allows examination of neuronal function, as well as cell vulnerability to neurotoxic agents at various stages of development. Supported by MH28942.

CHARACTERIZATION OF SPECIFIC [³H]NOREPINEPHRINE UPTAKE IN DISSOCIATED NORADRENERGIC CELL CULTURES FROM EMBRYONIC RAT RHOMBENCEPHALON. H.K. Raymon and E.M. Leslie. Dept. of Pharmacology, University of California, Irvine, CA 92717.

Many epigenetic factors have been shown to influence brain development. In order to study the direct effects of these factors on the maturation of a chemically defined system, the noradrenergic system, an *in vitro* cell culture model was established. Rhombencephali were dissected from the brains of rats at embryonic day 14. Cells were dissociated and plated in either a serum-containing or serum-free fully defined medium. [³H]Norepinephrine (NE) uptake was used as a marker for assessing the maturational stage of the noradrenergic cells. Specific uptake was defined as the difference in uptake in the absence and presence of 10 μM desmethylimipramine (DMI). [³H]NE uptake was temperature and sodium dependent. There was a non-linear relationship between plating density and [³H]NE uptake, with uptake plateauing at higher cell densities. Specific uptake was detectable by 4 days *in vitro* (DIV) and increased steadily up to 21 DIV. These data are consistent with the findings by Coyle and Axelrod, 1971 (J. Neurochem. 18, 2061-2075), of specific, DMI-inhibitable [³H]NE uptake into rat brain synaptosomes at 19 days gestation.

Previous studies have shown that treatment with KCl has no effect on [³H]NE uptake in mouse locus coeruleus explant cultures. In order to confirm that our system was similar to this well characterized tissue culture system, we tested the effects of 4 and 20 mM KCl in serum-containing and in serum-free medium. No significant effect of KCl on [³H]NE uptake was observed in either medium. The effects of cocaine and other drugs of abuse on the development of these noradrenergic cells are currently being examined.

EFFECTS OF NEONATAL 5,7-DHT TREATMENT ON FOREBRAIN 5HT₂ RECEPTORS. J.H. Haring and D. Sawyer*. Dept. of Anatomy and Neurobiology, St. Louis Univ., St. Louis, MO 63104.

Palacios and colleagues (Brain Res. 346:231, 1985 and 524:139, 1990) have shown high concentrations of 5HT₂ receptors to be present on the neurons of the neocortex and parts of the basal ganglia. The purpose of the present study was to examine the impact of neonatal 5HT reduction on the development of the forebrain 5HT₂ receptor population in the rat.

Neonatal Sprague-Dawley rats of both sexes received subcutaneous injections of 5,7-DHT (100mg/kg in saline) or saline alone on PND0 (i.e. day of birth) and PND1. On PND21, rats were euthanized by sodium pentobarbital overdose. Their brains were removed and rapidly frozen. The status of forebrain 5HT₂ receptors was assessed by ketanserin binding in 20 μm cryostat sections cut in the transverse plane. The distribution of 5HT₂ receptors was studied by film autoradiography, while saturation analysis measured receptor numbers (B_{max}) and binding affinity (K_d). 5,7-DHT treatment reduced 5HT uptake 50-60% in cortical synaptosomes by PND3. The reduction of 5HT innervation did not appear to change the previously described pattern of forebrain 5HT₂ receptors (e.g. the dense band in layer Va). Binding affinity values were lower in treated rats but not statistically different from controls. However, a significant decrease in B_{max} was detected in treated rats. These data suggest that 5HT innervation may not be necessary for the neuronal expression of 5HT₂ receptors, but may serve to influence the number of receptors during development. Support: NS25752 and DB07734.

CHARACTERIZATION OF ACUTELY DISSOCIATED AND CULTURED NEONATAL RAT OLFACTORY BULB NEURONS. R.L. Shoemaker, G. Bora*, and G. Kapatos. Dept. Psychiatry Wayne State Univ., Detroit MI 48235.

Periglomerular neurons (PGN) in the intact rat olfactory bulb (OB) exhibit both gamma-aminobutyric acid (GABA) and dopamine (DA) neurotransmitter phenotypes. Expression of the DA but not GABA phenotype is dependent upon olfactory receptor neuron (ORN) afferents. As a first step in elucidating the cellular interactions required for the maintenance of the PGN DA phenotype, we have established a culture system for neurons derived from the neonatal rat OB. In the hope of defining and isolating PGN OB neurons we have also examined the expression of voltage-sensitive calcium and sodium channels and glutamate receptors in acutely dissociated OB neurons. Survival of OB neurons in culture was greater with increasing plating density and required the presence of a feeder layer of OB astrocytes. The number of neurons, determined by cell counts after neuron specific enolase immunohistochemistry, was stable for at least 7 days *in vitro* (DIV). The neurons exhibited diverse morphologies. A majority of the neurons were immunoreactive for GABA, glycine, and glutamate. A small number of neurons, presumably PGN, continued to express tyrosine hydroxylase (TH) immunoreactivity, a marker for the DA phenotype, and their number increased with DIV. The number of TH positive neurons was not increased by nerve growth factor, forskolin or depolarization, suggesting that control of TH gene transcription in PGN by ORN may not involve transcriptional elements previously described for TH. Flow cytometric analysis of intracellular calcium and membrane potential demonstrated that virtually all OB neurons had L-type calcium channels. A subpopulation (35%) contained both L-type calcium channels and sodium channels. In addition, 35% of the total neurons expressed both L-type channels and glutamate receptors. Studies are currently underway to characterize these subpopulations with respect to neurotransmitter phenotype following sorting and culture. (Supported by NIH Grant NS26081).

DOPAMINE D₁ AUTORECEPTOR FUNCTION: POSSIBLE EXPRESSION IN DEVELOPING RAT PREFRONTAL CORTEX AND STRIATUM. M.H. Teicher, A.L. Gallitano*, H.A. Gelbard*, H.K. Evans*, E.R. Marsh*, R.G. Booth and R.J. Baldessarini. Departments of Psychiatry and Neuroscience Program, Harvard Medical School, Mailman Laboratories for Psychiatric Research, McLean Hospital, Belmont MA 02178.

Dopamine (DA) receptors modulating DA synthesis are known to be either type D₂ or D₃. Attempts to detect D₁ autoreceptors in the adult rat striatum have failed to elicit any compelling evidence for their existence. However, the density of D₁ receptors in forebrain changes markedly with development. We hypothesized that the transient postnatal surge in D₁ density might include some autoreceptors. To test this hypothesis we studied 294 developing rats (15 days - adulthood) using the γ-butyrolactone (GBL) technique of Walters & Roth. The selective DA D₁ agonist SKF-38393 inhibited DA synthesis in the striatum and prefrontal cortex (PFCTX) of 15 and 22-day-old rats, but did not inhibit synthesis in adults. The effects of SKF-38393 in developing rats were blocked by the D₁ antagonist SCH-23390, and were mimicked by the non-catechol D₁ agonist CY-208-243, suggesting receptor mediation. The mixed D₂/D₃ agonist quinpirole attenuated DA synthesis in striatum of both 16-day-old and adult rats, but failed to inhibit the GBL-induced increase in DA synthesis in the developing PFCTX. These findings suggest that synthesis-modulating D₁ function may emerge in developing forebrain. In the adult striatum these functions appear to be subsumed by D₂ or D₃ receptors, whereas synthesis-modulating DA receptor function appears to be essentially lost with age in the PFCTX.

L-DOPA DOES NOT ALTER THE LEVELS OF DARPP-32 mRNA IN MOUSE BRAIN. R. M. Lewis and R. Perez. Dept. of NACS, Univ. Pittsburgh, Pittsburgh, PA 15261.

DARPP-32 (dopamine- and adenosine 3',5'-mono-phosphate-regulated phosphoprotein of $M_r=32,000$) is a cytosolic phosphoprotein phosphatase inhibitor which is phosphorylated by cAMP-dependent protein kinase in response to dopamine. DARPP-32 is enriched in regions of the brain which have D1 dopamine receptors. Previous studies indicate that neither expression of DARPP-32 mRNA during development of the brain, nor maintenance of DARPP-32 mRNA levels in the adult appears to require dopamine. We tested the possibility that excess dopamine could down-regulate the expression of DARPP-32 mRNA. Mice were injected daily with 100 or 200 mg/ml L-DOPA (i.p., 30' after 50 mg/ml Ro 4-4602, i.p.) for one to five days, and sacrificed six hours after the last injection. Levels of DARPP-32 mRNA were assessed by *in situ* hybridization in sagittal sections of brain. No changes in DARPP-32 mRNA levels were detected in any region of the brain compared to saline-injected animals. This evidence supports the conclusion that DARPP-32 gene expression is independent of dopamine input.

QUINPIROLE-INDUCED ALTERATIONS IN K⁺-EVOKED DOPAMINE RELEASE IN THE NEOSTRIATUM OF DEVELOPING AND ADULT RATS. S.L. Andersen and R.A. Gazzara. Center for Developmental Psychobiology and Department of Psychology, SUNY-Binghamton, Binghamton, NY 13902-6000.

The effect of local administration of the D-2 agonist quinpirole, via the microdialysis probe, on K⁺-evoked dopamine (DA) release in the neostriatum was assessed in urethane-anesthetized pups aged 5, 10-11, 15-16, and 21-22 days, and adult rats. Samples were collected every 15 min and extracellular levels of DA, DOPAC, HVA, and 5-HIAA were measured with HPLC-ED.

A dose-response curve (0.1, 1, 10, and 100 μ M) of (-)-quinpirole was conducted within animals to study the development of release-modulating D-2 autoreceptors. Quinpirole did not produce significant decreases of K⁺-evoked DA release at all ages at all doses. Additionally, a developmental trend was found in that the adult group showed the largest decrease in K⁺-evoked DA release at the highest dose of quinpirole (100 μ M). The effect of quinpirole was blocked by the D-2 antagonist (-)-sulpiride. These data suggest that the DA D-2 autoreceptors are functional in the neostriatum by 5 days of age, but are not completely mature in their ability to regulate K⁺-evoked DA release. FREE RADICALS, MONOAMINE OXIDASE AND PARKINSON'S DISEASE. F.F. Oldfield, D.L. Cowan* and A.Y. Sun. Departments of Pharmacology and Physics*, University of Missouri, Columbia, MO 65212.

An electron spin resonance (ESR) spin trapping technique has been used to detect free radical formation during the enzymatic reaction of dopamine (DA) with either purified monoamine oxidase (MAO) or brain mitochondrial preparations. The ESR spectra were those of the hydroxyl adduct of the spin trap 5,5-dimethyl-1-pyrroline N-oxide (DMPO). When ethanol is added, hydroxyethyl adducts are observed, confirming the presence of hydroxyl free radical (\cdot OH). Quantitative analysis indicates that the number of hydroxyl radicals released to the solution is comparable with the number of dopamines oxidized. Hydroxyl adduct formation is eliminated by denaturing the MAO and decreased by addition of the MAO inhibitors Clorgyline, Pargyline and Deprenyl. Results with added Fe²⁺ and with the Fe chelators, Diethylenetriaminepentaacetic acid (DETAPAC) or Desferroxamine, implicate redox-cycled trace Fe in the \cdot OH radical production. Addition of superoxide dismutase strongly inhibits radical formation. The free radical formation by DA was substantially greater than that produced in an incubation medium containing an equivalent amount of the other neurotransmitters, serotonin or norepinephrine. These results support the hypothesis that oxidative stress associated with DA metabolism plays a role in the tissue injury and cell dysfunction seen in the Parkinsonian brain. (Supported by AA7585).

USE OF ³H-GBR12935 TO MEASURE DOPAMINERGIC NERVE TERMINAL GROWTH INTO THE DEVELOPING RAT STRIATUM. W.Le*, J.R.Bostwick, G.Crawford, and S.H.Appel. Dept. Neurology, Baylor Col. Med., Houston, TX. 77030

Various biochemical markers have been used to index dopaminergic innervation of the striatum during development. Earlier studies have shown that increases in tyrosine hydroxylase (TH) activity, high affinity dopamine (DA) uptake and DA content in the striatum are associated with nerve terminal formation. GBR12935, a potent and selective inhibitor of DA uptake, binds with high affinity to the presynaptic DA transporter. In this study we determined the temporal association between the appearance of the DA transporter, measured by ³H-GBR12935 binding, and other biochemical markers of DA nerve terminal growth into the developing striatum.

The B_{max} and K_d of ³H-GBR12935 specific binding in adult rat striatal tissue were 3.6 pmoles/mg protein and 2.8 nM, respectively. ³H-GBR12935 binding was minimally detected in the rudimentary striatum of ED14 rat brains, increased to 23% of the adult level by birth, and reached the adult level during the fifth postnatal week. This finding contrasts with a slower developmental increase in ³H-DA uptake, a functional measure of the transporter. TH activity levels followed a developmental curve similar to that of ³H-GBR12935 binding but did not reach adult levels until the seventh postnatal week. DA content increased at a slower rate, being only 10% and 92% of the adult level at birth and postnatal week eight, respectively. These results indicate that the appearance of a structural, but not optimally functional, DA transporter may be the earliest biochemical index of dopaminergic nerve terminal growth into the striatum during development.

153.10

CHARACTERIZATION OF NEOSTRIATAL DOPAMINE RELEASE AS MEASURED BY MICRODIALYSIS IN DEVELOPING AND ADULT RATS. R.A. Gazzara and S.L. Andersen. Center for Developmental Psychobiology and Dept. of Psychology, SUNY-Binghamton, Binghamton, NY 13902-6000.

We have used microdialysis to measure the extracellular levels of dopamine (DA) in the neostriatum of adult rats and 5-day-old pups. This study determined the neurogenic origin of the DA measured as defined by its calcium (CA) dependency and tetrodotoxin (TTX) sensitivity.

In urethane-anesthetized 5-day-old rat pups and adult rats, baseline levels of DA were measured during perfusion with a CA-containing dialysis solution. When the solution was switched to a CA-free solution, DA dropped to nondetectable levels in the rat pups, and to less than 20% of baseline levels in the adult rats. In a separate group of animals, when 1 μ M TTX was added to the dialysate, DA dropped to nondetectable levels in both groups. The CA dependency of high K⁺-evoked DA release was also determined in rat pups and adult rats. Baseline K⁺-evoked DA levels were measured during perfusion with CA-containing dialysis solution. When the solution was switched to a CA-free solution, the K⁺-evoked DA levels dropped to nondetectable levels in rat pups, and to less than 25% of baseline K⁺-evoked DA levels in adult rats.

These results suggest that the extracellular DA measured in 5-day-old rat pups is derived from neurogenic release as determined by its CA dependency and TTX sensitivity.

POSTNATAL CHANGES IN THE DISTRIBUTION OF ACETYLCHOLINESTERASE IN THE RABBIT VISUAL CORTEX. B. Ju* and E.H. Murphy, Department of Anatomy and Neurobiology, Medical College of Pennsylvania, Philadelphia, PA 19129. The rabbit visual cortex contains an extensive network of acetylcholinesterase (AChE)-positive fibers. Since there is evidence that cholinergic innervation influences cortical development and plasticity, we have studied the postnatal development of AChE in the visual cortex of the rabbit. Eye opening in the rabbit occurs on day 11 and their cortex is mature by day 50. We studied animals aged 1-48 days using a modification of Koelle's histochemical method. Labeled axons are present in all layers of area 17. In layer I, there is little change in AChE-positive fiber density during the first two postnatal weeks. Between days 15 and 20, AChE-positive fiber density increases rapidly, followed by a more gradual increase to adult levels over the next several weeks. In contrast, AChE positive fibers in layers II and III show their greatest increase in staining density between days 10 and 15. In layers IV-VI, levels of AChE positive fibers increase steadily throughout development. Beginning at day 12, AChE positive cell bodies are present in layers V and VI. We have shown that the time course of the increase in AChE staining intensity varies for different laminae of area 17. In addition, our results show that the dramatic increase in AChE staining intensity in layers II and III is correlated with eye opening.

NMDA RECEPTORS AND L-TYPE CALCIUM CHANNEL BINDING SITES RE-ORGANIZE DURING THE CRITICAL PERIOD FOR KITTEN VISUAL CORTEX PLASTICITY. M. Cynader, Y.L. Liu, W.G. Jia, V. Booth* and W. Jacobson†, Dept Ophthalmology, University of British Columbia, Vancouver, and †Div Reproductive Science, Toronto General Hospital, Toronto, Ontario, Canada.

Calcium entry into neurons plays an important role in many intracellular processes, including those associated with growth and activity-dependent plasticity. We compared the development of two calcium entry systems in the developing kitten visual cortex by using [¹²⁵I]MK-801 to label NMDA receptors, and [³H]PN-200 to label L-type calcium channels.

Both binding sites showed a changing laminar distribution during the peak period for visual cortex plasticity. In young kittens (0-10 days of age) both ligands showed concentrations in cortical layers IV and V. In older kittens (20 and 30 days of age), NMDA receptors were concentrated in the middle cortical layers (around Layer IV). By 40 days of age, their peak concentration was in the superficial layers (Layers I-III), and this distribution was maintained into adulthood. The PN-200 binding sites attained a final distribution similar to that of the NMDA binding sites, *i.e.*, concentrated in the superficial layers of the cortex, but they achieved this earlier in postnatal life than did the NMDA sites.

These results suggest that subtle differences in the spatial and temporal developmental pattern of these calcium entry systems play a role in critical period plasticity.

154.5

ULTRASTRUCTURAL LOCALIZATION OF ZINC IN THE DEVELOPING CAT VISUAL CORTEX; C. Beaulieu, R. Dyck, and M. Cynader, University of British Columbia, Dept. Ophthalmology, Vancouver, B.C. Canada.

Light microscopic studies have demonstrated that the distribution of the chelatable pool of zinc in the cerebral cortex and hippocampus appears to be developmentally regulated. In order to analyse the ultrastructural distribution of this pool of zinc, visual cortex of cats at postnatal days 0-1 (n=3), 15 (n=1), 52 (n=1), and adult (>6 months; n=3) were analysed. Zinc was revealed by using the selenide method developed by Danscher.

Zinc was found to be localized mostly in a population of terminals containing round vesicles and making asymmetrical synapses. In these structures, the reaction product was concentrated mostly over the synaptic vesicles. Some multivesicular bodies present in the cell cytoplasm were also found to contain zinc. This staining pattern is similar among the different ages studied. The staining intensity however varies among the different ages. The concentration of the silver grains over positive terminals is higher in adult animals than in young ones. This could be due to the greater number of synaptic vesicles present in terminals of adult cortex.

Since endogenous zinc has been shown to affect neuronal activity by modulating GABAergic and glutamatergic neurotransmission, we also analyzed the GABA- and glutamate-content of Zinc-positive terminals in adult cortex, by using a post-embedding immunogold technique. We found that no Zinc positive terminals evaluated to date were immunopositive for GABA. The glutamate content of the zinc-positive terminals is presently under investigation.

154.2

PRE-AND POSTNATAL DEVELOPMENT OF GLUTAMATE EXCITATORY AMINO ACID RECEPTORS IN MONKEY STRIATE CORTEX. #C. Shaw, +A. Hendrickson and **A. Erickson, #Depts. of Ophthalmology and Physiology U. British Columbia, Vancouver Canada V6T1Z3, Canada, and +Depts. of Biological Structure and Ophthalmology, U. Washington, Seattle 98195.

Using conventional in vitro autoradiographic methods, we have used [³H]MK801, [³H] kainate, and [³H] CNQX to examine the distributions of glutamate receptor subtypes NMDA, kainate, and quisqualate respectively from fetal day (F) 72 until adulthood. NMDA receptors were found in the cortical plate at F72, but showed no laminar preference until F152 when a faint band of denser labelling was present in layer 4. By P4-7wk layers 4C and 6 had the densest binding. At P10mo layer 4C was darker than the supragranular layers, a pattern which persisted into adulthood. Kainate receptors were first detected at F72 in a band at the bottom of the cortical plate. At F126 two clear bands of label were observed in deep layer 6 and 4. Around birth, layer 6 was the most heavily labelled, the bottom of layer 4C showed a narrow band of label, and layer 4C was lighter than the supragranular layers. At P4-7wk, the narrow band in layer 4C was gone. Layer 6 was still the most heavily labelled and some label was present in layer 5. After P13mo into adulthood layers 6 and 5 alone were heavily labelled. Quisqualate receptors were first detected at F126 and were most dense in layer 6. By F24 most of the cortex was labelled with the exception of layer 4C. A thin narrow band of label centered on layer 4A appeared just before birth and persisted into adulthood. By P7wk layers 4C and 4B were quite light. From P20wk to adulthood layers 5 and 6 were densely labelled, layers 4C/4B were light and layers 1-3 were moderately labelled.

These results reveal differences in the age of first appearance for the various glutamate receptor subtypes and complex changes in their laminar distribution during development. The lack of a general overlap of receptor populations in the thalamic input layer 4 raises questions about the possible role of glutamate receptors in mediating geniculo-striate developmental interactions. The role of visual experience in shaping the characteristics of these receptors is under investigation. (EY01208; MRC PG-29; B.C. Medical Services Fnd. Grant)

LOCALIZATION OF NERVE GROWTH FACTOR BINDING SITES IN DEVELOPING KITTEN VISUAL CORTEX. J. Cokgor, B.H. Dyck, M.S. Cynader, Department of Ophthalmology, University of British Columbia, Vancouver, B. C. Canada, V5Z 3N9

Nerve Growth Factor (NGF), is a target-derived neurotrophic protein that promotes the survival and growth of several specific populations of neurons. Extensive work now suggests that NGF, besides its actions on peripheral neurons, also plays a critical role in brain function and development. We studied NGF binding sites in developing cat visual cortex using the method of receptor autoradiography. Tissue sections from cats ranging in age from birth to adulthood were incubated for two hours in 100 pM [¹²⁵I] NGF (NEN Products). After incubation, the sections were washed for three minutes in three changes of Hepes buffer (20 mM) before they were exposed to X-ray film.

We found NGF binding sites to display strong concentrations in visual cortex only for the youngest kittens studied (0,10 days postnatal). These binding sites were concentrated in the most superficial cortical layers, where neurons are the least mature. In older kittens, no evidence for layer-specific concentrations of NGF binding sites was found in the visual cortex, although binding was found in nonvisual structures such as medial septum, and hippocampus. These results show that NGF may function as an endogenous neurotrophic factor in the developing cat visual cortex and is expressed only at younger ages.

154.6

Postnatal development and laminar distribution of noradrenergic (NA) fibers in cat visual cortex
Y.L. Liu and M. Cynader

Department of Ophthalmology, University of British Columbia, Vancouver, B.C. Canada. V5Z 3N9.

In our previous studies, we have demonstrated that adrenergic receptors ($\alpha 1$, $\alpha 2$, $\beta 1$ and $\beta 2$) showed significant changes either in laminar distribution or in number during the postnatal development of kitten visual cortex. In order to further investigate the postnatal development of this neurotransmitter system in kitten visual cortex, especially in relation to the critical period, we used a polyclonal antibody against dopamine- β -hydroxylase (DBH) to localize noradrenaline (NA)-containing afferents in visual cortex of kittens of various ages from birth to adulthood. In young kittens, less than two weeks of ages, NA fibers were sparse, short and randomly oriented, and were concentrated in layer I and in deep cortical layers V and VI. By postnatal day 40, the density of NA fibers was much higher than that of younger kittens. NA fibers were present throughout all cortical layers and exhibited higher densities in layers I, II, III, V and VI, with a band of lower staining in the layer IV. While tangential fibers predominated in layers I, V and VI, relatively straight radial fibers traversed layers II and III. After postnatal day 40, we did not find major changes either in the density or in the laminar distribution of NA fibers. This developmental laminar distribution pattern of NA fibers resembles that of the β -adrenergic receptors that we and others have studied in kitten visual cortex.

154.7

NEUROGRANIN: DEVELOPMENTAL EXPRESSION OF A GAP-43 RELATED PKC SUBSTRATE IN CAT VISUAL CORTEX; Y.H. Yucef#, J. Baudier* and M.S. Cynader#. #Dept. Ophthalmology UBC Vancouver, CANADA, * Lab. de Biologie Moléculaire du Cycle Cellulaire, Grenoble, FRANCE.

The developmental expression of neurogranin (NG), a brain specific protein kinase C (PKC) substrate, was investigated in cat visual cortex with immunocytochemical techniques using a specific anti-neurogranin polyclonal antibody. NG and GAP-43, bind calmodulin in the absence of calcium and share a 17 amino acid sequence that correspond to the PKC phosphorylation site and to the calmodulin binding domain. Immunoreactivity was localized mainly in cell bodies and occasionally in dendrites which contrast with axonal localization of GAP-43. In adult visual cortex, NG immunoreactivity was distributed in a trilaminar pattern: Layers I and layer II, layer IVa and Layer VI. Layers I and II showed the highest number of cells labelled and intensity of NG immunoreactivity. Layers IVa and layer VI also demonstrated marked immunoreactivity relative to the other layers. Pyramidal cells were the main cells identified by NG in the superficial layers, in contrast to the stellate cells identified in the deeper layers. In kitten visual cortex, at day P0, P10, in contrast to the adult pattern, immunoreactivity was bilaminar and higher in the deep layers, primarily in the pyramidal cell bodies and apical processes. At P90 and P120, the distribution of NG reactive cells was similar to that seen in the adult visual cortex. NG immunoreactivity in the developing cat visual cortex seems to show an "inside first and outside last" spatiotemporal distribution, paralleling the known developmental process in this structure. Its developmental expression and resemblance to GAP-43 suggest a role for this substrate of PKC protein in visual cortex development.

154.9

C-FOS EXPRESSION IN VISUAL CORTICAL AREAS OF DARK-REARED KITTENS FOLLOWING EXPOSURE TO LIGHT. C. Beaver*, D.E. Mitchell and H. Robertson. Departments of Psychology and Pharmacology, Dalhousie University, Halifax N.S. Canada B3H 4J1.

We have examined the possibility that expression of an immediate early gene (c-fos) may mediate or otherwise be linked to the substantial and rapid changes that occur in the mammalian central visual pathways in response to visual stimulation in early postnatal life. Thirteen kittens were placed with mothers in a darkroom within two days of birth. At 30 days of age, nine of them were introduced to an illuminated environment for either 1, 2 or 6 hrs at which time they were immediately sacrificed and perfused. The remaining 4 kittens were sacrificed at the same age in the darkroom after receiving equivalent motor stimulation as their littermates that received exposure to light. Immunocytochemical methods were employed to examine expression of c-fos in the midbrain, thalamus and various visual cortical areas. The animals deprived of any visual input showed no evidence of c-fos expression in any visual structure. However, those kittens exposed to light for 1 hr or more exhibited dense labelling in cortical areas 17, 18 and 19 as well as other cortical visual areas. Sparser label was also evident in the superficial and deep layers of area 19 and the suprasylvian visual areas as well as the ventral (but not dorsal) LGN. In animals exposed to light for 1 hr, labelled cells in areas 17 and 18 were distributed approximately uniformly across all layers. Following 2 hrs of visual exposure the labelled cells were concentrated more in superficial (II, III) and deep (VI) layers. This laminar distribution of labelled cells was even more apparent after 6 hrs of visual exposure and the overall number of cells was also very reduced.

154.11

SPECIFIC ELEVATION OF EXPRESSION OF THE mRNA FOR THE BETA ISOFORM OF PROTEIN KINASE C IN KITTEN VISUAL CORTEX DURING THE CRITICAL PERIOD. R.L. Neve and M.F. Bear. Dept. of Psychobiology, U. of Calif., Irvine, CA 92717; Center for Neural Science, Brown University, Providence, RI 02912.

The kitten striate cortex displays considerable synaptic plasticity during a critical period of postnatal development. We are exploring the possibility that cortex is rendered modifiable during this time by specific patterns of gene expression.

RNA isolated from visual cortex (A17), cortical area 6 (A6), and cerebellum of kittens at various postnatal ages was examined with Northern blots and quantitative slot blots to determine the developmental course of expression of genes encoding the protein kinase C (PKC) isoforms. Of particular interest is the developmental pattern of PKC beta, which is expressed at high levels in A17 (greater than 300% of postnatal day 84 [P84] value) during the critical period. The developmental profile of PKC beta expression in A6 is similar to that in A17 with the exception that it is maintained at a high level in A6 even at 12 weeks of age. The expression of PKC alpha rose slightly between P10 and P60, and dropped in both A17 and A6 by P84. PKC gamma and epsilon mRNAs varied among time points without displaying a developmental trend in both A17 and cerebellum. In situ RNA hybridization studies to define the laminar and cellular specificity of expression of PKC isoform mRNAs in the visual cortex are in progress.

154.8

DEVELOPMENTAL EXPRESSION OF THREE TRANSCRIPTION FACTORS IN KITTEN VISUAL CORTEX

C.M. Tidd, R. Bravo*† and M.S. Cynader. Dept. of Ophthalmology, University of British Columbia, 2550 Willow St., Vancouver, British Columbia, Canada, and †Bristol-Myers Squibb Company, P.O. Box 4000 Princeton, NJ

The developmental expression of three putative transcription factors, c-fos, jun-b and NGFI-A, was examined using immunocytochemistry. This was done in an attempt to identify genes that are important for the establishment of the critical period of plasticity in the development of kitten visual cortex. We found only low levels of neuronal expression of these molecules on the day of birth. The 10 day old kitten shows c-Fos staining in layer VI and JunB staining in all layers. Also, NGFI-A appears in layers II, III, and VI of area 17 and layer VI of area 18. At 20 days of age, c-Fos and JunB show staining in layers IV and VI of area 17 and lower levels of staining in layer VI of area 18. In contrast, NGFI-A appears in layers II, III, IV, and VI of area 17 and layers III and deep IV of area 18. Adult patterns of expression are established by 50 days of age. At this time, c-Fos and JunB show prominent staining bands in layers II, III and VI. NGFI-A-positive cells appear in layers II, III, very deep IV and VI. The identical nature of the c-Fos and JunB staining, with the exception of the day 10 animal, is consistent with their formation of heterodimers in order to bind to DNA. Staining of pyramidal and non-pyramidal cells is seen with all three transcription factors, and the localization of these proteins is restricted to the nuclei of expressing cells. The variation in expression of these molecules during the critical period suggests that they may be fundamentally involved in this phenomenon.

154.10

LIGHT EXPOSURE INDUCES A DEVELOPMENTALLY SPECIFIC GENOMIC RESPONSE IN RODENT VISUAL CORTEX. P.F. Worley, R.V. Bhat and J.M. Baraban. Depts. of Neurology and Neuroscience, Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205.

Recent studies indicate that synaptic activity induces a rapid genomic response in adult neurons that may be involved in neuroplasticity. Activity plays a major role in postnatal development yet relatively little is known about genomic responses to activity in developing brain. To examine and compare activity-dependent genomic responses to physiological stimuli in developing and adult cortex we are using a rodent model of visual deprivation. The model is based on classical studies indicating that development of the visual cortex is delayed (or altered) in animals raised in the dark and that subsequent visual experience can reinstate the activity-dependent developmental processes. Rodents are used because of the potential utility of this model for future molecular biological studies. Rat pups raised in complete darkness to 3-5 weeks are placed in normally illuminated cages for defined intervals prior to sacrifice. Levels of mRNA and immunostaining for c-fos, zif268, and jun-B are rapidly increased in neurons of the visual cortex of these animals following light exposure. This response involves a broader array of transcription factors and is much more robust than the response to light in dark-adapted adult animals. Aspects of the developmental time course, anatomic specificity and pharmacology of the response will be presented.

154.12

LAMINAR DISTRIBUTION OF EXCITATORY AMINO ACID- AND CARBACHOL-STIMULATED PI TURNOVER IN THE KITTEN STRIATE CORTEX. S.M. Dudek, M. Catalozzi* and M.F. Bear. Center for Neural Science, Brown University, Providence, RI 02906.

Work in our laboratory has focused on the possible role of excitatory amino acid (EAA) receptor mechanisms in ocular dominance plasticity in the kitten visual cortex. We have found that the developmental expression of the metabotropic EAA receptor, in particular, correlates closely with the critical period for this type of synaptic plasticity. However, lack of selective, high-affinity ligands for this receptor or insoluble products of receptor-stimulated PI hydrolysis have thus far hindered anatomical studies localizing EAA-stimulated PI turnover. Recently, Hwang, et al (*Science* 249: 802) described a method to visualize the sites of PI turnover utilizing tritiated cytidine. ³H-labeled cytidine diphosphate diacylglycerol is thought to accumulate in the tissue proportionately to levels of PI turnover. We used a variation of this technique to investigate the laminar distribution of EAA- and carbachol-stimulated PI turnover in the kitten visual cortex.

Trans-ACPD, an agonist of the metabotropic receptor, stimulated the accumulation of ³H in kitten Area 17 (P35-50). All layers showed activity above background, but layer IV was the most densely labeled. In contrast, the muscarinic acetylcholine agonist carbachol stimulated labeling in superficial layers, layer V, and lower layer VI. Work is in progress to examine whether these laminar patterns change during development and to test the hypothesis that metabotropic EAA receptors are located on the geniculocortical axon terminals. Supported by NIH grant EY06929.

IDENTIFICATION OF PROTEINS DOWN-REGULATED DURING POSTNATAL DEVELOPMENT OF THE CAT VISUAL CORTEX. P. Kind, C. Blakemore and S. Hockfield. Sect. Neurobiology, Yale Univ. Sch. Med., New Haven, CT 06510

The visual system of the cat has been used extensively as a model system for studying developmental plasticity in the mammalian nervous system. While numerous techniques exist for studying physiological and anatomical changes through development, few exist which permit the study of biochemical changes that underlie these functional changes. The present study was designed to identify proteins that may play a role in the development of the mammalian visual system and govern the parameters and termination of developmental plasticity.

An immunosuppression strategy (Hockfield, 1987) was used to generate monoclonal antibodies to antigens present in the 5 wk. kitten visual cortex (VC) but which are reduced or absent in the adult cat VC. Six neonatal mice were tolerized to homogenized adult cat VC (areas 17 and 18); three mice received a high dose (HD: 9 mg/injection) and three received a lower dose (LD: 4.5 mg/injection). Two weeks after the tolerizing injections, the mice were immunized with 5 wk. kitten VC (50 ug/injection) in the rear foot pads. Hybridomas derived from lymphocytes from the popliteal and inguinal lymph nodes were screened for antibody production immunocytochemically on 5 wk. VC; positive clones were subsequently tested on both 5 wk. and 15 wk. VC for differential staining patterns.

A total of 18 antibodies showed either a change in cortical distribution or a decrease in the amount of staining between the 5 wk. and 15 wk. VC (12 from the HD mice and 6 from the LD mice). Of the 18 clones, 11 were frozen after the first or second subcloning and 7 were further subcloned and their distribution, biochemistry and developmental expression partially characterized.

These results demonstrate that the biochemical make-up of the kitten VC is distinct from that of the adult, suggesting that molecular changes underlie developmental plasticity and its termination. They also show that neonatal tolerization can be an effective method of producing antibodies to a select group of antigens which are not shared between two tissues. CALBINDIN-D IS TRANSIENTLY EXPRESSED IN PYRAMIDAL CELLS OF NEONATAL KITTENS IN AN AREA DEPENDENT PATTERN. D. Hogan and N.E.J. Berman. Dept. of Anatomy and Cell Biology, Univ. of Kansas Medical Center, Kansas City, KS, 66103.

Calbindin-D (CalD) is a 28 kD calcium binding protein that has been shown to colocalize with GABA-ergic interneurons in mammalian neocortex. We have examined the ontogeny of CalD in neonatal kitten cortex from the day of birth (P0) through maturation of the brain (P101). Transient staining of immature layer V pyramidal cells was seen in kittens younger than three weeks. This is unusual since pyramidal cells are never labeled neonatally with other markers of GABA-ergic neurons such as parvalbumin, neuropeptide-Y or the related PYY, cholecystokinin, somatostatin 28, or its derivatives SOM 14, or SOM 28(1-14). This transient staining of pyramidal cells was most intense and the stained neurons were densest in cingulate cortex. Apical dendrites of pyramids in cingulate cortex were prominently stained and could be followed to layer I, where they were seen to branch extensively. CalD stained pyramidal neurons were nearly continuous throughout layer V in coronal sections though rostral brain at approximate AP levels A18-A20. In caudal sections, levels A4-A8, staining was most notable in its absence from area 17 of primary visual cortex. This lack of staining in visual cortex appeared to be selective, since this pattern was opposite to the rostrolateral to caudomedial progression of cortical maturation. Transient staining disappeared first from caudal and lateral areas, though it was lost first in the sulci and persisted longer in the gyri. Pyramidal neurons in the cingulate gyrus expressed CalD longest, but CalD expression by pyramidal neurons ceased by the third postnatal week in all areas of the brain. Supported by MH38399, BNS881997 and RCD8954894.

DEVELOPMENT OF CALBINDIN-D AND PARVALBUMIN IMMUNOREACTIVITY IN INTERNEURONS OF KITTEN VISUAL CORTEX. N.E.J. Berman and D. Hogan. Dept. of Anatomy and Cell Biology, Univ. of Kansas Medical Center, Kansas City, KS, 66103.

Calbindin-D (CalD) and parvalbumin (PV) are calcium binding proteins that have been shown to be markers of non-overlapping subpopulations of GABA-ergic interneurons in mammalian neocortex. We have examined the ontogeny of CalD and PV immunoreactive interneurons in five areas of kitten visual cortex from the day of birth (P0) through P101. During the first 3 postnatal weeks, PV-ir interneurons were dense in the more mature layers of cortex, but were not observed in the overlying cortical plate. At three weeks of age, when cortical lamination is mature, stained cells were found in all cortical layers except layer I. The density of PV-ir neurons within the mature layers did not change significantly with age. At all ages examined, area 17 contained twice the density of PV-ir neurons as did the most lateral visual areas. In addition, after 3 weeks of age, layers II/III of the cortex had a 30-50% higher density of PV-ir neurons than layers IV, V and VI in all five areas examined. By contrast, very few CalD-ir interneurons were seen during the first two weeks of life, when it is expressed transiently by pyramidal cells (see Hogan and Berman, '91). Those few observed were scattered in all layers of cortex, cortical plate, and white matter. The first increase in density of CalD-ir cells occurred in layer II of cortex around P14. In the mature cortex, the greatest density of CalD-ir cells remained in layer II, similar to the pattern of mature PV staining. In contrast to PV, interneurons in lateral areas express Cal-D sooner, but there was no difference in the distribution of CalD-ir neurons among visual areas at maturity.

AGE-RELATED Mg^{2+} EFFECTS ON PAIRED-PULSE FACILITATION AND LONG-TERM POTENTIATION IN CA1 HIPPOCAMPAL FIELD POTENTIALS. D.L. Deupree and D.A. Turner. Neurosurgery and Neurobiology, Duke Univ. Med. Ctr. and Durham VAMC, Durham, N.C. 27710.

The sensitivity of synaptic plasticity to bath Mg^{2+} was investigated in hippocampal slices from young (2 months) and old (24 months) male F344 rats. The concentration of Mg^{2+} in the ACSF was altered to study presynaptic and circuitry influences of Mg^{2+} , as well as the effects upon NMDA receptor involvement, in brief and long-lasting forms of synaptic enhancement.

Hippocampal slices ($n = 5$ for each trial) were prepared and extracellular population spike field potentials (50% maximal amplitude) were recorded from the CA1 region. The experiments included paired-pulse facilitation and long-term potentiation (LTP: 10 pulses, 50 μ sec each, at 100 Hz).

When bathed in 4.0 mM Mg^{2+} slices from young rats showed increased paired-pulse facilitation at 50 msec (compared to slices in either 1.0 or 2.4 mM Mg^{2+} : 4.0 mM $294 \pm 30\%$ baseline, 2.4 mM $200 \pm 12\%$; $p < 0.05$). Slices from aged rats showed no changes with manipulation of Mg^{2+} during paired-pulse experiments. Slices from both age groups showed equal decreases in LTP with increasing Mg^{2+} concentrations. However, at any given Mg^{2+} level, the degree of LTP in slices from aged rats was less than that in slices from young rats (in 2.4 mM Mg^{2+} : aged $128 \pm 13\%$, young $166 \pm 6.7\%$; $p < 0.05$).

The paired-pulse results suggest either circuitry changes or a deficit in Ca^{2+} handling in aged rats. The LTP results may indicate an age-related decrease in either NMDA receptor function or linkage to Ca^{2+} dependent biochemical processes underlying LTP. Overall, these experiments suggest that brain aging is associated with altered synaptic plasticity, which may underlie age-related memory deficits. Supported by the VAMC Research Service and ADRDA.

155.2

ALTERED ELECTROPHYSIOLOGICAL RESPONSIVENESS OF CAUDATE NEURONS IN AGED CATS TO EXCITATORY AMINO ACIDS RECEPTOR AGONISTS AND DOPAMINE. M.S. Levine, C. Cepeda, Z. Radisavljevic, M. Bertolucci. MRRRC, UCLA Los Angeles, CA 90024.

We have demonstrated decreased excitation in neostriatal neurons in cats and rats. Extracellular recordings in cat caudate (Cd) suggested that changes in excitation may be mediated by glutamate (GLU) receptors. The present study assessed the responsiveness of aged Cd neurons in slices (400 μ m) to application of excitatory amino acids (EAAs) and dopamine (DA). Results have been obtained from 5 aged (10-16 yrs) and 3 adult (3 yrs) cats. Average resting membrane potentials (74 ± 6.5 (S.D.) mV ($N=25$) aged vs 71 ± 6.5 mV ($N=12$) young), action potential amplitudes (68 ± 6.5 mV ($N=25$) aged vs 67 ± 5.3 mV ($N=12$) young) and input resistances (20.2 ± 4.3 M Ω ($N=25$) aged vs 18.9 ± 6.0 M Ω ($N=12$) young) were similar. In young Cd, GLU ($N=8$) or N-methyl-D-aspartate (NMDA) ($N=11$) produced a rapid depolarization accompanied by a train of action potentials. A population of aged Cd cells had higher thresholds for these responses (10/19 cells, current ≥ 290 nA). In aged Cd GLU evoked depolarizations without spikes (3/19) and both GLU (4/19) and NMDA (9/24) induced depolarizations with prepotentials, responses never observed in young Cd. DA modulated responses to GLU and NMDA. Aged cells had a higher threshold current (196 ± 95 nA ($N=16$) vs 113 ± 35 nA ($N=8$)). DA's ability to modulate synaptically responses was also decreased. In young Cd, DA decreased the amplitude of responses at low bath concentrations. In aged Cd, DA decreased amplitudes in 2/5 tests but at high concentrations (100 μ M). These findings indicate that in aged cats decreased excitation may be mediated by alterations in EAA receptors and the ability of DA to modulate responses is impaired. Supported by USPHS AG7462.

155.3

MK801 BINDING SITES DO NOT CHANGE SIGNIFICANTLY WITH AGE IN MOST CORTICAL REGIONS, IN CONTRAST TO NMDA BINDING SITES K.R. Magnusson and C.W. Cotman¹. Dept. of Anatomy & Neurobiology, Colorado State University, Fort Collins, CO 50623; ¹Dept. of Psychobiology, University of California-Irvine, Irvine, CA 92717.

We have previously reported that binding to N-Methyl-D-aspartate (NMDA) sites in the brains of BALB/c and C57Bl mice is decreased with increasing age (Soc. Neurosci. Abstr. 16:19.10). The present study was performed to determine whether other components of the NMDA receptor complex, specifically the channel protein, also exhibit similar declines during the aging process. Quantitative autoradiography was performed on horizontal sections which were incubated with either 10nM ³H-MK801 in the presence of 10μM each of glutamate and glycine (for the channel protein) or 100nM ³H-L-glutamate and 100μM each of kainate, AMPA and SITS (for NMDA sites). Significant differences between age groups (3, 10, and 30 months) and strains (BALB/c and C57Bl) for each brain region analyzed were determined by ANOVA of fmol/mg protein values. In both strains of mice, MK801 binding was only significantly decreased in old (30 months) mice, as compared with the 3 month old mice, in a few cortical subregions of frontal and parietal cortex. This is in contrast to binding to NMDA sites which was decreased in almost all cortical subregions analyzed in old C57Bl and BALB/c mice, as compared with 3 month old mice. These results suggest that either different components of the NMDA receptor complex are differentially regulated or that NMDA receptors are not lost with increasing age, but a subpopulation becomes "inactivated". TREATMENT OF HIPPOCAMPAL SLICES FROM AGED RATS WITH AN A₁ ADENOSINE RECEPTOR ANTAGONIST REVEALED AN NMDA RECEPTOR-MEDIATED SYNAPTIC RESPONSE COMPONENT. V.K. Gribkoff and L.A. Bauman. Neuropharmacology, Bristol-Myers Squibb Pharmaceutical Research Institute, 5 Research Parkway, Wallingford, CT 06492.

We have found that evoked population synaptic responses recorded in area CA₁ of hippocampal slices from aged (24+ mo Fischer 344) rats were smaller in amplitude than those potentials comparably recorded from slices obtained from young (2-4 mo Fischer 344) rats. In addition, in some slices from aged rats the response to Schaffer-collateral stimulation, while smaller, was more complex, with multiple peaks generated at high stimulus currents. This response profile was not observed in slices from young rats. Application of the A₁ adenosine receptor antagonist 8-cyclopentyltheophylline (8-CPT; 1 nM-2 μM) produced a significantly greater increase in synaptic responses in slices obtained from aged rats; only a small enhancement was observed in slices from young rats in response to incubation in 8-CPT. In addition, in slices from aged rats only, 8-CPT greatly increased the later components (multiple peaks), producing a hyperexcitable response profile.

In the presence of 8-CPT (1 μM), application of the N-methyl-D-aspartate (NMDA) excitatory amino acid receptor antagonists MK-801 (2-20 μM) or AP5 (20-50 μM) greatly reduced the later components of the population synaptic responses in slices from aged rats. A small reduction was also observed when NMDA receptor antagonists were applied to slices from aged rats incubated in control medium. No effect of NMDA antagonists was observed on responses evoked in slices from young rats under either experimental condition.

AGING INCREASES DIZOCLIPINE-INDUCED LEARNING IMPAIRMENT AND DECREASES HIPPOCAMPAL AND STRIATAL NMDA RECEPTOR CONCENTRATIONS IN RATS D.K. Ingram¹, P. Garofalo¹, E.L. Spangler¹, C. Mantione², J. Odano², and E.D. London². ¹Gerontol. Res. Ctr., NIA, NIH, and ²Addiction Res. Ctr. NIDA, ADAMHA, Baltimore, MD 21224.

Age-related declines in the densities of N-methyl-D-aspartate receptor (NMDA-r) in rat and monkey brain have been reported previously (G. Wenk *et al. Neurobiol Aging* 12:93, 1991). We have expanded these findings to show that aging increases the sensitivity to dizocilpine (MK-801), a non-competitive antagonist of NMDA-r, in a maze test that has produced robust evidence of age-related decline in learning performance (D. Ingram, *Neurobiol Aging*, 9:475, 1988). MK-801 (0.02 or 0.04 mg/kg) or saline was administered s.c. to 3-mo and 24-mo old male F-344 rats 20 min before training (15 trials) in a 14-unit T-maze. This shock-motivated task requires the rat during each trial to locomote through 5 segments each within 10 sec to avoid footshock (0.8 mA). Whereas MK-801 had no effects on maze performance in young rats at these low doses, aged rats were cognitively impaired at both doses as measured by errors committed. These rats were sacrificed about 1 week later, and brain tissue extracted for analysis of NMDA-r using [³H] glutamate as the radioligand in the presence of 20 μM quisqualate. Results revealed an age-related decline in NMDA-r in hippocampus and striatum but not in frontoparietal cortex or basal forebrain. These findings support the observation that aged rats are more sensitive to behavioral effects of antagonism of NMDA-r than are young rats and suggest that deficits in this system might underlie age-related loss in memory processing.

155.4

AGE-RELATED CHANGES IN GLUTAMATERGIC RECEPTOR BINDING IN RHESUS MONKEY BRAIN. M.V. Wagster, L.C. Cork and D.L. Price. Neuropathol. Lab., The Johns Hopkins University School of Medicine, Baltimore, Maryland 21205.

N-methyl-D-aspartate (NMDA) receptor binding was examined in the prefrontal cortex, striatum, thalamus and substantia nigra of 18 rhesus monkeys (*Macaca mulatta*) ranging from 8-34 years of age. *In vitro* receptor autoradiography using [³H] glutamate (GLUT) in the presence of kainate and quisqualate was employed to visualize NMDA sites. In the regions examined, [³H] GLUT (NMDA) binding concentration was highest in superficial layers of neocortex and in paraventricular nucleus of thalamus. Moderate levels were seen in deep neocortical layers, in medial dorsal and lateral dorsal nuclei of thalamus, and in striatum. Low levels were detected in the remainder of the thalamic nuclei and in substantia nigra. The [³H] GLUT (NMDA) binding concentration decreased with age in medial dorsal nucleus of thalamus; a slight decrease in binding with age was noted in prefrontal cortex. Neither striatum nor substantia nigra showed any consistent decrease in NMDA receptor binding with age.

IN VIVO EVALUATION OF HIPPOCAMPAL CHOLINERGIC FUNCTION THROUGH EAA RECEPTORS IN THE AGING BRAIN - EFFECT OF ACETYL-L-CARNITINE

¹L. Angelucci, ¹A. Imperato, M. Castorina*, A. M. Ambrosini*, M.T. Ramaccl. M.G. Scrocco*. Sigma Tau Institute for Research on Senescence, Pomezia, Rome; ¹Institute of Pharmacology II, La Sapienza University Rome, Italy.

Autoradiographic studies have evidenced a rich distribution of excitatory amino acid (EAA) receptors in the hippocampus. The aim of this study was to elucidate the role of quisqualate (QA) and N-methyl-D-aspartate (NMDA) receptors on ACh release in the hippocampus of 5- and 24-month-old Fischer rats. Perfusion with QA 10⁻⁶ M or NMDA 10⁻⁶ M enhanced ACh release in the hippocampus of young but not of old rats. Moreover, (3H) CGS 19755, a selective and competitive NMDA antagonist, showed a slight decrease of NMDA receptors in the hippocampus of old rats. Six-month treatment (100 mg/kg/day in drinking water) with Acetyl-L-Carnitine (ALCAR) significantly increased NMDA binding capacity in the hippocampus of 24-month-old rats, compared with their age-matched controls. These results suggest that ALCAR, besides improving behavior and expressing a neurotrophic activity, may also be used in age-dependent brain disorders in which the glutamatergic system may be involved.

EFFECTS OF AGING ON THE MESOSTRIATAL DOPAMINE SYSTEM: FOCUS ON THE STRIATUM. R. Burwell, I. Whealin, and M. Gallagher. Department of Psychology, University of North Carolina, Chapel Hill, NC 27599.

The effects of age on pre- and post-synaptic markers for the mesostriatal dopamine (DA) system were investigated by quantitative receptor autoradiography in behaviorally characterized aged and young rats. Twenty male Long-Evans rats completed a longitudinal study of reaction-time performance. At the end of the study, the aged rats combined with a cohort of 10 young rats were also tested for spatial learning in the Morris water maze.

Density of DA D1 receptor binding in the substantia nigra (SN) was significantly lower in the aged subjects. This pattern was observed in lateral, mediodorsal, and medial areas of the SN. Analysis of D1 binding in a series of anterior caudate sections revealed no reliable age differences. However, the D1 binding in the SN was significantly correlated with D1 binding in this region of the caudate for aged animals. Age-related differences in striatal patch and matrix compartments in the caudate were also assessed. Mu opiate receptor patches were localized in sections adjacent to those used to localize D1 receptor sites. Analysis revealed a non-significant trend toward higher density of D1 binding in the matrix compartment. Additional autoradiograms will be analyzed for age-related changes in lateral/medial and rostral/caudal gradients throughout the striatum.

Similar analyses for D2 receptor and DA uptake sites in the same brains are currently underway. Interrelationships among these markers as well as behavioral measures will be discussed.

Supported by NSF predoctoral Fellowship to RB, a NIMH RSDA to MG (KO2-MH00406, and grants NIMH MH39180 and NSF BNS 87-19881.

155.9

EFFECTS OF AGING ON MUSCARINIC BINDING IN THE STRIATUM OF BEHAVIORALLY CHARACTERIZED RATS. A. H. Nagahara¹, T. M. Gill, E. A. Liles^{*}, J.A. Willner, and M. Gallagher. Curriculum in Neurobiology¹ and Department of Psychology, University of North Carolina, Chapel Hill, NC 27599.

Age-related changes have been observed in the cholinergic basal forebrain/hippocampus that correlate with spatial learning ability. The present experiment investigated the effects of aging on the cholinergic system within the striatum using *in vitro* autoradiography. Total muscarinic, M1, and M2 binding were examined using [³H]-quinuclidinyl benzilate (QNB) alone and [³H]-QNB in the presence of the M1 receptor antagonist, pirenzepine. In addition, muscarinic binding in the striatal patch and matrix compartments was examined using adjacent brain sections labelled with [³H]-DAGO. Aged animals were separated into impaired and unimpaired subgroups based on spatial learning ability in the Morris water maze task.

Preliminary analyses revealed different topographical gradients for the muscarinic receptor subtypes in the striatum. The density of M1 binding was higher in the dorsal region of striatum than in the ventral region. M1 binding was also higher in lateral areas. In contrast, M2 binding was higher in medial regions of the striatum. The density of M2 binding was significantly lower in the matrix than in the patch compartment, while the density of M1 binding appears was comparable in both compartments. These patterns were similar in young and aged brains. Further analyses are in progress on these and additional autoradiograms to examine the effects of aging and the relationship to behavioral impairments. Supported by MH14277 to AHN, RSDA to MG (KO2-MH00405) and grants MH39180 and BNS 87-19881.

155.11

REORGANIZATION IN THE MOLECULAR LAYER OF THE DENTATE GYRUS IN AGED LEARNING-IMPAIRED RATS. M.M. Nicolle¹, A.H. Nagahara¹, J.A. Willner, & M. Gallagher. Curriculum in Neurobiology¹ and Department of Psychology, University of North Carolina, Chapel Hill, NC 27599

Lesion of the perforant path (PP) input onto dentate granule cells causes sprouting of other inputs into the denervated zone of the molecular layer (outer 2/3rd). One marker used to detect this reorganization is autoradiographic analysis of kainic acid binding which is normally confined to the inner 1/3rd of the molecular layer but expands outward in response to PP denervation. We compared the topography of [³H]-kainic acid binding in the dentate gyrus of young and aged rats that were characterized for spatial learning ability. The aged rats (N=14) included a subgroup that was impaired in the spatial task (N=7) and another subgroup that was unimpaired (N=7).

The peak density of [³H]-kainic acid binding in the molecular layer did not differ between young and aged rats. However, analysis of the topography of kainate binding in the same area (superior blade in the dorsal hippocampus) revealed a significant age-related increase in width of labeling over the molecular layer, an effect that was confined to the impaired aged subgroup. This change in the topography of kainate binding may reflect a reorganization of inputs to the molecular layer in response to decreased innervation from entorhinal cortex in learning-impaired aged rats.

155.13

EFFECTS OF DEPRENYL ON BRAIN NEUROTRANSMITTERS (NT) IN OLD MALE RATS. S. Thyagarajan and S.K. Quadri. Neuroendocrine Research Laboratory, Kansas State University, Manhattan, KS 66506.

Deprenyl, an irreversible monoamine oxidase-B inhibitor, is reported to increase the life span, correct certain age-related behavioral deficits and have beneficial effects in Parkinson's disease patients. Catecholamines (CA) and indoleamines (IA) in the hypothalamus (HT) are known to influence the aging process. However, it is not known how the metabolism of these NT, especially the IA, is affected in the HT of old male rats after long-term treatment with deprenyl. In this study, Sprague-Dawley male rats (18-23 mo.) were injected s.c. with 0.25 mg/kg (low dose; LD) or 2.5 mg/kg (high dose; HD) of deprenyl or the vehicle (saline; control). The animals were treated daily for 24 weeks. The concentrations of NT were determined in the HT, striatum (ST), and the hippocampus (HI) at the end of treatment by HPLC-EC. Serotonin (5-HT) concentration in the HT of the HD rats (62.5±3.4 pg/ug protein) was higher (p<0.0001) than that in the control rats (13.1±1.9 pg/ug protein) and LD rats (19.3±1.7 pg/ug protein). 5-HT concentration in the ST was 13.2±1.7 pg/ug protein in the control rats and 50.9±6.2 pg/ug protein (p<0.03) in the HD rats. Dihydroxyphenylacetic acid (DOPAC) concentration in the HT significantly (p<0.05) decreased in the HD rats. DOPAC concentration in the ST of the HD rats (7.3±3.1 pg/ug protein) was significantly (p<0.01) lower than that in the control rats (66.3±5.3 pg/ug protein) and LD rats (63.0±13.7 pg/ug protein). Dopamine concentration in the ST increased significantly (p<0.007) in the LD rats. Norepinephrine concentration in the HI was significantly (p<0.0001) higher in the HD rats (60.1±5.5 pg/ug protein) than that in the control rats (13.0±2.9 pg/ug protein) and LD rats (19.6±3.3 pg/ug protein). These results suggest that long-term treatment of old male rats with deprenyl significantly alters the synthesis and metabolism of the CA and IA not only in the striatum, but also in the hypothalamus and hippocampus. (Supported by NIH grant AG05980)

155.10

EFFECTS OF AGING ON MUSCARINIC RECEPTOR SUBTYPES IN BEHAVIORALLY CHARACTERIZED RATS. T.M. Gill & M. Gallagher. Department of Psychology, University of North Carolina, Chapel Hill, NC 27599.

The effect of aging on muscarinic binding within the medial septal region (MS), vertical limb of the diagonal band (VDB), hippocampus, laterodorsal tegmental nucleus (LDT), and pedunculo-pontine tegmental nucleus (PPT) was investigated using *in vitro* autoradiography. Tritiated Quinuclidinyl benzilate (QNB) alone and [³H] QNB in the presence of the M1 receptor antagonist, pirenzepine, were used to determine total muscarinic, M1, and M2 binding in young and aged brains. Based on spatial learning ability, the aged rats were separated into impaired and unimpaired subgroups.

A modest but significant decrease in total muscarinic binding was observed in the aged brains within the MS, VDB, dentate gyrus of the hippocampus, and LDT. The pattern of change for muscarinic receptor subtypes depended on brain region. Decreases for both subtypes were evident in the MS, VDB, and LDT, but within the dentate gyrus of the hippocampus there was an increase in M2 and a decrease in M1 binding. In all regions the most pronounced changes were observed in the aged impaired subgroup.

155.12

EFFECT OF AGE ON ³H-NISOXETINE BINDING TO UPTAKE SITES FOR NOREPINEPHRINE (NE) IN THE LOCUS COERULEUS (LC) OF HUMANS. S.M. Tejani-Bull¹ and G.A. Ordway². ¹Dept. Psych., Univ. of Pa Sch. of Med. & Dept. Vet. Affairs Med. Ctr., Phila., PA 19104, ²Dept. Psych., Case West. Res. Univ., Metro Health M.C., Cleveland, OH 44109.

The presynaptic uptake system for NE is receiving considerable attention in the overall assessment of monoamines in neurodegenerative and psychiatric disorders. We have shown recently that ³H-nisoxetine (³H-NIS) is a useful radioligand for mapping of sites associated with NE uptake in rat brain by quantitative autoradiography (Neurosci. Abstr. 16:524, 1990). In the present study, we have used ³H-NIS as a marker for the NE transporter to investigate age-related changes in noradrenergic innervation in the LC of humans. Sections (20µ) were taken from the LC (caudal region) from subjects who died from natural causes ranging in age from 20 to 80 years. Regression analysis of the data demonstrated an inverse correlation between age and the binding of ³H-NIS (r=-0.6; p<0.01) to uptake sites for NE in the LC. When the subjects were divided into two groups (<50 yr and >50 yr), a significant (p<0.01) age-related reduction in the binding of ³H-NIS was seen. A 45% decrease in the density of uptake sites for NE was observed in the group that was >50 yr as compared to the group that was <50 yr of age. Since considerable cell loss (40-60%) has been reported to occur with age in the LC, the lower binding of ³H-NIS most likely reflects loss of LC cells rather than a down-regulation of these sites. (Research funds from the Dept. of Vet. Affairs, NARSAD and USPHS grant MH 45472).

PRESERVATION OF THE DENSITY OF THE DOPAMINE UPTAKE COMPLEX IN AGING RAT BRAIN. Inglefield, J. B. and E. K. Richfield. Depts. of Neurobiology and Anatomy and Neurology, University of Rochester, Monroe Community Hospital, Rochester, NY 14620.

This aging study was performed to determine if there are selective regional or global changes in the density or pharmacology of the dopamine uptake complex (DAUC) of aged rodent. Fifteen regions of the Fischer 344 rat (aged 4, 12 and 24 months) central nervous system were analyzed for the density of the DAUC using [³H]GBR 12935 and *in vitro* quantitative autoradiography. Additionally, cocaine competitions were performed in the striatum of all of the animals. A 26-fold variation in the DAUC density was found in the regions sampled; however no significant age-related changes were identified. Intra-striatal analysis of the DAUC density revealed binding heterogeneities: decreasing lateral to medial and decreasing dorsal to ventral gradients. No significant effect of aging on striatal quadrants was observed. Also, the proportion of high and low affinity sites for cocaine was unchanged in the three age groups. Taken together, these findings suggest a stability of this dopamine neuron pre-synaptic marker in aging rat central nervous system.

THE EFFECTS OF AGING ON DOPAMINE DIFFUSION AND CLEARANCE IN THE STRIATUM OF THE FISCHER 344 RAT.

M.N. Friedemann and G.A. Gerhardt. Departments of Pharmacology and Psychiatry, University of Colorado Health Sciences Center, Denver, CO 80262.

Previous studies have shown that there are age-related changes in dopamine (DA) uptake sites (B_{max}) and rates (V_{max}). In order to further investigate the effects of aging on DA uptake processes, the present study combines *in vivo* chronoamperometric recordings and local drug application techniques which allow direct measurement of DA diffusion and clearance from the extracellular space. Male Fischer 344 rats, 6 and 24 months old were anesthetized with urethane and surgically prepared for *in situ* recording. DA (5-60 pmol) was pressure ejected 240 to 350 μ m away from a Nafion-coated carbon fiber electrode at sites within the dorsal or ventral striatum. No significant differences between the age groups for either the amplitude or the clearance time of the DA ejections were found. There were also no significant differences between dorsal and ventral striatum. In addition, the application of the uptake inhibitor, nomifensine, (20-200 pmol) just prior (30 sec) to the DA application resulted in significant increases in the amplitude and time course in dorsal striatum. However, in ventral striatum, nomifensine significantly increased the amplitude of the DA signal only in the 6 month old rats, while the time courses of the signals were significantly increased in both age groups. The inability of nomifensine to modulate the amplitude of the DA signal in the ventral striatum of aged rats suggests that these nerve terminals may be differentially effected by the aging process. Basal forebrain cholinergic anatomy in behaviorally characterized aged rats. **D.M. Armstrong, R. Sheffield, G. Buzsaki, K. Chen, and F. H. Gage.** Fidia Georgetown Institute for the Neurosciences, Georgetown University, Washington, D.C. 20007.

In the rat, cognitive impairments are often associated with deficiencies in cholinergic neurotransmission. In the present study we employed immunocytochemical techniques in order to quantitatively assay the age-related alterations of basal forebrain cholinergic neurons in three populations of behaviorally characterized female Fisher 344 rats: 6 months ($n = 10$), 27 months ($n = 8$) and 33 months ($n = 8$). As a group the three populations of animals were indistinguishable from each other with respect to the size and number of choline acetyltransferase (ChAT) positive neurons within the basal forebrain. However, when rats were categorized according to their performance on the Morris water maze the following observations were made: (1) in the medial septum (MS) and nucleus of the diagonal band ChAT-positive neurons were larger in the 27 month old non-impaired group compared to 27 and 33 month old behaviorally impaired animals and compared to young controls. We hypothesize that the neuronal swelling observed in the 27 month old non-impaired animals may represent a compensatory response which correlates with the intact functional status of the animal. (2) 33 month old impaired rats also exhibited a decrease in the number of ChAT-positive neurons in the MS compared to young controls and 27 month non-impaired rats. When this loss of cholinergic immunoreactivity was further examined using selected adjacent sections immunolabeled for nerve growth factor receptor (NGFR) we observed no apparent loss of NGFR-positive cells.

155.19

ALTERATIONS OF CHOLINERGIC CELL NUMBER AND SIZE IN THE MEDIAL SEPTAL NUCLEUS OF AGED RHESUS MONKEYS. **H.M. Strossner-Johnson, P.R. Rapp and D.G. Amaral.** The Salk Institute, La Jolla, CA 92037; UCSD, Group in Neurosciences, San Diego, CA 92037.

The number and size of cholinergic neurons in the medial septal nucleus (MS) was quantified in four aged (23-27 years) and four young (10-12 years) behaviorally characterized rhesus monkeys. Four sections at anatomically matched levels (300 μ m intervals) were immunohistochemically processed using a monoclonal antibody (AB8) against choline acetyltransferase (ChAT). The number of ChAT positive cells in which there was a clearly defined nucleus was determined using a computer-aided digitizing system. Cross-sectional area of labeled cells was measured from camera lucida drawings (final magnification 1250x) using a digitizing tablet.

Across the four rostro-caudal levels, there was a 24% decrease in the average number of ChAT positive cells in the aged group. This effect was regionally selective and predominantly confined to the caudal two sampled sections of the MS where there was a 42% decrease in average number of cells in the aged group.

A somewhat surprising finding was that the average cross-sectional area of cholinergic cells was significantly greater in the aged monkeys ($p < .05$). At caudal levels this effect was at least partly attributable to an apparent loss of small to medium sized ChAT positive cells in the aged group. However, the increase in average cell size at rostral levels of the MS occurred in the absence of significant cell loss. These results indicate that cholinergic cells in the MS of the nonhuman primate may undergo a variety of morphological alterations as a consequence of aging.

GABAergic SYSTEMS IN AGEING MOUSE BRAIN. **Pirjo Saransaari and S.S. Oja.** Tampere Brain Res. Ctr, Dept. Biomed. Sci., Univ. Tampere, Finland.

GABAergic transmitter systems are most likely involved in age-related alterations in physiological functions of the central nervous system. We studied in different brain areas the uptake, release and binding of GABA in mice of various ages from 3 to 24 months. The resting and potassium-stimulated (50 mM) release of GABA was measured with superfused tissue slices, uptake with isolated synaptosomes and binding to both A and B sites with purified synaptic membrane preparations. Potassium stimulation enhanced more than 15-fold the release of preloaded GABA from cerebral cortical slices in 3-month-old mice. This response decreased but the release of endogenous GABA increased with age in the same preparations. In some other areas the changes in the release of endogenous and exogenous GABA were also strikingly dissimilar but in the striatum the release of both exogenous and endogenous GABA significantly diminished during ageing. There must occur alterations in the relative sizes of the releasable GABA pools, since the total GABA concentrations did not change very dramatically during ageing. The uptake of GABA by cortical synaptosomal preparations was not either markedly affected by age, consisting always of two saturable components, high- and low-affinity. The maximal binding capacity of GABA to A sites decreased and the binding constant significantly increased between 3 and 18 months of age, suggesting that both the number of available receptors and their affinity for GABA diminished. The results clearly show how variable are the studied GABAergic parameters in different brain areas during normal ageing. (Supported by the Emil Aaltonen Foundation, Finland.)

RECOGNITION MEMORY DEFICITS IN A SUBPOPULATION OF AGED MONKEYS RESEMBLE THE EFFECTS OF MEDIAL TEMPORAL LOBE DAMAGE.

P. R. Rapp and D. G. Amaral. The Salk Institute, La Jolla, California, 92037.

Individual differences in recognition memory function in the aged monkey were assessed using a delayed nonmatching-to-sample (DNMS) procedure that critically depends on the functional integrity of the medial temporal lobe. Four young (9-11 years) and 10 aged (22-33 years) rhesus monkeys (*Macaca mulatta*) were initially trained to a learning criterion of 90% correct on the DNMS task using a 10 second delay between the sample and recognition phase of each trial. The memory demands of the task were then increased by gradually extending the retention interval from 15 seconds to 10 minutes. Three of the aged monkeys performed as well as the young subjects at all delays. The remaining aged monkeys performed well at the shortest delays (15 and 30 seconds), but progressively greater impairments emerged at delays of 60 seconds, 2 minutes, and 10 minutes ($p < .05$). The results suggest that recognition memory is compromised in only a subpopulation of aged monkeys. Moreover, aged monkeys that are impaired in the DNMS task exhibit the same delay-dependent pattern of impairment that is the hallmark feature of memory dysfunction resulting from medial temporal lobe damage.

155.20

Attenuation of the age-related decline in hippocampal muscarinic receptor density through daily exercise or underfeeding. **R.P. Farrar^{1,2,3}, D.E. Fordyce^{1,3} and J.W. Starnes^{2,3}** Institute for Neuroscience, ²Department of Pharmacology and ³Department of Kinesiology, The University of Texas at Austin, Austin, TX.

It was the intent of the present investigation to compare the effects of food restriction and exercise, on cognition associated hippocampal muscarinic receptor density during aging. Male F344 rats were subdivided into the following groups where numbers indicate months of age: sedentary groups: (10S, 12S, 24S, 27S). Sedentary groups (10S, 12S, 24S, 27S), rats underfed or exercised from 10 to 24 months of age (24U and 24E, respectively), rats underfed or exercised from 3 to 12 or 27 months of age (12U, 27U, 12E, 27E, respectively). Age resulted in significant reductions in muscarinic density in both sets of rats (24S vs. 10S and 27S vs. 12S). Underfeeding from 3 months to 12 months of age significantly increased muscarinic density (12U vs. 12S) and resulted in significantly greater muscarinic density compared to sedentary controls at old age (24U vs. 24S, 27U vs. 27S). Exercise appeared to maintain muscarinic receptor density in old animals to a level similar to that of middle-age sedentary controls, whether exercise is initiated at 3 months or 10 months (24E vs. 10S, 27E vs. 12S). In the present investigation, the physiological treatments of underfeeding and exercise both maintained hippocampal muscarinic receptor binding during the aging process in F344 rats. Underfeeding appeared to be more effective than exercise when the protocols were initiated at 3 months or 10 months of age.

156.1

AN INEXPENSIVE MICROCOMPUTER-BASED MAPPING SYSTEM FOR PLOTTING THE SPATIAL DISTRIBUTION OF LABELED CELLS AND FIBERS IN TISSUE. W.G. Tourtellotte and G.W. Van Hoese, Departments of Anatomy and Neurology, University of Iowa, Iowa City, IA 52242.

Plotting the spatial distribution of labeled cells or fibers in tissue is a valuable method for reducing the data generated by anterograde or retrograde tract tracing experiments, immunohistochemistry, in situ hybridization, or regional pathological analyses. We have developed a Computerized Charting System (CCS) to supersede conventional mapping techniques that use mechanical X-Y recorders for cell mapping and the camera lucida for high-resolution axon tracing.

The CCS is based upon an inexpensive and easy to configure microprocessor-based motorized microscope stage. The electronics are consolidated onto a circuit board that plugs directly into an IBM-PC compatible microcomputer. The circuitry controls the motorized stage movement and a joystick for remote positioning.

The CCS provides features that encode the stage position for tissue section contouring, mapping the distribution and enumerating up to 20 separate cell populations or other discreet markers, and plotting the distribution of labeled fibers. It provides other interactive features including scaling, windowed data entry, a photographic interface, position adjustments, and high-resolution plotting of either the entire tissue section or enlarged portions.

The CCS can provide an important technical contribution to mapping the location of labeled fibers and cells revealed by a variety of modern experimental techniques. We have used it in our laboratory for: (1) retrograde and anterograde neuroanatomical tract tracing using horseradish peroxidase, fluorescent dyes, PHA-L, and ³H-labeled amino acids; (2) mapping the distribution of cells identified with immunohistochemistry; (3) mapping the distribution of silver grain-positive cells using in situ hybridization; (4) mapping the spatial distribution of neurofibrillary tangles and neuritic plaques in Alzheimer's disease; and (5) mapping the pattern of congophilic angioopathy in human brain. (Supported in part by: NS 14944).

156.3

FEATURE-BASED MAPPING OF MAJOR CELLULAR REGIONS IN THE POSTERIOR CINGULATE GYRUS. E. Armstrong, R.L. Becker, Jr.*¹ and M. Carlotto*², A.F.I.P., Washington, D.C., 20306; TASC,² Reading, MA.

Information from molecular, cellular and physiological studies come from different levels of resolution. Their integration demands the mapping of common features and imaging techniques have the potential of providing objective maps automatically and reproducibly.

To begin refining the techniques we have digitized Nissl stained sections of the posterior cingulate cortex. Cytoarchitecturally defined regions were classified by using differences in optical densities perpendicular to the medial axis, after the binary image of the cortex had been segmented without holes and resampled into a series of vectors of fixed length.

Optical densities were smoothed and laminar structures and contrasts between textured regions were enhanced by filtering techniques based on anisotropic diffusion. Both geometric properties of the cortex, e.g., sulci, and fractal dimensions for measuring features like roughness and homogeneity were examined. Cellular regions were successfully discriminated. Signature vectors for the regions have shown that the clusters developed by these methods are unimodal.

SPECIFIC THREE-COLOR IMMUNOFLUORESCENCE BY LASER SCANNING CONFOCAL MICROSCOPY USING A Kr-Ar ION LASER. M. Wessendorf, T.C. Brelje*, W. Wu, R. Sorenson*, and R. Elde. Dept. Cell Biol. and Neuroanat., Univ. Minnesota, Minneapolis, MN 55455

Efforts to visualize two or more fluorophores in a single piece of tissue using laser scanning confocal microscopy have been hampered by the poor efficiency with which an argon (Ar) ion laser excites many fluorophores. Furthermore, in many circumstances an Ar ion laser is unable to excite more than one fluorophore specifically. For instance, in doubly labeled samples the red component of fluorescein (FL) emission is indistinguishable from the red emission of rhodamine or Texas Red. Both of these problems result from the limited range of excitation wavelengths available using an Ar ion laser. Thus we examined the usefulness of the krypton-argon (Kr-Ar) ion laser described in the previous abstract for visualizing multicolor immunofluorescent staining.

The ability of the microscope to visualize various fluorophores specifically was examined using brightly stained tissue. FL, tetramethylrhodamine, Lissamine rhodamine (LR), cyanine 3.18, Texas Red, allophycocyanin, Ultralight T680 and cyanine 5.18 (Cy5) were tested. It was found that FL, LR, and Cy5 could be visualized specifically using the filters for blue, yellow, and red excitation, respectively. To test their applicability to 3-color fluorescence immunocytochemistry in the nervous system, sections of rat spinal cord were triply stained for serotonin, TRH, and substance P using secondary antibodies labeled with FL, LR, and Cy5, respectively (Jackson ImmunoResearch). Numerous triply labeled processes were observed in the ventral horn and intermediate gray matter.

It is concluded that specific 3-color immunofluorescence employing a laser scanning confocal microscope is feasible using a Kr-Ar laser.

COMPUTER ASSISTED ANALYSIS OF MORPHOLOGICALLY DEFINED CORTICAL COLUMNS. D. Buxhoeveden and E. Armstrong. A.F.I.P., Washington, D.C. 20306

A method for analyzing linearity is important if cortical structure is to be understood. During ontogeny the originally uniform vertical arrangement of neurons becomes more varied. Consequently a morphometric analysis of columns that can objectively and reproducibly measure the amount of deviation from a straight line, offers a biologically based model by which cortical structures can be compared between areas, ages and species.

Nissl stained sections from temporal cortex (Tpt and AI) were digitized at 100X for adult brains and 200X for fetal brains to test the model. One program identified the center of horizontal neuronal clusters and was used to segregate cell columns. A second set of algorithms analyzed the linearity of columns by measuring total path lengths, nearest neighbor ratios, and linear regressions. Formulas and ratios of the data define characteristics for classifying columns by types. Columnar types can then be compared across areas, species and ages.

Supported in part by NSF 8820485 (EA).

THE Kr-Ar ION LASER: INCREASED SENSITIVITY FOR MULTICOLOR LASER SCANNING CONFOCAL MICROSCOPY. T.C. Brelje*, R.L. Sorenson*, M.W. Wessendorf, and R. Elde. Dept. Cell Biol. and Neuroanat., Univ. Minnesota, Minneapolis, MN 55455

The usefulness of laser confocal microscopy in multi-color fluorescence studies has been constrained by the limited range of excitation wavelengths available on an air-cooled argon (Ar) ion laser. The present study examined a krypton-argon (Kr-Ar) ion laser as an alternate light source.

A 15 mW Kr-Ar ion laser was obtained with simultaneous emission of 4-5 mW at 488 nm (blue), 568 nm (yellow), and 647 nm (red). Interference filters and dichroic mirrors were obtained that allowed visualization of green emission (using blue excitation), orange-red emission (using yellow excitation), and deep red emission (using red excitation). The characteristics of this laser were compared to that of an Ar ion laser with lines at 488 nm (blue) and 514 nm (blue-green).

A comparison was made between the abilities of the two lasers to excite Lucifer Yellow, BODIPY, fluorescein, tetramethylrhodamine, cyanine 3.18, Texas Red, Lissamine rhodamine, allophycocyanin, Ultralight T680, and cyanine 5.18. It was found that using the Ar ion laser, fluorescein, BODIPY, Lucifer Yellow, cyanine 3.18, and tetramethylrhodamine could be excited efficiently or moderately efficiently. In addition, Lissamine rhodamine and Texas Red could be excited, although with considerably reduced efficiency. However, with neither the 488 nor 514 nm "lines" could allophycocyanin, Ultralight T680, or cyanine 5.18 be visualized. In contrast, all of the fluorophores could be excited highly efficiently using the Kr-Ar laser.

It is concluded that the Kr-Ar ion laser is a more sensitive and versatile means of visualizing many fluorophores and that the Kr-Ar laser may be preferable for studies involving combined fluorescent probes. Supported by DA 05466, DA 06299, and DK 33655.

156.6

CONFOCAL SCANNING MICROSCOPY REVEALS LEARNING-ASSOCIATED CHANGES IN PKC CONCENTRATION IN HERMISSENDA PHOTORECEPTORS. S. IMPEY, J. FARLEY, and Y. CHOOI ODLE* Program in Neural Sciences, Dept. of Biology, and Institute for Cell and Molecular Biology. Indiana University, Bloomington, Indiana 47405.

Previous results implicate PKC activation as playing a crucial role in the induction and maintenance of persistent learning-associated changes in K⁺ currents in *Hermisenda* (Hc) Type B photoreceptors (Nature, 1986; 319:220; PNAS, 1991; 88). Confocal laser scanning microscopy, image analysis, and fluorescent phorbol ester derivatives were used to monitor PKC in living whole-mounted Hc nervous systems. When incubated in μ M concentrations of NDB-TPA, large numbers of neurons within the pedal and cerebropleural ganglia were fluorescently-labeled. Pre-incubation with unlabelled TPA decreased the fluorescence of NDB-TPA stained neurons in a dose-dependent manner. Double-label images of cells stained with NDB-TPA and rhodamine-conjugated phalloidin suggest a microfilament involvement in translocation. Quantitation of NDB-TPA fluorescence in optical sections of Type B photoreceptors from associatively-trained animals revealed a 2-3 fold increase in intensity, 2-5 days following training, relative to the same cells from untrained animals. These results suggest that associative learning results in increased PKC concentration in Type B photoreceptor plasmalemma membranes, which may contribute to the persistent suppression of K⁺ channel activity in these cells.

156.7

GOLGI-LIKE LABELING OF NEURONS WITH FLUORESCENT DEXTRANS VISUALIZED WITH CONFOCAL SCANNING LASER MICROSCOPY.

D.M. Nance. Departments of Pathology & Physiology, Faculty of Medicine, University of Manitoba, Winnipeg, MB R3E 0W3, Canada.

Small mol. wt. dextrans conjugated to fluorescein or tetramethylrhodamine are taken up by neuronal cell bodies and transported in an anterograde direction to produce intense terminal labeling following central injections (Nance & Burns, *Brain Res. Bull.*, 25: 139, 1990). Since both fluorophores are compatible with argon lasers, the terminal labeling and the injection sites were examined with confocal scanning laser microscopy (CSLM). The dextrans were injected into various brain areas of rats and 5-14 day later, animals were perfused and the brains sectioned at 40-100 μ m and visualized with a Sarastro CSLM. Confocal images were produced with Phoibos 1000 software running on a Silicon Graphics Personal Iris computer and displayed on a high resolution color monitor. In addition to focus-through images, stereo pairs and volume rendered (surface shaded) projections were generated. Three dimensional renderings of both terminal fields and injection sites provided detailed images of cell bodies and their dendrites as well as their terminal fields. Images of these extracellularly labeled neurons could be rotated and viewed at any angle and appeared qualitatively comparable to optimally stained golgi material. Thus, in addition to being sensitive anterograde tract tracers, these dextran conjugates can provide detailed morphological information about neurons labeled at the injection site when combined with CSLM. Supported by Medical Research Council of Canada and the Health Sciences Centre Research Foundation, University of Manitoba.

SIMULTANEOUS KINETIC IMAGING OF CALCIUM AND pH IN SINGLE LIVING CELLS.

Stephen J. Morris¹, Diane M. Beatty², Thomas B. Wiegmann³, Larry W. Welling⁴ and Bibie M. Chronwall⁵. ¹Mol. Biology and Biochem., and ²Cell Biology and Biophys., SBLs, UMKC, Kansas City, MO 64110-2499; ³Renal Sect. and ⁴Research Service, VA Med. Ctr., Kansas City, MO 64128.

There is a growing interest in resolving multiple images of "ratio" fluorophores like indo or SNARF™ or the emission from multiple dyes placed in the same cell system. For rapid kinetic studies, the problems of photodynamic damage and photobleaching on one hand and the need for good spatial and temporal resolution on the other, press the resolution of the instrumentation. Rapid resolution of multiple probes at multiple wavelengths presents a third set of problems. These are solved by a new design of ultra low light fluorescence video microscope for simultaneous, real-time capture of intensified images of cells containing dual wavelength "ratio" dyes or multiple dyes at video frame rates (30 frames/sec or faster) (BioTechniques 8:296-308 (1990)). This instrument has been improved to simultaneously acquire up to four images. This allows capturing intensified images of up to four dyes contained in the same cell system. These can be two dual-emission wavelength "ratio" dyes or multiple dyes.

We present three examples of simultaneous multi-parameter imaging. (1) Synchronous observations of calcium (with indo-1) and pH distribution (using SNARF-1™) in kidney epithelial cells, show differing kinetics in response to ionomycin treatment. Intracellular calcium increases rapidly when the bath Ca^{2+} is raised. The pH remains stable for several seconds, then suddenly collapses. (2) During fusion of human red blood cells (RBC) to fibroblasts expressing influenza hemagglutinin, movement of soluble and membrane-bound dyes follow different kinetics, depending on the molecular weight of the soluble dye. This implies that the fusion involves the formation of small metastable pores. Furthermore, the swelling of the RBC occurs after the onset of fusion, and therefore cannot provide the driving force. (3) Results from neuro-intermediate lobe cells in primary culture will also be presented.

INCORPORATION OF FLUORESCENT PHOSPHATIDYLCHOLINE INTO RAT HIPPOCAMPAL SLICES.

P.L. Huddie¹, D.L. Alkon² & D.S. Lester². ¹YONA Microscope & Instrument Co., Columbia, MD 21046 and ²Section on Neural Systems, NIH, Bethesda, MD, 20892

Fluorescently labelled phospholipid, NBD-phosphatidylcholine (NBD-PC) was incorporated into small unilamellar vesicles composed predominantly of phosphatidylcholine (bovine brain). Hippocampal slices (400 μ m) were incubated in HEPES buffer saline under aerating conditions for a period of up to 1 hour. Slices were washed and visualized with x20 and x40 long working distance objectives. The labelled lipid was concentrated in specific regions of the hippocampus. Visualization at higher powers showed that pyramidal cell bodies were consistently labelled in CA1, CA3 and the dentate gyrus; particular axons and fiber tracts were labelled throughout the hippocampus. This would suggest that this fluorescent phosphatidylcholine analog is incorporated into specific phospholipid pools. However, when another fluorescent lipid probe, Bodipy-phorbol ester, was used at various concentrations, the label was distributed with no specific localization. In *in vitro* assays, the PLA₂ probe changes its fluorescent properties (peak wavelength and fluorescent intensity) upon cleavage of the labelled fatty acid. We are evaluating whether these properties are observed upon activation of PLA₂ in intact slices.

SPATIAL AND TEMPORAL IMAGING OF CALCIUM TRANSIENTS IN CA1 HIPPOCAMPAL PYRAMIDAL NEURONS. S.R. Young, J. Ambati*, X. Liu*, C. Scheffey, R.K.S. Wong. Dept. of Pharmacology, SUNY Health Science Center, Brooklyn, NY 11203.

Whole cell patch clamp recordings (Hamill et al. *Pflugers Arch* 391:85, 1981) were made from acutely isolated pyramidal neurons of guinea pig hippocampus (Kay & Wong. *J Neurosci Meth* 16:227, 1986). The extracellular solution contained (in mM) NaCl (140), KCl (5), HEPES (10), CaCl₂ (1), MgCl₂ (1), Dextrose (25). The pipettes contained (in mM) Trizma base (115), HEPES (10), BAPTA (10), ATP (4), Leupeptin (0.1), cAMP (0.01), Phosphocreatine (10), Fura-2 (0.1), Creatine phosphokinase (50 U/ml). Distribution of fura-2 in the cells reached equilibrium within 5 minutes. Optical recordings of fura-2 fluorescence were made with a Photometrics CC200 CCD camera controlled by a host computer that recorded simultaneous current data from the patch clamp amplifier (Lasser-Ross et al. *Soc Neurosci Abst* 15:572, 1989).

Voltage clamp commands from a holding potential of -50 mV to -90 mV (250 ms), then to -10 mV (up to 750 ms) activated a calcium current with rapidly decaying and sustained components (Kay & Wong. *J Physiol* 392:603, 1987). Ratio images at 340 nM and 380 nM (Grynkiewicz et al. *J Biol Chem* 260:3440, 1985) show that $[Ca^{2+}]_i$ continues to rise throughout depolarizations of up to 750 ms. The spatial pattern of $[Ca^{2+}]_i$ increase activated by depolarization suggests that voltage dependent Ca^{2+} channels are present on the somata of pyramidal cells as well as on the dendrites.

DIFFERENTIAL EFFECTS OF EXTRACELLULAR ATP ON IONIC CURRENTS IN EXCITABLE AND NON-EXCITABLE CELLS. *A. Jesurum,

*M. Diverse-Pierluissi, E.W. Westhead and *D.J. Gross. Program in Molecular and Cellular Biology and Department of Biochemistry, University of Massachusetts, Amherst, MA. 01003.

Chromaffin cells derived from the neural crest have been shown to respond to externally applied ATP by either enhancing or inhibiting catecholamine secretion. Using electrophysiological techniques, we have shown that under voltage clamp whole-cell configuration, 20% of the chromaffin cells respond to a 100 μ M ATP stimulation with an increase in inward current. The response occurs within 50 msec and the cells rapidly desensitize in the continuous presence of the agonist. The response recovers after 5 minutes in the absence of ATP. By using the voltage sensitive fluorescent indicator di-8-ANEPPS, we have measured a -35mV depolarization in response to ATP. The video imaging data correlates with the voltage clamp data. Pretreatment of the cells with cholera toxin prolongs the ATP evoked depolarization by slowing the rate of desensitization.

ATP has been previously shown to act as a mitogen in A431 cells which are nonexcitable cells derived from a human epidermoid carcinoma. We show that in 80% of the cells tested, ATP mediates an increase in inward current (1-2 nA) which seems to be carried dominantly by calcium. The onset of the response shows a delay after stimulus, with 67% of the cells tested having a lag time of 4 seconds. As in chromaffin cells, the current is rapidly desensitized in the continuous presence of the agonist. Subsequent stimulations fail to yield responses of the same magnitude as the initial response and require longer exposure to ATP before responding. Di-8-ANEPPS fluorescence imaging of membrane potential in these cells indicates a rapid hyperpolarization. We believe that the imaging data reflects an outward Ca^{2+} -activated K^{+} current proposed to exist in these cells. Experiments performed using current clamp will be used to determine changes in membrane voltage evoked by ATP.

APPLICATION OF A MURINE EMBRYO CULTURE SYSTEM TO VISUALIZE EXPRESSION OF THE NEURAL CELL ADHESION MOLECULE (N-CAM) DURING EARLY MAMMALIAN EMBRYOGENESIS.

Poorni Iyer*, J.E. Martin**, T. Rick Irvin* and J.K. Daniloff*. Institute of Environmental Studies, *Dept. of Veterinary Anatomy and Pine Structure, Louisiana State University, Baton Rouge, La 70803.

We have demonstrated the expression of the neural cell adhesion molecule, N-CAM, during early mammalian embryonic development, employing double-labelling immunofluorescent microscopy in murine embryos grown *in vitro*. A monoclonal antibody to mouse N-CAM and indirect immunofluorescence with biotinylated and streptavidin-FITC conjugated antibodies were utilized to identify N-CAM expression in mouse blastocysts at the 72 hour culture stage. Embryos exhibited marked levels of fluorescence with localization specifically in the inner cell mass region. These findings demonstrate the presence of N-CAM in the mouse blastocyst after 72 hours in culture, and support the use of this embryo culture system to study localization and distribution of N-CAM at various timepoints during mammalian early embryogenesis.

ASSESSMENT OF NEURONAL ADHESION/SURVIVAL IN CULTURE IS FACILITATED BY LABELLING NEURONS WITH FLUORESCHEIN DIACETATE R.E. Petroski, V.O. Jenab, C. Gardner* and H.M. Geller Dept. of Pharmacology, UMDNJ-Robert Wood Johnson Medical School and The Graduate School, Rutgers University, Piscataway, NJ 08854.

Neuronal survival and differentiation is dependent on a complex set of interactions with glial cells in the mammalian central nervous system. In order to examine the contribution made by astrocytes on neuronal adhesion, survival and process outgrowth, reliable methods for quantitating neurons growing on a glial substrate must be developed. The use of fluorescein diacetate (FDA) to determine neuronal viability in conjunction with propidium iodide has been previously described (Jones & Senft, J. Histochem. Cytochem., 1985). We report the use of FDA to selectively label living neurons but not astrocytes grown in cell culture.

Embryonic rat hypothalamic neurons were plated on a substrate of confluent cortical astrocytes. Cultures were treated with 10 μ M FDA in DMEM/FCS for 30 min. in a humidified 5% CO₂ incubator. Live cultures were examined using fluorescein optics using a Zeiss Axioplan or Axovert microscope. Neurons displayed brilliant green somata as well as intensely labelled processes. The glial monolayer showed only a dim level of fluorescence which can be virtually eliminated by washing out the FDA-containing medium for 10 min. The fluorescent label lasts for several hours after wash out. The dye was used in conjunction with a laser cytometer (ACAS, Meridian Instruments) to enable automated cell counting. The dye was found not to harm neurons. Supported by NS 24168.

HIGH RESOLUTION AND IMPROVED SPEED FOR FLUORESCENT MICROSCOPY USING KODAK TECHNICAL PAN FILM T.C. Waters*, G.E. Hoffman, and S.L. Small Depts. Physiology and Neurology, Univ. Pittsburgh, School of Med., Pittsburgh, PA 15261

In the photomicrographic evaluation of fluorescence, short exposures (which reduce the fading of labile fluorophores) and minimal grain size (which improves image resolution) are both desired. Often a compromise of one or the other is necessary with standard film/development combinations. This abstract illustrates a method of developing Technical Pan (Kodak 2514) film providing high resolution and an effective speed equal to or higher than that commonly achieved with Kodak Tri-X, a standard high speed film. Brain sections processed for Texas Red immunofluorescence were used to evaluate negatives using Kodak's Technical Pan (TP) or Tri-X film over a wide range of exposure times. The following developers for TP were compared: D19 (68°F-4 min), HC 110-1:31 (68°F-6.0 min), and HC 110-1:10 (68°F 6.5 min); D76-1:1 (68°F-9.5 min) was used for Tri-X. Contrast range, granularity and speed were compared. D19 produced the highest contrast; both HC-developed negatives produced intermediate contrast ranges; Tri-X negatives were of very low contrast. Grain size for all TP negatives was minimal; Tri-X grain was large and irregular. TP developed in D19 and HC 110-1:31 produced excellent exposures of Texas Red stained cells (mag.100X) ranging from 3-4 sec; optimal exposure of HC 110-1:10 was 1.31 sec; Tri-X, yielded usable exposures over a wide range (21.38-1.54 sec). The use of HC 110-1:10 provided increased speed over other developers tested, little change in contrast and excellent resolution.

Supported by NIH NS 28477, NS28730 and NSF BNS 8919953.

STORAGE PHOSPHORS AS AN ALTERNATIVE TO PHOTOGRAPHIC EMULSION FOR RECORDING AND QUANTIFYING AUTORADIOGRAMS. N.M. Appel, S.A. Mathews*, G.M. Storti* and M.J. Kuhar NIDA Addiction Research Center, Baltimore, MD 21224; Quantex Corporation, Rockville, MD 20850.

Autoradiograms are often produced by apposing radiolabeled specimens (tissues, gels etc.) to photographic emulsion. There are deficiencies in this approach, however. Film optical density is not linearly related to exposure duration, the dynamic range of film is limited (saturation) and long exposure times may be necessary. Storage phosphors are materials that produce a trapped electron population that is proportional to radiation input. The electrons are trapped for long periods of time and are released when stimulated by light or heat. A characteristic visible light emission is produced when the trapped electrons are released. The emitted light can be monitored with a detector, recorded and stored on a computer for subsequent display and analysis. Autoradiograms were produced by apposing methylmethacrylate [¹²⁵I] standards (Amersham) to storage phosphor-coated acrylic screens and compared to autoradiograms produced when apposed to Ultrafilm ³H (Cambridge). The relationship between resulting optical density and radioactivity of or exposure duration to [¹²⁵I] was linear over a much longer range for the screens than for film. In addition, the dynamic range of screens was greater than film. Using screens autoradiograms were apparent after shorter exposures than with film or with lower radioactivity. Moreover, the screens are reusable and darkroom facilities (chemicals, plumbing, dedicated space) obviated. These features demonstrate the advantages of this technique as an alternative to film for generating autoradiograms.

EXPRESSION OF PROTEIN KINASE C (PKC) GENES IN NEURONAL AND GLIAL CELLS DERIVED FROM PRIMARY HUMAN BRAIN CULTURES.

N.P. Dooley, J. Nalbantoglu*, and V.W. Yong Neuroimmunology Unit, Montréal Neurological Institute, Montréal, Québec, CANADA, H3A 2B4.

PKC is encoded by a family of genes and to date seven isoforms of this enzyme have been identified. Our laboratory has shown that PKC is involved in glial cell proliferation and in oligodendrocyte (OL) process extension. We investigated the *in vitro* expression of four PKC isoforms in neuronal and glial cells obtained from adult human brain surgical specimens and from legal curettage abortions. Total RNA was isolated using the guanidinium thiocyanate-phenol-chloroform method from cultures of neuronal and glial cells of greater than 90% purity. Isoform expression was then determined following analysis of the radiolabelled products of the reverse transcriptase-polymerase chain reaction on non-denaturing polyacrylamide gels. In adults, primer pairs for PKC β_1 , PKC β_2 , and PKC α produced bands of predicted molecular weight in OLs, astrocytes (ASTs) and microglia. The same pattern of expression was observed in fetal ASTs and neuronal cultures. The PKC γ band was observed only in RNA extracts from intact adult whole brain. Currently, we are also investigating PKC expression in dedifferentiated glial cells (gliomas). The localization of PKC isoforms to specific neuronal and glial cells in the human central nervous system may aid in the elucidation of their possible distinct functions within each cell type.

EXCITABILITY PROPERTIES OF DORSAL COLUMN AXONS IN THE MYELIN-DEFICIENT (MD) RAT SPINAL CORD. D. Utzschneider, J.A. Black and J.D. Kocsis Dept. of Neurology, Neuroscience Program, and Sect. of Neurobiology, Yale Univ. Sch. Med., New Haven, CT; VAMC, West Haven, CT 06516

The md rat mutant virtually lacks CNS myelin due to a point mutation in the proteolipid gene product which results in a marked inhibition of oligodendrocyte development. We used *in vitro* electrophysiological methods to compare conduction properties of md rat spinal cord axons to control age-matched rats (18-26 days) and rats that received transplantations of myelin-forming precursor cells. Latency measurements of compound action potential (CAP) recordings obtained *in vitro* at room temperature with glass microelectrodes in the dorsal columns indicate that conduction velocity of md rat spinal cord axons is about 25% of age-matched controls (0.6 m/s vs 2.4 m/s). Both groups were able to follow high frequency stimulation (up to 400 Hz) for several hundred msec. Only at very prolonged stimulation presentations did the md spinal cord axons show greater conduction decrement as compared to controls. Both groups of axons are blocked by TTX and show variable changes in waveform following 4-aminopyridine application. GABA application resulted in reduced amplitude of the CAP and conduction slowing for both groups. Injections of fetal and neonatal brain suspensions containing myelin-forming precursor cells resulted in variable amounts of myelination within the dorsal columns. There was a higher frequency of isolated early field potential components in the transplant group as compared to controls.

These results indicate that myelinated md rat axons, while compromised with respect to conduction velocity, can sustain high frequency impulse firing for hundreds of msec. Additionally, the md axons have Na⁺ and K⁺ channels and GABA_A receptors as do controls. Transplantation of brain suspensions leads to anatomically defined myelination, and increased probability of early discrete field potential components. Supported by the NMSS and MSTP.

MORPHOMETRIC ANALYSIS OF NORMAL, MUTANT AND TRANSGENIC CNS: CORRELATION OF MBP EXPRESSION TO MYELINOGENESIS. H.D. Shine, C. Readhead, B. Popko, L. Hood, and R. L. Sidman. Department of Neurosurgery, Baylor College of Medicine, Houston, TX 77030.

The neurological mutant mice *shiverer* (*shi*) and *myelin deficient* (*shim^{ld}*) lack a functional gene for the Myelin Basic Proteins (MBP), have virtually no myelin in their CNS, shiver, seize, and die early. Mutant mice homozygous for an MBP transgene have MBP mRNA and MBP in net amounts approximately 25% of normal, have compact myelin, do not shiver or seize, and live normal life spans. Various combinations of the normal, transgenic, *shi* and *shim^{ld}* genes yield mice that express MBP mRNA at levels of 0%, 5%, 12.5%, 17.5%, 50%, 62.5%, and 100% of normal. MBP protein content correlated with predicted MBP gene expression. Immunocytochemical staining localized MBP to white matter in normal and transgenic *shi* mice with an intensity of staining comparable to the degree of MBP gene expression. An increase in the percentage of myelinated axons and the thickness of myelin correlated with increased gene expression up to 50% of normal and then remained constant at expression levels greater than 50%. Mean axon circumference of myelinated axons was greater than axon circumference of unmyelinated axons at each level of gene expression -- further evidence that oligodendroglial cells preferentially myelinate axons of larger caliber. These data suggest that oligodendroglial function is governed in part by the degree of MBP expression. Supported by NIH grants HD18655, NS20820, and AG07687 and the Retina Research Foundation.

REMYELINATIVE CAPACITY OF QUIESCENT OLIGODENDROCYTES FROM OPTIC NERVES FOLLOWING LONG TERM WALLERIAN DEGENERATION. Dr. S.K. Ludwin, Queen's University, Kingston Ontario.

We have previously shown that following Wallerian Degeneration (WD) in the rat optic nerve, some oligodendrocytes identified by antibodies to carbonic anhydrase and myelin oligodendrocyte glycoprotein could survive for periods of up to 2 years in the absence of axons.

We have now tested the remyelination and regenerative capacity of these quiescent oligodendrocytes. Fragments undergoing WD for periods from 13 months to 2 years were implanted into the brains of neonatal Shiverer mice which were studied 4 weeks later using antisera to myelin basic protein (MBP). Myelination was demonstrated outside and within the implant and the presence of MBP indicated that it was of donor origin. In addition, numerous oligodendrocytes, both within and outside the graft, displayed MBP positive cytoplasm, reminiscent of the pattern seen in development and remyelination. Silver stains demonstrated ingrowth of axons from the host tissue into the graft, and may have provided the stimulus for the production of MBP in the graft. Some of these axons were subsequently remyelinated by the oligodendrocytes remaining in the graft.

These results indicate a potential for recovery and remyelination by oligodendrocytes even when deprived of axonal stimulus for long periods, and their subsequent *in vivo* responsiveness to the presence of axons.

IN VIVO COMPARISON BETWEEN TWO MURINE MYELIN BASIC PROTEIN RESPONSIVE T_H CELL TYPES. E. Barbarese*, H.D. Soares, and R. Clark*. Dept of Neurology, Univ of CT Health Cntr., Farmington, CT 06030.

Experimental autoimmune encephalomyelitis (EAE) is an animal model disorder for multiple sclerosis, a human demyelinating disease. Genetically susceptible animals develop EAE following injections of either central nervous system (CNS) homogenates, myelin basic protein (MBP), or MBP responsive T helper (T_H) cell lines or clones. In mice, a CD4⁺CD8⁻, class II restricted, IL-2 dependent T helper cell elicits EAE symptoms (i.e. hindlimb paralysis and sometimes death). One approach towards characterizing EAE's pathological sequelae has focused upon MBP responsive T_H cell homing capabilities. The present experiment utilizes two types of MBP responsive T_H cells to examine CNS homing characteristics. One of the MBP responsive T_H lines, LNC8, causes EAE symptoms 6 days following injection. The other MBP responsive T_H cell clone, B48, fails to induce any of the disease's symptoms. Mice received i.p. injections of fluorescently labelled (Dil) LNC8 or B48 cells. Animals were sacrificed at 3 or 4 days following injections. The number of LNC8 T cells in brain and spinal cord rose from approximately 20 cells/cm² on day 3 to 150 cells/cm² on day 4. Conversely, the number of B48 cells in brain and spinal cord fell from approximately 50 cells/cm² on day 3 to basal levels on day 4. Histological analysis demonstrated lesions and astrogliosis in the CNS of LNC8 injected mice. Little neuropathological damage was observed in B48 injected animals. Both MBP responsive T_H cell types pass through CNS tissue, however, the disease causing LNC8 cells appear to accumulate in brain and spinal cord on day 4 while the B48 cells do not. Supported by NINCDS #19943.

DISTRIBUTION OF THE MYELIN-ASSOCIATED GLYCOPROTEIN IN MURINE OLIGODENDROCYTES IN VITRO. L.L. Bambrick. CNS Dept. University Hospital, London, Ontario, N6A 5A5.

The myelin-associated glycoprotein (MAG) is an adhesion molecule and the principal glycoprotein of myelin. It has been implicated in oligodendrocyte (ODG)-axon and ODG-ODG adhesion. We have previously shown that MAG has an association with the cytoskeleton in cultured rat ODG. In cultured murine ODG, antibodies to galactocerebroside (GC, an ODG glycolipid) induce the patching of GC into domains. These domains overlie patches of myelin basic protein and are demarcated by veins containing the cytoskeleton proteins actin and tubulin. It has been proposed that these domains correspond to areas of compacted and non-compacted myelin, respectively. *In vivo*, MAG is principally found in non-compacted myelin. To pursue the question of MAG localization in cells with respect to the cytoskeleton, we have investigated the localization of MAG in murine ODG membrane sheets *in vitro* using immunofluorescence in cells where domain patching has been initiated with anti-GC antibodies. We report some staining for MAG in unorganized sheets. In areas of GC patching, MAG staining is observed in the veins around the GC-positive domains. Probing for actin using a rhodamine-conjugated phalloidin shows that MAG is colocalized in these veins with the cytoskeleton protein actin. LLB is a Raymond C. Raymond fellow, the support of Drs. P.E. Braun and G.P.A. Rice is acknowledged.

INCREASED MYELINATION IN JIMPY MICE EXPRESSING BOTH PLP AND DM-20 TRANSGENES. N. Nadon, H. Arnheiter*, S. Wells* and L. Hudson*. Biology Dept., Univ. of Tulsa, Tulsa, OK 74104 and Lab. of Viral and Mol. Path., NINDS, NIH, Bethesda, MD 20892.

Proteolipid protein (PLP) is the major structural protein in myelin of the mammalian central nervous system (CNS). Adult mice express two isoforms of PLP, through the use of alternative splice sites in exon three. The less abundant isoform, DM20, lacks 35 amino acids in an extracellular domain, but is otherwise identical to PLP. Loss of PLP/DM20 function in the X-linked jimpy mouse mutant results in the development of tremors and premature death. Jimpy mice exhibit a reduction in the number of mature oligodendrocytes and severe hypomyelination of the CNS (<1% of the axons are myelinated). We have used a transgenic mouse system to analyze the roles of PLP and DM20 in the development of myelination. Previously, we reported that jimpy mice carrying a PLP transgene did not show any moderation of the dysmyelination, in spite of the high level of expression of the PLP transgene in wild-type mice (~70% of endogenous PLP/DM20 RNA levels). Transgenic mice have now been produced that express only the DM20 isoform. The DM20 lines examined to date express the transgene at ~10-30% of endogenous DM20 mRNA levels. DM20 transgenes have been bred into the jimpy background, alone and in combination with the PLP transgene. The level of myelination in jimpy mice expressing the DM20 transgene alone was no greater than in jimpy mice without the transgene. However, jimpy mice expressing both PLP and DM20 transgenes exhibited an increase in the number of axons myelinated, suggesting that both isoforms of PLP may be required for oligodendrocyte development. Further characterization of the PLP/DM20 transgenic jimpy mice will include analysis of the expression of the endogenous myelin proteins and their mRNAs, and the affect of the transgenes on oligodendrocyte survival and the lifespan of the jimpy mice.

ASTROCYTIC REACTION TO OLIGODENDROCYTE AND NEURONAL DEGENERATION. N.R. Bhat, Dept. Biochem. and Sanders-Brown Center on Aging, Univ. of KY, Lexington, KY.

Reactive gliosis is a common neuropathological feature of several neurodegenerative disorders. In this study, two primary culture models i.e., mixed glia and hippocampal cultures derived from newborn rat brain have been used to characterize astrocytic reaction to oligodendrocyte (OL) and neuronal degeneration resp. A week-old mixed glial cultures containing astrocytes, OL progenitors and microglia were treated with the monoclonal antibody A2B5 along with complement to lyse OL progenitors. Western blot and Northern analysis revealed an increased expression of GFAP after 2 days of immunocytolysis. There was also an increase in glutamine synthetase activity, another astrocytic marker. In the 2nd set of experiments, 10-12 day old hippocampal cultures containing both neurons and glia were exposed to either kainate or glutamate. A majority of the neurons succumbed to this excitotoxic insult within 24 h. Immunoblot analysis of the culture extract showed an increase in GFAP. Pure glial cultures did not respond the same way. Addition of purified microglia to hippocampal cultures resulted in an enhanced astrocytic response to neuronal death. The culture models described here should prove useful in further analysis of the intercellular signals involved in astrocytosis. (Funded in part by Center on Aging).

A TRANSGENIC TAG FOR TRACKING TRANSPLANTED GLIAL CELLS
O. Govt, R. de Santo, H. Arnheiter, L. Hudson, M. Dubois-Dalco*,
LVMP, NINDS, NIH Bldg 36/5D04, Bethesda MD 20892

Transplanted oligodendrocytes and their precursor cells can migrate and remyelinate focal demyelinating lesions produced by lysolecithin in *shiverer* mice (Gout et al., Neuroscience Lett. 87:195-199, 1988). However in these experiments the endogenous *shiverer* oligodendrocytes, which have a deletion for the myelin basic protein (MBP) gene, could not be readily distinguished from transplanted oligodendrocytes, which expressed MBP only transiently in their cell bodies. To investigate mechanisms of remyelination by grafted glial cells in normal mice, we have generated a constant supply of genetically marked oligodendrocytes. The marker was β -galactosidase, and the glial-restricted expression was specified by the selection of the promoter for the most abundantly expressed CNS myelin gene, proteolipid protein (PLP). Detection of enzymatically active β -galactosidase in a human fetal glial line transfected with a PLP promoter (1.2 kb) fused to the *E. coli lacZ* plasmid indicated that the construct was suitable for glial expression in transgenic mice. Several transgenic founder lines containing the PLP promoter-*lacZ* construct are being analyzed histochemically to determine the extent and the onset of β -galactosidase expression under the PLP promoter. Since the PLP gene is apparently activated before the actual onset of myelination, the transgene may likewise be turned on before final oligodendrocyte differentiation. This may then allow us to follow transgenic grafted cells during the process of migration and myelination.

GLIAL CELLS IN THE DEVELOPING OPTIC NERVE OF THE FROG *HYLA MOOREI*. D.E. Playford and S.A. Dunlop, Department of Psychology, University of Western Australia.

In the frog, numbers of retinal ganglion cell and axons increase throughout life. We have recently shown that, in fully mature *Hyla moorei* of 9 cm length (2+ years), 2% of optic axons are myelinated. Comparable numbers of myelinated axons are found behind the eye, at the foramen and at the chiasm. However, this mature pattern is achieved only gradually over 1-2 years by the differential addition of myelin along the length of the nerve. Thus, in tadpole stages when myelination is initiated, most myelinated axons are found at the foramen and fewer at the eye and chiasm. In young adults of 5 and 7cm length, there is a gradient along the nerve with most myelinated axons at the chiasm. We have examined changes in the glial cell population at the three levels in the nerve from tadpole stages to adulthood using ultrathin sections on formvar grids. Astrocytes were pale and contained neurofilaments; oligodendrocytes were dark and had microtubules. Immature glial cells were also observed. Glial cell numbers increased throughout life but, at all stages, astrocytes were predominant. However, the proportion that oligodendrocytes represented of the total glial cell population consistently mirrored the numbers of myelinated axons. Thus, in tadpole stages, the highest proportions of oligodendrocytes were found at the foramen; in young adults the highest proportions were found at the chiasm and in fully mature adults there were equal proportions at all three levels. Our data suggest that the differential patterns of myelination in the developing frog optic nerve are underpinned by changes in the proportions of oligodendrocytes. Funded by the National Health & Medical Research Council of Australia.

ONCOGENE-SPECIFIC DOWN-REGULATION OF MOUSE MYELIN P₂ EXPRESSION. Bharucha, V.A.¹, Peden, K.W.C.², Narayanan, V.³, and Tennekoon, G.I.¹ ¹Departments of Pediatrics and Neurology, The University of Michigan, Ann Arbor, MI 48109; ²National Institutes of Health, N.I.A.I.D., Bethesda, MD 20892; and ³Department of Pediatrics, University of Pittsburgh, Pittsburgh, PA 15261.

Myelin P₂ protein is a small (14,800 Da) basic protein that belongs to a family of proteins involved in fatty acid binding. In rodents, P₂ protein is found in myelin and in the cytosol of Schwann cells, while in other species, the protein is also found in oligodendrocytes. To study the regulation of this protein in the nervous system, we cloned the mouse P₂ gene and determined the transcription start sites by primer extension analysis. The 5'-flanking sequences contained a TATA box (-31), two CAAT boxes (-194, -232), and two AP-1 binding sites (-53, -391). To identify the transcriptional regulatory effects of these AP-1 sites, Schwann cell lines (MT4H1) were co-transfected with the chloramphenicol acetyltransferase (Cat) reporter gene under the control of the P₂ promoter with expression plasmids for c-jun, jun B, jun D, c-fos, and fra-1. Cat activity levels indicated that co-transfection of the P₂ promoter, along with a c-jun- and/or c-fos-containing plasmid, down-regulates myelin P₂ expression in Schwann cells. jun B, jun D, and fra-1 did not alter P₂ Cat activity. Results suggest that the presence of the AP-1 binding sites on the mouse myelin P₂ promoter inhibits the expression of this gene in Schwann cells. Furthermore, this down-regulation of myelin P₂, after co-transfection with c-jun, is reversed by forskolin at a concentration of 10 μ M. (Work supported by a grant from N.I.H. R01-NS 21700).

CEREBELLAR SLICES: A SYSTEM FOR STUDYING MYELINATION. J.W. Kasckow, P.N. Bullock*, S. Malek-Hedayat*, and L.H. Rome*. Dept. Biological Chem., UCLA Med. Ctr., Los Angeles, Ca. 90024.

Myelination *in vitro* has been studied using various systems including organotypic cultures (Silberberg et al., J Neurochem 19:11, 1972), mixtures of oligodendrocytes or Schwann cells added to dorsal root ganglia (Wood & Bunge, Nature 320:756, 1986) as well as glass microfibers coated with astroglial matrix (Bullock & Rome, J Neurosci Ref 27:383, 1990). We have modified and extended a previous method using cerebellar slices to enable the study of *in vitro* myelination. Cerebella from 1 day old rat pups were cut into 300 μ m sections. Slices were cultured onto 12 well plates of collagen coated petriperm in an enriched medium containing insulin, fetal calf serum and horse serum. Slices were metabolically labeled with radioactive sulfate and then disrupted with a chaotropic salt solution allowing efficient extraction of sulfolipids. Myelin biosynthesis as assessed by sulfolipid incorporation increased linearly up to 32 days *in vitro*. Slices were also examined by electron microscopy. As early as day 17, myelination around axons could be seen exhibiting the characteristic alternation of major dense and intraperiod lines. Supported by HD 06576 and NIMH 5T22 MH 17140-08..

IDENTIFICATION OF A RAT cDNA CLONE FOR MYELIN/OLIGODENDROCYTE GLYCOPROTEIN: M.V. Gardinier, P. Amiguet*, C. Linington*, and J.-M. Matthieu. Labo. de Neurochimie, CHUV, CH-1011 Lausanne, Switzerland

The myelin/oligodendrocyte glycoprotein (MOG; 26 and 28 kDa) is expressed specifically in central nervous system myelin. Our group and others have shown that: 1) MOG is localized on the external surface of the myelin sheath; and 2) anti-MOG antibodies can induce demyelination both *in vivo* and *in vitro*. Thus, MOG may represent an ideal target antigen involved in demyelinating disease. Protein sequence analysis of purified MOG yielded a sequence of 26 amino acids (aa). A rat oligodendrocyte-enriched cDNA library ($\approx 8 \times 10^5$ clones) was screened with a mixture of 3 MOG-specific monoclonal antibodies, and 3 putative MOG cDNA clones were isolated. These clones appear to contain identical inserts (≈ 1.1 kb). Initial sequence analysis reveals an open reading frame containing a Met codon, a possible signal peptide region (encoding 26 aa), followed by sequence encoding the amino acids identified by N-terminal sequence analysis. The nucleotide sequence revealed 2 aa changes (out of 26 aa), perhaps due to species differences (rat vs. mouse). A 1.5 kb MOG mRNA is detected on a Northern blot of brain polyA+ RNA.

COMPARISON OF OLIGODENDROCYTE MARKERS IN IMMUNOHISTOCHEMISTRY. L. Pertile*, N. Nousek-Goebel* and D. S. Grega*. R&D Division, Boehringer Mannheim Corp. and *Indiana Univ. School of Medicine, Program in Medical Neurobiology, Indianapolis, IN 46250.

The investigation of glial cells in the nervous system is increasingly important as their interaction with other neural cell types is still not well understood. Markers to distinguish glial cells, especially oligodendrocytes (oligos) and Schwann cells (both of which produce myelin) are proving to be valuable tools in the study of nervous system. Antibodies, functioning as discriminating markers, can be used in a variety of techniques, such as immunohistochemistry (IHC) and immunoblotting. In the present study, we describe the comparison of several oligo-specific antibodies in IHC of cultured cells, sectioned brain tissue and immunoblotting.

We present data using three monoclonal antibodies anti-CNase (2',3'-cyclic nucleotide 3' phosphodiesterase), anti-GalC (galactocerebroside) and anti-MBP (myelin basic protein). The IHC labeling by each is compared in fixed, rat oligo cultures from cerebral cortex. Anti-CNase and anti-GalC yield similar labeling in these cultures. Labeling patterns of the three antibodies in fixed sections of rat brain are also compared. The antibodies are used in immunodetection of Western blot transfer of delipidated rat brain extracts. The relative advantages and limitations of these antibodies are presented.

157.15

HUMAN OLIGODENDROCYTES ARE NOT SUSCEPTIBLE TO LYSIS BY NON-MHC RESTRICTED CD4+ LYMPHOCYTES. T.C.G. Ruijs, E.A. Brown* and J.P. Antel. Montreal Neurological Institute, McGill University, Montreal Quebec, Canada H3A 2B4.

In the putative autoimmune disease multiple sclerosis, CD4+ T-lymphocytes reactive to myelin antigens may play a role in injury to oligodendrocytes (hOL). CD4+ lymphocytes classically recognize only cells expressing Major Histocompatibility Complex (MHC) class II molecules, but hOL appear to lack expression of MHC class II. CD4+ lymphocytes can, under selected culture conditions, acquire non-MHC restricted cytolytic capability. We investigated the relative susceptibility of hOL to non-MHC restricted cytotoxicity mediated by enriched CD4+ lymphocytes activated with the lectin phytohemagglutinin (PHA). Following activation for 3-30 days, 84% ($\pm 3\%$) of T-lymphocytes were CD4+. These lymphocytes were cytotoxic to the control target cell line U937 in a 18-hour ^{51}Cr release assay, in the presence of lectin to increase effector-target cell contact ($25.8 \pm 1.9\%$ lysis at 10:1 effector to target ratio). CD4+ cells did not lyse hOL ($8.9 \pm 2.3\%$ lysis). In contrast, U937 and hOL were both lysed by non-MHC restricted PHA-activated lymphocytes of the CD8+ subset ($24.0 \pm 5.6\%$ and $28.3 \pm 5.8\%$ lysis respectively). Supernatants of cultures did not induce significant lysis of target cells.

RADIATION-INDUCED SCHWANN CELLS IN VENTRAL SPINAL CORD. S.A. Gilmore, N. Phillips*, P. White* and T.J. Sims. Dept. of Anatomy, Univ. of Arkansas for Medical Sciences, Little Rock, AR 72205-7199

Our earlier studies established that x-rays can be used to induce a predictable pattern of Schwann cell development in lumbosacral cords of immature rats. These intraspinal Schwann cells occur initially near the dorsal root entry zones between two and three weeks post-irradiation (P-I). Although intraspinal in location they undergo division, form myelin, and spread throughout the dorsal funiculi and into the dorsal gray matter. The area occupied by these cells is attained by 45 days P-I, and further spread is not evident by 60 days P-I, the longest interval studied in detail. Rarely, small clusters of cells resembling the dorsally situated intraspinal Schwann cells, but separated from them by clearly measurable distances, were noted in the ventral cord at 45 days P-I. This raised the question: do Schwann cells develop regularly but at a later post-irradiation interval in the ventral cord? This report summarizes findings from 53 rats perfused/fixated at intervals from 30 days to 7 months P-I. Interrupted, serial, transverse sections of lumbosacral cord were stained neurohistologically or immunohistochemically. Light microscopic evaluation revealed the presence of ventrally located intraspinal Schwann cells in 21 (40%) of the 53 rats. The distribution of these cells, however, was markedly different from that observed dorsally. In general, they formed small, isolated clusters which occurred more frequently in gray than in the white matter and appeared often to be closely associated with blood vessels. In a few cases a continuum of cells could be traced from the ventral root entry region, through the ventral white matter into the ventral gray matter, the usual pattern observed dorsally. Although these clusters were quite small in rats killed at the shorter intervals, they did not increase in size with a lengthening of the post-irradiation period. In summary, radiation-induced Schwann cells do occur in the ventral spinal cord but differ in many features from those noted dorsally. (Supported by NIH Grant NS-04761).

AXOPLASMIC PROTEINS OF NEURONAL AND GLIAL ORIGIN. S.L. Tanner*, E.E. Storm*, and G.D. Bittner. Dept. of Zoology, University of Texas, Austin, TX 78712.

When severed from its cell body, the distal (anucleate) stump of a medial giant axon (MGA) from the crayfish, *Procambarus clarkii*, continues to generate action potentials, retains an intact axolemma and cytoskeleton, and maintains axoplasmic proteins at a level consistent with that in an intact MGA. We are examining two mechanisms which could account for protein maintenance in an anucleate MGA: (1) axoplasmic proteins which are synthesized in the cell body and transported to the axon could have unusually long half-lives, (2) axoplasmic proteins may be renewed by proteins synthesized in glia and transferred to the axon.

To determine the relative contribution of mechanism #1 to axonal maintenance, we radiolabel MGA cell bodies and analyze the proteins in fast axonal transport within individual MGAs by SDS-PAGE/fluorography. To determine the contribution of mechanism #2, we incubate anucleate MGAs in radiolabelled amino acids and analyze by SDS-PAGE/fluorography. Although we have not yet determined turnover times of axonally transported proteins, our data suggests that glial cells are capable of synthesizing many of the proteins supplied to the MGA by axonal transport. Previous work in our lab has indicated that these proteins are transferred to the axon. Supported by NSF and TATP grants to GDB.

CHROMOSOMAL ASSIGNMENT OF A HUMAN OLIGODENDROCYTE-SCHWANN CELL MARKER GENE BY PCR AND SOUTHERN BLOTTING

T.J. Sprinkle¹, K.D. Lanclos², D.F. Lapp² & R.L. Borison³ Depts. Neurol¹, Biochem & Molec Biol², Psychiatry³, Med Coll GA & VA Med Ctr, Research Serv (151), Augusta, GA 30910 USA

Antibodies to the myelin-associated enzyme 2', 3'-cyclic nucleotide 3'-phosphohydrolase (EC 3.1.4.37, CNPase) have been useful to distinguish oligodendrocytes from astrocytes and neurons in brain and in cell culture. Although the CNS enzyme is capable of hydrolyzing over 4,000 $\mu\text{mol}/\text{min}/\text{mg}$ protein of 2', 3'-cAMP to 2'-AMP, the physiological role of this enzyme is not known. The mouse genes are located on two different chromosomes and one may be a pseudogene. In cases where chromosomal assignments are to two or more chromosomes, it is highly desirable to use non-coding flanking or intron relatively non-conserved for an unambiguous assignment. Pure intron human CNPase sequences were amplified in various somatic cell hybrid (hamster-human) DNAs in which human chromosomes 1-22, X and Y were each represented at least once in each panel. Two DNA panels were used and the PCR results were further confirmed by Southern blots on each panel as somatic and control DNA EcoRI digests. The primer pairs were selected for amplification did not amplify the host (hamster) DNA CNPase gene(s). We conclude that the human 2', 3'-cyclic nucleotide 3'-phosphohydrolase gene containing intron 3 is located on chromosome 17.

SCHWANN CELL DIFFERENTIATION IN VITRO: DIFFERENCES BETWEEN CELLS FROM ADULT RAT AND HUMAN NERVE.

T.K. Morrissey¹, N. Kleitman¹, M. Goddard², P. Aebischer², and R.P. Bunge¹. ¹The Miami Project and Dept. of Neurological Surgery, Univ. Miami School of Medicine, Miami, FL 33136 and ²Brown Univ., Artificial Organ Laboratory, Providence, RI 02912.

We recently described (Morrissey et al., J. Neurosci. in press) a method to isolate pure populations of adult derived Schwann cells (ASCs) from peripheral nerve. Rat (R-)ASCs proliferated in response to chemical and axonal mitogens and exhibited fully differentiated function, including support of neurite growth, basal lamina (BL) formation and myelination. We now report that, unexpectedly, similar culture conditions fail to support human (H-)ASC differentiation. In medium containing 10% serum, R-ASCs and monkey (M-)ASCs proliferated in response to axonal contact whereas H-ASCs did not. Coculture for 96h with either human or rat sensory axons stimulated proliferation of R- and M-ASCs (BrdU incorporation indices: 25% to 70%); neither axon stimulated H-ASC proliferation. When serum was elevated to 15% and ascorbate (0.05mg/ml) added, R-ASCs formed BL and ensheathed and myelinated both rat and human sensory axons. M-ASCs associated with neurites and formed BL, but failed to ensheath or myelinate. H-ASCs associated poorly with neurites and failed to myelinate under these culture conditions. Exploring this species variability may offer insights into the interactions between axons and Schwann cells. The conditions necessary for stimulation of full H-ASC functionality must be determined before such populations can be used clinically for transplantation into injured nerves.

A POSSIBLE ROLE FOR GLIA AND STRESS PROTEINS IN THE MAINTENANCE OF AXOPLASMIC PROTEINS. R.A. Sheller¹, B.M. Grossfeld², and G.D. Bittner¹. ¹Dept. of Zoology, University of Texas, Austin, TX 78712 and ²Dept. of Zoology, North Carolina State University, Raleigh, NC 27695

In the crayfish, *Procambarus clarkii*, the distal stumps of severed MGAs (anucleate MGAs) exhibit long term survival (LTS) for 50-200 days as measured by morphological, electrophysiological, and biochemical criteria (G.D. Bittner, TINS 14:188, 1991). MGAs are surrounded by several layers of glia which undergo hypertrophy during LTS of anucleate MGAs.

When intact or anucleate MGAs are incubated in ^{35}S -methionine, radiolabelled proteins are detected in axoplasm collected by perfusing the MGAs with an intracellular saline. Our data from SDS-PAGE analyses suggest that many radiolabelled proteins are synthesized in glia and transferred to the axoplasm of intact and anucleate MGAs. Radiolabelled actin is one such transferred protein identified with a monoclonal antibody on Western blots. Analyses of Western transfers also show that a 70 kD stress protein (SP70) may be synthesized in glia and transferred to axoplasm. Axoplasmic samples possess more SP70 immunoreactivity (N27F3-4 antibody) than glial sheath samples. The intercellular transfer of this protein may occur at a greater rate in heat shocked MGAs versus MGAs kept at room temperature. Stress proteins transferred from glia to axoplasm could be involved in the LTS of anucleate MGAs by stabilizing axoplasmic proteins. Supported by NSF and TAT grants to GDB.

BEHAVIOUR OF LABELED SCHWANN CELLS TRANSPLANTED IN A MYELIN LESION OF THE ADULT MOUSE SPINAL CORD. Baron-Van Evercooren A., Gansmuller A., Clerin E., Gumpel M. INSERM, U134, Hopital Salpêtrière, Paris, France.

In demyelination of the central nervous system (CNS), Schwann cells (Sc) participate with oligodendrocytes (O) in myelin repair. However, the modalities of intrusion of Sc into the CNS are largely unknown. The present study was designed to analyze the behaviour of transplanted Sc in response to a myelin lesion of the spinal cord. Purified rat Sc (RSc) and immortalized mouse Sc (MSc 80) were labeled prior transplantation with bisbenzimidazole (Hoechst 33342). Cells were transplanted in or at 8mm, of a 1% lysolecithin induced lesion of the shiverer mouse spinal cord. Codetection of Hoechst+ (H) RSc nuclei and P0+ peripheral myelin on cryostat sections, allowed to demonstrate that RSc transplanted in the lesion, formed myelin around host axons 7 d. post-transplantation (p.t.). Fourty d. p.t., the extent of repair had considerably increased. E.M. analysis of adjacent sections revealed that H+ RSc were associated in a 1:1 relationship with axons and were in process or had formed myelin. They were surrounded by a basement membrane and their myelin was compacted. Codetection of H+ RSc and P0+ myelin and their precise identification by E.M. on adjacent sections, allowed to demonstrate unequivocally, that the myelin of the lesion is formed by transplanted RSc and not by host ones. MSc 80 cells transplanted in the lesion are able to remyelinate demyelinated axons, to the same extent that RSc do. In addition, when transplanted at 8mm from a lesion, H+ MSc 80 were found 20 d. p.t., associated with P0+ myelin in the lesion. MSc 80 cells are thus recruited by a myelin lesion and participate, in competition with host O, to its repair. This experimental model will allow to evidence migration pathways of Sc underway towards a lesion. Supported by MSS RG 1773-B2, INSERM.

EXPRESSION OF PARVALBUMIN AFTER TRANSFECTION OF NEURONAL AND NON NEURONAL CELLS. Chr. Andressen, V. Gotzios and M.R. Celio. Institute of Histology, University of Fribourg, CH-1700 Fribourg.

Ca²⁺ in the brain plays a major role in the control of axoplasmic transport, neurotransmitter release, and neuronal excitability. Most of these phenomena are mediated or modulated by calcium binding-proteins such as parvalbumin. To understand the physiological function of parvalbumin we have manipulated its concentration in cultured cells. For this we transfected several parvalbumin-negative neuronal (PC12/Neuroblastoma) and non-neuronal (ovarian adenocarcinoma) cell lines with different constructs, leading to the expression of parvalbumin. We fused either the SV 40 promoter, the chicken β actin promoter or the inducible human metallothionein promoter with a full length cDNA of PV. To obtain a splice signal we used the SV 40 late viral protein gene 19 s splice donor/splice acceptor sequence. Transfection experiments were performed by using the CaPO₄ method and selection by G418. Cells in culture were filmed and the expression of parvalbumin was confirmed by immunohistochemistry. Transfected cells exhibited dramatic changes in their shape and in their motility as well as in the duration of their cell cycle. These results suggest that parvalbumin may be preferentially involved in the control of cytoskeletal events.

DIFFERENTIAL DISTRIBUTION OF THE HIGH MOLECULAR WEIGHT NEUROFILAMENT PROTEIN, NF-H, IN NEURONS OF DEVELOPING RAT BRAIN. M. Perazzolo^a, M.H. Lee^b, V. M-Y. Lee^b, H.M. Wisniewski^{c,c} & D. Soffer^{c,c}. ^aInstitute for Basic Research in Developmental Disabilities, Staten Island, NY 10314; ^bUniversity of Pennsylvania, Phila., PA 19104; ^cCSI/IBR Center for Developmental Neuroscience, S.I., NY 10314.

Sequential changes in the synthesis and processing of individual cytoskeletal proteins can serve as indicators of the maturation of specific groups of neurons. The neurofilament protein, NF-H appears relatively late in the development of retinal ganglion cells and spinal cord neurons and is differentially processed in different cytoplasmic domains. Western blot analysis of neurofilament proteins from tissue samples suggest that there are differential rates of appearance of the highly phosphorylated form of NF-H in different regions of developing mouse brain. Immunohistochemical analysis of serial sections of developing rat brain using phosphate dependent (RMO24.9) and independent (RMD09.5) monoclonal antibodies to NF-H allows the generation of a high resolution map of the developmental appearance of dephospho- and phospho-epitopes of NF-H. Discrete groups of neurons are labeled as early as embryonic day 18 (E18) while others do not express NF-H in their adult distribution until postnatal day 21 (P21). Our data allow the construction of a developmental map and database of the time course of expression and modification of NF-H during development and demonstrate that the NF-H gene is not homogeneously expressed in rat brain neurons during development and that NF-H protein is differentially phosphorylated in the axon as compared to perikaryon and dendrites of those cells expressing the protein.

IMMUNOCHEMICAL AND GENETIC ANALYSIS OF LAMPREY NEUROFILAMENTS. A. Jacobs, V. Lee, D. Lurie, J. Kamholz, D. Pijak, J. Garbern, M. Selzer. Dept. of Neurology & David Mahoney Institute of Neuroscience, Univ. of PA, Philadelphia, PA 19104

Unlike mammalian CNS axons, transected spinal axons of sea lampreys regenerate and their growth cones are packed with neurofilaments (NF). To study the role of lamprey NF in axonal regeneration, we are comparing them immunologically and genetically to their mammalian counterparts. Mammalian NF are heteropolymers of low-, middle- and high-molecular-weight subunits (NFL, NFM, and NFH), while lamprey NF are assembled from a single 180 kDa subunit (NF180). Immunologic evidence that lamprey NF180 is closely related to other members of the mammalian intermediate filament (IFA) family was first provided by the staining with anti-IFA mAbs of both the NF180 band on separations of lamprey spinal cord homogenates and neurons in tissue sections (Pleasure et al, 1989). To further investigate this relationship, we raised mAbs to lamprey cytoskeleton and found several which label NF180 on Western blots and stain axons in immunohistochemical sections. Thus far, two of these mAbs (LCM-3 & LCM-16) have been studied. On Western blots, LCM-3 binds NF180 and also putative cyokeratin bands of M_r 48 and 52k. This staining pattern is similar to that seen with anti-IFA. In tissue sections, LCM-3 labels large, intermediate and small axons, as well as some large dendrites. These staining characteristics lead us to believe that LCM-3 recognizes a core epitope of the lamprey NF protein. In contrast, LCM-16 does not stain the cyokeratin bands and in tissue sections, labels only large and intermediate size axons. cDNA probes for each of the mammalian NF genes were hybridized to Southern blots of lamprey genomic DNA. One to three unique hybridization bands were seen for each of the mammalian NF probes under conditions of lowered stringency, suggesting sequence similarities between the gene for lamprey NF180 and genes for each of the three mammalian NF subunits. Isolation and characterization of genomic and cDNA clones of lamprey NF gene(s) will enable us to study changes in expression of NF180 during regeneration.

BOTH HIGH AND LOW MOLECULAR WEIGHT SQUID NEUROFILAMENT PROTEINS ARE EXPRESSED FROM A SINGLE GENE BY ALTERNATIVE RNA SPLICING. James Way¹, Ben Szaro¹, Harish Pant, Philip Grant, Harold Gainer, and James Battey. Lab. of Neurochem., NINDS, NIH, Bethesda MD 20892, and ¹Dept. of Biol., SUNY Albany, Albany NY 12222.

Previous studies have shown that two low molecular weight neurofilament proteins (NF 60 and NF 70) from the squid, *Loligo Pealei*, are generated from distinct mRNAs transcribed from a single gene (Szaro et al., submitted). In this study, we have isolated cDNA clones encoding a high molecular weight neurofilament protein (putative NF 220) from a stellate ganglion cDNA library by low stringency screening using NF 60 rod domain cDNA probes. Structural analysis of these cDNAs reveals that this neurofilament protein is also generated by alternative processing of the primary transcript from the same gene that encodes the NF 60 and NF 70 proteins. All three proteins are identical in the structure of their amino terminal, lamin-like rod domains. They differ in the structure of their carboxy terminal tail sequences. In contrast to the relatively short tail segments of the NF 60 and 70 proteins, the longer tail domain of the high molecular weight neurofilament protein has multiple copies of a tandemly repeated sequence motif containing Lys-Ser-Pro (KSP). This repeated motif is similar to the tail domains of mammalian NF-M and NF-H proteins, where these serine residues are often extensively phosphorylated. Hence, diversity in neurofilament protein structure is generated in the squid by alternative RNA processing from a single gene, in contrast to mammals where it is derived from three distinct genes.

PHOSPHORYLATION, CALMODULIN BINDING AND CALPAIN-MEDIATED DEGRADATION OF INDIVIDUAL NEUROFILAMENT PROTEINS. J.A. Greenwood, J.C. Troncoso, A.C. Costello* and G.V.W. Johnson. Dept. of Psychiatry, Univ. of Alabama at Birmingham, Birmingham, AL 35294 and Depts. of Pathology and Neurology, The Johns Hopkins Univ., Baltimore, MD 21205.

Protein phosphorylation has been hypothesized to regulate neurofilament metabolism. Neurofilaments consist of three phosphoproteins with apparent molecular masses of 70 kD (NF-L), 150 kD (NF-M) and 200 kD (NF-H). Both NF-H and NF-M have extensively phosphorylated COOH-terminal domains that are highly conserved across species.

In this study, quantitative immunoblot analysis, calmodulin affinity chromatography and blot overlay techniques were used to examine the role of phosphorylation and calmodulin binding on the *in vivo* calpain-mediated degradation of the individual neurofilament proteins.

Our results indicate that the phosphorylation state of NF-M directly modulates its susceptibility to calpain hydrolysis; dephosphorylated NF-M was proteolyzed significantly faster than native NF-M. In contrast, native and dephosphorylated NF-H were apparently proteolyzed at similar rates. However, the presence of calmodulin significantly inhibited the calpain-induced degradation of native NF-H. The proteolysis of NF-M and NF-L were unaffected by the presence of calmodulin. In the presence of Ca²⁺, calmodulin selectively bound to NF-H and this association appears to be modulated by the phosphorylation state of NF-H. In a neurofilament-enriched fraction with all three subunits present, calmodulin retained its selective binding to NF-H. These results suggest that protein phosphorylation may act either directly or indirectly to regulate the *in vivo* metabolism of the two higher molecular weight neurofilament subunit proteins.

BRAIN TISSUE CONTAINS TWO ISOFORMS OF THE SPECTRIN BINDING PROTEIN AMELIN. W. E. Zimmer*, L. A. Casoria*, I. S. Zagon and S. R. Goodman. Dept. of Structural and Cellular Biology, Univ. of South Alabama, Mobile, AL 36688 and Dept. of Anatomy, The Milton S. Hershey Medical Center, Hershey, PA 17033.

Amelin is a 93 kDa spectrin binding protein found in mammalian neural cells. It was first identified as an antigenic analog of RBC protein 4.1 found in the cell bodies and dendrites of neurons, as well as in the cell bodies of certain glial cells. We have produced an antisera to the brain protein isolated from 2-D gel analysis of total brain homogenates. Our antibody demonstrated specific binding to the 93 kDa amelin protein in total brain homogenates which comigrates with purified protein, however, this antibody does not recognize RBC 4.1. The brain amelin antibody demonstrates binding with a 97 kDa protein in embryonic brain tissue which is diminished in content during mouse brain development. Additionally, a 93 kDa protein recognized by this antibody is initially expressed during the second postnatal week of development increasing in content with maximal expression found in adult brain tissue. In contrast, the same homogenates probed with anti-RBC 4.1 demonstrated significant quantities of the 93 kDa protein in embryonic brain which decreases in content during development. Moreover, our brain amelin antibody demonstrated specific antigen localization in axons within the medullary layer of adult mouse cerebellum. These data, in addition to 2-dimensional peptide mapping analyses, demonstrate that these are two isoforms of the spectrin-binding protein amelin in mammalian brain cells; one which is antigenetically similar to RBC 4.1 located in soma and dendrites, and a second which is distributed within axons of mammalian brain. This work has been supported by NIH grant #RO1 NS26536-04.

CULTURED RETINAL NEURITES IN A HYPOTONIC ENVIRONMENT. H. Takahashi¹, S. Akiya^{1*}, T. Ogata^{2*} and H. Horie³. ¹Dept. of Ophthalmol., UOEH, Kitakyushu ²Dept. of Ophthalmol., Keio Univ., Tokyo and ³Dept. of Physiology, Yokohama City Univ., Yokohama, Japan.

New glaucoma hypothesis that a hypotonic environment affects the axonal transport and that the optic nerve swells in the lamina cribrosa was reported *in vivo*. Cultured mammalian neuronal cell bodies and neurites can adapt to a hypotonic environment (Horie, et al, Brain Res 477:233, 1989; Takahashi, et al, Soc Neurosci Abstr 15:159, 1989). In this study, retinal neurons from newborn mice were cultured for 2-3 days and their neurites were analyzed by a phase contrast microscope equipped with a video-system. When a half osmolal (1/2 Na⁺) concentration of Tyrode solution was applied to neurites, they partially swelled and then recovered to the initial sizes. These swellings were strongly enhanced after 1 hr treatment with 1x10⁻⁵ M colchicine. Ultrastructural studies revealed that microtubule density was lower in the swollen than unswollen portions, and that abundant organelles, especially mitochondria and vesicles, were in the swollen portions. These suggest that the distribution of microtubules might not be homogeneous in neurites, and that there might be such specific portions in the lamina cribrosa.

158.6

DISTRIBUTION OF PLECTIN, AN INTERMEDIATE FILAMENT BINDING PROTEIN, IN THE RAT NERVOUS SYSTEM. L. Errante¹, R. Foisner^{2*}, G. Wiche² and G. Shaw¹. ¹Dept. of Neuroscience, Univ. of Florida College of Medicine, Gainesville, FL 32610 and ²Institute for Biochemistry, Univ. of Vienna, A-1090 Vienna IX, Austria.

Plectin is a 300kDa protein that was originally identified and characterized as a major component of the cytoskeleton in the rat glioma C6 cell line (Pytella and Wiche, 1980). Recent work in our laboratory has shown that a similar 300kDa protein may be a cytoskeletal component of the bovine and rat spinal cord. To further elucidate the presence of the plectin in neural tissue, mono- and polyclonal antibodies against plectin have been used to localize plectin within the rat nervous system. Preliminary results show that plectin is localized to: ependymal cells lining the ventricles, choroid plexus cells; tanyocytes of the hypothalamus; Bergmann glia cells in the cerebellum; radial glial cells in the spinal cord; a subset of astrocytes in white matter; and a subset of motoneurons within the brainstem and spinal cord. Double-label immunocytochemistry shows that plectin and vimentin are often detected in the same cell, but their distribution is distinct; plectin staining tends to be punctate whereas vimentin is filamentous. In addition plectin is concentrated in cells and cell processes lining the ventricles and close to the pia surface, suggesting a possible role in the maintenance of the blood-brain and blood-CSF barrier.

158.8

EVIDENCE ON THE ASSOCIATION OF cAMP PROTEIN KINASE WITH COLD-STABLE MICROTUBULES IN RAT CEREBRAL CORTEX. D. Tincelli*, J. Perez*, C. Cagnoli*, P. Pecini*, L. Steardo and G. Racagni. Center of Neuropharmacology, Inst. Pharmacol. Sci., Univ. of Milan, Italy.

In the central nervous system cAMP can affect microtubule functions through its effect on a cAMP protein kinase (cAMP pk, type II), bound to the microtubule associated protein 2 (MAP2). The effects of phosphorylation are well described only in the fraction that undergoes depolymerization at cold temperatures (cold-labile), during temperature dependent polymerization-depolymerization cycles.

We investigated the possible association of cAMP pk and its substrates to cold-stable microtubules from rat cerebral cortex. cAMP binding has been evaluated by photoaffinity labeling with 8-azido-[³²P]-cAMP. A cAMP receptor with apparent M_w of 52 kDa was present in cold-stable preparations. This cAMP receptor (pk R subunit) is in the inactive holoenzyme form since endogenous phosphorylation (with 5 μM cAMP) shows an increase in ³²P incorporation in different protein bands (M_w=52, 70, 280 kDa). This effect is mediated by the activation of catalytic subunit of pk since it is completely inhibited by a specific pk inhibitor. The binding of the complex 8-azido-[³²P] cAMP/RII with nitrocellulose blotted proteins of cold-stable microtubules identifies bands at 52, 70 and 280 kDa as possible substrates able to bind R subunit.

In conclusion, the results demonstrate the presence of cAMP pk in cold-stable microtubules in rat cerebral cortex.

158.10

PHOSPHORYLATION OF τ PROTEIN IN τ -TRANSFECTED 3T3 FIBROBLASTS. L. Sygowski*, A.W. Fieles*, M.M.S. Lo, A.I. Salama, V.M.-Y. Lee & C.B. Caputo. Pharm Dept., ICI Americas Inc., Wilm. DE 19897 & U of Pa Sch of Med., Phila., PA 19104.

τ phosphorylation was assessed in 2 clones of 3T3 fibroblasts stably transfected with the gene for 3 repeat human τ . Western blots of cell extracts were probed with antibodies tau-14 & tau-46. Both clones expressed τ which migrated in 2 bands that were slightly higher than the band for the same τ expressed in E.coli. No expressed τ was detected in extracts from untransfected 3T3 cells. Only the upper τ band reacted with T3P, an antibody which reacts with a phosphorylated τ epitope, while both bands reacted with tau-1, an antibody which reacts with only a non-phosphorylated τ epitope. After treating blots of cell extracts with alkaline phosphatase, the intensity of the T3P-reactive band decreased while that of both tau-1 bands increased, suggesting that some τ in the upper band is phosphorylated at both the T3P & tau-1 sites. Autoradiographs of extracts of cells labeled with ³²P-H₃PO₄ showed the higher tau-14 reactive band to be heavily labeled. Adding 8-Br-cAMP, phorbol dibutyrate and okadaic acid resulted in a small increase in the radiolabel, with 2393 dpm incorporated into τ vs. 1715 dpm for vehicle-treated cells. Thus τ -transfected 3T3 cells express τ protein, which is phosphorylated in cultured cells. This phosphorylation is enhanced slightly by adding kinase cofactors and a phosphatase inhibitor.

158.11

DIFFERENTIAL SUBCELLULAR DISTRIBUTION OF PARTICULAR mRNAs DURING THE DEVELOPMENT OF HIPPOCAMPAL NEURONS IN CULTURE R. Kleiman, G. Banker and O. Steward. Department of Neuroscience, University of Virginia, Charlottesville Virginia, 22908.

Previous studies have demonstrated a differential subcellular distribution of particular mRNAs within hippocampal neurons in culture. The mRNAs encoding actin, tubulin, and GAP-43 are confined to the cell body, whereas the message encoding the dendritic protein MAP2 is found far into the dendrites. (Kleiman et al., *Neuron*, 5:821-830, 1990). This study evaluates when during neuronal development the selective sorting of RNA into cell body or somatodendritic compartments begins.

The intracellular distribution of mRNA encoding actin, tubulin, GAP-43 and MAP2 was evaluated by *in situ* hybridization with ³⁵S-labeled cRNA probes. Neurons were fixed after 1, 2, 3, 5, 7, 10, or 14 days in culture and stored in 70% ethanol until hybridization.

Actin, tubulin, and GAP-43 mRNA was detectable in the cell bodies of cultured neurons at all developmental stages examined. These mRNAs were never detected in dendrites. Only low levels of MAP2 mRNA was detectable in neurons that were fixed at 2 or 3 days in culture and at these times there was no detectable labeling in dendrites. The level of MAP2 mRNA expression increased as a function of time in culture. Beginning at approximately 5 days, MAP2 mRNA was detected in the dendrites of a few neurons. At later time points, a larger percentage of the neurons exhibited dendritic labeling with the MAP2 probe. By 10 days in culture, most neurons exhibited significant dendritic labeling.

It is of interest that MAP2 mRNA first becomes detectable in dendrites at approximately 5 days in culture, which coincides with the beginning of significant dendritic outgrowth in these neurons. Supported by NIH NS23094 to GB and OS. RJK received a predoctoral fellowship from NIH HD07323.

SYNAPTOSOMAL RNA: ASSESSMENT OF CONTAMINATION BY GLIA AND COMPARISON WITH TOTAL RNA. A. Rao and O. Steward. Dept. of Neuroscience and Neurosurgery, Univ. Of Virginia Health Sciences Center, Charlottesville, VA 22908

Previous studies suggest that synaptosomes include dendritic fragments which contain RNA, amongst which are mRNAs that encode synaptic proteins (Rao and Steward, *J. Neurosci.*, in press). Thus, synaptosomes may be a source for the population of mRNAs that are localized in dendrites (Chicurel et al., 1990). However, synaptosomes may be contaminated by fragments of glia. In the present study we evaluate: 1) the degree of contamination of synaptosomal RNA by mRNA from glia. 2) the overall complement of synaptosomal mRNA compared to mRNA from cell body fractions or from whole brain.

Total RNA was isolated from synaptosome and cell body (P1) fractions from young rats, and from whole forebrains. Levels of GFAP mRNA (which is specific to astrocytes) were assessed by Northern and dot blot hybridization. Levels of mRNA for the alpha subunit of CAM kinase2 were assessed as a positive control, since this mRNA is known to be present in dendrites (Burgin et al., 1990, *J. Neurosci.*, 10,1788). Overall mRNA complexity was evaluated using a reticulocyte lysate system, and comparing the pattern of labeled polypeptides using PAGE-fluorography. The mRNA for CAM kinase was detected in all three samples, as was the mRNA for GFAP. These results suggest that mRNA from astrocytes is a significant contaminant of synaptosomal RNA. Fluorographic analysis of the translation products revealed fewer labeled bands in synaptosomes compared to whole brain and differences between the three samples in the pattern of labeled bands. These results support previous suggestions that synaptosomes contain a complement of mRNAs that is different from that found in total tissue RNA. Supported by NIH NS12333 to O.S.

REGULATION OF GENE EXPRESSION II

159.1

PARAMETERS AFFECTING THE USE OF HUMAN POSTMORTEM BRAIN FOR MOLECULAR BIOLOGICAL STUDIES.

S. Leonard, J. Logel, D. Luthman*, M. Casanova, D. Kirch and R. Freedman. Veterans Administration Medical Center, Denver, Colorado, and Division of Clinical Research, NIMH, Washington, D. C.

The isolation of RNA from human postmortem brain tissue is a necessary procedure for the study of gene expression and preparation of cDNA libraries. We have evaluated the competence of RNA, isolated from human brain stored for various periods at -70°C, for use in molecular biological studies. mRNA was quantitated by two separate methods: Northern blot hybridization and quantitative analysis of polymerase chain reaction products. Biological activity was assessed both by cDNA synthesis and *in vitro* translation. Neither postmortem interval nor holding of tissue on wet ice for short periods affect the quality of the RNA. However, results suggest that prolonged freezer storage of postmortem human brain will preclude its use for library construction or *in vitro* expression, but not for isolation of nucleotide sequences or evaluation of gene expression by PCR.

159.3

ACTIN AND TUBULIN ARE COMPONENTS OF A HETEROGENEOUS mRNA POPULATION PRESENT IN THE SQUID GIANT AXON. A. Gioio, C. Perrone*, M. Crispino*, A. Giuditta, and B. Kaplan. Dept. of Psychiatry, Univ. of Pittsburgh, Pittsburgh, PA 15213.

Previously we have reported that the squid giant axon contains a biologically active population of poly(A)⁺mRNAs and polyribosomes (see Giuditta et al. 1991 *J. Neurosci. Res.* 28:18). The sequence complexity of this RNA population is sufficient to encode ca. 100-200 different mRNA species. To initiate characterization of the axonal mRNA population, a cDNA library was constructed in a λ -Zap vector using a modification of the Gubler-Hoffman method. The library contained ca. 1.6×10^5 pfu with insert sizes ranging from 600-4000 bp in length. Dideoxy sequence analysis of several relatively abundant clones yielded cDNAs encoding β -actin and β -tubulin. The actin and tubulin cDNAs were ca. 1.8 and 2.0 kb in length, respectively and contained the entire coding portions of the cognate mRNAs. The predicted amino acid sequence of squid actin and tubulin share $\geq 95\%$ sequence identity to the mammalian forms of the protein. Results of *in situ* hybridization analyses provide additional evidence for the axonal localization of these mRNAs. Taken together, these findings (1) provide direct evidence for the existence of mRNAs in the squid giant axon, (2) establish the identity of two components of the axonal mRNA population, and (3) raise the possibility that key elements of the cytoskeleton are synthesized locally in the squid giant axon.

159.2

mRNA AT THE SYNAPSE: ANALYSIS OF A PREPARATION ENRICHED IN HIPPOCAMPAL DENDRITIC SPINE mRNA. M.E. Chicurel¹, D.M. Terrian², K.M. Harris³ and H. Potter¹. ¹Program in Neuroscience, Dept. of Neurobiology, Harvard Medical School, Boston, MA 02115. ²Dept. Anatomy and Cellular Biology, East Carolina University Sch. of Medicine, Greenville, NC 27858. ³Dept. of Neurology Research, Children's Hospital, Boston, MA 02115.

Synaptic transmission and its regulation involves multiple neurotransmitters/neuromodulators, ligand receptors, ion channels and intracellular second messengers. The nature, function and regulation of another kind of synapse-associated molecule—mRNA—is only beginning to be appreciated. In addition to the cell body, mRNA is found in dendrites and astrocytic processes and may be specifically targeted to these locations to direct local protein synthesis. We have found that a specific mRNA population is closely associated with a synapse in the vertebrate CNS. Specifically, our anatomical data indicate that the branched spines of the mossy fiber (MF)-CA3 hippocampal synapse contain a large number of polyribosomes. Because of their unusual association with the MF boutons, the branched spines can be isolated as part of a synaptosomal complex that includes the MF boutons and the fine astrocytic processes associated with this synapse. We have been able to prepare and analyze intact mRNA from this synaptosome preparation. The results indicate that certain mRNAs (mRNAs coding for CaM kinase II and MAP-2, for example) are enriched in the synaptosomal complex preparation as compared to the total hippocampus; other mRNAs are less prevalent or altogether absent (i.e., mRNAs coding for synaptophysin, the Glu-RK1 kainate receptor, and tubulin). A subtractive hybridization protocol was designed to identify and clone mRNAs localized in the dendritic spines (rather than the astrocytic processes) and these are now being analyzed. In summary, our results suggest that a *localized* translational regulation of gene expression may be important in establishing and modulating synaptic function. Supported by the NIH. MULTIPLE MRNA SPECIES OF THE TYPE I CORTICOSTEROID RECEPTOR EXIST IN THE RAT HIPPOCAMPUS. S.P. Kwak, P.D. Patel, H. Akil, and S.J. Watson. Mental Health Research Institute, University of Michigan, Ann Arbor, MI 48109.

Cloning of the type I, mineralocorticoid receptor cDNA from the rat hippocampus (Patel et al. *Mol. Endo.* 3:1877, '89) revealed that the 5' untranslated region (5'UT) of this clone (β) varied significantly from the 5'UT of the species present in human kidney (α) described by Arriza et al. (*Science*, 237:268, '87). The β UT exon was subsequently found 2Kb upstream of the α exon on the rat MR gene (Patel et al. *Neurosci. Abst.* 1989). Results from RNase protection studies indicate that these two species account for approximately 60% of the total type I receptor mRNA pool, suggesting that other 5' variants of the mRNA exist.

We have employed "rapid amplification of cDNA ends" (RACE) reaction (Frohman et al., *PNAS* 85:8998, '88) to identify other 5'UT variants of the type I receptor mRNA in the hippocampus. Oligonucleotides complementary to a region within the open reading frame (common to all variants) were used to generate a cDNA pool. After a second round of amplification by polymerase chain reaction, we isolated a cDNA variant of the type I receptor mRNA which contained a unique 5'UT of 130bp. The new 5'UT (γ) exon was localized ~500bp upstream of the β exon on the type I receptor gene by southern blot analysis. RNase protection assay revealed that this variant was rarely expressed (<5% of the total type I mRNA) in normal animals. We are currently isolating other 5'UT variants of the type I receptor mRNA in the hippocampus.

TWO NOVEL POU SEQUENCES ARE PRESENT IN THE DEVELOPING RAT CNS AND PERIPHERY. *W.S. Young, III, C. Le Moine, and D.J. Bradley.* Lab. of Cell Biology, NIMH, Bethesda, MD 20892

The family of POU transacting factors present in the CNS was expanded by He et al. (Nature 340:35) who used PCR to clone 4 new sequences and suggested the presence of many more. We used primers based on the sequence at the 5' and 3' ends, either exactly for the SCIP (Tst-1) POU-domain or degenerate (courtesy Dr. S. Sato, NIH) for the class III POU domain. We isolated two clones whose identities are different from previously describe class III POU genes. Over the POU domains, RHS-1 differs in only one amino acid each from human Brm-1 and Brm-2, whereas RHS-2 differs by 6 and 4, respectively. They differ from each other and SCIP at the nucleotide level by about 20-25%. Northern analyses of total rat brain RNA using ³²P-labeled oligonucleotide probes detected bands of 3.9 and 3.3kb for RHS-1 and RHS-2, respectively.

The sequences were inserted into pGEM vectors from which ³⁵S-riboprobes were generated for hybridization histochemistry. RHS-1 and RHS-2 probes detected mRNA in rat neuroectoderm as early as embryonic days 9.5 (especially cranial) and 11.5, respectively. Transcripts were detected throughout the rat CNS into adulthood. RHS-1, to a much greater degree than RHS-2, also detected mRNA in developing peripheral tissues, especially in the kidney and developing bone. Both probes labeled mRNA in different locations about the vibrissae Anlagen. These probes are unlikely to cross-hybridize to each other under our conditions, but they may detect other POU sequences. These concerns and functional studies will be better studied with full-length clones.

ESCAPE FROM TRANSLATIONAL DEGRADATION: THE NEURONAL GROWTH-ASSOCIATED ALPHA-TUBULIN mRNA, α T₁, IS PREFERENTIALLY STABILIZED IN PC12 CELLS. *J.G. Toma and F.D. Miller.* Dept. of Anat. and Cell Biol., Univ. of Alberta, Edmonton, Alberta, CANADA.

Both α - and β -tubulin mRNAs are posttranscriptionally regulated: as the intracellular tubulin monomer:polymer ratio increases the partially-translated mRNA is degraded on the ribosome (Cleveland D.W. TIBS, 13:339, 1988). We have previously demonstrated that two α -tubulin mRNAs encoding virtually identical proteins are differentially regulated in mammalian neurons. α T₁ α -tubulin mRNA is expressed at high levels during the growth of developing and mature neurons, while T26 mRNA is constitutively expressed. In this study, we have examined the post-transcriptional regulation of these two mRNAs in C6 glioma and PC12 cells. Northern blot analysis indicates that, in C6 glioma cells, agents that increase the monomer:polymer tubulin ratio, such as colchicine and nocodazole, lead to decreased steady-state levels of both α T₁ and T26 mRNAs. In contrast, in PC12 cells, treatment with these same two drugs decreases the levels of T26 mRNA, but does not affect the levels of α T₁ mRNA. The preferential stabilization of α T₁ α -tubulin mRNA occurs in the presence or absence of NGF. Thus, this one particular tubulin mRNA escapes translational degradation in a cell-type specific manner, possibly as a cellular mechanism for maintaining high levels of tubulin synthesis during neuronal growth. Since the nucleotide sequences of α T₁ and T26 mRNAs are virtually identical over the entire coding region, we are currently swapping the 5' and 3' untranslated regions, in an attempt to map the sequences that confer this "escape".

THE DIFFERENTIAL REGULATION OF GLIAL-SPECIFIC GENE EXPRESSION BY IL-6 AND RETINOIC ACID IN C6 GLIOMA CELLS. *W.A. Schreier and J. de Vellis.* UCLA Mental Retardation Research Center, Los Angeles, CA 90024, USA.

We have studied the effects of two differentiating agents, Interleukin-6 (IL-6) and retinoic acid (RA), on the regulation of the expression of three glial-specific genes in the C6 rat glioma cell line. Glutamine synthetase (GS, E.C.6.3.1.2) and glycerol phosphate dehydrogenase (GPDH, E.C.1.1.1.8) are differentially regulated by IL-6 and RA. A 24 hour treatment of confluent C6 cultures with 50 U/ml IL-6 induces a 40-60% increase in GS enzymatic activity, and causes a 20-40% decrease in GPDH activity. IL-6 treatment also causes a 40% decrease in GPDH mRNA levels. In contrast, RA treatment causes a 20-60% decrease in GS activity, and induces a 60-100% increase in GPDH activity. RA produces a slight (20%) increase in GPDH mRNA levels, which is enhanced 80% by cycloheximide (10 μ g/ml). IL-6 causes a 2-fold increase in the astrocyte-specific intermediate filament protein, GFAP, as measured by immunoblotting, and a 2-fold increase in GFAP mRNA which is completely blocked by cycloheximide. RA produces no detectable increase in GFAP protein, but does cause a 30% increase in GFAP mRNA which is also blocked by cycloheximide.

The elucidation of the mechanisms by which these factors differentially regulate astrocyte and oligodendrocyte specific genes will hopefully yield some insight into normal gliogenesis and cell differentiation.

SEQUENCE ANALYSIS OF VASOPRESSIN mRNAs IN THE HOMOZYGOUS BRATTLEBORO RAT WHICH CODE FOR GLYCOPEPTIDE IMMUNOREACTIVITY. *A.P. Evans*, R. Ivell*, F.W. Van Leeuwen*, M. Corner and J.P.H. Burbach*.* Rudolf Magnus Institute, University of Utrecht, Utrecht, The Netherlands, and ²Institute for Hormone and Fertility Research, Hamburg, F.R.G., and ³Netherlands Institute for Brain Research, Amsterdam, The Netherlands.

A single base deletion in the vasopressin (VP) gene is the cause of diabetes insipidus (di) in the homozygous (di/di) Brattleboro rat. The di/di rat expresses a mutant VP precursor with an altered C-terminus. A striking feature of the di/di rat is the appearance of apparently normal VP gene products together with the mutant precursor protein in solitary hypothalamic neurons. The di/+ phenotype of these VP neurons in the di/di rat suggests the existence of VP mRNAs which code for the normal VP precursor protein (Van Leeuwen et al. PNAS 1989: 86, 6417). The aim of the present study was to elucidate the nucleotide sequence of these VP mRNAs of the di/di rat. The strategy used included specific amplification of VP cDNAs by PCR, followed by cloning of VP cDNAs in an expression vector. Clones containing VP cDNAs with restored reading frame were selected by immunoscreening using a rat glycopeptide antiserum. Sequence data, obtained so far on a limited number of clones, indicate that single nucleotide insertions in the mutated VP mRNA are present. These preliminary findings can explain the presence of normally immunoreactive VP gene products in the di/di rat.

EFFECT OF DOPAMINERGIC TREATMENTS ON PREPROENKEPHALIN (ppENK) mRNA EXPRESSION: ADRENAL VS. STRIATUM.

J.D. DeCristofaro, Y. Sharon and E.F. La Gamma. Dept of Peds and Neurobiology, SUNY at Stony Brook, NY.

Dopaminergic pathways are known to regulate expression of ppENK mRNA in the striatum. Treatments with D1 antagonists or D2 agonists result in enhanced expression (TINS 13:244, 1990). We sought to determine whether there was a synergistic effect when both D1 antagonist and D2 agonist were given simultaneously and whether there was any effect on ppENK mRNA in the adrenal medulla which also has dopaminergic receptors. Eight adult male Sprague-Dawley rats were divided into four groups: Vehicle treated, D1 antagonist SCH 23390 (50 μ g/kg/dose), D2 agonist LY171555 (1 mg/kg/dose), or both D1 and D2 treated. Rats were treated twice daily for 7 days subcutaneously. Treatment with the D1 antagonist alone or D2 agonist alone resulted in significant increases in striatal ppENK mRNA levels as previously reported, but little change in adrenal ppENK levels. When given together striatal ppENK mRNA levels also increased, but no more than with either agent alone. The combined effect on the adrenal was more dramatic, decreasing ppENK mRNA levels to undetectable, without influencing adrenal TH mRNA. This suggests that dopaminergic signal transduction mechanisms differ in these tissues and that transmitter regulation of transplanted adrenal tissue into the striatal region may be unpredictable.

159.10

REGULATION OF VASOACTIVE INTESTINAL POLYPEPTIDE GENE EXPRESSION BY CALCIUM INFLUX. *E.M. Adler* and J.S. Fink.* Molecular Neurobiology Lab, Massachusetts General Hospital, Charlestown, MA 02129.

Second messenger regulation of gene expression provides a means by which cells can transduce environmental stimuli into long-term changes in phenotype. Synthesis of vasoactive intestinal peptide (VIP) is stimulated by activation of 2nd messenger pathways, including cAMP, protein kinase C and calcium (Ca). cAMP and kinase C activation enhance VIP gene transcription through a 17-bp DNA sequence termed the cAMP-responsive element (CRE, JBC 262:8743, PNAS 85:6662). To determine if Ca also activates VIP transcription, confluent cells of the VIPergic neuroblastoma cell line SH-SY5Y were exposed to 60 mM KCl or 5 μ M A23187. VIP mRNA levels, measured by Northern blot using a VIP cRNA probe, increased 2-fold to KCl and 20-fold to A23187, demonstrating that Ca stimuli enhance VIP transcription. Ca and cAMP also interacted to regulate VIP gene expression: VIP mRNA was induced 9-fold by forskolin (10 μ M) and isobutylmethylxanthine (IBMX, 0.5 mM) alone, 12-fold by forskolin and IBMX together with 60 mM KCl, and 22-fold by forskolin, IBMX and A23187. To determine if the CRE could mediate transcriptional activation by Ca, PC12 cells stably transfected with the CRE linked to the reporter gene chloramphenicol acetyltransferase (CAT) were studied. Treatment with 30 or 60 mM KCl or 5 μ M A23187 alone had no effect on CAT activity, either in undifferentiated cells or when cells were differentiated for 3 days by exposure to 50 ng/ml nerve growth factor, but Ca stimuli (30 mM KCl or 5 μ M A23187) markedly enhanced the effect of 10 μ M forskolin. These data demonstrate that Ca influx activates VIP gene transcription and that Ca and cAMP stimuli interact at the CRE to activate transcription. The ability of a Ca stimulus alone to activate VIP gene transcription in SH-SY5Y cells may reflect a 2nd Ca-responsive element outside the CRE, indirect elevation of cAMP by Ca in this line, or differences in basal levels of kinase/phosphatase activity or transcription factor expression in different cell lines.

159.11

c-AMP REGULATES GAD₆₇ GENE EXPRESSION IN C6 CELLS. J. Segovia, N.J.K. Tillakaratne and A.J. Tobin. Department of Biology, Brain Research Institute, and Molecular Biology Institute, University of California, Los Angeles, CA 90024.

Dopamine deafferentation with 6-OHDA leads to an increase, in the ipsilateral striatum, of the mRNA encoding GAD₆₇, one of the two forms of glutamate decarboxylase, with parallel changes in GAD activity. We are now testing the hypothesis that alterations in GAD₆₇ mRNA depend on changes in cAMP. We have employed the C6 rat cell line, which expresses GAD₆₇ mRNA and possesses GAD activity. Our preliminary results indicate that GAD activity and GAD mRNA levels can be regulated by increasing cAMP levels. Both the addition of dibutyryl cAMP (1 mM) into the culture media and forskolin (50 μM) lead to a marked decrease of GAD activity. Northern blot analysis shows comparable decreases in GAD₆₇ mRNA levels after these treatments. (Supported by NIH grants NS20356 & NS22256)

DOPAMINE RECEPTOR AGONISTS INDUCED THE EXPRESSION OF DYNORPHIN AND c-Fos IN PRIMARY CELL CULTURES OF RAT X-P HE* and J.S. Hong LMIN, NIEHS/NIH, Research Triangle Park, NC 27709

The effects of dopamine receptor agonists on the expression of dynorphin(DYN) and Fos or Fos-related antigens (FRA) were studied in primary striatal cultures from rats. Cultures were established on poly-L-lysine-coated plastic 4-chamber slides from 7-day-old pups. Levels of DYN, c-Fos or FRA immunoreactivities and their mRNAs were investigated using immunocytochemical and *in situ* hybridization techniques (ISH). Activation of DA receptors by apomorphine, a mixed D1 and D2 agonist, at 10 mM, bid, (3 daily administration for peptide and 1 day administration for mRNA) resulted in an increase in number of DYN⁺ cells in striatal cultures. Apomorphine treatment also induced c-Fos and FRA staining, and its maximal effect appeared about 4 hours after administration. ISH experiments showed the maximal induction of c-Fos mRNA 2.5 h after treatment. The specific D1 dopamine receptor agonist, SKF 38393, but not the specific D2 dopamine receptor agonist, quinpirole, increased the level of striatal c-Fos message. In order to further understand the cellular mechanisms underlying the regulation of DYN expression by the dopamine system, the effects of forskolin, a cAMP activator, on DYN and c-Fos were examined. Forskolin induced an increase in number of both DYN⁺ and c-Fos⁺ cells, indicating that cAMP may be involved in the regulation of c-Fos and DYN expression.

LONG-TERM POTENTIATION: PROTEIN KINASES AND SECOND MESSENGERS

DETECTION OF THE THR²⁸⁶- OR THR²⁸⁷-AUTOPHOSPHORYLATED Ca²⁺/CALMODULIN-DEPENDENT PROTEIN KINASE II BY A SPECIFIC ANTIBODY. T. Suzuki¹, K. Okumura-Noji¹, A. Ogura², Y. Kudo², & R. Tanaka¹ ¹Dept. of Biochem., Nagoya City Univ. Med. Sch., Nagoya 467, Japan, ² Mitsubishi Kasei Inst. of Life Sci., Tokyo 194, Japan

The antibody specific to the Ca²⁺/calmodulin-dependent protein kinase II (CaM KII) which had been autophosphorylated only at the site of Thr²⁸⁶ of the α-subunit was prepared as follows. The peptide Y-66 with a sequence of Met²⁸¹ to Cys²⁸⁹ of the α-subunit was synthesized and its Thr residue was phosphorylated by the CaM KII. The phosphorylated Y-66 (PY-66) was purified, and used as an immunogen after coupling to hemocyanine. IgG was purified after removal of anti-hemocyanine and anti-Y-66. ELISA proved that the IgG obtained reacted specifically with PY-66. Western blot showed that the antibody reacted specifically to the autophosphorylated CaM KII both in purified and PSD-bound form. Immunocytochemistry showed clearly the CaM KII autophosphorylation in the cultured hippocampal neurons treated with NMDA.

Induction of c-fos mRNA following electroconvulsive shocks in rat cerebellum. Y.S.Kim^{1*}, J.B.Park^{2*}, C.D.Bae^{2*}, J.Kim³ and P.G.Suh^{4*} Dept. of Psychiatry¹, Biochemistry² and Physiology³, Seoul Natl.Univ.College of Med., Seoul, Korea, 110 and Dept. of Life Sci⁴, POSTECH, Pohang, Korea 790.

We examined the possible refractory period or down-regulation on the induction of c-fos mRNA following electroconvulsive shocks (ECS) in rat cerebellum by Northern analysis with total RNA.

We confirmed that single ECS induces the expression of c-fos mRNA. When we administered two consecutive ECS spaced 2hr, the second ECS could induce the expression of c-fos mRNA. This suggests that the first ECS does not result in an apparent refractory period to the second ECS on the induction of c-fos mRNA. And when we examined the effect of chronic ECS on the induction of c-fos mRNA, we were able to observe the induction of c-fos mRNA even after 5 and 10 daily ECS. According to our observations with chronic ECS, there were no apparent down-regulation on the c-fos expression by multiple daily induction of the gene.

159.14

c-FOS IS SPONTANEOUSLY INDUCED IN THE RAT BRAIN IN THE ACTIVITY PERIOD OF THE CIRCADIAN CYCLE.

G. Grassi Zucconi, M. Menegazzi¹, A. Carcereri de Prati¹, C. Cosi¹, M. Bentivoglio². Istituto Biologia Cellulare, Università di Perugia, Istituto Chimica Biologica and Istituto Anatomia Umana, Università di Verona, ITALY.

A rapid and transient induction of c-fos in response to several different stimuli has been reported on neuronal cell cultures, as well as *in vivo* in the CNS. Altogether these findings have pointed to c-fos as a high resolution marker of neuronal activity, and suggest that c-fos could also monitor physiological states of CNS activity. The brain undergoes a spontaneous alternation of activity and rest cycles, coincident in part with the sleep-wakefulness cycle. We investigated the possible correspondence between these circadian oscillations and c-fos mRNA levels in different brain areas. Preliminary findings, based on Northern blot hybridization with a ³²P labelled v-fos cDNA probe, indicate a spontaneous induction of c-fos in various CNS areas at 9 pm, 1 am, and 5 am, corresponding in the rat to states of prevalent alertness and wakefulness. The expression of c-fos is low or absent during the light hours (9 am, 1 pm, 5 pm). The highest expression appears at 9 pm, when the behavioural observation reveals awakening and intense motor activity. The signal is higher in the brainstem and cerebellum, and lower in cerebral cortex, thalamus and hippocampus. Previous studies on this aspect were based on c-fos induction in the suprachiasmatic nucleus by the photic stimulation. We here report for the first time a spontaneous induction of c-fos in several CNS areas, coincident with the period of activity of the rat. Immunohistochemical and *in situ* hybridization studies are now in progress.

160.2

LTP INDUCED BY TETRAETHYL AMMONIUM INCREASES SYNAPSIN I PHOSPHORYLATION AT ITS CAM KINASE II SITES. E.M. Dudek, C. Moore^{*}, K. Miller^{*} and M.D. Browning, Dept. of Pharmacology, Univ. of Colorado Hlth. Sci. Cntr., Denver, CO 80262

Long-term potentiation (LTP) is a form of synaptic plasticity that is widely thought to underlie certain forms of learning. Clear evidence has shown that LTP involves increases in transmitter release, but little is known about the molecular mechanisms which underlie this enhanced release. Protein phosphorylation is widely recognized as the primary molecular mechanism for regulation of protein function and a family of phosphoproteins known as the synapsins have been shown to regulate transmitter release. We have tested the possibility that synapsin phosphorylation might play a role in the increased transmitter release seen with LTP. We have focussed in these studies on LTP that is induced by tetraethyl ammonium (TEA) (Aniksztejn and Ben-Ari, Nature 349:67-69, 1991) and have confirmed that TEA produces long-lasting potentiation of the field epp in CA1 mini-slices. In parallel experiments, CA1 slices were incubated in the absence or presence of 25 mM TEA and then homogenized in 5 mM zinc acetate. The synapsin proteins were then extracted and assayed in a modification of the back phosphorylation assay of Forn and Greengard (PNAS 75:5195, 1978). Ca²⁺/calmodulin kinase II (CAM kinase II) is inactive in the extracts used for the Forn and Greengard assay. This is likely to be due to residual zinc in the extracts, as we have found that zinc is a potent inhibitor of CAM kinase II (K_i ~4 μM). Therefore we have exhaustively dialyzed the extracts before the back phosphorylation assay. Using this modification of the assay we have found that the basal level of synapsin phosphorylation in hippocampal slices is quite low but that TEA incubation leads to a significant increase in the phosphorylation state of the CAM kinase II sites on synapsin I. Supported by PHS grant NS26377.

160.3

ACTIVATION OF Ca²⁺/CALMODULIN-DEPENDENT PROTEIN KINASE II AND PROTEIN KINASE C BY GLUTAMATE IN CULTURED HIPPOCAMPAL NEURONS.

¹K. Fukunaga, ²T.R. Soderling and ¹E. Miyamoto*, ¹Dept. of Pharmacol., Kumamoto Univ. Med. Sch., Kumamoto 860, Japan, ²Vollum Institute, Oregon Health Sciences Univ. Portland, Oregon, 97201 U.S.A.

The role of Ca²⁺/calmodulin-dependent protein kinase II (CaM kinase II) and protein kinase C (PKC) has been implicated in the induction of long-term potentiation (LTP) in the CA1 region of the hippocampus. Furthermore, the persistent activation of the protein kinases has been reported to be important for the maintenance of LTP. We have investigated the activation mechanisms of CaM kinase II and PKC by glutamate in cultured hippocampal neurons. Glutamate did elevate the Ca²⁺-independent activity of CaM kinase II. The response was potentiated by the addition of 1 μM glycine and by the removal of extracellular Mg²⁺, and blocked by the specific antagonists of NMDA receptor, indicating the involvement of the NMDA receptor. In addition, glutamate stimulated the translocation of PKC from the cytosol to the membrane fraction. The effect was not blocked by NMDA receptor antagonists and partially blocked by DL-2-amino-3-phosphonopropionate, and quisqualate or (trans)-1-amino-cyclopentyl-1,3-dicarboxylate produced a similar effect on the translocation of PKC, showing the action of the metabotropic quisqualate receptor. These results suggest that glutamate can activate CaM kinase II and PKC through the ionotropic NMDA receptor and the metabotropic quisqualate receptor, respectively, and induce the LTP in the hippocampal neurons.

160.5

INDUCTION OF LONG-TERM POTENTIATION (LTP) IN THE RAT SUPERIOR CERVICAL GANGLIA (SCG) BY THE PRESYNAPTIC ACTIVATION OF PROTEIN KINASE C (PKC). T.J. Heppner¹, M. Bachoo², J.F. Fiekers¹, and C. Polosa². ¹Anat. & Neurobiol. Dept., Coll. Med., Univ. VT, Burlington, VT, 05405, U.S.A. ²Physiol. Dept., McGill Univ., Montreal, Canada H3G 1Y6.

The action of phorbol 12,13 dibutyrate (PDBu) was examined on the isolated SCG of adult Sprague-Dawley rats using extracellular and intracellular recording techniques. PDBu increased the postsynaptic compound action potential (CAP) amplitude for nearly 2 hours. Inactive phorbols did not activate LTP and pretreatment with H7 blocked the induction of LTP by PDBu. The concentration of Mg²⁺ required to block the CAP amplitude at 50% of control was significantly increased in PDBu. Intracellular recordings from SCG neurons showed an increase in the average amplitude of unitary EPSPs to 263 ± 39% (n=7) of control after PDBu addition. An increase in quantal content without significant changes in the input resistance, membrane potential, threshold and the amplitude of the ACh-induced potentials, suggests that LTP is mediated by the activation of PKC in presynaptic terminals. This work supported by NIH grant#NS 27319 to JFF and MRC #MT-2475 to CP.

160.7

LTP IS ASSOCIATED WITH A PERSISTENTLY ACTIVATED FORM OF PKC PRESENT IN THE CYTOSOLIC FRACTION. E. Klann, S.J. Chen and J.D. Sweatt. Div. of Neuroscience, Baylor College of Medicine, Houston, Texas, 77030.

We have previously reported that the maintenance phase of long-term potentiation (LTP) in area CA1 is associated with an NMDA receptor-mediated, persistent increase in protein kinase activity (Soc. Neurosci. Abstr. 16:144, 1990). We have further investigated this phenomenon by measuring the phosphorylation of selective synthetic peptide substrates for protein kinase C (PKC) and the Ca²⁺/calmodulin-dependent protein kinase (CaMKII). LTP of the Schaffer collateral input into area CA1 of rat hippocampal slices was studied. Slices were frozen, dissected and homogenized in buffer containing 50 mM HEPES, pH 7.4, 10 mM MgCl₂, 1 mM EGTA and 1 mM EDTA. Kinase reaction mixtures contained homogenate, 1 mM Na⁺ pyrophosphate, 100 μM ³²P-ATP and either 7.5 μM S6(229-249), a selective substrate for PKC, or 8.3 μM [Arg³-GS(1-10)], a selective substrate for CaMKII. We detected an LTP-associated increase in phosphorylation of S6(229-249) (259±38% of control, n=10), that was blocked by the addition of 1 μM PKC(19-36), a selective peptide inhibitor of PKC (- PKC(19-36), 343±69% of control; + PKC(19-36), 184±78% of control, n=4). In contrast, we detected only a slight increase in [Arg³-GS(1-10)] peptide phosphorylation (141±26% of control, n=5). These results suggest that PKC activity rather than CaMKII activity is elevated. To localize the elevated PKC activity, control and LTP homogenates were centrifuged at 133,000 g for 45 minutes and separated into pellet and soluble fractions. Fractions were assayed using either S6(229-249) or myosin light chain as the substrate. Homogenates exhibited an LTP-associated increase in substrate phosphorylation (244±42% of control, n=6) as did the soluble fraction (237±69% of control). The pellet fraction showed no increase in substrate phosphorylation (118±13% of control). These findings suggest that a novel, persistently active, cytosolic form of PKC is associated with the maintenance phase of LTP. This work was supported by the McKnight and Klingenstein Foundations.

160.4

TOWARD A FUNCTION FOR THE RC3 PROTEIN; A POST SYNAPTIC, CALMODULIN BINDING, PROTEIN KINASE C SUBSTRATE WHICH IS A PUTATIVE COMPONENT OF LTP. D.D. Gerendasy, K. Wong, J.G. Sutcliffe. Dept. Molecular Biology, Research Institute of Scripps Clinic, La Jolla, CA 92037.

The RC3 mRNA, isolated by subtractive hybridization, encodes a 78 AA protein, highly conserved among mouse, rat and cow, which has a region of homology with GAP-43/b50/F1. Like GAP-43, the RC3 protein (independently identified by Baudier and colleagues as neurogranin) is a substrate for protein kinase C and binds calmodulin in the absence of Ca²⁺. RC3 exhibits a postnatal onset and is significantly enriched in the cerebral cortex, striatum and hippocampus where it is primarily localized to dendrites in association with post-synaptic densities. These qualities suggest the hypothesis that it plays a postsynaptic role with respect to LTP, memory and associative learning.

We have expressed RC3 in bacteria and purified it to homogeneity. The recombinant protein binds to calmodulin in the absence of Ca²⁺ and serves as a substrate for protein kinase C in vitro. This preparation is suitable for structural (NMR and X-ray crystallography) and electro-physiological (microinjection into hippocampal brain slice neurons) studies.

Studies are also in progress to create transgenic mouse lines which display a spectrum of RC3 expression. To date, we have generated one mouse line which contains, integrated into its genome, an anti-RC3 ribozyme under the control of the neuron specific enolase promoter. Experiments are currently underway to determine whether this ribozyme is expressed and is able to depress RC3 expression. If our hypothesis is correct, mutant mice are expected to display memory and/or learning deficits.

160.6

PREFERENTIAL INVOLVEMENT OF PKC(α) IN THE LTP MODEL OF SYNAPTIC PLASTICITY. M. Sundsmo¹*, U. Staubli², D. Otero¹*, G. Cole¹, and T. Saitoh¹. ¹Univ. California, San Diego, Dept. of Neurosciences, La Jolla, CA 92093 and ²McGill University, Dept. of Psychology, Montreal, QC H3A 1B1.

Phosphorylation of ion channels, receptors, cytoskeletal proteins, and other proteins by PKC has been suggested to play an important role in CNS synaptic plasticity. PKC exists in at least 8 isoforms, four Ca²⁺-dependent and four Ca²⁺-independent enzymes. This study will attempt to delineate which of four Ca²⁺-dependent PKC isoforms (α, βI, βII, and γ) are involved in hippocampal LTP expression. Asymptotic levels of LTP were produced in 5 freely-moving rats with 4 episodes of high frequency stimulation to the lateral perforant path (ten trains of ten 400 Hz pulses repeated at 3, 24 and 27 hours). Low frequency stimulation was given to 5 control animals (100 pulses, one per 15 sec). Hippocampi were removed one hour after the last stimulation episode. PKC concentration and distribution were determined by Western blotting using affinity purified polyclonal antibodies against peptides specific for each isozyme. We found a reduction in PKC(α) in the particulate fraction from the LTP-induced animals when compared to the control group receiving only low frequency stimulation. Our data suggest involvement of PKC(α) in this modification of synaptic transmission. Immunohistochemical localization of the various isoforms is under study as is the time course of PKC alteration during the course of LTP expression.

INDUCTION OF CEREBELLAR LONG-TERM DEPRESSION IN CULTURE REQUIRES PKC ACTIVATION. D.J. Linden and J.A. Connor. Dept. of Neurosciences, Roche Inst. of Molecular Biology, Nutley, NJ 07110

Long-term depression (LTD) of the parallel fiber-Purkinje neuron (PF-PN) synapse may be induced in vivo by co-activation of climbing fibers (CFs) and PFs. In cultured mouse PNs we have demonstrated that a similar depression may be induced when iontophoretic glutamate pulses and PN depolarization are substituted for PF and CF stimulation, respectively, and that this form of LTD is dependent upon activation of metabotropic quis receptors (Linden et al. *Neuron*, in press). As one consequence of metabotropic quis receptor activation is PKC activation via diacylglycerol liberation, we chose to apply PKC inhibitors and activators to determine their effects on LTD induction in culture. Inhibitors which act at both the catalytic site (Ro-31-8220) and the regulatory site (calphostin C) of PKC blocked LTD induced by glutamate/depolarization conjunction when applied during the conjunctive stimulus, but had no effect when applied 10 min after the conjunctive stimulus. Conversely, application of PDAC, a PKC activator, induced a depression of AMPA, but not NMDA test pulses. This selectivity was also seen when LTD was induced by glutamate/depolarization conjunction. In addition, preliminary evidence indicates that depression induced by PDAC and glutamate/depolarization conjunction are non-additive, suggesting that they share common mechanisms. These observations confirm and extend a previous report that LTD in vivo may be induced by phorbol esters (Crepel and Krupa, *Brain Res.* 458:397).

B-50 PHOSPHORYLATION FOLLOWING DIFFERENT PATTERNS OF ELECTRICAL STIMULATION IN RAT HIPPOCAMPAL SLICES. C. Gianotti*, M.G. Nunzi, B. Bacchi, F.W. Gispen¹ and R. Corradetti². Fidia Research Laboratories, 35031 Abano Terme (PD), Italy, ¹Rudolf Magnus Institute, Utrecht University, 3521 GD Utrecht, Netherlands and ²Dept. Preclin. and Clin. Pharmacology, Florence University, 50134 Florence, Italy

We studied B-50 (GAP43/F1) phosphorylation by quantitative immunoprecipitation, using a polyclonal anti-B-50 antiserum in ³²Pi-prelabelled rat hippocampal slices (400 μ m) incubated in an interface-type chamber. From each animal, one slice was left unstimulated while two others were stimulated (0.017 Hz) in the stratum radiatum; the responses were extracellularly recorded in the CA1 region. To elicit long-term potentiation (LTP), a train of high-frequency stimuli (100 Hz, 1s) was used. In potentiated slices B-50 phosphorylation was significantly ($p < 0.05$) higher (146 \pm 8%, n=7) than in unstimulated controls or in low frequency stimulated slices (107 \pm 7%, n=7). These data are consistent with the hypothesis that an increase in neurotransmitter release, probably due to a PKC-dependent phosphorylation of protein B-50, occurs during LTP. In view of the role of B50 in synaptic plasticity, we are exploring whether age-induced alterations in LTP expression may be related to changes in B-50 phosphorylation.
